In the present study, at temperatures between 500° and 950°C in an oxygen ambient, a flux of either negative or positive oxygen ions, generated via a corona discharge, is directed to the upper surface (the front side) of a silicon wafer. Here, the combined effects of both electric fields and ion beam species on the oxidation rate are manifest. The effects of the electric field alone are manifest on the opposite side of the wafer (the back side) (11). Both polarities of oxygen ion beams lead to oxidation rate enhancement, but, because we have used a point-to-plane discharge technique (13, 14) which produces a nonuniform (bell-shaped) ion flux profile in the gas near the surface, the oxide thickness profile on the wafer is quite different in the two cases even though the ion beam current density profiles in the gas phase at the surface are believed to be almost identical.

*Electrochemical Society Student Member.

Experimental Techniques

A complete description of the apparatus used for positive and negative ion beam processing has been published elsewhere (13, 14); therefore, only a few necessary details will be given here. The ion beams are generated by applying a negative or positive voltage of ± 0.05 to ± 2.0 kV to a platinum needle (the point) relative to a silicon wafer (the plane), as illustrated in Fig. 1a. The ions are generated in a narrow zone close to the needle because of the strong field enhancement at that location. The polarity of the ions generated is the same as the sign of the voltage applied to the point, and these ions are repelled from the point by the local field. The ions spread out as they travel from the point to the plane and form a bell-shaped ion beam current density profile on the surface of the plane.

A portion of the ion beam generating apparatus is shown in Fig. 1b. A platinum needle with a tip diameter of 0.003 in. is suspended 0.5 cm above the silicon wafer which rests upon a 63.5 mm diam, 1.6 mm thick quartz disk. The bottom of the quartz disk is coated with a 1 μ m thick sputter-deposited layer of platinum. In addition to providing electrical contact to the back side of the wafer, the quartz disk acts as a diffusion barrier between the Pt and the Si wafer. The quartz has a sufficiently high electrical conductivity at 900°C to cause a voltage drop of < 100 V at a beam current of ~ 10 μ A (14). The entire assembly rests on a 0.002 in. Pt sheet which is connected to the high voltage power supply via Pt lead-in wires (14).

The Pt lead-in wires are separated by sapphire rods to minimize electrical leakage between them. Since a portion of this leakage current is picked up by the sample lead-in wire, it produces an error in the measurement of the ion beam current. It was observed that this leakage current is at its maximum value when the discharge is first switched on and decays to a value ≤ 0.25 μ A after ~ 10 min. It is believed that this is due to electrical polarization effects in the sapphire standoffs. Thus, in order to minimize the current measurement error during the oxidation experiments, the discharge was initially switched

Fig. 1. a: Schematic diagram of the point-to-plane ion beam generator. b: An illustration of the experiment setup.

on in nitrogen for a period of 10 min before changing the ambient gas from N_2 to O_2 . For oxidation temperatures less than 800°C , a more suitable contact technique involving platinum silicide formation was utilized (13, 14).

Silicon samples were first given a 15 min ultrasonic clean in warm soap and deionized (DI) H_2O to degrease and remove particles, followed by a 5 min rinse in DI H_2O . The wafers were then cleaned according to the following schedule: (i) boil for 10 min in (5:1:1) H_2O : H_2O_2 : NH_4OH , (ii) rinse in DI H_2O for 3 min, (iii) boil for 10 min in (5:1:1) H_2O : H_2O_2 : HCl , (iv) rinse in DI H_2O for 3 min, (v) 30s dip in (50:1) H_2O : HF , and (vi) rinse in DI H_2O for 5 min.

After the above cleaning, the wafers were hydrophobic and were "pulled dry" and placed directly in the wafer boat. This eliminated the need to blow the wafers dry with N_2 . The larger pieces of quartz apparatus, *i.e.*, diffusion tubes, wafer boats, etc., were cleaned using a soap and DI H_2O degrease followed by a 10 min etch in (10:1) HF : (DI) H_2O ($\rho \geq 18 \text{ M}\Omega \text{ cm}$). Platinum parts were degreased by an ultrasonic soap and warm DI H_2O bath, then by boiling in TCE, acetone, and methanol, followed by a DI H_2O rinse.

Experimental Results

Negative point.—Oxide thickness profiles.—Oxide thickness profiles on $\langle 111 \rangle$ Si substrates for a range of oxidation times at 900°C in 100% O_2 with a constant needle current of $-5 \mu\text{A}$ are shown in Fig. 2. The bell-shaped profiles, which were measured via ellipsometry, mimic those of the ion beam density such that the peak oxide thickness lies directly below the tip of the point electrode and the constant background level occurs where the beam intensity has fallen to zero. Figure 3 shows that the $\langle 111 \rangle$ and $\langle 100 \rangle$ Si substrate results are similar but with the $\langle 100 \rangle$ being below the $\langle 111 \rangle$ by a constant offset which, for the case of an oxidation at 900°C for 1h at $-5 \mu\text{A}$, is about 100\AA .

Peak oxide thickness variations.—In Fig. 4 and 5, the peak oxide thickness, X_p , is plotted as a function of time, t , for a range of temperatures, T , beam currents, I , and the substrate orientations $\langle 111 \rangle$ and $\langle 100 \rangle$. Each data point is the average of several experiments. The data are presented on a background of the conventional $I = 0$ data for $\langle 111 \rangle$ Si. We note a marked difference in the $I < 0$ data from the $I = 0$ data.

In the $600^\circ\text{--}800^\circ\text{C}$ range, the peak oxide thickness, for a constant beam current, I , is relatively insensitive to

Fig. 2. Oxide thickness profiles for Si $\langle 111 \rangle$ wafers oxidized in 100% oxygen at 900°C with $I = -5 \mu\text{A}$ for various times.

Fig. 3. Oxide thickness profiles for Si $\langle 111 \rangle$ and Si $\langle 100 \rangle$ wafers with $I = -5 \mu\text{A}$ oxidized at $T = 900^\circ\text{C}$ for 0.5h with $P_{O_2} = 1 \text{ atm}$.

Fig. 4. Oxide thickness at the profile peaks for Si $\langle 111 \rangle$ and Si $\langle 100 \rangle$ wafers for $T = 900^\circ\text{C}$ with $I = -5 \mu\text{A}$ and $P_{O_2} = 1 \text{ atm}$. Each datum is the average of several experiments. The $I = 0$ data are shown for reference.

changes in temperature and begins to increase markedly only in the $900^\circ\text{--}1200^\circ\text{C}$ range (see Fig. 6). At temperatures lower than $\sim 600^\circ\text{C}$, it became difficult to produce a stable discharge in 100% oxygen. The datum at 500°C represents an experiment carried out despite the fact that significant instability or "flicker" was present in the ion beam.

As has been stated earlier, in the experiments carried out at temperatures below 800°C , a PtSi contact to the back side of the wafer was used instead of the quartz contact because of the greatly reduced electrical conductivity of the quartz and the relatively slower silicide formation rate at these temperatures. A cross-check of these two contact schemes was performed to insure consistent results. Samples were oxidized at 900°C with a beam current of $-5 \mu\text{A}$ for 1h, and the resulting oxide thickness

Fig. 5. Oxide thickness at the profile peaks for Si $\langle 111 \rangle$ and Si $\langle 100 \rangle$ wafers for $T = 700^\circ\text{C}$ with $I = -5 \mu\text{A}$ and $P_{\text{O}_2} = 1 \text{ atm}$. The $I = 0$ data is shown for reference. Each datum is the average of several experiments.

Fig. 6. Oxide thickness at the profile peaks for Si $\langle 111 \rangle$ wafers with $I = -5 \mu\text{A}$ for $t = 1 \text{ hr}$ at a number of temperatures and $P_{\text{O}_2} = 1 \text{ atm}$.

profiles were found to be identical regardless of which technique was used to contact the back side of the wafer.

Oxygen partial pressure dependence.—An investigation of the effects associated with a reduced oxygen partial pressure, P_{O_2} , was carried out at 700°C using an admixture of O_2 in P_{O_2} argon. In Fig. 7, values of the peak oxide thickness at $I = -10 \mu\text{A}$ for 1 hr are shown for a range of P_{O_2} . We note that a reduction of P_{O_2} by a factor of ten leads to a reduction in X_p of only $\sim 18\%$.

Substrate doping dependence.—A series of experiments was conducted on $\langle 111 \rangle$ Si substrates doped with either boron or phosphorus at $I = -5 \mu\text{A}$ and $t = 1 \text{ hr}$. The substrate resistivity was varied from 0.5 to 20 $\Omega \text{ cm}$ with no observable differences in the resulting oxide thickness profiles.

Fig. 7. Oxide thickness at the profile peaks for Si $\langle 111 \rangle$ wafers with $I = -5 \mu\text{A}$ at 700°C for 1 hr at a range of P_{O_2} in argon ($P_{\text{total}} = 1 \text{ atm}$).

Positive point.—Oxide thickness profiles.—In Fig. 8, oxide thickness profiles for Si $\langle 111 \rangle$ wafers at 900°C and $I = +5 \mu\text{A}$ for dry O_2 are shown as a function of position on the wafer. The profiles are seen to have a bimodal shape with a crater appearing directly beneath the needle. In Fig. 9, the 2h $I = +5 \mu\text{A}$ profile is compared with that obtained with a negative point at $I = -5 \mu\text{A}$ for 2h. The reference markers at 0.725 and 1.275 in. indicate the half-width of both the positive and negative ion beams measured at low temperatures. While there is a clear correspondence between the ion beam current density and the oxide thickness profile for the negative ion case, there appears to be virtually none for the positive ion case.

The manner by which the back side of the wafer was contacted did not influence the front-side oxide thickness profile since virtually identical profiles were obtained with or without a silicide back-side contact.

Crater effects.—The normal sample, which was a quarter section of a 3 in. wafer placed on the quartz plate beneath the needle, exhibited the type of oxide profile sketched in Fig. 10a. The dark and light areas correspond to regions of thick and thin oxide, respectively. Figure 8 was generated by plotting the oxide thickness found along the line $Y_1 Y_2$ from point A to point B. From Fig. 10a, we note that the oxidation-enhancement effect disappears completely between the contour Q_1 and the edge of the sample. In addition, the region between the center of the crater C_1 and the contour Q_1 is nonuniformly enhanced; e.g., the oxide is somewhat thicker in the lower right-hand portion of the enhanced region.

To investigate a possible sample edge effect, a whole 3 in. wafer instead of a quartz wafer was used. From Fig. 10b, we see that the enhanced area does, in fact, expand, whereas the total beam current was held constant at +5

Fig. 8. Oxide thickness profiles for Si $\langle 111 \rangle$ wafers obtained at 900°C for $I = -5 \mu\text{A}$ and $P_{\text{O}_2} = 1 \text{ atm}$.

Fig. 9. Comparison of oxide thickness profiles for Si $\langle 111 \rangle$ wafers at 900°C for 2h at $I = +5$ and $-5 \mu\text{A}$. The vertical arrows indicate the half-width of the positive ion beam at room temperature.

Fig. 10. Illustration of Si<111> wafer surfaces oxidized at 900°C for 1h at $I = +5 \mu\text{A}$. The light and dark areas correspond to thinner and thicker oxides, respectively.

μA . Under identical oxidation conditions, the craters C_1 and C_2 are the same size, while the contour Q_2 is much larger than the contour Q_1 . The elongation of Q_2 was found to be along the direction taken by the Pt needle lead-in wire inside its quartz conduit above the wafer.

As a check to see if the crater effect could be due to electrolytic thinning of the SiO_2 layer (15, 16), several wafers with different oxide thickness were subjected to positive ion beams of up to $+20 \mu\text{A}$ for 1h in argon at 900°C. For wafers with oxides about 1000Å thick, a change of less than 5-10Å was observed. This is considered to be an insignificant effect; therefore, electrolytic thinning does not seem to be responsible for the cratering.

Because of the nonuniform nature of the positive point results and the fact that the oxide thickness profiles tended to vary somewhat from experiment to experiment, a detailed investigation of the temperature, time, and ion beam current density dependence was not attempted.

Discussion

Negative point.—Thickness as a function of time.—Figure 4 shows that the oxide growth curves for $I = 5 \mu\text{A}$ are concave upward with the <100> data falling below the <111> data at short times while, for long times, the two sets of data are essentially identical. These phenomena can be understood in terms of a simple interpretation of the interaction between the ion beam and the native growth process. We assume that the flux of oxidant due to the ion beam and due to the native growth process add linearly at the Si/SiO₂ interface. Thus, for short times, the ion beam-enhanced data approach those of the native process because the rapid native oxidation rate in the thin oxide regime is much greater than that due to the ion flux at low values of I . For long times, the growth rate becomes dominated by the ion flux. As the oxide thickness approaches 1 μm , the growth curves tend toward a slope of unity. If the ion flux had not been present, the growth

curves would have tended towards a slope of 1/2, corresponding to diffusion-limited growth. Freedom from diffusion-limited growth, via the agency of the ion beam, strongly enhanced the overall oxidation rate.

If the temperature is low enough ($T \leq 700^\circ\text{C}$), so that the contribution of the native oxidant to the growth rate is negligible, then the growth rate is dominated by the ion beam flux (see Fig. 5). In this case, we have

$$X_p \approx X_N + \frac{J_p t}{qN_o} \quad [1]$$

where X_p is the peak oxide thickness with an ion beam, X_N is the native oxide thickness, J_p is the peak current density, t is the oxidation time, q is the magnitude of the electronic charge, and N_o is the density of network oxygen atoms in vitreous SiO_2 .

In Eq. [1], the value of J_p is related to I via the low temperature measurements (13, 14). It is assumed to be independent of temperature although first-order analysis predicts that it will decrease slightly as T increases. Assuming a value for X_N of $\sim 20\text{Å}$ at low temperatures, one calculates $X_p = 820\text{Å}$ for $I = -5 \mu\text{A}$, $t = 1\text{h}$, and $N_o = 4.5 \times 10^{22}$ atom/cm³. This agrees fairly well with the extrapolated value of 875Å given in Fig. 6. As the temperature is increased above 700°C, X_N accounts for a thickness increase of $\sim 30\%$ above that due solely to the ion beam at $T \leq 700^\circ\text{C}$. Thus, at $T \leq 700^\circ\text{C}$, the ion beam flux essentially dominates the growth process.

Independence of native oxidant species and ionic fluxes.—Figure 11 shows the results of two experiments wherein profiles for samples oxidized at -10 and $-5 \mu\text{A}$ for 1 and 2h, respectively, are overlaid upon each other. We note that the $-10 \mu\text{A}$ profile has a reduced peak and a broadened base and question whether this is due to differing beam shapes for the two current levels and corresponding voltages or it, instead, reveals an interaction between the native and ionic fluxes of the oxidant species.

Considering the beam shape factor, we have found (3) that, for the apparatus shown in Fig. 1a with a gap of a 0.5 cm at room temperature in air, the beam width is given by

$$W_B = 1.3 + 0.05I \quad [2]$$

where W_B is the beam width in centimeters and I is the beam current in microamperes. Thus, the beam width increases by 16% in going from -5 to $-10 \mu\text{A}$ at room temperature. This is due to the enhanced electrostatic repulsion associated with the increased ion density and is consistent with the $\sim 16\%$ oxide profile width change of Fig. 11. The corresponding decrease in oxide peak height, X_p , on increasing the total beam current from -5 to $-10 \mu\text{A}$ should then be due to the reduced value of the peak current density. Again, a 1:1 correlation with the room temperature results was found. Since the beam-shape factor is able to account for the data of Fig. 11, it appears reasonable to assume that little, if any, interaction occurs be-

Fig. 11. Oxide thickness profiles for Si<100> wafers at 700°C for 1h at $I = -10 \mu\text{A}$ and 2h at $I = -5 \mu\text{A}$.

tween the native oxidant and ionic fluxes at these temperatures and that they act independently.

Temperature dependence.—One of the most striking features of the negative point results is the apparent insensitivity of the oxide thickness profile to changes in temperature. The smooth curve in Fig. 6 has been linearly extrapolated to 400°C without regard to the datum at 500°C. This implies that, if one controls the beam flicker which sets in at $T < 650^\circ\text{C}$, the corrected data will lie on the projected curve. It is also likely that, due to the greatly reduced ionic mobility, at lower temperatures, the large voltages needed across the SiO_2 to sustain a constant beam current result in sufficiently strong electric fields in the SiO_2 such that electrons would dissociate from the O. Thus, the current becomes increasingly electronic as T is decreased.

To test this hypothesis, samples of Cu, Ni, Al, and Si were subjected to a current of $-10\ \mu\text{A}$ for 1h at room temperature in air under a laminar flow hood. By visual observation of the interference patterns, it was determined that the greatest amount of oxide formed on the Cu sample with successively less oxide forming on the Ni and Al samples. Virtually no oxide was observed to form on the Si sample. This ordering of the relative oxide thicknesses is consistent with the relative magnitudes of both anion and cation diffusion coefficients measured in the corresponding oxides (16-24), i.e., D^+ and D^- are highest for Cu_2O and least for SiO_2 . Thus, in SiO_2 , because the diffusion coefficients and solubilities of anions and cations are relatively low, very large electric fields ($> 10^7\ \text{V cm}^{-1}$) (25) are necessary to induce ionic motion and hence form an anodic oxide. Because of these high fields, electron and hole injections into the conduction and valence bands, respectively, become likely. The consequence is that many electrons and holes cross the oxide layer, whereas few cations and anions move. Thus, for Si at room temperature, anodic oxidation via corona discharge is a very inefficient process, and under the present experimental conditions we do not expect to be able to readily form an anodic oxide of appreciable thickness.

From the foregoing, we can conclude that, in the low temperature regime, $25^\circ < T < 600^\circ\text{C}$, the ionic transport efficiency, η , defined as the ratio of ionic to total current, increases from $\sim 3 \times 10^{-2}$ (25) at 25°C to ~ 1.0 at 600°C . Thus it is likely that the combined effects of the ion beam "flicker" and the reduced transport efficiency are responsible for the reduced values of X_p for $T < 600^\circ\text{C}$. In the intermediate temperature regime, $600^\circ < T < 800^\circ\text{C}$, $\eta \approx 1$, and the native oxidant flux plays a minor role compared to the ion beam flux in the overall growth rate. In the temperature regime $T \geq 800^\circ\text{C}$, $\eta = 1$, and both the native oxidant flux and the ion beam flux contribute significantly to the growth rate and hence to X_p .

P_{O_2} dependence.—From the results of Fig. 7, we can infer that, with 100% O_2 gas, the concentration of free electrons is very small since X_p decreases by only $\sim 2\%$ per percent decrease in P_{O_2} content of the argon. The explanation for this behavior is related to the strong electron affinities of O (1.75 eV) and O_2 (0.4 eV) (26). Because of the relatively large electron collision cross section and the large number of collisions to be made between the needle electrode and the SiO_2 surface, very few electrons will cross the gap without attaching to oxygen molecules in the 100% oxygen case. For $T \geq 200^\circ\text{C}$, once O_2^- ions have formed they will readily dissociate to generate O plus O^- (27). Because the electron affinity for O^- is $\sim 1.75\ \text{eV}$, there is very little chance that O^- species will deionize before crossing the gap. Thus, even in the 10% oxygen case, the number of electrons surviving to reach the SiO_2 surface is only $\sim 18\%$.

Positive point.—Unlike the negative point case, it is clear that the positive point results cannot be explained simply by a flux of interstitial ions (positive in this case) injected into the oxide by the ion beam which are transported across the oxide in parallel with the native oxidant species. First, in contrast with the negative point results,

the oxide thickness profiles obtained with a positive point bear little, if any, resemblance to the ion beam current density profile (see Fig. 9). Second, the crater-shaped oxide thickness profiles imply that multiple interactions affecting the oxidation rate are present in the positive point case. A simple explanation for the crater-shaped oxide-thickness profiles involving a growth-enhancement factor due to the positive ions and a retardation factor due to electrolytic thinning of the oxide can be ruled out since a pregrown oxide was not found to thin after being subjected to a positive ion beam treatment in an inert ambient. Furthermore, as seen in Fig. 10, the spatial extent of the enhanced area increased when the wafer size was increased even though the ion beam current was held constant. From the above, we conclude that more work will be necessary in order to fully explain the positive point results.

Conclusions

Oxidation enhancement occurs for both the negative point and positive point cases with the negative point case providing the larger effect. In the negative point case, (i) the geometry of the oxidation enhancement mimics the ion beam profile in the gas, (ii) the effect seems to be independent of the native oxidant, (iii) the effect decreases slowly with decrease in P_{O_2} content of the gas, and (iv) the effect is linearly proportional to the product of the local ion beam current density and the time. The above results imply that the native oxidant species is/are electroneutral since the negative ion enhancement effects appear to be independent of the presence of the native oxidant species.

In the positive point case, a shallow crater develops under the ion beam. This crater is surrounded by a ridge of oxide thickness enhancement which falls off radially as the outer edge of the wafer is approached. Although no explanation for these results is provided, we conclude that electrolytic thinning of the oxide due to the positive voltage developed across the oxide is not a significant factor. Additional work is currently in progress to provide an explanation of the positive point results.

Resist Materials Utilizing Oxygen Plasma Resistance of Iodine Compounds

Hitachi, Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

Relative rates were measured for polymer film loss in an oxygen plasma environment. Both polymers doped with iodine compounds and iodinated polymers show high resistance to the oxygen plasma. Our ESCA studies on iodinated polystyrenes indicate that the oxygen plasma converts the iodo-substituent to iodine oxides. Through taking advantage of the oxygen plasma resistance of iodine compounds, we have been able to come up with a two-layer photolithography system for microfabrication. In the context of this two-layer process, evaluations were made of a positive photoresist formulated from OFPR-800 (Tokyo Ohka Kogyo Company) and 2,4,6-triiodophenol, as well as a negative deep-UV resist composed of iodinated poly(vinyl phenol) and 3,3'-diazidodiphenyl sulfone.

Resist system requirements for modern IC fabrication are becoming more and more difficult to meet as the minimum feature size is reduced. One of the most serious problems in conventional single-layer resist systems is that it is very difficult to control resolution and linewidth control over high steps in different parts of the wafer topography. This problem can be alleviated by using a multi-layer resist system (1-3). Utilizing a thick planarizing layer at the bottom and a thin imaging layer on top, multilayer resist systems offer improved linewidth control and height-to-width aspect ratio of the resist image. Since an oxygen plasma etching is used for transferring the pattern to an underlying planarizing layer, an understanding of the factors leading to polymer resistance to an oxygen plasma environment is important in a multilayer system.

Here, we report on measurements of oxygen plasma removal of polymer film, and on high oxygen-plasma resistance of polymers doped with iodine compounds and iodinated polymers. We apply this high oxygen-plasma resistance of iodine compounds to develop a novel two-layer photolithography system which uses resists containing iodine compounds as a top image layer.

Experimental

Materials.—*Iodinated polystyrene (IPS)*.—IPS was prepared by iodination of polystyrene using the previously described method (4). While the reaction vessel was kept at a temperature of $90 \pm 2^\circ\text{C}$, polystyrene was dissolved in nitrobenzene. Iodine, iodine pentaoxides, carbon tetrachloride, and sulfuric acid were added to the polystyrene solution. From the infrared spectrum, it is confirmed that iodination takes place at the *para* position. The iodination degree was defined as the mole fraction of 4-iodostyrene monomer units in IPS and evaluated using elementary analysis with a Hitachi 026 CHN analyzer.

Chlorinated polystyrene and brominated polystyrene.—Chlorinated polystyrene was prepared by polymerization from a mixture of the freshly distilled 4-chlorostyrene and styrene monomers using α,α' -azobisisobutyronitrile as a catalyst. Brominated polystyrene was polymerized from a mixture of 4-bromostyrene and styrene monomers in the same manner. The chlorination degree and bromination

degree were defined as mole fractions of 4-chlorostyrene and 4-bromostyrene monomer units in chlorinated polystyrene and brominated polystyrene, respectively.

Iodinated phenolic resin (IP).—Poly(vinyl phenol) obtained from Maruzen Oil Company and morpholin were dissolved in ethanol. While stirring the solution at room temperature, ethanol solution of iodine was added dropwise. The polymer precipitated after stirring for 2h. It was purified by precipitation using dioxane and water. From NMR analysis, it was ascertained that the polymer obtained was poly(3,5-diiodo-4-hydroxystyrene).

Poly(styrene sulfone).—Poly(styrene sulfone) was prepared by copolymerization of styrene with sulfur dioxide according to the previously reported method (5).

Other polymers and resists.—Most polymer and resist samples were obtained from external suppliers, i.e., Scientific Polymer Products Incorporated, Tokyo Ohka Kogyo Company, Maruzen Oil Company, Hoechst AG, Daikin Kogyo Company, and Mead Associates.

Oxygen plasma etching.—All oxygen plasma etching in our study on relative removal rates was carried out using an LFE Company, Model PDE/EDS-301 etcher which was modified to make it into a diode-coupling plasma etcher. Operating conditions were 0.5 torr and 55W. The diameter of the aluminum electrode was 60 mm. Several sections of silicon wafers spin coated with polymer films were etched on the lower-grounded electrode. A silicon wafer section coated with polystyrene was etched on the electrode as a standard for checking the oxygen plasma condition. Film thicknesses were measured with an interferometer both before and after etching.

Surface analysis.—ESCA spectra measurements were made with a VG Company Model ESCA-1 spectrometer.

Oxygen Plasma Removal of Polymer Films

Removal rates for polymer and resist films.—Absolute rates, for oxygen plasma removal were obtained from the slope of film thickness vs. etching time plots, as shown in Fig. 1. The oxygen plasma removal rates for polymers and resists relative to polystyrene, k_r , are summarized in Table I. Taylor and Wolf (6) have measured the rates of oxygen plasma removal for 40 polymer samples, and dis-

*Electrochemical Society Active Member.

Fig. 1. Thickness remaining vs. oxygen plasma etching time at 55W and 0.55 torr.

cussed the mechanism of polymer film removal by an oxygen plasma. Our results do not completely agree with those reported by Taylor and Wolf. This discrepancy may be due to differences between the oxygen plasma etchers used: we used a diode coupling system, whereas they used an inductive coupling system.

The most striking result in Table I is that iodinated polystyrenes (IPS) (4) have remarkably small values of k_r , while the k_r values for other polymers and resists are in the range of 0.7-3.5. We measured in some detail the k_r values for IPS having various iodine percentages. Plots of k_r as a function of iodine content are shown in Fig. 2. This figure indicates that the oxygen removal rate for IPS decreases as the iodination degree increases.

Table I. Relative rates (k_r) of oxygen plasma removal for polymers and resists

Polymer	MW (10 ⁶)	k_r
Polystyrene	2.7	1.0
Iodinated polystyrene		
2% I ^a	2.7	0.89
4% I	2.8	0.86
13% I	3.1	0.72
27% I	3.6	0.51
61% I	4.5	0.10
85% I	5.5	0.04
Chlorinated polystyrene		
10% Cl	9.4	1.25
100% Cl	11	1.15
Brominated polystyrene		
10% Br	10	1.12
100% Br	20	0.98
Poly(α -methyl styrene)	0.39	0.95
Poly(vinylbenzylchloride)	75	1.12
Poly(styrene sulfone)	4.1	0.71
Poly(styrene-co-maleic anhydride)	0.5	1.20
Poly(epichlorohydrin)	7.0	3.5
Novolac resin		1.0
Poly(vinylphenol)	0.07	1.1
Brominated poly(vinylphenol)	0.14	1.65
AZ 1350J		0.84
Poly(methyl methacrylate)	6.8	1.69
Poly(glycidyl methacrylate)	1.4	1.69
Poly(methyl methacrylate-co-acrylonitrile)	6.3	1.61
Poly(glycidyl methacrylate-co-ethyl acrylate)		1.44
Poly(hexafluorobutyl methacrylate)	5.3	1.82
Poly(methyl isopropenyl ketone)	3.13	1.8
Cyclized poly(isoprene)		1.33
OMR-83 ^b		1.0
Polyimide ^c		0.83

^a The halogenation degree is defined in the Experimental section.

^b A negative photoresist composed of cyclized poly(isoprene) with a bisazide manufactured by Tokyo Ohka Kogyo Company.

^c Polyimide was prepared by baking spin-coated PIQ (obtained from Hitachi Chemical Company) at 200°C.

Fig. 2. Dependence of relative rates of iodinated polystyrene film loss on iodination degree.

To confirm that iodinated compounds have inherent properties of high resistance to oxygen plasma, we measured the removal rates for mixtures of polystyrene and such iodinated compounds as iodoform and 1,4-diiodobenzene. The results for mixtures of iodoform and polystyrene are shown in Fig. 3. This figure indicates that the removal rate decreases with an increase of iodoform concentration in the polystyrene matrix. A sample baked at 80°C over 10 min gives the same removal rate as for polystyrene. This is due to the volatilization of iodoform from the polymer matrix during the baking process. Similar results were obtained for mixtures of diiodobenzene and polystyrene. These results make it evident that polymers doped with iodine compounds and iodinated polymers have high resistance to an oxygen plasma.

The removal rate for IPS with reactive ion etching (RIE) was also measured as shown in Fig. 4. Here it can be seen that the IPS rate is smaller than that for polystyrene. The RIE process is less selective in terms of etching speed than the oxygen plasma etching process (7).

Surface analysis.—We analyzed the polymer surface using ESCA, so as to elucidate the reason for oxygen plasma resistance by iodine compounds. ESCA spectra for IPS (83% iodination), both before and after the oxygen plasma treatment, are shown in Fig. 5 and 6. Those figures, respectively, show wide-band spectra and I_{3d} core level signals for IPS, taking the carbon signal C_{1s}

Fig. 3. Thickness remaining vs. oxygen plasma etching time at 55W and 0.55 torr for polystyrene as well as mixtures of polystyrene and iodoform. Molar ratios of iodoform to polystyrene monomer units: 0%, \circ ; 6%, Δ ; 13%, \square ; 24%, ∇ .

Fig. 4. Thickness remaining for IPS (83% iodination) and polystyrene, shown vs. reactive ion etching time at 24W and 20 mtorr.

(284.6 eV) as an internal standard. It is clear from Fig. 5 that the oxygen core level signal appears after oxygen plasma treatment. In Fig. 6, the I_{3d} core level signals after oxygen plasma treatment shift to larger binding energies than those before treatment.

It is known that the binding energy of an oxide is larger than that of a pure element. In fact, the value of I_{3d} binding energy for diiodo pentaoxide (I_2O_5) is 3.4 eV larger than that for IPS. The above results suggest that a thin layer of iodine oxide is formed on the surface of the polymer during the initial stage of oxygen plasma treatment and that this thin surface layer protects the bulk polymer from further etching.

Two-Layer Photolithographic System

Through utilizing the oxygen plasma resistance of iodine compounds, we were able to produce a two-layer resist system. Resists containing iodine compounds, after exposure and development, act as an etch mask for pattern transfer to the underlying planarizing polymer in an oxygen plasma.

Fig. 5. Wideband ESCA spectra for IPS (83% iodination): (a) before and (b) after oxygen plasma treatment.

Fig. 6. I_{3d} core level ESCA signal of IPS (83% iodination): before, a, and after, b, oxygen plasma treatment.

Top imaging layer.—Resists evaluated as the top imaging layers were a positive photoresist applicable to the reduction projection aligner and a negative deep-UV resist.

Positive photoresist.—Investigations were made of a phenolic resin-quinone diazide photoresist mixed with various kinds of iodine compounds. A resist comprised of 2,4,6-triiodophenol (TRIP) and OFPR-800 (Tokyo Ohka Kogyo Company, a quinone diazide photoresist) was used.

Twelve parts of TRIP by weight were dissolved in an OFPR-800 resist solution. The rate of oxygen plasma removal for OFPR-TRIP was measured as shown in Fig. 7. The etching ratio of OFPR-800 to OFPR-TRIP was 4 to 1. OFPR-TRIP sensitivity was almost the same as that for OFPR-800.

Negative deep-UV resist.—A deep-UV negative resist composed of an iodinated phenolic resin and an azide compound was studied. Iodinated phenolic resin (IP) was synthesized by iodination of poly(vinyl phenol). 3,3'-Diazidodiphenyl sulfone (DS), which was used as an azide compound for deep-UV resist (8), was selected. The IP-DS resist was prepared by dissolving the IP and DS [20 weight percent (w/o) based on the resin] in cyclohexanone. The etching ratio of OFPR-800 to IP-DS was 5 to 1.

Fig. 7. Thickness remaining vs. oxygen plasma etching time at 55W 0.55 torr for polystyrene, \circ , OFPR, \square , and a mixture of OFPR and triiodophenol, \triangle .

Fig. 8. SEM photograph of two-layer patterns generated by a Hitachi RA-101 Reduction Projection Aligner. A positive photoresist formulated from OFPR, and triiodophenol was used as the top imaging layer.

Fig. 9. SEM photograph of two-layer patterns transferred by deep-UV exposure. A negative deep-UV resist formulated from iodinated poly(vinyl phenol) and 3,3'-diazidodiphenyl sulfone was used as a top imaging layer.

Bottom polymer layer.—Requirements for the underlying polymer layer were the following: the underlying layer should be free from any mixing with the top layer; it should not dissolve in the top-layer developer; and it is desirable that it show resistance to dry etching of the substrate. OFPR-800 baked at 200°C meets these requirements.

Lithographic characteristics of the two-layer system.—OFPR-800 was spin cast on a silicon wafer to a thickness

of 1-2 μm , and hard baked at 200°C for 20 min. The top imaging layers described above were coated over the underlying layer and baked at 80°C for 20 min. After exposure and development of the top layer in an aqueous base solution, the resulting pattern was transferred to the bottom OFPR layer by oxygen plasma etching. The results for OFPR-TRIP used as a top imaging layer are shown in Fig. 8. The optical exposure was carried out with a Hitachi RA-101 Reduction Projection Aligner. IP-DS results are shown in Fig. 9. Deep-UV light was exposed through the test pattern mask which was in contact with the resist. It is clearly demonstrated in these photographs (Fig. 8 and 9) that the top layer formed by photolithography was transferred to the OFPR layer by oxygen plasma etching.

Conclusion

Iodinated polymers and polymers doped with iodine compounds are found to have a high resistance to an oxygen plasma. Our ESCA studies indicate that thin surface layer iodine oxides are formed during the early stage of oxygen plasma etching. Utilizing the oxygen plasma resistance of iodinated compounds, we propose a two-layer photolithographic system. Two resists, a positive photoresist containing triiodophenol and a deep-UV resist comprised of an iodinated phenolic resin as well as an azide compound, were evaluated for use as a top imaging layer. Good quality patterns are obtained as a result of a sequence starting with exposure followed by development of the top imaging layer and transferring the image by means of oxygen plasma etching to the bottom layer.

ABSTRACT

It is well known (1-4) that substantial amounts of chlorine can be incorporated in HCl grown thermal oxides on silicon to effectively passivate sodium ions. It has been of interest to find out if similar effects can be obtained for oxides chlorinated by implanting Cl ions at the surface of SiO₂ films on Si. It appears (5, 6), however, that when these films are annealed at temperatures in excess of 700°C, no Na neutralization property is evident. In this paper, we show with the help of ⁴He ion Rutherford backscattering (RBS) experiments on chlorine implanted into a thermal oxide film on Si that the oxide loses about 10 (50) percent of the implanted Cl during annealing at 600°C (1100°C) in nitrogen for 30 min. We obtain the diffusion coefficient *D* of Cl in SiO₂ at various temperatures with the help of a process simulation program (SUPREM II) and show that for $D \sim D_0 \exp(-E_a/kT)$, $D_0 = 10^{-12}$ cm²/s and $E_a \sim 0.5$ eV. Corrections for system resolution and energy straggling effects are made to obtain the actual Cl density profiles in the SiO₂ film. It is seen that Cl at 50 keV has a range of 440Å in SiO₂ with a standard deviation of 220Å for a gaussian form.

It is a well-established fact that small addition of a chlorine containing species (such as HCl, Cl₂, C₂HCl₃) to the oxidizing atmosphere (oxygen) during thermal oxidation of silicon can lead to several beneficial effects on the stability of the oxide, quality of the interface, dielectric breakdown properties, etc. (1, 2). The basic physicochemical mechanisms of many of the phenomena associated with chlorinated oxidations, however, are not fully understood. Mention in this regard may be made of thresholds observed for chlorine incorporation and for sodium ion passivation in the HCl to O₂ volume ratio, and in the oxidation temperature (3, 4). Convincing explanations also remain to be given as to the precise role of Cl in Na⁺ neutralization. Elimination of the use of a corrosive gas like HCl for chlorination of oxides has been recently attempted with the help of the chlorine-implantation technique (5-7). This idea, however, has the following problems. First, since rather large amounts ($> 10^{15}$ cm⁻²) of incorporated chlorine ions are required to achieve appreciable Na passivation (4), the resulting radiation damage in the oxide as well as at the interface is rather severe. It is necessary to anneal the implanted samples at temperatures in excess of 800°C in order to achieve adequate recovery of the damaged oxide and of the deteriorated Si/SiO₂ interface (8). Second, no Na passivation property is exhibited by chlorine implanted oxides annealed at temperatures in excess of 700°C (5-7). These observations may imply that the sodium neutralization mechanisms which operate in the case of HCl oxides are absent in the chlorine-implanted oxides. The recent work on x-ray microanalysis and electron microscopy of HCl oxides (9-11) has established that a Cl containing separate amorphous phase is formed at the Si/SiO₂ interface during HCl oxidation in the Na passivation regime. This result has received further support from x-ray photoelectron spectroscopy study of chlorine incorporation in HCl oxides (12). Formation of such a phase is possible when reactions of Si both with Cl and O are competing as they are at the O-deficient oxidation front at the interface. The correlation of formation of this phase with significant Na neutralizations has been demonstrated (9-11). It is not clear whether a similar phenomenon is possible in the case of Cl-implanted oxides in view of the larger Si-O bond energy as compared to the Si-Cl energy. There is also the possibility that a considerable loss of Cl takes place during thermal annealing of Cl-implanted oxides at temperatures exceeding 700°C, in contrast to the observations that the amount of Cl incorporated in HCl grown oxides does not reduce appreciably unless the annealing temperatures well exceed 1100°C (13, 14). This, of course, would be the

case if the chemical state of a Cl atom is not the same in the two situations. The purpose of the present paper is to report the result of our nuclear (Rutherford) backscattering (NBS or RBS) experiments on Cl incorporated in SiO₂ by ion implantations. They provide clear evidence that the implanted Cl atoms diffuse away as the annealing temperatures exceed 600°C. We further deduce that the diffusivity of implanted Cl is characterized by a small activation energy of about 0.5 eV.

Experimental

Silicon wafers [(100), n-type, phosphorous-doped, 2.6-3.2 Ω cm, polished] were thoroughly cleaned in standard H₂O₂-based basic and acidic solutions along with dilute HF dips and DI water rinses. They were then oxidized in dry O₂ for 75 min at 1100°C. Ellipsometric measurements made on a Gaertner Scientific Model 117 gave a thickness of 1415.8Å and refractive index 1.46 for these oxides. [The measured value of the thickness increased to about 1450Å on implantation due to the dilation effect (8).] ³⁵Cl ions obtained from a cobalt chloride source were implanted uniformly all over the front side of the oxidized wafers after removing the oxide on the back surface. The implantation dose was 8×10^{15} cm⁻² at an energy of 50 keV. The expected range of Cl in SiO₂ at 50 keV from the plots of calculations based on an improved Lindhard-Sharff-Schiott formulation (15) is about 500Å. The wafers were then cut into four quarters each and collected into four groups called C(1), C(2), C(3), and C(4). Samples C(2), C(3), and C(4) were separately annealed in dry N₂ for 30 min at 600°, 850°, and 1100°C, respectively, while C(1) was left unannealed. The moisture level in the dry oxygen and nitrogen used in these experiments was stated by the suppliers to be about 4 ppm. Samples C(1), C(2), C(3), and C(4) were now cut to obtain pieces with the dimensions 8 × 6 mm, suitable for mounting in the RBS measurement setup. ⁴He ions of energy 2 MeV were incident on the samples at a current of 20 nA to give integrated charge of 10 μC. The surface barrier detector detected the backscattered particles at a scattering angle of 165°. The detector solid angle was 1.9 msterad. The vacuum in the system was about 10⁻⁶ torr. To obtain the channel number to energy conversion, RBS experiments for scattering from Al and Au target films were also carried out.

Results and Discussion

We first briefly discuss the process of Rutherford backscattering (16) and the associated kinematics with the help of Fig. 1 as follows. The scattering cross section in the center of mass (c.m.) frame is

Fig. 1. (a) Kinematics of Rutherford backscattering of ^4He ions from atoms in SiO_2 on Si. (b) The expected energy spectrum of the backscattered ions (schematic).

$$\sigma_c = \frac{1}{16} \frac{zZe^2}{\frac{1}{2}\mu v^2} \sin^4(\theta_c/2) \quad [1]$$

where $z(m)$ and $Z(M)$, respectively, are the projectile and target charges (masses), v is the c.m. velocity, and $\mu = mM/(m + M)$. The laboratory frame cross section is given by

$$\sigma_L = \left(\frac{zZe^2}{4E}\right)^2 \frac{4}{\sin^4 \theta} \frac{\left\{ \left[1 - \left(\frac{m}{M} \sin \theta\right)^2 \right]^{1/2} + \cos \theta \right\}^2}{\left[1 - \left(\frac{m}{M} \sin \theta\right)^2 \right]^{1/2}} \quad [2]$$

$$\approx \left(\frac{zZe^2}{4E}\right)^2 \left[\sin^{-4} \frac{\theta}{2} - 2 \left(\frac{m^2}{M}\right) + O\left(\left(\frac{m}{M}\right)^4\right) \right] \quad [3]$$

where E is the energy before scattering. The energy of particles scattered by the atoms at the surface is related to the incident energy E_0 by

$$E_1 = K_M E_0 \quad [4]$$

where

$$K_M = \left(\frac{m}{M+m}\right)^2 \left[\cos \theta + \left(\frac{M^2}{m} - \sin^2 \theta\right)^{1/2} \right]^2 \quad [5]$$

To convert the RBS data of yield per channel into yield *vs.* energy, the observed spectra due to scattering from Si and O atoms in SiO_2 and from Au and Al films can be used to obtain a plot of the channel number at the high energy edge E_1 of the various peaks *vs.* the corresponding kinematic factors K_M (Eq. [5]). The standard practice (in the case of peaks broader than the resolution width) is to associate the scattering from surface atoms with the half-height points on the leading edge. We found that scattering from O, Al, Si, and Au atoms on the sur-

face occurs at channel no. 183, 289, 299.5, and 500, respectively, whereas the corresponding values of the kinematic factor K_M are given by 0.3635, 0.5555, 0.568, and 0.923. This leads to a straight line plot with a slope of $\psi = 3.53$ keV/channel and an offset of -35 keV. It is now possible to express RBS spectra in terms of yield *vs.* energy. The target atoms inside the surface of a substrate see less energetic ions due to the energy loss in the traversed path. Atoms in a thin SiO_2 film close to the Si/SiO₂ interface, for instance, see ions of energy $E_2 \approx E_0 - (dE/dt) t_{\text{ox}}$, where (dE/dt) is the rate of energy loss at the incident energy. The displacement of detected energy δE from E_1 is related to the depth δt in SiO_2 by

$$\delta E = [S] \delta t \quad [6]$$

where the stopping factor $[S]$ given as

$$[S] = \left[(dE/dt)_{E_{\text{in}}} K_M + (dE/dt)_{E_{\text{out}}} \frac{1}{\cos \theta} \right] \quad [7]$$

is related to the stopping cross section $[\epsilon]$ by $[S] = [\epsilon]N$, where N is the density of SiO_2 units. For thin films and when the E dependence of $[\epsilon]$ is insignificant, one can obtain the energy width ΔE corresponding to the full thickness of the film under the surface energy approximation. Since t_{ox} is given by ellipsometric measurements to be about 1400\AA , $[\epsilon]_{\text{SiO}_2}$ at 2 MeV for scattering from Si in SiO_2 is $2.26 \times 10^{-1} \text{ eV cm}^2$ (16), and, taking N_{SiO_2} to be $2.3 \times 10^{22} \text{ cm}^{-3}$, one obtains $\Delta E(\text{Si})$ to be 72.7 keV. This, using $\psi = 3.53$ keV/channel, can be seen to correspond to about 20 channels. Using $\Delta E(\text{Cl}) = \Delta E(\text{Si})\eta$ where $\eta = [S]_{\text{Cl}}/[S]_{\text{Si}}$ [which is about 1.01 (14)], and Eq. [4] for Cl, one has $K_M(\text{Cl}) = 0.637$, $E_1(\text{Cl}) = 1.2736$ MeV, and $\Delta E(\text{Cl}) \approx 73.4$ keV.

Figure 2 shows the RBS yield against channel number spectra for samples C(1), C(2), C(3), and C(4). The results provide clear evidence for the loss of the Cl atoms during postimplant annealing. This is to be contrasted with the fact that no appreciable loss of Cl incorporated in the HCl-grown oxides occurs unless the annealing temperatures well exceed 1100°C (13, 14). This may be taken as an indication that the physicochemical environment of Cl atoms in the two cases is quite different. The results of Fig. 2 can, to some extent, explain the observed failure (5-7) of Cl-implanted samples in exhibiting Na passivation when annealed at temperatures of 700°C or higher. It must, however, be pointed out on the basis of Fig. 2 that the loss of Cl is not complete even at 1100°C [sample C(4)]. The failure of Na passivation in Cl-implanted samples, therefore, raises questions such as: is the presence of large Cl concentrations alone enough for Na passivation? Since the neutralizing negative charge must come from the silicon substrate, is the vicinity of the Cl containing phase to Si/SiO₂ interface crucial for Na passivation? Further study to clarify these aspects will be necessary.

Coming now to obtaining chlorine density profiles in SiO_2 from the RBS spectra, we note that Eq. [6] can be utilized to obtain the energy to depth conversion. In the ideal case, the ^{35}Cl peak can be well separated from the Si peak provided $E_4(\text{Cl}) > E_1(\text{Si})$ (see Fig. 1) which requires

$$\frac{E_1(\text{Si})}{[S]_{\text{Cl}}^{\text{SiO}_2}} \left(\frac{K_M(\text{Cl})}{K_M(\text{Si})} - 1 \right) > t_{\text{ox}} \quad [8]$$

For $E_0 = 2$ MeV, one can estimate the left-hand side of Eq. [8] to be about 2500\AA . In practice, however, the line shapes show departures from the ideal case (16) due to: (i) system resolution limitations, (ii) energy straggling for the projectile ions inside a target substrate, (iii) background counts due to pulse "pile up" on the high energy side, and (iv) dependence of various cross sections on the energy of the scattering ions, etc. These factors can affect the shapes of both the low and high energy edges and can also lead to slopes in the plateau region. In order to obtain the correct chlorine concentration profiles from the data of Fig. 2, one needs to eliminate the effects of the above factors as far as possible. To estimate the effects of the

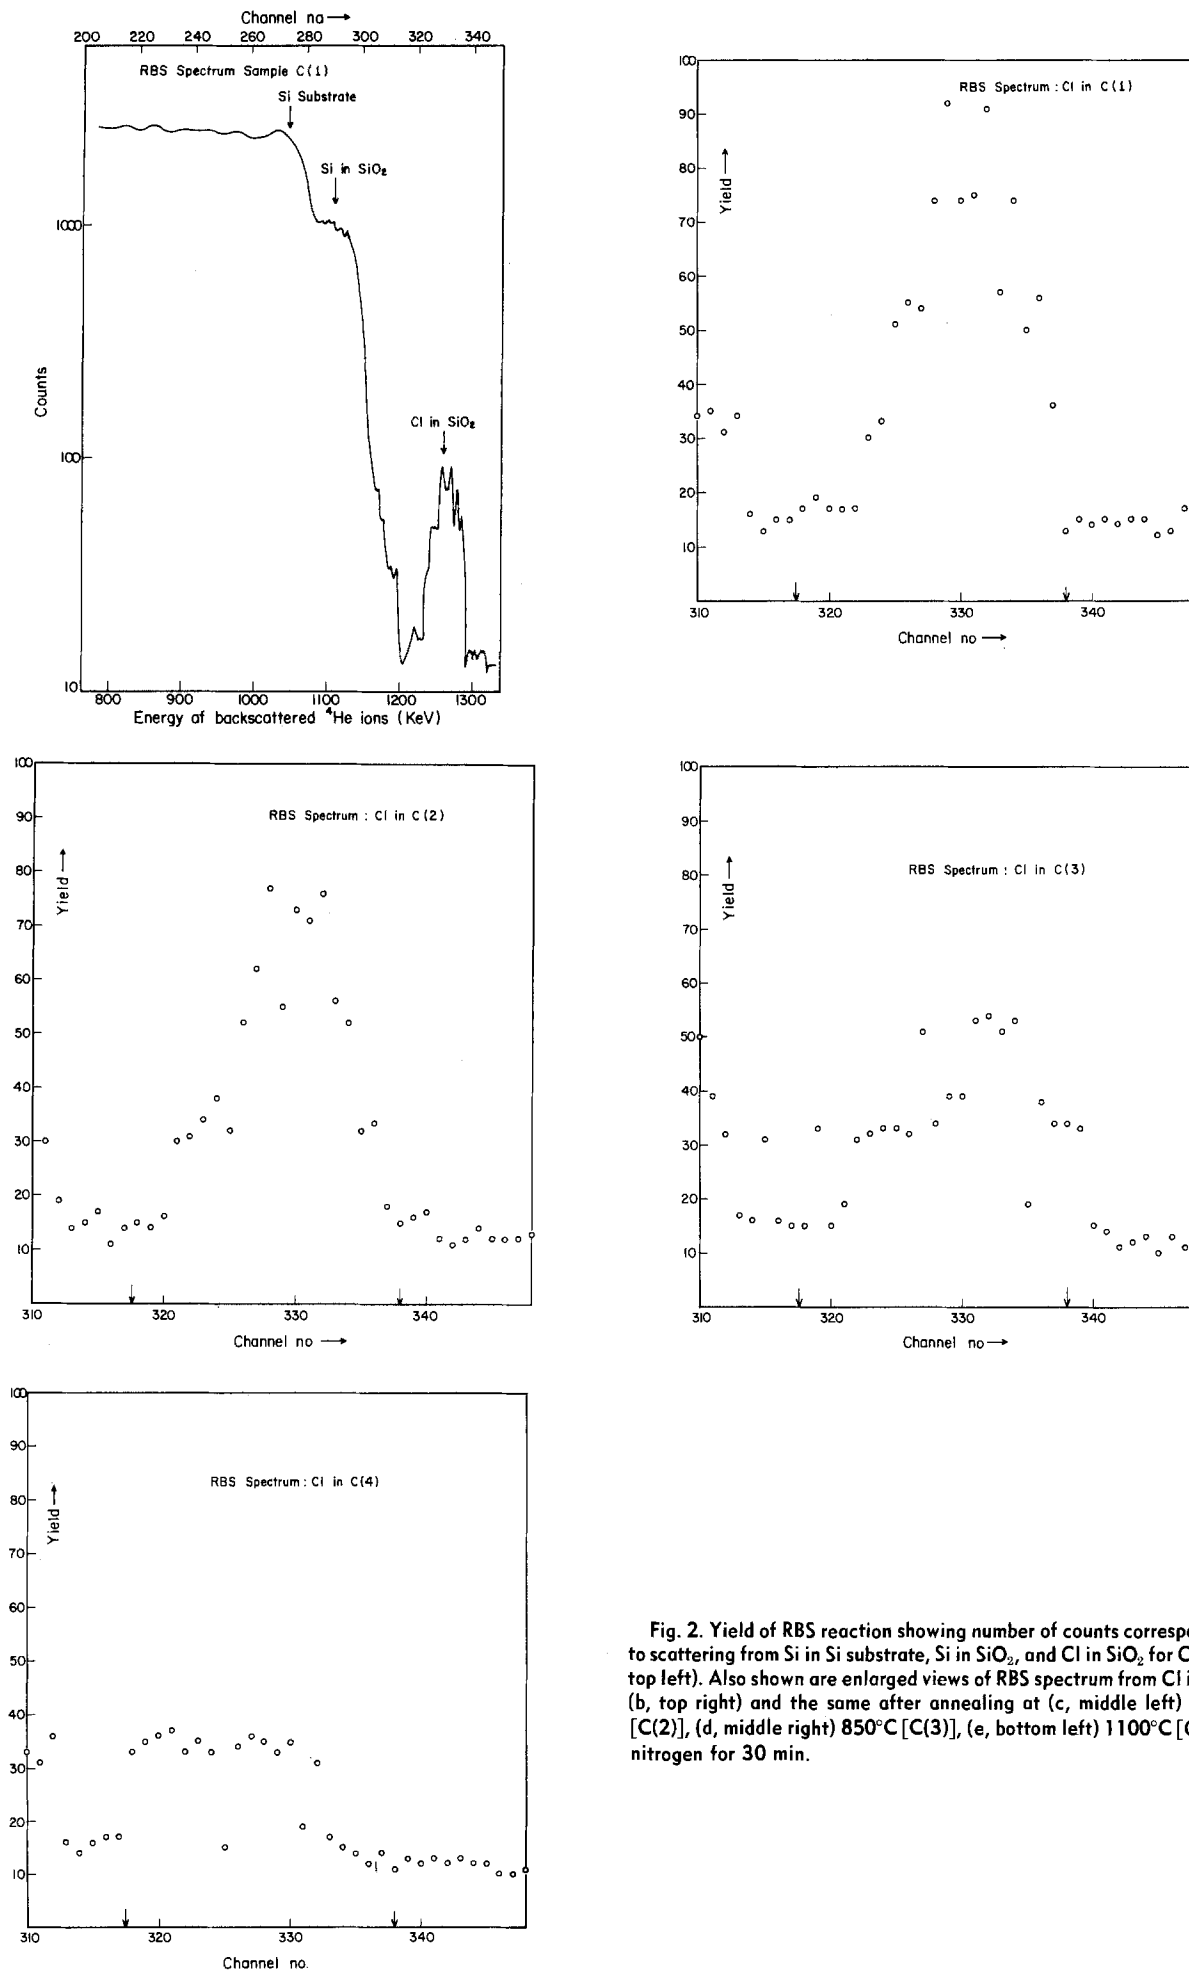

Fig. 2. Yield of RBS reaction showing number of counts corresponding to scattering from Si in Si substrate, Si in SiO_2 , and Cl in SiO_2 for C(1) (a, top left). Also shown are enlarged views of RBS spectrum from Cl in C(1) (b, top right) and the same after annealing at (c, middle left) 600°C [C(2)], (d, middle right) 850°C [C(3)], (e, bottom left) 1100°C [C(4)] in nitrogen for 30 min.

system resolution, it is customary to assume a gaussian form for the detection response function and estimate its full width at half maximum (FWHM) either by obtaining

the energy difference for the points on high energy edge for Si in SiO₂ corresponding to 12% and 88% of the peak height or by measuring FWHM of the peak for a very thin

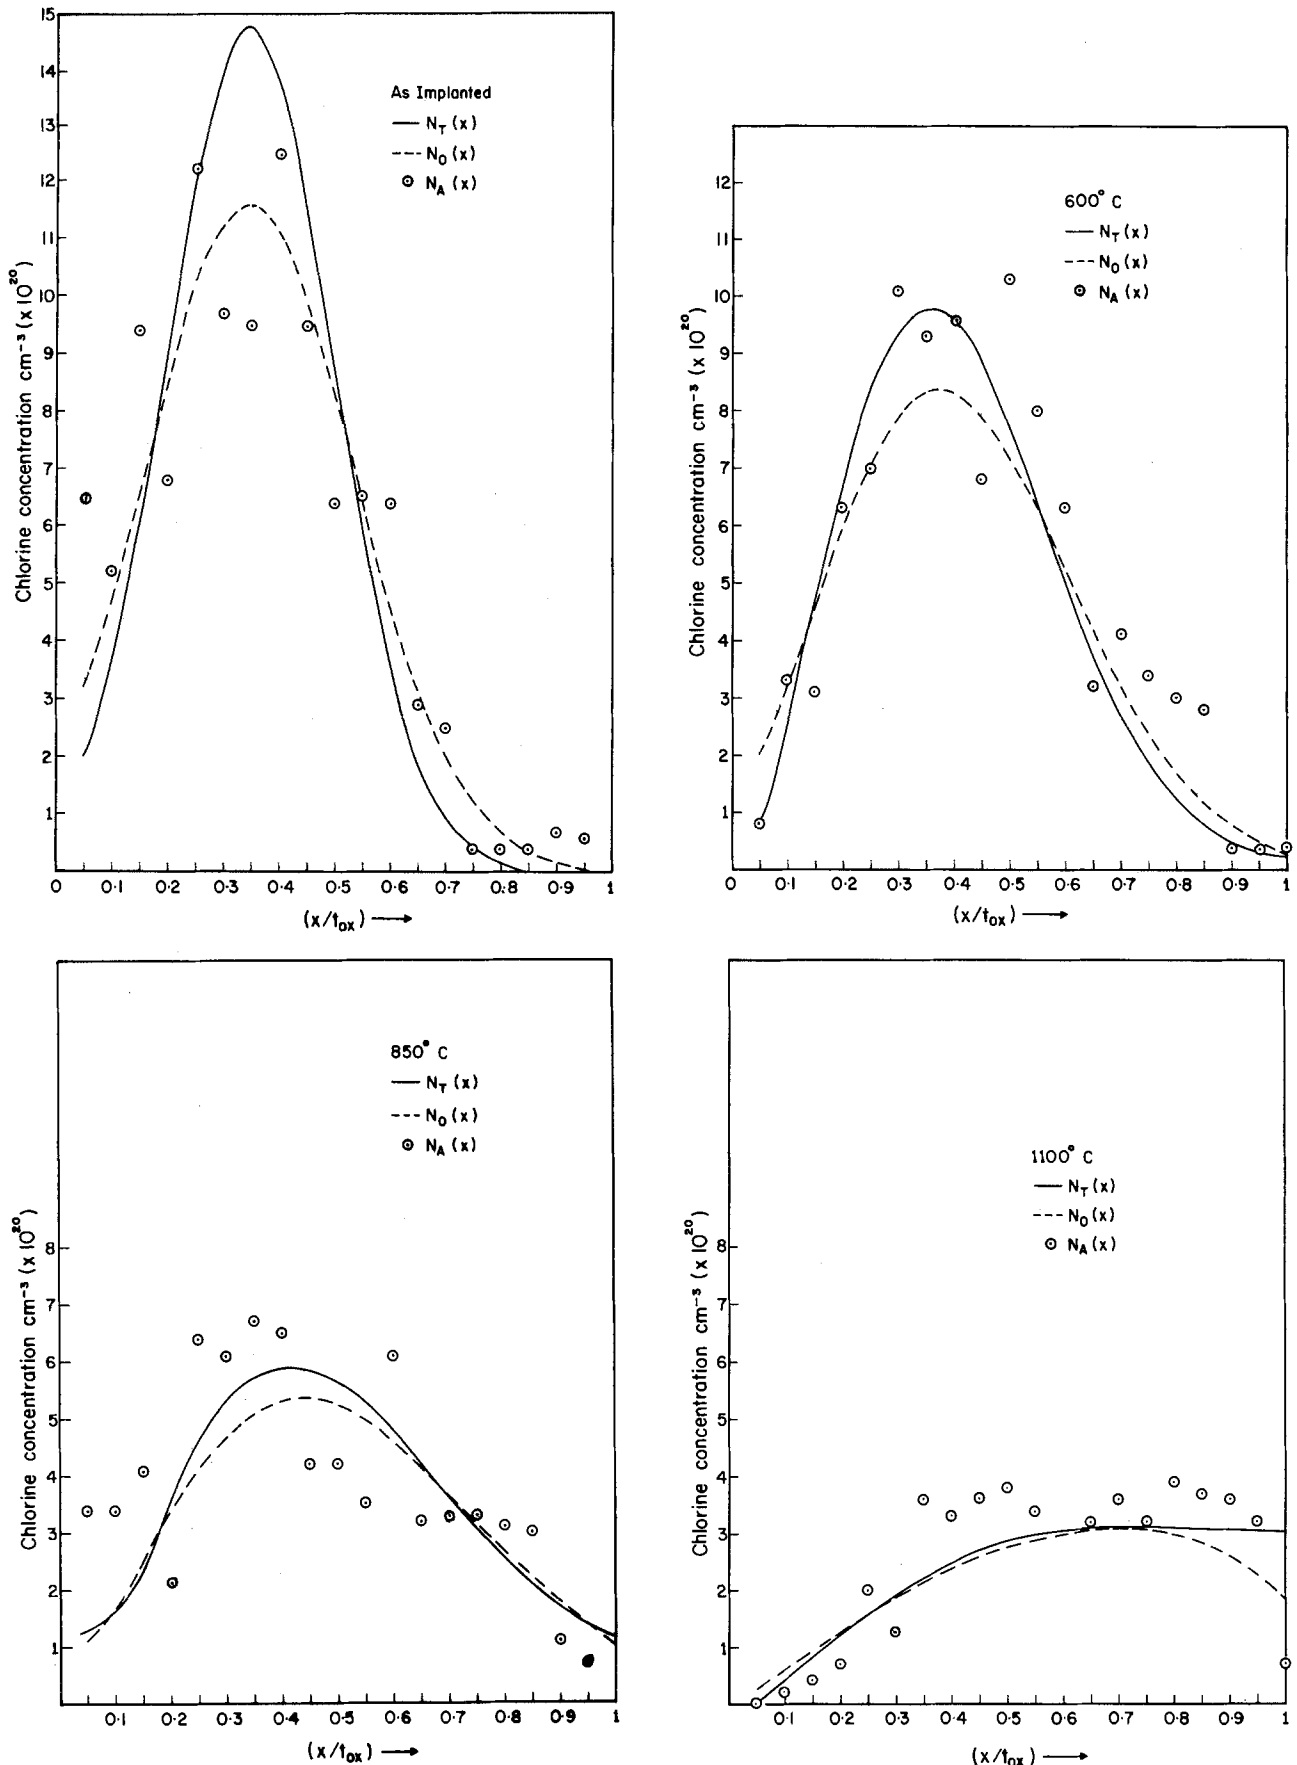

Fig. 3. (a, top left) Chlorine depth profile after implantation in SiO₂ at 50 keV with a dose of $8 \times 10^{15} \text{ cm}^{-2}$ and the profiles for samples C(2) (b, top right), C(3) (c, bottom left), and C(4) (d, bottom right) after annealing. N_O are the fits to the data points N_A , while N_T give the true profiles (corrected for resolution, see text), $(x/t_{\text{ox}}) = 0.0$ is the oxide surface.

Au film. We have obtained from both these methods an estimate for the system resolution FWHM of about 21 keV. The standard deviation Ω_R of the resolution function is to be equated to FWHM/2.355. The second factor, namely, the energy straggling due to fluctuations in the number of collisions (and the energy lost in each) the incident ions experience in traversing a distance inside the substrate, has a smaller effect in the case of a thin film such as the one we have. One usually estimates the energy straggling variance for a thin film with the help of the formula (16)

$$\Omega_S^2 = \Omega_B^2 (K_M + 1/\cos \theta) \quad [9a]$$

where

$$\Omega_B^2 = 4\pi (Ze^2)^2 (ZN)_{\text{SiO}_2} t \quad [9b]$$

as given by Bohr's theory (16), $(ZN)_{\text{SiO}_2} = (Z_{\text{Si}} + 2Z_{\text{O}})N_{\text{SiO}_2}$ and $t =$ traversed depth in SiO_2 . For $t = t_{0x}$, Ω_B can be estimated to be about 3.0 keV, while an average of Ω_S^2 over "t" is about 2.7 keV. (We use this value as an approximation in the analysis to be described presently.) As for the background contribution to the yield due to pulse pile-up, one needs to use pile-up rejection electronics in the detection system. Not having done this, we have corrected the yield for chlorine by subtracting out a constant which is an average of the rather flat background seen for about 20 channels on the high energy side of $E_1(\text{Cl})$. Using the formula

$$(Nt)_{\text{Cl}} = \frac{A_{\text{Cl}}}{H_{\text{Si}}} \frac{\sigma_{\text{Si}}(E_0)}{\sigma_{\text{Cl}}(E_0)} \frac{\psi}{[\epsilon_0]_{\text{SiO}_2}^{\text{Si}}} \quad [10]$$

in the case of C(1), the corrected data points give $(Nt)_{\text{Cl}} = 8.49 \times 10^{15} \text{ cm}^{-2}$, which reproduces the nominal Cl implantation dose of $8 \times 10^{15} \text{ cm}^{-2}$ reasonably well. Here H_{Si} is the height of Si peak (for Si in SiO_2) and $A_{\text{Cl}} = \sum_i H_i(\text{Cl})$ is the area under the Cl peak. [Surface energy approximation is used in Eq. [10] along with $\sigma_{\text{Si}}(E_0)/\sigma_{\text{Cl}}(E_0) = 0.638$.] The chlorine peak density is obtained from

$$N_{\text{Cl}}^{\text{Peak}} = \frac{H_{\text{Cl}}^{\text{Peak}}}{H_{\text{Si}}} \left(\frac{\sigma_{\text{Si}}(E_0)}{\sigma_{\text{Cl}}(E_0)} \right) \frac{[\epsilon_0]_{\text{SiO}_2}^{\text{Cl}}}{[\epsilon_0]_{\text{SiO}_2}^{\text{Si}}} N_{\text{Si}}^{\text{SiO}_2} \quad [11]$$

to be $1.26 \times 10^{21} \text{ cm}^{-3}$, where $N_{\text{Si}}^{\text{SiO}_2} = 2.3 \times 10^{22} \text{ cm}^{-3}$. Now we express the "observed" density profile $N_O(E)$ in terms of the true profile $N_T(E)$ as follows (18)

$$N_O(E) = \int_{\text{all channels}} N_T(E') R(E - E') dE' \quad [12]$$

where R is the resolution function and is assumed to be a gaussian with a standard deviation of $(\Omega_R^2 + \Omega_S^2)^{1/2}$ where Ω_S may take channel number dependent values. To extract $N_T(E)$ from Eq. [12], we have followed the following

procedure. First: $N_T(E)$ is initially obtained from process simulation program SUPREM II (17) using trial input parameters such as implantation dose, range, and standard deviation as well as diffusion, surface transport, and segregation coefficients. Since chlorine diffusion is not considered in SUPREM II, we use As as the dummy name to simulate Cl diffusion in SiO_2 by appropriately varying the above parameters. The second step is to use Eq. [12] to obtain $N_O(E)$, which is a smooth function and is expected to serve as a fit to the actual data points $N_A(E)$. We vary the values of the input parameters in $N_T(E)$ until Eq. [12] obtains a least χ^2 fit $N_O(E)$ to $N_A(E)$. Here $\chi^2 = \sum_i ([N_O(E_i) - N_A(E_i)]/\delta N_A(E_i))^2$ and δN_A is the error in N_A given by $\sqrt{N_A}$ for Poisson statistics. A reasonable, simplifying approximation is made by restricting the integration in Eq. [12] to those channels which correspond to Cl in SiO_2 . The procedure outlined earlier is used to obtain the energy to depth scale conversion. Figure 3 shows the data points $N_A(x)$ along with the fit $N_O(x)$ to those points and the corrected line shapes $N_T(x)$. It may be noticed that the 50 keV Cl implantation in SiO_2 [sample C(1)], Fig. 3a, follows a gaussian form with a range of 440Å and a standard deviation of 220Å. These may be compared with the predicted values of 500 and 160Å, respectively, based on Lindhard-Shorff-Schiott theory (15). Table I summarizes the values of the various parameters used to obtain $N_O(x)$ and $N_T(x)$ by allowing SUPREM II to simulate Cl diffusion in SiO_2 during annealing at 600°, 850°, and 1100°C for 30 min in N_2 , given the initial distribution of Fig. 3a. We first reach a minimum χ^2 point by varying $D_{\text{Cl}}(\text{SiO}_2)$. Then all the parameters are varied to obtain smaller χ^2 . We find that the fits and χ^2 are not very sensitive to variations in S_G , S_T , and $D(\text{Si})$. To get an idea of this behavior, Table I shows various values of S_G , S_T , and $D(\text{Si})$ and the corresponding χ^2 . Figure 4 shows the plot of $D_{\text{Cl}}(\text{SiO}_2)$ given by SUPREM II against $1000/T$. From the line shown in Fig. 4 as an attempt to fit these points, one can deduce that $D = D_0 \exp(-E_a/kT)$, where $D_0 \cong 10^{-12} \text{ cm}^2/\text{s}$ and the activation energy $E_a \cong 0.5 \text{ eV}$. This rather small activation energy is comparable to that for H_2 diffusion in SiO_2 (-0.7 eV) (19). The pre-exponent in $D(\text{Cl})$, however, seems to be smaller than that for most impurities in SiO_2 . It may be noted that Greeuw and Hosper (5) had earlier suggested a much larger estimate of $E_a \sim 2 \text{ eV}$ based on their long wavelength x-ray analysis of Cl-implanted oxides, D_0 was given to be $2 \times 10^{-6} \text{ cm}^2/\text{s}$. Their value of D can be found to vary between 10^{-17} and 10^{-13} in the range 600°-1100°C. The orders of magnitude of these numbers are comparable to those of this paper. On the other hand, the value $D = 10^{-11} \text{ cm}^2/\text{s}$ estimated by Schaeffer *et al.* (20) at 750°C from their tracer experiments on radioactive chlorine (^{36}Cl) solution on SiO_2 is much larger. The sources of this discrepancy are not immediately clear. Figure 5, in which we show R ,

the percentage loss of Cl against temperature T , indicates that about 56% of implanted charge has been lost from SiO_2 after annealing at 1100°C in nitrogen for 30 min. We find that $R \sim bT$, where $b \sim 0.08^\circ\text{C}$.

Conclusion

We have shown in this paper, with the help of our experiments on Rutherford backscattering from Cl ions implanted in a thin thermal SiO_2 film on Si, that: (i) the implanted Cl atoms diffuse away as one anneals the samples at temperatures in excess of 600°C . (ii) the chlorine implantation profile shows a gaussian form ($\sim \exp -((x - R_p)^2/2\Delta R_p^2)$) with $R_p = 440\text{\AA}$ and $\Delta R_p = 220\text{\AA}$ after corrections for system resolution and energy straggling effects. We have also obtained the chlorine profiles (corrected for system resolution and projectile energy straggling effects) after diffusion in SiO_2 during annealing at 600° , 850° , and 1100°C in nitrogen. An estimate based on the process simulation program SUPREM II indicates an Arrhenius relation $D = D_0 \exp(-E_a/kT)$ for the Cl diffusion coefficient in SiO_2 with $D_0 \sim 10^{-12} \text{ cm}^2/\text{s}$ and $E_a = 0.5 \text{ eV}$. The results show that the implanted Cl has a diffusivity different from that of Cl in HCl-grown oxides.

Acknowledgments

We wish to express our gratitude to Professor S. C. Jain, Director, Solid State Physics Laboratory, New Delhi, Dr. K. K. Laroia and other staff for providing the Cl implantation facility in their laboratory. We gratefully acknowledge the help of Mr. Animesh Jain of Bhabha Atomic Research Centre, Bombay, where the RBS measurements were carried out. We thank Mr. P. R. Apte for his help in use of SUPREM II.

Oxygen RIE-Resistant Deep-UV Positive Resists: Poly (trimethylsilylmethyl methacrylate) and Poly (trimethylsilylmethyl methacrylate-co-3-oximo-2-butanone methacrylate)

E. Reichmanis and G. Smolinsky

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The polymer, P(SiMA), derived from trimethylsilylmethyl methacrylate and the copolymer, P(SI-OM), with 3-oximino-2-butanone methacrylate are resistant to oxygen reactive ion etching in the pressure range 20-100 μm and thus are effective patterning masks for planarizing layers such as hard-baked HPR-204. At 100 μm of O_2 , the latter material is etched about 40 times faster than either methacrylate resin. P(SI-OM) is sensitive to short wavelength (≤ 260 nm) radiation. A resin containing 25% oxime requires an exposure dose of 0.25 J/cm^2 to delineate 0.75 and 1.0 μm lines and spaces. These materials are potentially useful in a bilevel resist system.

Incorporation of silicon into organic polymers generates materials which are resistant to oxygen reactive ion etching (RIE) and thus are potentially useful in two-level photoresist processes. The effects of silicon were first reported by Taylor and Wolf (1), who suggested that a protective layer of SiO_2 was formed when the polymers were exposed to an oxygen discharge. These findings laid the basis for the development of resist systems which could be employed in a multilevel RIE pattern-transfer process as depicted in Fig. 1. Specifically, the chemical incorporation of silicon into a novolak-base polymer (2) has proved effective in enhancing the oxygen RIE resistance of these polymers. Several silicon-substituted, negative, deep-UV resists have also been reported. The trimethylsilyl group has been used to lower the oxygen discharge erosion rate of styrene-chlorostyrene (3) and styrene-chloromethylstyrene (4) copolymers, and thin films of dialkylsiloxane polymers have themselves proved useful as deep-UV negative resists (5).

Since a positive deep-UV resist is desirable to ensure high resolution capabilities, we previously investigated the efficacy of siloxane substitution on methacrylate polymers for improving the oxygen RIE resistance of poly(methyl methacrylate) (PMMA) without destroying its high resolution properties (6). Terpolymers of methyl methacrylate, methacrylic acid, and pentamethyldisiloxypropyl methacrylate are high resolution, RIE-resistant materials, which, however, lack photosensitivity. While improvements in resist sensitivity should obtain upon incorporation of such photoreactive chromophores as the α -keto-oxime in 3-oximino-2-butanone methacrylate (7-9) preparation of the four-component polymers may be complicated.

Sensitive, high resolution, oxygen RIE-resistant, deep-UV resists have been prepared using trimethylsilylmethyl methacrylate and 3-oximino-2-butanone methacrylate as components. Etching rate ratios relative to hard-baked HPR-204 (novolac-quinonediazide conventional photoresist) of 12 to 45:1 have been observed, and it is demonstrated that these resists are useful as oxygen RIE masks in two-level photoresist systems employing dry etching pattern-transfer techniques.

Experimental

Materials.—3-Oximino-2-butanone methacrylate was prepared as described in the literature (7). Trimethylsilylmethyl methacrylate was obtained from Petrarch Systems, Incorporated. High molecular weight ($M_w \sim 250,000$) poly(methyl methacrylate) was obtained from the Aldrich Chemical Company and used without further purification. HPR-204 photoresist was obtained from the Philip A. Hunt Chemical Company. Hexane, cyclohexane, cyclopentanone (Gold Label spectroquality solvents), and methyl isobutyl ketone were obtained from the Aldrich

Chemical Company. Ethyl acetate and toluene were obtained from MCB, Incorporated.

Poly (trimethylsilylmethyl methacrylate) and copolymers of trimethylsilylmethyl methacrylate and 3-oximino-2-butanone methacrylate were prepared and purified by standard techniques. Conversions were carried out to $<20\%$. Molecular parameters for these polymers are given in Table I.

Processes.—Under typical processing conditions, the polymer (10 weight percent [w/o]) was dissolved in cyclopentanone, filtered through a 0.5 μm membrane, applied with a spin coater (Headway Research Spinner, Model EC101) operated at 4000 rpm, to either silicon, hard-baked HPR-204 on silicon, or NaCl substrates and baked at 150°C for 60 min. HPR-204-coated silicon substrates were prepared in the same manner to give nominal 1 μm thick films which were baked at 250°C for 60 min.

The oxygen RIE resistance of each polymer was determined by etching the appropriately coated silicon substrate in a Cooke Vacuum Products, Incorporated, Model C71 RIE system. The etching rates were determined from the slope of the least squares linear fit of points obtained

from a measurement of thickness as a function of elapsed etching time. The rates are essentially linear with time.

Resist sensitivity and contrast were ascertained by contact/proximity printing the coated substrates through a quartz Multidensity Resolution Target (Model B, Opto-Line Corporation) with a deep-UV exposure system (Model 29DH, Optical Associates, Incorporated) optimized for use at 260 ± 20 nm.

Infrared spectra of resist films coated on NaCl substrates were obtained with a Nicolet Model 5DX FT-IR spectrophotometer.

Results and Discussion

Poly(trimethylsilylmethyl methacrylate) [P(SiMA)] was examined for its physical properties and ability to withstand oxygen RIE treatment. The relatively high glass transition temperature (T_g) of this material (108°C) obviates the need for enhancement via copolymerization. It is possible to increase the photosensitivity of the system

through incorporation of such monomers as 3-oximino-2-butanone methacrylate. To this end, three different compositions of poly(trimethylsilylmethyl methacrylate-co-3-oximino-2-butanone methacrylate) [P(SI-OM)] were prepared. In all cases, the amount of silicon actually incorporated into the polymer was lower than that anticipated from the monomer ratios. While this may result partially from solvent trapped in the resin, it also implies that the reactivity ratios (r) for the two components are unequal. A higher value for the α -keto-oxime would explain the increased incorporation of the nonsilicon containing species.

Examination of Table I reveals that the absorbance of (nominal) $1 \mu\text{m}$ films of P(SI-OM) increases with increasing keto-oxime content. Absorbance values are listed for 248 nm and for the maximum at 215 nm. Figure 2 compares the absorption spectra of P(SiMA) and P(SI-OM)

Fig. 2. The absorption spectra of nominal $1 \mu\text{m}$ films of P(SiMA) (—) and P(SI-OM) (77:23) (---).

(77:23). The degradation mechanism of these materials should be similar to that observed for PMMA and copolymers of methyl methacrylate and 3-oximino-2-butanone methacrylate, and is outlined in Fig. 3.

Oxygen RIE behavior.—The oxygen RIE rates of P(SiMA) and P(SI-OM) at a pressure of 20 μm are given in Table II. The values for PMMA and HPR-204 are included as reference points. As expected from the study of etching rate vs. silicon content in the series of pentamethyldisiloxypropyl methacrylate polymers (6) (where only small incremental reductions in etching rate were observed with increased silicon content above about 8-10%), only minor variations in the oxygen RIE rate are observed for the polymers investigated in the current study.

P(SI-OM)	90:10	14.33	70	(25)
P(SI-OM)	77:23	10.80	125	70
P(SI-OM)	62:38	9.61	150	70

While an increase in power effects an increase in etching rate of both HPR-204 and P(SiMA) (Fig. 4), an increase in oxygen pressure results in a decrease in the etching rate of P(SiMA). Figure 5 depicts the etching rate vs. time for P(SiMA) at low and high oxygen pressure. A comparison of the rates obtained for HPR-204, P(SiMA), and P(SI-OM) at an oxygen pressure of 20 vs. 100 μm is given in Table II. The silicon substituted species generally show a decrease in etching rate with increased pressure, while the converse is true for HPR-204. This effect appears linear with respect to pressure, as seen in Fig. 6, which depicts the RIE rate of HPR-204 and P(SiMA) as a function of oxygen pressure. An etching rate ratio ranging from 12:1 to >40:1 may be obtained for the silylated polymers vs. HPR-204.

The divergence observed in the etching rates of P(SiMA) and HPR-204 vs. oxygen pressure (see Fig. 6) is readily explained. An increase in pressure effects an increase in the concentration of reactive species in the discharge. Thus, a polymer such as HPR-204, which generates only volatile etching products, will erode more rapidly as the pressure rises. However, P(SiMA) represents a situation in which both volatile and nonvolatile (*i.e.*, SiO_2) products result from RIE. Thus, if sufficient silicon is present in the polymer, an increased concentration of reactive oxygen species will more efficiently produce a uniform barrier of silicon oxide which will protect the underlying polymer from further RIE. Concomitantly, the increased pressure causes a decrease in the sputtering efficiency of the discharge which slows the removal of the silicon oxide layer and further enhances the etching rate differential between the HPR-204 and P(SiMA).

Oxygenated silicon species are formed upon oxygen RIE treatment of P(SiMA) and its α -keto-oxime analogs. Although we have been unable to conclusively show the formation of SiO_2 , it is clear from the changes in the IR spectra before and after etching that Si-O bonds have been generated.

Lithographic characteristics.—The silylated polymers are positive working photoresists whose sensitivities are far improved over the parent, PMMA. The exposure dose required for complete development of the irradiated regions with minimum loss of film thickness in the unirradiated areas is given in Table III. It was not possible to

find a suitable developing solvent for P(SI-OM) (90:10), *i.e.*, the polymer was simply too soluble in all solvents examined. Generally, silylation of methacrylate polymers affords increased solubility in organic solvents. This is evidenced by the need to use the hydrocarbon solvents hexane and cyclohexane for the development of P(SI-OM) (77:23) and P(SI-OM) (62:38), respectively.

The improved absorption characteristics of P(SI-OM) relative to P(SiMA) (see Fig. 2 and Table I) lead to improved sensitivity of these copolymers relative to P(SiMA) and PMMA (Table III). The exposure required to clear an area of 1 cm^2 drops from 1.05 J/cm^2 for P(SiMA) to 0.13 J/cm^2 for P(SI-OM) (77:23). Table III also gives the dose required to delineate 0.75 and $1 \mu\text{m}$ features in the

resists examined. Of interest are the doses required for P(SI-OM) (77:23) and P(SI-OM) (62:38), which are 0.3 and 0.25 J/cm^2 , respectively.

Resist contrast (γ), the rate at which a resist responds to incident light, is given in Table III along with the sensitivity data. Figure 7 depicts the contrast curves for P(SiMA) and P(SI-OM) (62:38). The values are approximately equal to that of PMMA (~ 2).

The high resolution characteristics of PMMA have been retained in the silicon containing analogs. Figure 8 depicts lines and spaces with nominal dimensions of 0.75 , 1.0 , and $0.75 \mu\text{m}$ contact/proximity printed in $\sim 0.7 \mu\text{m}$ of P(SiMA), P(SI-OM) (85:15), and P(SI-OM) (62:38), respectively. The developers employed were those used to determine resist sensitivity and contrast, and are given in Table III. Deviations from the stated feature sizes result primarily from linewidth variations in the mask and imperfect mask to wafer contact.

Two-level photoresist processing.—The high resolution characteristics and oxygen RIE resistance of P(SiMA) and P(SI-OM) combine to produce deep-UV positive resists which act effectively as etching masks for a two-level pattern-transfer process such as that depicted in Fig. 1. Micron and submicron features printed in these resists are readily transferred through a hard-baked HPR-204 planarizing layer to the substrate. Figures 9a and 9b depict, respectively, nominal 0.75 and $1.25 \mu\text{m}$ lines and spaces obtained in P(SiMA) ($\sim 0.7 \mu\text{m}$) after RIE pattern transfer into HPR-204 ($\sim 1.2 \mu\text{m}$) at an oxygen pressure of $25 \mu\text{m}$. The effect of raising the pressure to $95 \mu\text{m}$ is

Fig. 8. SEM micrographs depicting nominal $0.75 \mu\text{m}$ lines and spaces printed in P(SiMA) top, $1.0 \mu\text{m}$ lines and spaces printed in P(SI-OM) (77:23), middle, and $0.75 \mu\text{m}$ lines and spaces printed in P(SI-OM) (62:38) bottom.

Fig. 11. SEM micrographs depicting nominal 1.25 μm , top, and (b) 2.0 μm , bottom, lines and spaces printed in P(SiMA) after RIE pattern transfer at an oxygen pressure of 25 μm followed by dilute HF rinse.

shown in Fig. 9c and 9d, which depict 1.5 and 1.25 μm lines and spaces, respectively, printed in the same resist. High resolution is observed at both pressures. However, the effects of residual photoresist on the surface of the planarizing layer are more pronounced at the higher oxygen pressure; for example, note the ragged left edge of the 1.25 μm lines shown in Fig. 9d, which is presumably due to both a decrease in sputtering and etching rate of the resist. Also, the surface of the polymer appears less rippled when higher oxygen pressures are employed. Decreased sputtering may result in decreased redeposition of material. Figure 10 depicts nominal 1.0 and 1.25 μm , and 0.75 and 1.5 μm lines and spaces printed in P(SI-OM) (77:23) and P(SI-OM) (62:38), respectively, followed by a 9 μm oxygen RIE pattern transfer. In these cases, the

photodefining layers were clearly delineated. While the increase in oxygen pressure does effect slight isotropic etching (compare, in particular, Fig. 10b with 9b), somewhat less residue is apparent in the larger open spaces because of a decrease in sputtering and consequent redeposition of material (*i.e.*, the effects of backsputtering are alleviated). With either high or low oxygen pressure, the residue appears to be primarily SiO_2 , which can be removed from the substrate by a brief (1 min) rinse with dilute aqueous HF (5%). This is demonstrated in Fig. 11, which depicts 1.25 and 2.0 μm lines and spaces printed in P(SiMA) followed by oxygen RIE pattern transfer and an HF rinse.

Summary

P(SiMA) has been shown to be a high resolution, oxygen RIE-resistant, deep-UV photoresist. Incorporation of 3-oximino-2-butanone methacrylate into this polymer renders it sensitive to short wavelength (≤ 260 nm) radiation without loss of resolution or etching resistance. P(SI-OM) (62:38) requires an exposure dose of 0.25 J/cm^2 to delineate 0.75 and 1.0 μm lines and spaces. The oxygen RIE rate of the polymer is on the order of 100 $\text{\AA}/\text{min}$ and decreases with a rise in pressure. P(SiMA) and P(SI-OM) (77:23) and (62:38) are effective etching masks for such planarizing materials as hard-baked HPR-204. Oxygen pressure-dependent etching ratios relative to the HPR-204 ranging from 12:1 to 45:1 have been observed.

An Optical Study of the Deposition, Discharge, and Recharge of Manganese Dioxide Films

J. L. Ord* and Z. Q. Huang¹

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

The galvanostatic electrodeposition of manganese dioxide films onto a platinum substrate is studied over a thickness range from 0 to 2000 nm. At the upper end of the thickness range, optical absorption causes the ellipsometer null settings to approach within 0.02° of the infinite thickness limit, at which the films are indistinguishable from substrates. The optical extinction coefficient increases with film thickness over the range 0-50 nm, but from 50 to 160 nm the films have optical constants which are independent of thickness but which depend on the deposition current density. Beyond 160 nm, the optical data become progressively more difficult to interpret in terms of uniform isotropic or anisotropic film models. When relatively thin films (50 nm) are transferred to alkaline electrolyte and are cycled galvanostatically, optical changes are observed which correlate well with the electrochemical behavior for both reversible partial discharge cycles and irreversible complete discharge cycles.

In a previous ellipsometric study (1), Spricis *et al.* found the optical properties of manganese dioxide films to be quite sensitive to the deposition conditions. The deposition was carried out using a sequence of potentiostatic pulses which enabled the process to be studied using a conventional ellipsometer, and increases in deposition potential and pulse duration were both reported to lower the extinction coefficient of the film by as much as a factor of two. For thicknesses below 40 nm, both the refractive index and the extinction coefficient were reported to vary somewhat with film thickness, and above about 70 nm the optical data were found to deviate from the theoretical curves. The thickness dependences were attributed to insular structure in the thinner films and surface roughening in the thicker films, and the extinction coefficient variation was attributed at least partially to a change in porosity.

In this paper, we use an automated ellipsometer to follow the galvanostatic deposition and charge-discharge cycling of manganese dioxide films. We study deposition over a current density range of 64 for thicknesses up to 2000 nm to see whether the reported dependence on thickness and deposition rate is found also under galvanostatic conditions. In the optical analysis, we use both isotropic and anisotropic film models to see whether or not the dependence of refractive index on film thickness is an artifact resulting from isotropic analysis of an anisotropic system. The objective of the study of charge-discharge cycles in alkaline electrolyte is more to evaluate the usefulness of ellipsometry for such measurements than to provide any definitive statement about the processes involved. Ellipsometry is an effective tool for the study of homogeneous film-conversion processes, but heterogeneous processes can only be studied if the film remains stratified.

This investigation forms part of our continuing study of oxidation and reduction processes which involve ionic transport through thin solid films. Included in this category are both the growth of films of fixed oxidation state by the anodic oxidation of a substrate and the oxidation or reduction without film growth which occurs in batteries and electrochromic displays. Our ellipsometric studies of charge-discharge cycles on nickel hydroxide (2, 3) and color-bleach cycles on tungsten oxide (4) and iridium hydroxide (5) lead us to conclude that all of the processes involve the homogeneous conversion to oxyhydroxide by a mechanism in which hydrogen ions from the electrolyte move into the film and back out again, exactly the same mechanism proposed for the initial reversible stage of the discharge of manganese dioxide (6). DeSmet and co-workers have carried out ellipsometric

investigations of heterogeneous electrochromic processes in the anodic oxides of vanadium (7) and molybdenum (8), but these processes can be reversed and may have little in common with the heterogeneous stage of the discharge of manganese dioxide.

Experimental

The manganese dioxide films were deposited onto a platinum single-crystal electrode from 0.1M MnSO₄ + 0.017M H₂SO₄, the same pH 2 electrolyte used in the earlier potentiostatic study (1). The alkaline electrolyte used for the charge-discharge cycles was 0.05M NaOH. The cell consists of a hollow equilateral glass prism with standard-taper joints for the working electrode holder, a platinum counterelectrode, a gas dispersion tube, and the mercury-mercurous sulfate electrode to which all potentials quoted in this paper are referenced. The electrolyte was maintained at room temperature (22°C), and was air saturated, except in experiments testing for the effect of dissolved oxygen, where it was argon saturated. The working electrode is in the form of a cylinder with a flat on one side for optical measurements, and when it is clamped between Teflon washers in its holder and mounted in the cell, it exposes a vertical surface 1.44 cm² in area to the electrolyte.

The self-nulling ellipsometer uses quadrature Faraday modulation decoded by a two-phase lock-in amplifier and fed back to ministepping drives through voltage-to-frequency converters. Under typical operating conditions, the instrument has a response time of a few tenths of a second and a resolution of a few thousandths of a degree. The angle of incidence is set at 60° to accommodate the equilateral cell, and refractive index values quoted here are for a wavelength of 632.8 nm, the wavelength of the helium-neon laser source.

A process-control computer operates the circuitry used with the cell and records current and potential along with polarizer and analyzer settings at specified time intervals. Potentials are digitized by a 16-bit analog-to-digital converter with a 25 μs conversion time. The operation of the ellipsometer is monitored on a four-trace oscilloscope, and progress of the experiment is followed on two storage displays and an X-Y plotter which are updated by the computer.

Results and Discussion

Figure 1 shows results from a deposition experiment at a current density of 44 μA/cm². Aside from a minor initial overshoot, the potential-time plot in the lower portion of the figure is featureless. However, the polarizer *vs.* analyzer (P-A) plot of the ellipsometer null settings in the upper portion of the figure shows a great deal of structure, spiraling outward from point A to form open loops, then spiraling inward toward a different point as the film becomes quite thick. P-A curves of this type are characteris-

Fig. 1. Galvanostatic deposition onto a platinum substrate at $44 \mu\text{A}/\text{cm}^2$.

tic of the growth of a film which absorbs some of the light passing through it. An ellipsometer measures the change in polarization resulting from interference between light reflected at the electrolyte-film and film-substrate interfaces, and growth of a transparent film produces a P-A "loop," which closes when the product of film thickness and the cosine of the angle of refraction is equal to half the wavelength of light in the film. If the film is partially absorbing, the loop does not close, and an outward spiral results. Light reflected at the substrate interface traverses the film twice before superimposing on light reflected at the electrolyte interface, and hence its amplitude becomes progressively smaller as the film grows if the film is optically absorbing. When film growth reaches the point where the amplitudes are greatly different, interference can have only a small effect on the polarization of the reflected light, and the P-A locus spirals rapidly inward. The point toward which it spirals is the point at which the film becomes the substrate as far as optical measurements are concerned. For the deposition experiment in Fig. 1, this point (not shown in the figure) is reached by the end of a 6h deposition.

Deposition experiments at the other current densities give optical results which are similar in their general character, but different in specific detail. The P-A curves all start at the same point (determined by the platinum substrate) and have a spiral structure, but they differ in the number of loops in the inward and outward spirals, and the asymptote of the inward spiral. Figure 2 shows the first-loop data for current densities ranging from 11 to $704 \mu\text{A}/\text{cm}^2$ (the loop at $704 \mu\text{A}/\text{cm}^2$ overlaps the loop at $176 \mu\text{A}/\text{cm}^2$). The ten points at fixed charge interval used in the analysis are identified on each curve. In the analysis, a value is first chosen for the film index N , then the P-A data are used to calculate a set of values for the film thickness L and extinction coefficient K . The value of N is then varied to minimize the standard deviations in the values of K and L/Q , the film thickness to accumulated charge ratio (9). This analysis procedure implicitly assumes that the composition and structure of the film do not vary appreciably as the film grows, and hence N and K are independent of film thickness. Since this may not be true here, the thickness range over which deviations are minimized is also varied in the analysis.

Analysis of the data from Fig. 2 using this procedure shows that the films have well-defined properties over the thickness range of 50-160 nm. The value of N , 1.9, does not depend on deposition current density, but the values of K decrease from 0.187 at $11 \mu\text{A}/\text{cm}^2$ to 0.096 at $704 \mu\text{A}/\text{cm}^2$, and the standard deviations in K and the L/Q ratio are approximately 4 and 2%, respectively. Figure 3 shows the dependence of film thickness on accumulated charge at each deposition current density (the $44 \mu\text{A}/\text{cm}^2$ results overlap the $176 \mu\text{A}/\text{cm}^2$ results and are not

Fig. 2. First-cycle optical data for galvanostatic deposition onto a platinum substrate at current densities from 11 to $704 \mu\text{A}/\text{cm}^2$. The optical analysis uses a common value of 1.9 for N and finds the value of K which gives the best fit to the data. The cycle at $704 \mu\text{A}/\text{cm}^2$ (with $K = 0.096$) overlaps the cycle at $176 \mu\text{A}/\text{cm}^2$ and is not shown.

plotted). Least squares lines fitted to the results have slopes of 2.62, 2.97, 3.00, and $2.78 \text{ nm}/\text{mC}/\text{cm}^2$ in order of increasing deposition current density.

If we know the composition of the film and the number of electrons transferred to the electrode per molecule deposited, we can use the slopes in Fig. 3 to calculate values for the film density (assuming roughness and efficiency factors of unity). If we assume that the films are entirely manganese dioxide deposited by transferring two electrons per molecule (10), we calculate density values which range from 1.50 to $1.72 \text{ g}/\text{cm}^3$ and bracket the $1.65 \text{ g}/\text{cm}^3$ found under potentiostatic deposition conditions (1). If we assume that the film contains some MnOOH and that deposition requires the transfer of only 1.9 electrons per molecule on average (11), we get slightly higher values, but the average is still only about one-third the density of a compact film of manganese dioxide. This low a density value does not appear to be consistent with a refractive index as high as 1.9.

Since neither roughness nor efficiency factors can account for a density value which is unreasonably low, we were forced to consider other possibilities. We ruled out effects due to dissolved oxygen when deposition in

Fig. 3. Dependence of film thickness on accumulated charge for the data from Fig. 2. The slope is steepest at a deposition current density of $176 \mu\text{A}/\text{cm}^2$, shallowest at $11 \mu\text{A}/\text{cm}^2$, and intermediate at $704 \mu\text{A}/\text{cm}^2$. The data at $44 \mu\text{A}/\text{cm}^2$ overlap the data at $176 \mu\text{A}/\text{cm}^2$ and are not shown.

deaerated electrolyte gave a density value which agreed with the value in air-saturated electrolyte at the same current density to within half a percent. We tested for the presence of other deposition processes by tracking film growth optically after opening the circuit, and found that at a deposition current density of $44 \mu\text{A}/\text{cm}^2$ perhaps 10% of the film growth could be attributed to nonelectrochemical processes. The only alternative left is to assume that manganese dioxide is deposited by a one-electron process similar to the solid phase oxidation of MnOOH . If we make this assumption, and assume further that the 10% MnOOH content of the film is not electrochemically deposited, we calculate density values which are on the order of three quarters of the density of a compact film. We will test these assumptions later when we compare the deposition charge with the charge passed on charge-discharge cycles in alkaline electrolyte

Films thinner than 50 nm appear to have extinction coefficients which are lower than those fitted over the 50-160 nm thickness range. This is most likely due to the fact that the film nucleates in an insular structure and grows into a uniform film by the time its thickness reaches 50 nm. The 160 nm upper limit of the fitting range, on the other hand, appears to be due to a limitation of the optical model, not to a change in film structure. The model assumes homogeneous films of uniform thickness, and, although nonideal films may fit such a model over a reasonable thickness range, the deviation of the experimental data from theoretical curves generated by the model becomes progressively larger as the thickness increases. This point is illustrated in Fig. 4. The optical data in the lower portion of the figure are from the same experiment as the data in Fig. 1. Deposition on a bare platinum substrate begins at point A, and the film thickness reaches 1000 nm at point B if the proportionality between thickness and charge determined in Fig. 3 remains valid throughout the deposition. Point C, reached after 6h of deposition, marks the infinite thickness limit, the point at which the film behaves optically as if it were a substrate. Two theoretical curves for 1000 nm of film growth are shown in the upper portion of the figure. Curve A-B has $N = 1.9$ and $K = 0.126$, the values fitted to the first loop data in Fig. 2, and A-C has $N = 1.548$ and $K = 0.689$, the values obtained by treating the infinite thickness limit as a substrate. The high extinction coefficient causes growth curve A-C to approach within 0.01° of the infinite thickness limit by the time the thickness reaches 500 nm. Clearly, theoretical curve A-C does not fit the

Fig. 4. Lower portion: optical data from Fig. 1 for deposition from 0 to 1000 nm (A-B) and at the infinite thickness limit (C). Upper portion: theoretical 0-1000 nm curves for films with $N = 1.9$, $K = 0.126$ (A-B) and $N = 1.548$, $K = 0.689$ (A-C).

experimental data in either the thin film or thick film regions, whereas A-B fits the data in the thin film region and describes the shape of the curve in the thick film region fairly accurately, although it spirals about a different infinite thickness limit.

We initially thought that the "tilt" between the theoretical and experimental curves in Fig. 4 was due to optical anisotropy, and we spent a great deal of time developing procedures to deal with the parameters involved in the analysis of absorbing anisotropic films. We found, however, that even for anisotropic films the measured P and A values at the infinite thickness limit require that the extinction coefficient be so high that the growth curve cannot spiral appreciably as it approaches this point. We regard the N and K values fitted to the first-loop data in Fig. 2 as characteristic of the film right through to the infinite thickness limit, and attribute the deviation between the theoretical and experimental curves in Fig. 4 to the inhomogeneous codeposition of oxide and oxyhydroxide, even though we have no quantitative model to support this viewpoint.

The results of an experiment in which the deposition is followed by cycling in 0.05M NaOH are shown in Fig. 5. The optical results in the upper portion of the figure include the deposition data (A-B), but the potential-time plot in the lower portion of the figure shows only the cycles in the alkaline cell. The current density was $44 \mu\text{A}/\text{cm}^2$ throughout, and the duration of the deposition was 405s. To avoid overlap of the cycling data, segments E-H and J-K are omitted from the optical plot.

The optical cycling data exhibit many qualitative features which correlate well with features in the electrochemical data. The optical changes on the first anodic cycle are consistent with oxidation of the MnOOH in the deposited film, and the changes on the initial restricted range cycles which reverse completely with no residual offset are consistent with reversible MnO_2 to MnOOH conversion. The first complete discharge cycle (D-E) is an inflection in the optical data at the x, which marks the beginning of a second change in the structure of the film, a change which appears irreversible. Further cycling produces progressive optical changes which correlate well with changes in the structure of the potential-time plot.

Quantitative optical analysis of the cycling data is complicated by inhomogeneity problems which are encountered when thicker films are cycled in alkaline electrolyte. Ideally, we would like to base the optical analysis on data from cycles which span a wide range of film thickness, but here our thicker film data are not reliable. To

Fig. 5. Deposition at $44 \mu\text{A}/\text{cm}^2$ (A-B, optical data only) followed by cycling at $44 \mu\text{A}/\text{cm}^2$ in 0.05M NaOH.

the unaided eye, thicker films appear transparent in the reduced state and highly absorbing in the oxidized state, and they give the sharpest ellipsometric nulls in the fully reduced state. If we assume that $K = 0$ for fully reduced films, we can determine values for N and film thickness at point E in Fig. 5 without using thicker film data. However, if we take point E from Fig. 5 and a similar point obtained by cycling a thicker film, we can find common values of N and K which fit both points. The first approach gives $N = 1.64$ with an assumed $K = 0$, and the second gives $N = 1.57$, $K = 0.02$. No matter which approach we follow, we find that both N and K are significantly lowered by reduction, and that there is a corresponding 10% increase in film thickness. We do not have sufficiently reliable data on thicker films to enable us to calculate optical constants at the point x , the inflection point on the first discharge cycle, but the shape of the optical curve between D and x indicates that the conversion is a homogeneous process.

The electrochemical aspects of the conversion process can be studied by comparing the cycling time intervals with the deposition time, since the same constant current density is used throughout. The initial cycling between C and D is designed to determine the charge required to oxidize any MnOOH in the deposited film to MnO₂. The cathodic time interval required to return the film to its initial optical state, 45s, is a more reliable charge indicator than the anodic charging time because it avoids oxygen evolution corrections. The 45s interval is one-ninth of the 405s deposition time, a result which is consistent with our earlier assumption of a one-electron deposition process and a 10% MnOOH content in the deposited film. With this assumption, a 450s time interval produces a unit change in the oxidation state of the film, or in the more common nomenclature, a change of 0.5 in the value of x in MnO _{x} (6). In terms what happens to the value of x , the cycling in Fig. 5 begins from 1.95 at C, goes to 2.00, 1.95, back to 2.00 at D, then to 1.75 at x , and finally 1.19 at E. These x values appear reasonable, and it is worth noting that a change in the conversion process has been reported at $x = 1.75$, the midpoint of the MnO₂ to MnOOH conversion (11). What is more worthy of note is the fact that un-

reasonably low x values (0.54 at E) result from assuming that deposition is a two-electron process, and hence the cycling results support the conclusion we reached initially on the basis of the refractive index of the deposited film.

As we stated at the outset, the primary objective of the cycling study was to see whether the film-conversion processes in alkaline electrolyte are suitable for study by ellipsometry, and the answer appears to be a qualified yes. There is scope for further profitable ellipsometric study of the system, but problems with inhomogeneity may eventually limit the amount of useful information which can be obtained.

Gallium Contamination of InP Epitaxial Layers in InP/InGaAsP Multilayer Structures Grown by Hydride Transport Vapor Phase Epitaxy

ABSTRACT

Gallium contamination of InP epitaxial layers grown in CVD reactors designed for InGaAsP/InP multilayer structures was observed by secondary ion mass spectrometry (SIMS). Defect characterization of gallium-contaminated InP buffer layers by the damage-free grooving and etching technique showed misfit dislocations and an interfacial layer containing a high density of saucer pits. Cross-sectional transmission cathodoluminescence further indicated that these defects are nonradiative recombination centers. Results from x-ray double-crystal diffractometry on a successively chemically stripped InP buffer layer indicated that the misfit was confined to the region near the interfacial layer which was consistent with the SIMS profile where the gallium content peaked near the interfacial layer. By presaturating the reactor with PH_3 , the amount of the gallium which was incorporated into the InP was found to be reduced. SIMS profiles of gallium on layers grown after the withdrawal of the gallium source from the reactor indicated that the indium melt was cross contaminated even though the reactor was designed to physically exclude the gallium source from the indium source. Small amounts of As, Fe, Si, Cr, and Zn were also found. The possible mechanisms which lead to the cross contamination are discussed. The evidence seems to support the suggestion that Ga is incorporated preferentially in the growth of ternary and quaternary compounds. In a four-layer laser structure consisting of n-InP(buffer)/InGaAsP(active)/p-InP(cap)/p⁻-InGaAsP(contact) layers, both gallium and arsenic contamination were observed in p-InP and n-InP regions by Auger spectroscopy.

Hydride transport vapor phase epitaxy has been demonstrated (1, 2) to be a viable technique for the fabrication of low threshold InGaAsP/InP heterostructure laser diodes operating in the wavelength region of 1.3-1.5 μm . The high throughput and large area uniformity possible via vapor phase epitaxy render the technique particularly attractive for large-scale production. However, because of the large number of input gases involved and the complication of the gas phase reaction chemistry, the reactor design has to take into consideration various factors such as the flexibility and rapidity of switching gas types, the requirement of separate source tubes to prevent reactive gas mixing before reaching the deposition zone, and the degree of turbulence for reactive gas mixing before deposition, etc. Although we have successfully demonstrated the growth of low threshold heterostructure lasers (2), a systematic investigation of the defect structure associated with the VPE layers has only been performed recently. In this work, we report the observation of gallium contamination of InP epitaxial layers grown in a reactor designed to produce InGaAsP/InP multilayer structures. The defect structure associated with the contaminated layers has been characterized, and various factors leading to the contamination will be discussed. Results for contaminants other than gallium will also be presented.

Experimental

Undoped InP buffer layers were grown on S-doped (100) InP substrates by hydride transport vapor phase epitaxy using a computer-controlled vapor phase epitaxial reactor described previously (2, 3) and designed to grow InGaAsP/InP multilayer structures. Briefly, the VPE reactor made out of quartz tubes consisted of two temperature zones, i.e., the source zone at 800°-840°C and the deposition zone at 700°C, as shown in Fig. 1. The source zone was constituted of four separate small quartz tubes: two of the tubes were used for the metal sources (In and Ga contained in the graphite boats), the third supplied AsH_3 (4% in H_2) and PH_3 (5% in H_2), and the fourth tube was used to add dopants. The Group III metals were transported in the form of chlorides by reacting the molten metals with input HCl (5% in H_2 over In and 1.5% in H_2 over Ga) at high temperature (800°-840°C). All

the input gases were controlled by mass flow controllers interfaced with a minicomputer. The reactor had a continuous flow of purified hydrogen at 4 liter/min all the time to prevent air from leaking in. An overnight bake out period at the operating temperature was utilized each time when the reactor was restarted from shutdown for service. Since each source tube has a constant flow of H_2 at 1 liter/min, cross contamination of the elements in different source tubes was not expected. For the growth of epitaxial layers, Group III chlorides emerging from a large nozzle were mixed and reacted with Group V hydrides in front of the substrate wafer, and deposition of the III-V compound then occurred on the surface of the substrate at 700°C. The four-layer laser structure used in this study was grown by manually retracting the substrate wafer to the loading zone after the growth of each individual layer. The reactive gases were then turned off and the reactor was flushed with hydrogen. The reactive gas flow controllers were then reset for the succeeding layer and turned on after the wafer was reinserted into the deposition zone. The elapsed time between the growth of individual layers is ~5 min. No preheating and cooling of the wafer was incorporated. Prior to the growth of a multilayer structure, the melts were presaturated with chlorides. For InP, only In was presaturated with chloride, while if the structure involved both In and Ga compounds both melts were presaturated with chlorides. A typical growth condition of a four-layer structure is given in Table I.

Analysis of the laser structure was made by SIMS, Auger spectroscopy, double-crystal x-ray diffractometry, a damage-free grooving and etching technique, and cross-sectional transmission cathodoluminescence.

SIMS mass spectra and depth profiles were obtained with a Cameca IMS-3F ion microanalyzer. An O_2^+ primary

Table I. Typical growth condition of a four-layer structure

Reactive gases	Reactive gas mole fraction			
	n-InP	Q	p-InP	p ⁺ -Q
InCl (5% HCl/H ₂)	3.4 × 10 ⁻³	5 × 10 ⁻³	3.4 × 10 ⁻³	5 × 10 ⁻³
GaCl (1.5% HCl/H ₂)		1.5 × 10 ⁻⁴		0.7 × 10 ⁻⁴
PH ₃ (5% in H ₂)	3.4 × 10 ⁻³	1.0 × 10 ⁻³	3.4 × 10 ⁻³	4.0 × 10 ⁻³
AsH ₃ (4% in H ₂)		1.0 × 10 ⁻³		0.6 × 10 ⁻³
Typical growth rate	10 μm/h	15 μm/h	10 μm/h	15 μm/h

ion beam at a net energy of 6.1 keV was used at a current of 2000 nA. The primary beam was rastered over a 500 μm square area from which only ions from a 150 μm diam circle at the center were detected. Sputter rates were in the range of 5-25 Å/s. Only positive secondary ions were analyzed. Crater depths were measured with a profilometer. The background pressure in the sample chamber was approximately 5 × 10⁻⁹ torr with the primary beam off and 5 × 10⁻⁸ torr with the beam on.

The composition profile of the four-layer laser structure was determined by Auger spectroscopy using a Physical Electronics 590A system. Data were taken from a nominally 5° angle-lapped sample and by direct depth profiling. These two methods provided complementary data that were necessary for correctly interpreting the results. The angle-lapped sample provided data with a good signal-to-noise ratio as well as an expanded depth scale, while the depth profile data provided good depth resolution. The angle-lapped sample could be cleaned by ion milling away only about 100 Å of the surface; in fact, if more than 1000 Å was milled off, the depth scale became distorted due to differing ion milling rates of the various layers. The Auger vacuum system is pumped by ion pumps; therefore, Ne ions were used for depth profiling to avoid the Ar instabilities.

The actual lattice mismatch was measured using an x-ray double-crystal diffractometer. The first crystal of the double-crystal diffractometer was (100) LEC InP, and rocking curves were made for the (400) reflection with Cu Kα radiation.

The defect morphology of the InP epilayer was characterized using a damage-free grooving and etching technique described previously (4). This method exposes the multilayer structure on a cylindrically lapped surface by chemical means. The defect structure was revealed via a dislocation etch (5).

The distribution of the defects associated with the non-radiative recombination centers was imaged using transmission cathodoluminescence (TCL) on both grooved and cross-sectioned samples. Details for the preparation of thin cross-sectional samples containing the multilayer structure was similar to that for preparing the cross-sectional samples for TEM (6). TCL was performed inside an ETEC Autoscan SEM using a silicon photodetector.

Results and Discussion

InP buffer layer.—Gallium contamination was first examined on buffer layers grown during the initial runs after the start-up of a new reactor where the gallium source was never exposed to the input HCl. The reactor was baked out in H₂ overnight before the first run to remove oxide films on the metal sources. The as-grown surface morphology of undoped buffer layers grown during the initial runs were highly specular and revealed a typical wavy structure for VPE layers under the Nomarski interference contrast microscope. The layer thickness of sample run number 4 was around 10 μm. Although gallium was not expected to be present, SIMS mass spectra showed strong *m/e* 69 and *m/e* 71 ion intensities in the correct isotopic abundance for Ga. SIMS depth profiles indicated the Ga was concentrated in the buffer layer. X-ray wavelength dispersive analysis gave an estimated

Fig 2. SIMS depth profile of ³¹P⁺, ¹⁰⁰GaP⁺, and ⁸⁵GaO⁺ in the InP buffer layer run no. 4.

concentration in the order of 1.0 atomic percent (*a/o*). The Ga⁺ ion current was excessive, and, therefore, the depth profiles were made for GaO⁺ and GaP⁺ because these ions are less intense than Ga⁺ but would have a similar depth profile. Figure 2 shows the ⁸⁵GaO⁺ and ¹⁰⁰GaP⁺ distributions *vs.* the depth from the surface of the buffer layer. The two profiles conform to each other and are around three orders of magnitude higher in the epilayer as compared to the substrate. Furthermore, the profile contains two peaks as it approaches the interface. These peaks are not due to secondary ion yield enhancement caused by the presence of some other possible species, such as oxygen, because the P matrix ion current is constant from the surface to the substrate. The exact cause of high Ga concentration near the interface is not clear. However, it does reflect an initial transient behavior of the source of contaminant. Defect characterization using a damage-free grooving and etching technique revealed an interfacial layer containing a high density of saucer pits, as shown in Fig. 3. The origin of the saucer pits is believed to be associated with point defect clusters. The cross-grid pattern oriented along the <110> directions in-

Fig. 3. Interfacial layer of the InP buffer layer (sample no. 4) revealed by a damage-free grooving and etching technique. The marker represents 50 μm.

Fig. 4. Cross-sectional transmission cathodoluminescence of a [110] cross section of InP buffer layer (sample no. 4). The thickness of the cross section is less than $50 \mu\text{m}$.

indicates the existence of misfit dislocations near the interfacial layer, which is consistent with the high concentration of gallium in the buffer layer.

Cross-sectional transmission cathodoluminescence on a $50 \mu\text{m}$ thick [110] cross section showed a dark interfacial layer as seen in Fig. 4. The irregularity of the dark contrast indicates that it is composed of overlapping dark spots which were observed before in a layer containing a high density of saucer pits (4). The dark spots distributed over the buffer layer are believed to be the dislocations.

The width of the interfacial layer as revealed by chemical etching and measured by Dektak is usually larger than the width of the peaks measured from the SIMS profile.

X-ray double-crystal rocking curves for sample no. 4 are shown in Fig. 5a. The linewidth of the as-grown wafer was 62 arcseconds, which is twice as large as that measured for the substrate alone. Such a broad linewidth is attributed to the defect structure described above. The mismatched layer near the epitaxial interface was further demonstrated by etching away $8 \mu\text{m}$ of the $10 \mu\text{m}$ epitaxial InP layer and making another rocking curve. This rocking curve is shown in Fig. 5b. The major rocking curve is from substrate InP, while the shoulder on the right indicates that the remaining $2 \mu\text{m}$ were mismatched with $\Delta a/a = -4.3 \times 10^{-4}$, where the minus sign indicates that the $2 \mu\text{m}$ layer had a smaller lattice parameter than that of the substrate. An application of Vegard's law (7) yields 0.6% for the Ga concentration.

By presaturating the reactor with PH_3 (at mole fraction of 2×10^{-3} in 5 liter/min H_2 flow) for 5 min prior to the growth of InP, the incorporation of the gallium into the InP buffer layer was found to be greatly reduced. Figure 6 shows a SIMS profile of $^{31}\text{P}^+$, $^{85}\text{GaO}^+$, and $^{100}\text{GaP}^+$ of

Fig. 5. X-ray double-crystal diffractometer measurements of, a, rocking curve of $10 \mu\text{m}$ InP buffer layer (run no. 4) and b, rocking curve of substrate InP with $\sim 2 \mu\text{m}$ buffer layer after etching.

sample number 16, for which this was done. The gallium content is only two orders of magnitude higher in the buffer layer than in the substrate and has only one peak at the interface between the buffer layer and substrate. The defect structure of the buffer layer was found to be greatly improved. Defects revealed by the damage-free growing and etching technique did not show misfit dislocations and saucer pits. This is shown in Fig. 7. However, an interfacial layer is still present. Furthermore, cross-sectional TCL revealed a uniform luminescence intensity across the entire buffer layer as shown in Fig. 8. The overall low luminescence efficiency of the buffer layer compared to that of the substrate is attributed to the undoped nature of the buffer layer.

In order to determine the cause of the gallium contamination, the gallium source was completely removed from the reactor just prior to run number 127. Between run numbers 16 and 127, the reactor was occasionally used to grow InGaAs. Figure 9a shows SIMS profiles of a buffer layer grown during the tenth run after the removal of the gallium source. The amount of gallium observed inside

Fig. 7. Interfacial layer of sample no. 16 revealed by a damage-free grooving and etching technique does not show misfit dislocation and saucer pits. The marker represents $50 \mu\text{m}$.

Fig. 8. Cross-sectional transmission cathodoluminescence of a [110] cross section of sample no. 16.

the buffer layer was similar to that found for run number 16.

Figure 9b shows SIMS profiles of $^{69}\text{Ga}^+$, $^{100}\text{GaP}^+$, and $^{85}\text{GaO}^+$ for the same sample as in Fig. 9a, but at reduced sputter rate in order to show the similarity of the shapes of the profiles and the relative intensity of the three ions. Since the reactor was cleaned thoroughly after each run by passing HCl through the deposition zone, the remaining possibility which leads to the contamination of the InP buffer layer is that the indium melt was cross contaminated. This was confirmed later by examining the buffer layer grown during run 410, which is more than 200 runs after the removal of the gallium source. Because of the consumption of the indium metal, the indium had been replenished in the meantime. A SIMS profile of $^{69}\text{Ga}^+$ ion in sample 410 (Fig. 9c) showed that the gallium content had dropped to a level only slightly higher than that of the substrate, and the GaO^+ and GaP^+ were reduced almost to background levels. The Ga peak at the interface has been totally eliminated. We conclude that the indium source for the early runs had indeed been contaminated with gallium.

n-InP/InGaAsP/p-InP/p⁺-InGaAsP laser structure.—Gallium contamination of InP epilayers was also examined in a four-layer laser structure. Figures 10a and 10b show the Ga and As profiles from a four-layer structure obtained by scanning Auger spectroscopy on a 2°-5° beveled surface. The presence of Ga on both sides of the active Q layer is clearly visible. The As line scan will be discussed in the next section.

Figure 10c shows Auger depth profiles for all four elements. The abscissa is the milling time and therefore is a distorted depth scale. The relative thickness of the various layers do not agree with those of Fig. 11 (see below); this disagreement is probably due to ion milling artifacts, but the detailed explanations are not yet understood. The concentration profiles are normalized to 100 a/o using approximate sensitivity factors. It is clear that gallium is present in both n- and p-InP regions as indicated by the arrows. A complementary lowering of the In concentration is also observed. A similar situation is observed for As and P.

Defect characterization using damage-free grooving and etching revealed an orange peel morphology in both InP regions, as seen in Fig. 11. High magnification photographs show that they are composed of a high density of saucer pits which is similar to that observed previously in Fig. 3. Furthermore, TCL imaging of the buffer layer region also indicates a high density of dark spots as shown in Fig. 12. These results indicate that the gallium contained in the buffer layer is probably on the order of 1 a/o. The orange peel morphology in the p-InP region is less distinct because of the difference in etching rate of the defect revealing etchant on p-type InP. A similar amount of the gallium is believed to be present in the p-InP, as indicated by the Auger profile.

Other contaminants.—Besides the gallium contamination observed, small amounts of arsenic were found in the InP epilayer. Figure 13 is a SIMS profile of $^{31}\text{P}^+$ and $^{75}\text{As}^+$ obtained from run number 4. The arsenic concentration in the epilayer is around an order of magnitude higher than that found in the substrate. The same amount of arsenic was observed in most of the single layers. For a

four-layer laser structure, scanning Auger spectroscopy on 2°-5° beveled surface also detected arsenic in both InP buffer and cap layers, as seen in Fig. 10b.

SIMS profiling of InP single layers also indicated that small amounts of Fe, Si, Cr, and Zn accumulated at the substrate-epilayer interface. These contaminants are believed to have come from the reaction of HCl with the steel cylinder or with the stainless steel gas handling system.

Possible factors leading to contamination.—Gallium contamination.—Gallium contamination of InP buffer layers which have been studied may be ascribed either to transport of Ga from a contaminated In₍₁₎ source or to transport of volatile Ga containing compounds from the Ga₍₁₎ source. Assuming that Ga contamination of the In₍₁₎ source was accidental (loss of H₂ flow while the reactor was hot, or cross contamination during preparation of the metal sources), only transport of Ga from the Ga₍₁₎ source will be considered. Three aspects of the Ga contamination in the samples studied above require explanation: (i) the source of Ga in InP epilayers grown without

Fig. 12. Transmission cathodoluminescence imaging of a n-InP buffer layer on as-grooved sample.

Fig. 13. SIMS depth profile of $^{31}\text{P}^+$ and $^{75}\text{As}^+$ ion in a single buffer layer.

exposure of the $\text{Ga}_{(l)}$ source to HCl; (ii) the effect of passing PH_3 through the reactor immediately prior to growth on suppressing Ga contamination; and (iii) Ga contamination of InP in multilayer structures with at least one layer containing Ga.

Several of the InP buffer layers examined contained large amounts of Ga even though the $\text{Ga}_{(l)}$ source was not exposed to HCl (run numbers 4-15). The two most likely sources of Ga transport in the absence of HCl include atomic Ga ($P_{\text{Ga}} \sim 10^{-10}$ atm at 700°C) (8) and Ga_2O formed by reaction of trace O_2 or H_2O contained in the H_2 carrier gas. For growth of InP, the InCl partial pressure (P_{InCl}) is on the order of 3.4×10^{-3} atm at a total flow rate of 4 liter/min. Assuming that Ga contamination from atomic Ga occurs according to

with P_{P_4} at 5×10^{-4} atm typical for InP growth, the equilibrium P_{Ga} is calculated (9, 10) to be $\sim 10^{-12}$ atm. Since this is much less than P_{Ga} expected from evaporation of $\text{Ga}_{(g)}$ from the liquid source, it is unlikely that this source could account for contamination levels as high as $\sim 1\%$.

A more plausible source of Ga contamination involves the formation of Ga_2O , which has been used as the transport agent in epitaxial growth of GaP (11). Although the H_2 used for growth is purified using commercial Pd diffusers, it is possible that contamination with O_2 occurs in the gas manifold (valves, mass flow controllers) or connections to the reactor. This may be particularly true for the early runs owing to the possibility of outgassing of new components which constitute the growth system. Assuming an upper limit of ~ 10 ppm H_2O over the $\text{Ga}_{(l)}$ source at 800°C , thermodynamic data for Ga_2O predicts a $P_{\text{Ga}_2\text{O}}$ of 5×10^{-7} atm (8). Based on calculations by Seki and Minagawa (12) for the system $\text{In}_x\text{Ga}_{1-x}\text{P}$ and substituting $\text{Ga}_2\text{O}/\text{H}_2\text{O}$ for GaCl/HCl as the transport system, the assumed level of H_2O contamination is thermodynamically sufficient for the incorporation of 1% Ga in InP.

The effect of PH_3 presaturation on Ga incorporation in InP buffer layers may be due to the deposition of GaP on the reactor walls prior to layer growth. The presence of such deposits may serve to getter Ga and prevent its incorporation into the growing InP layer. By nucleating such deposits prior to growth, both high Ga content at the interface of the grown layer and the substrate, as well as the Ga content in the remainder of the layer, would be reduced.

The growth of multiple layer structures which include at least one ternary or quaternary layer require transport

of Ga using HCl. In order to assure stable conversion of HCl to GaCl (InCl) in the reactor source zone, the $\text{Ga}_{(l)}$ ($\text{In}_{(l)}$) source is usually saturated with HCl prior to growth of any layers. Recent optical absorption studies of InCl and GaCl formation in these reactors have demonstrated that transport continues for over 10 min after the HCl in the reactor is turned off because of evaporation of GaCl (InCl) dissolved in the $\text{Ga}_{(l)}$ ($\text{In}_{(l)}$) sources (13). This effect is responsible for the high Ga content observed in both InP buffer and cap layers of the four-layer laser structure described above.

Additional contaminants.—The presence of additional contaminants, with the exception of As, is probably due to the reaction of HCl with the steel components of the growth system. Since AsH_3 and PH_3 pass through the same lines in the manifold, outgassing of these lines during InP growth may contribute to the presence of As in InP buffer layers. Another possibility is due to the presence of trace amounts of AsH_3 in the PH_3 used for growth. In multiple-layer structures which involve at least one As containing layer, contamination may also be due to evaporation of As_4 from deposits formed on the reactor walls during ternary or quaternary growth, or from elemental As deposited in the source end of the reactor due to the extremely rapid pyrolysis of AsH_3 at the point where the reactor enters the furnace (14). If the wall deposit contains As containing compounds, the reaction with unreacted HCl can also form As_4 .

Conclusions

We have observed the gallium contamination of InP epitaxial layers grown in a hydride transport VPE reactor designed for InP/InGaAsP multilayer laser structures by secondary ion mass spectrometry and Auger spectroscopy. Despite the fact that the Ga and In sources are physically excluded from each other, the initial InP layers grown from a new reactor were found to contain Ga at levels as high as ~ 1 a/o. Defect structure characterization of the InP epitaxial layer revealed misfit dislocations and an interfacial layer containing a high density of saucer pits. Cross-sectional transmission cathodoluminescence further confirmed that these defects were nonradiative recombination centers. Results from x-ray double-crystal diffractometry indicated that the mismatch was confined to the region near the interfacial layer which is consistent with the SIMS profile of Ga which showed a peak in the same region. Since the Ga source had not been exposed to HCl, the exact cause leading to the Ga contamination was not clear. A plausible transport agent for Ga was suspected to be the formation of Ga_2O due to a trace amount of O_2 or H_2O in the H_2 carrier gas.

For a four-layer laser structure, the Ga contamination of InP is further complicated by the evaporation of the GaCl dissolved in the Ga source after the turn-off of HCl. This delay turn-off of GaCl contributes to the major Ga contamination of InP in multilayer laser structure.

A small amount of As was also present in the single buffer layer. This can be attributed to the outgassing of AsH_3 absorbed on the walls of the input tubing and to trace amounts of AsH_3 in the PH_3 gas used for growth. However, in a four-layer laser structure, considerable amounts of As were present in both the InP buffer and cap layers. A possible explanation is the evaporation of As containing deposits formed on the reactor walls during the growth of ternary or quaternary layers. The fact that the InP buffer layer contains the same amount of As as those in the subsequent InP cap layer indicates that these deposits were formed in the previous runs. The small amounts of Fe, Si, Cr, and Zn found at the substrate-buffer layer interface are believed to derive from the reaction of HCl with the steel cylinder or gas handling system.

ABSTRACT

Both reversible and irreversible resistance switchings have been investigated in boron- and arsenic-doped LPCVD polycrystalline silicon film resistors. The effects of film thickness and doping concentration on the transition voltage and current have been characterized for different length resistors having film thickness from 0.1 to 1.2 μm and doping concentration ranging from 5×10^{16} to $1 \times 10^{20} \text{ cm}^{-3}$. Under a large voltage bias, the resistor can be switched to a conductive "on" state or to a "short" state having resistance reduction by a factor of 10^3 - 10^6 , or it can be blown "open". The transition voltage and current and the resistance after switching depend strongly on film thickness, doping concentration, and applied power. A simple qualitative model is proposed to explain these resistance switching phenomena.

Polycrystalline silicon (polysilicon) films have been widely used as solar cell and integrated-circuit elements, and such applications have stimulated extensive studies of the electrical properties of this material. Both reversible and irreversible resistance switching phenomena have been reported (1-3). The irreversible resistance switching has been extensively applied to integrated-circuit applications, such as a memory element in fusible-link PROM's (3-5) and a fuse or antifuse in redundancy circuits in high density RAM's (6). However, there are a limited number of papers in the literature systematically studying resistance switching properties of polysilicon resistors. Greve studied the programming mechanism of heavily doped polysilicon resistor fuses and showed that formation of a second-breakdown state is necessary to blow open the fuses (1). He also studied n^+ - p - n^+ polysilicon devices and showed that the dopant migration and the aluminum penetration in molten filaments through polysilicon devices are the mechanisms for resistance switching (7, 8). On the other hand, Mahan reported a reversible switching phenomenon in undoped polysilicon resistors having high value resistance (2).

This work reports new experimental results on the effects of film thickness, doping concentration, and device dimensions on resistance switching behavior in polysilicon resistors. The resistances before and after switching, the switching I-V curves, and the transition voltage

and current beyond which the switching occurs were characterized extensively. Different switching patterns have been clearly identified from this systematic study, and a better physical understanding of the switching behavior in polysilicon resistors has been obtained from a qualitative model.

Sample Preparation and Measurements

A 0.80 μm thick oxide was grown at 1100°C on top of N-type (100) silicon wafers with resistivity of 4 ~ 7 $\Omega\text{-cm}$. Undoped polysilicon films with thickness ranging from 0.1 to 1.2 μm were deposited in a low pressure CVD reactor at 620°C with deposition rate of 80 $\text{\AA}/\text{min}$. Either boron or arsenic dopants were then implanted with various doses to yield doping concentrations from 5×10^{16} to $1 \times 10^{20} \text{ cm}^{-3}$ for arsenic and from 5×10^{16} to $2 \times 10^{18} \text{ cm}^{-3}$ for boron. After polysilicon resistors were patterned by plasma etching, an 8000 \AA CVD oxide layer was deposited at 430°C to avoid dopant evaporation during subsequent thermal steps. For p-type samples, the contacts were either undoped or heavily doped with boron. For n-type samples, the contacts were all heavily doped with arsenic to avoid Schottky barrier formation. All samples were annealed at 900°C for 60 min to activate and uniformly redistribute the dopants, as well as to remove the implantation damage. A 1.0 μm thick aluminum layer was deposited and etched to form the contact pattern. The contacts were sintered in N_2 at 450°C for 20 min.

*Electrochemical Society Active Member.

The thickness of polysilicon films was measured by an optical method (Nanospec Model Axp-010-0180) and an α -step profiler. Measured electrical properties of polysilicon resistors include zero bias resistance and I-V characteristics. The measurement systems were: (i) an HP 4140B picoampere meter with dc programmable voltage source, coupled to an HP-85 microcomputer to measure the zero bias resistance, and (ii) a Tektronix 576 curve tracer to observe I-V characteristics and to trigger polysilicon-resistance switching. The surface of resistors after switching was studied by an optical microscope and a scanning electron microscope (SEM).

Results

The general behavior of the I-V characteristics of polysilicon resistors is illustrated in Fig. 1. The I-V curve of polysilicon resistors before switching follows the predicted hyperbolic sine function (curve 1) (9, 10) to a certain point A. It was found that the high voltage part of curve 1 was not stable for most device configurations. The resistivity drastically decreases with increasing voltage, and would contract to a stable curve 2 ("off" state) (2).

When voltage increases along curve 2, a negative resistance behavior may appear. When the voltage further increases, the I-V curves of devices of light doping concentration and short dimensions were switched to a more conductive "on" state (curve 3). When the power of the curve tracer was limited below a certain value, the negative resistance characteristic is stable and the switching between curve 2 and 3 is reversible. This reversible switching in polysilicon film was reported by Mahan as "threshold switching" (2). When more power was added into the resistor, a sudden change from "on" state (curve 3) to the "short" state (curve 4) occurred for thick film devices. However, for thin film devices, more power can cause the resistor to "open" (curve 5). Both switchings from curve 3 to 4 and from 3 to 5 are irreversible. For medium and heavily doped polysilicon resistors, the switching always jumps directly from "off" state to either "open" or "short" state without going through the "on" state. For example, in boron-doped samples with $N_A \geq 5 \times 10^{17} \text{ cm}^{-3}$, no switching to "on" state has been observed. However, for short and lightly doped samples ($N_A \leq 1 \times 10^{17} \text{ cm}^{-3}$, and nominal length less than $15 \mu\text{m}$), reversible switching was observed.

Similar observations were made on arsenic-doped polysilicon resistors, and the same conclusions were obtained. These various switching patterns are summarized in Fig. 1. The reversible switching is more likely to occur for short and lightly doped samples. No reversible switching has been observed for our samples with doping level higher than $1 \times 10^{17} \text{ cm}^{-3}$ and/or longer than $15 \mu\text{m}$.

Along the stable curve 2, the voltage beyond which the switching occurs is defined as "transition voltage," V_T , and the corresponding current as "transition current," I_T . The zero bias resistance before switching is defined as R_b and after switching as R_a .

Figure 2 shows the transition voltage and resistance vs. doping concentration for boron-doped resistors with lengths of 10 and $5 \mu\text{m}$ before and after switching. The resistance before switching strongly depends on the doping concentration, especially around a critical doping concentration N^* where most of the grains change from total depletion into partial depletion, thus causing a drastic change of resistance (10). An interesting phenomenon is that the transition voltage has shown a maximum around N^* . Away from N^* on the heavily doped side, the transition voltage generally follows the decreasing pattern of R_b . It was also found that the transition voltage scales proportionally to the resistor length. Resistance after switching decreases by a factor of 10^3 - 10^6 . For the short and lightly doped samples, the resistor mostly switched first to "on", then to "open" rather than "short".

As the maximum power of the curve tracer was raised from 0.5 to 2.2W, the resistance after switching (already "short") can be further reduced by a factor of 10^2 - 10^4 . Fi-

Fig. 1. The general I-V switching behavior of polysilicon resistors

nal resistance is approximately several ohms and relatively independent of doping concentration (Fig. 3). Shiny aluminum penetration path was found in these further "short" state resistors, which accounts for the low resistance.

Figure 4 shows the relationship between film thickness and measured resistances before and after switching for two doping concentrations of 1×10^{17} and $2 \times 10^{18} \text{ cm}^{-3}$. The resistance before switching decreases drastically as the film thickness increases for resistors at doping concentration of $2 \times 10^{18} \text{ cm}^{-3}$, but not so much for resistors at doping concentration of $1 \times 10^{17} \text{ cm}^{-3}$. The details of effect of doping effect on resistivity vs. film thickness was investigated by Lu *et al.* (12). Almost all the devices with film thickness less than 2000\AA were switched to "open" state, and R_a is infinite.

The behavior of V_T vs. film thickness is shown in Fig. 5. It is similar to the relationship of R_b vs. film thickness in Fig. 4, except that for the thinnest sample at doping level of $2 \times 10^{18} \text{ cm}^{-3}$, the transition voltage decreases and the postswitching was an "open" state instead of a "short" state. The similar behavior between V_T and R_b suggests that Joule heating plays an important role in the switching mechanism (1, 2).

Figure 6 shows the V_T and I_T of boron-doped resistors at doping level of $2 \times 10^{18} \text{ cm}^{-3}$ for various film thicknesses. There is no significant difference whether the contacts have been heavily doped or not (12). It is found that over the observed range of film thickness, I_T and V_T obey an

empirical expression

$$I_T = I_0[\exp(V_0/V_T)]$$

where I_0 and V_0 are empirical parameters.

Discussion

A simple qualitative model is proposed to understand the above observations. When the applied voltage is below the transition voltage, the I-V characteristics of polysilicon resistor can be described by the carrier trapping and dopant-segregation models (9-13). According to these models, the active dopant concentration can be obtained by subtracting the inactive segregated dopant concentration from the actual doping concentration (10, 11), and the grain-boundary trapping states can trap free carriers from the ionized active dopants and act as recombination centers (14, 15). This trapping process reduces the number of free carriers and creates built-in potential barriers surrounding the grain boundary, which impede carrier motion from one crystallite to another. The carrier transport across the grain boundary and the built-in potential barriers by thermionic emission and tunneling processes show a hyperbolic sine function I-V characteristic (13).

As the applied voltage further increases, the forward-biased space-charge barrier can eventually be flattened

and a great number of carriers is then injected into the resistors. Once this happens, bulk resistance of silicon crystallite becomes dominant, and the I-V characteristic exhibits a transition from "grain-boundary limited" to "bulk-limited" condition. Thus the observation that transition voltage reaches a maximum value around the critical doping concentration can be understood by the fact that the highest built-in potential barrier exists at this doping concentration (10) and, therefore, a higher voltage is needed to flatten the forward-biased built-in potential barrier.

For lightly doped polysilicon films, the crystallites are totally depleted by the grain-boundary trapping states, and hence the films are nearly intrinsic. The resistivity of totally depleted polysilicon films is very high, and this semi-insulating property is mainly due to carrier depletion rather than mobility degradation (10). If a finite voltage which is large enough to flatten the built-in potential barrier is applied across the resistor, a large number of electrons and holes can be injected at the cathode and the anode, respectively. Because there are more unfilled grain-boundary traps for capturing minority carriers than for majority carriers, the lifetime of minority carriers is shorter.

If the resistor is long compared to the mean free path of minority carriers, the minority carriers are not able to transverse the resistor, and this condition results in single injection. Under a high current level, majority-carrier single injection is space-charge limited (16). However, as the bias is further increased, the field across the resistor eventually becomes high enough to allow the minority

Fig. 4. Resistance vs. film thickness before and after switching

Fig. 6. Transition voltage and transition current vs. film thickness

carriers to reach the other end of the resistor. This double injection process causes the majority space-charge barrier to be lowered and minority carrier lifetime (mobility) to increase, permitting more carriers to transit the resistor; as a result, a lower voltage is required to provide the current for maintaining the condition. This positive feedback process results in negative resistance characteristics. The condition causing this negative resistance behavior is that the minority carrier transit time is equal to their lifetime. It is clear that in a shorter resistor it is easier to reach this condition. Eventually, the high level injection condition will be reached when the lifetimes of minority and majority carriers are equal. At this point, two-carrier recombination-limited current flow prevails and the negative resistance behavior terminates; the polysilicon resistor can then switch to the "on" state. This double injection mode is much more likely observed for small grain and/or lightly doped polysilicon films which have plenty of recombination centers for both majority and minority carriers (17).

Similar phenomena have been observed in many amorphous semiconductors where the initiation of switching and the maintenance of the "on" state in threshold switching can be satisfactorily explained as a double injection electronic process (18, 19). Undoped or lightly doped polysilicon films of small grain size have many properties close to amorphous films. Just like any electronic transport process, heat will be generated by current, and thermal effects will accompany this electronic injection process. For short polysilicon resistors, however, the high field induced carrier generation is more likely to occur before thermal effects take over the major role. Therefore, if the double injection process and positive feedback mechanism occur before Joule heating makes any microstructure change, a reversible threshold switching occurs. However, if more power is fed into the "on" state resistor, the Joule heating will finally become large enough to cause an irreversible switching from "on" state to "short" or "open" state.

For heavily doped polysilicon films, although the grain-boundary trapping states are completely filled up with majority carriers, the concentration of free majority carriers is still substantially larger than the intrinsic carrier concentration and of the same order of magnitude as the active doping concentration (10, 11). The lifetime of minority carrier is much shorter than that of majority carrier. This majority carrier transport process is not space-charge limited. The double injection condition is hardly reached even under a relatively large bias. Usually, the thermal process will then prevail to induce current filamentation (20). Thermal current filamentation results in irreversible switching to either "short" or "open" state, depending on the configuration of resistor and programming conditions. For thick and short resistors, thermal filamentation can induce either dopant migration or aluminum penetration through the molten filament to form "short" state (1). For thin and long resistors, Joule heating can simply evaporate the polysilicon film to leave a void (21), or the applied field can be strong enough to sweep the molten silicon ions to form an "open" gap (1).

It should be noted that the coexistent electronic and thermal processes always compete and influence each other. Therefore, the device configuration, composition of the resistor, and the programming conditions all have their roles and become a control parameter in some particular stage of this complex switching phenomenon.

Conclusion

Several distinct patterns of polysilicon resistance switching have been observed for both arsenic- and

boron-doped materials over a wide range of doping concentration and film thickness. The transition voltage reaches a maximum value around the critical doping concentration, which separates the totally depleted and partially depleted cases. Beyond this point, toward higher doping levels, the transition voltage generally follows the variation of R_b . As applied power increases, resistance after switching to "short" state can be further decreased and becomes less dependent on film thickness and doping level and, finally, aluminum penetration occurs, causing a resistance of only a few ohms.

Lightly doped resistors are more likely to show reversible threshold switching, probably due to their abundant recombination centers. Short and thick resistors are more likely to switch to "short" state, and the aluminum penetration path can be easily observed. Long and thin resistors are more likely to switch to "open" state, and a physical gap is observed. These distinct patterns have been understood by a qualitative model.

ABSTRACT

We report, for the first time, the success of GaAs molecular layer epitaxy (MLE) using AsH₃ as an As containing gas and trimethyl-gallium (TMG) as a Ga containing gas. Growth conditions for a single layer by layer deposition process were investigated as a function of the substrate temperature, the pressure in the growth chamber, the admittance quantity per cycle, and photoirradiation. The substrate temperature of 500°C fulfilled the conditions for a monolayer growth, where the film thickness per one cycle is saturated with the admittance quantity, at the higher temperature that increased with the TMG admittance quantity. The electrical properties of the film grown by MLE method strongly depended on the gas admittance rate, *i.e.*, pressure in the growth chamber. The carrier density of the film proportionally decreased with increasing AsH₃ pressure and decreasing TMG pressure. However, all growth films show p-type behavior with a carrier density of 1×10^{18} - 10^{20} cm⁻³. Photoirradiation during the growth by a high pressure Hg lamp, Ar laser (514.5 nm), and with a doubler (257.3 nm) largely improved the surface morphology and electrical properties of the films by MLE.

In recent years, there has been an increasing demand for high speed integrated circuits, micro- and millimeter wave devices, optical devices, and optoelectronic integrated circuits. Nishizawa proposed an ideal static induction transistor (ISIT) and estimated the maximum gain bandwidth product as 780 GHz for GaAs. Tunnel injection types of SIT may operate in the region of Tera Hz (1, 2). For such high speed devices, the control of epitaxial layer thickness to within single atomic dimension becomes necessary. Molecular layer epitaxy can afford such demands. In this paper, we report for the first time the success of GaAs molecular layer epitaxy (MLE).

The halide-transport vapor phase epitaxy (VPE), the metalorganic chemical vapor deposition (MO-CVD), and molecular beam epitaxy (MBE) are well known as vapor phase epitaxial techniques for III-V compound semiconductors. Very recently, atomic layer epitaxy (ALE) has appeared in the academic publications (3, 4).

VPE and MO-CVD, however, are not available techniques for preparing semiconductor thin films with an atomic-order accuracy. MBE is a widely used technique for producing semiconductor thin films with an atomic-order control, which is based on the vacuum deposition technique in UHV region (5). Typical problems, however, appear owing to the vacuum deposition. Out gassing due to heating the source cell, evacuation of evaporants, and complicated replenishment of the source material become considerable problems for a vacuum system. Furthermore, growth-rate control has been achieved by the evaporation rate monitored by a quartz microbalance oscillator or mass spectrometer. As a result of the complexity of controlling the evaporation rate, epitaxial films with an accuracy of a single molecular layer have been difficult to prepare and confirming the achievement of a stoichiometric film is equally difficult.

Very recently, Suntola *et al.* reported ALE (6, 7) producing II-VI compound films like CdTe and ZnTe using conventional MBE equipment. Since the film grows by a monolayer per reactant pulse in the ALE method, the film thickness is exactly determined by the number of cycles of the reactant pulses.

We define molecular layer epitaxy (MLE) as follows. MLE is a crystal-growth method using chemical reaction of adsorbates on the semiconductor surface, where gas molecules containing one of the semiconductor elements are introduced alternately into the growth chamber by which a single layer of film growth develops. ALE is the crystal-growth method where a specific atomic element is alternately deposited on the substrate. Suntola also tried MLE preparing ZnS polycrystalline films and Ta₂O₅,

amorphous films, but no single-crystal films were obtained (8). Furthermore, Si and GaAs, the most popular semiconductor materials, which are widely used for VLSI circuits today, have not been investigated.

Photoepitaxy was proposed by the author (J. Nishizawa) in 1961 and has been applied to Si and GaAs vapor phase epitaxy, resulting in higher crystal quality at lower epitaxial temperatures (9-12). A combination of MLE and photoepitaxy may increase the film quality by MLE at even lower temperatures, and photostimulated processes of the crystal growth can be better controlled.

We report here the MLE method applied to GaAs using AsH₃ as an As containing gas and TMG as a Ga containing gas.

Experimental Procedure

A main part of the experimental setup used here, shown in Fig. 1, consists of a gas-admittance system, a mass spectrometer for reaction species determination, a heating lamp system, a temperature controlling unit with a pyrometer, and a pumping system. After the substrate is etched by a usual treatment, the substrate is set in the preparation chamber and evacuated to 1×10^{-5} Pa. The substrate is transported from the preparation chamber to the growth chamber ($p \leq 5 \times 10^{-6}$ Pa). The growth chamber is evacuated for as long as 30 min. The substrate is heated by the lamp system situated outside of the growth chamber. The temperature measurement is achieved by the pyrometer, and the power of the heating lamp is controlled by an automatic controlling unit coupled to the output signal of the pyrometer. The substrate temperature could be stabilized within $\pm 1^\circ\text{C}$ during the epitaxial growth.

After heating the substrate up to 600°C for evacuating the surface contaminants mainly consisting of oxides, AsH₃ gas is admitted for 2-200s at the pressure of 10^{-1} - 10^{-5} Pa and evacuated; then TMG is admitted for 0.5-20s at the rate of 10^{-3} - 10^{+1} Pa-liter/s and evacuated. Such a periodic gas admittance cycle is repeated up to the desired film thickness. Figure 2 shows the dependence of the growth chamber pressure on time during gas admittance.

No deposition on the insulating material was observed in the case of MLE. Using a mask pattern of an insulating film, the film thickness was measured by the alpha step. GaAs substrates (100) and off-angle were etched more than 2 μm deep by H₂SO₄ etchant (H₂SO₄:H₂O₂:H₂O = 4:1:1 and 10:1:1). Thereafter, a Si₃H₄ film was deposited by plasma CVD \sim 200 nm, and mask patterns were made on the substrate. Furthermore, the liftoff area of the substrate was etched by Cica TMK-1 (Kantokagaku, Tokyo) 150Å deep, producing a contamination-free surface.

Results and Discussion

Monolayer film growth.—The diffraction pattern of a film of GaAs grown by MLE is shown in Fig. 3, which was prepared by alternately introducing AsH_3 and TMG at the inlet pressure of 7×10^{-3} and 1.3×10^{-3} Pa for a gas admittance mode (20", 1", 2", 1") at the growth temperature of 500°C. A beautiful spot pattern clearly indicates the single-crystal nature of the growth film.

For a purpose of finding out the growth condition of monolayer epitaxial growth, film thickness per cycle was measured as a function of TMG admittance quantity at the substrate temperature of 500°C. The admittance time of TMG was kept constant for the measurements only, except for the maximum quantity for which it was varied. Therefore, the transverse axis of Fig. 4 represents also the admittance rate corresponding to the inlet pressure. As the admittance rate of TMG increased from 1.0×10^{-2} to 0.6 Pa-liter/s, the film thickness per cycle was nearly saturated and indicated 2.2–2.3 Å/cycle. When the admittance rate decreased to 0.33×10^{-2} Pa-liter/s, the thickness reduced to 1.2 Å/cycle, nearly one-half of the saturated value. As the admittance quantity becomes lower than 2.7×10^{-2} Pa-liter, the supplied quantity is no longer suffi-

Fig. 2. The pressure in the growth chamber during the gas admittance. AsH_3 is introduced 20s and evacuated 3s, then TMG is introduced 4s and evacuated 3s (20", 3", 4", 3"). This is a standard gas admittance mode in this paper. Such a periodic cycle preparing one monolayer film growth is repeated up to the desired film thickness.

Reflection electron beam diffraction pattern of epi-layer ($T_{\text{sub}} = 500^\circ\text{C}$)

Fig. 3. The diffraction pattern of GaAs growth film by MLE, which is prepared by alternately introducing AsH_3 and TMG at the inlet pressures of 7×10^{-3} and 1.3×10^{-3} Pa for a gas admittance mode (20", 1", 2", 1") at $T_{\text{sub}} = 500^\circ\text{C}$.

cient for monolayer adsorption coverage. So, the film thickness per cycle was dropped. The dashed and dotted line indicates 2.83Å corresponding to a single monolayer of GaAs (100) surface.

At the growth temperatures of 600°, 550°, and 450°C, the film thickness per cycle was also investigated, and the data, along with those at 500°C, are shown in Fig. 4 in semilog scale. At the substrate temperature of 600°C, the film thickness increases with increasing TMG admittance rate, which is quite different compared with the growth at 500°C. In the case of $T_{\text{sub}} = 500^\circ\text{C}$, a mirrorlike surface is maintained during the growth, even as the admittance quantity per cycle is increased up to 2.4 Pa-liter, while at $T_{\text{sub}} = 600^\circ\text{C}$, the film surface becomes white at the admittance quantity of 0.7 Pa-liter/cycle. It indicates that decomposed products from adsorbed TMG on the

Fig. 4. Film thickness per cycle as a function of TMG admittance rate (closed circle) and quantity (open circle) at the substrate temperature of 600°, 550°, 500°, and 450°C with a gas admittance mode (20", 3", 4", 3") (closed circle) and other modes (open circle). AsH_3 pressure is always kept 7×10^{-3} Pa. The film thickness is nearly saturated at 2.2–2.3 Å/cycle at $T_{\text{sub}} = 500^\circ\text{C}$. The dashed and dotted line indicates 2.83Å corresponding to a single monolayer of GaAs (100) surface.

substrate may supply more than is consumed by chemical reaction with AsH_3 to film growth.

At the lower temperature, TMG is deposited on the substrate as some kind of Ga complex, and monolayer adsorption may take place as a character of the chemical adsorption. With increasing the substrate temperature, CH_3 radical can be released from the Ga complex, which becomes adsorbed in the form of a single Ga element, so at higher pressures a condensation of Ga takes place to multiple layer adsorption. Now we suppose N molecules of TMG adsorbed on the substrate may be divided into two parts

$$N(\text{TMG})_{\text{ad}} = (1 - \alpha)N(\text{Ga-complex})_{\text{ad}} + \alpha N(\text{Ga})_{\text{ad}}$$

where α is the ratio of adsorbed TMG as a single Ga element, which is written as a function of the substrate temperature, surface state, adsorption time, and so on. If one chooses the condition $\alpha \ll 1$ and the vapor pressure of TMG to be not too high, as a typical result of a chemisorption the saturated value is independent of the admittance quantity of TMG and monolayer growth is able to be realized. The substrate temperature of 500°C fulfills the conditions for such a monolayer growth.

The influence of AsH_3 pressure on the film growth has been investigated at the substrate temperature of 500°C, a TMG admittance rate of 0.2 Pa-liter/s, and a gas admittance mode (20", 3", 4", 3"). With increasing AsH_3 pressure, the film thickness per cycle increased nearly one monolayer, corresponding to 2.83Å, which is indicated as a dashed and dotted line in Fig. 5. The AsH_3 pressure, however, influences the film thickness less than the TMG pressure under these experimental conditions. The measured values are gradually saturated at first in the pressure region of $p \approx 2 \times 10^{-2}$ Pa, which corresponds to the AsH_3 admittance quantity of 10^3 L. It is worthwhile to note that, with increasing AsH_3 pressure, the surface morphology of the growth film is improved.

Photo MLE.—During the film growth by MLE, the substrate has been irradiated by a high pressure Hg lamp (500W), Ar laser (514.5 nm), and Ar laser plus Doubler (257.3 nm). Irradiation light is injected through the two ports of the heating lamp house in Fig. 1 onto the substrate. It is worthwhile to note that the temperature increase of the substrate is determined by a pyrometer to be less than 1° under any photoirradiation. This means that any changes of the film quality or the growth behavior by irradiation are purely influenced by photons and are not due to the temperature increase. The photon flux levels at the substrate were about 3 mW/cm², 0.1 W/cm², and 0.1

Fig. 5. Film thickness per cycle as a function of AsH_3 pressure in the growth chamber. With a gas admittance mode (20", 3", 4", 3") and a TMG admittance rate of 0.2 Pa-liter/s at the substrate temperature of 500°C. The dashed and dotted line indicates 2.83Å corresponding to a single monolayer of GaAs (100) surface. With increasing AsH_3 pressure, the film thickness per cycle becomes close to that of one monolayer.

Table I. Electrical properties of films prepared by MLE and photo-MLE under the same gas-admittance conditions

T_{sub}	Light source	μ_n (cm ² /V-s)	Carrier density (cm ⁻³)	Type
600°C		56	1.9×10^{19}	p
600°C	Hg lamp	103	1.3×10^{18}	p
700°C		68	1.2×10^{19}	p
500°C	Hg lamp	103	3.1×10^{18}	p
500°C	Laser (257.3 nm)	84	4.6×10^{18}	p
500°C	Laser (257.3 + 514.5 nm)	110	2.4×10^{18}	p

mW/cm² for a Hg lamp for 514.5 and 257.3 nm, respectively.

The surface morphology of grown films by MLE at $T_{\text{sub}} = 500^\circ\text{C}$ without photoirradiation and with photoirradiation by a Hg lamp are shown in Fig. 6a and 6b, respectively. The film surface with a Hg lamp irradiation is smoother than that without irradiation. At $T_{\text{sub}} = 350^\circ\text{C}$, film growth was observed with the Hg lamp irradiation, while at $T_{\text{sub}} = 400^\circ\text{C}$ film growth was not observed without irradiation under the same experimental conditions. An electron diffraction pattern of this growth film at $T_{\text{sub}} = 350^\circ\text{C}$ clearly indicates single-crystal nature. This growth temperature is the lowest value ever reported for MO source and AsH_3 . MO-MBE reported by Takahashi *et al.* needed a growth temperature of more than 500°C (13). This demonstrates that photo-MLE growth largely decreases the growth temperature and improves the surface morphology.

Electrical properties of the growth film.—In the case of MO-CVD, electrical properties of the films are strongly influenced by the AsH_3 and the TMG flow rate and the ratio during the growth. We found that the carrier density of the films grown by MLE are strongly dependent on

($T_{\text{sub}} = 500^\circ\text{C}$)

Fig. 6. Optical photos of the growth film by MLE without photoirradiation (a) and with irradiation by a Hg lamp (b) at $T_{\text{sub}} = 500^\circ\text{C}$. The film surface with irradiation by a Hg lamp is smoother than that without irradiation.

Fig. 7. Carrier density of growth film (~ 200 nm) by MLE as a function of TMG admittance rate (open circle) and AsH_3 pressure (closed circle) at the substrate temperature of 500°C with a gas admittance mode (20", 3", 4", 3").

the gas admittance rate, *i.e.*, TMG and AsH_3 pressure. Figure 7 shows the carrier density of these films as a function of the TMG admittance rate at the constant AsH_3 pressure of 6.7×10^{-3} Pa and as a function of the AsH_3 pressure at the constant TMG admittance of 0.2 Pa-liter/s at the substrate temperature of 500°C . All films for these measurements were grown only ~ 200 nm on the n^+ Si-doped substrates of (100) and of (100) misoriented 4° to $\langle 110 \rangle$ faces. All growth films show p-type behavior. Carrier densities were calculated by including a correction of depletion layer widths. A depletion layer width of an abrupt approximation is estimated to be about 400\AA for GaAs at the carrier density of 10^{18} cm^{-3} .

With decreasing TMG admittance rate from 1 to 10^{-2} Pa-liter/s, the carrier density proportionally decreased from 10^{20} to 10^{18} cm^{-3} , while with decreasing AsH_3 pressure the carrier density increased. It demonstrates that the quality of the film grown by MLE can be tremendously improved with slower TMG admittance rate and higher AsH_3 pressure. However, under these experimental conditions, all growth films are p-type with a carrier density in the order of $10^{18}\text{--}10^{20}\text{ cm}^{-3}$. Such a high impurity level suggests the existence of a deviation from the stoichiometry and contaminations, such as carbon doped in the film during the growth. At the moment, we will not comment in detail on such a marked influence of TMG and AsH_3 pressure during the film growth. Those will be discussed in another paper. The influence of the photoirradiation on the electrical properties was studied and is summarized in Table I. Photoirradiation significantly improved the Hall mobility and decreased the carrier density.

Selective film growth by MLE.—An observation of the growth film surface by an optical microscope indicates no deposits on the Si_3N_4 film used for a mask pattern.

Auger electron spectroscopy shows neither Ga nor As components on the Si_3N_4 mask film. On the contrary, film growth occurred only on the region of GaAs surface without Si_3N_4 film. These facts indicate that the selective adsorption and selective reaction for crystal growth of TMG and AsH_3 took place on the substrate. We can conclude that MLE is a crystal-growth technique that progresses by a chemical adsorption reaction, *i.e.*, surface catalysis.

It is quite interesting to note that the substrate orientation does not influence the film growth by MLE. No significant differences between (100) and (100) misoriented 4° to $\langle 110 \rangle$ substrates have been observed on the growth rate and on the electrical properties of the film. However, films on the (100) substrate have a better surface morphology than those on the (100) misoriented 4° to $\langle 110 \rangle$.

Conclusion

For the first time, single-crystal GaAs films were prepared by MLE using TMG and AsH_3 and monolayer growth conditions were determined as a function of the gas admittance mode and substrate temperature. At the substrate temperature of 500°C , monolayer film growth was realized. The electrical properties of the film were strongly influenced by the TMG and AsH_3 pressure. Those were improved by increasing AsH_3 pressure and decreasing TMG pressure at the gas admittance. Photoirradiation improved the surface morphology and the electrical properties of the growth film by MLE. At the substrate temperature of 350°C , single-crystal film growth was realized by the irradiation of a Hg lamp.

ABSTRACT

In this paper, the effect of low temperature preanneal followed by rapid thermal annealing on arsenic-implanted Si is studied. The electrical properties and impurity distribution of the annealed Si are discussed. Sheet mobility and dopant activation of the implanted Si (100) samples (As⁺: 80 keV, 1×10^{15} and 1×10^{16} cm⁻² doses) as functions of annealing temperature are reported. TEM measurements on samples with and without preanneal (550°C, 1h) are presented. RBS and channeling results on samples with and without preanneal are also included. It is found that the dopant diffusion during RTA of 1×10^{15} cm⁻² dose As implants can be reduced somewhat by employing a 550°C, 1h furnace preanneal prior to RTA. However, the preanneal does not have significant effect on the carrier profiles of the 1×10^{16} cm⁻² dose implants. In some cases, the preanneal increases the dopant activation slightly.

In the fast developing VLSI technology, the trend is to have smaller device dimensions and shallower junctions. More stringent requirements have thus been imposed on the annealing of ion-implantation damage. One promising technique is rapid thermal annealing (RTA), during which the implanted wafer is heated by a short exposure to an incoherent light. The wafer is usually thermally isolated, and its maximum temperature is limited by a balance between absorbed and radiated power. Compared with furnace annealing, RTA is found to be capable of more efficient dopant activation with minimal diffusion. In the past two years, many researchers have reported their findings on the RTA of ion-implanted Si. Being a well-behaved dopant for Si, arsenic is of special interest; its RTA behavior has been studied extensively (1-6). Hodgson *et al.* used ion backscattering, channeling, and TEM to study the As-implanted (100) Si rapidly annealed with an arc lamp (1). Wagner *et al.* did research on photoluminescence from rapidly annealed, As-implanted Si (2). Kalish *et al.* reported their SIMS results of As implants annealed with a tungsten halogen RTA system (3). Fair *et al.* have modeled the As diffusion during RTA and suggested the possibility of enhanced diffusion for As during RTA (4). Wilson *et al.* reported the RTA results of As implants using a Varian IA-200 graphite annealing system (5). Recently, Seidel presented a paper in which he reported the absence of enhanced diffusion during RTA for arsenic implants (6).

In this paper, the two-stage annealing process using a low temperature furnace preanneal and a high temperature rapid thermal anneal for high dose As⁺ implants is investigated. Emphasis has been given to the electrical properties and the damage removal of the annealed samples.

Experimental

Si wafers of (100) orientation and 7 Ω-cm p-type resistivity were implanted with As⁺ ions at an energy of 80 keV to a dose of 1×10^{15} or 1×10^{16} cm⁻². The implantation was performed at room temperature with the substrate tilted 7° off the direction of the incident beam to minimize channeling. Some of the samples were preannealed in a quartz-tube furnace at 550°C for 1h in a flowing N₂ ambient. Both the preannealed and unannealed samples were then exposed to radiation from high intensity tungsten

lamps in a flowing N₂ ambient. The annealing time was 2s, and the annealing temperatures were about 1000°, 1050°, and 1100°C. The temperature of each sample was measured during the irradiation using a thermocouple contacted to the back of the same sample. The sample heating rate was 150°C/s, and the initial cooling rate was 90°C/s. Hall effect measurements using the van der Pauw method in conjunction with anodization and layer removal were used to determine the carrier concentration, sheet resistance, and mobility. The microstructures of the samples were studied by transmission electron micros-

copy (TEM). Channeled RBS measurements were also taken from a group of unannealed and annealed samples with and without furnace preanneal. The results obtained are discussed and correlated to those from TEM and Hall measurements.

Results

Hall and TEM Measurements.—Figure 1 shows the dopant activation efficiency, sheet mobility, and sheet resistivity as functions of RTA temperature for the $1 \times 10^{15} \text{ cm}^{-2}$ samples (both with and without preanneal). Nearly complete electrical activation was achieved for all the samples with or without preanneal. Figure 2 shows the carrier concentration and mobility profiles for the 1000°C RTA sample without preanneal, and the results for the

Fig. 3. Carrier concentration and mobility profiles for 80 keV, $1 \times 10^{15} \text{ cm}^{-2}$ dose arsenic implants preannealed at 550°C in furnace, followed by RTA at 1000°C for 2s.

Fig. 4. Planar TEM micrograph of 80 keV, $1 \times 10^{15} \text{ cm}^{-2}$ dose arsenic implants preannealed (550°C , 1h), followed by RTA at 1000°C for 2s.

preannealed, 1000°C RTA sample are shown in Fig. 3. The sample with the preanneal has a shallower concentration profile and higher peak carrier concentration than the sample without preanneal. This result indicates that the preanneal may have some effect on the dopant diffusion during RTA, resulting in a shallower junction. Figure 4 is a planar TEM micrograph of the preannealed, 1000°C RTA sample. The regrown layer (lower portion of the micrograph) is defect free, although defects (dislocations) are observed underneath this layer. The depth of the defects was evaluated from the number of thickness fringes produced by the dynamical diffraction conditions in the wedge-shaped sample. The defects were found to be about $0.13 \mu\text{m}$ deep, roughly corresponding to the position of original amorphous-crystalline interfaces.

The activation efficiency, sheet mobility, and sheet resistivity for the $1 \times 10^{16} \text{ cm}^{-2}$ samples without and with preanneal are shown in Fig. 5, respectively, as a function of RTA temperatures. The activation efficiency increases with temperature, while the mobility and sheet resistivity

decrease slightly with temperature. This is probably due to the effect with a high As dose. Figures 6 and 7 show the carrier concentration and mobility profiles for the non-preannealed samples with RTA temperatures of 1000°C and 1100°C , respectively. The carrier concentration profiles are relatively flat in comparison with the gaussian profiles for the $1 \times 10^{15} \text{ cm}^{-2}$ samples shown in Fig. 2 and 3. This difference is observed because the As concentration for the $1 \times 10^{16} \text{ cm}^{-2}$ samples exceeds the equilibrium solid solubility near the peak of the implanted dopant distribution, and the As near that region is only partially activated.

The 1100°C RTA sample (Fig. 7) shows a much deeper profile due to better activation and dopant diffusion. Figures 8 and 9 are the carrier concentration and mobility profiles for the preannealed samples with RTA tempera-

Fig. 8. Carrier concentration and mobility profiles for 80 keV, $1 \times 10^{16} \text{ cm}^{-2}$ dose arsenic implant preannealed at 550°C in furnace, followed by RTA at 1000°C for 2s.

tures of 1000° and 1100°C , respectively. Higher activation efficiency ($\sim 50\%$) is observed for the preannealed 1000°C sample of Fig. 8 compared to the sample of Fig. 6, which was not preannealed. For the 1100°C sample, shown in Fig. 9, higher carrier concentrations are achieved, giving rise to higher activation efficiency compared to that of 1000°C sample of Fig. 8. The profile is slightly shallower than that of the sample without preanneal in Fig. 7. Since this difference is within the experimental uncertainty of the Hall measurement, as far as the carrier concentration profile is concerned, the preanneal did not seem to have very much effect. This contrasts with the results reported by Fair *et al.* (4), who found a significant reduc-

tion of atomic profile broadening in preannealed samples.

Figure 10 shows the TEM micrographs of the 1000°C RTA samples without (Fig. 10a) and with (Fig. 10b) preanneal. "Hairpin" dislocations are present in the regrown layers for both samples. However, the sample without preanneal has a higher density of As precipitates, resulting in poorer activation. Figure 11 shows the TEM mi-

crographs for the 1100°C RTA samples without (Fig. 11a) and with (Fig. 11b) preanneal. No dislocations are observed for either sample.

RBS/channeling measurements.—Rutherford backscattering (RBS) and channeling measurements of 2.275 MeV He ions were made at Charles Evans Associates. The "rotating random" orientation technique was used when measuring the total As dose in each of the samples. The sample was continuously moved through all crystal orientations during the data acquisition phase so that an average or "random" crystal orientation is obtained. The description of the samples analyzed is summarized in Table I.

Figures 12-17 present the backscattering spectra in <100>-aligned and random directions for the samples. The channelled spectra are denoted with the suffix "CC," while random spectra are denoted with the suffix "RR." The aligned backscattering yield is identical to the yield

in Table II. The following equation was used to calculate the values of S

$$S = \frac{1 - X_{\text{impurity}}}{1 - X_{\text{host}}}$$

These S values are only first estimates (7). However, they do correlate well with the values from Hall measurements.

Fig. 16. Rutherford backscattering spectra in $\langle 100 \rangle$ aligned and random directions for 80 keV, $1 \times 10^{16} \text{ cm}^{-2}$ dose arsenic implant preannealed (550°C, 1h), followed by RTA at 1100°C for 2s.

from a virgin crystal for all the annealed samples (with or without preanneal). The minimum scattering yields (X_{min}) for the annealed samples are around 0.03-0.04, indicating that the recovery of the crystal is nearly perfect. The total arsenic dose measured in each sample is shown in Table I, and the first-order substitutional fractions S are shown

Fig. 14. Rutherford backscattering spectra in $\langle 100 \rangle$ aligned and random directions for 80 keV, $1 \times 10^{15} \text{ cm}^{-2}$ dose arsenic implant rapidly annealed at 1100°C for 2s.

Fig. 17. Rutherford backscattering spectra in $\langle 100 \rangle$ aligned and random directions for 80 keV, $1 \times 10^{16} \text{ cm}^{-2}$ dose arsenic implant preannealed (550°C, 1h), followed by RTA at 1050°C for 2s.

Summary and Discussion

For arsenic implants with $1 \times 10^{15} \text{ cm}^{-2}$ dose, a 1000°C RTA results in nearly complete activation, but many residual defects still exist even after a 550°C , 1h furnace preanneal prior to RTA. Higher temperature ($> 1050^\circ\text{C}$) is needed for better defect removal. For a dose of $1 \times 10^{16} \text{ cm}^{-2}$, a 1000°C RTA results in $\sim 50\%$ activation, and many residual defects still exist even after a 550°C furnace preanneal, which seems to increase the activation slightly. An 1100°C RTA, with or without preanneal, removes most of the residual dislocations and results in an activation better than 80% . We have found that dopant diffusion during RTA of $1 \times 10^{15} \text{ cm}^{-2}$ dose As implants can be reduced somewhat by employing a low temperature furnace preanneal prior to RTA. For $1 \times 10^{16} \text{ cm}^{-2}$ dose, there is no significant difference between the carrier concentration profiles with and without preanneal. However, the preanneal treatment in some cases increases the dopant activation efficiency.

Fluence (Dose) Monitoring of Energetic H^+ , B^+ , N^+ , P^+ , and As^+ Ions Using Ionization in a Radiachromic Film

Kranti V. Anand and Myron Cagan^{*1}

Fairchild Research Center, Palo Alto, California 94304

ABSTRACT

We have measured the increase in optical density vs. ion fluence (dose) of H^+ , B^+ , N^+ , P^+ , and As^+ ions implanted at 80 and 150 keV energies using a radiachromic dye in a nylon matrix. The technique, with some modification to the substrate, would be suitable for automatic, routine monitoring of low ion implant doses in the range of about 10^{11} to 10^{13} cm^{-2} . The data have been theoretically analyzed, and a model for optical density saturation (or bleaching) at high doses is proposed.

In this paper, we describe a method for monitoring the implant fluence² (dose) for H^+ , B^+ , N^+ , P^+ , and As^+ ions at 80 and 150 keV. These species are commonly used in the silicon integrated circuit industry, and the energies cover the values typically encountered. The method is particularly suitable at low doses (typically in the range of about 10^{11} cm^{-2} - 10^{13} cm^{-2} , depending on the ion species) which are at least an order of magnitude lower than the other commonly employed method such as sheet resistivity (ρ_s) (1). However, the technique of threshold voltage measurement using either MOSFET's or MOS structures (2) suffers from the disadvantage that complete wafer processing is required. This new technique to be described has the advantage, because it is rapid, that it can be used for routine monitoring of implanter performance. The measured dose is accurate and absolute in the sense that, unlike ρ_s measurement, it does not depend on mobility and free carrier concentration after a high temperature anneal. It is also capable of being automated, so that a dose map of each wafer can be obtained. It should be pointed out that a system similar to the one proposed, but relying on optical changes in photoresist, is commercially available (3). Though that system has the advantage of a wider dose range capability (5×10^{12} - $5 \times 10^{15} \text{ cm}^{-2}$), the low end of the range is approximately an order of magni-

tude higher than that observable with the proposed method.

Experimental Details

The ions were implanted into a sample of $1 \text{ cm} \times 1 \text{ cm} \times 40 \mu\text{m}$ thickness of radiachromic dye (RCD) using an implanter³ with a hot cathode ion source. The RCD was originally developed by McLaughlin and Chalkley (4, 5) and is commercially available as self-supporting flexible films as thin as about $8 \mu\text{m}$ (6, 7). The films consist of a nylon matrix containing a dye of hydroxyethyl-substituted aminotriphenyl methane nitrile. Such materials are used mostly for x-ray, gamma ray, and electron dosimetry in radiation processing and medical fields. Shaw *et al.* (8) have used this material⁴ for lithographic applications and have given details of its sensitivity to UV radiation, x-rays, electron beams, and, to a smaller extent, H^+ and Ga^+ ion beams. During implantation, the sample is held on a stainless steel backing fixture, and a circular area of 7.5 cm diam is exposed to the beam. The measured beam currents with and without the RCD sample were found to be essentially the same, indicating that there were no anomalies in charge collection due to the presence of the RCD. Similar conclusions were reached by Rosenstein and co-workers (9) for the same material when bombarded with 1.5 MeV electrons and with 3 MeV protons. Hansen *et al.* (10) have also exposed it to 3 and 16 MeV protons, 10 MeV α particles, 21 MeV Li^+ ions, 42 MeV N^+

²Fluence is defined as the number of incident ions per unit area (cm^{-2}). However, since in the semiconductor industry this is referred to as dose, we shall call it by that name from now on.

³High Voltage Engineering, Model 300 keV/LS5.

⁴Far West Technology, Incorporated, Goleta, California 93117.

ions, and 64 MeV O^+ ions. Since the RCD is sensitive to UV and normal fluorescent light, all operations are carried out under yellow light. The optical density (OD) was calculated from transmission data measured using a UV spectrometer⁵ at 610 nm wavelength. The minimum transmission actually occurs at 600 nm, but we found better repeatability at 610 nm.

Analysis of Experimental Results

As can be seen in Fig. 1a and 1b, the response data for this dye to the various ions consists of an initial regime in which the OD increases with dose. It is followed by a saturation and a bleaching regime. The dose at which the maximum in OD occurs we shall refer to as D_{max} .

We find (solid lines in Fig. 1a and 1b) that the initial regime can be fitted to a theoretical curve of the form of Eq. [1]

$$OD = K[1 - \exp(-D/D_0)]^m \quad [1]$$

This equation results from the "one or more hit" theory (11, 14) and was shown to apply to a wide range of detectors. Though in the past this treatment has been applied to megaelectron volt gamma rays and protons, Sharma *et al.* (11) have discussed its applicability to heavy ions as well. The theory uses Poisson statistics to work out the probability of photoionization events as a function of the radial distance from the particle track. The model assumes that it is the energetic secondary electrons which cause the radiolytic ionization process and that the direct particle contribution is negligible.

Table I gives the calculated values of the three constants k , D_0 , and m ; m is called the "target" or "extrapolation" number. We note that for H^+ , the value of m is 1, implying that it is a one-hit detector as referred to by Sharma and Katz (11). This has also been observed by Rosenstein *et al.* (9) with 3.0 MeV protons and by Hansen *et al.* (10). However, as seen in Table I for the other ions, $m \neq 1$. For this reason, the ionization process appears to be more complex. In spite of this, the theory gives a satisfactory fit to the ions and energies which were used.

We proceed now to calculate the saturation dose, D_{max} , from a different set of theoretical considerations. In the discussion above, we have neglected the nuclear energy

loss of the penetrating ion. We calculate the parameter E_{TN} (defined below), together with the projected range R_p , using a range theory developed by one of us (K.V.A.) using a semi-Monte Carlo technique (12, 13). The theory uses a Thomas-Fermi screening potential for calculating the nuclear energy loss. The values of E_{TN} and R_p are also given in Table I. If we were to assume that bleaching occurs when the total nuclear energy absorbed by the RCD reaches a constant value, which is independent of the type of ion or its initial energy, then for the best fit to our experimental data, this constant is as given by Eq. [2].

$D_{max}E_{TN} = \text{total nuclear energy absorbed (const.)} = 2.3 \times 10^{14} \text{ keV-cm}^{-2}$ [2] where E_{TN} is total nuclear energy loss in [keV-(ion)⁻¹] over its stopping track length. Table I shows the theoretical (using Eq. [2]) and experimental values of D_{max} . As can be seen, the correspondence is good, implying that our assumption that bleaching is caused by nuclear energy loss is correct.

It should be noted that, as expected, the highest calculated range (10,350Å) is that of the lightest ion, H^+ , at 150 keV and the lowest calculated range (930Å) is for the heaviest ion, As^+ . However, the total nuclear energy loss when bleaching occurs is the same for each ion, *i.e.*, $2.3 \times 10^{14} \text{ keV-cm}^{-2}$. This means that the average nuclear energy loss per unit volume for As^+ is an order of magnitude higher than for H^+ . This suggests that bleaching is not due to the primary reaction between the incoming ion and the material. Instead, it is caused by secondary processes which distribute the nuclear energy loss over a much wider range. Since H makes up 60% of the atomic density of the dye matrix and has the requisite long range, it is proposed that it is primarily responsible for the bleaching action by directly disrupting the dye molecule.

Measurement of Ion Dose Using the Dye

The experimental data given in Fig. 1a and 1b can obviously be used to calculate dose from the measured value of OD on any given sample. The accuracy with which the dose can be measured using this data depends on the accuracy of the OD measurement. Our spectrometer is capable of measuring the transmission through the dye with a maximum error of $\pm 0.1\%$. Using the functional relationship between OD and dose as given by Eq. [1], we calculate the dose that can be measured with an accuracy of

⁵Perkin-Elmer UV spectrophotometer (Model 320).

Fig. 1. The experimental data (points) and the best theoretical fit (in solid lines) for optical density increase at 610 nm as a function of ion fluence (dose) using Eq. [1] for 80 keV (a) and 150 keV (b) for the various ions. Arrows indicate the values of D_{max} as calculated by Eq. [2].

Table I. This shows for H⁺, B⁺, N⁺, P⁺, and As⁺ the various parameters defined in the text associated with the ions at the two implant energies of 80 (columns 2-9) and 150 keV (columns 10-17)

$\pm 5.0\%$. This dose, D_{min} , is also shown in Table I. D_{min} ranges from $8.0 \times 10^{10} \text{ cm}^{-2}$ for the light ion H⁺ at 150 keV to $1.2 \times 10^{12} \text{ cm}^{-2}$ for As⁺ at 80 keV. For doses above D_{min} , the accuracy will be better than $\pm 5.0\%$ up to a dose close to D_{max} , where accuracy drops again due to the maximum in the response curve. Hence, for implant monitoring purposes, a dose value should be chosen within this range to give the best dose precision depending on the energy and ion type. We calculate that, using this method, the precision of the dose measurement would be $\pm 0.5\%$.

It should be pointed out that the experimental scatter in the measured OD in comparison to the smooth curve shown in Fig. 1a and 1b is occasionally greater than the instrument OD error. This is because the standard deviation of the OD of the unexposed material is specified by the RCD manufacturer is $\pm 5\%$. In order to realize the best accuracy for dose measurement, an OD map of the RCD detector should be obtained prior to implantation (a reference check). Then the implanted sample would be mapped and corrected using the reference measurement on a point-by-point basis. With this technique, it will be possible to realize the dose measurement accuracies discussed above.

In principle, it should be possible to use this technique for doses larger than D_{max} (when OD begins to go down due to the bleaching action). However, since our interest was primarily in low dose monitoring, this was not investigated. It should, however, be noted that dose error near D_{max} will be very large. Hence, measurement near that region should be avoided.

It is envisaged that, in a semiconductor manufacturing facility, the dye would be deposited on a glass or quartz plate whose dimensions conform to silicon wafer specifications. After implantation in the usual way, the RCD containing wafer would be mapped automatically on a spectrophotometric dosimeter (at 610 nm) with a computer-controlled X-Y stage. Such a system would produce an X-Y map of the ion implantation dose distribution using the calibration data shown in Fig. 1a and 1b.

Conclusions

We have shown that for a wide mass range of ions such as H⁺, B⁺, N⁺, P⁺ and As⁺ implanted into RCD at energies of 80 and 150 keV the relationship between OD and dose at the low doses can be modeled on the basis of Eq. [1]. The three constants associated with this model equation have been calculated from our experimental data and allow dose calibration to be made from OD data. As the dose increases, a bleaching action causes a maximum in OD to be reached. Our detailed calculations of the energy-

loss mechanism suggests that this bleaching action is primarily due to the hydrogen-assisted nuclear energy loss disrupting the dye molecule.

We estimate that this technique can be successfully used for dose monitoring in ion implantation systems with an accuracy of better than $\pm 5.0\%$ down to very low doses of about 10^{11} cm^{-2} for most ions and typical acceleration potentials in the 50-200 keV range used in the semiconductor industry.

Acknowledgments

Low Pressure Metalorganic Vapor Phase Epitaxy of InP in a Vertical Reactor

Mamoru Oishi* and Koichi Kuroiwa¹

Nippon Telegraph and Telephone Public Corporation, Atsugi Electrical Communication Laboratory, 1839 Ono, Atsugishi, Kanagawa 243-01, Japan

ABSTRACT

InP growth characteristics in low pressure metalorganic vapor phase epitaxy (MOVPE) in a vertical reactor were studied. A maximum mobility of 32,000 cm²/V s at 77 K was obtained. Selective epitaxy was also investigated, and completely selective epitaxy was realized for 15 μm wide SiO₂ masks at 40 torr. Preliminary results are shown for a hybrid LPE/MOVPE-grown distributed-feedback laser diode. Single longitudinal mode operation under pulsed current injection was achieved at room temperature.

Recently, InP has become increasingly important because of its applications to optoelectronic devices and to monolithic integration of lasers, detectors, and FET's. For such device integration, ultrafine lithography and larger surface areas with smooth specular layers will be required. Large-area epitaxial films can be obtained fairly easily by metalorganic vapor phase epitaxy (MOVPE) or metalorganic chemical vapor deposition (MOCVD) (1). MOVPE has proven its suitability for GaAs and GaAlAs epitaxial growth and for device applications (2, 3). The principles of MOVPE operation and reactor design are comparatively simple, and materials with uniform device quality over large areas are readily obtained, particularly for GaAs.

Application of the MOVPE technique to the growth of InP has been investigated through a variety of approaches (4-13); triethylindium (TEI) + phosphine (PH₃) (4-8), adducts (9, 10), trimethylindium (TMI) + PH₃ (11, 12), and TMI + trimethylphosphine (TMP) (13). Early problems encountered for the MOVPE growth of In containing compounds are attributed to the parasitic reaction between TEI and PH₃ in the gas phase to form nonvolatile polymeric liquids upstream from the substrate. To solve these problems, some groups have adopted the use of adducts, such as TMI-TMP (9) or TMI-triethylphosphine (TEP) (10), as sources. These molecules do not themselves form nonvolatile polymers, hence the disadvantages of this approach are the low vapor pressures of the adducts, which necessitates heating the tubing and reactor walls upstream from the substrate, and the difficulty for growing multicomponent systems. The other approach is to use TMI instead of TEI. TMI was observed to participate in the gas phase reactions less than TEI. A disadvantage of this method is the low melting point of TMI; precisely controlled transport to a reactor is difficult because TMI is solid at near room temperature. At the present stage, therefore, the conventional sources, TEI and PH₃, have fewer problems. In using TEI and PH₃, effective approaches are to adopt the low pressure growth technique (5), to pyrolyze PH₃ (5), or to keep the reactants separated until the last possible moment in the growth process using a special guide which also plays a role of the oven for PH₃ pyrolysis (6). There have been some successes with these approaches.

Note that these studies have used horizontal reactor (HR) systems. Although successful results were obtained using vertical reactor (VR) systems for GaAs MOVPE (14, 15), no successful results have yet been reported concerning the InP growth using a VR system. The reasons for this may arise from difficulties involved in a VR system: (i) parasitic reaction problem, or (ii) thermal convection problem. These problems are more crucial in a VR system than in an HR system. In fact, the radiation from the heated susceptor in a VR system directly promotes the premature decomposition of MO molecules far from

the substrate and accelerates the parasitic reaction. Moreover, some turbulent gas flow is liable to develop in a VR system, because the pronounced thermal convection due to the heated susceptor impedes the smooth stream of the source gases. So, finding a way out of the difficulties mentioned above and applying a VR system to MOVPE of InP is worth investigating.

In addition, a highly selective epitaxy technique, once accomplished, can extend the design flexibility of integrated devices and reveal the growth mechanism. In many cases, MOVPE is carried out over the entire area of planar substrate surfaces. Selective MOVPE has been investigated for application with GaAs (16-19), but very little attention has been paid to InP (20).

The authors investigated the promising application of a vertical reactor system to MOVPE of InP and selective epitaxy using TEI and PH₃. The techniques of low pressure MOVPE and separate introduction to source gases are adopted to overcome the problems mentioned above. As a test of the quality of the films produced and their applicability to devices, a hybrid liquid phase epitaxy (LPE)/MOVPE technique was used to fabricate distributed-feedback buried-heterostructure (DFB-BH) lasers.

In this paper, the growth and properties of InP films produced by low pressure MOVPE in a vertical system are reported. Selective epitaxy is also investigated to establish the necessary conditions for completely selective epitaxy. An application to distributed-feedback buried-heterostructure (DFB-BH) laser fabrication together with LPE (a hybrid LPE/MOVPE technique) is also reported.

Experimental

Growth system.—The growth system used in this study is similar to one previously reported (21), a schematic diagram of which is shown in Fig. 1. The reactor gas manifold and mixing system were constructed of stainless steel, and all gases were controlled by mass flow controllers. Triethylindium [TEI, In(C₂H₅)₃] was used as the indium source, and PH₃ diluted to 10% in hydrogen was used as the phosphorus source. TEI was contained in a stainless steel bubbler and maintained at constant temperature with a thermostat. PH₃ was contained in a commercially supplied high pressure gas cylinder. The carrier gas was palladium-diffused high purity hydrogen. PH₃ flow-rate values refer to the flow rates of diluted gases.

The cold-walled growth reactor was a quartz tube 40 cm long. It was of 4 cm diam for its upper one-quarter, 10 cm for the lower three-quarters, and had O-ring seals for separation at the base. Two lines for TEI and PH₃, respectively, are separately connected to the reactor to suppress the parasitic reaction. TEI is introduced via a fine tube to the vicinity of the pedestal, while PH₃ flows down from the reactor top end. A rotatable pedestal made of high purity graphite is inductively heated (300 kHz). Temperature is measured by a thermocouple inserted into this pedestal within the quartz tube. All temperature values given refer to readings of this thermocouple.

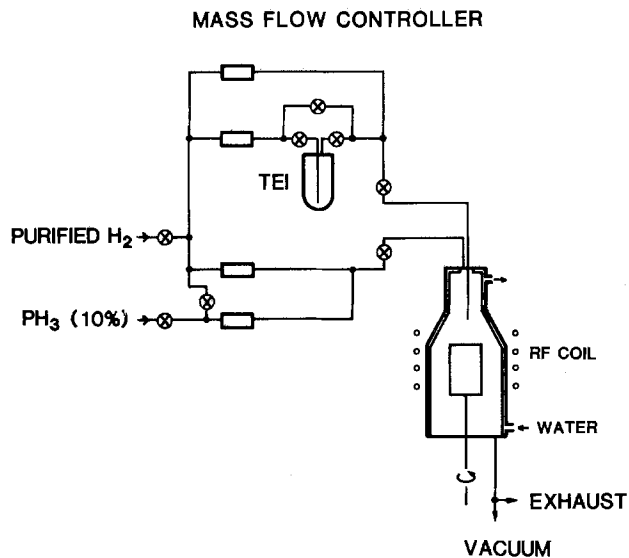

Fig. 1. Schematic diagram of vertical MOVPE growth system

Growth at reduced pressure was carried out by incorporating a rotary pump at the outlet of the reactor tube. To monitor the pressure within the reactor and the gas manifold, diaphragm pressure gauges were used. A molecular sieve was used to impede oil back-diffusion at the input of the pump. The working pressure was adjusted by varying the line conductance using a valve.

Epitaxial growth was carried out (i) on iron-doped semi-insulating InP substrates to facilitate subsequent electrical evaluation, (ii) on masked InP substrates for the study of selective epitaxy, and (iii) on p-type InP substrates for fabricating DFB-BH lasers. The substrates were obtained commercially and had one side polished. The orientations of the substrates were (100) and 3° off the (100) plane toward [110]. Identical results were obtained for both substrate orientations.

Growth procedures.—The substrates were cleaned with trichloroethylene, acetone, and isopropyl alcohol. They were etched first in an $\text{H}_2\text{SO}_4\text{-H}_2\text{O}_2\text{-H}_2\text{O}(3:1:1)$ mixture and then in 10% Br-methanol just prior to growth, then rinsed in deionized water, and finally dried.

Substrates for the study of selective epitaxial growth were also prepared. First, an SiO_2 layer about 300 nm thick was RF sputtered on the cleaned surface of the substrates. Five different types of masks (patterns A-E shown in Fig. 2) were formed along the [110] or $[\bar{1}\bar{1}0]$ directions with conventional photolithography techniques and using buffered HF as the etchant. Prior to loading in the growth system, the substrates were cleaned again in organic solvents.

The substrates were placed perpendicular to the gas stream on the quartz susceptor which was set on the graphite pedestal. After loading the substrates, the reac-

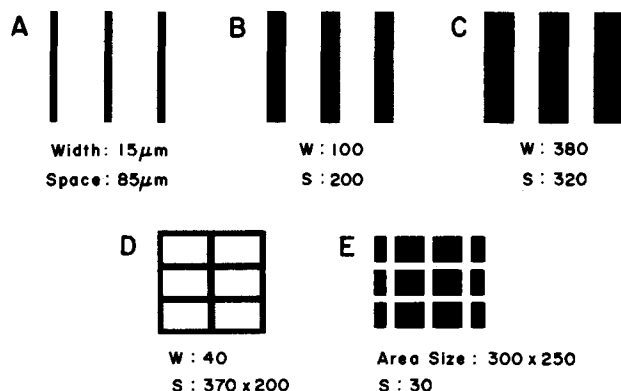

Fig. 2. Five mask patterns for the study of selective epitaxy

tor was purged with a hydrogen flow of 5 liter/min for 60 min, and the pressure was brought down to the working level. After the pressure had stabilized, heating was begun. The PH_3 flow was maintained as long as the temperature stayed above 450°C . Typical growth parameters are listed in Table I.

Sample evaluation.—The samples grown in this study were evaluated using van der Pauw-Hall effect measurements. The measurements were taken on rectangular samples by placing Sn dots around each sample periphery. The Hall effect was measured in 1 kG magnetic fields. To measure the thickness of the epitaxial layers, staining technique was applied to cleaved sections.

Photoluminescence (PL) was excited with the 530.8 nm line of a Kr⁺ laser. The excitation intensity was typically 5 W/cm^2 .

InP epitaxial layers on Fe-doped InP substrates were studied by x-ray diffraction using a double-crystal monochromator, in which the first crystal was a (100) InP wafer and the (400) (+, -) parallel arrangement was used. The x-ray beam size incident on a sample surface was less than 1 mm in diameter. The extinction distance of the (400) reflection of an InP crystal is $1.2 \mu\text{m}$ (22). This is shorter or the same as the thicknesses of the InP epitaxial layers grown here. For this reason, the x-ray diffraction is considered to be mainly from the InP epitaxial layers with only a negligible contribution from the substrates themselves.

DFB laser fabrication by the hybrid LPE/MOVPE technique.—MOVPE was applied to distributed-feedback buried-heterostructure (DFB-BH) laser fabrication. In the fabrication of DFB lasers, the melt-back or deformation of the corrugated layers has often been observed during LPE growth (23). However, MOVPE is expected to keep the shape of the corrugation.

MOVPE was applied to grow the on-corrugation layer and the other layers were made by LPE (hybrid LPE/MOVPE technique) because at the stage of this work doping was not investigated. Figure 3 shows the schematic diagram of a DFB-BH laser grown by this hybrid LPE/MOVPE technique. It was fabricated by the following process. A three-layer structure, composed of a Zn-doped InP buffer and a lower cladding layer ($5 \mu\text{m}$ thick, $p = 3 \times 10^{17} \text{ cm}^{-3}$), an undoped InGaAsP active layer ($0.25 \mu\text{m}$ thick, $\lambda = 1.55 \mu\text{m}$), and a Sn-doped InGaAsP waveguide layer ($0.25 \mu\text{m}$ thick, $n = 2 \times 10^{18} \text{ cm}^{-3}$, $\lambda = 1.3 \mu\text{m}$), was grown on a Zn-doped (100) InP substrate ($p = 5 \times 10^{17} \text{ cm}^{-3}$) by the conventional LPE technique (Fig. 4a). A second-order corrugation was then formed on the InGaAsP waveguide layer by holographic photolithography and chemical wet etching (24) (Fig. 4b). The pitch and the depth of the corrugation were typically 460 and 160 nm, respectively. The direction of the corrugation was [110].

The corrugated surface was overgrown with an undoped InP layer formed by MOVPE (Fig. 4c). Prior to the loading of the wafer into the MOVPE reactor, the corrugated surface was cleaned in hot acetone, concentrated H_2SO_4 , and HF. The growth temperature and the reactor pressure were 600°C and 90 torr, respectively. Doping was not utilized at this stage of the MOVPE study.

After the MOVPE growth, a buried-heterostructure was formed by the selective LPE technique (25) (Fig. 4d). First, reverse-mesa stripes were formed in the [110] direction with the SiO_2 masks. Next, successive n- and p-type InP layers were grown. The width of the active region was $19 \mu\text{m}$. Ohmic contacts were made by evaporating

Au-Zn on the p side, and Au-Ge-Ni on the n side. One facet of the laser was formed by cleavage and the other was tilted by the etching technique to suppress oscillation in the Fabry-Perot modes. The length of the laser fabricated was 500 μm .

Results and Discussion

Study of growth.—The layers grown showed good surface quality over a wide range of growth conditions. Furthermore, the morphology was found to be essentially independent of the TEI or PH_3 flow rates as long as the mole ratio introduced, PH_3/TEI , was greater than 1. Figure 5 shows a surface feature of the epitaxial layers. Figure 6 presents a roughened surface grown under the PH_3 -depleted condition. Indium droplets were formed on the rectangular pits which had been the result of thermal damage.

Figure 7 shows the growth rate of the epitaxial layers as a function of TEI flow rate. The linear variation in the growth rate with the TEI flow rate and the independence of the growth rate from the PH_3 flow rates, which had been widely reported in the MOVPE literature (26), was also observed here. Other parameters, such as substrate temperature and PH_3/TEI ratio had no effect on growth rates. The growth rate was, thus, mass-transport limited as long as plane substrates were used.

The undoped InP layers are n-type with carrier concentrations of $(0.5\text{--}10) \times 10^{15} \text{ cm}^{-3}$. The electron mobilities typically ranged from 3000 $\text{cm}^2/\text{V s}$ at room temperature

Fig. 5. Photomicrograph of the surface of an epitaxial layer grown

Fig. 6. Micrograph of a roughened surface grown under PH_3 depleted condition.

to 30,000 $\text{cm}^2/\text{V s}$ at 77 K. The lowest carrier concentration and the highest mobilities are $5 \times 10^{14} \text{ cm}^{-3}$, 4100 $\text{cm}^2/\text{V s}$ (room temperature), and 32,000 $\text{cm}^2/\text{V s}$ (77 K), respectively. These values are comparable to the epitaxial layers grown from TEI and PH_3 using an HR system (6, 8) and from adducts (9, 10).

The photoluminescence (PL) spectrum of undoped InP epitaxial layers at 77 K is shown in Fig. 8. PL intensity is

Fig. 7. Growth rate as a function of TEI flow rates

Fig. 8. PL spectra of undoped InP epitaxial layer at 77 K

as high as that of the best sample of MBE-grown InP (22). It has only one peak and a trace of a second peak; the peak is centered at 1.41 eV with a full width at half maximum (FWHM) of 11 meV, which is a near band-edge emission, and the trace is near 1.38 eV. The peak intensity ratio of the 1.38 eV peak to the 1.41 eV peak has often been reported as 1/10 or more (6, 7). In this case, however, the ratio was as small as 1/100. Assuming that the 1.38 eV peak results from the transition due to the acceptors (6), this difference can be attributed to the concentrations of the residual acceptor-like impurities in the unintentionally doped layers.

The FWHM of the x-ray rocking curve of the epitaxial layer is as small as 20s. This value is comparable with those of the substrates used in the study.

Application to DFB-BH laser fabrication.—Figure 9 shows SEM photographs of the corrugated structure before (Fig. 9a) and after (Fig. 9b) MOVPE overgrowth. The shape of the corrugation was hardly affected during MOVPE overgrowth.

Figure 10a shows light output/current characteristics at 25°C under pulsed operation (pulse width = 5 μs; duty cy-

Fig. 9. SEM photographs of the corrugated structure before (a, top) and after (b, bottom) MOVPE overgrowth.

cle = 3 kHz). The threshold current I_{th} was 400 mA, which corresponds to a current density of 6.8 kA/cm². Figure 10b shows the emission spectra. Single longitudinal mode operation was achieved. The lasing wavelength was 1.55 μm (at 25°C), and the temperature dependence of the lasing wavelength was 0.11 nm/K.

In the present diode structure, doping was not utilized for the MOVPE-grown InP cladding layer and the width of the active layer was not so narrow as that of the conventional BH lasers. These factors are considered to cause low injection efficiency and high I_{th} . Therefore, further reduction of I_{th} can be achieved by optimizing the structure.

Fig. 10. Light output/current characteristics and emission spectra (inset) of a hybrid LPE/MOVPE grown InGaAsP/InP DFB-BH laser.

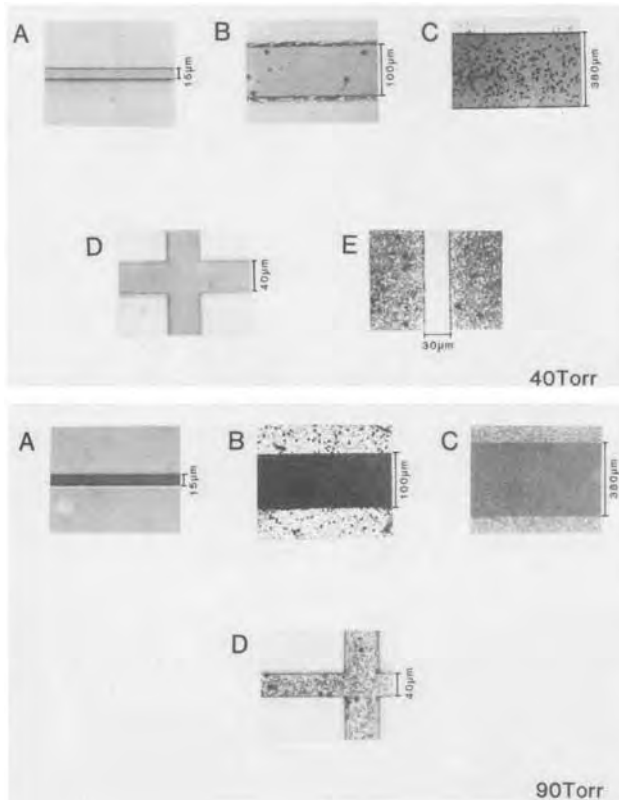

Fig. 11. Epitaxial InP on SiO₂ masked substrates. Pressure is 40 and 90 torr.

Selective epitaxy.—InP was grown on SiO₂-masked substrates under 90 and 40 torr. Figure 11 shows photographs of the surfaces grown. Results are summarized in Table II from the viewpoint of selectivity. Here the symbol O indicates “completely selective epitaxy,” that is, no deposition was observed on the SiO₂ masks and mirror-smooth InP was grown on the InP region. The symbol Δ shows that mirror-smooth InP was obtained on the InP region and polycrystalline InP was partly deposited on the masks. The symbol × shows that polycrystalline InP was obtained over the entire area of the masks and mirror-smooth InP was grown on the InP region. Finally, ×× means that polycrystalline InP was deposited both on the masks and on the InP region.

“Completely selective epitaxy” was achieved for 15 μm wide stripes at 40 torr. The selectivity became more effective with the narrowing of the stripes and the lowering of the working pressure. It can be supposed from this result that the surface mobility of In decomposed from TEI is higher on the SiO₂ masks than on the InP region, which makes it possible for InP nucleation or growth on the InP region to be larger than that on the SiO₂ masks.

Typical growth features on the mesa and reverse-mesa structures are shown in Fig. 12. For GaAs, Azoulay *et al.* demonstrated single-layer growth on a mesa-etched substrate without the use of masks (19). In their report, one layer grown covers the entire mesa structure (25 μm wide), and straight edges perpendicular to the substrate are obtained after growth over a long period. In this experiment, however, the sidewall of the layers grown coincided with the reverse-mesa edges when the reverse-mesa was fabricated. When the mesa structure was fabricated,

Table II. Summary of selective epitaxy results (see text)

Pressure (torr)	Mask patterns				
	A	B	C	D	E

40	O	Δ	×	Δ	×

Fig. 12. Growth features on mesa, a, and reverse-mesa, b, structures

the growth front climbed over the SiO₂ masks. The lateral growth rate in the direction of [110] is larger than that in the direction of [110], or, rather, (111) planes on reverse-mesa have the function of limiting the growth towards [111].

This technique for the growth of epitaxial layers on SiO₂ masked substrates, and especially on reverse-mesa substrates, will be useful in obtaining buried structures with flat surfaces.

Conclusion

We have investigated the low pressure MOVPE of InP in a vertical reactor. Without making any special considerations, InP epitaxial layers with free carrier concentrations of as low as $5 \times 10^{14} \text{ cm}^{-3}$ have been obtained. The highest mobility is $4100 \text{ cm}^2/\text{V s}$ at room temperature and $32,000 \text{ cm}^2/\text{V s}$ at 77 K.

Selective epitaxy by this technique has also been studied. The conditions for completely selective epitaxy have been established. It has also been demonstrated that we can achieve completely selective MOVPE of InP on 15 μm wide SiO₂-striped InP substrates. This technique is promising for the fabrication of integrated devices.

DFB-BH lasers have been fabricated by a hybrid LPE/MOVPE technique. Room temperature pulsed operation has been achieved. These devices operated stably in a single longitudinal mode at room temperature under pulsed operation.

Acknowledgments

The authors would like to thank Y. Itaya and Y. Noguchi for LPE growth, T. Matsuoka for the fabrication of the corrugation, Y. Suzuki for laser chip fabrication, and N. Shibata for assistance in sample evaluation. They are also grateful to T. Ikegami, K. Kurumada, and H. Nagai for their fruitful discussions and comments and to M. Fujimoto for his continuous encouragement throughout the course of this work.

An Optical Imaging Method for Wafer Warpage Measurements

K. H. Yang

IBM East Fishkill Facility, General Technology Division, Hopewell Junction, New York 12533

ABSTRACT

A simple optical imaging method is developed for quick evaluation of wafer surface quality and warpage. Surface irregularities 50-100Å deep can be detected by this method. The detection limit is about 270m for the radius of curvature. The sense of curvature can be unambiguously determined by image contrast and image size. The principle of this method for warpage measurements is described. A comparison of this method with the optical interference method and the x-ray method is given and discussed.

Wafer warpage can lead to serious degradation in device yield. The warpage, in general, is generated by excessive thermal stresses during hot processings, or by elastic stresses due to thin film deposition. At present, measurement of wafer warpage and film stresses relies mainly on techniques such as the surface profiling method (1), the Newton-ring method (2), the x-ray method (3-6), and the optical interference method (7, 8). The first three methods can only produce a single scan of surface profile or measure warpage at two reference points. Recording a warpage map of an entire wafer through these methods is difficult and time consuming. The optical interference method is the only one that can provide a contour map of an entire wafer. The contour map is represented by fringes at equal height. For severely warped wafers and rough surfaces, the contour map sometimes becomes too complex and difficult to be recognized. Availability of a simple method capable of examining the warpage of an entire wafer surface is therefore most desirable.

Recently, Kugimiya (9) reported an optical method that allows one to examine irregularities and warpage of an entire wafer surface. In this method, a projection lens is used to form a defocused image of a wafer surface. The use of the projection lens, however, imposes some restrictions on the flexibility and sensitivity of this method. Namely, the wafer size has to be smaller than the size of the projection lens, and the sensitivity is limited by the magnification power of the lens. As a result, this method has a relatively low sensitivity, about 500Å for surface irregularities and 100m for the radius of curvature. Because of the low sensitivity, it can hardly be used to measure thin film stresses. In 1980, we developed a similar optical method, which required no projection lens. With elimination of the lens, our method is capable of examining wafers of any size and has a greater sensitivity. The detection limit is 50-100Å for surface irregularities, and 270m for the radius of curvature.

In this paper, we first describe the experimental setup and principle of our optical imaging method. The results of our measurements are expressed in measurable parameters, which can be used to calculate radius of curvature,

wafer warpage, and film stresses. Optical imaging photographs of warped wafers and surface irregularities are also given as examples.

Experimental

82 mm (100) wafers processed through MOS processings or deposited with Si₃N₄ thin film were used as samples for warpage measurements. The MOS processed wafers were covered with 0.5 μm thermal SiO₂ and 1.5 mm Al dots on the wafer front side and with 1 μm Al contact film on the back side. The deposition temperatures were 1000°C for atmospheric pressure CVD (APCVD) Si₃N₄ and between 200° and 300°C for plasma Si₃N₄. Wafer warpage due to the MOS processing on the film deposition was measured by the optical imaging method.

The experimental setup of the optical imaging method is shown schematically in Fig. 1. A collimated beam (divergence of about 1.4°) is used as a light source. The beam passes through a transparent square grid. The lines of the square grid are projected onto a wafer surface. The wafer is mounted on a goniometer, which provides a three-dimensional rotation. The square lines on the wafer surface are reflected back horizontally at an angle of 2α, which is approximately 12°, and vertically at nearly 0°. A matt-glass image screen intercepts the reflected beam to produce an image that can be photographed. For practical purposes, the angle, α, between the incidence beam and the wafer surface normal is kept as small as possible. Thus, the difference in image size between the vertical and the horizontal directions is kept to a minimum. For the present setup with α = 6°, the image difference is only 0.5%.

The image distortion produced by a warped surface is schematically shown in Fig. 2. Figure 2 shows that two beams A and B (with a small divergence of 2β) incident at positions W₁ and W₂ on an optically flat wafer surface W will reflect and form a magnified image I₁, I₂ in the image plane I. For the convex surface W', the image formed is I', I'₂. From simple geometry, the size of the image is

$$I_1 I_2 = W_1 W_2 + 2L \tan \beta \quad [1]$$

Fig. 1. Experimental setup of the optical imaging method

and

$$I'_1 I'_2 = W_1 W_2 + 2L \tan(\beta + 2\Theta) \quad [2]$$

where L is the distance between the image plane and the wafer surface, and 2Θ is the angle of bending for the convex wafer. The image distortion due to the convex surface is

$$d = I'_1 I'_2 - I_1 I_2 = 2L(2\Theta) \quad [3]$$

for small Θ and β .

The magnification factor m , defined as the ratio of reference image $I_1 I_2$ and reference spacing $W_1 W_2$, $m = I_1 I_2 / W_1 W_2$, can be measured from an optically flat mirror or obtained from Eq. [1].

The images $I_1 I_2$ and $I'_1 I'_2$ are reduced by a factor of n in the recorded picture. The image size in the recorded picture becomes $I_p = I_1 I_2 / n$, $I'_p = I'_1 I'_2 / n$, and the image distortion, $d_p = d/n$.

Knowing the values of m and n , the angle of bending can be readily obtained from a recorded picture as

$$2\Theta = nd_p / 2L \quad [4]$$

The radius of curvature is

$$R = \text{arc } W_1 W_2 / 2\Theta \cong 2L I_p / m d_p \quad [5]$$

The wafer warpage of a wafer diameter D is calculated from simple geometry as

$$h = 2R \times \sin^2[(2\Theta)/4] \cong D^2 / 8R \quad [6]$$

For $m = 2.3$, $n = 2.8$, $D = 82$ mm, $I = 49$ mm (obtained from a flat mirror), and $L = 3175$ mm, Eq. [4]-[6] reduce to

$$2\Theta = 91.6 d_p \text{ (seconds)} \quad [7]$$

$$R = 135 / d_p \text{ (meters)} \quad [8]$$

$$h = 6.21 d_p \text{ (micrometers)} \quad [9]$$

where d_p in millimeters can be measured from the difference in I_p between the sample and an optically flat mirror.

The sense of warpage can be determined unambiguously. A convex surface will produce a magnified image with a dark contrast, while a concave surface will give a demagnified image with a bright contrast.

The film stress is calculated from R according to

$$\sigma_f = \pm 1/6 (t_s^2 / t_f R) E / (1 - \nu) \quad [10]$$

where $+$ and $-$ denote tensile and compressive stresses, respectively, t_s is the wafer thickness, t_f is the film thickness, E is the Young modulus of the wafer, and ν is the Poisson ratio of the wafer. For (100) Si wafers, the value of $E/(1 - \nu)$ is 1.85×10^{12} dyn/cm² (6).

The results of the optical imaging method were compared with those obtained by both the x-ray method and the optical interference method. In the x-ray method, the angle of bending was measured from the difference in the Bragg angle between two reference points (6). Both transmission and reflection arrangements were used. In the transmission arrangement, the difference in the (220) Bragg angle between two points at a spacing of 50 mm was measured through an x-ray topographic camera using MoK α radiation. In the reflection arrangements, the (444) Bragg angles at a spacing of 20 mm were mea-

Fig. 2. The principle of the optical imaging method

sured by the Bond technique (10) using CuK α radiation. The reflection x-ray method is more sensitive to lattice distortion in the surface layer, while the transmission method is more sensitive to internal lattice distortion. The application of the optical interference method for film-stress measurements has been described by Irene (7).

Results

Si₃N₄ film stress.—Figure 3a shows the optical imaging photograph of an 82 mm wafer covered with 4000Å plasma Si₃N₄ on the front side. Measurements of the spacing between nine lines indicate that the I'_p is 60 mm. The reference spacing I_p is 49 mm. Therefore, the image distortion is +11 mm. The positive sense of the image distortion indicates that the curvature of warpage is convex. This implies that the plasma Si₃N₄ film is under a compressive stress and that the substrate at the Si₃N₄/substrate interface is under a tensile stress.

The film stress of as-deposited plasma Si₃N₄, as measured by the optical imaging method, the optical interference method, and the x-ray method, is plotted as a function of film thickness in Fig. 4. Note that the optical imaging method and the optical interference method yield almost identical profiles. The film stress increases gradually as the film thickness increases. The agreement obtained by these two methods is within 30%. On the other hand, transmission x-ray measurements yield a completely different profile. The film stress decreases as the film thickness increases. The discrepancy between the transmission x-ray method and the other two methods is substantial, especially at low values of film thickness.

We further investigated the effect of thermal annealing on the film stress. The annealing is carried out at 1000°C in H₂ for 15 min. As shown in Fig. 3b, the curvature of the substrate reverses from convex in the as-deposited state to concave after annealing. This results in a tensile stress in the plasma Si₃N₄ film. The tensile stress probably arises from a densification of the plasma Si₃N₄ during annealing. As a result of densification, holes and cracks are generated in the wafers deposited with 0.2 and 0.4 μm thick plasma Si₃N₄ films. The film stresses measured by the optical imaging method and the transmission x-ray method are shown in Fig. 4. Again, both methods show substantial discrepancies.

The film stress for LPCVD and APCVD Si₃N₄ films is also measured by the optical imaging method. The film stress is $(15.8 \pm 6.0) \times 10^9$ dyn/cm² for LPCVD Si₃N₄ and $(10.2 \pm 3.0) \times 10^9$ dyn/cm² for APCVD Si₃N₄. Both films are in tension. The value of the film stresses is in good agreement with that obtained by the optical interference method (7) and by the Newton-ring method (2).

Process-induced warpage.—Wafer warpage induced by hot processings can be easily monitored through this technique. Figure 5a shows a severely convex wafer, while Fig. 5b shows a severely concave wafer induced by MOS processings. The convex wafer exhibits a magnified image with a dark contrast, while the concave wafer exhibits a demagnified image with a bright contrast. The process-induced warpage in general has a nonuniform curvature across the wafer. This can be seen from the variation in line spacings. In some cases, the shape of warpage is very complex. The advantage of this optical imaging method is that the shape of warpage can be immediately visualized.

The elastic and plastic deformations in a warped wafer can be measured by successive removal of surface thin films. For example, these MOS-processed wafers are covered with 5000Å thermal oxide and 1.5 mm Al dots on the front side and with 1 μm Al contact film on the back side. As shown in Fig. 6, removal of Al film and dots has negligible change in image distortion, thus indicating negligible Al film stresses. However, removal of thermal oxide shows a decrease of d_p in convex wafers or an increase of

d_p in concave wafers. The value of d_p is very consistent, even though two of these wafers, shown in Fig. 5, are severely warped. The average of d_p is 2.25 ± 0.22 mm. From Eq. [10], the SiO_2 film stress is calculated as $(2.23 \pm 0.21) \times 10^9$ dyn/cm² in compression. The film stress is in good agreement with published values of $2 \sim 3 \times 10^9$ dyn/cm² (1, 3, 5). The results of transmission x-ray measurements as shown in Fig. 6 are less consistent, and the SiO_2 film stress so obtained is $(1.30 \pm 0.78) \times 10^9$ dyn/cm² with a standard deviation of more than 50%. After removal of elastic film stresses, the residual warpage due to plastic deformation is obtained. It is given in Fig. 6.

Damage-induced warpage.—As will be shown later, mechanical damage in a wafer back side tends to generate a concave front surface. Various degrees of mechanical damage were introduced in the wafer back sides. Subsequently, the bending in the front surface was measured by both the optical imaging method and the reflection x-ray method using the Bond technique (10). The degree of bendings 2θ , at a spacing of 60 mm, is shown in Fig. 7. Figure 7 shows that the agreement between these two methods is very good for $2\theta > 500''$. The agreement becomes relatively poor for small bending. The bending obtained by the optical imaging methods tends to be higher than that obtained by the x-ray method. For 2θ between $100''$ and $500''$, the agreement is within 20%. At the detection limit of the optical imaging method (about $46''$), the disagreement increases to 50%.

Surface irregularity.—In addition to stress and warpage measurements, the optical imaging method is very sensitive in detecting irregularities on a wafer surface. For investigation of surface irregularity, the square grid in Fig. 1 is removed in order to improve the image resolution.

Figure 8a shows the front surface of an 82 mm wafer. Three irregularities are noticed. First, residual saw marks run nearly vertically across the wafer. Second, a bright spot at the left corner results from laser-scribed serial numbers on the wafer front surface. Third, bright letters and numbers, A, B, C, 1, 2, and 3, result from hand-scribed letters and numbers on the wafer back surface. The bright and dark contrast of the saw marks corresponds to the valleys and ridges, respectively. The valleys are locally concave surfaces, which gives stronger intensity in the reflected light. The ridges are locally convex surfaces, which give weaker intensity. For the same reason, the brightness of laser-scribed serial numbers and hand-scribed letters and numbers indicates that they are

Fig. 4. Film stress of as-deposited and annealed plasma Si_3N_4 as measured by the optical imaging method, the transmission x-ray method, and the optical interference method.

Fig. 5. Optical imaging photographs of severely warped wafers induced by MOS processing. a: Convex surface. b: Concave surface

surface depressions. It is interesting to note that the serial numbers are laser scribed on the wafer front surface, while the letters and numbers are hand scribed on the wafer back surface. The same bright contrast obtained from two opposite surfaces indicates that laser scribing and hand scribing produce stresses of opposite sense in the wafer. Laser scribing generates a compressive stress due to surface contraction and causes a locally concave surface. Hand scribing generates a tensile stress due to surface tension and causes a locally convex surface.

This is further confirmed by examining the back side of the wafer, as shown in Fig. 8b. Figure 8b shows that the contrast of the laser-scribed serial numbers and the hand-scribed letters becomes dark, in contrast to the bright contrast observed on the front side, Fig. 8a. The dark contrast indicates a locally convex surface. The size of the dark contrast area resulting from a convex surface is larger than that of the bright contrast area obtained from a concave surface. This is evident by comparing the size

of laser-scribed serial numbers in Fig. 8a and 8b. These results indicate again that the sense of the stresses introduced by laser scribing and hand scribing are opposite. Laser scribing generates a compressive stress, and the hand scribing generates a tensile stress. When the stresses are large enough, they propagate to the opposite side of the wafer and result in local bending of opposite sense. This method unambiguously displays this effect.

In order to appreciate the sensitivity of this method, two surface profiles, 1 and 2 in Fig. 8a, are measured by a Sloan surface profile unit. Profile 1 measures the profile of saw marks only. Profile 1, Fig. 8c, shows that the height of saw marks varies from 100 to 350Å. The variation of the height correlates with the contrast in Fig. 8a. The valley corresponds to the bright contrast area, and the ridge corresponds to the dark contrast area. In addition to the saw marks, profile 2 intersects once the bottom of letter B and three times the number 2. The intersections at the number 2 clearly give three dips, as indicated by the arrows in Fig. 8c. The depth of the dips is about 50-100Å. The dip is consistent with the bright contrast of a locally concave surface introduced by hand scribing on the wafer back side.

This method is extremely valuable in the evaluation of the surface quality of chem-mech polished wafers. Wafers

obtained from different vendors usually show different characteristics in surface finish.

Discussion

This optical imaging method uses the image distortion of a reflected beam from a warped surface as a means to detect surface irregularities and wafer warpage. This allows one to examine surface irregularities and wafer warpage simultaneously. The technique can be used as a tool for quality control. Several examples for the measurement of surface irregularities, process-induced warpage, and thin film-induced warpage have been given.

The sensitivity of this method, as indicated in Eq. [2], depends on L . For the present setup, $L = 3175$ mm, and with a measurable d_p of 0.5 mm, the detection limit is 270m for R , 45.8" of arc for 2θ , and $3.1 \mu\text{m}$ of warpage h for 82 mm wafers. This sensitivity is sufficient for most practical purposes. The detection limit can be improved through the use of more sophisticated optics or simply by the increase of L . For examination of extremely rough surfaces and severely warped wafers, the sensitivity should be decreased by decreasing L . This approach can also be used to examine saw masks after slicing.

Measurements of plasma Si_3N_4 film stresses indicate that the agreement between the optical imaging method and the optical interference method is within 30%. This agreement is considered to be good in consideration of the errors involved in these two methods. For example, the optical interference method has a relatively poor accuracy for highly warped wafers, while the accuracy for the optical imaging method is relatively poor for low warpage.

A comparison of the optical imaging method with the reflection x-ray method (Bond's technique) also shows a reasonable agreement of 20% for a wafer bending larger than 100". However, the agreement between the optical imaging method and the transmission x-ray method is poor, especially at low film stresses. The poor agreement arises probably from a difference in the principle of measurements. The optical imaging method and the optical interference method use the curvature of a wafer surface for warpage measurements. The reflection x-ray method measures the lattice distortion in a surface layer. These three methods are more sensitive to the curvature change and the lattice distortion in a wafer surface. As a result, a reasonable agreement among these three methods is observed.

On the other hand, the transmission x-ray method, which uses a transmission diffracted beam for the warp-

age measurements, is sensitive not only to external film stresses, but also to internal lattice distortion. At low film stresses, the contribution of internal lattice distortion is significant in comparison with film stresses. This results in a substantial disagreement between the optical imaging method and the transmission x-ray method.

Summary

A simple optical imaging method was developed for quick evaluation of wafer surface quality and warpage. Surface irregularities of 50-100Å can be detected by this method. The detection limit for the radius of curvature is about 270m. The agreement between this method and the optical interference method is within 30%. A comparison of this method with the reflection x-ray method also shows a reasonable agreement of 20%. A substantial discrepancy exists between this method and the transmission x-ray method. The discrepancy arises mainly from the fact that the transmission x-ray method is also sensitive to internal lattice distortion. The film stress obtained by this method is $(2.23 \pm 0.21) \times 10^9$ dyn/cm² in compression for thermal SiO_2 , $(15.8 \pm 6.0) \times 10^9$ dyn/cm² in tension for LPCVD Si_3N_4 , and $(10.2 \pm 3.0) \times 10^9$ dyn/cm² in tension for APCVD Si_3N_4 .

Dry Etch-Back of Overthick PSG Films for Step-Coverage Improvement

J. S. Mercier,* H. M. Naguib,*¹ V. Q. Ho, and H. Nentwich

Northern Telecom Electronics Limited, Semiconductor Components Group, Ottawa, Ontario, Canada K1Y 4H7

ABSTRACT

In this article, we present the results of a study initiated to improve the step coverage of phosphosilicate glass (PSG) obtained with a low temperature LPCVD process and intended for use in VLSI multilevel interconnect structures. It is shown that increasing the PSG film thickness leads to a substantial improvement in the PSG step-coverage profile, but could create problems for subsequent patterning steps. We have alleviated these problems through the use of dry etching to reduce the thickness of these films to values more compatible with VLSI multilevel interconnect technology, while successfully maintaining the superior step-coverage profile obtained with the thicker PSG films.

A very important requirement of interlayer dielectric films in multilevel interconnect structures is smooth and conformal coverage of the underlying topography (1-9). For the intermetal dielectric level, the need for compatibility with an underlying aluminum alloy interconnect also precludes any high temperature treatments. The dry etching techniques required for the fine line lithography of VLSI chips produce features that can be much sharper than the wet etching methods used in LSI technology. As a consequence, with currently available dielectric deposition techniques, it has become very difficult to obtain satisfactory as-deposited coverage over these sharp features, thereby leading to poor overlying metallization. To overcome this difficulty, work was initiated in our laboratory to investigate methods of improving the step-coverage characteristics of phosphosilicate glass (PSG) films obtained using low temperature oxidation of silane and phosphine in a low pressure chemical vapor deposition (LPCVD) system.

Preliminary experiments included varying the deposition parameters and increasing the ratio of PSG film thickness (t) to underlying step height (h) (9). It was found that variations of the deposition conditions, within the parameter ranges investigated, did not result in any appreciable step-coverage improvement, while a significant improvement could be obtained by increasing the ratio of t/h . In the present study, the deposition of overthick PSG films is followed by a dry etch-back cycle to reduce the glass film thickness to values compatible with VLSI multilevel interconnect technology, while preserving the superior step-coverage profile obtained with the thicker PSG films.

Experimental Procedure

The test structure used for step-coverage evaluation is shown schematically in Fig. 1. A thin (100 nm) silicon dioxide layer was first thermally grown at 1000°C over a (100) Si substrate. An LPCVD polysilicon film was then deposited at 625°C, phosphorus doped with a POCl_3 cycle at 900°C, and patterned into sharp steps using plasma etching.

The PSG films were deposited in a conventional horizontal tube, hot-wall, LPCVD system using the following typical hydride oxidation conditions: gas flow ratios of 6/5 for O_2/SiH_4 and 1/10 for PH_3/SiH_4 , total gas flow rate of 335 sccm, deposition temperature of 410°C, and pressure of 0.4 torr. These conditions resulted in a deposition rate of 26 nm/min and a nominal phosphorus concentration in the PSG films of 4 weight percent (w/o).

A layer of Al-Si alloy was sputtered over the PSG films to evaluate the effect of the PSG film step coverage on subsequent metallization. The deposition was performed in an MRC DC-Magnetron sputtering system (Model 603), using a double-pass procedure under the following condi-

tions: target composition of Al-(1%)Si, Ar pressure of 0.01 torr, power of 8 kW, wafer preheat temperature of 300°C, and dc bias voltage of 50V. The deposition rate was approximately 700 nm/min.

Scanning electron microscopy (SEM) was used to examine the step-coverage profile of all test samples. The SEM cross-sectional micrographs were taken near the center of the cleaved wafers. The polysilicon-PSG interface was delineated with a $\text{CF}_4\text{-O}_2$ plasma etch of the cross section. Figure 2 shows an SEM micrograph of a 1.1 μm thick PSG film deposited over a 0.9 μm high polysilicon step having a step angle $\psi = 70^\circ$, for a t/h ratio of approximately 1.2. A 1.2 μm Al-Si layer was sputtered over the PSG film. In this case, the PSG step-coverage profile is characterized by an acute reentrant angle θ of about 75° and a sidewall thickness ratio t_{sw}/t of approximately 0.75. Such a difficult topography resulted in even poorer step coverage of the Al-Si metallization, as shown in Fig. 2, where the metal step-coverage angle ϕ is approximately 70° and its sidewall thickness ratio T_{sw}/T is about 0.2. In the present study, we have used the PSG profile of this control sample as a reference for comparison with later experimental results to determine step-coverage improvement.

Reactive ion etching (RIE) of the overthick PSG films was performed in an AMT 8110 system which uses a hexagonal cathode configuration. Typical RIE conditions were as follows: gas flow ratio of 5/3 for CHF_3/O_2 , total gas flow rate of 83 sccm, pressure of 0.05 torr, and discharge power of 1350W. These conditions yielded an etch rate of approximately 50 nm/min. The amount of PSG removed was determined with laser interferometry.

Plasma etching was also tested in a Perkin-Elmer Omni-Etch system. The etching conditions were as follows: gas flow ratios of 2/1 for CF_4/CHF_3 and 5/1 for $\text{Ar}/(\text{CF}_4 + \text{CHF}_3)$, total gas flow rate of 364 sccm, pressure of 1.8 torr, and discharge power of 255W. An etch rate of approximately 12.5 nm/s was obtained under these conditions. This value was used to calculate the duration of the etch cycle for control of the amount of PSG removed.

Results and Discussion

Effect of film thickness.—In the first series of experiments, PSG films ranging in thickness from 0.6 to 2.3 μm were deposited over polysilicon steps with height varying from 0.3 to 1.2 μm , and the ratio of t/h was varied from 0.6 to 4.7. The results are shown in Fig. 3, where the dependence on the ratio of t/h for the PSG step-coverage angle θ and the sidewall thickness ratio of t_{sw}/t are plotted.

The scatter of the results in these graphs can be attributed partly to our measurement accuracy for θ , which is $\pm 5^\circ$. Furthermore, the angle ψ at the bottom of the polysilicon steps defined in Fig. 1 varied from 65° to 75° and has been modeled to have a direct influence on the PSG step-coverage angle θ (10). Finally, in most cases, the corners at the bottom and at the top of the polysilicon steps were quite sharp. Indeed, the top corners of most of the steps were actually acute, displaying a "dog-ear" feature. The radius of curvature of these corners, although quite small, could not be controlled very well and may have had an influence on the reproducibility of our results. Modeling of small variations in these radii of curvature has shown that they are likely to be amplified by subsequent PSG film deposition (11).

Despite the sources of variation discussed above for our results, a definite trend emerges from the plots in Fig. 3,

namely, that significant improvement in PSG step coverage results from an increase in the ratio of t/h . This can be clearly seen in the micrograph of Fig. 5a, where the step angle ψ is about 67° and the ratio of t/h has a value of approximately 3.0. The angles θ (PSG) and ϕ (Al-Si) have both increased to more than 125° , as compared to a value of about 75° for θ and 70° for ϕ , for $t/h \approx 1.2$ (Fig. 2). Also, the sidewall thickness ratio of t_{sw}/t (PSG) has increased from approximately 0.75 to almost 0.95, while the sidewall thickness ratio of T_{sw}/T (Al-Si) went from about 0.2 to more than 0.75, a substantial improvement.

It should be pointed out that a test structure step angle ψ of approximately 70° does not constitute the worst-case topography that an angle ψ close to 90° would offer to the deposition of glass films. Nevertheless, it can represent a realistic situation for VLSI applications, since tapered etching techniques are being actively developed in many laboratories.

Various studies involving atmospheric pressure chemical vapor deposition (APCVD) reported that the PSG film coverage exhibited a more pronounced reentrant profile (*i.e.*, a decrease in θ) with an increase of t/h (1, 3, 4, 12-14). In other APCVD studies (5, 7), the step-coverage angle θ was reported to increase up to 90° as t/h was increased to unity, but remained at 90° when t/h was increased further.

For LPCVD, an improvement in step coverage with an increase in t/h was observed for the pyrolysis of tetraethyl orthosilicate (TEOS) (1). This improvement has been attributed to the inherent conformality of the TEOS process which minimizes the self-shadowing effect that initiates a reentrant profile in other processes. In effect, good initial step coverage should get better, while poor initial step coverage should get worse.

Since the initial step coverage obtained in our experiments was not conformal, but improved with an increase in the ratio of t/h , this explanation does not apply to our results. Therefore, further work is required to understand the mechanisms involved in the improvement of step coverage obtained with increasing the thickness of PSG films produced with low temperature LPCVD.

This film growth from a diffuse deposition source has recently been modeled by Ross and Vossen (10). In addition to the effect of the ratio of t/h on the sidewall thickness ratio t_{sw}/t , the influence of the underlying step angle ψ has been taken into account. The impact of the proximity of closely spaced steps, represented by the ratio of the spacing between steps w to the step height h , was also in-

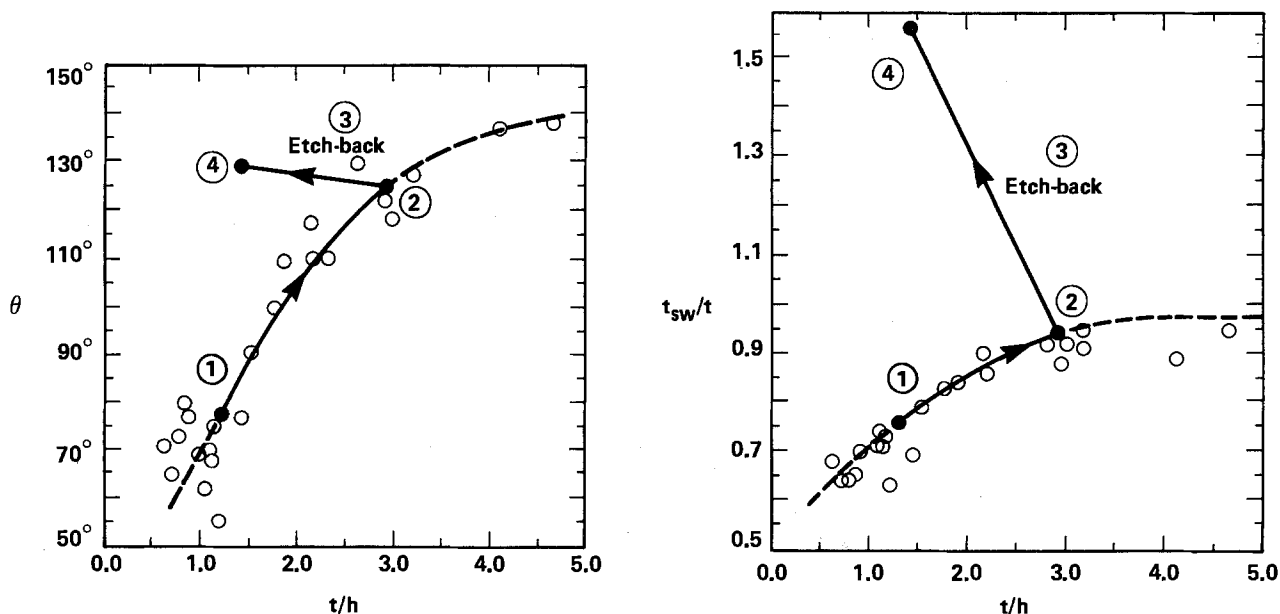

Fig. 3. Effect of ratio of PSG film thickness t over underlying step height h on step-coverage angle θ , (a, left), and sidewall thickness ratio of t_{sw} over t , (b, right). The underlying step angle ψ varied between 65° and 75° . Points 1-4 correspond to the process steps explained in the diagram of Fig. 4.

corporated in the model. In effect, the step-coverage test structure used in Ref. (10) is a groove of width w and of depth h . The overlap with our experimental results is minimal, since the highest value considered in their calculations for t/h is unity. Nevertheless, for isolated steps and for all values of the step angle ψ considered, one of their findings was that the sidewall thickness ratio t_{sw}/t becomes independent of t/h , for $t/h \leq 1$. Our experimental findings, shown in Fig. 3b, appear to contradict these theoretical results. Furthermore, for $t/h = 1$, $\psi = 75^\circ$, and $w/h \rightarrow \infty$, the value calculated in Ref. (10) for t_{sw}/t is below 0.5, while our experimental results for $\psi \approx 65^\circ\text{--}75^\circ$ are grouped around 0.7, as shown in Fig. 3b. More theoretical work is therefore required to resolve these discrepancies.

A conclusion of this theoretical study indicates the possibility that unacceptable step coverage would be obtained for narrow, deep and vertical trenches (*i.e.*, small values of w/h and ψ close to 90°). This conclusion can also be reached intuitively from geometrical shadowing considerations. As the glass films on opposing vertical sides of each groove get closer and closer, it becomes increasingly difficult for a fresh supply of reactant gases to reach the bottom of the trench and this results in a lower local deposition rate. Furthermore, opposing vertical PSG walls will eventually touch and at that point, the glass step-coverage angle Θ must be at least 90° because the top part will touch before the bottom part and a triangular void will be formed (1).

For $\Theta > 90^\circ$, a minimum value of $t/h \approx 1.5$ can be derived from Fig. 3a and a corresponding value of $t_{sw}/t \approx 0.8$ is obtained from Fig. 3b. For this case, the vertical glass film has a uniform thickness equal to t_{sw} and the minimum step separation w is equal to $2t_{sw}$. After the proper substitutions, a minimum value of approximately 2.5 is derived for the step spacing ratio w/h .

It must be noted that, since the results of Fig. 3a and 3b are for isolated steps ($w/h \approx 10$), the shadowing effect of a neighboring step is not taken into account in the above deduction although it is not expected to be dominant for $w/h \approx 2.5$. The specific minimum value for w/h would, of course, increase with the underlying step angle ψ .

Etch-back of overthick PSG films.—The use of overthick PSG films may present problems in subsequent patterning steps for VLSI multilevel interconnection structures, especially if sloped-wall vias are to be dry etched through the glass layer. Accordingly, in a second series of experiments, we explored the use of dry etching techniques to reduce the ratio of t/h to a value more suitable for VLSI processing. This concept of anisotropic etch-back of overthick PSG films is illustrated in the diagram of Fig. 4, where the step-coverage profile of an as-deposited PSG film with t/h near unity is also shown for

Fig. 4. Dry etch-back of overthick PSG film. 1: Thin as-deposited film. 2: Thick as-deposited film. 3: Dry etch-back. 4: Final etched-back film.

comparison purposes. The micrographs of Fig. 5 show the cross section of a $2.1 \mu\text{m}$ thick PSG film, as deposited over a $0.7 \mu\text{m}$ step ($\psi \approx 67^\circ$) and after an etch-back cycle, using RIE, down to a thickness of about $1.0 \mu\text{m}$ ($\psi \approx 75^\circ$). Similar results were obtained with plasma etching.

The superior step-coverage profile obtained with the thick as-deposited PSG film was clearly conserved during the etch-back cycle. As t/h decreased from approximately 3.0 down to 1.4, the step-coverage angle Θ (PSG) actually increased slightly from 125° to almost 130° , while the step-coverage angle ϕ (Al-Si) remained close to 125° . The changes in Θ during the etch-back procedure are illustrated in the graph of Fig. 3a (closed circles). The etch-back cycle also resulted in rounding of the bottom of the PSG step-coverage profile. Furthermore, Fig. 3b shows that the sidewall thickness ratio of t_{sw}/t (PSG) increased from less than 0.95 to almost 1.6 during the etch-back cycle, while the sidewall thickness ratio of T_{sw}/T (Al-Si) remained close to 0.75. It should be noted that the above improvements were observed despite the fact that the step angle ψ was larger under the etched-back film (75°) than under the overthick film (67°).

An attractive feature of the etch-back method, aside from its being a low temperature technique, lies in its simplicity as compared to more elaborate step-coverage

Fig. 5. SEM micrograph showing the step coverage of an overthick PSG film before ($t/h \approx 3.0$), (a, left), and after ($t/h \approx 1.4$) the etch-back procedure, (b, right). An Al-Si layer has been sputtered on both PSG films.

improvement schemes reported elsewhere (15-20). The etch-back technique does not need sacrificial planarization layers, such as resists (15, 16) or silicon nitride (17, 18), where precise characterization and control of differential etch rates are essential. It is very simple compared to complicated lift-off procedures where low temperature directional deposition processes, such as electron cyclotron resonance plasma deposition, are needed to obtain a suitable SiO₂ layer (19). In other methods, RF-bias sputtering is used in a complex technique involving simultaneous deposition and resputtering of SiO₂ to obtain self-planarized as-deposited films (20). Indeed, for the etch-back procedure described in this work, deposition and dry etching equipment readily available in most production lines can be used directly, with minimal optimization needed.

However, the creation of triangular voids during the deposition of overthick PSG films over closely spaced steps would limit the applicability of the etch-back method to cases where the step separation ratio w/h is sufficiently large. In our case (*i.e.*, $\psi = 70^\circ$), if we apply the criterion derived above ($w/h \geq 2.5$), 0.8 μm thick interconnect lines could not be closer than about 2.0 μm . Since for more vertical steps (*i.e.*, $\psi \approx 90^\circ$) this minimum required separation would be even larger, some taper etching of the underlying steps would be needed.

Conclusion

This study demonstrates the feasibility of a procedure designed to improve the step coverage of LPCVD phosphosilicate glass films over sharp, dry-etched steps. A dry etching technique was successfully applied to overthick PSG films to reduce the ratio of the PSG film thickness to underlying step height towards unity while preserving the superior step-coverage profile obtained with the thicker PSG films. The low temperature feature of this method makes it compatible over aluminum alloy interconnections in multilevel metallization structures. However, in this experiment, the applicability of the procedure over closely spaced vertical steps appears to be limited to step separation over step height ratios (w/t) larger than approximately 2.5.

Preparation and Characterization of Boron- and Phosphorus-Doped Hydrogenated Amorphous Silicon Nitride Films

Y. K. Fang, C. F. Huang, C. Y. Chang,* and R. H. Lee

Semiconductor and System Laboratories, National Cheng Kung University, Tainan, Taiwan, China

ABSTRACT

Hydrogenated amorphous silicon nitride (a-SiN) films were deposited on silicon wafers by plasma-enhanced chemical vapor deposition and *in situ* doped with boron or phosphorus. Film properties, including both wet and dry etching rate, refractive index, dielectric constant, breakdown strength, dc resistivity, and pinhole density vs. doping percentage were systematically investigated and compared with the undoped films. It has been found that the films with doping concentrations around 2-3% exhibit the best film quality, which drastically deteriorate when the doping concentrations are beyond 6%.

Plasma-enhanced chemically vapor-deposited hydrogenated amorphous silicon nitride SiN films are useful for semiconductor passivation and for diffusion or oxida-

tion barriers (1-7). However, plasma-deposited SiN films are extremely sensitive to the deposition conditions, including the reactant gas composition, RF power, substrate temperature, gas flow rate, and reactor pressure (6, 7).

* Electrochemical Society Active Member.

Efforts have been made to investigate the relationship between deposition conditions and the properties of these films, and it has been found a SiN film with lower chemical etch rate and higher optical refractive index can be obtained by tailoring the process conditions (6, 8). Nevertheless, in real fabrication process, due to diffusion or auto-doping, the SiN films may be incorporated with the dopant impurities (*i.e.*, P or B) and change the properties.

Little research about this phenomenon has been reported. In 1976, Bind and Bigger reported that suitable addition of impurities (*i.e.*, boron carbide, boron, or alumina) can make the silicon carbide more dense and resistive. It is the purpose of this study to investigate the change of doped SiN film properties as a function of dopant impurities (*i.e.*, P or B) with various doping concentrations. The properties include etch rate in 49% HF, buffered HF, 180°C H₃PO₄, and CF₄ + O₂ plasma, dc resistivity, dielectric breakdown strength, pinhole density, dielectric constant, and deposition rate. The chemical composition and doping traces in SiN film were examined by Auger electron spectroscopy and infrared (IR) spectroscopy.

Film Preparation

The samples used in this study were prepared by RF glow discharge both silane gas and doping gas on silicon wafers with an Anelva PECVD 301 plasma CVD system. The stainless steel reaction chamber of the system possesses one pair of capacitive electrodes, which can create the RF glow-discharged plasma by a 13.56 MHz RF high voltage power supply. Also, the chamber contains a rotary susceptor equipped heating elements.

First, the (100)-oriented, 4-7 Ω-cm n-type silicon wafers were cleaned sequentially by acetone, deionized (DI) water, H₂SO₄/H₂O mixture, and HNO₃ solutions, then rinsed thoroughly in DI water and blown dry with nitrogen (N₂) gas. After the cleaning process was completed, the wafers were placed on the susceptor and we began to pump down the chamber. At the same time, the substrate was heated up to 350°C.

When the total pressure in the chamber was pumped down to 1.33×10^3 Pa (10 torr), diluted silane (25% SiH₄ + 75% N₂), ammonia (NH₃), and diluted diborane (1% B₂H₆ + 99% N₂) or phosphine (1% PH₃ + 99% N₂) were introduced into the chamber and adjusted the valves of the system to obtain a 133 Pa (1 torr) reaction pressure in chamber.

During the deposition of SiN films, the flow rates of diluted SiH₄ and NH₃ were kept at 60 and 20 sccm, respectively, and those of B₂H₆ and PH₃ were varied from 15 to 100 sccm, according to the doping percentage desired.

The RF power was kept at 150W (which is a power density of about 4.34 kW/m²). The cathode voltage was kept at 2.6 kV.

Film Analysis

To identify the quantities of doping impurities P or B in the doped SiN films, the Auger spectroscopy (AES) was employed. Infrared (IR) spectroscopy was used to examine the structure of doped SiN films.

Auger analysis.—From the Auger spectrum (with Anelva AAS-200 Auger Spectroscopy) of phosphorus- or boron-doped SiN films, the films were found to contain Si, N, O, C, B, or P. The existence of boron or phosphorus identifies the effectiveness of the doping processes, and their related peak amplitudes were used to calculate the individual doping concentration in the films. However, the doping concentrations of P or B are dependent on the PH₃ or B₂H₆ flow rate during film deposition and will be discussed in the next section. The presence of oxygen and carbon may be due to the residues from cleaning process or surface contamination during exposure to the air.

IR analysis.—IR spectroscopy gives information on the type and nature of the chemical bonds.

To prepare for IR analyzing, the SiN films were deposited on 1000 Ω-cm, (100)-oriented silicon wafers. The higher intrinsic property of silicon eliminates auto-doping

Fig. 1. The measured deposition rate of phosphorus- or boron-doped plasma-deposited silicon nitride films as a function of doping concentration in weight percent.

effect. The IR spectrum shows N-H absorption at 3300 cm⁻¹, a Si-H bond at 2100 cm⁻¹, a Si-O bond at 1120 cm⁻¹, and a Si-N bond at 870 cm⁻¹. The N-H bond at 3300 cm⁻¹, Si-H bond at 2100 cm⁻¹, and Si-N bond at 870 cm⁻¹ show

Fig. 2. The measured etch rate of phosphorus- or boron-doped SiN films by various etching solutions or methods as a function of doping concentration in weight percent. The black dots indicate the B-doped films, and the blank dots P-doped films. The circles, triangles, squares, and hexagles indicate the etching by BHF, H₃PO₄, 49% HF, and CF₄ + O₂, respectively.

the structure of doped SiN, which is the same as the undoped one. The Si-O bond at 1120 cm^{-1} indicates the incorporation of O and coincides with the results from the AES analysis.

Deposition Rate vs. Doping Concentration

Deposition rate vs. doping concentration is shown in Fig. 1. For undoped films, the deposition rate is around 15 nm/min . However, it decreases with increasing boron or phosphorus concentration to a minimum around 3% doping and then increases again to 5% doping. The lower deposition rate at 3% doping concentrations causes the more dense SiN film with better bonding scheme, as seen from the higher dielectric constant and lower etch rate of films with 3% P- or B-doped as presented in the following sections. The reason why 3% B- or P-doped SiN films get lower deposition rate is not clear. More studies should be made in the future.

Chemical Etching Properties

Various kinds of etching solutions, including wet etching in 180°C of H_3PO_4 , 49% HF, buffer HF(BHF), and 96% $\text{CF}_4 + 4\% \text{O}_2$ plasma dry etching are used to investigate the etching rate of doped SiN films. Figure 2 shows the results. It is interesting to note that the 2-3% B- or P-doped SiN films possess the lowest etching rate in these various etching solutions, except the etching rate of films in 49% HF solution is higher and lower in BHF and H_3PO_4 solutions, respectively. For dry etching in 96% $\text{CF}_4 + 4\% \text{O}_2$ plasma (with Plasmaline Plasma Etcher) as indicated with hexangular dots in Fig. 2, the tendency is also similar to the previous wet etchings, i.e., in both P- or B-doped SiN films, the etch rate decreased to a minimum at 2 or 3% doping concentration (2% for B-doped, 3% for P-doped) and then increased again with increasing doping concentration. However, in general, the etching rate of doped films with dry etching is higher than the wet etching, except in the case of the 2% B-doped or 3% P-doped films, where the etching rate of 49% HF wet etching is larger than that of the dry etching.

Electrical Properties

The effect of doping P or B on the electrical properties of plasma-deposited nitride films could be found from

Fig. 3. The measured resistivities of P- or B-doped SiN as a function of doping concentration in weight percent.

the change of resistivity, breakdown field strength, and dielectric constant of the doped SiN film as a function of doping concentrations, as described below.

Resistivity vs. doping concentration.—The doped films were measured with a six-point probe (Four-Dimension, Incorporated). As shown in Fig. 3, the resistivities of both P- and B-doped films increase to a maximum of $6 \times 10^{10}\ \Omega\text{-cm}$ at 3%P doped or 5%B doped, then decrease with increasing the doping concentration. In this measurement, it is noteworthy that both the P- and B-doped SiN films possess higher resistivities than the undoped ones. This is a positive performance for these films used as passivation layer of devices.

Breakdown field strength vs. doping concentration.—A Tektronix 577 curve tracer was applied for evaluation of the breakdown field strength of both P- and B-doped films by measuring the breakdown voltage of Al-SiN-Si MIS diodes.

Figure 4 shows the breakdown field strength as a function of doping concentration. The tendency is also similar to that of resistivity. The maximum breakdown field strengths are $9 \times 10^5\ \text{V/cm}$ and $8 \times 10^5\ \text{V/cm}$ for 2-3% phosphorus and boron doped, respectively. The maximum field strength of doped films is almost 2-3 times larger than that of undoped ones.

Dielectric constant vs. doping.—With measuring the capacitance of Al-SiN-Si MIS diodes biased with reverse constant voltage, the dielectric constant of SiN film was calculated, as shown in Fig. 5. Again, the dielectric constant increases to a maximum at a doping concentration of 2-3% both for P and B and then decreases with further increasing the doping. The maximum dielectric constant value for the P-doped film is 8.3, whereas it is 7.6 for the B-doped one.

Pinhole Density

The pinhole density of doped SiN was measured by the copper decoration method (10). The samples were inserted into copper plating solution first, and then the silicon substrate was plated with copper through the pinhole. The pinhole density is calculated with the aid of microscopy. Figure 6 shows the measured results.

Fig. 4. The measured breakdown field strength of P- or B-doped SiN films as function of doping concentration in weight percent.

Fig. 5. The measured dielectric constant of P- or B-doped SiN films as a function of doping concentration in weight percent.

For phosphorus-doped films, the lowest pinhole density was found at 2% doping. For boron-doped ones, it occurred beyond 5% doping. The thickness of these SiN films is around 100 nm.

Discussion and Conclusions

In general, the resistivity, dielectric constant, and breakdown field strength of both P- and B-doped film increase to a maximum value at 2-3% of doping, and then decrease with increasing doping concentration. The deposition rate, pinhole density, and etching rate show an opposite tendency.

These results show that film quality is enhanced with P or B doping of 2-3%, but deteriorates for higher doping. The cause of enhancement is considered to be the correct slow growth rate in deposition of 2-3% P- or B-doped films. The slower growth rate provides a better bond scheme of the film and thus higher film quality. However, the mechanism of lower growth rate in deposition of these P- or B-doped films is still not clear. More experiments are required to understand this doping effect and

Fig. 6. The measured pinhole density of P- or B-doped SiN films as a function of doping concentration in weight percent.

the application of these doped films, e.g., passivation, diffusion, or impurity barriers in device fabrication.

Sulfidation Properties of Fe-Al Alloys (6-28 a/o Al) at 1173 K in Sulfur Vapor at $P_{S_2} = 1.45 \times 10^{-3}$ Pa

P. C. Patnaik* and W. W. Smeltzer**

Institute for Materials Research and Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

Sulfidation properties of Fe-6, 9, 18, and 28 atomic percent (a/o) Al alloys were investigated at 1173 K in sulfur vapor at the dissociation pressure of FeS. The Fe-6 Al alloy exhibited internal sulfidation; the Fe-9 and 18 Al alloys exhibited internal sulfidation along with formation of an external $FeAl_2S_4$ scale. Compositions of the internal sulfide precipitates corresponded to $FeAl_2S_4$ in the Fe-6 Al alloy and to $FeAl_2S_4$ - Al_2S_3 in the alloys containing 9 and 18 a/o Al. The Fe-28 a/o Al alloy upon sulfidation only formed an Al_2S_3 external scale. The apparent permeability of sulfur in the alloy of the internal sulfidation zone as defined by $N_s^{(S)}D_s$ product increased linearly with alloy composition. Growth of the sulfide precipitates which extended as plates across the internal sulfidation zones is satisfactorily interpreted by a model involving enhanced sulfur diffusion along the interfaces between the internal sulfides and alloy matrix. Transition from internal sulfidation to internal sulfidation plus external scale formation and finally to only external scale formation based upon the alloy aluminum composition is discussed.

The sulfidation resistance of iron in sulfur as well as H_2S bearing atmospheres is improved considerably by addition of aluminum as an alloying element (1-7). The reaction kinetics of these alloys are generally complex due to growth of a multilayered scale and internal sulfidation (7). The present paper is concerned with obtaining an understanding of the sulfidation properties of Fe-Al alloys with respect to internal sulfidation and of the transition to external sulfide scale formation. Accordingly, Fe-Al alloys containing up to 28 atomic percent (a/o) Al have been sulfidized at 1173 K in sulfur vapor at the dissociation pressure of FeS (1.45×10^{-3} Pa) to prevent formation and influence of this rapid growing phase on the reaction mechanism.

Experimental

Alloys of nominal compositions 6, 9, 18, and 28 a/o Al were prepared by electric arc melting of iron (99.99% pure) and aluminum (99.98% pure) in an argon atmosphere gettered of oxygen by titanium chips. Chemical analyses for impurities in the pure metals are given in Table I. Actual compositions of these ferritic solid solution alloys were 5.8, 8.8, 18.2, and 27.8 a/o Al. The alloy ingots were annealed at 1473 K for 12h in a furnace equipped with a continuous ultrapure argon flow system. The average grain size of any alloy was usually large; it varied from 0.1 mm to about 0.8 mm. Small cylindrical plates approximately 1-3 mm thick and of 10 mm diam were prepared from the alloy ingots using silicon carbide cutting blades. These specimens were polished on all sides through a series of silicon carbide papers using water as a lubricant. Final polishing was carried out on napless cloths impregnated with 6 and 1 μm diamond paste with kerosene as the lubricant.

Sulfidation of the alloys was carried out at 1173 K in sulfur vapor set at the dissociation pressure of FeS equal to $P_{S_2} = 1.45 \times 10^{-3}$ Pa (8) by means of the reaction cell assembly shown in Fig. 1. Two alloy specimens suspended in open-ended alumina tubes by platinum wires and a pressed Fe + FeS porous compact were encased in an evacuated quartz tube. The alloys were sulfidized for periods extending up to 20 ks. Metallographic examination of the Fe + FeS compacts after sulfidation runs demonstrated that these compacts retained their porosity without any evidence of a protective iron layer.

Sulfide phases were identified by x-ray diffraction powder analyses using Ni-filtered $Cu-K\alpha$ radiation. Optical microscopy was used to study the morphology of the reaction products and to measure the depths of internal sulfidation zones. Electron probe microanalyses (EPMA) were used to determine composition profiles within the sulfidation zones.

Results

Sulfidation kinetics.—These kinetics for the alloys containing 6, 9, and 18 a/o Al were determined by measuring the depths of internal sulfidation and the sulfur uptakes. As demonstrated by the plots of these results in Fig. 2 and 3, these reaction kinetics were of parabolic type. The depths of internal sulfidation in the alloys after corresponding exposures decreased with aluminum content only up to 9 a/o Al; the alloy containing 18 a/o Al exhibited the largest penetration depth. This is also indicated by the corresponding parabolic rate constants for internal sulfidation (see Table II). A scale on the Fe-9 Al alloy was only observed at isolated small areas over the alloy surface. The scale on the Fe-18 Al alloy which sulfidized both internally and externally was continuous and grew parabolically at $8.9 \times 10^2 \mu m/s^{1/2}$. Sulfidation led only to growth of a scale on the Fe-28 Al alloy which grew at $7.2 \times 10^{-2} \mu m/s^{1/2}$.

Scale morphological development.—The internal sulfide precipitates formed in the Fe-6, 9, and 18 Al alloys were acicular in morphology, and they extended as plates across the internal sulfidation zones largely oriented normal to the alloy surface, with the exception of some alloy

grains in which they were oriented at an angle slightly less than 90° . Figure 4 illustrates these features. The advancing front of an internal sulfidation zone was quite uniform, although slight irregularities were found occasionally at the corners of the specimens. Preferential intergranular sulfidation was not observed in these alloys.

Figure 5 shows transverse sections of the internal sulfides at different depths from the surface of the alloy

containing 9 a/o Al. The sulfide platelets are oriented in several crystallographic directions. Those platelets existing deep within the internal sulfidation zone near its advancing front in this alloy contained more than one phase, one enveloping the other (Fig. 5, bottom), apparently due to conversion of Al_2S_3 into FeAl_2S_4 . The sulfide precipitates right at the internal sulfidation front were composed of only the Al_2S_3 phase.

Table II. The parabolic rate constants for internal sulfidation of Fe-Al alloys in S_2 (Fe/FeS) at 1173 K

Alloy composition	Parabolic rate constant k_p ($\mu\text{m}^2/\text{s}^{1/2}$)
Fe-6 a/o Al	7.4
Fe-9 a/o Al	5.1
Fe-18 a/o Al	8.5

In all the alloys, the platelike internal sulfide precipitates ranging from 0.5 to 2 μm thickness and 10 to 20 μm widths extended either from just below the gas/alloy interface or from the external scale/subscale interface across the internal sulfidation zone as shown in Fig. 6. As shown in Fig. 7, the spacing between sulfide platelets within the internal sulfidation zones decreased with increasing aluminum content in the alloy. Table III presents the variation of this spacing with alloy composition. These spacings are average values of measurements carried out at various depths in the internal sulfidation zone for each alloy. It was not possible by this measurement technique to distinguish any variation in spacing at various depths within the internal zone.

An external scale without any associated internal sulfidation was observed to grow on the Fe-28 Al alloy. This compact adherent scale spalled off the alloy during cooling. Its morphology is shown in Fig. 8.

Sulfide compositions and structures.—Compositions of the internal sulfide precipitates corresponded most closely to FeAl_2S_4 in the Fe-6Al alloy and $\text{FeAl}_2\text{S}_4\text{-Al}_2\text{S}_3$ platelets in the alloys containing 9 and 18 a/o Al. The FeAl_2S_4 phase appeared to be at least 80-90% of a sulfide

Fig. 6. Photomicrographs illustrating the cross section of an internal sulfidation zone near the alloy and external scale/alloy interface for (top) Fe-9 a/o Al and (bottom) Fe-18 a/o Al alloys.

platelet, based upon the metallographic observations; in particular, the Al_2S_3 precipitates were present toward the internal sulfide/alloy interface. In the case of Fe-9 and 18 Al alloys, the internal sulfidation zones of $\text{FeAl}_2\text{S}_4\text{-Al}_2\text{S}_3$ were overgrown by FeAl_2S_4 external scales. Figure 9 shows microprobe traces for iron and aluminum across the internal sulfidation zone of the Fe-9Al alloy. The alloy is depleted of aluminum near the internal sulfidation zone interface which caused a slight enrichment of aluminum in the sulfidation zone. The x-ray diffraction pattern from the internal sulfidation zone of the Fe-9Al alloy corresponding to the presence of FeAl_2S_4 is illustrated in Fig.

Table III. Intersulfide spacings for Fe-Al alloys at 1173 K in S_2 (Fe/FeS)

Alloy composition	Spacing (μm)
Fe-6 a/o Al	7.9 ± 0.5
Fe-9 a/o Al	3.8 ± 0.6
Fe-18 a/o Al	2.6 ± 0.5

Discussion

In order to present a diffusion model for growth of the internal sulfide platelets in the Fe-6, 9, and 18 a/o Al alloys, a comparison is made of the permeabilities ($N_s^{(s)}D_s$)

for these alloys calculated from the classical diffusion model for internal sulfidation (9-12). According to this latter model, the depth, ξ , of the internal sulfidation zone is a parabolic function of time. It can be shown that for the Fe-Al alloys

$$\frac{N_s^{(s)}}{N_{\text{Al}}^0} \ll \frac{D_{\text{Al}}}{D_s} \sim 0.1-1 \quad [1]$$

Fig. 8. Photomicrograph of the cross section of the sulfide scale (Al_2S_3) formed on the Fe-28 a/o Al alloy

Fig. 9. Electron microprobe traces for iron and aluminum in the internal sulfidation zone of Fe-9 a/o Al alloy

Therefore, the depth of the internal sulfidation is described as (9)

$$\xi = \frac{N_S^{(S)}}{\nu N_{Al}^0} (\pi \phi D_S t)^{1/2} \quad [2]$$

where $N_S^{(S)}$ and N_{Al}^0 are the atomic fractions of dissolved sulfur at the alloy surface and of aluminum in the bulk alloy, respectively, and $\phi = D_S/D_{Al}$ is the ratio of diffusivities of sulfur and aluminum in the alloy. The limiting case in Eq. [2] corresponds to significant diffusion of aluminum, hence its enrichment within the internally sulfidized zone. In the presence of an external receding scale as the source of sulfur, the depth of internal sulfidation zone is given by (13, 14)

$$\frac{\xi(\xi - \xi')}{2t} = \frac{N_S^{(S)} D_S}{\nu N_{Al}^0} F(\eta) \quad [3]$$

where the auxiliary function $F(\eta)$ is defined as

$$F(\eta) = \pi^{1/2} \eta \exp(\eta^2) \operatorname{erfc}(\eta) \quad [4]$$

with

$$\eta = \xi/2 (D_{Al} t)^{1/2} \quad [5]$$

and ξ' is the position coordinate of the alloy/scale interface at any time. Equations [3] and [4] were used, respectively, to calculate the apparent permeabilities¹ of sulfur in the Fe-6, 9, and 18 a/o Al alloys (see Table IV).

A linear increase in the apparent permeability with alloy composition is observed, as illustrated in Fig. 11. In order to account for this behavior, a model involving sulfur diffusion within the internal sulfidation zone in the alloy matrix and along the boundaries between the sulfide and the alloy matrix is considered. The model which we employ corresponds to that advanced by Whittle and co-workers (15) to account for enhanced diffusion of oxygen in the internal oxidation of Ni-Al alloys.

The effective sulfur flux through the internal sulfidation zone is expressed as the sum of sulfur fluxes through the alloy lattice, J_1^S , the internal sulfide/alloy interface, J_i^S , and the internal sulfide particles, J_{sulf}^S , as illustrated schematically in Fig. 12. Thus

$$J_{eff}^S = J_1^S A_1 + J_i^S A_i + J_{sulf}^S A_{sulf} \quad [6]$$

where A_1 , A_i , and A_{sulf} are the area fractions of alloy phase, alloy/sulfide interfaces, and sulfide, respectively, in a unit cross section cut parallel to the external surface. Sul-

¹In the subsequent text, the product $N_S^{(S)} D_S$ is termed as the apparent permeability.

Table IV. Apparent permeability of sulfur in Fe-Al alloys at 1173 K

Alloy composition	Apparent $N_S^{(S)} D_S$	Equation used
Fe-6 a/o Al	5.7×10^{-10}	[3]
Fe-9 a/o Al	9.7×10^{-10}	[4]
Fe-18 a/o Al	18.3×10^{-10}	[4]

Fig. 11. Plot of apparent permeability of sulfur as a function of alloy aluminum content.

fur diffusion in the sulfide can be neglected in comparison to diffusion in the alloy lattice and along the interfaces. Assuming a common sulfur concentration gradient, the effective sulfur diffusion coefficient in the internal sulfidation zone is given by

$$D_{s,eff} = D_{s,l}A_1 + D_{s,i}A_i \quad [7]$$

where $D_{s,l}$ is the lattice diffusion coefficient for sulfur, and $D_{s,i}$ the interfacial or boundary diffusion coefficient.

The area fractions A_1 and A_i are calculated as follows. The thickness and width of the platelets are designated as d and w (Fig. 12), and it is assumed that they extend continuously through the internal sulfidation zone up to its depth, ξ , below the metal surface. If the mole fraction of the sulfide is expressed as $N_{(AlFe)S_2}$, the number of sulfide platelets z per unit cross-sectional area is calculated to be

$$\frac{N_{(AlFe)S_2}\xi}{V_{alloy}} = z \frac{wd\xi}{V_{sulf}} \quad [8]$$

assuming that no volume expansion has occurred due to internal sulfidation. In this equation, V_{sulf} and V_{alloy} are the molar volumes of sulfide and alloy phase, respectively. The fractional area of the interface is given by

$$A_i = 2(w + d)zb_1 \approx 2wzb_1 \quad [9]$$

since $d \ll w$ for thin plates and b_1 is the width of the in-

Fig. 12. Schematic internal sulfidation model for Fe-Al alloys sulfidized in S_2 vapor at the dissociation pressure of FeS .

terface. Therefore, the fractional cross-section area available for lattice diffusion is given by

$$A_1 = 1 - A_i - A_{sulf} = 1 - 2wzb_1 - zwd \quad [10]$$

Substituting Eq. [8]-[10] into Eq. [7] with the restriction that $b_1 \ll d$ gives upon rearrangement

$$\frac{D_{s,eff}}{D_{s,l}} = 1 + \left[2 \frac{b_1}{d} \frac{D_{s,i}}{D_{s,l}} - 1 \right] \frac{V_{sulf}}{V_{alloy}} N_{(AlFe)S_2} \quad [11]$$

Thus, the effective diffusion coefficient in the internal sulfidation zone is a linear function of the mole fraction of internal sulfide precipitate. This parameter is proportional to the original atom fraction of aluminum in the alloy, N_{Al}^0 if one assumes that aluminum enrichment into the internal sulfidation zone by diffusion can be expressed by a factor α independent of alloy composition (11)

$$\frac{N_{s}^{(S)}D_{s,eff}}{N_{s}^{(S)}D_{s,l}} = 1 + \left[2 \frac{b_1}{d} \frac{D_{s,i}}{D_{s,l}} - 1 \right] \frac{V_{sulf}}{V_{alloy}} \alpha N_{Al}^0 \quad [12]$$

The sulfur solubility at the interface does not depend upon alloy aluminum composition, since the alloy matrix is virtually pure iron due to the selective sulfidation of aluminum. The ratio on the left-hand side of Eq. [12] corresponds to the ratio of the apparent $N_{s}^{(S)}D_s$ product obtained by extrapolating to pure iron. A plot of Eq. [12] is shown in Fig. 13; a linear fit is obtained with 0.997 correlation coefficient. The slope of the linear plot in Fig. 13 corresponds to

$$\left(2 \frac{D_{s,i}}{D_{s,l}} \frac{b_1}{d} - 1 \right) \frac{V_{sulf}}{V_{alloy}} \alpha = 1030 \quad [13]$$

The ratio $D_{s,i}/D_{s,l}$ was calculated using Eq. [13] to examine whether the parameters in Eq. [13] are physically reasonable. Since the internal sulfide precipitates were largely composed of $FeAl_2S_4$, $V_{sulf} = 8 \times 10^{-5} \text{ m}^3$, $V_{alloy} = 7.2 \times 10^{-6} \text{ m}^3$, $\alpha = 2$, $b_1 = 1 \text{ nm}$, and the thickness of the internal sulfide precipitates ranged from 0.5 to 2 μm , the calculated $D_{s,i}/D_{s,l}$ ratio has values in the range $1.2-8.4 \times 10^4$. These values compare well to a calculation of the ratio from independently determined values for sulfur grain boundary diffusion (16) and lattice diffusion in iron (17, 18), $D_{s,i}/D_{s,l} = 8.3 \times 10^3$.

Fig. 13. Plot of the ratio of apparent sulfur permeability in Fe-Al alloys to that in pure iron as a function of alloy aluminum content (Eq. [15]).

The average intersulfide spacing decreased from $7.9 \pm 0.5 \mu\text{m}$ for Fe-6Al alloy to $2.6 \pm 0.5 \mu\text{m}$ for Fe-18Al alloy, but the dependence of platelet size with distance into a specific alloy could not be quantitatively assessed. It is not possible, therefore, to give a more complete analysis to account for the diverse internal sulfidation phenomena involving an unusual dependence of the reaction rate which does not decrease regularly with alloy composition presumably caused by different properties of the alloy/sulfide boundaries with respect to sulfur diffusion.

Three modes of sulfidation were exhibited by the alloys dependent upon their aluminum composition: internal sulfidation, internal-external sulfidation, and sole growth of an external sulfide scale. The sequence of the stability of FeAl_2S_4 and Al_2S_3 with increasing Al contents of the alloy is consistent with the ternary thermodynamic properties (20). The growth of the Al_2S_3 scale on the alloy of high aluminum content of 28 a/o proceeded at a very slow rate. It would appear that this transition from internal sulfidation to sole growth of an external scale is determined by the criterion that the diffusion path in this alloy phase contacts without crossing the sulfur solubility curve into the two-phase alloy-sulfide phase field at an alloy composition determined by solid solution thermodynamics and diffusion (10, 19). It is necessary to postpone an analysis of this sulfidation behavior to a subsequent paper in which the internal-external sulfidation transition is analyzed with respect to positive interactions which occur between sulfur and aluminum alloying solutes in the Fe-Al-S ternary system (21).

Summary

High temperature sulfidation properties of Fe-Al alloys at the dissociation pressure of FeS were investigated at 1173 K, with special interest given to the microstructure and growth of internal sulfide precipitates and the transition from internal sulfidation to external scale formation. The alloys sulfidized parabolically and the alloy of highest Al content (27.8 a/o) only exhibited growth of a protective external scale.

The Fe-6 a/o Al alloy exhibited growth of FeAl_2S_4 acicular platelets which extended into and across the internal sulfidation zone. In the cases of Fe-9 and 18 a/o Al alloys, the internal sulfidation zones containing FeAl_2S_4 - Al_2S_3 platelets were overgrown by external FeAl_2S_4 scales. A diffusion model was advanced to describe the sulfidation behavior of these alloys involving enhanced sulfur diffusion along the interfaces between the internal sulfides

and the alloy matrix. In the internal sulfidation zones of these alloys, the apparent permeability of sulfur $N_s^{(SD)}$ increased with increasing alloy aluminum content. The ratio of boundary to lattice diffusivities of sulfur in iron estimated from this model were in satisfactory agreement with the values available in the literature.

Transition from Internal Sulfidation to External Scale Growth on Fe-Al Alloys at 1173 K

W. W. Smeltzer* and P. C. Patnaik**

Institute for Materials Research and Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

The transition from internal sulfidation to exclusive growth of an external scale on Fe-Al alloys sulfidized at 1173 K in sulfur vapor at the dissociation pressure of iron sulfide was studied using the criterion that the diffusion path in the alloy contacts the sulfur solubility curve without crossing into the alloy-sulfide phase field. This analysis based upon a vacancy mechanism for diffusion of aluminum and sulfur and repulsive interaction between sulfur and aluminum is used to show the effect of diffusion coefficients, the parabolic scaling rate constant, and the Wagner sulfur-aluminum interaction coefficient on the relationship between the diffusion path and the sulfur solubility curve in the alloy. It is demonstrated that the critical atom fraction of aluminum required for exclusive growth of an Al_2S_3 scale can only be defined when account is given to positive values of the sulfur-aluminum interaction coefficient.

In our preceding paper (1), an investigation was reported on the sulfidation properties of Fe-Al alloys at 1173 K in sulfur vapor at the dissociation pressure of iron sulfide. Emphasis was given to examining the growth and morphologies of the $FeAl_2S_4$ scale and $FeAl_2S_4$ - Al_2S_3 internal precipitates and to the transition for exclusive growth of an external protective Al_2S_3 scale. A diffusion model was employed to account for internal-external sulfidation.

In this paper, a diffusion analysis is carried out to account for the transition from internal sulfidation to external scale formation by a model in which account is given to sulfur diffusion by a vacancy mechanism and to repulsive interaction between sulfur and aluminum in the alloy. The problem is posed in terms of ternary diffusion and solution thermodynamics, and equations are deduced for describing the sulfidation phenomena based on assertions relating to the locus of the virtual diffusion path on the Fe-Al-S phase isotherm. Since the methodology corresponds closely to that previously introduced by Smeltzer and Whittle (2) to define the criterion for onset of internal oxidation beneath the oxide scale on binary alloys, direct reference is made whenever possible to equations employed in that paper.

The Ternary Sulfidation Model

Placement of representative diffusion paths on the Fe-Al-S isotherm determined at 1173 K (3) is shown in Fig. 1. Diffusion path (1 in Fig. 1) corresponds to exclusive growth of an Al_2S_3 scale. Here, the virtual diffusion path contacts, or, in the limit, tangents, the sulfur solubility curve and corresponds to the actual diffusion profile in the alloy sulfidizing by parabolic kinetics. This sulfidation behavior was exhibited by the Fe-28 atomic percent (a/o) Al alloy (1). Path 2 in Fig. 1, corresponds to the case for Al_2S_3 scale formation and Al_2S_3 internal precipitation in the alloy by relief of sulfur supersaturation. Consequently, the criterion for the absence or presence of internal sulfidation during scaling is based upon the relationship between the locus of the virtual diffusion path and the sulfur solubility curve in the alloy. If path 2 in Fig. 1, was to cut across the alloy- $FeAl_2S_4$ - Al_2S_3 field into the alloy- $FeAl_2S_4$ field before contacting the alloy sulfur solubility curve, sulfidation would lead to precipitation of $FeAl_2S_4$ - Al_2S_3 precipitates in the alloy beneath the $FeAl_2S_4$ scale as encountered for the alloys containing 9-18 a/o Al (1).

Ternary solution thermodynamics determine the shape of the sulfur solubility curve as a function of metal solute alloy content, as illustrated in Fig. 2. Sulfur solubility over a region of alloy composition is determined by the following reaction equilibrium

where Al, Fe, and S refer to the alloy components, and $\nu = 1.5$ and $\delta \ll 1$ represent the small iron solubility of 0.3 a/o in Al_2S_3 (3). If the non-Henrian solution behavior of sulfur in this alloy is interpreted by Wagner interaction coefficients, equilibrium of reaction [2] can be represented by Eq. [32] of Ref. (2)

$$(N_S)_{NH} = \left(\frac{K}{N_A \gamma_{Al}^0 \gamma_S^{\nu}} \right)^{1/\nu} \exp - \epsilon_S^A N_A$$

$$= \left(\frac{K_H}{N_A} \right)^{1/\nu} \exp - \epsilon_S^A N_A \quad [2]$$

where $(N_S)_{NH}$ is the non-Henrian sulfur solubility, K and K_H are the actual and Henrian equilibrium constants, respectively, γ^0 is a Henrian activity coefficient, and ϵ_S^A is the Wagner interaction coefficient for sulfur with aluminum. The sulfur solubility curves exhibit minima with negative values of ϵ_S^A at larger sulfur concentrations and smaller alloy contents with increasing negative values of this interaction coefficient.

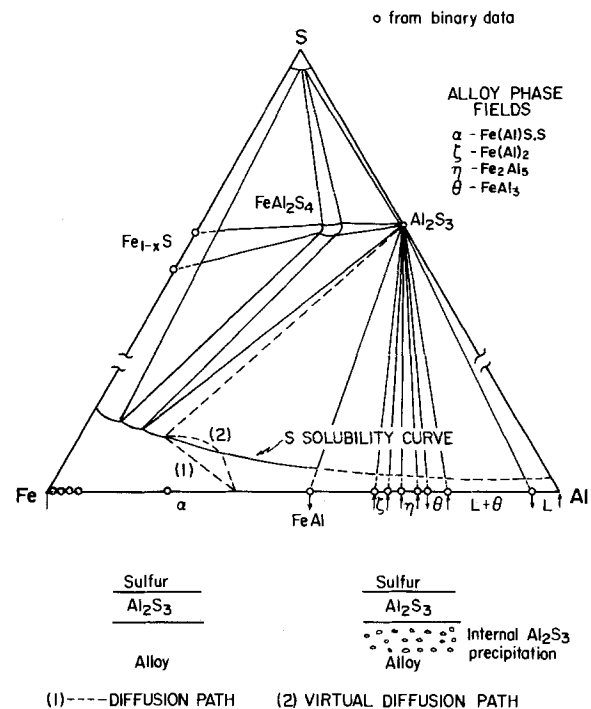

Fig. 1. Diffusion paths for metal and sulfur superimposed on the A-B-S ternary isotherm. Diffusion path, 1, corresponds to exclusive growth of an external Al_2S_3 scale. Virtual diffusion path, 2, leads to internal-external sulfidation.

Fig. 2. The shape of the sulfur solubility curve in the Fe-Al alloy as a function of alloy aluminum atom fraction for Henrian ($\epsilon_S^A = 0$) and nonideal ($\epsilon_S^A \neq 0$) solid solution behavior.

In the previous analysis for internal-external oxidation of a binary alloy (2), account was given to oxygen diffusion in the alloy by an interstitial mechanism and oxygen interaction with the alloying solute element of an attractive kind (negative Wagner interaction coefficient). These properties, however, do not apply to the Fe-Al-S system. Sulfur diffusion in bcc iron proceeds by a vacancy mechanism (4-6), and the thermodynamics of liquid Fe-Al alloys containing dissolved sulfur are determined by a repulsive interaction between sulfur and aluminum (positive Wagner interaction coefficient) (7, 8) even though Al_2S_3 is a relatively stable compound (3). Consequently, the diffusional analysis for sulfidation in contrast to oxidation of the Fe-Al alloys must take into account a different type of diffusion mechanism and of thermodynamic behavior. We are able to demonstrate, notwithstanding, that this analysis is similar to that previously carried out and gives a more detailed general understanding of internal-external oxidation phenomena.

The scale-alloy diffusion model is shown schematically in Fig. 3. Then, equations describing diffusion in the alloy when the gaseous solute element is regarded as diffusing on both its own and metal gradient are as follows

$$j_A = -D_{AA} \frac{dN_A}{dx} \quad [3]$$

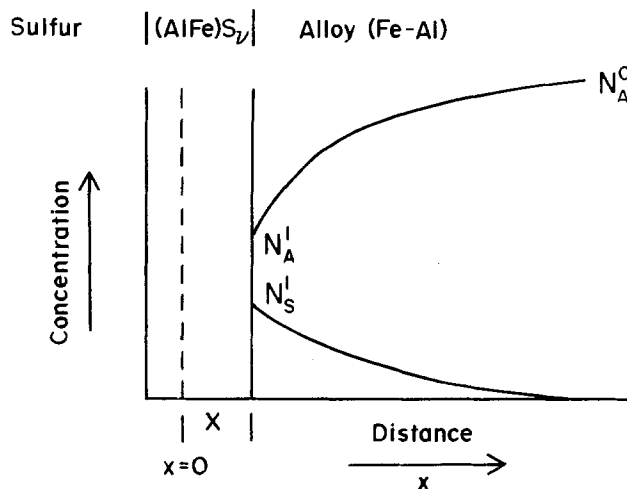

Fig. 3. The ternary scale-alloy sulfidation model

$$j_S = -D_{SS} \frac{dN_S}{dx} - D_{SA} \frac{dN_A}{dx} \quad [4]$$

where D is a diffusion coefficient for aluminum and sulfur and D_{SA} is the off-diagonal diffusion coefficient. For the ternary dilute substitutional solid solution approximation and a solute vacancy diffusion mechanism (9)

$$D_{SA} = D_{SS} N_S \left\{ \epsilon_S^A - N_S \left(\frac{D_{AA}}{D_{SS}} - N_B \frac{D_{BB}}{D_{SS}} \right) \right\} \quad [5]$$

Since $N_S \ll 1$; $D_{SS} \sim 10 D_{AA}$ or D_{BB}

$$D_{SA} = \epsilon_S^A D_{SS} N_S \quad [6]$$

in exact correspondence to the previous case for interstitial oxygen diffusion in a binary alloy, Eq. [36] of Ref. (2). Thus we may utilize Eq. [1] and [39] of Ref. (2) to define the atom fraction of aluminum and sulfur at any distance x within the alloy

$$N_A = N_{A0} - (N_{A0} - N_A) \frac{\text{erfc } x/2 \sqrt{(D_{AA}t)}}{\text{erfc } \sqrt{(k/2D_{AA}t)}}; x \geq X \quad [7]$$

$$N_S = \frac{D_{SA}}{D_{SS}} (N_{A0} - N_A) \frac{\text{erfc } [x/2 \sqrt{(D_{AA}t)}]}{\text{erfc } (k/2D_{AA}t)^{1/2}} + N_S \frac{\text{erfc } [x/2 \sqrt{(D_{SS}t)}]}{\text{erfc } (k/2D_{SS}t)^{1/2}} - \frac{D_{SA}}{D_{SS}} (N_{A0} - N_A) \frac{\text{erfc } [x/2 \sqrt{(D_{SS}t)}]}{\text{erfc } (k/2D_{SS}t)^{1/2}}; x \geq X \quad [8]$$

Fig. 4. Sulfur solubility curves calculated according to Eq. [2] with diffusion paths calculated by means of Eq. [7]-[9] superimposed for an Fe-20 at% Al alloy. The region above a solubility curve corresponds to the alloy-sulfide phase field.

$$X = \sqrt{2kt} \quad [9]$$

Diffusion paths are determined from Eq. [7]-[9] by calculating the metal and sulfur profiles and then eliminating the variable x/\sqrt{t} . In Fig. 4, calculated diffusion paths have been superimposed on alloy sulfur solubility curves for an alloy of composition $N_{A_0} = 0.2$ and Henrian ($\epsilon_s^A = 0$) and non-Henrian ($\epsilon_s^A > 0$) sulfur solution behavior. The values of the equilibrium constant, diffusivities, and the parabolic sulfidation rate constant correspond to those for growth of Al_2S_3 on the Fe-Al alloy at 1173 K. As was emphasized earlier, the solubility curves with positive interaction coefficients did not exhibit minima but they decreased markedly in value with increase in the positive value of ϵ_s^A . Moreover, the calculated diffusion paths in all cases cut into the two-phase alloy and sulfide phase field (region above each solubility curve) in a manner such that the interfacial aluminum concentrations do not practically depend on the value of ϵ_s^A even though the sulfur interfacial concentration decreases by several orders of magnitude. It also is to be noted that a decrease in the value of ϵ_s^A decreases the slopes of both the diffusion path and the sulfur solubility curve; it is the relationship between these two parameters which governs the critical atom fraction of aluminum necessary for prevention of internal oxidation.

Transition from Internal Sulfidation to External Sulfide Scale Growth

For scale growth only, one has the relationship (2)

$$\left(\frac{dN_s}{dN_A}\right)_{x=X}^{DP} \leq \left(\frac{dN_s}{dN_A}\right)_{x=X}^{Sol} \quad [10]$$

where the slopes of the sulfur diffusion and solubility profiles in the alloy are designated as DP and Sol, respectively. Since the diffusional analysis for sulfidation has been shown to correspond to that for oxidation, Eq. [26a], [42], and [57] of Ref. (2) can be utilized to define the expressions in Eq. [10] and the critical atom fraction of aluminum, $N_{A_0^*}$, for suppression of internal sulfidation and exclusive growth of the Al_2S_3 scale.

$$\epsilon_s^A (N_{A_0^*})^2 + \left\{ \frac{1 - F(u)}{F(u)} \left[1 + \frac{u}{v} \left(\frac{\pi D_{SS}}{D_{AA}} \right)^{1/2} \right] - \epsilon_s^A [1 + F(u)] \right\} (N_{A_0^*}) + \left\{ \epsilon_s^A F(u) - [1 - F(u)] - \frac{u}{v} \left(\frac{\pi D_{SS}}{D_{AA}} \right)^{1/2} \frac{1 - F(u)}{F(u)} \right\} = 0 \quad [11]$$

where u replaces $k/(2D_{AA})^{1/2}$ and $F(u)$ represents the auxiliary function

$$F(u) = \sqrt{\pi} u \exp u^2 \operatorname{erfc} u \quad [12]$$

Thus, $N_{A_0^*}$ depends on the two diffusion coefficients D_{SS} and D_{AA} , the alloy/sulfide interfacial recession rate as given by the parabolic scaling rate constant k and the thermodynamics of sulfur solubility in the alloy dependent upon the interaction coefficient ϵ_s^A .

Equation [11] was used to calculate $N_{A_0^*}$ as a function of negative and positive values of ϵ_s^A , several values of k/D_{AA} , $K_H = 10^{-10}$ (10, 11), and $D_{SS}/D_{AA} = 10$ (4, 12). These results are shown in Fig. 5. An increase in the metal diffusivity or decrease in the parabolic sulfidation rate constant decreased the initial bulk atom fraction of aluminum required for exclusive scale formation. $N_{A_0^*}$ may be larger or smaller than the concentration given by Henrian or ideal solution behavior ($\epsilon_s^A = 0$). With increasing negative values of ϵ_s^A corresponding to stronger attractive interactions between the alloy solutes, $N_{A_0^*}$ becomes of smaller value. The converse is valid under solute repulsive interactions: $N_{A_0^*}$ increases with increasing positive values of ϵ_s^A . Moreover, the variation in $N_{A_0^*}$ is largest in the range $-50 < \epsilon_s^A < +50$ if $k/D_{AA} > 10^{-3}$.

It is appropriate here to consider sulfidation of the Fe-Al alloys at 1173 K in sulfur vapor at the dissociation pressure of FeS. The Fe-18 a/o Al alloy exhibited internal-external sulfidation giving rise to $FeAl_2S_4$ - Al_2S_3 internal

Fig. 5. The critical atom fraction of aluminum in the Fe-Al alloy, $N_{A_0^*}$, for exclusive external oxidation as a function of k/D_{AA} and the interaction parameter ϵ_s^A , $D_{SS}/D_{AA} = 10$. The region above the calculated $N_{A_0^*}$ represents alloy compositions for external scale formation only.

precipitates and an $FeAl_2S_4$ scale, whereas the Fe-28 a/o Al alloy exhibited exclusive growth of an Al_2S_3 scale. The values $k = 1.9 \times 10^{-12}$ cm/s^{1/2} for scale growth (1), $D_{AA} = 5.8 \times 10^{-10}$ cm²/s (12), and $D_{SS} = 1.3 \times 10^{-9}$ cm²/s (4) were used in these calculations. If $\epsilon_s^A = 0$, the initial alloying concentration is 12.7 a/o Al. Thus, a $\epsilon_s^A > 0$ must be considered. Under this condition of an aluminum-sulfur repulsive interaction, more aluminum alloy content is necessary to take up the sulfur and to permit the transition from internal sulfidation to external scale growth. $N_{A_0^*}$ was determined as a function of positive values of ϵ_s^A by Eq. [11], and these results are shown in Fig. 5. Values of $9 < \epsilon_s^A < 15$ correspond to aluminum alloy contents 18 a/o $< N_{A_0^*} < 28$ a/o Al. Thus, positive interaction coefficients must be considered for suppression of internal sulfidation. These values, however, can only be compared to values presently available for liquid Fe-Al alloys, $\epsilon_s^A = 4.4$ -6.7 at 1823 K (7, 8), which, upon extrapolation to 1173 K, yield $\epsilon_s^A = 12$ -18 (8).

This analysis has demonstrated that repulsive interactions between sulfur and aluminum ($\epsilon_s^A > 0$) must be taken into account to define the critical atom fraction of aluminum to prevent internal sulfidation of Fe-Al alloys. A consideration of this interaction coefficient was reasonable even though values of $\epsilon_s^S = -3.3$ and $\epsilon_A^A = 5.3$ have been reported for liquid alloys at 1823 K (7). The sulfur solute interaction coefficient only occurred as a factor $\epsilon_s^S N_s$ in the diffusion and sulfur solubility equations, and this factor is negligible, since $N_s \ll 1$ in the solid alloys. ϵ_A^A only occurred in the equations as a factor $(\epsilon_A^A + \epsilon_s^A) N_A$ and therefore did not alter the form of the equations within the approximations carried out to obtain expressions in analytical form.

Kinetics of the Hydrogenation of Silicon Tetrachloride

William M. Ingle and Marilyn S. Peffley

Motorola, Incorporated, Semiconductor Products Sector, Phoenix, Arizona 85008

ABSTRACT

The hydrogenation of SiCl_4 in the presence of silicon, was investigated at temperatures between 525° and 650°C and at various pressures. It was found that increasing the temperature increased the HSiCl_3 conversion efficiency and throughput. Increasing the pressure increased the conversion efficiency at the expense of the reaction rate and adding CuCl catalyst enhanced the HSiCl_3 conversion efficiency and throughput. An energy of activation of 10-15 kcal/mol was found for the SiCl_4 hydrogenation with CuCl catalyst and 20-25 kcal/mol without catalyst. A HSiCl_3 throughput rate of 2578 $\text{kg/m}^3 \text{ h}$ was observed at 5.1 atm with a residence time of ~0.5s and conversion efficiency of 18.5%. Finally, the effect of HCl being added to the reactants and products was examined and a reaction mechanism was proposed. Without CuCl catalyst, the addition of HCl slightly enhances the concentration of HSiCl_3 in the products; with CuCl catalyst, the addition of HCl slightly reduces the concentration of HSiCl_3 in the products. When HCl is added to the effluents of the hydrogenation reaction in a cooler zone (~325°C) above the first stage, then HSiCl_3 conversion efficiencies and throughputs are markedly increased. Virtually 100% of the HCl is converted into HSiCl_3 .

The majority of all of the high purity silicon used for manufacturing of semiconductor devices is produced by the chemical vapor deposition (CVD) of silicon from HSiCl_3 onto hot filaments in a bell jar-type reactor

The molar SiCl_4 to HCl ratio of approximately 1:2 is typical of the effluents for hot-filament reactors.

The HCl can be reacted with metallurgical-grade silicon (MG silicon) to regenerate HSiCl_3 , which, when purified, is suitable for high purity silicon production

In the reaction of HCl with MG silicon, anhydrous HCl is injected into a bed of silicon particles in a fluidized bed-type reactor. The reaction is highly exothermic and requires heat exchange to minimize overheating. However, hot spots do occur which reduce HSiCl_3 conversion efficiency and degrade the reactor.

The recycling of the SiCl_4 by-product, which accounts for approximately 70% by weight of the HSiCl_3 feed, is an important consideration in the overall economics of the silicon-production process. One process currently used is to hydrolyze or burn the by-product SiCl_4 in a O_2/H_2 mixture to recover HCl and by-product SiO_2 .

Investigations at Union Carbide Corporation (1), Massachusetts Institute of Technology (2), Solar Electronics (3), and Dow Corning Corporation (4) have examined the hydrogenation of SiCl_4 in the presence of silicon at high temperatures and intermediate to high pressures

The hydrogenation of SiCl_4 in the presence of silicon is suggested as a combination of two reactions

In this work, the combined reaction is referred to as STH (an acronym for SiCl_4 hydrogenation), which differentiates the combined reaction from the SiCl_4 hydrogenation reaction (step 1) and the silicon hydrochlorination reaction (step 2).

Typically, a SiCl_4/H_2 mixture was passed through a heated vertical tubular reactor containing silicon particles with catalyst. Reactor temperature, pressure, residence time, H_2 to SiCl_4 ratio, and presence of catalyst dictate the SiCl_4 to HSiCl_3 conversion efficiency and HSiCl_3 throughput rate.

The purposes of the present investigation were as follows: (i) to study process parameters affecting HSiCl_3 throughputs and conversion efficiencies, (ii) to obtain kinetic data and postulate a reaction mechanism, and (iii) to study the effect of the addition of HCl on conversion efficiencies, HSiCl_3 throughputs, and reaction rates of the STH reaction.

Experimental Apparatus

The STH reactor was constructed of Incoloy 800H after the basic design of Mui (2). Incoloy 800H was chosen because of its superior corrosion resistance and mechanical strength at high temperatures. Mui's reactor design was modified to include a heat-exchange coil to preheat the incoming H_2/SiCl_4 mixture. This preheater helped to provide a more uniform temperature distribution over the entire reactor length and ensure that the reactor inlet was at reaction temperature.

Near the completion of the STH experiments, the reactor was modified to allow for HCl to be mixed with incoming H_2/SiCl_4 or injected into the effluents of the STH reaction in a cooler zone (stage 2) as depicted in Fig. 1.

The H_2/SiCl_4 mixture was formed by bubbling hydrogen through two SiCl_4 cylinders arranged in series to ensure a saturated SiCl_4/H_2 gaseous mixture. The SiCl_4/H_2 ratio was set by controlling the temperature and pressure in the two SiCl_4 cylinders. Internal temperatures were monitored at three points in each cylinder and pressures were monitored at each cylinder. As the SiCl_4 was consumed, the level in the first cylinder would drop and the liquid level could be determined at the point where the sharp temperature gradient occurred. A rapid increase in temperature was observed when the liquid level dropped below each of the three thermocouple points. When the liquid level in the first cylinder dropped below the level of the lowest thermocouple, positioned about one-quarter of the way up from the bottom, the reactor and apparatus would be shut down for emptying and recharging SiCl_4 in the cylinders and the silicon and catalyst in the reactor.

Fig. 1. Two-stage STH reactor

Analysis of the reaction products was accomplished via a Hewlett-Packard 5880A gas chromatograph with level four logic and in-line automated injection and with a Finnigan 3300 GC/MS with data system equipped with a heated six portal manual GC sampling valve. Reaction products were diluted with nitrogen and passed through a heat-traced line to the GC sampling valves. Sampling in this manner assured that a representative sample would be analyzed for accurate determination of reaction product concentration. The unanalyzed portion of the reactor effluent was scrubbed in a continuous-spray water scrubber.

The SiCl_4 utilized in the experiments was of semiconductor-grade (SG) quality and contained $<0.1\%$ HSiCl_3 . The H_2 , HCl , N_2 , and other gases utilized in these experiments were of "Ultrahigh Purity" grade. The SG and MG silicon used in these experiments had been crushed in a jaw crusher and sieved to a particle size smaller than 10 mesh. The CuCl catalyst was in the form of a fine powder and of A.C.S. reagent grade.

Results

Residence times and HSiCl_3 production throughput rates were calculated for each of the various pressures, temperatures, and flow rates. Typically, the 200g silicon charge would occupy a volume 181.8 cm^3 with a bed density 1.1 g/cm^3 . This is 50% of the solid silicon density of 2.2 g/cm^3 , which yields a free bed volume of 90.9 cm^3 for the nominal 200g charge in a static bed.

The high pressure studies (35 atm) were conducted at 525° , 550° , and 600°C at a H_2 to SiCl_4 ratio of 2 to 1 on SG silicon with CuCl catalyst. H_2/SiCl_4 flow rates were varied to yield varying residence times with corresponding SiCl_4 to HSiCl_3 conversion efficiencies and HSiCl_3 production rates [e.g., see Ref. (2)].

In Fig. 2 is depicted the high pressure reaction rate data generated by plotting the mole fraction of the HSiCl_3 in the product vs. the residence time. The highest conversion efficiencies were observed at higher temperatures

Fig. 2. Percentage of HSiCl_3 product at $\text{H}_2:\text{SiCl}_4$ ratio of 2:1 at 35 atm.

($600^\circ > 550^\circ > 525^\circ\text{C}$), longer residence times, and with a CuCl catalyst.

The intermediate pressure studies (5.1 atm) were conducted at 550° , 600° , and 650°C , at a 2 to 1 H_2/SiCl_4 ratio on MG silicon, with and without CuCl catalyst. Again, H_2/SiCl_4 flow rates were varied to generate throughput and rate data. A plot of the mole fraction of the HSiCl_3 in the chlorosilane product vs. residence time is depicted in Fig. 3. Again, highest conversion efficiencies were observed at higher temperatures, with longer residence times and CuCl catalyst.

The low pressure studies (2.7 atm) were conducted at 600° and 650°C , with a 2 to 1 H_2/SiCl_4 ratio on MG silicon with and without catalyst and with and without HCl injected into the H_2/SiCl_4 feed mixture. In Fig. 4 is depicted a plot of reaction rate data at 600° and 650°C with and without catalyst. Higher temperatures and presence of CuCl catalyst enhanced the conversion efficiency.

In Table I are listed HSiCl_3 production rates for the CuCl catalyzed STH reaction at 35, 5.1, and 2.7 atm. It is worth noting that even though the equilibrium conversion efficiencies continued to drop with decreasing pressure ($35 > 5.1 > 2.7 \text{ atm}$), the enhanced reaction rates at lower pressures had compensating effects and therefore similar HSiCl_3 production rates were observed over this wide pressure range.

In Table II, the effect of variable HCl concentrations on HSiCl_3 conversion efficiency at 2.7 atm with and without CuCl catalyst is found. It was observed that without CuCl catalyst the addition of HCl slightly increased the HSiCl_3 concentration in the product mixture. However, increasing concentrations of HCl in the presence of CuCl catalyst apparently diminished the HSiCl_3 concentration in the

Fig. 3. Percentage of HSiCl_3 product at $\text{H}_2:\text{SiCl}_4$ ratio of 2:1 at 5.1 atm.

Fig. 4. Percentage of HSiCl_3 product at H_2/SiCl_4 ratio of 2:1 at 2.7 atm.

product mixture. The addition of 25 mole percent (m/o) HCl shortened the residence time about 0.4s with a corresponding reduction in conversion efficiency of 1.0%. Even though these increases and decreases in HSiCl_3 conversion efficiency were quite small, the method of data collection suggests that the trends are reproducible. Specifically, the data for the uncatalyzed and catalyzed sets of experiments were collected in a continuous manner on one silicon charge for each with the HCl flow rate being varied from 0 to 33 m/o two or three times. During this collection period, the data were very reproducible.

In a final series of experiments, varying amounts of HCl were added to stage 2 of the STH/HCl (Fig. 1) reactor, while the H_2/SiCl_4 flow rate remained constant. In these experiments, stage 1 of the reactor was set at 650°C and stage 2 was set at 325°C with an inlet pressure of 5.1 atm. The results of these experiments are depicted in Table III. The addition of 25 m/o HCl ($\text{H}_2/\text{HCl}/\text{SiCl}_4$ ratio equaled 2/1/1) resulted in a marked increase of the percent HSiCl_3 in the product from 20.5 to 33.3%. Calculations contrasting theoretical *vs.* observed yields suggest that under these reaction conditions, 100% of the HCl reacts to form HSiCl_3 .

A critical reaction temperature of about 325°C was required in stage 2 over a length of about 40-45 cm to obtain these results. Under these experimental conditions, this volume and flow rate suggest a minimum residence time of about 0.5s for the HCl to react with the silicon. When part of the stage 2 reaction zone was below approximately 300°C, HCl was detected in the reactor effluents accompanied by a decrease in percent HSiCl_3 in the effluent. When the temperature of part of the zone drifted above approximately 350°C, SiCl_4 was formed from the HCl reacting with the HSiCl_3 with a corresponding loss of percent of HSiCl_3 .

At the completion of the HCl addition experiments, the reactor was dismantled and inspected for corrosion

Table I. HSiCl_3 production rates calculated for the STH reaction

Pressure (atm)	Residence time (s)	Catalyst	HSiCl_3 concentration in product (%)	Calculated HSiCl_3 production rate ($\text{kg}/\text{m}^3\cdot\text{h}$)
5.1	1.4	none	15.3	785
2.7	0.25	none	10.4	15.24
35	5.6	CuCl	25.0	1695 ^a

2.7	0.25	CuCl	13.5	1730

Experimental conditions: temperature of 600°C, H_2/SiCl_4 ratio of 2:1, MG silicon, with and without CuCl catalyst.

^a 35 atm HSiCl_3 production rate limited by heat-exchange capacity of the H_2/SiCl_4 preheater.

Table II. Effect on mole fraction of HSiCl_3 in effluent through the addition of HCl to H_2/SiCl_4 feed

HCl (m/o)	No CuCl catalyst	
	HSiCl_3 in product (%)	Residence time (s)
0	13.3	1.1
6-7	13.4	1.0
20-21	13.9	0.8
33-34	14.0	0.7
CuCl catalyst (5%)		
0	17.4	1.1
2-3	17.4	1.1
5-6	17.4	1.1
11-12	17.4	0.9
16-17	16.8	0.85
20-21	16.7	0.8
32-33	16.4	0.7

Experimental conditions: 600°C, H_2/SiCl_4 ratio of 2:1, MG silicon, with and without CuCl catalyst at 2.7 atm.

and/or "hot spots." No evidence of corrosion or hot spots was observed in the cooler second stage of the reactor. This correlates with observations made during the actual HCl addition experiments. In the presence of a H_2/SiCl_4 mixture, moderation of the hydrochlorination reaction occurs which results in a more uniform temperature distribution without "hot spots."

Discussion

Previous publications on the investigations of the STH reaction (1-4) have focused mainly on the data collection for HSiCl_3 conversion efficiency calculations and engineering design for scaled-up HSiCl_3 production facilities. In a recent report, Mui (3) demonstrated that the reaction of H_2 with SiCl_4 in the presence of CuCl catalyst was not the rate-limiting step.

The following discussion will serve to integrate the results of the previous experiments. Rate constants and energies of activation will be calculated as in previously reported data. A mechanism will be suggested which is more consistent with the body of knowledge defining the STH reaction.

One of the initial goals of the conversion enhancement studies was to identify the reaction parameters which led to enhanced conversion efficiency and increased HSiCl_3 throughput. In Table IV are summarized the trends which were observed during the current investigation.

In order to generate rate data, temperatures and flow rates continued to be varied even though higher temperatures and flow rates yielded greatest HSiCl_3 throughputs. Experiments were conducted at high pressure (35 atm), intermediate pressure (5.1 atm), and low pressure (2.7 atm) to generate conversion efficiency data and to evaluate the feasibility of operating the STH process at considerably reduced pressure.

A simple first-order rate equation of the form

$$\ln \frac{X_e}{X_e - X} = \frac{K_1 a}{X_e} t$$

Table III. Effect on mole fraction of HSiCl_3 in effluent through the addition of HCl to two-stage STH/HCl reactor

HCl (m/o)	Two-stage STH/HCl reactor	
	HSiCl_3 in product (%)	Residence time (s)
0.0	20.5	0.69
8.3	23.5	0.69
16.6	25.3	0.69
25.0	33.3	0.69

Experimental conditions: Temperatures of 650°C for stage 1 and 325°C for stage 2; H_2/SiCl_4 ratio of 2:1; MG silicon with CuCl catalyst at 5.1 atm.

Table IV. Summary of effects of process parameters on conversion efficiency, HSiCl₃ throughputs, reaction rates, and energy of activation for the STH reaction

Process parameters	Conversion efficiency	HSiCl ₃ throughput	Reaction rate	Energy of activation
Increased temperature	Increases	Increases	Increases	No measurable effect
Reduced pressure	Decreases	Compensating effects	Increases	No measurable effect

Particle size	No measurable effect	No measurable effect	No measurable effect	No measurable effect
Increased residence time	Increases	Decreases	—	—
HCl addition				
Stage 1	Minor	Increases	Compensating effects	Insufficient data
Stage 2	Increases	Increases	—	—

was applied to the STH reaction (2). In solving the pseudo-first-order kinetics for the rate of conversion of SiCl₄ to HSiCl₃, X is the concentration of HSiCl₃ at time t , X_e is the equilibrium concentration of HSiCl₃, and a is the initial concentration of SiCl₄.

The pseudo-first-order rate equation was applied to each set of the 35, 5.1, and 2.7 atm data. Individual partial pressures of HSiCl₃ (P_{HSiCl_3}), initial SiCl₄ partial pressures (P_{SiCl_4}), and equilibrium partial pressure of HSiCl₃ (P_{eHSiCl_3}) were calculated at each residence time from conversion efficiency and flow data. Plots of $\ln P_{\text{eHSiCl}_3}/P_{\text{HSiCl}_3} - P_{\text{HSiCl}_3}$ vs. residence times yielded straight lines with slopes equal to $K_1 P_{\text{SiCl}_4}/P_{\text{eHSiCl}_3}$. Multiplying the slope by P_{eHSiCl_3} and dividing by P_{SiCl_4} yielded the rate constant K_1 for various reaction conditions.

Table V contains the rate constants calculated from data depicted in Fig. 2, 3, and 4. It is interesting to observe the inversely proportional effect of reaction pressure on rate constant K_1 . Specifically, as the pressure is reduced from 35 to 5.1 to 2.7 atm, the rate constant is observed to increase from 0.07 to 1.0 to 5.0 (600°C with CuCl catalyst).

The activation energy, E , was determined by plotting the log of K_1 vs. the inverse temperature $1/T$, in the Arrhenius equation

$$k_1 = Ce^{-\Delta E/RT}$$

$$\ln K_1 = \ln C - \frac{\Delta E}{RT}$$

where R is the gas constant (1.987 cal/mol°C) and C is a constant. Values calculated for energies of activation are also found in Table V.

The fluctuations that were observed in the calculated activation energy values for the STH reaction were due in part to the variations in the reaction conditions that occurred as the flow rates were increased and in part to the simplicity of the pseudo-first-order rate treatment. At

low flow rates (*e.g.*, residence times of $\geq \sim 10$ s), the silicon particle bed behaved as a packed bed, at intermediate flows (*e.g.*, residence times of 1-10s) as a fluidized particle bed, and at high flows (residence times of ≤ 1 s) the bed behaved as a turbulent flow bed (5). These changing conditions dramatically affect free volume, catalyst distribution, pressure drops, and gas/solid interaction within the silicon particle bed.

In Table II, the effect of the addition of HCl on the STH reaction with and without CuCl catalyst are contrasted. The interpretation of the significance of these results was a key factor in the postulation of a mechanism for the STH reaction.

Previous experimental studies have suggested a plausible reaction pathway involving the following stepwise reaction

Furthermore, the assumption has been made that step 1 is slow and step 2 is fast (*i.e.*, $K_2 > K_1$). If step 2 is faster than step 1, then the addition of HCl to the reaction should increase the concentration of HSiCl₃ via step 2. This was indeed the case when CuCl was not present. Apparently, without CuCl catalyst H₂ reacts slowly with SiCl₄, possibly in the following manner (step 1)

However, in the presence of a CuCl catalyst, step 1 could proceed through a previously identified, labile, low energy route (6) as follows

Thus it is postulated that step 1 reaction rate is considerably enhanced by the addition of Cu (CuCl). This is consistent with the lower activation energies associated with the CuCl-catalyzed STH reaction (Table II).

Table V. Comparison of rate constants and energies of activation under various process conditions

Reaction parameters	Rate constants	Energies of activation (kcal/mol)
35 atm/MG silicon		
CuCl 5%, 600°C	0.07	10-15
CuCl 5%, 500°C [Ref. (2)]	0.007 s ⁻¹	13.2
5.1 atm/MG silicon		
CuCl 5%, 600°C	1.0	15-20
No catalyst, 600°C	0.26	25-30
2.7 atm/MG silicon		
CuCl 5%, 600°C	5.0	~10
No catalyst, 600°C	1.6	~15

Fig. 5. Blockage of reactive sites by SiCl_4 .

A plausible explanation for the retarded reaction rate of HCl with silicon and consequently the inverse dependency of the reaction rate on pressure is as follows: (i) SiCl_4 forms a Si-SiCl_4 dipole-induced dipole bond at the surface of the silicon particles as depicted in Fig. 5, (ii) at high pressures the density of these groups is greatly enhanced (*i.e.*, more SiCl_4 molecules per unit area), and (iii) HCl has to diffuse through the SiCl_4 to react with the silicon (step 2). The enhanced density of these SiCl_4 groups at high pressure greatly retards this reaction rate of HCl with silicon. Consequently, the reaction rate of HCl with silicon in the presence of SiCl_4 would be expected to be reduced as the pressure is increased.

Observations made while conducting experiments on the two-stage STH/HCl reactor are also consistent with the two-step mechanism. Previous investigators studying the direct reaction of HCl with silicon (step 2) have found that the highest HCl to HSiCl_3 conversion efficiencies are obtained when the reaction is maintained at about 300°C - 325°C (7, 8). Above about 350°C , HCl also reacts with HSiCl_3 to form SiCl_4 , which reduces the HSiCl_3 product as follows

In the current investigation, it was found that a reaction zone about 40-45 cm long was required to completely react the HCl with the silicon particles in the two-stage reactor.

If temperatures in this zone rose above $\sim 350^\circ\text{C}$, SiCl_4 concentrations increased at the expense of the HSiCl_3 . If

the temperature of this zone dropped below $\sim 300^\circ\text{C}$, unreacted HCl was observed at the expense of the HSiCl_3 . The length of this zone suggests that a residence time of about 0.5s is required for the complete reaction of HCl with silicon in the presence of SiCl_4 . This residence time is only a small amount less than the 0.69s required to complete the entire STH reaction which combines steps 1 and 2.

Consequently, if the assumption is made that steps 1 and 2 are mutually independent and if step 2 requires about 0.5s, then step 1 must occur in approximately 0.19s and $K_1 > K_2$. Thus, it would appear that in the presence of CuCl at 5.1 atm that step 1 does occur at a faster rate than step 2. As stated earlier, this observation is considerably different than what is commonly accepted in the literature.

Acknowledgments

The authors extend considerable appreciation to Dr. H. S. N. Setty, Professor Morey Ring (San Diego State University), and Professor James Birk (Arizona State University) for their assistance with the interpretation of the kinetic results. In addition the technical assistance of Robert Darnell, Manu Patel, Sid Palmer, and Roger Nikirk was also appreciated.

Oxidative Purification of Chlorosilane Silicon Source Materials

William M. Ingle and Robert D. Darnell

Motorola, Incorporated, Semiconductor Products Sector, Phoenix, Arizona 85008

ABSTRACT

At temperatures above $\sim 180^\circ\text{C}$, trace levels of oxygen react with the Si-H bond of HSiCl_3 to form an "Si-OH" species, which in turn complexes impurities in the HSiCl_3 , such as BCl_3 or PCl_3 . Purification occurs during a subsequent distillation step which separates the purified HSiCl_3 from the less volatile complex BCl_3 and PCl_3 . In the laboratory-scale studies, 1 mol of oxygen was found to complex 0.38 mol BCl_3 . In the pilot-scale studies, the addition of 0.025% (mol/mol) oxygen to a $\text{HSiCl}_3/\text{SiCl}_4$ mixture reduced both the acceptor (boron) and donor (phosphorous) concentrations of 1.2 and 1.0 ppb to ≤ 0.05 ppb.

Currently, commercial purification of HSiCl_3 for the semiconductor industry occurs via a combination of repetitive distillation steps and chemical complexing operations. Repetitive distillation steps are capable of rendering HSiCl_3 of suitable purity for semiconductor device fabrication. However, chemical purification can reduce the number of these repetitive steps and offers a higher

level of purification than distillation alone. Furthermore, the introduction of a chemical purification step into a chlorosilane recovery loop can reduce the probability of a potential impurity buildup.

Previous studies (1-6) suggest that boron impurity levels in silicon could be reduced by a number of techniques. The first of numerous patents using partial hy-

drolysis purification of chlorosilanes was that of Rosenberger (6) in 1954. The purified HSiCl_3 is separated from the partially hydrolyzed polysiloxane residue via distillation. If bromine or iodine is added to HSiCl_3 containing elemental boron or phosphorous, Bradley *et al.* (2) also suggest that the respective bromides and iodides can be formed which facilitate separation by distillation.

In the first part of the present investigation, a laboratory-scale apparatus was constructed for the demonstration of the BCl_3 complexation via partial oxidation of HSiCl_3 . The BCl_3 concentration was monitored by low temperature distillation mass spectroscopy. The second part of this investigation was conducted in a pilot-scale silicon production operation. Oxygen was added to a heated $\text{HSiCl}_3/\text{SiCl}_4$ mixture and, after a one-step distillation, the HSiCl_3 was analyzed for boron and phosphorous content.

Experimental

The laboratory-scale purification apparatus was constructed primarily of stainless steel hardware, 6.35 mm tubing, valves, gauges, and tanks due to the corrosive properties of HSiCl_3 . In this apparatus, 0.2 standard liter/min (SLM) of compressed nitrogen at 4.4 atm was bubbled through a 95 liter trap containing semiconductor-grade HSiCl_3 doped to 1.0% with BCl_3 . The $\text{HSiCl}_3/\text{BCl}_3$ mixture was maintained at 26°C to ensure a constant delivery rate and constant BCl_3 concentration. Oxygen was metered through a calibrated mass flowmeter and mixed with the $\text{HSiCl}_3/\text{BCl}_3/\text{N}_2$ mixture just prior to heating. In this way, various oxygen flow rates could be selected to determine the effect of oxygen concentration on the extent of BCl_3 complexation. All desired gases flowed into the reactor, where they were heated to determine the effects of temperature on BCl_3 complexation rate.

Construction materials of the reactor consisted of 50 mm stainless steel tubing, 2m long with Swagelok fittings at each end. Clam-shell heaters were fitted around approximately 70 cm of the lower portion of the vertical reactor tube. Temperatures inside the reactor were monitored by placing a multizone thermocouple in a stainless steel sheath along the center axis of the tube. Regulation of the reactor temperature was controlled manually by variable voltage regulators, one each for the top and bottom heating elements.

Analysis of the reaction products was accomplished with a Finnigan 3300 GC/MS with data system. Exhausting gases passed through a heat-traced line to a heated six-port manual GC sampling valve. Sampling in this manner assured that the same sample size would be analyzed for accurate determination of reaction product concentration. The unanalyzed portion of the reactor effluent was scrubbed in a continuous-spray water scrubber.

Inasmuch as the analysis of BCl_3 on a standard chromatography column was not possible (7), a new analytical technique was adopted. For these experiments, a distillation column was designed and built of 6.35 mm quartz tubing packed with crushed quartz sieved to a size of 10-20 mesh. The crushed quartz had been etched with 5% HF, rinsed, and dried before being packed into the column. The packed column was fitted into the GC/MS and conditioned before experimental runs by injecting $\text{BCl}_3/\text{HSiCl}_3$ samples every 2 min for 1h.

To initiate the analysis of a sample, the distillation column was cooled with liquid N_2 in a Dewar flask for 1 min. Data collection was initiated and a sample was injected via the sampling valve and allowed to freeze onto the column for 1 min. The Dewar flask was then removed, the column would come to ambient temperature, and the individual components would distill into the MS. All laboratory-scale samples were analyzed by this procedure.

The pilot-scale HSiCl_3 oxidative purification facility was designed and engineered to operate 24h per day. Under normal operation, a chlorosilane mixture consisting

mainly of HSiCl_3 and SiCl_4 flowed out of a storage tank, through a particulate filter, and into a small metering pump where the pressure was increased to about 6.8 atm. The chlorosilane mixture then flowed through the first of two heat exchangers, where incoming chlorosilanes were heated at the expense of exhausting chlorosilanes. Oxygen (10.7 sccm) is metered from a regulated cylinder and added to the heated HSiCl_3 . Additional heating occurs in a second heat exchanger located within a small 1600W furnace. The exhausting chlorosilanes are cooled via a water-cooled heat-exchange unit and filtered before entering the distillation unit. Pressure gauges at the inlet and outlets of the filter register pressures.

In addition, internal thermocouples (J type) were located at strategic points throughout the system to monitor and control the purification process temperature. The thermocouples were monitored via a five-channel Doric Trendicator, and the temperature was controlled via a two-channel Doric temperature controller.

Under normal operation, power to the furnace was regulated via a 110V variable transformer set at 90V. The process stream temperature was maintained at $210^\circ \pm 30^\circ\text{C}$. The apparatus was operated 24h/day for the duration of the experiments.

The flow of chlorosilanes through the purification unit averaged about 11.4 liter/h. An oxygen flow rate of 10.3 sccm was utilized which was equivalent to 0.025 mol oxygen/mol chlorosilane.

During the subsequent distillation process, HSiCl_3 was separated from the SiCl_4 which now contained the higher boiling complexed impurities. The purified HSiCl_3 was collected at a rate of about 2.5 liter/h and retained for boron and phosphorous analysis. Analysis included wet chemical analysis for boron and seven-pass float-zone analysis technique for both boron (acceptor) and phosphorous (donor) concentrations.

The minimum detectable limit in the boron wet chemical analysis was approximately 0.050 ppb (mol/mol) with an uncertainty of 5%. The limiting factor was the reproducibility of the spectrophotometer.

In an alternate analysis procedure, acceptor (boron) and donor (phosphorous) concentrations were measured in the HSiCl_3 by growing a small polysilicon rod in a metal analysis reactor followed by a gas pass and seven-pass vacuum float-zone analysis. Wet chemical and float-zone analysis were conducted once a day throughout the experiment.

The HSiCl_3 utilized in the laboratory-scale experiments was of semiconductor-grade quality doped to 1.0% with BCl_3 to facilitate BCl_3 analysis. The $\text{HSiCl}_3/\text{SiCl}_4$ mixture utilized in the pilot scale studies represented a "reclaimed" chlorosilane mixture generally containing 2-3 ppb of combined donor and acceptor impurities. All other gases utilized throughout the experiments were of ultra high purity grade.

Results

In a series of preliminary experiments, nitrogen was bubbled through separate cylinders of HSiCl_3 and BCl_3 and then mixed. Periodically, samples of the gaseous product mixture were injected into the GC/MS for spectral analysis. Various flows of BCl_3 and HSiCl_3 were utilized. Total separation of the individual products was not always accomplished via low temperature distillation mass spectroscopy. However, calculations of the peak areas of the BCl_3 component peaks was accomplished by monitoring the total BCl_3^+ ion in the single ion mode and comparing it with the total SiCl_3^+ ion. With this technique, it was found that the areas of the BCl_3^+ ion peaks were indicative of the BCl_3 concentration in the gas stream. In this manner, the BCl_3 detection limits were also established for the process.

In the initial laboratory-scale oxidative HSiCl_3 purification experiments, flow rates of both HSiCl_3 and oxygen were set at 3.0×10^{-4} mol/min. Below 170°C no reaction was observed between the oxygen and HSiCl_3 . However, at higher temperatures ($\geq 180^\circ\text{C}$) the oxidation of HSiCl_3 is

rapid and the consumption of oxygen complete. In fact, no trace of oxygen could be detected via GC/MS (< 1 ppm).

The major HSiCl_3 oxidation products were examined, and it was found that at low temperatures one small chain species predominated. For example, the only detectable HSiCl_3 oxidation product found in the $170^\circ\text{--}225^\circ\text{C}$ range had a molecular weight of $m/e = 248$. The following structure is consistent with this molecular weight

At higher temperatures, higher molecular weight species resulted (at the expense of the $m/e = 248$ species). The m/e values were consistent with linear and cyclic compounds containing three and four silicon atoms.

In Fig. 1 are depicted the results from the laboratory-scale studies in which oxygen concentrations were varied. In this series of experiments, the BCl_3 flow rate was set at 3.0×10^{-4} mol/min and the oxygen flow rate was alternately selected between 0.0, 2.0×10^{-4} , and 4.0×10^{-4} mol/min. A straight line with a slope of 0.38 was obtained while varying the oxygen concentration. This indicates that, under these experimental conditions, 1 mol of oxygen reacts with 0.38 mol of BCl_3 . The data depicted in this graph were extracted from more than 4000 spectra and 1.5×10^6 data points. A mean value was then selected for each data point.

It was postulated that during the intra/inter molecular rearrangement that the BCl_3 could possibly react further with the intermediate species or final products. This would result in enhanced purification at higher temperatures. From the results represented in Fig. 2, it was concluded that no additional purification was observed at higher temperatures.

In Fig. 3 is depicted the average daily boron concentration in the HSiCl_3 recovered off the top of the 4 in. distillation column of the pilot-scale purification unit. During the first seven days of operation, no oxygen was added to the chlorosilanes, but analyses were conducted and served as base-line studies. Over the next seven days, oxygen was added to the chlorosilane mixture at a rate of $0.01 \text{ mol O}_2/\text{mol HSiCl}_3$. A 2 day lag time was observed between when the oxygen flow is initiated and when purification was definitely occurring. During an additional 5 days at the conclusion of the experiment, oxygen flow was terminated. Similarly, a 4 day lag time was observed between when the oxygen flow was terminated and when purification ceased.

In Fig. 4 is depicted the daily phosphorous concentration in the HSiCl_3 recovered from off the top of the 4 in. distillation column of the pilot-scale purification unit. The reduction in phosphorous levels parallels those of the boron levels.

Upon completion of the pilot-scale experiments, the purification reactor, heat exchanger, and filters were dis-

Fig. 1. Rate of BCl_3 complexed via oxidation during laboratory-scale purification of HSiCl_3 .

assembled and checked for residues and/or potential problems. In the various filters and tubing were found small quantities of metal flakes and corroded metallics, but no sign of liquid or solid polysiloxane residues was observed.

Discussion

The oxidative purification of HSiCl_3 can be described by the following equations

Competing side reaction:

The initial step in this process is written as the formation of an $[\text{HOSiCl}_3]$ intermediate. The justification for this type of species is the formation of only $\text{Cl}_3\text{Si-O-SiCl}_2\text{H}$ during the low temperature oxidation studies. The driving force in this reaction is the thermodynamically favorable formation of strong Si-O and H-Cl bonds.

The addition of SiCl_4 to the HSiCl_3 during oxidative purification can have the following advantages.

1. The oxidative purification process increases the boiling points of most of the unwanted impurities. The subsequent distillation/separation of the SiCl_4 from HSiCl_3 facilitates the separation of these impurities from HSiCl_3 .

2. SiCl_4 will reduce the amount of HSiCl_3 consumed in the competing side reaction as follows

3. The SiCl_4 also undergoes the same degree of purification after subsequent distillation.

The pilot-scale demonstration of the oxidative HSiCl_3 purification process presented some unique problems in data interpretation at the sub-parts per billion levels. For example, (i) typical wet chemical analysis of boron took 8-12h of laboratory work per sample, (ii) a typical float-zone analysis on a silicon rod took 75-95 liter of purified HSiCl_3 , which limited the number of analyses to one per day, (iii) Every 3-4 days, a new shipment of HSiCl_3 would be delivered to the plant which could affect the boron and phosphorous background concentrations, (iv) the turnover rate of HSiCl_3 through the purification system, distillation column, transfer lines, and collection tank was about 1.5 days. Bearing in mind this turnover period, it still appears that purification continued to occur even after the termination of oxygen flow. This effect suggest the presence of an undetectable substance or coating which remains active even after the oxygen flow has stopped.

In order to compare the oxidative HSiCl_3 purification with hydrolysis purification, wet nitrogen was reacted with HSiCl_3 in the laboratory scale reactor at 200°C. During the operation, sizable quantities of solid and semi-solid residues were formed which after a few hours of operation clogged the transfer lines and made smooth con-

tinuous operation of the reactor impossible. GC/MS of the reaction products revealed numerous small polysiloxane species, the most abundant having a $m/e = 214$. The following structure is consistent with this molecular weight

Even though both purification processes (1, 8, 9) are believed to complex boron impurities in a similar manner (for example, the formation of an "Si-O-B" bond), each appears to have advantages. The advantage of the hydrolysis purification process is that it occurs at ambient temperatures, where as the advantage of the oxidative purification process is that no solid residues were observed when the reaction was carried out below ~250°C.

Structure of Selective Low Pressure Chemically Vapor-Deposited Films of Tungsten

M. L. Green* and R. A. Levy*

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Tungsten films have been selectively deposited (*i.e.*, deposited on Si and TaSi₂ to the exclusion of SiO₂) by LPCVD via the reduction of WF₆ by either Si or H₂. Films formed by H₂ reduction can be unlimited in thickness; however, those formed by Si reduction are self-limited in thickness to about 150Å. The effects of deposition parameters such as temperature and WF₆ and H₂ flow rates on the properties of the W films have been investigated. To prevent excessive erosion of Si in window areas, the volumetric flow ratio of H₂ to WF₆ must be larger than the critical value of about three. Typical films are polycrystalline with an average grain size of 2000Å and exhibit a tensile film stress of about 7 × 10⁹ dyn/cm². W film resistivity is found to be about 13 μΩ-cm for a 1000Å film, resulting in a sheet resistance of 1.3 Ω/□. The W films exhibit good contact resistance to N⁺ and P⁺ Si, and are also found to be excellent diffusion barriers between Al and Si at annealing temperatures up to 450°C.

Tungsten (W) is a very useful metal for VLSI processing. As a diffusion barrier between Al and Si (1, 2), it prevents spiking (interdiffusion of Al and Si), thereby permitting the use of shallow junction contacts. As an alternative to aluminum and aluminum alloys for second-level metallization (3, 4), W has the advantage of superior electromigration resistance due to its high melting point. Therefore, although W has a higher resistivity than Al (5.3

μΩ-cm as opposed to 2.6 μΩ-cm) it may be a useful second-level metallization in circuits with high current densities and/or high operating temperatures.

W can be chemically vapor deposited by the hydrogen reduction of WF₆ or WCl₆ (1-6), or by the pyrolysis of W(CO)₆ (7, 8). For several reasons, the hydrogen reduction of WF₆ has proven to be the most favorable deposition chemistry. First, W can be deposited selectively from WF₆ and WCl₆, *i.e.*, W can be deposited on Si, silicides, and metals to the exclusion of SiO₂ (2, 9). The deposition of W

* Electrochemical Society Active Member.

from $W(CO)_6$ does not exhibit such selectivity (8). W films deposited from WF_6 have an advantage over those deposited from WCl_6 : lower contact resistance to Si (4). Finally, WF_6 is a liquid that boils at about room temperature, whereas WCl_6 is a solid that melts at 275°C, making its use as a CVD source more difficult.

Although significant work has been devoted to CVD W, extensive characterization of the structural aspects of the films is lacking.

Deposition Chemistry

W can be chemically vapor deposited by the reduction of WF_6 at temperatures as high as 700°C (4, 6). However, by lowering the deposition temperature to approximately 300°C, one can achieve selective deposition of W on Si (2). This becomes very advantageous for diffusion barrier applications, because the W barrier layer can be deposited exclusively in the windows to N^+ or P^+ Si, as is shown in Fig. 1, thereby bypassing the usual patterning and etching steps.

Extensive evaluation of the kinetic literature pertaining to the hydrogen reduction of WF_6 (10)

has led to the conclusion that the rate-limiting step in reaction [1] is the dissociation of H_2 into atomic hydrogen

(H) on the reaction surface. Therefore, selectivity is achieved by depositing at a temperature below which glass (e.g., thermally grown SiO_2 , phosphorus-doped glass grown by CVD, etc.) will not catalyze H_2 dissociation, but Si, with its thin ($\sim 20\text{\AA}$) native SiO_2 layer, will. At temperatures below about 400°C, this is apparently the case and selectivity is observed; above this temperature, W will deposit on both Si and glass simultaneously. In addition, even in the selective temperature regime, the selectivity mechanism is only operative for films of a given thickness. Once the selective W deposit reaches a thickness of about 2500Å, W begins to deposit on thermal SiO_2 . The exact thickness of W that can be deposited selectively on Si before nonselective deposition occurs depends upon the composition of the glass (9). For example, it has been found in this work that phosphorus-doped SiO_2 (PSG) tends to enhance selectivity more than thermal SiO_2 ; therefore, one can deposit thicker selective W films on devices surrounded by PSG than on devices surrounded by thermal SiO_2 . Compositional variations of the glasses lead to variations in selectivity behavior most probably because of differences in the etch rate of the glass by WF_6 (9). Obviously, if a fresh glass surface is being created, W film nucleation will be difficult.

An alternate reduction scheme for WF_6 exists, the so-called displacement reaction

in which Si reduces the WF_6 (3, 5). Displacement will compete with hydrogen reduction, Eq. [1], when hydrogen is present, and will occur exclusively when hydrogen is absent. Both reactions are thermodynamically possible, the free energy being -285 kcal/mol for the hydrogen reduction, Eq. [1], and -364 kcal/mol for displacement, Eq. [2], (both at 327°C).

The displacement of Si by WF_6 imparts some interesting structural features to the W film, with some important consequences for VLSI processing. First, the displacement reaction is self-limiting. Once a substantially thick film of W ($\sim 150\text{\AA}$) is formed by displacement, the reaction stops because the WF_6 can no longer diffuse through the W (product) film to react with the underlying Si. In addition, the reaction of WF_6 with Si causes erosion of the Si. As is demonstrated in the Appendix, about twice as much thickness of Si is consumed for a given thickness of W film formed.

The displacement reaction will not, in general, be self-limiting on a device wafer. This is because a fresh supply of Si, needed to react with WF_6 , is present at the Si/SiO_2 interfaces of the windows. Figure 2 illustrates an effect, called the "halo effect," which results from the erosion, by WF_6 , of the Si at the Si/SiO_2 interface of a device feature, in this case, a window. A self-limiting W film has formed in the center of the window area, (Fig. 2a and 2b), but the displacement reaction has then eroded the Si at the interface. Because the interface is a region of high stress, this erosion is a stress-assisted corrosion reaction reminiscent of many bulk metallurgical phenomena. Haloing can be so extensive that neighboring windows become completely linked under the SiO_2 (Fig. 2c).

The sample illustrated in Fig. 2 was grossly overexposed to WF_6 with no H_2 present, in order to produce a pronounced halo effect. By controlling the ratio of the hydrogen flow rate to the WF_6 flow rate during film deposition, haloing can be prevented. A simple explanation for this is that by controlling $\dot{V}_{H_2}/\dot{V}_{WF_6}$, where \dot{V} is the volumetric flow rate, the ratio of W produced by reduction to that produced by displacement is controlled. Figure 3 illustrates the effect of $\dot{V}_{H_2}/\dot{V}_{WF_6}$ on haloing behavior. In this figure, the extent of the halo effect is followed by optical microscopic investigation of windows on a device. When $\dot{V}_{H_2}/\dot{V}_{WF_6}$ is greater than about 20 (Fig. 3a), no haloing is observable. When H_2 is absent ($\dot{V}_{H_2}/\dot{V}_{WF_6} = 0$), haloing is seen to extend to the window-pad boundaries (Fig. 3c). An intermediate case, $\dot{V}_{H_2}/\dot{V}_{WF_6} \approx 5$, reveals the beginnings of haloing (Fig. 3b).

Fig. 1. Two views of CVD W selectivity deposited in windows to Si. Deposition conditions: 290°C, $P = 800$ mtorr; $\dot{V}_{H_2}/\dot{V}_{WF_6} = 20$. Larger opening of phosphorus-doped SiO_2 (thicker upper layer) is due to preferential dry etching of this layer as compared to undoped SiO_2 layer (thinner, lower layer) during opening of window.

Fig. 2. Three views of the halo effect (stress-assisted corrosion) observed on a typical device wafer. Deposition conditions: 290°C ; $P = 600$ mtorr; $\dot{V}_{\text{H}_2}/\dot{V}_{\text{WF}_6} = 0$.

Film Deposition

The W films were deposited in a hot-wall CVD reactor, depicted in Fig. 4. Many different deposition schemes, based on the reduction and/or displacement reactions, with temperature, pressure, and H_2 and WF_6 flow rates as variables, were studied. All of the deposition schemes can be thought of as variations of the one- and two-step procedures outlined in Fig. 5. One-step processes involve deposition by reduction or displacement only. Two-step processes involve deposition by displacement followed by deposition by reduction.

The substrates consisted of 4 in. diam unpatterned (monitor) Si, SiO_2 , or TaSi_2 wafers, and device wafers. The Si monitors and the device wafers were precleaned by immersion in buffered 30:1 HF for 2 min, followed by a 10 min rinse in H_2O (18 MΩ quality) and spin drying. This resulted in Si surfaces with native oxides of $\sim 20\text{\AA}$, as measured by an ellipsometer. The SiO_2 and TaSi_2 monitors were precleaned in the same way, to remove some surface oxide and contamination. Usually, 40 wafers were placed in the furnace for each run. Depending upon whether a one-step or a two-step deposition procedure was used, the various steps outlined in Fig. 5 were followed. Deposition

Fig. 3. Halo effect observed optically on a device wafer. Deposition conditions as follows. a: 290°C ; $P = 600$ mtorr; $\dot{V}_{\text{H}_2}/\dot{V}_{\text{WF}_6} \approx 20$. b: 290°C ; $P = 600$ mtorr; $\dot{V}_{\text{H}_2}/\dot{V}_{\text{WF}_6} \approx 5$. c: 290°C ; $P = 150$ mtorr; $\dot{V}_{\text{H}_2}/\dot{V}_{\text{WF}_6} = 0$. Circular features (windows) are $2.5\ \mu\text{m}$ diam.

temperatures were varied between 260° and 400°C . Deposition pressures ranged between 100 and 1000 mtorr. WF_6 , H_2 , and Ar flow rates were varied between 0.5 and 100 sccm, 100 and 2000 sccm, and 500 and 2000 sccm, respectively. Optional heat-treatments after deposition, to evolve gases trapped in the films or cause interdiffusion (silicidation) of W and Si, ranged between 290° and 750°C ,

Fig. 4. Schematic diagram of apparatus used to deposit CVD W films

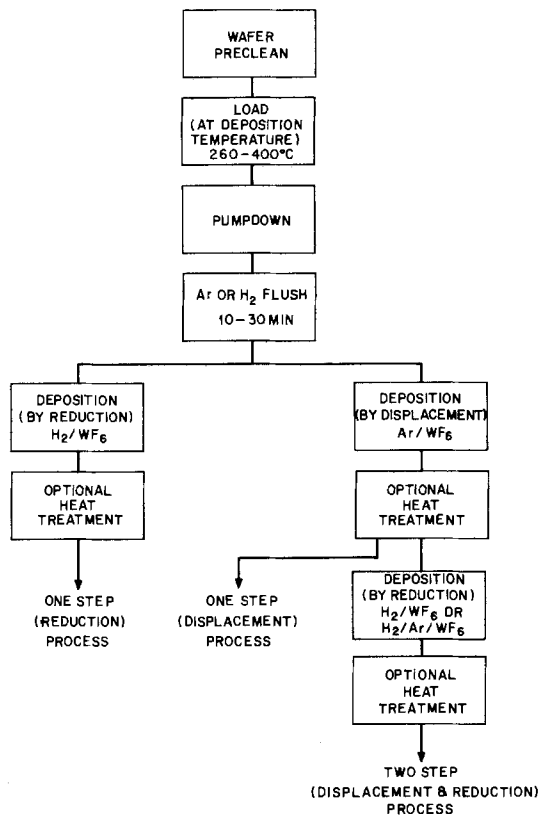

Fig. 5. Process flow diagram for one- and two-step selective CVD W

all for 30 min. The exhaust furnace (see Fig. 4), which was kept at 600°C, prevented unspent WF_6 from entering the pumping system. At the end of the deposition, which usually lasted between 20 min and 3h, depending upon deposition conditions, the wafers were removed.

The thickness of the W films was measured using a mechanical stylus profilometer on steps etched in the film. Steps are readily etched in W using 30% H_2O_2 . Figure 6 is a plot of W film deposition rate as a function of WF_6 flow rate for W films produced by hydrogen reduction. The data of Fig. 6 were gathered for deposition runs at essentially the same total pressures, in the range 600-800 mtorr. The flow-rate ratio, $\dot{V}_{H_2}/\dot{V}_{WF_6}$, is not constant for this data, but there was no satisfactory correlation between this ratio and the deposition rate. Rather, the deposition rate seems to be a function of the WF_6 flow rate only, implying that the deposition rate is controlled by the rate of WF_6 adsorption on the wafer surfaces. Our deposition conditions are therefore characterized as mass-transport limited. Films deposited by displacement (no

Fig. 6. Deposition rate as a function of WF_6 flow rate, for hydrogen-reduced W films. $P_{total} = 600-800$ mtorr; 290°C.

Fig. 7. Wafer-to-wafer uniformity (film thickness vs. wafer position) for a typical CVD W deposition.

hydrogen present) were self-limited to about 150Å in thickness at 290°C, and formed in less than 1 min. The deposition rate for displaced films is, therefore, faster than that of reduced films.

Figure 7 illustrates the wafer-to-wafer uniformity that can be achieved under typical experimental conditions. Forty Si wafers were placed back to back in a wafer boat, the spacing between each pair being 3/4 in. It can be seen from Fig. 7 that the 24 wafers between positions 34 and 56 are within $\pm 10\%$ of each other in thickness. More precise manipulation of the temperature gradient in the three-zone CVD furnace would have further extended the uniformity zone. Thickness variations on each wafer (center to edge) were $< 5\%$. This degree of wafer-to-wafer, as well as center-to-edge uniformity, is sufficient for W barrier technology, since the barrier thickness is not critical as long as it is thicker than about 400Å.

Film Characterization

Electrical resistivity.—The sheet resistance of the CVD W films was measured on a four-point probe. Figure 8 is a plot of sheet resistance, R_s , as a function of film thickness, for films produced by displacement and/or reduc-

Fig. 8. Sheet resistance of selective CVD W films as a function of film thickness.

Fig. 9. Resistivity of selective CVD W films as a function of film thickness.

tion. The sheet resistance, when multiplied by the film thickness, is converted to film resistivity, which is plotted in Fig. 9 as a function of film thickness. Several observations can be made from Fig. 9. First, as film thickness increases, the resistivity decreases and tends toward the bulk resistivity of W, $5.3 \mu\Omega\text{-cm}$. Also, it can be seen that for films between about 500 and 1500Å , the film resistivity falls between 10 and $15 \mu\Omega\text{-cm}$, which is in very good agreement with earlier data (4). Finally, film resistivity increases dramatically for films less than 500Å thick. The increase is believed to be due in part to thin film electron scattering effects and due in part to the four-point probe's lack of precision in measuring voltage drops in this thickness range.

Film stress and adhesion.—Figure 10 is a plot of film stress vs. film thickness for selective CVD W on Si. All of the films whose stress data is represented in Fig. 10 were adherent to the Si substrates, *i.e.*, they did not come off when subjected to a transparent adhesive tape peel test. The stress is seen to be a maximum for films less than 400Å , a minimum for films between 500 and 600Å , and at

Fig. 10. Film stress vs. film thickness for CVD W films deposited on Si

an intermediate and fairly constant level for thicker films. Figure 10 can be interpreted in terms of an interfacial stress and a volume stress. The largest contribution to the residual film stress usually comes from the interfacial stress. For the thin W films, the stress is dominated by this contribution, which falls off rapidly away from the interface (thicker films), at which point the largest contribution to the stress is the volume-generated stress. The combination of these two stress contributions gives rise to a stress-thickness curve reminiscent of Fig. 10 (11). The observed stress is tensile, which is contrary to that observed in earlier CVD W films (4). However, those films were significantly thicker ($>1 \mu\text{m}$), and were deposited at higher temperatures ($\sim 700^\circ\text{C}$); therefore, the stress state is likely to be different.

Table I is a summary of film adhesion data based on the transparent adhesive tape peel test. It can be seen that displaced films tend to adhere to the Si. Hydrogen-reduced films show an increasing tendency to adhere to the Si as the volumetric flow-rate ratio, $\dot{V}_{\text{H}_2}/\dot{V}_{\text{WF}_6}$ increases. Two-step films tend not to adhere to Si unless they are given a postdeposition anneal at 450°C , or if the second step (reduction) occurs at 350°C . The fact that raising only the first-step (displacement) temperatures $\geq 350^\circ\text{C}$ does not give rise to adhesion implies that the adhesion inhibiting mechanism is active in the reduction step. These results will be explained later in terms of the deposition chemistry.

CVD W films deposited on TaSi_2 were always adherent and generally had lower stress than the films deposited on Si, *i.e.*, 0 to $3 \times 10^9 \text{ dyn/cm}^2$ (tensile). W films on TaSi_2 showed no stress dependence on film thickness.

Film microstructure.—Figure 11 is a TEM photomicrograph of a typical W film, showing that it is composed of grains ranging between 1000 and 3000Å in diameter. Figure 12 is an x-ray diffraction pattern of a typical W film, compared to a stick figure pattern of a randomly oriented W standard. It can be seen that the grains comprising the W film are randomly oriented in the film, as there is a one-to-one correlation between observed and standard intensities.

Figure 13 is a TEM photomicrograph of a W film deposited on a Si window, exhibiting a tunnel-type defect in the Si substrate. That the defects are actually tubular voids has been proven by contrast experiments in the TEM. The tunnels are observed only at the rim of the window, suggesting that the interfacial stress present there has aided in their nucleation. The tunnels are not observed in Si onto which W has been deposited solely by displacement (no hydrogen). Therefore, HF gas, a by-product of W deposition by reduction with hydrogen, is

thought to be the agent responsible for attacking the Si and etching out the tunnels.

Silicidation experiments.—Attempts were made to form WSi_2 from the deposited W films by reaction with the Si substrates. As is illustrated in Fig. 14b, a temperature of 750°C is sufficient to cause all of the W to convert to WSi_2 (tetragonal form). Since the W did not react at 675°C (Fig. 14a), the silicide formation temperature is somewhere between 675° and 750°C. This is in good agreement with earlier data (12). We did not observe the hexagonal form of WSi_2 at lower reaction temperatures, as has been reported (12).

Discussion

Our results demonstrate that high quality, selective CVD W films can be grown in a reproducible manner. We would like to discuss the observations of haloing behavior and film adhesion in some detail, as they are very

much related to film processing history and reveal important subtleties of CVD W processing.

Haloing behavior, depicted in Fig. 2 and 3, is the stress-assisted reaction between WF_6 and exposed Si. As such, one would expect the state of stress at the Si/SiO₂ interface to influence the course of this reaction. We believe that this influence is illustrated in Fig. 3c, where haloing behavior is observed to be nearly complete under the SiO₂ pads that contain the windows to Si, but is observed to stop abruptly at the pad boundaries. Whereas the pads are comprised of $\sim 1 \mu\text{m}$ of PSG on top of 1000Å of undoped SiO₂, both deposited by LPCVD at 430°-460°C, the oxide between the pads is field oxide, $\sim 7000\text{Å}$ thick, and is grown at 950°C. The LPCVD film stress is about $3 \times 10^9 \text{ dyn/cm}^2$ (tensile) (13), whereas the thermal oxide stress is approximately zero (14). Therefore, it is believed that the near-zero stress state of the field oxide prevents the WF_6 attack of the underlying Si from spreading.

Adhesion tests, using the transparent adhesive tape peel method, were carried out on at least one Si monitor wafer placed in every run. Variables such as room humidity, change of gas cylinders, and slight unintentional variations in wafer cleaning procedure resulted in less than 100% predictability of film adhesion. However, as the adhesion data of Table I reveal, there are several interesting

Fig. 12. X-ray diffraction pattern of a typical selective CVD W film, deposited on (100) Si at 290°C. The one-to-one intensity correlation between the observed pattern and the W standard (stick figure), indicates that the film is composed of randomly oriented grains.

Fig. 13. TEM of a W film deposited on a window to Si on a tester device (wet-etched window). Note tunnels in the Si emanating from the window edges.

Fig. 14. X-ray diffraction patterns of typical selective CVD W films, deposited on (100) Si at 290°C, and reacted with Si substrate at 675°C for 30 min (top) and 750°C for 30 min (bottom) both in hydrogen.

trends in adhesion behavior that are related to deposition processing.

The data in Table I suggest that a chemical species causes lack of adhesion. This is most strikingly demonstrated for the two-step films, where it can be observed that films deposited at 350°C, or postdeposition annealed at 450°C after 290°C deposition, exhibit good adhesion. However, two-step films deposited at 290°C rarely exhibit adhesion in the as-deposited state. Although information is lacking regarding low temperature interactions between W and Si, it is likely that there is no significant interdiffusion between the two at temperatures less than about 500°C. Therefore, the effect of the higher deposition temperature and postdeposition anneal is most probably the evolution of the chemical species, thereby restoring adhesion.

There is much circumstantial evidence to support this hypothesis. First, Table I shows, for the case of single-step reduced films, that adhesion is possible at 290°C, if $\dot{V}_{H_2}/\dot{V}_{WF_6}$ is large enough, further suggesting that lack of adhesion is due to some sort of interfacial film. That the adhesion improves as $\dot{V}_{H_2}/\dot{V}_{WF_6}$ increases indicates that the species causing lack of adhesion might be a reaction by-product, which is diluted and pumped out to a greater extent when this ratio is high. Furthermore, in some 40-wafer runs, the films in the front of the reactor (furthest from pumps, upstream of flowing gases, see Fig. 4), adhered, whereas those near the back did not. Again, the reason may be the preferential incorporation of larger amounts of by-products in wafers positioned in the back of the reactor, as that is where their concentration will be highest.

Some recent work on the computer analysis of the thermodynamics of CVD W on a variety of substrates has rationalized the adhesion behavior in terms of the formation of reaction by-products (15). Poor adhesion of W is observed on substrates that form nonvolatile fluorides during reduction of WF_6 . Therefore, the lack of adhesion observed for certain W films deposited on Si can be due to the presence of, for example, WF_4 , which has previously been identified as the cause of porosity in CVD W thermionic emitters (16). WF_4 melts at 502°C and boils at 627°C, and therefore becomes increasingly volatile as temperatures increase; however, it would be nonvolatile at our deposition temperatures. As many subfluorides (*i.e.* WF_3 , WF_2 , etc.) probably exist (17), others of them can be invoked to explain the lack of adhesion. The existence of partially reduced WF_6 compounds is even more likely as the concentration of H_2 is decreased; therefore, it is not surprising that adhesion gets worse as $\dot{V}_{H_2}/\dot{V}_{WF_6}$ decreases. Finally, since the free energy for Si reduction of WF_6 exceeds that of the H_2 reduction at 327°C (-364 *vs.* -285 kcal/mol), one would expect there to be more reduction of WF_6 , and, therefore, less incorporation of W subfluorides in displaced films. This is supported by the observation from Table I that single-step displaced films almost always adhere. Indeed, lack of adhesion is determined during the hydrogen reduction step, as two-step films, even those whose displacement step has occurred at $T \geq 350^\circ\text{C}$, do not adhere after a 290°C reduction step, as is indicated in Table I.

Conclusions

W films have been chemically vapor deposited by the reduction of WF_6 , and extensively characterized. W films can be deposited selectively, *i.e.*, on Si and TaSi₂ to the exclusion of SiO₂, thereby eliminating the need for patterning and etching of a diffusion barrier layer. Whereas W films of unlimited thickness can be deposited by H_2 reduction of WF_6 , W films formed by Si reduction (displaced films), are self-limited to about 150Å in thickness. However, on actual device wafers, uncontrolled displacement reaction (haloing) can occur if the volumetric flow-rate ratio, $\dot{V}_{H_2}/\dot{V}_{WF_6}$, is between zero and approximately 15. Haloing behavior is aggravated by a high stress state at the Si/SiO₂ interface of device features.

W films were deposited by H_2 and/or Si reduction of WF_6 , under a variety of temperatures and pressures. The hot-wall, horizontal CVD reactor was mass-flow limited, *i.e.*, the W growth rate was proportional to the WF_6 flow rate. The films were specular, with resistivity of $\sim 13 \times 10^{-6} \Omega\text{-cm}$, and a sheet resistance of 1.3 Ω/\square for a 1000Å thick film. The films are composed of grains averaging 2000Å diam, and have a tensile film stress of about 7×10^9 dyn/cm². Film adhesion was almost always observed if any of the following steps were taken: deposition at 350°C, deposition at 290°C followed by a 450°C postdeposition anneal, or the use of very high H_2 to WF_6 volumetric flow-rate ratios. That these steps lead to adhesion suggests that the incorporation of nonvolatile WF_x (W subfluoride) into the W at the 290°C deposition temperature is the cause of the lack of adhesion sometimes observed.

CVD W films are excellent diffusion barriers between Al and Si. In view of the physical attributes of the films reported here and the convenience of depositing selective W, these films are good candidates for diffusion barriers in shallow junction VLSI technologies.

APPENDIX

During the displacement reduction of Si by WF_6

what thickness of Si is consumed in forming a W film of a certain thickness?

$$V_w = A_w t_w = \frac{m_w}{\rho_w} = \frac{n_w MW_w}{\rho_w}$$

where V_w is the volume of W film, A_w the area of W film, t_w the thickness of W film, m_w the mass of W film, ρ_w the density of W (19.3 g/cm³), n_w the number of moles of W in the film, and MW_w the molecular weight of W (183.85 g/mol). Therefore

$$n_w = \frac{A_w t_w \rho_w}{MW_w}$$

similarly

$$n_{Si} = \frac{A_{Si} t_{Si} \rho_{Si}}{MW_{Si}}$$

where n_{Si} is the moles of Si displaced by W, A_{Si} the area of Si displaced by W, t_{Si} the thickness of Si displaced by W, ρ_{Si} the density of Si (2.33 g/cm³), and MW_{Si} the molecular weight of Si (28.09 g/mol). For every mole of W formed, 3/2 mol of Si are required. Therefore

$$n_{Si} = \frac{3}{2} n_w$$

or

$$\frac{A_{Si} t_{Si} \rho_{Si}}{MW_{Si}} = \left(\frac{3}{2}\right) \frac{A_w t_w \rho_w}{MW_w}$$

but

$$A_{Si} = A_w$$

Therefore

$$\frac{t_{Si}}{t_w} = \left(\frac{3}{2}\right) \left(\frac{\rho_w}{\rho_{Si}}\right) \left(\frac{MW_{Si}}{MW_w}\right) = \left(\frac{3}{2}\right) \left(\frac{19.3}{2.33}\right) \left(\frac{28.09}{183.85}\right)$$

$$\frac{t_{Si}}{t_w} = 1.90$$

The thickness of Si consumed to form a W film of thickness t_w by displacement is, therefore, about twice t_w .

ABSTRACT

The absorption of water by powders of sodium, potassium, and lithium beta alumina was observed using thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), and x-ray powder diffraction. For samples derived from Union Carbide beta alumina, no water absorption/adsorption was observed for potassium beta alumina, about 2.1 molecules of water per unit cell for sodium beta alumina, and about 4 molecules per unit cell for lithium beta alumina. All of these results are at 25°C with the composition at 400°C as a base line. Some samples also were observed to react with CO₂ in the presence of water to form complex hydrated carbonates, which underwent multistage decomposition reactions upon heating.

Since the rediscovery of the beta aluminas (1, 2), it has been widely recognized that various compounds of this family react with water. The effects of hydration vary greatly. Water absorption by sodium beta alumina, for example, decreases its Na⁺ ion conductivity (3). In contrast, a high water content is essential for high conductivity in various protonic beta⁺ aluminas (4). Hydration reactions of powders of the beta aluminas can influence their behavior during forming and sintering into polycrystalline ceramics.

Over the past few years, the absorption of water by various beta aluminas has been investigated extensively. A complete picture of the phenomenon does not yet exist. It is complicated by the many ions which can substitute for sodium in the beta aluminas, their nonstoichiometric compositions, and the fact that their hydration reactions may be influenced by particle size.

Beta (typically M_{1.24}Al₁₁O_{17.12}) and beta⁺ alumina (typically M_{1.67}Mg_{0.67}Al_{10.33}O₁₇) in which M is Na⁺, Li⁺, (4, 5) or H⁺ (6) are known to hydrate in air at room temperature. Most experimental evidence indicates that water is not localized in cracks or micropores but enters the conduction planes and is bulk rather than surface water. The extent of hydration is strongly influenced by the identity of the mobile ion. Na⁺ beta alumina absorbs less water than Li⁺ beta alumina. In contrast, even with powder samples, we have been unable to measure any water uptake for Ag⁺, K⁺, Tl⁺, and Rb⁺ beta aluminas (7). To our knowledge, a phase diagram for a water/beta alumina system has only been explored for Li⁺ beta alumina above 200°C (8), a temperature range in which water diffuses more rapidly in the compound but in which the hydration equilibrium is

shifted toward a lower bulk water content. The study, by Dudney *et al.* (8), found the maximum hydration state of Li⁺ beta alumina single crystals to be 1.6 water molecules per unit cell at 235°C.

The hydration reactions of the beta aluminas are quite complex. Considerable spectroscopic evidence indicates that water can dissociate in the compounds and that a number of different water complexes can exist (8-10). Kuhns *et al.* (11), Hayes *et al.* (12), and Dunn (3) have suggested that, during hydration, the sodium in beta⁺ alumina ceramics is replaced by protonic species. They suggested that the sodium migrates to the surface to form hydroxides, which can react with CO₂. These reactions can be reversed by heating.

This paper reports the results of our recent investigations of the hydration and carbonation of Na⁺ and Li⁺ beta alumina powders. It demonstrates that the hydration reactions of beta alumina are strongly influenced by the

source of the material, that powder samples absorb more water than single crystals, and that carbonation reactions occur readily with various powdered beta and beta' aluminas.

Experimental Description

Beta aluminas from four sources were examined.

1. *Melt-grown Na⁺ beta alumina obtained as single crystals from the Union Carbide Corporation.*—The composition of the crystals was determined to be Na_{1.22}Al₁₁O_{17.12} by measuring the weight change after complete substitution of Na⁺ by Ag⁺. Single-crystal samples were ground to fine powders, and a set of sieves from 40 to 400 mesh was used to select powder fractions. Powders with average grain sizes of about 20 and 10 μm were obtained by further grinding of the finest fraction. The particle size distributions were determined with a Coulter (TM) Counter particle analyzer.

1. *Mg-stabilized Na⁺ beta alumina crystals grown by the flux evaporation method (13).*—Crystals were grown at several different temperatures between 1650° and 1700°C and had compositions of Na_{1.67}Mg_{0.67}Al_{10.33}O₁₇ based on the weight change observed after Na⁺ exchange with Ag⁺.

3. *Monofrax Na⁺ beta alumina from the Carborundum Corporation.*—This had a particle size of 44-105 μm.

4. *Na⁺ beta alumina that was synthesized as a powder from sodium carbonate and alumina.*—Powder x-ray diffraction analysis detected no phases other than sodium beta alumina. The particles nearly all passed through a 44 μm sieve. This material was by no means as well characterized as the previous three. Because it was not derived from a well-analyzed single crystal, its behavior cannot be considered to define the intrinsic properties of sodium beta alumina. Nevertheless it is included here because it is an example of the kind of beta alumina from which polycrystalline tubes are prepared.

Beta alumina containing ions other than Na⁺ was synthesized by ion exchange. Li⁺ beta alumina was prepared from large single crystals of Union Carbide sodium beta alumina by ion exchange in either LiCl at 650°C or LiNO₃ at 350°C. K⁺ beta alumina was prepared from the same Union Carbide starting material by ion exchange in molten KNO₃ at 350°C. All salts were greater than 99.99% pure, and the molten salt baths were changed three or four times in order to maintain a low Na⁺ concentration. The weight change measured on large single crystals was that expected for the complete replacement of Na⁺.

Thermal analysis was carried out with du Pont 990 and 1090 systems. The crystallographic parameters of the samples were obtained with an x-ray powder diffractometer equipped with a thermal attachment which permitted control of both temperature (−180° and 900°C) and atmosphere.

Results and Discussion

Union Carbide Na⁺ beta alumina.—A TGA for a sample of Na⁺ beta alumina with grain size 44 μm < d < 63 μm in dry nitrogen is shown in Fig. 1, along with a DSC analysis for the same material. The DSC plot includes a base-line trace observed with a sample of K⁺ beta alumina. Both the Na⁺ and K⁺ beta alumina powders had been exposed to air for one year at room temperature after grinding.

The TGA results indicate that water desorption occurs by a process which is well described by first-order kinetics. No further weight loss was observed from 300° to 1000°C. In the DSC trace, the expected endotherm was seen in the same temperature region as the dehydration in the TGA plot. A small but reproducible deviation in the exothermic direction sometimes occurred near 250°C. The endothermic peak in the DSC plot gives an enthalpy of dehydration of 14.5 kcal/mol H₂O. Similar values of dehydration enthalpies were obtained for samples which were exposed to air for shorter times and contained less water than that of Fig. 1.

A previous report (5) indicated that water uptake in powder samples of this type occurs in two steps: a fast

Fig. 1. TGA (top) and DSC (bottom) results for Union Carbide Na⁺ beta alumina powder in nitrogen. Particle size distribution: 44 μm < d < 63 μm.

one which may affect only a narrow band near the surface, and a slow one which is controlled by two-dimensional diffusion into the bulk. The previous work obtained a good fit of the grain size dependence for the fast uptake process by assuming that it involved a 3.3 μm wide band at the crystal surface which was uniformly filled with one water molecule for each sodium ion. We have checked this model by measuring the weight lost during heating of Na⁺ beta alumina samples having an average grain size of 10 μm. Samples which were allowed to stand for a few hours in air after grinding had a weight loss that corresponded to 2.8 weight percent (w/o) water (1.9 H₂O/unit cell), which agrees well with the model. After several weeks or months in air, samples gained slightly more water, 3.10-3.15 w/o (2.10-2.13 H₂O/unit cell).

The chemical diffusion coefficient of water in Na⁺ beta alumina was estimated from the rate of weight increase of the Na⁺ beta alumina powder with particle diameter (d) < 44 μm and was found to be 2 × 10⁻¹³ cm²s⁻¹ at 27°C and 1 × 10⁻¹² cm²s⁻¹ at 50°C. These data correspond to an activation energy for diffusion of 0.56 eV, a figure which is clearly quite uncertain, because only two points were used to obtain it.

The chemical diffusion coefficients are also average values. They were calculated assuming a uniform particle radius of d = 33 μm, even though the actual sample had a distribution of particle sizes. The radius of 33 μm was chosen because it yielded the best fit to the data. In addition, during the portion of the diffusion-controlled uptake that was analyzed, the overall water content changed from 1 to 2.5% by weight. There is no reason to assume that the diffusion coefficient of water is independent of its concentration.

Monofrax Na⁺ beta alumina.—The total weight loss of a sample of particle size d < 45 μm which had been exposed to air for two months at room temperature after grinding was 2.6% (see Fig. 2), about the same as for the

Fig. 2. TGA (top) and DSC (bottom) results for Monofrax Na⁺ beta alumina powder in nitrogen. Particle size distribution $d < 44 \mu\text{m}$.

Union Carbide material described in the previous section. However, as Fig. 2 shows, the TGA and DSC plots for the dehydration of this sample are very different from those for the Union Carbide material. The sharp peak in the DSC plot corresponds to the rapid weight loss of about 1% which occurs at 115°C. Sharp peaks around 100°C have also been observed with beta^{''} alumina and type 4 beta alumina. They are believed to be due to the decomposition of products formed on the surface of powders exposed to ambient air for extended periods of time. Possible products are discussed later in this paper.

Union Carbide K⁺ beta alumina.—No evidence of hydration or dehydration reactions was observed with TGA and DSC analysis of finely ground powders of K⁺ beta alumina prepared by ion exchange from Union Carbide Na⁺ beta alumina crystals.

Union Carbide Li⁺ beta alumina.—The general phenomena of water absorption/desorption in Li⁺ beta alumina are qualitatively similar to the parent sodium compound. However, preparation conditions appear to influence the hydration reactions of Li⁺ beta alumina. Fine powders of Li⁺ beta alumina prepared by ion exchange in molten LiNO₃ and equilibrated in air lost considerably more water, 6.2-6.3 w/o (4.2 H₂O/unit cell) vs. 3.0-3/2 w/o (2.1 H₂O/unit cell), than comparable powders of Na⁺ beta alumina when heated from 100° and 400°C. Weight losses observed with samples prepared by ion exchange in LiCl were systematically lower, typically 5.1-5.2 w/o (3.4 H₂O/unit cell).

We also have observed that the amount of water absorbed by Li⁺ beta alumina depends on grain size. Figure 3 illustrates the water lost upon heating of freshly ground powders of LiCl-exchanged beta alumina as a function of grain size. TGA analysis of the crystals before crushing showed about 1.5% weight loss to 400°C. After grinding, samples were exposed to air for about 12h, then heated to 400°C at 1°C/min and held at 400°C until constant weight was attained.

Fig. 3. Weight loss of Li⁺ beta alumina powders upon heating from 25° to 400°C, as a function of particle size. Samples prepared by ion exchange in LiCl.

The solid curve in Fig. 3 has been drawn according to a model which assumes that the grains homogeneously hydrate to a level of 1.5 w/o (1 H₂O/unit cell) and that those portions of the grains within 30 μm of the surface hydrate to a maximum water content of 5.1 w/o (3.4 H₂O/unit cell). The penetration depth and maximum hydration level were chosen to give a best fit to the data. The data actually do appear to reach a limiting hydration level of about 5.2 w/o for particle sizes less than 50 μm, which is consistent with this model. A similar experiment and model for sodium beta alumina gave a penetration depth of 3.3 μm and no background water in the crystals (5).

Changes in the c-lattice parameter for a Li⁺ beta alumina powder exchanged in LiNO₃ ($d < 45 \mu\text{m}$) were measured during heating/cooling cycles. The data are plotted in Fig. 4 along with the results of parallel TGA experiments. Regardless of the water content, the c-axis expands as the sample is heated from 60° to 140°C. It contracts from 140° through 300°C, the region in which most of the water is lost, and then expands again above 300°C. When a sample is then cooled to 160°C in dynamic vacuum, only the expected thermal contraction is observed. Although it was possible to cool samples to 160°C without significant water uptake, it was never possible to prepare anhydrous Li⁺ beta alumina powders ($d < 45 \mu\text{m}$) at room temperature. Weight increases were always observed when samples were cooled below about 60°C, even if the experiment was carried out under dynamic vacuum (10^{-3} torr or lower) or under a flow of dry gas.

The Li⁺ beta alumina samples lost no weight between 400° and 750°C, but they lost about 0.5% between 750° and 850°C. The source of this weight loss is not known, but it is irreversible and accompanied by a number of changes in the sample. X-ray powder diffraction patterns were taken for a sample before and after being held for 16h at 850°C. After heating, the formerly transparent crystals were opaque and no longer reacted with water. These results are consistent with an earlier report (14), which indicated that Li⁺-Na⁺ beta alumina decomposes in this temperature range by a process that involves the irreversible migration of Li⁺ into the spinel blocks of the structure.

Na⁺ beta alumina synthesized as powder.—This material, which had a particle size of $d < 44 \mu\text{m}$, had been in contact with air for several years. Its x-ray pattern before heating showed several weak reflections which do not belong to beta alumina. Immediately after annealing at 600°C, the positions and intensities of these foreign reflections had changed. The original spectrum was eventually restored after months of exposure to air. A very reasonable explanation for the extra reflections is that

Fig. 4. Weight change (top) and corresponding change in *c*-lattice parameter (bottom) function of temperature for Li^+ beta alumina powder. Li^+ beta alumina prepared by exchange in LiNO_3 . [●]: First heating in air. [○]: First cooling in air. [▲]: Second heating in air. [△]: Second cooling in air. [x]: Cooling in vacuum.

they arose from the hydration and, possibly, carbonation reactions which these powders underwent upon prolonged standing in air. The formation of carbonates and bicarbonates on the surface of beta alumina powders was previously reported by Garbarczyk *et al.* (15-17) and Harbach (18).

A TGA, taken under dynamic vacuum, of a sample of this powder more than two years old is shown in Fig. 5. Various steps are apparent in the weight-loss process. However, the steps are not clearly distinguished even at very slow heating rates ($1^\circ\text{C}/\text{min}$). Although the exact weight lost in each step is uncertain, the total weight lost from room temperature to 700°C is reproducibly 9-10%.

During cooling at $0.5^\circ\text{C}/\text{min}$ from 700°C to room temperature in air, the weight increased about 3%. After five months of exposure to air, the powders reproduced the thermal behavior of Fig. 5.

Fig. 5. TGA results and humidity detector output during heating of sample of Na^+ beta alumina powder (type 4) in dry nitrogen at $10^\circ\text{C}/\text{min}$.

To determine whether all of the weight losses in Fig. 5 actually correspond to the evolution of water a P_2O_5 humidity detector was connected in series with the gas stream exiting the TGA chamber. Its output is also plotted in Fig. 5. A downward trace represents an increased water signal. What is most interesting is that only the high temperature weight loss ($> 600^\circ\text{C}$) is not accompanied by water evolution. A reasonable explanation is that it is the result of the decomposition of carbonates on the surface of the powder.

To explore this possibility, a series of TGA analyses were carried out in various atmospheres. Fresh samples of Na^+ beta alumina were heated to 800°C and then cooled to room temperature at $0.5^\circ\text{C}/\text{min}$. Gas flows of 8 liter/h were maintained over the samples. The total weight increases from 800°C to room temperature were 1.4% for a wet nitrogen atmosphere with no CO_2 , 0.4% for dry CO_2 , and 5.5% for wet CO_2 . These results demonstrate that simultaneous carbonation/hydration can be responsible for considerable weight increase in these beta alumina samples.

Moist CO_2 presumably leads to the formation of bicarbonate and carbonate species on the surface of the beta alumina powders. Separate TGA analyses on sodium bicarbonate and sodium carbonate show that the former decomposes to the carbonate between 100° and 200°C , and the carbonate begins to decompose above 800°C . The decomposition of bicarbonate/carbonate species can therefore account not only for the high temperature weight loss in these powders, but also for some of the complexity of the low temperature weight losses.

To further corroborate the role of CO_2 in these reactions, infrared spectroscopy (IR) measurements using a Nicolet FTIR spectrometer with a HgCdTe detector were carried out on powder samples. The results were consistent with the presence of various sodium carbonates, bicarbonates, and their hydrates.

Additional evidence for carbonate formation was obtained by bubbling the effluent from the TGA into a water trap and measuring the pH as a function of weight loss. Distinct acidic peaks were observed to correspond with weight loss regions. The largest occurred above 500°C , the temperature range in which CO_2 evolution is expected from carbonate decomposition. The second largest peak was observed at 100°C and correlates well with bicarbonate decomposition.

The high temperature weight loss signaling the presence of carbonates did not appear with all samples. It was absent with those prepared from Union Carbide crystals. Some weight loss which could indicate the presence of carbonation was observed with Monofrax Na^+ beta alumina. It was observed with sodium beta alumina powders prepared from single crystals of Mg-stabilized material and also with Li^+ beta alumina crystals prepared from Union Carbide crystals.

Summary and Conclusion

We have studied the hydration reactions of various beta aluminas under conditions that were intentionally quite different from those of several previous investigations that used large single-crystal samples. The prior work yielded considerable insight into the nature of the hydration processes at high temperatures and over long diffusion pathlengths. We have emphasized the other extreme—low temperatures and short diffusion pathlengths. Our conditions required powder samples, which made it more difficult to obtain structural insight into the process of water intercalation in these compounds. Nevertheless, the data obtained from powder samples are quite important. They highlight reactions that may be too slow to be observed with larger crystals, and the short hydration pathlengths of powders reveal reactions that occur in regions very near the surface. Understanding reactions of this type is especially important in the study of interfacial ion transfer.

Our results underscore that the beta alumina hydration reactions are strongly influenced by the ion present in

the conduction plane. The behavior of K^+ beta alumina is one extreme. Even in fine powder form, it neither adsorbs nor absorbs significant amounts of water. In contrast, at 100°C , Na^+ beta alumina intercalates the equivalent of about 2.1 H_2O molecules per unit cell. At the same temperature, Li^+ beta alumina absorbs about 4 H_2O molecules per unit cell, which is considerably greater than the maximum of 1.6-1.8 H_2O molecules per unit cell reported by Dudney *et al.* (8) from studies of single crystals.

The fact that fine powders of K^+ beta alumina do not hydrate indicates that surface hydration reactions and the condensation of water in microcracks probably are minor mechanisms for the trapping of water by this material. Assuming that the physical characteristics of powders of other beta aluminas are similar to those of K^+ beta alumina, microcrack condensation can be generally ignored. In addition, if general surface adsorption is invoked to help explain the greater water uptake by powders of Na^+ and Li^+ beta alumina, it must be strongly influenced by the ion in the conduction plane.

On the basis of these results, we suggest that the near-surface region of beta alumina hydrates more rapidly and to a greater extent than the interior. As shown previously (5) and confirmed here, the hydration behavior of Na^+ beta alumina powders is well explained by assuming that regions $3.3\ \mu\text{m}$ wide around the edges of each particle hydrate rapidly to a level of about two H_2O molecules per unit cell. The interior region hydrates to a lower water content. The behavior of Li^+ beta alumina powders can be explained by assuming regions $30\ \mu\text{m}$ wide which hydrate to about four H_2O molecules per unit cell. Since Li^+ beta alumina is an extremely powerful desiccant, it is not clear whether a truly anhydrous form has ever been prepared.

Our results indicate that some beta aluminas react with CO_2 , especially in the presence of water, to form bicarbonates and carbonates. These are presumably surface reactions. We have no evidence to indicate that CO_2 penetrates the conduction planes near the surface. The extent of carbonation varies greatly. Powders of Union Carbide Na^+ beta alumina show no evidence of carbonation. But, Na^+ beta alumina powders synthesized as powders and Mg-stabilized Na^+ beta alumina both have high temperature weight losses that are not the result of the loss of water vapor. IR analyses with the beta alumina samples reveal multiple absorptions characteristic of bicarbonates/carbonates. Felsche (18) has identified x-ray diffraction lines as being due to sodium sesquicarbonate, $Na_3H(CO_3)_3 \cdot 2H_2O$. The decomposition of such a species is probably responsible for the sharp weight losses observed in the $70^\circ\text{--}115^\circ\text{C}$ temperature range. Li^+ beta alumina powders from Union Carbide crystals also have a high temperature weight loss that may be the decomposi-

tion of carbonates, although we have no clear evidence that it is.

COMMENTS

Each issue of the **Journal** will have a section of "Comments." In this section, we provide a means via short pieces, *i.e.*, one column or less, to applaud, dispute, or otherwise discuss the papers published in the **Journal**. Space will be provided for one response by the paper's author(s) to each comment.

Since space available in each issue for the "Comments" section is limited, it is important to be concise.

Comments should be sent to the Editor, Dr. Norman Hackerman, President's Office, Rice University, P.O. Box 1892, Houston, TX 77251.

Martensitic Transformation of Gd

S. Yamaguchi

(pp. 1145-1146, Vol. 129, no. 5)

A. E. Curzon¹ and **M. Gasgnier**²: The paper by Yamaguchi³ reporting martensitic transformations in Gd and Dy is open to criticism because it does not take into account numerous well-known results of other workers. Space restrictions preclude a full discussion. Important points are as follows.

1. As pressure is increased, the rare earths follow the structure-sequence hcp, Sm-type, dhcp, fcc.^{4,5,6,7} Sometimes, unstable structures can be "frozen in."⁴ Because the hcp and Sm-types of Gd and Dy have not been observed to coexist, it is even less likely that the hcp and fcc forms which are at opposite ends of the sequence should coexist.

2. Yamaguchi reports fcc Gd is paramagnetic and not ferromagnetic like the bulk phase. This is attributed to change in bond length but could be due to impurities.

3. The polytype sequence gives $a_0 = 5.10\text{\AA}$ ⁴ for fcc Gd. Yamaguchi obtains 5.51\AA , indicating that other elements are present.

The above points strongly suggest that impurities should be considered. The rare earth metals react readily with oxygen and hydrogen.^{4,8,9,10,11,12,13,14} The plane spacings of the strong reflections from Gd₂O₃ [bcc, space group T_h⁷ (Ia3)] agree to ~2% with those reported by Yamaguchi. The lattice parameter of fcc Gd calculated from the individual reported reflections³ ranges from 5.41 to 5.60Å, indicating an error of about 2%. Thus, the likely explanation of the results is that the reported fcc Gd and Dy are due mainly to strong reflections of the oxide R₂O₃ with the possibility of the presence of some hexagonal metal or of the dihydride RH₂ (fcc). Similar arguments apply to results for fcc Tb.¹⁵

Physicochemical Effects of Heating Gold Thin Films on Gallium Arsenide

S. Leung, L. K. Wong, D. D. L. Chung, and A. G. Milnes

(pp. 462-468, Vol. 130, no. 2)

A. J. McEvoy¹⁶ In the report by Leung *et al.*¹⁷ on interface effects on heating between a gallium arsenide substrate and an evaporated gold overlayer, etching of the substrate, dissociation of the semiconductor, diffusion of the dissociated species through the overlayer and consequent evolution of arsenic, and formation of a gold-gallium intermetallic were all noted. However, by scanning Auger spectroscopy, the presence of gallium and arsenic on the gold surface prior to heating was also established. While the dissociation may be initiated by the condensation of gold on the semiconductor surface, an effect of particular relevance for device structures in that it determines the Fermi level pinning in the initial stages of Schottky barrier formation^{18,19}, it does continue at ambient temperatures, as verified in the time-dependance measurements of Hiraki *et al.*²⁰ There it was established that ambient temperature interdiffusion eventually produces a non-abrupt interface between the semiconductor and the metal overlayer, extending over a depth of some 200Å.

In Schottky barrier photovoltaic devices, the metallization is limited to 100Å if it is to be sufficiently transparent. It is therefore thinner than other of those reported,^{7,20} and thin relative to the interdiffusion depth. It is known empirically that the deliberate introduction of an oxide layer between semiconductor and metal gives a higher Schottky barrier, and the resulting MOS solar cell is a more efficient device.²¹ Optimum oxide thickness is some 35Å, *i.e.*, significantly thinner than the interdiffusion layer formed at an intimate metal-semiconductor junction.²² The oxide does not completely suppress interdiffusion, however, and gallium and arsenic species have been detected by ESCA on the surface of a MOS cell. Nonetheless, the thermodynamic data²³ does establish the relative stability of the oxides of gallium and arsenic in contact with gold, so some inhibition of interdiffusion must occur.

In the literature on photovoltaic devices, the consistent approach is to consider the MOS cell as a planar sequence

of layers, with interfaces abrupt on the atomic scale. It is now suggested that the experimental evidence does not allow of such models. The role of the oxide may be the better to define the interface, so that the barrier characteristics are not unduly degraded by the ambient temperature interdiffusion process. It is noted that for silicon, where the MOS structure also displays superior photovoltaic behavior, a similar interdiffusion has been observed.²⁴

The conclusion is drawn that there is still a need for careful comparative microanalytical profiling of intimate Schottky barrier and MOS structures to determine the consequences of the presence of the oxide layer in the latter case, for the interfacial reactions and consequent interdiffusion. From those data, a more definitive theoretical understanding could arise, with consequences for device design.

I. Mojzes and R. Veresegyházy:²⁵ Gold and gold-based alloys are frequently used as contact materials to compound semiconductors. Contact technology involves high temperature heat-treatment. During this technological step, an interaction of the metallization with the semiconductor material to be contacted takes place. The investigation of this interaction is of high interest from point of view of the device parameters and the reliability of devices.

In the cited paper,¹⁷ the physicochemical effects taking place in the system Au-GaAs were investigated using the evolved gas analysis (EGA) technique, completed by various analytical methods. These techniques mentioned later were applied *ex situ*.

The character of the As₂ ion-temperature profile presented in the cited paper is in good agreement with our results^{26,27} published partly during the edition period of the cited paper.¹⁷ The giant peak, observed in both laboratories, found for the Au contact could be completely eliminated by coevaporating Ga with the gold contact material. The same effect was observed for other contact materials²⁷ and for the InP-Au system.²⁸ It should be noted that Ga in this relation could not be replaced by In.²⁸

Based on our earlier experiments, we concluded that the temperature belonging to these giant peaks does not depend on the heating rate or the thickness of the metal layer.²⁶ Concerning the effect of the heating rate Leung and co-workers found that it is smaller than the systematic error of temperature measurement. During the last year, we studied the role of the layer thickness. A definite dependence on the layer thickness was found. Some of our results are shown in Fig. 1. For comparison, results from the work of Leung *et al.* are also shown. These results are in good agreement. Based on these experimental results, one should conclude that the arsenic evolution temperature also depends on the heating rate. The effect of heating rate on the arsenic yield was also investigated.²⁶ Our results show that the arsenic yield depends on the heating rate. A higher heating rate causes lower arsenic yield for both the first and second heat cycle. During the EGA experiments, the evaporation of Ga was also monitored. In the case of GaAs, no Ga evolution was detected by us, either.²⁶ In the case of InP, a small evaporation of In was registered.²⁹ This is in good agreement with Guthbier's earlier results³⁰ obtained for the thermal decomposition of pure, *e.g.*, uncovered compounds.

Surface morphology and microstructural changes are also to be investigated. To investigate these phenomena, practically the same experiments have been carried out in our laboratory as are described by Leung *et al.* Au-GaAs

Fig. 1. Peak arsenic evolution temperature vs. layer thickness for Au-GaAs system. The points are averages of several measurements, the scattering was approximately $\pm 10^\circ\text{C}$. \square : Present work; heating rate $150^\circ\text{C}/\text{min}$. \circ : Present work; heating rate $50^\circ\text{C}/\text{min}$. \triangle : Results of Leung *et al.*; heating rate $25^\circ\text{C}/\text{min}$.

samples were quenched at several points of the heat cycle. Typical dendritic structures were obtained, when the samples were quenched at the peak arsenic evolution temperature (Fig. 7B of the work of Mojzes *et al.*²⁶). Surface morphology observed during our study was slightly different from those described by Leung *et al.* Different layer thicknesses, different sample preparation techniques, and different heat-treatment parameters are or may be responsible for this inconsistency. It should be noted that rectangular protrusions were also observed by us in the case of contact system with additional Ga.^{26,31} It may be that in the case of Leung *et al.* this amount of Ga originates from the decomposition of GaAs, because of the longer heat-treatment cycle used in their work. It is of technological interest to investigate the electrical characteristics of the processes taking place during the annealing. For this purpose, the *in situ* electrical resistance measurement,^{32,33} and the control of the barrier height³⁴ could be used. The heating rates which have to be used to obtain good quality ohmic contacts make the electrical measurements almost impossible. By using these techniques in the future, useful new information may be obtained. That is to say, no single technique provides a complete description of the processes that take place during the heat-treatment.

Summarizing our results, we conclude that the peak arsenic evolution temperature depends on the heating rate and layer thickness. The effect causes the giant As₂ peak which is not yet identified. Further experiments with other compounds and layer structures are in progress in our laboratory.

Fabrication of Via Holes in 200 μm Thick GaAs Wafers

S. P. Yenigallo and C. Z. Gosh

(pp. 1377-1378, Vol. 130, no. 6)

H. Beneking:³⁵ It should be mentioned that the fabrication of via holes is used for through connections of GaAs MESFET's since 1972 and was first presented in 1973.³⁶

we were able to measure the impedance of the via contact itself, the value being less than $\text{pH } 13$ and 0.2Ω , depending on the thickness of the gold covering.

Phosphorus-Doped Polycrystalline Silicon via LPCVD

I. Process Characterization

B. S. Myerson and W. Olbricht

(pp. 2361-2365, Vol. 131, no. 10)

A. Learn:⁴⁰ In the paper listed above, data are presented for the radial variation of growth rate of polycrystalline silicon phosphorus-doped during growth. Film growth was performed under low pressure (LPCVD) conditions using SiH_4 and PH_3 source gases. Similar growth rate variations were observed for semi-insulating polysilicon⁴¹ (SIPOS) and silicon dioxide⁴² grown at low pressure from $\text{SiH}_4/\text{N}_2\text{O}$ and SiH_4/O_2 reactions, respectively. The SIPOS growth rate characteristics were interpreted⁴¹ on the basis of the following sequence: reduction of SiH_4 to $\text{SiH}_2 + \text{H}_2$ at an oxygen containing site on the substrate surface, adsorption of SiH_2 on a silicon containing site where growth would normally occur, and reaction of SiH_2 with SiH_4 to form Si_2H_6 . The net effect of the SiH_2 is, therefore, to reduce the growth rate. If the SiH_2 concentration varies radially, then the growth rate will vary correspondingly. Slight modification to the SIPOS model leads to quantitative agreement with growth rate data for oxide.⁴² In this case, a proportionality for growth rate, GR, is derived as follows

$$\text{Gr} \propto d \frac{r_c^2 - r^2}{r_c d + r_w^2 - r^2} \quad [1]$$

where d is wafer-wafer spacing, r_c is the inner radius of the tube surrounding wafers, r_w is the wafer radius, and r is the radial position on a wafer. Wafer-center growth rate data for polycrystalline silicon from the subject paper are plotted in Fig. 4 as a function of wafer spacing. The solid line represents relationship [1], where $r_c = 2.0$ in., $r_w = 1.125$ in., and $r = 0$. The proportionality constant was determined by fitting the curve to the data point at $d = 0.15$ in. The correlation coefficient between theoretical and experimental points is near unity (0.997). A second test of relationship [1] is shown in Table I where observed and predicted radial variations near the wafer edge are compared.

⁴⁰Anicon, Incorporated, San Jose, California 95134.

⁴¹M. L. Hitchman and J. Kane, *J. Cryst. Growth*, **55**, 485 (1981).

⁴²A. J. Learn, *This Journal*, **132**, 390 (1985).

Fig. 4. Doped-polycrystalline-silicon growth rate at wafer center as a function of wafer spacing. The solid line is a plot of relationship [1].

Table I. Ratio of GR at wafer edge and center

Wafer spacing, d (in.)	Observed	Predicted at $r = r_w$
0.15	1.98	3.58
0.31	1.71	2.08
0.47	1.54	1.61
0.63	1.37	1.37

Agreement between predicted and observed values is good, particularly for the large d values. Part of the difference at small d may be accounted for by the inability to measure precisely at the wafer edge. As a matter of interest, relationship [1] predicts no radial variation for d equal to 1.37 in. For larger d , a lower GR at wafer edge than at wafer center is predicted. The reasonably close agreement between theory and experiment suggests that the models used for SIPOS and oxide may also be relevant to doped-polycrystalline silicon growth. Adsorbed-phosphorus sites could thus play the same role as oxygen containing sites. The fact that observable amounts of Si_2H_6 were detected, as reported in this paper, lends additional credence to the type of mechanism discussed above.

B. S. Meyerson:⁴³ There are several aspects of radical chemistry that must be discussed to properly respond to this comment. First, the overall reaction

is derived from observations⁴⁴ of chemistry in the gas phase, and is an insertion reaction of the SiH_2 diradical into SiH_4 . The two unbound electrons of the diradical insert across an Si-H bond in the silane molecule to produce Si_2H_6 . Our experiments have shown that silane, when adsorbed on the silicon surface, bonds to that surface via a dissociative adsorption, where a hydrogen is transferred to the surface, and the silane then bonds across the now free orbital to another site. Thus, although written as "bound" SiH_x , where $x < 4$, there are not $4 - x$ unbound and active electrons on the bound SiH_x . Chemisorbed SiH_2 is thus quite distinct from the gas phase spe-

⁴³IBM Corporation, Thomas J. Watson, Research Center, Yorktown Heights, New York 10598.

⁴⁴P. John and J. H. Purnell, *J. Chem. Soc., Faraday Trans.*, **69**, 1455 (1973).

cies as it is unlikely that an unbound and active electron pair exists.

Although one can propose this bound SiH_2 reacts with incoming SiH_4 to give Si_2H_6 , many other steps for Si_2H_6 formation are possible, such as the surface recombination of adsorbed SiH_3 . There is no *a priori* reason to assume SiH_2 is involved in the chemistry, if any occurs, that would take place on the surface.

Second, the rate of insertion of SiH_2 into phosphine has been measured by Blazejowski and Lampe⁴⁵ and was found to be roughly four times the rate of insertion of SiH_2 into silane. Were there silylene present on the surface, as argued in the comment, it would preferentially insert into and likely remove the phosphine from the surface, reacting to a lesser degree with silane. Thus, any SiH_2 present would serve to primarily interact with adsorbed phosphine. This directly contradicts our observation that the presence of silane near a phosphine saturated silicon surface fails to produce any effect. Were phosphine acting as an active site for the production of SiH_2 from SiH_4 , as argued in the comment, rapid insertion of SiH_2 into the P-H bond of adsorbed phosphine would be expected, yet was not observed. It was found⁴⁶ that with phosphine present on the Si surface, no silane adsorption or decomposition occurred. However, with a bare Si surface, silane dissociated and adsorbed even at room temperature, until saturation coverage by resulting molecular fragments was obtained. Thus, in fact, the silicon surface itself promoted silane decomposition, while phosphine suppressed it. Furthermore, as the comment argues that phosphine promotes the decomposition of SiH_4 , eventually producing Si_2H_6 , it predicts an increase in silane consumption (forming Si_2H_6 rather than film) as phosphine on the surface should promote silane pyrolysis. The opposite of this is observed, as noted in Fig. 5 of our work. When phosphine is added to the silane LPCVD process, silane consumption decreases significantly.

Finally, the presence of Si_2H_6 as reported in our paper is attributed by us to the homogeneous, gas phase pyrolysis of silane.⁴⁴ As SiH_2 insertion into SiH_4 is well known to produce Si_2H_6 in the gas phase, its presence is expected. In summary, we find the deposition mechanism proposed in the comment at odds with numerous aspects of our experimental data, and thus implausible.

Polydithienothiofene: A Novel Polymer Electrode for Lithium Batteries

M. Mastragostino

Istituto Chimico "G. Ciamician," University of Bologna, Bologna, Italy

B. Scrosati*

Dipartimento di Chimica, University of Rome, "La Sapienza," Rome, Italy

The recent discovery that conductive polymers can be doped electrochemically has opened the possibility of using these materials as electrodes in rechargeable batteries. In this respect, polyacetylene has been the most studied polymer and various papers have been published on the behavior of p-doped (cathode) or n-doped (anode) polyacetylene in lithium batteries (1-4). The most of the results indicate that polyacetylene suffers of poor coulombic efficiency and of instability and thus the possibility of its use as a cathode in high-energy, long-life lithium batteries, is now somewhat doubtful (4-6). However, the interest in polymer electrodes remains high and various new electrochemically active polymers are presently under investigation.

In this paper we report preliminary results on the electrochemical behavior of doped polydithienothiofene (pDTT), whose chemical structure is shown in Figure 1.

Figure 1- Chemical structure of polydithienothiofene.

As previously described (7,8), this conductive polymer can be prepared electrochemically on a Pt or on a SnO₂-coated glass support, by constant current electrolysis of a methylene

chloride solution containing the monomer dithieno (3,2-b:2',3'-d) thiofene (DTT) and MX (M⁺=N(Bu)₄⁺, X⁻=ClO₄⁻, PF₆⁻) as the supporting salt. The oxidation of the monomer starts at 1.2V vs. SCE with the growth on the electrode support of an electroactive adherent film. The polymer so formed may be repeatedly reduced to the neutral state and oxidized to the conducting state with a cycling regime which involves about 20% of the total charge consumed in the initial electrochemical preparation. The electrochemical doping-undoping process is accompanied by a color change since the oxidized film is black and the neutral film is red (7,8).

The good cyclability and the color change of the electrochemical reaction open the possibility of using pDTT as electrode in rechargeable batteries and in electrochromic displays (8). In this prospective, we have examined the behavior of pDTT in a cell having a Li counter electrode, a Li reference electrode and a solution of lithium perchlorate in propylene carbonate (LiClO₄-PC) as the electrolyte.

In Figure 2 are shown the 1st and the 9th consecutive cyclic voltammograms of a pDTT electrode in the LiClO₄-PC electrolyte. The pDTT electrode used for these voltammograms was electrosynthesized on Pt in the oxidized form for a total charge of 450 mC and then reduced to the neutral state, in a N(Bu)₄⁺ClO₄⁻, CH₂Cl₂ solution.

The voltammograms of Figure 2 reveal that the polymer may be doped both anodically (presumably with ClO₄⁻ as the p-doping specie) and cathodically (presumably with Li⁺ as the n-doping specie).

However, while the p-doping process shows a narrow separation and a good reproducibility of the oxidation and reduction waves, the peaks of the n-doping process are different in shape and far apart. This indicates that favourable kinetics are to be expected for the p doping-undoping process only.

Figure 2-Cyclic voltammograms of a pDTT electrode in the LiClO_4 -PC electrolyte. Cycle 1 starts with a neutral pDTT electrode from 2.5V vs. Li in the anodic direction. Scan rate: 40 mV/s.

This suggests that pDTT might be considered as a good cathode material in lithium, organic electrolyte batteries. Some preliminary results obtained in our laboratories confirm this suggestion since cells of the type $\text{Li}/\text{LiClO}_4\text{-PC/pDTT}$ may be cycled at a constant current of the order of $50 \mu\text{A}/\text{cm}^2$ with charge-discharge coulombic efficiencies of the order of 75%.

Interpretation of Sodium-Sulfur Cell Characteristics Using an Alternating Current Resistance Technique

Bradley R. Karas*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

An alternating current (ac) resistance technique for sodium-sulfur cells is described. The method has been applied to central sodium and central sulfur cells with between 16 and 650 Ah capacity. The shape of the ac charge resistance-capacity plot has been correlated with resistive layer composition. Anomalies in direct current (dc) resistances for oriented-mat sulfur electrode cells are explainable in conjunction with ac analysis. The increased sensitivity of ac compared to dc measurements has been utilized to identify incipient electrolyte failure and sodium electrode problems not discernable by the latter technique.

The sodium-sulfur (beta) cell is comprised of liquid sodium and sulfur electrodes separated by a solid sodium beta- or beta"-alumina electrolyte. Interest in this secondary battery arises from its high energy density, efficiency, achievable current densities, and the availability and cost of the electrode components. Since it was first described by Kummer and Weber in 1967 (1), the beta cell has reached a fairly advanced state of development (2). Typical cells are tubular, and both central sodium (sodium contained within the beta" electrolyte) and central sulfur designs exist. Considerable development effort has been devoted not only to the sodium-sulfur cell itself, but also to the individual cell components (2). For example, alternating current (ac) impedance techniques have been applied to the electrolyte (3), sodium-electrode in sodium-sodium cells (4), and the sulfur electrode (5). Although ac impedance or resistance methods have been utilized in other battery systems (6), little work in this area has been performed on beta cells (13). This paper describes such an ac technique developed to analyze and evaluate sodium-sulfur cell performance.

Cell Operation and Description

During cell discharge, sodium is oxidized at the anode (negative electrode). The sodium ions are transported through the electrolyte to the cathode compartment where sulfur is reduced. Electrons flow from the sodium to the sulfur electrode via an external circuit. The low electronic conductivity of sulfur is overcome by incorporating a conductive carbon mat in the sulfur-electrode compartment. It is generally accepted that the initial reaction product is Na_2S_3 (2). At the cell operating temperature of 330°C, sulfur and Na_2S_3 are immiscible liquids. Thus, a "two-phase" region yielding a constant cell open-circuit voltage (OCV) of 2.08V is defined and exists until all the sulfur has reacted. Continued discharge produces lower polysulfides, which are miscible. At this point, the cell potential begins to drop and a "one-phase" region is created. A polysulfide composition corresponding to Na_2S_3 represents complete discharge. The existence or absence of Na_2S_3 as a discrete species in polysulfide melts is disputed. The formulation is used here simply to refer to a quantity of charge passed, sufficient to produce an overall sodium to sulfur ratio of 2:3 in

the cathode compartment (7). Discharge much beyond this point produces insoluble polysulfides at the temperatures normally employed for cell operation (2, 7a, 8).

The electrode processes are reversed during cell charging. If sodium polysulfide oxidation occurs directly at the solid electrolyte/conductive mat interface, then the beta"-alumina electrolyte becomes passivated with a layer of elemental sulfur when the cell enters the two-phase region. The high sulfur resistivity hinders further recharge (2). This problem can be circumvented by the use of a high resistivity, porous matrix adjacent to the electrolyte surface (9). This matrix is commonly referred to as the "resistive mat" or "barrier layer."

Most of the cells utilized in this study were 16 Ah with respect to Na_2S_3 , central-sodium laboratory cells. The letter preceding the cell number indicates the type of seals employed, and the last letter designates the sodium-fill technique. The cells were either filled electrolytically (10) from reagent-grade NaNO_3 , or via vacuum filling of the liquid metal. For example, B800L contained two thermo-compression bonded seals and was vacuum filled with liquid sodium. The "800" refers to the cell number. The sulfur electrode was cast and contained sulfur purified by the Bacon-Fanelli process (11). Union Carbide Thornel VMA® carbon fiber as the conductive mat, and a carbon- or ceramic-based resistive layer. Carbon-based resistive layers were made from 0.006 in. thick nonresilient paper, hereafter referred to as NRP-6, purchased from Fiber Materials, Incorporated (Biddeford, Maine). Two types of ceramic-based resistive layers were used, Saffil® alumina fiber (Imperial Chemical Industries, England), and alumina-based papers (F. K. Fiber, Incorporated, Wilmington, Delaware) designated Al-2 and Al-4 which were nominally 0.020 and 0.040 in. thick, respectively. The electrolytes were 99% beta"-alumina and had an ~3 $\Omega\text{-cm}$ 330°C specific resistivity.

A Hewlett-Packard 9825B minicomputer was used to control an automated test system. Laboratory cells were cycled at 330°C and a constant direct current (dc) of 108 mA/cm^2 with respect to the electrolyte area. Each cell operated between individually preset voltage limits. The system monitored each cell voltage every 3 min. Every 27 min, the cells were removed from load and placed on open circuit. At the conclusion of the 3 min open-circuit period, the voltage was again recorded and the cell returned to test. The difference between the OCV and load

* Electrochemical Society Active Member.

voltage at the same depth of discharge (or charge) divided by the current yielded the dc resistance. The dc resistance calculated in this manner will contain a contribution from concentration polarization effects. This fact should be borne in mind.

Alternating Current Resistance Technique

Alternating current resistance measurements were performed concomitantly with dc testing. The experimental arrangement is depicted in Fig. 1. An ac signal was generated by a Princeton Applied Research (PAR) Model 121 lock-in amplifier/phase detector or a Model 5204 lock-in analyzer. This signal flowed across an in-series, 1 k Ω carbon-film resistor to the cell. The 1 k Ω resistor fixed the ac current and prevented direct current from passing through the ac circuit. Two voltage probes were connected between the cell and the lock-in amplifier. The lock-in amplifier output was fed to a Houston Instrument Superscribe 4950, dual-pen, strip chart recorder. The PAR Model 5204 has analog outputs for both the signal-phase and magnitude, whereas the Model 121 has only a magnitude output. In the latter case, the phase was read off a front-panel meter. Measurements performed at 1000 Hz on a 100 Ω resistor yielded almost no phase shift between the reference signal and measured ac voltage. Thus, the dc output from the lock-in amplifier was proportional to the ohmic portion of the ac impedance. Both lock-in amplifiers were checked in a similar manner.

To prevent disruption of dc testing and measurements, the ac signal was maintained at less than 2 mA_{rms}. This implies that the ac voltage between the probes was typically less than 100 μ V_{rms}. The automated recording system has a 1 mV sensitivity. Further, the 10 Ω limiting resistor used in the dc circuit is at least 100 times larger than the measured cell resistance. Thus, the ac signal flowing through the dc circuit should be minimal. Ideally, the ac resistance, R_{ac} , should be insensitive to dc effects or flow. Most cells display little difference in R_{ac} whether under load or open-circuit conditions (*vide infra*). If, however, dc effects are present, it is expected that R_{ac} will increase when the cell is removed from load during discharge and decrease under similar circumstances during charge.

The above technique has been applied to nonlaboratory central sodium (100-650 Ah) and central sulfur (25-150 Ah) cells as well. Measurements on these cells were made similarly, except the low, \sim 1-3 m Ω , resistance of the 650 Ah utility cell required a PAR Model 124A lock-in amplifier. The Model 124A has an increased ac reference signal and enhanced detector sensitivity relative to both the Model 121 and 5204.

Fig. 1. Apparatus for four-probe ac resistance measurements. In measurements on laboratory cells, the dc current leads are connected to a Hewlett-Packard 9825B minicomputer-controlled power controller. The 9825B is interfaced to a digital voltmeter which monitors cell voltage every 3 min.

Results and Discussion

The sections below detail the effects of cell components and quality on the resistance fingerprint.

Laboratory cell B800L was examined in half-decade frequency increments between 10 and 100,000 Hz at 1 Ah intervals during both charge and discharge. In these experiments, the PAR Model 121 was used as both the signal generator and detection device between 10 and 1000 Hz, and the signal generator for the Model 5204 detector between 1000 and 100,000 Hz. Data obtained from both instruments at 1000 Hz generally agreed to within 10%. The experimental setup was checked out by measuring the resistance and phase dependence of 1 and 0.1 Ω resistors. Measured resistances were within 10% of the actual values and phase shifts less than 10 $^\circ$ were detected. More precise phase shifts are difficult to obtain with a lock-in amplifier. Crossover from the Model 121 to the 5204 was necessitated by inductance in the Model 121, the effects of which became evident at \sim 10,000 Hz.

Load measurements on cell B800L were performed at 10, 100, and 1000 Hz in the 3 min interval preceding an open-circuit period. The depth of discharge varies only 0.1 Ah per 3 min. The open-circuit period was extended to 9 min in order to examine the desirable frequency range. Less than 5% deviation was detected between the load and open-circuit impedance values. Figures 2 and 3 present frequency vs. impedance plots for charge cycle number 266 and discharge cycle number 267, respectively. Little phase shift, $< 10^\circ$, was observed in these experiments except at high depths of discharge, $> 80\%$, and even then it was only 15 $^\circ$ -20 $^\circ$ at 100,000 Hz. When present, the phase shifts were capacitive; however, the general flatness of these curves indicates that capacitive and inductive contributions to the impedance are minimal. Therefore, single frequency measurements at any frequency between 10 and 3000 Hz can be utilized to probe cell performance.

The discharge-charge resistance behavior for cell B800L is shown in Fig. 4. Data were recorded in cycle 353. The time increment between each datum is 30 min, and the ac frequency was 1000 Hz. The drop in resistance at the beginning of discharge (Fig. 4a) is attributed to removal of sulfur deposited during the previous charge cycle (*vide infra*). Alternating current and dc resistance values differ due to electrode polarization effects and the inclusion of concentration polarization effects to the dc value. These arise because the dc measurement is not made rapidly enough, *i.e.*, electrochemical changes occur during the measurement time interval. Although no discernable break was seen in the dc data during charge (Fig. 4b), a sharp increase was detected at \sim 60% depth of discharge by the ac measurement. The resistance rise coincides with recharge into the two-phase region and oxi-

Fig. 2. Plots of ac impedance vs. frequency for cell B800L. The cell operated at 330 $^\circ$ C and 108 mA/cm 2 . Data were recorded during charge cycle 266.

Fig. 3. Alternating current impedance-frequency graphs for cell B800L. Operating conditions same as those in Fig. 2. Data were collected during discharge cycle 267.

dation of sodium polysulfide to sulfur. The resistance break indicates that the resistive layer is not completely effective in preventing sulfur deposition on the beta"-alumina electrolyte surface.

Resistive layer materials.—Examination of ac charge resistance vs. depth of discharge plots indicates that the "hump" or "break" which occurs during cell charging is more pronounced, *i.e.*, greater in magnitude and narrower in breadth, in cells containing a NRP-6 resistive mat (Fig. 5a), and flatter and broader in cells with Saffil- or alumina-resistive layers (Fig. 5b). A possible explanation is afforded by the equivalent-circuit model of Brennan (12). Brennan divided the sulfur electrode compartment into 1000 annular segments, and then calculated the effect of varying felt resistance on electrochemical activity. He found that when r_2 , the resistive mat resistivity, equaled r_1 , the conductive mat resistivity, that the reaction rate was greatest at the electrolyte/resistive mat interface. As r_2/r_1 increased, the percent reaction occurring at the solid electrolyte/resistive mat interface decreased, and a reaction spike formed at the resistive mat/conductive mat interface.

When the resistive and conductive mats are NRP-6 and Thornel VMA, respectively, r_2/r_1 is ~ 600 (9). One might presume that very little reaction should occur at the NRP-6/beta"-alumina interface. However, NRP-6 has a finite electrical conductivity; therefore, some reaction still occurs at the electrolyte surface. During charge, sulfur coats the beta"-alumina surface, and an abrupt change in ac resistance occurs. Whether or not this phenomenon is de-

Fig. 4. Cell resistance vs. percent discharge (with respect to Na_2S_3) for cell B800L. The cell contains an unoriented-sulfur electrode and a NRP-6 resistive layer. Data from cycle 353. a: Discharge-alternating current resistance (+) at 1000 Hz. See text for dc resistance. (\square): calculation technique. b: Same as in a, except charge cycle.

Fig. 5. The effect of resistive layer composition on charge resistance. a: DC (\square) and ac (+) resistance for cell containing carbon-based resistive layer. b: Same as in a, except alumina-paper resistive layer cell. Alternating current resistances measured at 1000 Hz.

tected in the dc calculation is dependent on the severity of sulfur deposition (*cf.* Fig. 4b and 5a).

In contrast, when a Saffil- or alumina-resistive layer is employed, r_2/r_1 approaches 10^{10} . These resistive layers act as electronic insulators. In effect, the electrochemical reaction takes place at the resistive mat/conductive mat interface. The increased surface area of this interface compared to the electrolyte surface area makes it much more difficult to deposit a continuous sulfur blocking layer the entire length of the cell. Therefore, the charge resistance increase should be more gradual (Fig. 5b). The ideal curve shape is one in which no break and no resistance increase occurs. Although cells have been constructed and tested which display only a minimal break, such as B857L shown in Fig. 5b, all cells display a gradual resistance increase during cell charging.

Conductive mat orientation.—The standard laboratory cell sulfur electrode was manufactured by shredding the Thornel VMA conductive mat, twisting the mat fibers together, adding the resistive layer, and molding. Each electrode consisted of three sections in which the mat fibers were randomly oriented. A new electrode was developed which consisted of oriented-mat segments. Mat orientation within each segment was radial and axial. Orientation was achieved by proper manipulation of the layered bulk mat. Cells containing the new electrode had lower resistance, improved chargeability, and increased efficiency, *e.g.*, 91% vs. 87% for oriented- and non-oriented-sulfur electrode containing cells, respectively, operating at 330°C and 108 mA/cm².

Figure 6 presents resistance vs. percent capacity plots for cell B888L. This cell contained an oriented-sulfur electrode and a Saffil-resistive layer. The improved chargeability of cells with oriented electrodes can be seen by comparing the discharge inception points in Fig. 4a and 6a and the final charge depths. Further, the improved chargeability was achieved with an ~ 140 mV lower cutoff

Fig. 6. Cell resistance vs. percent discharge for cell B888L. The sulfur electrode was comprised of oriented-conductive mat fibers and a Saffil-resistive layer. Data from cycle 26. a: Discharge; DC (\square) and ac (+) resistances. b: Charge; symbols have same meaning as in a. Alternating current resistances measured at 1000 Hz.

voltage in cell B888L than in cell B800L. Also note the reduced sulfur polarization effect in cell B888L at the beginning of discharge and end of charge compared to cells B800L (Fig. 4) or A834L (Fig. 5a, charge only). Both of these latter two cells contained nonoriented-sulfur electrodes.

Other than magnitude, the ac resistance plots for cell B888L were similar to those presented for cell B800L. The dc behavior, however, has been considerably altered. Cell B800L displays a gradually declining discharge resistance. In contrast, as cell B888L neared the two-phase/one-phase transition and then entered the one-phase region, the dc resistance increased, displayed a broad maximum, and then declined again. A similar type of behavior has been reported by Mennicke on metal-oxide containing electrodes (13). Although the resistance increase reported herein was not as great as that discussed by Mennicke, increases as large as ~25% have been observed. A more perplexing situation is shown in Fig. 6b, where the dc charge resistance decreased upon nearing the one-phase/two-phase transition. Declines up to ~20% have been observed. In contrast to the decreasing dc resistance, the ac charge resistance continued to increase throughout this period.

The sodium-sulfur cell resistance contains contributions from the leads, carbon-fiber to sulfur canister contact resistance, sulfur electrode, beta" electrolyte, and a polarization resistance due to electrochemical processes. If contact resistances are lumped together with the sulfur-electrode resistance, the major contributors to cell resistance are the sulfur electrode and beta" electrolyte (14). Therefore, a crude ac sulfur-electrode resistance can be calculated by subtracting the electrolyte resistance from the overall cell resistance. Aging studies and pre- and post-test resistivity measurements on RS-1 electrolytes substantiate the validity of this type of approach (15).

Breiter and Dunn developed a sulfur electrode model which allows direct calculation of a sulfur electrode resistance (16). Manipulation of their equations and utilization of Cleaver *et al.* sulfur/polysulfide data (17) allow calculation of the conductive mat resistivity. A 330°C resistivity value of 2.8 and 0.45 Ω -cm was obtained for the standard- and oriented-sulfur electrode, respectively. Out-of-cell resistivity measurements employing Pt electrodes confirmed these values (18).

Brennan studied the effects of fiber orientation on cell recharge characteristics, in particular, mat resistivity and reaction zone thickness (19). Using Le Carbone RVC 4000® carbon felt, he found an ~2.5-fold increase in resistivity between parallel and perpendicular mat orientations. Orientations are referenced to the direction of current flow. The discrepancy between his value and the factor of ~6-7 reported herein results from the use in this study of an oriented and a completely unoriented electrode. In contrast, both Brennan's electrodes had oriented fibers. Further, differences in carbon fiber-sulfur canister and interfiber contact resistances exist between the present electrodes and Brennan's electrodes (18, 20). Brennan also stated that the lower the mat resistivity, the greater the percentage reaction located adjacent to the electrolyte. The high electronic resistivity of Saffil- or alumina-resistive layers implies that conduction through these porous matrices is via parallel ionic paths (16). The resistive layers can, therefore, be considered extensions of the solid electrolyte.

Based on these considerations, more reaction should occur at the electrolyte/conductive mat interface in cells with oriented-sulfur electrodes. At the current density employed in this study, mass-transport limitations exist. During cell discharge, melt adjacent to the electrolyte becomes overreduced, "overdischarged," with respect to the bulk melt. Overreduction refers to a condition in which polysulfides lower than Na_2S_5 are formed when sulfur still exists within the melt. This lowers the working voltage. In the open-circuit periods, the melt reequilibrates. The calculated dc resistance is thus larger than expected and increases with time near the two-phase/one-phase

transition. This is because the potential of Na_2S_x ($x < 5$) is lower than the constant two-phase potential of 2.08V (21). In the one-phase region, the potential difference between the various polysulfides formed decreases, and R_{dc} , the dc resistance, declines.

Upon charge inception, R_{dc} increases as expected. Again, however, diffusional limitations are present and the melt near the electrolyte surface becomes overoxidized. When Na_2S_5 first forms, the OCV jumps abruptly to near the two-phase value of 2.08V. Sudden increases as large as ~60-70 mV have been observed between two successive open-circuit periods. The working voltage remains relatively constant, however. This causes a drastic reduction in R_{dc} . Direct current resistance plots are relatively flat in the two-phase charge region, whereas ac resistance curves continue to increase. This is because the ac measurement is sensitive to changes in melt composition. The ac resistance behavior of cells containing oriented- and unoriented-sulfur electrodes is similar. The disparate dc resistance traits are an artifact of the manner in which the dc resistance is calculated.

Electrolyte related phenomena.—Since the lock-in amplifier output is recorded on a strip chart recorder, R_{ac} can be determined for any point during the discharge/charge cycle. This capability is unaffected whether or not direct current flows. Changes in R_{ac} within a cycle, between cycles, or during open-circuit periods are easily detected and most informative. Figures 7a and 7b display discharge and charge, respectively, ac resistance behavior for a typical sodium-sulfur cell containing an unoriented-sulfur electrode. Resistance is presented on the ordinate and time on the abscissa. The $|x|$ symbols represent open-circuit periods and were separated by 30 min or 0.9 Ah. As can be seen in the figures, passage of direct current had little effect on the ac measurement. Furthermore, the ac changes which did occur

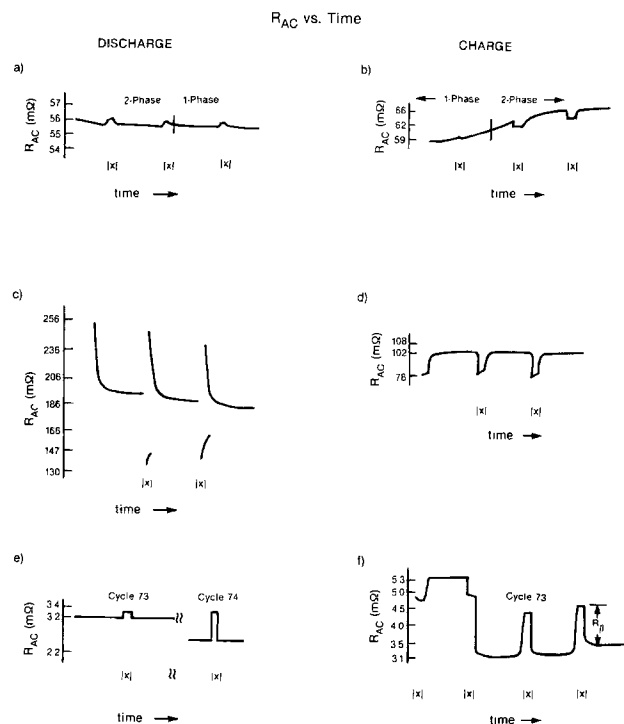

Fig. 7. Alternating current resistance-time response traces. Discharge depicted in a, c, and e, and charge in b, d, and f. Traces shown in a and b are for a typical laboratory cell with an unoriented electrode. Cell operated at 330°C, 108 mA/cm². The $|x|$ delineate open-circuit periods and are separated by 0.9 Ah. The effect of a sodium-side electrolyte film on ac-cell resistance is shown in c and d. Operating conditions were the same as in a and b. Figures e and f are data collected on a 650 Ah utility cell. This cell operated at 350°C and 150 mA/cm² discharge, 105 mA/cm² charge rate. The $|x|$ are separated by 37.8 Ah during discharge and 27.0 Ah during charge. The discharge data were recorded at ~66% depth of discharge. f: Cycle 73 charge.

during the open-circuit periods were abrupt, *i.e.*, ohmic in nature.

Asymmetric behavior has been observed in sodium-sulfur cells and is characterized by a greater discharge than charge resistance (10, 22). This phenomenon depends upon ceramic electrolyte composition, its phase, and previous handling, and has been attributed to film formation on the sodium side of the solid electrolyte. The presence and level of certain impurities within the beta' electrolyte or sodium can induce asymmetry. Recently, the distribution and composition of the film has been determined (23).

Alternating current resistance measurements on asymmetric cells also showed enhanced discharge resistances. In contrast to "normal" cell behavior, however, a large dc effect was observed, *i.e.*, passage of direct current affected the ac resistance value. During discharge open-circuit periods, R_{ac} varied by as much as 50% from the load value. An ~30% decrease is depicted in Fig. 7c for a cell with unusually high calcium species present in the sodium electrode (15). The resistance was not constant and displayed diffusional limitations. Similar trends were seen during charge, as shown in Fig. 7d. Differences in the discharge load-resistance behavior are also readily apparent (cf. Fig. 7a and 7c). These arise from changes in the electrolyte surface film and changes in sodium wetting, which may or may not be related to the surface film (10, 22, 23).

Frequency dependence of the ac resistance has been detected in asymmetric cells; however, the resistance time-dependent nature makes quantification difficult (22). Although the magnitude of the dc effect varied, cells with sodium-side problems were characterized by the ac-resistance traits depicted in Fig. 7c and 7d. This is in sharp contrast to "normal" cell behavior and to cells with sulfur-electrode problems. The latter situation is discussed elsewhere (8).

Alternating current resistance measurements on 25-650 Ah central sulfur or central sodium cells were very similar to those described above on laboratory sodium-sulfur cells. The same discharge/charge characteristics, *e.g.*, electrode orientation effects, were found regardless of cell size or configuration.

Examination of utility cell F09115, 650 Ah capacity, was conducted between cycles 72 and 75. This cell operated at 350°C and was discharged and charged at 150 and 105 mA/cm², respectively. The ac resistances at the end of cycles 72D and 72C (D represents discharge, C charge) were ~3.2 and ~4.7 mΩ, respectively. The next discharge cycle was relatively uneventful until ~65% depth of discharge was reached (discharge limit was 90%). At this point, R_{ac} began to fluctuate. No dc effect was apparent and R_{ac} at the end of the cycle was ~3.4 mΩ. Alternating current resistance oscillations of the sort detected are usually associated with cell failure. This is evidenced by abnormalities in the dc load voltage-time relationship and/or a decrease in cell voltage to zero. In the present example, however, the voltage appeared normal.

The subsequent charge cycle began normally. However, at ~33% depth of discharge (charge limit was 18%), R_{ac} dropped drastically (Fig. 7f). A dc effect was apparent and opposite in direction to that previously observed. Interestingly, for a given depth of discharge, R_{ac} was approximately the same in this cycle, 73C, when no direct current flowed as in previous charge cycles. In fact, during an extended open-circuit period at the conclusion of the cycle, R_{ac} was ~4.7 mΩ. The next discharge cycle, 74D, was initiated, and a large dc effect was noted (Fig. 7e). Again, as in the preceding charge cycle, the resistance increased during open-circuit periods and at the same depth of discharge matched previous discharge cycle resistances.

Specific resistivity measurements on similar ceramics yielded an electrolyte resistance of ~1.1 to ~1.3 mΩ. This value corresponded to the magnitude of the dc effect. It is felt that the electrolyte underwent a noncatastrophic failure which was detected in the ac, but not the dc, measurement. When direct current flowed, sodium was pushed

through the flaw and the beta' electrolyte was partially shorted from the sodium side. Hence, R_{ac} dropped. Interruption of dc flow broke the sodium short and reintroduced the electrolyte resistance into the ac measurement. Another indication of a beta'-alumina ceramic fracture would be a reduction in cycle-to-cycle capacity. During this period, however, the capacity did not follow any specific trend. Comparison of R_{dc} at a particular depth of discharge in this and 10-15 cycles previous revealed a decrease in R_{dc} . This is also an indication of a short.

Conclusion

An alternating current resistance technique for sodium-sulfur cells has been described. The trends observed were independent of size (16-650 Ah), configuration (central sodium or central sulfur), and seal type. Except for severely asymmetric cells, no frequency dependence was observed in 16 Ah laboratory cells between 10 and 100,000 Hz. Alternating current resistance analysis has proven most useful in identifying resistive mat and electrode orientation effects on cell performance. Furthermore, ac measurements are more sensitive to electrolyte failure, asymmetric contributions, and changes in cycle-to-cycle behavior than traditionally used techniques. The method has been applied to the investigation of current density, temperature, and polysulfide composition effects on cell performance and life (8).

The Effects of Current Density, Temperature, and Discharge Beyond Na_2S_3 on Sodium-Sulfur Cell Performance and Life

Bradley R. Karas* and Randall N. King

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The effects of current density (54-865 mA/cm²), temperature (330°-355°C), and discharge depth (Na_2S_3 to $\text{Na}_2\text{S}_{2.4}$) on sodium-sulfur cell efficiency, resistance, capacity, and longevity are presented. Equal discharge and charge cycle times obtained on 16 Ah laboratory cells at 865 mA/cm² and 335°C demonstrated the resistive layer effectiveness in preventing sulfur passivation of the beta"-alumina electrolyte surface during cell charging. Elevated temperatures increased cell efficiency ~3%/10°C, decreased resistance, and increased capacity. A group of cells operating at 216 mA/cm², twice the standard current density, and 330°C have obtained ~700 cycles, ~900 Ah/cm², with little performance deterioration. The cells are ~82% efficient and display ~80% of theoretical capacity. Alternating current resistance analysis of typical laboratory cells revealed an increase in discharge resistance occurred when cells were cycled between Na_2S_3 and Na_2S_2 . Correlations with the sodium-sulfur phase diagram indicate the resistance rise was due to precipitation of Na_2S_2 . Upon subsequent charge inception, the ac resistance dropped. However, an increased two-phase charge resistance was recorded. This suggested that Na_2S_2 deposition occurred at the resistive-mat/conductive-mat interface.

The sodium-sulfur (beta) cell has a myriad of potential uses, for example, load leveling, vehicle propulsion, or satellite power. The exact application determines the cell size, power requirements, and cycling conditions. Circumstances will arise, however, which will necessitate aggressive cell operation. The effects of current density (54-865 mA/cm²), temperature (330°-355°C), and discharge level (between Na_2S_3 and $\text{Na}_2\text{S}_{2.4}$) on sodium-sulfur cell performance and life are discussed herein.

Experimental

Tubular, central-sodium cells of nominally 14-16 Ah capacity were utilized in this study. The sulfur electrode contained a Union Carbide Thornel VMA® carbon-fiber conductive-mat and either a Saffil® or alumina-fiber paper resistive layer. Incorporation of a porous, high resistivity layer adjacent to the beta"-alumina electrolyte prevents deposition of a passivating sulfur layer on the solid electrolyte during cell charging (7, 11). Saffil, an alumina-based material, was obtained from Imperial Chemical Industries (England), and the alumina-fiber papers from F.K. Fiber, Incorporated (Wilmington, Delaware). Two styles of sulfur electrode were employed: oriented and nonoriented. Unoriented-sulfur electrodes were formed by shredding the conductive mat, twisting the mat fibers together, adding the resistive layer, and finally casting with sulfur. This process yielded an electrode comprised of three randomly oriented sections. Oriented-fiber electrodes were produced by appropriate manipulation of the layered bulk mat (1). The fiber orientation within the sulfur electrode was both radial and axial.

The electrolyte was polycrystalline beta"-alumina (99%), with an ~3 Ω-cm 330°C specific resistivity. The cells utilized in this study contained thermocompression-bonded seals and were vacuum filled with liquid sodium.

Cells were cycled under constant current conditions between individually preset voltage limits at 330°-355°C. Current densities are referenced to the 18.5 cm² β'-

alumina electrolyte. An automated test system monitored cell voltage every 3 min. Cells were placed on open circuit for 3 min every 0.5h. Cycles performed at current densities ≥400 mA/cm² employed a 15 min interval between open-circuit periods. Direct current (dc) resistances were calculated from the difference in open-circuit voltage (OCV) and load voltage at the same depth of discharge divided by the load current (1).

Simultaneous alternating current (ac) resistance measurements were performed with a lock-in amplifier. Details of the experimental arrangement were described previously (1), and will therefore only be briefly summarized herein. Appropriate precautions were taken to prevent interaction of the dc and ac systems. The alternating current signal, generated by the lock-in amplifier, flowed across an in-series limiting resistor to the cell. Two voltage probes were connected between the cell and lock-in amplifier. Single frequency measurements between 10 and 100,000 Hz on 16 Ah cells revealed that, except for severely asymmetric cells, no frequency dependence of impedance was observed (1). This indicated that capacitive and inductive contributions to cell impedance were minimal. Therefore, ac measurements were conducted at 1 kHz.

Efficiencies were the quotient of energy out during cell discharge and energy in during cell charge. Capacities were determined by dividing the ampere-hours removed during discharge by the theoretical capacity. An effective polysulfide composition corresponding to Na_2S_3 was the theoretical limit. Oei (2, 3) and Janz *et al.* (4) have shown that, at temperatures greater than ~100°C, Na_2S_3 is a eutectic mixture of Na_2S_2 and Na_2S_4 . While this is generally accepted, there remains some controversy over the exact polysulfide ion composition and distribution within the melt (5, 6). The sodium trisulfide formulation used herein simply refers to a quantity of charge passed sufficient to produce an overall sodium-to-sulfur ratio of 2:3 in the sulfur-electrode compartment. Likewise, similar chemical symbolizations, for example, $\text{Na}_2\text{S}_{3.4}$ or $\text{Na}_2\text{S}_{2.6}$, indicate

* Electrochemical Society Active Member.

sodium-sulfur ratios, not necessarily discrete polysulfide species.

Results and Discussion

Current density and temperature.—The intent of this study was to evaluate cell quality, and in particular, to assess resistive layer performance and durability vis-à-vis aggravated cycling regimens. Identical discharge and charge current densities were utilized in each test. Current densities from 54 to 865 mA/cm² were examined between 330° and 355°C; normal operating conditions were 330°C and 108 mA/cm². The highest cycle rate, 865 mA/cm², was tested only at 335°C. When operated at current densities ≥ 400 mA/cm², the cells were placed on open circuit every 15 min to increase the number of open-circuit data points. A 16 Ah cell operating at 108 mA/cm² requires ~12-14h per complete cycle (both charge and discharge), and typically yields 14 or 15 open-circuit voltage points per half-cycle, i.e., for the discharge or charge half-cycle. Operation at 432 mA/cm² was completed within 4h, which would have resulted in only 3 or 4 OCV readings per half-cycle without the extra open-circuit periods. The paucity of OCV points was further manifested at 865 mA/cm². These measurements were performed on sodium-sulfur cells with both oriented- and nonoriented-sulfur electrodes. Unless otherwise stated, the results were independent of sulfur electrode type.

Charge-discharge plots as a function of current density at 335°C are presented in Fig. 1. Further details are contained in Table I. As can be seen in Table I, high efficiencies were maintained at current densities ≤ 250 mA/cm². Efficiency declines at 432 and 865 mA/cm² resulted from increased IR drop and enhanced concentration polarization effects. The latter resulted from growing reaction heterogeneity caused by an inability of the melt to diffuse rapidly enough. Reaction nonuniformities are particularly evident in the rapid drop in discharge load voltage at ~80% capacity during the 865 mA/cm² measurement (Fig. 1). An attendant increase in dc and ac resist-

^e Alternating current resistance measured during discharge at a polysulfide composition corresponding to Na₂S_{3.6}.

ance was noted. A lesser increase in ac resistance was observed at 432 mA/cm². No change in the 432 mA/cm² dc resistance was detected because of the 15 min interval between open-circuit, hence, resistance points.

Small, intercycle capacity fluctuations may have resulted due to "limit" errors. These errors have more impact at higher current rates. For a given temperature, voltage cutoff limits were calculated from the limits employed at 108 mA/cm². The data in Table I indicate that, except for the 216 mA/cm² case presented, the limits were reasonably correct. Similar agreements were retained at the other temperatures studied. At a given temperature, decreased resistances at elevated current densities may have resulted from heating effects. A thermocouple laid on the thermocompression bond registered only a 3°C change during the 432 mA/cm² cycle. Fluctuations in the thermocouple reading may not accurately reflect internal cell variations. However, thermocouple insertion directly into the cell is difficult from an engineering viewpoint. Direct attachment of several thermocouples to the sulfur canister of a 120 Ah, central-sodium cell revealed that the cell temperature changed from 373° to 375°, 377° to 385°, and 373° to 403°C when the cell was cycled at 96, 192, and 383 mA/cm², respectively.

During cell charging, sodium polysulfides are oxidized, eventually to sulfur. This latter reaction occurs at the resistive-mat/conductive-mat interface (1). Except for specially designed cells, sodium-sulfur cells with a poorly performing or no resistive layer cannot be charged at appreciable rates, ≥ 100 mA/cm², much beyond the one-phase/two-phase border (7). This results from formation of a blocking layer of sulfur on the solid electrolyte surface. The two-phase region extends between ~60 and 0% depth of discharge, and derives its name from the immiscibility of the sulfur and Na₂S₃ present. One measure of the resistive-mat effectiveness in preventing sulfur deposition on the beta"-alumina electrolyte surface, is the degree of charge acceptance. This is the number of ampere-hours returned to the cell during charging, expressed as a percentage of the theoretical capacity. A charge acceptance of 0% corresponds to a sodium trisulfide melt, i.e., the fully discharged state, and a charge acceptance of 100% represents a pure sulfur melt, i.e., a completely charged state.

The Saffil-resistive layer efficacy in preventing sulfur deposition on the beta"-electrolyte surface is depicted in Fig. 1. Note the relative flatness of the 108-432 mA/cm² two-phase charge curves and the high, ~85-90%, charge acceptance achieved at all current densities. An alternate analysis method is to compare the discharge and charge cycle times. It was expected that the larger current densities, 432 and 865 mA/cm², would cause excessive sulfur deposition during charge and inhibit the time of the charge cycle. In fact, the discharge/charge times agreed to within 6 min or less. The automated test system moni-

Fig. 1. Charge-discharge characteristics of a 16 Ah laboratory cell operating at 335°C.

tored cell voltages every 3 min. No changes in cycling conditions, *i.e.*, whether a cell is charging or discharging, can be made in shorter time intervals. Thus, charge/discharge time agreement to within two clock periods is considered excellent. Apparent discrepancies shown in Fig. 1 arose from current density effects. At 108 mA/cm², only 0.1 Ah (0.63% with respect to depth of discharge) were passed per 3 min clock period, whereas 0.8 Ah (5.00%) were passed at 865 mA/cm².

The humps observed in the 865 mA/cm² charge curve were reminiscent of those seen in sodium-sulfur cells with a carbon-based resistive layer (1). This material has a moderate electrical resistivity (11) and thus allows some passivation of the solid electrolyte surface by sulfur (1). Cyclic voltammetric studies on oxidation of Na₂S₄ to sulfur by Tischer and Ludwig (6) demonstrated that sulfur was removed from their electrode surface by a chemical reaction which followed the electron transfer step. At low enough charge rates, <100 mA/cm², resolubilization by chemical reaction is faster than sulfur deposition and no passivation occurs. At intermediate rates, ~100-250 mA/cm², a balance between sulfur deposition and removal is maintained, and the large resistive-mat/conductive-mat interfacial area precludes formation of a continuous blocking layer. The sulfur deposition and removal imbalance becomes further aggravated at elevated current densities. Net sulfur deposition occurs and a blocking layer forms. This causes an erratic and rapid increase in cell voltage.

Temperatures between 330° and 355°C influenced the data listed in Table I. For the cells examined, temperature increased efficiency by ~3% per 10°C. The increase became less at the lower current densities as the efficiency approached the IR-limited value. For a given current density, resistance decreased with increasing temperature in a nonsystematic manner. Capacities increased with temperature. Increases were more apparent at elevated current densities, 432 mA/cm². This was not unexpected since diffusional limitations were less at higher operating temperatures. Therefore, more ampere-hours could be removed before reaction nonuniformities depressed the cell voltage beyond the cutoff limit.

A group of cells containing various sulfur electrode types was placed on test at 216 mA/cm² and 330°C to assess the effects of more rapid cycling on cell performance. This current density was selected based on lifetime expectations and experimental ease. These cells have accumulated ~900 Ah/cm² (~700 cycles) with only minimal changes in cell characteristics. The efficiencies and capacities remain about 82 and 80%, respectively.

Discharge between Na₂S₃ and Na₂S₂.—The theoretical capacity of a sodium-sulfur cell is calculated from the quantity of sulfur loaded into the cell during assembly, referenced to the number of coulombs required by Faraday's law to convert all the sulfur to Na₂S₃. Capacities are typically expressed in terms of ampere-hours or percentages of the theoretical capacity. Based on this definition, values in excess of 100% are possible when the final discharge depth is such that the effective polysulfide composition is Na₂S_x, and where $x < 3$. Full charge, 0% depth of discharge, corresponds to a pure sulfur melt.

The terms "overdischarge" or "deep discharge" are used herein to refer to situations in which polysulfides lower than Na₂S₃ were formed. Lowering or decreasing the discharge cutoff voltage limit, *e.g.*, changing the limit from 1.7 to 1.6V, allows more discharge time, and is termed "increasing the discharge depth." Increasing or raising the discharge cutoff voltage limit produces shorter discharge times, and implies that the discharge depth was "decreased." These conventions are shown diagrammatically in Fig. 2, and are used throughout the remainder of this paper.

While typical laboratory cells were constructed with electrochemically equivalent sodium and sulfur weights, the effects of overdischarge on cell performance were studied in cells specially designed to be sulfur limited.

The cells utilized in this part of the study were filled with excess sodium and underfilled with sulfur. Sulfur weight reduction not only decreased the theoretical capacity, but also served to increase the volume available for polysulfide formation within the sulfur-electrode compartment. Deep discharge experiments were conducted on these 14.2 Ah, 25.5g sulfur cells at 108 mA/cm² and 330°C. Although the discharge voltage limit was varied, a constant charge cutoff voltage was employed. No dependence of the results on sulfur-electrode orientation, *i.e.*, whether the cell contained an oriented- or unoriented-sulfur electrode, was observed.

Alternating current resistance measurements were performed several times on cell B878L during the first 28 cycles. The results indicated that performance had stabilized. The lower limit, *i.e.*, discharge cutoff voltage, had been set at 1.80V. A dc cell resistance of 50 mΩ at the end of discharge implies that the IR-corrected voltage corresponds to a 1.90V potential. Interpolation of Gupta and Tischer's (8) open-circuit voltage data indicates that Na₂S_{3.6} has this potential. The cell cycled to ~Na₂S_{3.7} and ~Na₂S_{3.6} in cycles 5 and 28, respectively. Based on further interpolation of Gupta and Tischer's data, a new lower limit was chosen, and the cell should have discharged 14.2 Ah to Na₂S₃. The data in Table II indicate that this was indeed the case, *cf.* cycle 33. In examining the polysulfide composition column of Table II, one might think, that the capacity for this cycle should have been 100%. The capacity was not 100% because the cell had not recharged completely to sulfur at the end of the previous cycle. This fact should be borne in mind when utilizing this table. The cell was cycled in this manner a total of nine cycles. A very slight increase in ac resistance at the end of discharge was observed in these cycles, although no overall increase in resistance was evident.

Two unsuccessful attempts were made to cycle the cell to Na₂S_{2.6}, *cf.* Table II, cycles 41 and 43. The lower limit was decreased further and the cell cycled to Na₂S_{2.6}. Surprisingly, the cell resistance, both ac and dc, was higher at the end of discharge than at the beginning (Table II, cycle 44). One should not presume that the resistance rose the entire cycle. Rather, it increased at the end only. In fact, the ac resistance climbed from ~33 mΩ at 13.2 Ah depth of discharge to ~96 mΩ at the end of discharge. The effects of discharge depth on the cell ac resistance behav-

^a Discharge cutoff voltage.

^b Discharge capacity. Based on sulfur loading of 25.5g, which yields Na₂S₂ at 14.2 Ah. Note: capacity may not be 100% even though final composition is Na₂S₃ because previous charge cycle did not charge to 0 Ah depth of discharge (cf. text).

^c Energy out during discharge/energy in during charge.

^d Average polysulfide composition at end of discharge.

^e Weight percent sulfur in melt at end of discharge. Based on average composition and assumes no solid deposition occurred.

^f Alternating current discharge resistance at percentage of theoretical discharge listed parenthetically.

^g Discharge depth in ampere-hours.

^h No value obtainable due to equipment malfunction.

ⁱ Direct current resistance increase from ~50 to ~57 mΩ occurred between cycles 41 and 53. The resistance increase was partially offset by utilization of a lower cutoff voltage.

ior are shown in Fig. 3. When cell charging was initiated, the ac resistance plummeted to ~39 mΩ. Other than an increase in the two-phase charge resistance, there were no apparent effects of overdischarging the cell on the charge curve (*vide infra*). The data in Table II demonstrate the overall consistency in discharge performance throughout these measurements.

Although the discharge cutoff voltage limit remained fixed for ten cycles, the discharge depth decreased. Note, for example, that the next cycle depth of discharge, cycle 45, was the same as in cycle 43, even though the cycle 43 cutoff voltage was 100 mV higher. Figure 4 presents an overlay of cycle 28 and 45 discharge/charge behavior. The rapid resistance increase at the end of discharge in cycle 45 is evident in the figure. During these ten deep cycles, the dc resistance rose from ~50 to ~57 mΩ and the depth of discharge reached a plateau at ~Na₂S_{2.8}. The importance of this composition is discussed below.

The discharge voltage was raised in cycle 55. The cell was reexamined in cycle 56. The data for cycle 56 in Table

II imply a return to normalcy occurred. As in previous cycles over a similar polysulfide composition regime, no resistance increase was detected at the end of discharge. The two-phase charge resistance was lower than in cycles 44 to 54; however, it was elevated with respect to the cycles 5 to 28 values. The cell failed two cycles later. Therefore, it was not possible to determine if the cell would completely return to its original performance.

At the time cell B878L failed, it was unclear whether or not the failure was related to the overdischarge experiments. Therefore, a second cell, B890L, was constructed. These two cells were identical with respect to sodium and sulfur weights and resistive layer materials. They differed only in the design of the sulfur electrode. Cell B890L contained an oriented-sulfur electrode. This cell was broken in for ~35 cycles before the deep discharge experiments were initiated. A rise in the discharge resistance was ob-

Filled and open squares represent discharge and charge open-circuit voltages, respectively. Note the precipitous drop in discharge voltage and the open-circuit voltage plateau beyond 14 Ah in cycle 45. No open-circuit voltage data are displayed for cycle 28. Theoretical capacity is 14.2 Ah.

Fig. 5. Alternating current cell resistance vs. percent theoretical capacity for cell B890L. Data recorded during cycle 41 at 108 mA/cm² and 330°C.

served when the cell was cycled at or below Na₂S₃. The magnitude of the resistance rise was dependent on the final discharge depth. Figure 5 displays the ac resistance behavior obtained when cell B890L was discharged to an effective polysulfide composition corresponding to Na₂S_{2.4}. The current was reversed at this point for several reasons. First, the load voltage had dropped to ~0.6V.

Second, the ac discharge resistance increased from ~28 to ~210 mΩ. The initially lower ac resistance of cell B890L compared to cell B878L results from sulfur-electrode orientation effects (1). Interestingly, upon charge initiation, the ac cell resistance was ~34 mΩ. Cell B890L behavior further mimicked that of cell B878L, in that only the two-phase charge resistance increased (as discussed above and shown for cell B878L in Fig. 3).

In contrast to the regimen employed for cell B878L, the lower voltage limit for cell B890L was returned to its original value after only one deep discharge cycle. After ~30 invariant cycles, the lower voltage limit was once again decreased to permit discharge beyond Na₂S₃. Within approximately ten cycles, the discharge depth began to decrease (Fig. 6). The upper curves in the figure display the charge and discharge capacity limits vs. cycle number. Changes in the discharge cutoff voltage are marked. Although the depth of discharge was limited with respect to the "very deep" cycles, the charge-discharge plots displayed characteristics reminiscent of severe overdischarge, cf. curve for cell B878L cycle 45 in Fig. 4. Alternating current resistance analysis revealed that extreme overdischarge was indeed occurring. The decline in discharge depth and its erratic nature were very similar to the behavior observed in cell B878L just before its failure. Therefore, cell B890L was removed for examination (9).¹

The cause of the resistance rise at the end of discharge is explained with the aid of Table II and Figs. 3, 5, and 7. Figure 7 presents a sodium sulfur phase diagram (2, 5, 8). An isothermal line has been drawn at 330°C, the cell operating temperature, and several key points labeled. During discharge, sodium is injected into the sulfur compartment and sodium polysulfides of various compositions form. The exact composition is dependent on the amount of sodium injected and the quantity of sulfur present. Until the sulfur content in the polysulfides reaches ~78 weight percent (w/o), an immiscible mixture

¹ Post-test examination of sodium-sulfur cells is part of an ongoing research effort. Results obtained on cell B890L will be reported separately.

Fig. 6. Cycle limits (upper) and resistance (lower) vs. cycle number for laboratory cell B890L. Ampere-hours are referenced to discharge state. The corresponding effective polysulfide compositions are listed on the right-hand vertical axis. Cell operated at 108 mA/cm² and 330°C. Changes in the discharge cutoff voltage limit are marked.

Fig. 7. Sodium-sulfur phase diagram (2, 5, 8)

of sulfur and Na_2S_5 results. This area is to the right of A in Fig. 7. Point A represents pure Na_2S_5 . Further discharge results in the formation of a homogeneous mixture of Na_2S_5 and Na_2S_4 , A to B. The exact composition of the mixture varies with depth of discharge. As the sulfur content drops below $\sim 74\%$, point B in Fig. 7, increasing amounts of Na_2S_2 form (5, 6). At the cell operating temperature, Na_2S_3 is really an equimolar mixture of Na_2S_2 and Na_2S_4 (2-5) both of which remain in solution. A slight resistance increase at the end of discharge, cycle 33 in Fig. 3, for example, indicates that the Na_2S_2 solubility was exceeded. An equilibrium exists between solid and liquid Na_2S_2 . As the discharge depth increases, the amount of Na_2S_2 present increases. If the quantity of Na_2S_2 present is greater than the solubility limit, solid Na_2S_2 will precipitate and the resistance is expected to rise. Local current nonuniformities can affect the "calculated" composition at which solid Na_2S_2 forms. This implies that just because the coulombs passed indicate a particular polysulfide composition exists, regions of the cell may be overdischarged unknown amounts. This was demonstrated by a resistance rise at the end of discharge during the 432 and 865 mA/cm^2 cycles discussed above.

Point C in Fig. 7 is critical. To the right exists a homogeneous solution of Na_2S_2 and Na_2S_4 ; to the left is solid Na_2S_2 and a solution of composition C. This point corresponds to $\text{Na}_2\text{S}_{2.8}$, which contains ~ 66 w/o sulfur. Discharge leading to precipitation of Na_2S_2 with an overall resultant composition in the BC region should be reversible. However, little is known about discharge into the CD region. If the morphology of the deposited Na_2S_2 changes, it may not be possible to resolubilize the solid. The studies of Tischer and Ludwig (6) and South *et al.* (10) indicate that electrochemically formed Na_2S_2 may be more effective than chemically formed Na_2S_2 in producing a blocking layer within the cell. Chemically formed Na_2S_2 is sodium disulfide produced by disproportionation of Na_2S_3 or in a chemical reaction following an electron-transfer step. Electrochemically formed Na_2S_2 results from the reduction of higher polysulfides.

Examination of cell B878L data in Table II reveals that the cell was discharged more deeply than point C during cycles 41 to 53. Figures 3 and 5 clearly demonstrated the effect of solid precipitation on cell resistance. It is extremely important to note that the ac discharge resistance remained virtually unchanged in the two-phase region and in the one-phase region until solid deposition occurred. Further, the ac discharge resistance increased

more rapidly during subsequent cycling. Interestingly, the resistance rise stabilized and the capacity leveled out at point C.

The OCV data for the cycles listed in Table II were plotted against percent discharge. Some of these curves are shown in Fig. 8. The solid line represents the "ideal" curve generated from the original cell sulfur weight and Gupta and Tischer's data (8). The horizontal line represents the constant two-phase voltage, and the sloped line the varying one-phase values. Data from cycles 28 and 33 (Fig. 8a) closely follow the ideal curve and indicate that the sulfur weight was reasonably accurate. Deviations from ideality within these two cycles result from concentration polarization effects. Cycle 41 was the first cycle conducted to $\text{Na}_2\text{S}_{2.8}$. As can be seen in Fig. 8a, a very small shift relative to previous cycles and ideality towards lower percent discharge occurred. Additional shifts were seen during cycles 43 and 45 (Fig. 8b). The OCV percent discharge performance stabilized and did not return to its original relationship even when the discharge cutoff voltage was returned to its starting value. This can be seen by comparing cycle 28 (Fig. 8a) to cycle 56 (Fig. 8b). The cycle 56 data was coincident with that from cycles 45 to 53. Although not shown, similar trends were seen in cell B890L.

These curves imply that cycling at or below $\sim \text{Na}_2\text{S}_{2.8}$, point C in Fig. 7, results in permanent sulfur loss. For a given number of ampere-hours removed, utilization of a corrected, *i.e.*, decreased, sulfur weight would yield a greater percentage discharge and shift the OCV curves to the right in Fig. 8. Further these curves serve to illustrate the difference between electrochemically and chemically formed Na_2S_2 (6). Resolubilization of electrochemically formed Na_2S_2 was not accomplished under the conditions of these tests. In contrast, chemically formed Na_2S_2 did not result in permanent sulfur loss, *cf.* Fig. 8a, cycle 33. This concept was tested in a sodium-sulfur cell. Following break in, the discharge limit was lowered and a cell cycled to $\text{Na}_2\text{S}_{2.95 \pm 0.05}$ for ~ 30 cycles. A small resistance rise was observed at the end of discharge. The cutoff voltage limit was then returned to its original value. Comparisons to the initial cell performance indicated that the cell continued to operate with no change in performance, shift in the OCV-percent discharge plot, or resistance increase, ac or dc, for ~ 200 cycles before it was lost due to an oven failure. Although it was possible to discharge cells below $\text{Na}_2\text{S}_{2.8}$ as computed from the initial sulfur weight, it seems that repeated discharge beyond this point resulted in permanent sulfur loss and decreased cell life.

Severe overdischarge like that shown in Fig. 5 or for cycle 44 in Fig. 3 was observable by both ac and dc resistance techniques. Evidence of overdischarge discernible in dc measurements was a rapid drop in cell voltage, cycle 45 in Fig. 4, and a leveling out of the OCV at $\sim 1.76\text{V}$, cycle 45 in Fig. 4 and cycles 43 and 45 in Fig. 8b. The latter phenomenon is consistent with Gupta and Tischer's open-circuit voltage data (8). More mild overdischarge, cycle 33 in Fig. 3, was usually only detected in ac measurements. This was due to the 30 min interval between dc resistance points.

The effect of deep discharge on the charge resistance was extremely enlightening. Examination of Fig. 3 indicates that the one-phase ac resistance was affected minimally by the depth of discharge. However, the two-phase resistance increased substantially. Comparison of cycle 44 and either cycle 28 or 33, reveals that a slight increase occurred in the one-phase region in cycle 44. The effect on the two-phase charge resistance was not as benign. For example, an $\sim 30\%$ increase was observed in cycle 44 relative to cycle 28 at $\sim 42\%$ depth of discharge. This strongly suggests that Na_2S_2 precipitates at the conductive-mat/resistive-mat interface. If solid deposition occurred on the beta' electrolyte or in the bulk of the sulfur electrode, both charge and discharge resistances would be affected. During charge, reentry into the two-phase region is when the resistive-mat performance is

Fig. 8. Plots of open-circuit voltage vs. percent theoretical capacity for cell B878L. Curves obtained at 330°C. Empty and filled data points represent charge and discharge, respectively. Solid-line curve represents ideal curve (8).

most crucial. Solid Na_2S_2 formation in this area should hinder sulfur formation and further aggravate the normally observed resistance rise.

Conclusions

An ac resistance technique has been applied to the study of current density and depth of discharge effects on sodium-sulfur cell performance and life. 16 Ah laboratory cells were discharged and charged at current densities between 54 and 865 mA/cm². The equality of the charge and discharge cycle times demonstrated the extreme effectiveness of ceramic-based resistive layers in preventing sulfur passivation of the beta"-electrolyte surface. Temperatures between 330° and 355°C increased cell efficiency, ~3% per 10°C, and capacity, and decreased cell resistance. Cells operated at twice the normal current density have achieved ~700 cycles, ~900 Ah/cm², while remaining ~82% efficient. The capacities were ~80% of theoretical.

The effects of overdischarge, *i.e.*, formation of polysulfide species Na_2S_x where $x < 3$, on cell performance were studied in cells specially constructed so as to be sulfur limited. Final effective compositions of $\text{Na}_2\text{S}_{2.6}$ and $\text{Na}_2\text{S}_{2.4}$ were achieved in separate cells. An ac resistance rise was detected when either cell was discharged at or below Na_2S_3 . The magnitude of the rise was dependent on the final discharge depth. Direct current measurements are less sensitive and showed abnormal behavior only in the case of severe overdischarge. The resistance rise was attributed to having exceeded the Na_2S_2 solubility limit, thus causing solid Na_2S_2 deposition. The one-phase ac charge resistance and subsequent discharge resistance were unaltered. In contrast, the two-phase charge resistance increased. This implied that precipitation of Na_2S_2 occurred at the resistive-mat/conductive-mat interface. The results of these tests indicated that severe overdischarge can be tolerated in laboratory cells to a very limited degree and for a very limited number of cycles. Whether this limit is one or two cycles has not been deter-

mined. On a recurring or repeated basis, however, discharge beyond $\text{Na}_2\text{S}_{3-x}$, where $x \geq 0.2$, shortened life. Discharge "to" Na_2S_3 appeared satisfactory; this is attributed to the differences in behavior of chemically and electrochemically formed Na_2S_2 .

Mathematical Modeling of the Chlorine Flow-Through Porous Graphite Electrode in the Zinc-Chloride Battery

Emad Roayaie¹ and Jacob Jorné

Department of Chemical Engineering, University of Rochester, Rochester, New York 14627

ABSTRACT

A mathematical model which includes mass transfer within the pores has been applied to the flow-through porous graphite electrode during the discharge of the zinc-chloride battery. The purpose of the model is to obtain key design parameters such as potential distribution, concentration distribution of dissolved chlorine and zinc chloride, and local reaction rate distribution within the porous electrode. The resultant coupled nonlinear differential equations have been solved numerically for the galvanostatic operation. Potential, concentration, and reaction-rate distributions have been obtained for various operating conditions such as specific area of the porous electrode ($100\text{-}1000\text{ cm}^{-2}$), electrolyte flow velocity ($0.5\text{-}3.0\text{ cm/min}$), discharge current density ($30\text{-}100\text{ mA/cm}^2$), electrode thickness ($0.2\text{-}0.4\text{ cm}$), and direction of flow. The results can be used in the optimization of the energy efficiency of the zinc-chloride battery.

The zinc-chloride battery, presently being developed for load leveling and electric-vehicle applications, incorporates porous electrodes. Porous electrodes accommodate the heterogenous nature of electrochemical reactions by providing large reaction rates per unit volume. The effectiveness of the porous electrodes is restricted by the ohmic resistance of the electrolyte in the pores and mass-transfer limitations on the supply of reactants to the porous matrix. To overcome these difficulties, new reactor designs and methods of predicting reactor performance have become increasingly popular (1, 2). The purpose of this study is to apply a mathematical model (3, 7) for improving the porous-graphite chlorine electrode employed in the zinc-chloride battery.

Figure 1 shows the flow configuration of the chlorine electrode in the zinc-chloride battery. The ZnCl_2 electrolyte solution, containing dissolved Cl_2 and KCl and NaCl supporting electrolyte, enters at $x = 0$, flows through the porous graphite, and exits at $x = L$. During discharge, dissolved chlorine is reduced to chloride ion (Cl^-) in the porous electrode $\text{Cl}_2 + 2e \rightarrow 2\text{Cl}^-$ and zinc ion species are produced at the downstream zinc counterelectrode. A mathematical model is developed to evaluate the concentration distribution of dissolved Cl_2 , potential distribution, and local reaction rate within the porous electrode region during discharge.

Mathematical Model

The porous graphite is considered to be of uniform porosity and specific area throughout. The porous electrode is assumed to behave in a one-dimensional manner in which mass transfer within the pores is included. The hydrodynamic motion is assumed to be a plug flow, transport parameters are assumed constant, and activities can be replaced by concentrations. External diffusion resistances are negligible.

Scanning electron micrographs of porous graphite (Union Carbide, PG-60) are shown in Fig. 2. The specific macroarea can be estimated from Fig. 2a to be around $100\text{-}600\text{ cm}^{-2}$. A 500 times magnification of a single pore is shown in Fig. 2b, from which the pore diameter is estimated at 10^{-2} cm ($100\text{ }\mu\text{m}$). It is assumed that only the macroarea is being used since the reaction of chlorine is quite fast and diffusion within the micropores is limited.

In the absence of electrical migration, the following mass-conservation equation can be written for dissolved chlorine (3)

$$-\epsilon D \frac{d^2 c_R}{dx^2} + v \frac{dc_R}{dx} = a j_{Rn} \quad [1]$$

where c_R is the dissolved chlorine concentration, ϵ is the porosity, D is the effective diffusion coefficient, v is the

superficial velocity, and a is the specific interfacial area (cm^{-1}). J_{Rn} is the local flux of dissolved chlorine between the solution and the pore wall, and can be expressed by the average mass-transfer coefficient k_m

Fig. 1. Flow configuration of the flow-through porous chlorine electrode during discharge.

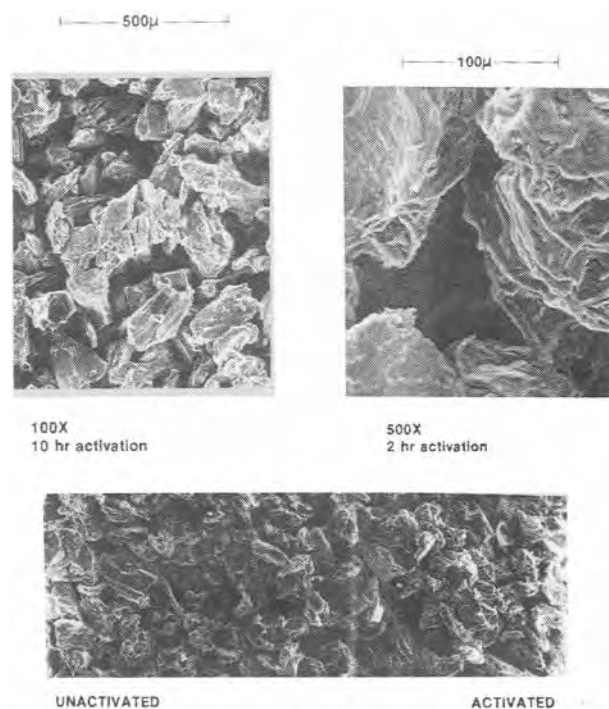

Fig. 2. Scanning electron microscope of porous-graphite (Union Carbide PG-60). A (top left): After 10h activation in H_2SO_4 . B (top right): Close-up of a single pore. C (bottom): Cross-sectional view of 0.15 cm thick porous graphite activated on one side.

¹Present address: Department of Chemical Engineering, Wayne State University, Detroit, Michigan 48202.

$$j_{Rn} = -k_m(c_{Rf} - c_{Rw}) \quad [2]$$

where c_{Rw} is the concentration of dissolved chlorine at the wall.

The local flux can be also expressed by the Butler-Volmer equation

$$J_{Rn} = \frac{S_R i_{0R,ref}}{nF} \left\{ \exp \left[\frac{\alpha_a F}{RT} (\phi_1 - \phi_2) \right] - \frac{c_{Rw}}{c_{Rf}} \exp \left[- \frac{\alpha_c F}{RT} (\phi_1 - \phi_2) \right] \right\} \quad [3]$$

where the dependence of the exchange current density on the concentration of the reduced specie (Cl^-) is neglected, since its concentration is much higher (100-1000 times) than that of the oxidized specie (Cl_2). Thus, Eq. [3] is identical to the Butler-Volmer equation for metal deposition.

The local pore-wall flux j_{Rn} is obtained by eliminating the wall concentration from the mass-transfer equation and the Butler-Volmer equation (3)

$$j_{Rn} = \frac{\frac{c_{Rf}}{c_{Rf}} - \exp[(\alpha_a + \alpha_c)F\eta/RT]}{\frac{1}{k_m c_{Rf}} - \frac{nF}{S_R i_{0R,ref}} \exp[\alpha_c F\eta/RT]} \quad [4]$$

where c_{Rf} is the feed concentration, k_m the mass-transfer coefficient, $S_R = -1$ is the stoichiometric coefficient, and $i_{0R,ref}$ is the exchange current density which is assumed to have a nonlinear composition dependence, according to Trainham and Newman (3). The overpotential $\eta = \phi_1 - \phi_2$, where ϕ_1 and ϕ_2 are the potentials in the matrix and the solution, respectively, measured vs. a reference electrode of the same kind at the feed conditions. The equation for the potential is given by

$$\frac{d^2 \eta}{dx^2} = \left(\frac{1}{\kappa} + \frac{1}{\sigma} \right) \left(\frac{nF}{S_R} \right) \alpha j_{Rn} \quad [5]$$

because in the presence of large excess of supporting electrolyte the current density in the solution is governed by Ohm's law. κ is the effective conductivity in the solution, and σ is the effective conductivity of the solid matrix.

The following boundary conditions must be satisfied (1, 3)

$$\text{At } x = 0 \quad c_{Rf}v = c_{Rf}v - \epsilon D_a \frac{dc_R}{dx} \quad \frac{d\eta}{dx} = -\frac{i}{\sigma} \quad [6]$$

$$\text{At } x = L \quad \frac{dc_R}{dx} = 0 \quad \frac{d\eta}{dx} = \frac{i}{\kappa} \quad [7]$$

where i is the applied current density. The above boundary conditions apply for the case of a downstream counterelectrode and galvanostatic discharge conditions. The downstream boundary condition for dissolved chlorine is the Dankwerts, Wehner-Wilhelm condition, where the axial diffusion and dispersion are included. Since the conductivity of graphite is high, $\sigma \gg 0$, the second boundary condition in Eq. [6] is practically $d\eta/dx = 0$.

Results and Discussion

The coupled nonlinear differential equations were first linearized about a trial solution and then put into finite difference form. The trial matrix was then inverted, and a solution was obtained by an iteration process resulting in a successive improvement of the trial solution, until convergence was achieved, which corresponds to the applied current density (1-3).

Results have been obtained for the following operating discharge conditions: $i = 0.03-0.10$ A/cm²; $v = 0.5-3.0$ cm/min (5); and $\alpha_c = \alpha_a = 0.5$ (4). The exchange current density was measured on pyrolytic graphite, $i_0 = 10^{-5}$ A/cm² (7). The specific area $a = 500$ cm⁻¹ has been estimated from the SEM pictures (Fig. 2). The length of the

electrode is $L = 0.2$ cm and the inlet chlorine concentration is $c_{Rf} = 0.028M$. The mean mass-transfer coefficient k_m is calculated according to Wilson and Geankoplis (1)

$$k_m = \frac{1.09}{\epsilon[6(1-\epsilon)]^{2/3}} (v)^{1/3} (aD_0)^{2/3} \quad [8]$$

where ϵ is the porosity, v is the superficial flow velocity, a is the specific area, and D_0 is the diffusion coefficient for dissolved chlorine. The solution is taken as 2.5M ZnCl₂, 4.0M KCl, and 1.0M NaCl for which the specific conductivity at room temperature is $\kappa = 0.3$ Ω⁻¹ cm⁻¹. The solubility of chlorine is taken as 2 g/liter (5).

The distribution of dissolved chlorine for two electrolyte velocities is shown in Fig. 3. For the given conditions, the difference between the bulk and wall concentrations is very small. At a low velocity of 0.5 cm/min, the reaction proceeds to a higher degree of completion and the outlet chlorine concentration is lower in comparison to that at a higher electrolyte velocity of 2.0 cm/min.

The overpotential distribution is shown in Fig. 4. The overpotential at the downstream, $x/L = 1$, represents the total overpotential contribution of the chlorine electrode. By increasing the velocity from 0.5 to 2.0 cm/min, the overpotential drops from -71 to -66 mV. At higher velocity, the effect of increasing velocity on the overpotential is negligible.

The dimensionless reaction rate can be defined as

$$J = \frac{j_{Rn} a L}{i} \quad [9]$$

The calculated distribution of J is shown in Fig. 5. The reaction rate is higher downstream due to the potential distribution. The increase in the upstream side is due to the higher chlorine concentration. The reaction-rate distribution inside the electrode depth is somewhat interesting. For the case of low flow rate, 0.5 cm/min, the reaction rate declines steadily. Even though the higher overpotential at the outlet portion of the electrode should result in higher reaction rates at the outlet, the low chlorine concentration there dominates the effect of higher overpotential. On the other hand, for higher flow rates such as 2.0 cm/min, the effect of higher overpotential at the electrode outlet results in higher reaction rates at that position.

The effect of electrode thickness.—The effect of increasing the electrode thickness from 0.2 to 0.4 cm is shown in Fig. 6. Increasing the thickness results in a substantial de-

Fig. 3. Distribution of dissolved chlorine for the different flow-through velocities.

Fig. 4. Overpotential distribution during discharge for two different flow-through velocities.

Fig. 5. Dimensionless reaction-rate distribution during discharge for two different flow-through velocities.

Fig. 6. The effect of electrode thickness on the overpotential distribution.

crease in the overpotential and a corresponding improvement in the voltaic efficiency of the battery during charge.

The effect of discharge current density.—The effect of discharge current density on the overpotential of the flow-through porous chlorine electrode is shown in Fig. 7 in the form of a polarization curve. For example, by increasing the current from 0.03 to 0.10 A/cm², the overpotential increases by about 50 mV.

The effect of increasing the current density from 0.02 to 0.10 A/cm² on the current distribution is shown in Fig. 8, where the dimensionless reaction rate is plotted vs. the dimensionless distance. By increasing the current density, the current distribution becomes less uniform and the depth of penetration is higher.

The effect of reversing the flow.—The results above are referred to the case where the counterelectrode (the zinc electrode) is located in the downstream position (see Fig. 1). By reversing the flow in the battery, a situation in which the counterelectrode is located in the upstream position can be achieved. This flow is represented schematically in Fig. 9.

The boundary conditions for this situation are given by the boundary conditions presented in Eq. [6] and [7], except $x = 0$ is located at the edge facing the zinc electrode and $x = L$ corresponds to the far face of the porous electrode.

Fig. 7. Polarization curve for flow-through porous graphite under chlorine reduction.

Fig. 8. The effect of discharge current density on the distribution of the dimensionless reaction rate.

Fig. 9. Flow configuration of the flow-through porous chlorine electrode for upstream location of the counterelectrode.

The distribution of dissolved chlorine concentration is very similar (see Fig 1) to the distribution for the case of a downstream position of the counterelectrode.

The overpotential distributions for upstream and downstream positions of the counterelectrode are compared in Fig. 10. It appears that under the practical operating conditions of the battery, reversing the flow makes very little difference from a voltaic efficiency point of view.

The effect of reversing the flow on the current distribution is shown in Fig. 11, where the dimensionless reaction rate is plotted vs. the dimensionless distance from the zinc facing edge of the porous electrode. As can be seen, the reaction rate is higher at the entrance for the upstream counterelectrode because both the overpotential and the chlorine concentration are higher there. For the case of a downstream counterelectrode, the reaction rate is also nonuniform. A minimum can be observed due to the opposing effects of the overpotential distribution and chlorine concentration distribution. This behavior is in agreement with the analysis of Trainham and Newman (8) concerning the effect of the counterelectrode placement.

Conclusions

The mathematical model suggests the following conclusions.

CONDITIONS:
 $a = 500 \text{ cm}^{-1}$
 $i_0 = 10^{-5} \text{ A/cm}^2$
 $v = 2.0 \text{ cm/min}$
 $k_m = 0.01 \text{ cm/sec}$
 $i = 0.03 \text{ A/cm}^2$
 $L = 0.2 \text{ cm}$

Fig. 10. Comparison of overpotential distribution for upstream and downstream location of the counterelectrode.

CONDITIONS:
 $a = 500 \text{ cm}^{-1}$
 $i_0 = 10^{-5} \text{ A/cm}^2$
 $L = 0.2 \text{ cm}$
 $C_{Cl} = 0.028 \text{ M}$
 $v = 2.0 \text{ cm/min}$
 $i = 0.03 \text{ A/cm}^2$

Fig. 11. Comparison of distribution of dimensionless reaction rate for upstream and downstream location of the counter distribution of the dimensionless reaction rate.

1. The macroarea is the most important since the actual area available for the electrochemical reaction is based on the macropores.

2. It appears that mass transfer within the pores is of no importance under the practical operating conditions where the flow-through velocity is greater than 2 cm/min.

3. The lower limit of the flow depends on the mass transfer of dissolved chlorine to the wall.

4. The reaction rate distribution is quite uniform. For an electrode thickness of 0.2 cm the entire electrode participates in the reaction.

Effect of Reinforcement on the Pitting Behavior of Aluminum-Base Metal Matrix Composites

Denise M. Aylor* and Patrick J. Moran**

David Taylor Naval Ship Research and Development Center, Bethesda, Maryland 20084 and Department of Materials Science and Engineering, Johns Hopkins University, Baltimore, Maryland 21218

ABSTRACT

This paper examines the effect of graphite and silicon carbide reinforcements on the pitting behavior of graphite/aluminum (Gr/Al) and silicon carbide/aluminum (SiC/Al) metal matrix composites. Electrochemical corrosion tests were performed on both Gr/Al and SiC/Al composite specimens. Identical tests were completed on powder metallurgy processed aluminum and wrought aluminum of the same composition. The electrochemical behavior of the SiC/Al composites was essentially identical to that of the powder processed and wrought aluminum alloys; however, the pitting attack on the SiC/Al composites was distributed more uniformly across the surface, and the pits penetrated to significantly less depths. The presence of graphite in the Gr/Al composites did not cause an electropositive shift in corrosion potential as anticipated, but caused a substantial decrease in resistance to passive film breakdown. This effect is the predominant reason for the poor performance of Gr/Al composites in marine environments.

Interest in implementation of metal matrix composites (MMC) in marine applications is rapidly expanding due to the materials' higher strength and modulus than that which can be attained by conventional alloying. Utilization of MMC in marine environments requires adequate corrosion resistance. To date, composites considered for marine application are typically aluminum-based, specifically 5000 series or 6061 Al, with reinforcements of graphite (Gr) and silicon carbide (SiC). It has been reported that aluminum alloys suffer localized attack by pitting in chloride environments (1, 2). A reinforcement of Gr or SiC added to the aluminum matrix could potentially decrease the corrosion resistance as compared to an unreinforced alloy due to the structure of the composite. Continuous graphite/aluminum (Gr/Al) composites typically consist of Gr/Al wires (graphite multifilament tows infiltrated with aluminum) diffusion bonded between aluminum foils. This composite configuration could promote wicking of the electrolyte (thereby increasing the corrosion rate) at the foil-to-wire and wire-to-wire interfaces once pitting corrosion progresses through the aluminum foils. The structure of the discontinuous silicon carbide/aluminum (SiC/Al) composites, that of silicon carbide whiskers or particles blended into a powder aluminum matrix could increase the probability of pitting/crevice corrosion at exposed SiC-Al interfaces in the composite.

Dull *et al.* (3, 4) studied the Gr/Al system in 3.5% NaCl. They concluded that the corrosion rate was slightly higher for Gr/Al relative to 6061 aluminum alloy controls. The explanation for this increased corrosion rate was galvanic corrosion at the graphite fiber-aluminum interface. Trzaskoma *et al.* (5) studied the SiC/Al system in 0.1N NaCl. They concluded that the SiC whiskers did not influence the susceptibility of 6061 aluminum to pit initiation, but promoted the development of a smaller size pit morphology relative to 6061 aluminum controls.

In this research, both SiC/Al and Gr/Al composites were evaluated in the laboratory utilizing an electrolyte of ASTM ocean water, which simulates the inorganic constituents of marine environments more closely than sodium chloride. Also, a series of exposures was conducted in two natural marine environments. The results of the laboratory tests are correlated with actual exposure behaviors.

Background

Pitting corrosion involves two stages: pit initiation and propagation. Initiation of pitting occurs at local discontinuities or flaws in the natural oxide film on the aluminum surface (6). Numerous investigators (7-11) have shown evidence of flaws in aluminum passive films,

attributing the defects to voids, inclusions, or other impurities. At each initiated pit site, a high local anodic current density is created with a very low oxygen concentration due to limited access into the pit. The high concentration of aluminum cations within each pit encourages chloride ion migration to maintain charge balance. Precipitation of $Al(OH)_3$ occurs once the solution inside the pit is adequately concentrated with aluminum cations. This lowers the pH within the pit and creates a solid corrosion product. A low pH and a high chloride ion concentration accelerates the anodic dissolution reaction, thereby facilitating the aluminum corrosion process (12, 13). Work by Trzaskoma *et al.* (5) states that in addition to the localized corrosion from structural flaws in the aluminum passive film, surface variations due to the presence of ceramic reinforcements in the matrix could also promote increased corrosion.

Both potential- and current-controlled electrochemical techniques have been utilized to study the pitting mechanism in aluminum alloys (5, 14-30); however, controversy still exists among researchers as to which electrochemical method accurately assesses the pitting corrosion mechanism. Characteristic potentials determined from these methods are E_p , the breakdown or pitting potential, and E_{prot} , the protection or repassivation potential. E_p is defined as the critical potential at which pitting will initiate and propagate, and E_{prot} is the potential at which propagating pits repassivate.

In this investigation, cyclic anodic potentiodynamic polarization was used to determine E_p and E_{prot} values on graphite/6061 aluminum (Gr/6061 Al), silicon carbide (whisker)/powder metallurgy 6061 aluminum ($SiC_w/6061$ Al), silicon carbide (whisker)/powder metallurgy 6061-T6 aluminum ($SiC_w/6061-T6$ Al), 6061-T6 aluminum (6061-T6 Al), and powder metallurgy 6061 aluminum (PM6061 Al) specimens. The anodic potentiodynamic polarization test was chosen because both the susceptibility to initiation, estimated by E_p , and the potential below which pitting would not occur, E_{prot} , could be readily determined and compared. While the significance and reproducibility of E_p by this technique is debated, it can be adequately employed to compare the susceptibility to pit initiation for a variety of materials. Also, potentiostatic tests were conducted on specimens held between E_p and E_{prot} in order to compare the extent and morphology of pitting between SiC/Al and Al materials.

Experimental Procedure

Gr/Al composites, containing approximately 30 volume percent (v/o) graphite, were fabricated by first forming Gr/Al wires. The wires were then stacked and hot-press diffusion bonded between 6061 aluminum surface foils to a 3.8 mm (0.150 in.)¹ final plate thickness. The $SiC_w/6061$

¹Imperial dimensions are actual and stated to appropriate precision; derived metric dimensions are approximate.

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

Al composites were fabricated from atomized 6061 Al powder and 25 v/o discontinuous silicon carbide whiskers (approximately 0.1 to several microns in diameter, 1-50 μm in length). The 6061 Al powder and SiC whiskers were consolidated into plate form, and the plate was vacuum hot pressed and then forged to its final 2.5 mm (0.1 in.) thickness. SiC_w/6061-T6 composites were additionally tempered to a T-6 condition after forging. PM6061 Al material was fabricated using the same procedures as for the SiC_w/6061 Al MMC but without the added SiC reinforcement. The 6061-T6 Al alloy was conventional wrought, T-6 tempered material in the form of a 6.4 mm (0.25 in.) thick plate.

Marine environment testing.—Corrosion test panels of Gr/6061 Al, SiC_w/6061 Al, SiC_w/6061-T6 Al, 6061-T6 Al, and PM6061 Al were exposed at the LaQue Center for Corrosion Technology in environments of (i) quiescent, filtered natural seawater controlled at $30^\circ \pm 2^\circ\text{C}$ ($86^\circ \pm 3.6^\circ\text{F}$) (full immersion), and (ii) marine atmosphere, 25m (80 ft) from the ocean. The test panels, with surface areas ranging from 77 cm² (12 in.²) to 168 cm² (26 in.²), were exposed for 1-12 months and some exposures are still in progress. Panels are periodically inspected during exposure to assess the pitting corrosion behavior.

Electrochemical testing.—Electrochemical testing included corrosion potential (E_{corr}) monitoring, cyclic anodic polarization, and potentiostatic holds. All electrochemical tests were conducted in ASTM ocean water, prepared according to ASTM Standard D1141-75 (31). Composite specimens of Gr/6061 Al, SiC_w/6061 Al, and SiC_w/6061-T6 Al were mounted to mutually expose both the Gr or SiC reinforcement and the aluminum matrix. Corrosion potentials were monitored for 30 days on specimens of Gr/6061 Al, SiC_w/6061 Al, SiC_w/6061-T6 Al, 6061-T6 Al, and PM6061 Al immersed in aerated ocean water.

Cyclic anodic polarization testing was carried out on Gr/6061 Al, SiC_w/6061 Al, SiC_w/6061-T6 Al, 6061-T6 Al, and PM6061 Al materials. These tests were conducted to make a qualitative assessment of the susceptibility to breakdown for both composite and control materials. Specimens were mounted to expose a 2 cm² area. A Princeton Applied Research (PAR) system was utilized in these tests (Model 173 Potentiostat, Model 175 Programmer, and Model RE0074 X-Y Recorder). Each specimen was allowed to reach a stable corrosion potential in partially deaerated, ambient temperature (21-27°C) ocean water before testing began. Partial deaeration was necessary to clearly observe the breakdown and repassivation potentials. Testing was initiated at the stabilized corrosion potential and a scan carried out in the electropositive direction at a rate of 0.1 mV/s until a breakdown potential (E_p) was reached. This potential is marked by a rapid increase in the current. Once E_p was reached and the current density increased to approximately 1-5 mA/cm², the scan was reversed and continued at the same rate until this electronegative direction scan crossed the original electropositive direction curve. This crossover point was taken as the repassivation potential (E_{prot}), where active pits are repassivated.

Potentiostatic tests were also conducted on SiC_w/6061 Al, SiC_w/6061-T6 Al, 6061-T6 Al, and PM6061 Al materials. The test began by imposing potentiostatic control of each specimen at the previously stabilized corrosion potential. The potential was then shifted in the electropositive direction at a rate of approximately 50 mV/s to 0 mV vs. a saturated calomel reference electrode (SCE) to initiate pitting, and then immediately reversed at the same rate to -700 mV vs. SCE. Each specimen was held at -700 mV vs. SCE, and the currents were monitored for approximately one week. This potential was chosen, based on the anodic polarization tests, as the potential at which pits would continue to propagate for all specimens. In other words, the -700 mV potential is between E_p and E_{prot} for all specimens tested. The specimens were cleaned after testing according to ASTM Standard G1-81 (32).

Results and Discussion

Marine exposures.—A thorough review of the marine exposures for Gr/6061 Al, SiC_w/6061 Al, and 6061-T6 Al is covered elsewhere (33). The major results of the above panel exposures as well as exposures of SiC_w/6061-T6 Al and PM6061 Al are described in this section.

6061-T6 Al and PM6061 Al panels exposed in filtered seawater exhibited more accelerated corrosion than the aluminum alloy panels exposed in the marine atmosphere. For both marine environments, the quantity of pitting was similar between the two 6061 alloy processing forms, but the depth of attack was slightly greater for the PM6061 Al specimens. Corrosion of the SiC_w/Al panels also proceeded by pitting on the surfaces, with the 6061 Al controls exhibiting superior corrosion resistance to the composites. Figure 1 exemplifies the increased corrosion resistance of the 6061-T6 Al controls relative to the SiC_w/6061 Al after 60 days in filtered seawater. The surface deposits observed on the panels are corrosion products resulting from pitting processes beneath. SEM analysis of a metallographically polished cross section through the aforementioned SiC_w/6061 Al panel (Fig. 2) revealed that the pitting corrosion was concentrated around the silicon carbide whiskers, suggesting that the crevices formed at each SiC-Al interface are preferential sites for pitting corrosion.

Marine exposures of the Gr/6061 Al panels in filtered seawater exhibited severe attack for exposure periods of 1-4 months. Figure 3 presents a typical failure of a Gr/6061 Al MMC, which occurred after 60 days in filtered seawater. Severe blistering of the aluminum surface foil along one edge is evident, which exemplifies the accelerated corrosion which takes place when the aluminum surface foil is penetrated and the graphite fibers and the aluminum are mutually exposed to the environment. The severity of attack observed in these field exposures is significantly more severe than that reported by other investigators (3, 4).

It should be emphasized that the corrosion resistance of Gr/Al composites is highly dependent on the integrity of the aluminum surface foils. For example, Gr/6061 Al panels from another phase of this program were exposed in the marine atmosphere and other marine environments for up to 20 months and revealed no severe attack. Only light surface pitting of the foils and no penetration into the Gr/Al matrix occurred. Corrosion of the aluminum surface foils will proceed at a rate typical for marine aluminum alloys until the foils are penetrated, whereby both graphite and aluminum are exposed to the environment

and accelerated corrosion of the Gr/Al occurs. Thus, the service life of Gr/Al composites is determined solely by the corrosion resistance of the aluminum surface foils. This has also been reported by other researchers (33, 34), who suggested that the accelerated corrosion following penetration is due to anodic polarization of the aluminum by the graphite, *i.e.*, classical galvanic corrosion.

Stabilization of corrosion potentials.—Average corrosion potentials for three specimens each of Gr/6061 Al, SiC_w/6061 Al, SiC_w/6061-T6 Al, 6061-T6 Al, and PM6061 Al immersed in aerated ASTM ocean water are shown in Table I. The average E_{corr} value listed for Gr/6061 Al is more electronegative than the average E_{corr} for the unreinforced Al controls in the same solution, indicating that the graphite fibers do not polarize the composite in the electropositive direction (as would be expected in normal galvanic corrosion). An explanation of this shift in E_{corr} will be discussed below. The similarities seen in the corrosion potentials between the SiC/Al and Al specimens suggest that the E_{corr} of the SiC/Al composites is not affected by the presence of the silicon carbide. This is not

Fig. 3. Gr/6061 Al MMC panel after 60 day filtered seawater exposure

Table I. Average corrosion potentials for Gr/Al, SiC/Al, and Al immersed in aerated ASTM ocean water for 30 days

Material	Average E_{corr} (mV vs. SCE)
Gr/6061 Al	-840
SiC _w /6061 Al	-740
SiC _w /6061-T6 Al	-735
6061-T6 Al (Control)	-750
PM6061 Al (Control)	-720

an unexpected result because of the known poor electrical conductivity of silicon carbide.

Potentiodynamic tests.—Figure 4 shows the cyclic anodic polarization results for 6061-T6 Al and PM6061 Al. The solid curves represent a range of potential and current density values based on four PM6061 Al specimens tested. The dashed curves represent a range of values for four 6061-T6 Al specimens. The shaded areas represent the range of E_p and E_{prot} values for both 6061 Al alloy forms. The measured corrosion potentials exhibited a large amount of scatter because the extent of deaeration was not carefully controlled.

A wide range of breakdown potentials is evident for both 6061-T6 Al and PM6061 Al, yet the most electronegative values for each material are identical. Further, the repassivation potentials for both materials tend to fall within a narrow band, showing good reproducibility for the E_{prot} parameter. The E_{prot} range for the PM6061 Al is somewhat electronegative to the E_{prot} values for the 6061-T6 Al. In general, though, the similarities seen in the pitting scans between 6061-T6 Al and PM6061 Al suggest that the differences in the processing forms of 6061 Al alloy do not significantly affect the anodic polarization characteristics.

Potentiodynamic polarization curves generated for SiC_w/6061 Al and SiC_w/6061-T6 Al specimens are included in Fig. 5. These curves also represent a range of values based on four specimens evaluated for each material. Again, a large scatter in E_{corr} is evident and is due to differences in the extent of deaeration of the solution. As in the 6061 Al alloy specimens, the breakdown potentials for the SiC/Al composites extend over a wide range of values, demonstrating the difficulty in reproducibility of the E_p parameter. However, the lowest detected breakdown potentials for both SiC_w/6061 Al and SiC_w/6061-T6 Al composites are electropositive relative to the lowest breakdown potentials for the aluminum alloys. Therefore, the presence of the SiC in the composite does not increase the susceptibility of the aluminum surface film to breakdown. This result is consistent with the work of Trzaskoma *et al.* (5). In addition, the repassivation potentials for both SiC/Al composites were quite reproducible (as with the Al alloys) and general similarities in these potentiodynamic scans suggest that heat-treating does not

Fig. 4. Cyclic anodic polarization of 6061-T6 Al and PM6061 Al

Fig. 5. Cyclic anodic polarization of SiC_w/6061 Al and SiC_w/6061-T6 Al

significantly influence the anodic polarization behavior of the SiC/Al composites.

SEM examination of all specimens after cyclic anodic polarization revealed irregular pitting scattered over the surfaces. The maximum pitting size on the SiC/Al specimens was generally an order of magnitude smaller than on the Al specimens, ranging in the 10-50 μm size for the SiC/Al and in the 100-500 μm size for the Al. Although the maximum pitting size range was smaller on the SiC/Al composites as compared to the Al alloys, there were a larger number of pits on the SiC/Al specimens. An explanation for this phenomenon is that the SiC/Al interfaces are preferred sites for passive film breakdown and are more numerous than preferred sites on the unreinforced alloy.

Cyclic anodic polarization curves for the Gr/Al MMC are presented in Fig. 6. Again, this figure represents a range of potential and current density data based on four specimens tested. Both E_p and E_{prot} values are quite reproducible. The E_{prot} values are similar to those reported for the SiC/Al and Al materials, but the Gr/6061 Al E_p values are significantly more electronegative than those materials, indicating that the passive film of the Gr/Al composite is more susceptible to breakdown compared to the other materials tested. This result, coupled with the fact that this composite does not exhibit an electropositive shift in corrosion potential, suggests that classical galvanic corrosion is not the predominant cause of the accelerated corrosion. The diffusion of carbon into the aluminum matrix and the possible formation of aluminum carbides at the reinforcement-matrix interface may change the properties of the aluminum surface film in these localities, rendering it more susceptible to breakdown. This theory, also postulated by Pfeifer (35), explains the electronegative shift in corrosion potential of Gr/Al composites which is presumably caused by active

Fig. 6. Cyclic anodic polarization of Gr/6061 Al

Fig. 7. Representative pitting of SiC/Al and Al surfaces after potentiostatic testing. Left: SiC_w/6061-T6 Al. Right: 6061-T6 Al.

dissolution at such sites, the observed decrease in the breakdown potential, and the concentration of attack at the graphite fiber-aluminum interfaces. Further, if mechanical disturbance alone was responsible for the lowering in E_p , it would have been expected to cause similar behavior for the SiC/Al composites, which it did not. These results and explanations contradict those of previous investigators (3, 4).

Pitting morphology tests.—Potentiostatic testing of SiC_w/6061 Al, SiC_w/6061-T6 Al, 6061-T6 Al, and PM6061 Al consisted of holding each specimen at -700 mV, a potential between E_p and E_{prot} where the pitting propagated, as previously described. The resultant currents, monitored over a one week period, ranged from 5 to 8 mA/cm² for all specimens. SEM photomicrographs showing typical pitting on the specimen surfaces after the potentiostatic testing are seen in Fig. 7. The pitting morphology of the potentiostated specimens generally correlated with the size range and extent of pitting seen on the composite and Al control specimens after cyclic anodic polarization testing. The size and distribution of pitting was similar between SiC_w/6061 Al and SiC_w/6061-T6 Al specimens and between 6061-T6 Al and PM6061 Al specimens, with the composites exhibiting a maximum pit size generally an order of magnitude smaller than that seen on the Al surfaces. These results agree with the work of Trzaskoma *et al.* (5). The potentiostated specimens were held at approximately the same current densities, indicating that the overall corrosion rates were similar for all specimens. Since there are more active sites on the SiC/Al as compared to the Al alloys, the pitting on the SiC/Al will be more uniformly distributed on the surface and the depths of pitting attack will be less. An interpretation of this result is that the silicon carbide whiskers present in the aluminum matrix distribute the pitting corrosion across the surface and subsequently limit the depths of attack.

Conclusions

1. Breakdown potentials as determined from cyclic anodic polarization testing on both SiC/Al and Al materials exhibit a wide range of values; however the repassivation potentials are highly reproducible.
2. Utilization of different 6061 Al processing forms (wrought *vs.* powder metallurgy) and SiC/Al composite heat-treating (as-fabricated *vs.* T-6 temper) does not affect the anodic polarization characteristics of SiC/Al and Al.
3. The presence of SiC in the 6061 Al matrix does not alter the corrosion potential in aerated ocean water. Further, the SiC does not increase the pitting susceptibility of the SiC/Al composite.
4. The morphology and extent of pitting differs between SiC/Al and Al materials. SiC/Al composites exhibit pitting concentrated predominantly at the SiC/Al interfaces, with the pitting being greater in number, smaller in size, and more shallow in penetration depth relative to the unreinforced aluminum alloys.
5. Accelerated corrosion of Gr/Al occurs when the aluminum surface foils are penetrated and the graphite and the aluminum are mutually exposed to the marine environment. Electrochemical test results indicate that the accelerated Gr/Al corrosion is not predominantly due to classical galvanic corrosion. The suggested explanation for the corrosion is that carbon diffuses into the alumi-

num at the reinforcement-matrix interfaces during fabrication, which causes a decrease in the surface film integrity at these localities and renders the composite more susceptible to breakdown.

Establishment of the Zn Corrosion Rate in NaHSO₃ Aqueous Solutions

Blanca M. Rosales and S. L. Granese

Departamento de Investigaciones en Corrosion, CITEFA/CONICET, Buenos Aires, Argentina

ABSTRACT

By means of electrochemical techniques, the corrosion of Zn in NaHSO₃ aerated and deaerated aqueous solutions at 25°C was studied. The kinetic equations proposed from values obtained in the Tafel region were in good agreement with those provided by computer program POLCURR (1) developed by Gerchakov *et al.* for overpotentials of ±20 mV. On those bases and analyzing by x-ray, the corrosion products formed an overall reaction was proposed which would be controlled by an adsorption-oxidation step.

The aim of this paper is to contribute to establishing the mechanism of corrosion of Zn in aqueous NaHSO₃ solutions.

Usually, corrosion rates are determined by an electrochemical technique, originally described by Wagner and Traud (2) and by Stern *et al.* (3), designed herein as the Stern-Geary or polarization resistance technique.

In this work, the POLCURR computer program was used to obtain some kinetic parameters controlling the corrosion of Zn in NaHSO₃ solutions. It accepts initial estimates for all parameters and applies the Gauss-Newton method to generate a new set of parameter estimates. This process is repeated until the nonlinear residual error fails to change by more than a preset value. The initial estimated values for these parameters are provided by CORFIT (4) program, which was incorporated as a subroutine into POLCURR.

The CORFIT program is based on an expansion in a Taylor series of the expression

$$I = \frac{1}{2.303 R_p} \left(\frac{1}{\frac{1}{B_a} + \frac{1}{B_c}} \right) \left[\exp \left(\frac{2.303(\phi - \phi_c)}{B_a} \right) - \exp \left(\frac{-2.303(\phi - \phi_c)}{B_c} \right) \right] \quad [1]$$

which is derived from a combination of the theoretical expression of the polarization curves (2) proposed by Wagner and Traud and of the definition of the polarization resistance (R_p) (3)

$$I = I_c \left[\exp \left(\frac{2.303(\phi - \phi_c)}{B_a} \right) - \exp \left(\frac{-2.303(\phi - \phi_c)}{B_c} \right) \right] \quad [2]$$

$$\left(\frac{\partial i}{\partial \phi}\right)_{\phi=\phi_c} = \frac{1}{R_p} = 2.303I_c \left(\frac{1}{B_a} + \frac{1}{B_c}\right) \quad [3]$$

I_c and ϕ_c being the corrosion current and potential and B_a , B_c the anodic and cathodic, respectively, Tafel constants used for mechanistic considerations. Truncating Eq. [1] and providing an initial estimate of one of the unknown parameters, an expression results which is linear with respect to the unknown parameters and may be solved by the usual method of linear least squares.

The electrochemical parameters were estimated introducing the experimental results for overpotentials in the mixed potential range ($|\Delta\phi| < 20$ mV) obtained from the polarization curves in deaerated solutions.

A subroutine CORFIT on the POLCURR program was applied. POLCURR reelaborates the data and calculates the estimates of the parameters with a high level of statistical significance. The program was adapted to the Fortran IV plus language and processed in a Digital PDP11 computer.

Experimental

The test samples were 99.99% Zn sealed in a polyester orthophthalate methacrylate resin, catalyzed by MEK, leaving exposed areas of 0.2 cm². For each test, the sample was polished with 0.25 μ m diamond paste washed with water, followed by an alcohol polish, and was finally dried with a jet of air. The aqueous solutions were prepared with pure reagents and bidistilled water over alkaline permanganate. The tests were all performed at 25°C.

Open-circuit potentials were measured with respect to the saturated calomel electrode (SCE) in NaHSO₃, NaCl, and Na₂SO₄ (10⁻⁵-1.0M) in oxygenated solutions during 24h. This was also done in phthalic-phthalate buffered solutions, at pH = 4, in the concentration range 10⁻⁴-10⁻¹M in NaHSO₃ (Fig. 1).

Polarization curves in the absence of oxygen, in the buffered solutions, were collected after deaerating by 99.99% N₂ bubbling for 2h and cathodic cleaning at -1.300 mV (SCE) for 30 min. Potentiostatic polarization curves were measured after maintaining the potential at each given current density for 15 min. For the oxygenated solutions, air bubbling and magnetic stirring were maintained during the polarizations (Fig. 2 and 3).

Results and Discussion

The results shown in Fig. 1 correspond to the behavior described by Brasher (5), where $E = a - b \log c$, with $b = 40$ mV for NaCl, Na₂SO₄, and in diluted NaHSO₃ nonbuffered solutions.

According to Brasher *et al.* (6), the potential decrease with the concentration increase would be due to the predominance of the film rupture by the anion over its repair by oxygen, as can be proposed for Cl⁻ and SO₄²⁻ over the whole range of concentrations tested. For HSO₃⁻ concentrations above 5 × 10⁻³M, the potential is independent of concentration. This effect is associated with competi-

Fig. 1. Stationary open-circuit potentials of Zn. pH = 4. Circles: NaCl. X: Na₂SO₄. Triangles: NaHSO₃. Squares: NaHSO₃.

tive adsorption (7) between SO₂ and HSO₃⁻, being pH dependent, as can be seen from the following equilibrium

$$\log \frac{[\text{HSO}_3^-]}{P_{\text{SO}_2}} = -1.82 + \text{pH} \quad [6]$$

At low concentrations, the HSO₃⁻ anion presents a similar behavior to species SO₄²⁻ and Cl⁻, as can be seen in Fig. 1. Its adsorption would cause the oxide film rupture, while SO₂ exhibits a protective effect strongly dependent on the pH of the solutions (8-10). Two distinct behaviors are observed depending on the anion concentration. For HSO₃⁻ concentrations lower than 5 × 10⁻³, the same slope as for aggressive Cl⁻ and SO₄²⁻ ions can be associated to [HSO₃⁻]/P_{SO₂} > 100, introducing in Eq. [6] the pH values 7-4 produced by the salt dissolution.

For HSO₃⁻ concentrations 5 × 10⁻³M or higher, the pH value obtained is approximately 4. The opposite effects associated to both species seem to compensate to each other due to the constant relation [HSO₃⁻]/P_{SO₂} ~ 100 for constant pH value produced. To confirm that interpretation, stationary potentials of Zn, in buffered solutions at pH = 4, were measured. They were independent of the salt concentration over the whole range, as is shown in Fig. 1. The overall reaction proposed for [HSO₃⁻] > 5 × 10⁻³M is

The stoichiometric HSO₃⁻ coefficient ν can be calculated from the variation of the corrosion potential of Zn with its concentration

Fig. 3. Polarization of Zn in aerated NaHSO₃ solutions. Solid lines: 10⁻¹M. Dot-dashed line: 2 × 10⁻²M. Dashed line: 10⁻²M. Dash-two dots line: 5 × 10⁻³M. Dash-circle line: 10⁻³M.

$$\frac{\partial E_c}{\partial \log C_{\text{HSO}_3^-}} = \frac{2.303RT}{nF} \nu_{\text{HSO}_3^-} \quad [8]$$

The slope ($\partial E_c / \partial \log C_{\text{HSO}_3^-}$) of the respective curve in Fig. 1 is 0; in Eq. [8], $n = 2$ (total number of exchanged electrons), then $\nu_{\text{HSO}_3^-} = 0$, in good agreement with the Eq. [7] proposed. The corrosion products show the presence of S, O, and Zn. Their presence was determined by electron probe microanalysis. By x-ray diffraction, $\text{ZnSO}_3 \times 2\frac{1}{2} \text{H}_2\text{O}$ was determined.

The overall reaction for $[\text{HSO}_3^-] < 5 \times 10^{-3} \text{M}$ is

Following the same scheme from Eq. [8] as $n = 4$ and the $\partial E_c / \partial \log C_{\text{HSO}_3^-} = 40 \text{ mV}$, then $\nu_{\text{HSO}_3^-} = 2$, in agreement with Eq. [9]. In dilute solution, nonprotective corrosion products are formed. It was not possible to confirm the presence of the reduced specie $\text{S}_2\text{O}_3^{2-}$, owing to its low concentration and to the interference by other sulfur compounds (11) produced during the reduction of SO_3H^- .

In order to get mechanistic information about the corrosion of Zn, polarization curves were recorded in buffered solutions at pH 4 of ionic strength high enough to act as support electrolyte for solutions as diluted as 10^{-3}M in NaHSO_3 . The results are shown in Fig. 2.

Using the computer program POLCURR previously described, the Tafel slopes B_a and B_c , the polarization resistance R_p , and the corrosion current I_c were calculated from the experimental data obtained for $|\Delta\phi| < 20 \text{ mV}$. The results are summarized in Table I.

B_a and B_c were also determined from the Tafel region of the overall polarization curves, and were found in good agreement with those determined by the computer method in the vicinity of ϕ_c . The kinetic parameters were calculated from the expressions

$$B_a = 2.303 \frac{RT}{\alpha F}$$

and

$$B_c = 2.303 \frac{RT}{\alpha F}$$

with $\bar{\alpha}$ and $\vec{\alpha}$ being the transfer coefficients for the anodic and cathodic reactions. The electrochemical anodic and cathodic reaction orders with regard to HSO_3^- were obtained from the Tafel region in order to avoid the reverse reactions. We plotted $\log i$ vs. $\log [\text{HSO}_3^-]$ for different potentials

$$\left(\frac{\partial \log |i|}{\partial \log [\text{HSO}_3^-]} \right)_\phi = n_{a,c}$$

with

$$\phi > \phi_c \pm \frac{RT}{F}$$

n_a and $n_c = 0.5$ were obtained.

The kinetic equations consistent with the results summarized in Table II are

$$i_a = K_a [\text{HSO}_3^-]^{0.5} \exp \left[1.62 \frac{F\phi}{RT} \right] \quad [10]$$

Table I. Electrochemical results from the POLCURR program

$[\text{HSO}_3^-]$ (M)	$-\phi_c$ (mV SCE)	I_c (A cm ²)	R_p (Ω)	B_a (mV)	B_c (mV)
10^{-3}	1076	2×10^{-5}	674.2	36	125
10^{-2}	1080	2.8×10^{-4}	237.1	40	130
10^{-1}	1083	8.2×10^{-4}	71.8	35	120

Table II. Kinetic parameters

Polarization	B	$\bar{\alpha}$	$\vec{\alpha}$	n_a	n_c
Anodic	37	1.62	—	0.5	—
Cathodic	125	—	0.48	—	0.5

$$i_- = K_- [\text{HSO}_3^-]^{0.5} \exp \left[-0.48 \frac{F\phi}{RT} \right] \quad [11]$$

The corrosion product formed by immersion in NaHSO_3 solutions buffered at pH = 4 was $\text{ZnSO}_3 \times 2 \frac{1}{2} \text{H}_2\text{O}$. The dependence of the potential-current curves on the surface state of the test sample indicates that the process contains a heterogeneous reaction. These facts enabled us to understand the role of HSO_3^- on the corrosion of Zn through an adsorption-oxidation mechanism with the following possible steps for the anodic reaction

From Eq. [11], applying the Frumkin isotherm

$$\frac{\Theta_{(\text{ZnHSO}_3)_{\text{ad}}}}{1 - \theta} = K_I C_{\text{HSO}_3^-} e^{-g\theta} \quad [15]$$

with $K_I = k_I/k_{-I}$ and g the variation in the apparent adsorption free energy with the coverage: $g = \partial \Delta G_{\text{ad}}^\circ / \partial \theta$.

For intermediate values of θ , applying the Temkin approximation

$$e^{g\theta} = K_I C_{\text{HSO}_3^-} \quad [16]$$

For reaction [13] in quasi-equilibrium state

$$\Theta_{(\text{ZnHSO}_3)_{\text{ad}}}^{-} k_{\text{II}} \exp \frac{(1 - \beta)F\Delta\phi}{RT} \\ = k_{-II} \Theta_{(\text{ZnHSO}_3)_{\text{ad}}} \exp \frac{-\beta F\Delta\phi}{RT}$$

$$\Theta_{(\text{ZnHSO}_3)_{\text{ad}}} = K_{\text{II}} \exp \frac{F\Delta\phi}{RT} \Theta_{(\text{ZnHSO}_3)_{\text{ad}}}^{-} \quad [17]$$

where $K_{\text{II}} = k_{\text{II}}/k_{-II}$ with equation (14) as rds

$$v_{\text{III}} = k_{\text{III}} \Theta_{(\text{ZnHSO}_3)_{\text{ad}}} \exp \frac{\beta F\Delta\phi}{RT} e^{g\theta} \quad [18]$$

Neglecting the pre-exponential $\Theta_{(\text{ZnHSO}_3)_{\text{ad}}}^{-}$ in Eq. [17] and replacing Eq. [16] and [17] in Eq. [18]

$$v_{\text{III}} = k_{\text{III}} K_{\text{II}} K_I^\alpha C_{\text{HSO}_3^-}^\alpha \exp \frac{F\Delta\phi}{RT} \exp \frac{\beta F\Delta\phi}{RT} \\ = K_{\text{III}} C_{\text{HSO}_3^-}^\alpha \exp \frac{(1 + \beta)F\Delta\phi}{RT}$$

with $K_{\text{III}} = k_{\text{III}} K_{\text{II}} K_I^\alpha$.

Considering the symmetry coefficients α and $\beta = 0.5$

$$v_{\text{III}} = K_{\text{III}} C_{\text{HSO}_3^-}^{0.5} \exp 1.5 \frac{F\Delta\phi}{RT} \quad [19]$$

The stoichiometric coefficient of the anodic process is

$$\nu = \frac{n}{\bar{\alpha} + \vec{\alpha}} = 1$$

Using $n = 2$, Eq. [13], [14], $\bar{\alpha} = 1.62$, and $\vec{\alpha} = 0.48$ were calculated (Table II).

The theoretical expression (12) of the transfer coefficients enabled us to verify the consistency of the proposed steps with the experimental results

$$\bar{\alpha} = \bar{\gamma} / \nu + \beta r = 1.5$$

and

$$\vec{\alpha} = \vec{\gamma} / \nu + r - r\beta = 0.5$$

with $\bar{\gamma}$ being the number of steps previous to the controlling one, $\vec{\gamma}$ the number of steps after the controlling one, r the number of electrons transferred in that step, and β the symmetry coefficient.

Derivation of log of Eq. [19] for high anodic overpotentials leads to

$$B_a = \left(\frac{\partial \log E}{\partial \log i} \right)_{C_{\text{HSO}_3^-}} = \frac{2.303}{1.5} \frac{RT}{F} = 40 \text{ mV}$$

which is in good agreement with the experimental value of the Tafel slope. Equation [19] also fits the anodic reaction order in HSO_3^- .

Cathodic curves in the presence of O_2 were also determined to complete the analysis of the reactions occurring during the atmospheric corrosion of Zn. The limiting current for the O_2 reduction increased with the concentration of the salt, as can be seen in Fig. 3, indicating the positive effects of the anion, as it was also observed for NO_3^- for the O_2 reduction on Zn (13). The variation of the limiting current i_L for O_2 reduction with the anion concentration

$$\frac{\partial \log i_L}{\partial \log [\text{HSO}_3^-]} = 0.65$$

indicates that the reaction is under diffusion control at which a reaction overpotential is superposed with a heterogeneous reaction order 0.65 in the anion concentration.

For this reason, mechanistic conclusions cannot be obtained. The O_2 reduction would depend on the coverage of the electrode by the adsorption complex formed.

Conclusions

From the results presented here, the following can be concluded.

1. The Tafel constants and corrosion rate obtained from the POLCURR program in the vicinity of the corrosion potential are in good agreement with those extrapolated in the Tafel region.

2. In the absence of O_2 , the Tafel constants and the reaction orders experimentally obtained for the anodic reaction, shown in Eq. [10] and [11], are in good agreement with the electrochemical parameters of the theoretical Eq. [19] derived on the base of an adsorption-oxidation sequence of reactions.

3. The controlling step in the oxidation of Zn is the charge transfer reaction [14] giving as final product $\text{ZnSO}_3 \times 2 \frac{1}{2} \text{H}_2\text{O}$.

4. The O_2 reduction implies a heterogeneous reaction depending on the adsorption complex.

5. The overall reactions proposed, in aerated solutions are for

and for

Mechanical and Current Oscillations in Corroding Electrodes

O. Teschke,* F. Galembeck, and M. A. Tenan

Instituto de Fisica and Instituto de Química, Universidade Estadual de Campinas, 13100 Campinas, SP, Brasil

ABSTRACT

Mechanical oscillations of the solution meniscus risen around a corroding wire electrode were observed in synchronism with electrical current oscillations. Scanning electron microscopy coupled to microprobe analysis was used to investigate the topochemistry of the system under study. Solution capillarity effects on iron and on iron compounds are related to the oscillations detected in this system.

Iron corrosion by acids is a rather complex phenomenon (1-5), involving many steps of chemical and physical transformation of the system constituents. A recent work (6) shows that anodically polarized electrodes made of pure iron, immersed in sulfuric acid, are covered with ferrous salts; oxide formation occurs underneath these. The oscillatory phenomena observed during passivation of iron seems to be related to the formation and dissolution of salt films (7).

During experiments on the behavior of iron immersed in sulfuric acid solution, we have observed mechanical oscillations (i.e., oscillatory vertical movement of sulfuric acid solution touching an iron tip, anodically polarized) coupled to electrical current oscillations. This observation suggests that capillary phenomena may be relevant to understand the behavior of passivating systems, at least in the case of incompletely immersed metal. The interpretation of capillary effects requires information on the topochemistry of the system under study, for which reason we have used scanning electron microscopy cou-

Fig. 1. Experimental setup

pled to microprobe analysis to examine corroding iron electrode. Results of these experiments are reported in this paper.

Experimental

The apparatus in which oscillations were observed consists of a borosilicate glass cylinder (8 cm diam, 15 cm height) as shown in Fig. 1. There is a lateral tubing (5 mm id at its top) exiting the cylinder. The cylinder volume is at least 100 times bigger than the capillary tube volume. A convex meniscus at the wetted capillary end (see detail in Fig. 1) was obtained by keeping the liquid level in the main cylinder a few millimeters above the meniscus level.

Reagent-grade chemicals were used without further purification. 1N aqueous H_2SO_4 was prepared using twice-distilled water. A 99.99% pure (C. Erba) iron wire 0.3 mm thick, cleaned with methanol and rinsed with twice-distilled water, was used as anode.

The iron electrode was grounded. Voltage was applied between the counterelectrode, a platinum wire with a downed area of at least 20 times larger than the area of the iron tip, and a saturated calomel electrode (SCE). An operational amplifier-based potentiostat kept the electrode voltages at the desired level, independent of the current. A constant voltage of +300 mV was applied between the iron electrode and the SCE. The current-time curves were recorded on a 7100 BM Hewlett-Packard Strip Chart Recorder. The photographs of the liquid level changes were taken using a Nikon F-2 reflex camera fitted with extension tubes for greater magnification. In order to obtain reproducible current-time curves, it was necessary to use a fresh solution and a new iron electrode tip for each experiment.

The topography and composition of deposits formed during iron corrosion were examined using a scanning electron microscope. The pictures were obtained by secondary electron imaging, and the composition by x-ray microanalysis using a beam energy of 20 keV. The data reduction was made by a computer correction program. Since the x-rays producing regions in the sample are about $2 \mu m$ wide, it was possible to characterize different regions of the surface. The results obtained were then related to the most likely compounds of iron, sulfur, and oxygen to identify the substance in each point analyzed.

Results

A typical current-time oscillation is given in Fig. 2. It was observed that the oscillation period depends on the applied voltage, the diameter of the iron tip, and the ra-

dus of curvature of the liquid surface. Oscillation periods for other radii of curvature of the liquid surface were measured, but the results reported here are for a tube diameter of 5 mm (id).

It was found that the peak maximum was affected by a number of physical factors including magnetic stirring of the solution, concentration, shape of the conducting (iron) tip, and the exact placement of the iron tip with respect to the liquid interface. In the experiments reported here, the iron wire was cut normal to its axis. The iron tip was placed approximately at the center of the liquid meniscus, and it was positioned to touch the liquid surface gently by using micromanipulators. By capillary action, the liquid rises immediately, wetting the lower part of the iron electrode.

After an induction period of a few minutes, mechanical oscillations of the liquid level around the iron electrode are observed. The oscillation occurs between the levels shown in Fig. 3a and 3b. These oscillations are sustained for periods of up to 1h with changes of frequency and pulse amplitude.

The measured solution electrolyte contact angle on a surface covered with iron sulfate is approximately 30° , and for an oxide-covered metallic iron surface this is approximately 83° (measured directly from photograph prints). This change in the contact angle for the initial and final product of the electrode reaction indicates a considerable change in the iron tip wetting ability as it is cor-

Fig. 3. Photograph of the liquid level changes at the iron electrode tip. a(left): Lower level. b(right): Upper level

Fig. 4. SEM photograph of an iron tip. a(top left): Low amplification photograph showing the base iron (or oxide covered iron) as dark regions covered by a lighter overlayer of iron sulfate. b(top right): A detailed view of the drowned area of iron wire. c(bottom left): Oxide layer found under a crystal of iron sulfate removed in the SEM. d(bottom right): A detailed view of iron wire surface above the meniscus upper level.

roded by sulfuric acid. Note that these angles cannot be observed in Fig. 3 because the shape of the iron tip is being continuously altered by corrosion.

After some oscillations, the iron tip was gently removed from the solution and dried in air. SEM photographs were taken from these samples showing in detail the microstructure of the product formed at the movable air-liquid-metal interline.

A corroded iron tip is pictured in Fig. 4a. It is partly covered with thick pieces of light material appearing as bright, white areas. This material is also spread along the iron wire which was in contact with the solution, as shown in Fig. 4b. Microprobe analysis showed this material to contain iron and sulfur in different proportions: 9.52 atomic percent (a/o) Fe and 10.72 a/o S (Fe:S ratio ~ 1), and 19.32 a/o Fe and 12.70 a/o S (Fe:S ratio ~ 3:2). These two different measured Fe:S ratios may correspond to $\text{FeSO}_4 \cdot n\text{H}_2\text{O}$ and $\text{Fe}_3(\text{OH})_2(\text{SO}_4)_2$, respectively, or could be attributed to the different compactness presented by the sample in different regions. This is a low conductivity solid which acquires charge under the SEM beam. It is possible to remove chunks of this material by allowing the sample to stay for some time under the beam. Under the iron sulfate pieces, we find the material shown in Fig. 4c, appearing as white, patched areas. From microprobe analysis, we obtained a composition of 52 weight percent (w/o) Fe and only ca. 1 w/o S. This material has a composition corresponding to that of hydrous iron (III) oxide. The dark product below this oxide layer is pure iron (95+ %, perhaps covered with an oxide layer much thinner than the microprobe sampling depth).

Examination of another area which corresponds to a point above the liquid-iron-air line, shown in Fig. 4d shows three main features: (i) bright spots which contain 20.73 a/o Fe and 13.27 a/o S (Fe:S ratio ~ 3:2), (ii) dark, rough areas (24 w/o Fe, 0.88 w/o S), and (iii) dark, even areas (100% Fe). From the microprobe analysis data, it is clear that the flat areas are made of bare metal. The highly reflecting areas are rich in iron sulfate, and the dark, rough areas contain less sulfate than the former; their composition corresponds to that of an hydrous iron oxide contaminated with some sulfate mixture. The features described above were found in other samples, but in many instances bare metal was not detected. Varying Fe:S ratios were frequently observed, indicating the occurrence of phases containing different proportions of oxide and sulfate.

Figure 5 shows a SEM photograph of the morphology of an area of the iron wire produced by the movement of the liquid-iron-air boundary. The iron wire was removed from the solution a few minutes after the mechanical oscillations started. The dark region (iron or iron oxide) surrounded by the lighter overlayer of iron sulfate was located just on the triple-phase boundary for the meniscus upper level. The dark area shown had its layer of iron sulfate removed by the liquid fall.

Discussion

From the results reported here, some conclusions may be drawn: (i) iron sulfate precipitates on mechanically oscillating iron electrodes, forming rather large crystals which tend to bulge out of the surface, instead of making films; (ii) other deposits are found which still contain some sulfate (perhaps as the result of adsorption or absorption in amorphous iron hydroxide); these are neither as prominent, nor as strongly insulating (at least regarding their ability to acquire electrostatic charge in the SEM beam); (iii) bare metal may also be detected, contiguous to areas covered with salt and oxide. However, this occurs less frequently than the other features found. Oxide films were found to form a porous layer under the iron sulfate in agreement with another recent report (6); (iv) the liquid-iron-air line movement removes the iron sulfate layer from the iron wire lateral surface, producing a region of bare metal.

The following mechanism is then proposed to justify the mechanical oscillations of the liquid level.

Fig. 5. SEM photograph of an iron tip removed from the solution a few minutes after mechanical oscillations started. The dark region (iron or iron oxide) surrounded by the lighter overlayer of iron sulfate was located just on the triple-phase boundary for the meniscus upper level.

1. Fe^{2+} ions are generated at the surface of the corroding positive electrode.

2. Metal oxidation is accompanied by a slow rise of the liquid level because the reaction products deposited on the metal surface are more hydrophilic than the metal itself. This resulting change in the contact angle for the initial and final product at the electrode surface plays an important role in the oscillation phenomenon. As can be seen from the equation for the total weight W of a liquid column rising above a flat liquid surface

$$2\pi r g \int_r^{\infty} h(x) x dx = W = 2\pi r \gamma \cos \theta \quad [1]$$

(where the integration variable x represents the radial distance from the wire axis), the static equilibrium height $h(x=r)$ attained by the meniscus above the liquid surface is expected to be (i) an increasing function of both the wire radius r and the liquid-air surface tension γ and (ii) a decreasing function of the solid-liquid contact angle θ . According to Eq. [1], a change in the wettability conditions of the solid wall corresponding to a contact angle change from 80° to 30° leads to a fourfold increase in the weight of the liquid column supported by capillary action. The change in the exposed area of the electrode wire as suggested by this considerable weight increase can thus be responsible for the current rise prior to the current pulse. Figure 2 shows this increase of ca. 125% measured from the minimum current at the end of the sharp peak to the beginning of the next one. In analogy to liquid flow in cylindrical capillaries (8, 9), we can estimate for the conditions found in our experiments a time of a few seconds for the meniscus to attain its maximum height. This corresponds to the time of the slow rise of the current before the current pulse (see Fig. 2). Consequently, meniscus oscillations and current oscillations fit into the same time frame.

3. The liquid level oscillates between lower level and upper level shown in Fig. 3a and 3b. The liquid is at the upper level at the beginning of the current pulse. The liquid level stays at this position only for a very short period. Then the liquid falls rapidly, removing from the iron metal surface the iron solid compounds and forming a visible stream of solid products. As the solid layer falls off, the new bare metal surface reacts with the draining solution generating a current pulse. Figure 2a (lower

level) shows the position corresponding to the current minimum.

4. The time of the slow rise of the meniscus determines the spacing between current pulses, as shown in Fig. 1, and it increases after each oscillation. This is a consequence of the removal of the lateral cylindrical surface material by corrosion. The removal is faster at the tip in contact with the liquid. The iron corroded surface is gradually cone shaped in the successive motion steps until, finally, the liquid loses contact with iron electrode. At this point, the iron tip diameter has decreased so much that the surface tension forces are unable to stop the liquid downward movement (*cf.* Eq. [1]).

Conclusion

The meniscus oscillations described herein are induced by the combined action of three phenomena: capillarity of the liquid on the wire wall, wetting changes on the wire surface due to chemical reaction, and gravity. The iron oxidation reaction produces changes in the physical and chemical characteristics of the substrate solid surface, making the electrode wall more hydrophilic, up to the moving triple-phase boundary of the meniscus. Capillarity is thus responsible for the meniscus rise around the vertical wire. Gravity, on the other hand, is responsible for the liquid fall when, due to the poor wetting character of the iron surface at which oxide was converted to sulfate, the liquid-metal adhesion force is not sufficient to hold the liquid column.

Mechanical oscillations and current oscillations at an anodically polarized iron tip are thus interdependent for

the system described. They are related to the formation and destruction of passivating oxide films. We believe that these findings should be relevant to the understanding of metal corrosion at liquid-air-metal intersection lines.

Current and Potential Transients during Localized Corrosion of Stainless Steel

Hugh S. Isaacs* and Yuichi Ishikawa¹

Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

The currents flowing from a localized corrosion site (LCS) on passive stainless steel in air-saturated 0.25M NaCl have been studied using a vibrating probe electrode. The potential behavior during applied currents was analyzed by assigning equivalent circuits to the passive surface and the localized site so that the paths of the current across the passive surface and the LCS could be calculated and compared with the measured values. The equivalent circuit of the passive surface without active localized corrosion was determined from potential transients and was found to be dependent on the prior history of the electrode. The LCS was equated to a resistance with an EMF which were calculated from the LCS current and specimen potential. The variations of this resistance were attributable to changes in solution resistance adjacent to the LCS. It was found that the capacitance of the passive surface played a major role during potential transients and the initiation of pitting.

Potential fluctuations, observed during open-circuit exposure of stainless steels (1-5) and other passive metals (6-8) have been associated with the onset of chloride-induced localized corrosion. The potential of the passive metal depends on the behavior of both the freely exposed surface and the growing localized corrosion site (LCS). Under freely corroding conditions with rapid cathodic kinetics, for example, in ferric chloride solutions, the potential variations are determined by the polarization of this reaction. When these cathodic polarization currents are known, the corrosion rate can be determined directly from the potential (5). The potential has been observed to decrease relatively slowly when pits initiate and grow, but increase almost immediately when they repassivate in these solutions (4, 5). In contrast, when the cathodic reaction is slow, as with dissolved oxygen, the behavior becomes more complex. The potential then drops rapidly

during the onset of pitting and increases slowly following repassivation (1-3, 6). The causes of the potential variations have not been presented in detail.

This work describes an approach to this problem which also closely resembles the exposures to which stainless steels are generally subjected. The approach developed from an analysis of results obtained with a scanning vibrating probe which has been used to monitor current from a LCS and leads to a number of interesting conclusions and possible applications.

Experimental

The location and monitoring of the currents from localized corrosion sites was accomplished using a scanning vibrating electrode. This technique was developed by biologists to overcome the noise interfering with amplification by masking small dc voltages (9, 10). The specific frequency of vibration enabled other signals associated with the noise to be filtered out and signals of the order of a few nanovolts to be measured (10). The design used

* Electrochemical Society Active Member.

¹ Visiting Scientist from Hitachi Limited, Mechanical Engineering Research Laboratory, Tsuchiura 300, Japan.

in this and other studies (11-13) was based on the work of Jaffe and Nuccitelli (10). The vibrating electrode was a coated platinum wire of 0.12 mm diam and coated with an insulation layer, having only the tip of the wire exposed to the solution. The tip scanned above the steel surface at a height of 0.1 mm. A similar wire was positioned well above the surface and was incorporated to reduce noise. The wires were attached to a piezoelectric bimorph reed and vibrated perpendicular to the steel surface. Generally, the frequency was about 600 Hz and the vibration amplitude about 0.03 mm, which could be adjusted by changing the voltage to the piezoelectric reed.

A schematic of the apparatus is shown in Fig. 1. The (Vibrating Probe Company) Probe Vibrator Power Supply activated the reed and also supplied a reference signal for the (Princeton Applied Research, Model 5204) Lock-in Amplifier. The experiments were computer controlled (Hewlett-Packard Desktop Computer, Type 9845T and Control and Data Acquisition Unit, Type 2240). The stage on which the vibrating probe was held was positioned with computer-activated stepping motors giving a single-step distance of 0.005 mm.

Samples of Type 304 stainless steel (Cr 18.88, Ni 8.61, Si 0.68, Mn 1.58, C 0.07, P 0.026, S 0.007 weight percent) with one 20×13 mm face exposed to the solution. The samples with insulated leads were mounted in epoxy resin (Buehler Type Epo Quick). The exposed surface was wet abraded down to a 600 grade silicon carbide finish. A series of samples with known crevice sizes was also prepared, but, as corrosion generally initiated at the interface with the epoxy, the carefully characterized crevices were discarded. The polarization measurements were made on samples with the edges coated with lacquer to reduce the initiation of localized corrosion leaving an area of 10×15 mm exposed.

All measurements were made at room temperature in 0.25M NaCl solutions prepared from deionized water and analytical-grade salt. The solutions were aerated before use and held in an open square flat-faced glass cell to allow observation of the probe from the side with a stereoscopic microscope. The cell also contained a calomel reference electrode and a platinum counter electrode.

Results

Localized corrosion was initiated and maintained by applying currents of about $1 \mu\text{A}$. When the potential continued to drop for a few minutes after its initial rapid increase, the position of the localized corrosion was located by scanning the entire sample to ensure only one localized corrosion site (LCS) was present. If more than one site did initiate, it was repassivated by washing with a jet of solution or the sample was cathodically polarized below the protection potential and the process repeated. When only a single LCS was found, the scanning was repeated around the site on a finer scale to more accurately determine the position of the maximum current density over its center. The vibrating probe was then positioned at this place and the effects of applied currents on the potential and the current from the LCS were studied. No effect of the vibrating probe on the behavior of the LCS was observed.

The output from the lock-in amplifier was calibrated against the applied current. When the potential showed only slow changes (<1 mV/s) and the LCS current approached a constant value, it was considered that a very small fraction of applied current flowed across the passive surface and the currents from the LCS were equal to the applied current. The calibration was linear and gave a slope of $4.3 \mu\text{V}/\mu\text{A}$ with an accuracy for the currents from the LCS of $\pm 0.1 \mu\text{A}$. The linear calibration also implied the LCS behaved as a point source, because the current density measured was proportional to the current.

Figure 2 shows the variations of the potential and the LCS current following step changes in the applied current. Immediately following the step, they both changed linearly with time for a short period. The linear change in the potential was indicative of no significant series resist-

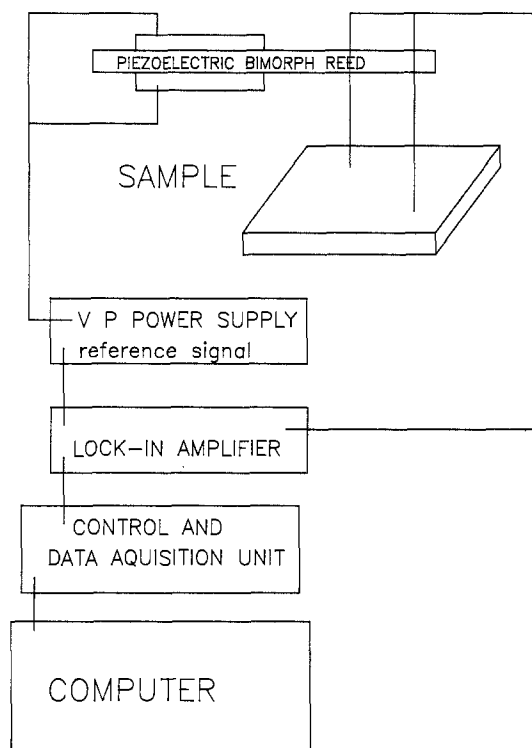

Fig. 1. Schematic of the vibrating electrode instrumentation

ance and a dominant capacitance. The value of the effective capacitance (C) was calculated from the equation

$$C = \frac{\Delta i}{dE/dt} \quad [1]$$

where Δi was the change in applied current and dE/dt the linear slope of the potential curve. The value of the capacitance was $95 \pm 15 \mu\text{F}$ ($36 \mu\text{F}/\text{cm}^2$). On increasing the applied current, the potential initially increased and if the current change was relatively large ($>0.5 \mu\text{A}$) the potential reached a maximum before decreasing. The opposite effect was seen on decreasing the potential. If the current changes were small ($<0.5 \mu\text{A}$), no maxima or minima were observed. The LCS currents approached constant values when the applied currents were above $0.6 \mu\text{A}$, but below this value the LCS currents generally decreased until the LCS repassivated. Following repassivation, the potential increased rapidly until a new LCS initiated. After the results shown in Fig. 2 were recorded and the sample was at open circuit, the potential rose to a steady value of -110 mV, following repassivation of the LCS. This potential was taken as the EMF of the passive surface.

The behavior of passive surfaces was studied without any localized corrosion occurring on the surface. The open-circuit potential and the impedance derived from potential or current transients, as well as the polarization behavior, all depended on the history of the electrode. At open circuit, a freshly abraded surface initially increases in potential and reaches around -120 mV after a few hours and about -75 mV after a few days. During these exposures, there were very few indications of LCS initiation events. If, however, the sample was anodically polarized repeatedly in the chloride solution to potentials above 250 mV, the long-term open-circuit potential was about 200 mV (the applied potential was turned off immediately after any initiation), and repeated initiation events having similar shapes were observed at open circuit. An example of such an initiation event is shown in Fig. 3. The potential dropped rapidly as the initiated site grew and after its repassivation the potential rose slowly over a period of 1000s. This behavior is typical of initiation and repassivation events in solutions containing only oxygen as the cathodic reactant.

Fig. 2. Variation of potential and LCS current following step changes in applied current

Polarization measurements of the passive surface were carried out both potentiodynamically and, essentially, galvanostatically. Figure 4, taken after 20h cycling at 0.1 mV/s, shows the currents depended on the potential direction. Over the range of -200 to 50 mV, the polarization curves had a greater slope (or impedance) on increasing the potential. The increased polarization impedance was also observed when a "square" current wave was stepped between two fixed values of -15 and -165 nA/cm² at 1 mHz. The magnitude of the potential response increased with time, indicating an increased electrochemical impedance. It was about 24 mV after 0.5h and 160 mV after about 21h. This change was less rapid than expected from the inverse current-time dependence at more positive potentials with passive metals (14, 15).

The potential response to a square current wave was analyzed at 5 mHz, as this frequency correlated with the changes in the applied current when a LCS was active (see Fig. 2). Figure 5 shows the potential response to a step current wave of -125 and 75 nA/cm². The asymmetric response again indicated a higher impedance on increasing the potential. The equivalent circuit for each of these half cycles was determined graphically (16) in terms

of a series of resistances (R_n) with parallel capacitances (C_n). The equation representing the response is

$$V = 0.5I \sum_{n=1}^n R_n [1 + \tanh(T/C_n R_n)] [1 - \exp(-t/C_n R_n)] \quad [2]$$

where I is the peak-to-peak current (200 nA/cm²), T is half the period of the cycle (100s), and t the time. The results with $n = 2$ are given in Table I and have an accuracy of about 10%.

Discussion

The analysis of the behavior of the passive surface with an active localized corrosion site (LCS) has been carried out by considering the electrical analogue of the steel/solution interface shown in Fig. 6a. Z_a represents the LCS, Z_c the passive surface with both metal oxidation and oxygen reduction taking place, I the externally applied current, i_a the LCS current measured with the vibrating probe electrode, and E the potential measured against a calomel reference electrode. Because of their electrochemical nature, Z_a and Z_c must also incorporate a potential generator or EMF.

The impedance of a passive surface has been attributed to the dielectric, resistive, and space-charge properties of the oxide (17) or to the presence of adsorbed species on the surface (18). Neither of these models has been unequivocally demonstrated, and an equivalent circuit based on either model will be controversial. In view of this, we chose an analogue for convenience of analysis of the response of the systems rather than attempt to confine to a particular model. The analysis of the potential response was in terms of capacitors with parallel resistors and offered sufficient accuracy for the present results and the time frame of minutes for the purposes of these discussions.

Table I shows the magnitude of the capacitors and resistors obtained from Fig. 5 and were used to partly replace Z_c . An EMF source having the value of the open-circuit potential observed after the LCS had repassivated (i.e., $E_c = -110$ mV) was added to complete the analogue of the passive surface. The polarization curve in Fig. 4 shows curvature, indicating that the equivalent circuit changed with potential direction. The derived equivalent circuit was therefore an approximation covering the potential over which the LCS measurements were made and was also dependent on the direction of potential change. The open-circuit potential also depended on the potential history, as was shown by the effects of anodic pretreatment and the results in Fig. 3, which led to higher potentials than observed with the specimen following the LCS current measurements. The value of -110 mV was taken because it was representative of the particular sample for

Fig. 6. a (top): An equivalent circuit showing the impedance of the LCS, Z_a , the passive surface, Z_c , the applied current, I , and the LCS current, i_a measured using the vibrating electrode. b (center): An equivalent circuit showing the experimentally derived analogue components. c (bottom): The simplified equivalent circuit during the early stages of pit initiation.

which a simulation of the potential variations and LCS current were carried out.

The equivalent circuit of the LCS was determined from the analysis of the current flowing through the LCS (i_a) and the potential in Fig. 2 and does not incorporate the passive surface. In order to characterize the behavior of the LCS, the LCS current was plotted against the potential of the specimen in Fig. 7. These plots indicated that there was a linear relation between LCS current and the potential immediately following the changes in the applied current. The linear relation was indicative of a resistive response having a resistance equal to the slope of this line. A second observation was the extrapolations of these lines all intersected the ordinate at close to -230 mV, as emphasized by their inclusion in Fig. 7 for the various applied currents. It is clear from the results in Fig. 7 that the value of the resistance varied with time. There is obviously a representational difficulty involved with this approach. Generally, inductances and capacitances are invoked to account for time variations, and indeed an added inductance and series resistance, placed in parallel with a resistance, could possibly be used to fit the potential responses. However, a single inductance could not fit the results. In addition, when small changes in applied current were made (<0.5 μ A), there was no in-

dication of inductive behavior, and trials with inductances led to resonances not observed experimentally.

Potentials close to that of the constant intercept in Fig. 7 have also been observed in other studies (19, 20) and result from the localized corrosion cell consisting of the active metal and the concentrated chloride electrolyte with dissolved corrosion products within the LCS. The open-circuit potential for this cell, and the Type 304 alloy used in these experiments, has been observed to be about -250 mV and was dominated by the presence of copper corrosion product from the alloy (19).

The above consideration led to an equivalent circuit for the LCS consisting of a resistor (R) and an EMF (E_a) in parallel with that of the passive surface giving an equivalent circuit shown in Fig. 6b. The LCS resistance was calculated from the results in Fig. 2 or 7 from the equation.

$$R = (E - E_a)/i_a \quad [3]$$

Graphically, this was the slope of the line between the intercept on the potential axis and the point on the curve obtained at the time of interest.

The results of Fig. 2 and 7 are related to the dissolution characteristics of the LCS as the applied current was changed. The best measure of the state of the LCS was the resistance R , which generally decreased after the current was increased and vice versa. This was obviously caused not by changes in size of the LCS because a particular resistance could be obtained repeatedly on cycling, but rather by a result of the changes in the localized environment. One explanation could be the effect of changes in the concentration of dissolution products, chlorides, and pH on the conductivity in and around the LCS. The conductivity range of the solution that could possibly be present varies from that of 0.25M NaCl having a resistivity of about 45 Ω -cm to that within the LCS with a resistivity of around 5 Ω -cm. Similar effects have been discussed by Newman (21). The difference in solution conductivity of, say, nine times is adequate to account for the observed changes in R which from Fig. 7 and Eq. [3] were calculated to vary from 75 to 275 k Ω .

In order to confirm the equivalent circuit, the potential changes and LCS currents were computer calculated. The changes in R were used as input to the calculation. The passive surface impedance which depended on the direction of potential was taken from Table I, and the values of E_c and E_a were fixed at -110 and -230 mV (SCE), respectively. A comparison of the observed and calculated values are shown in Fig. 8, showing good agreement between the observed and the calculated potentials and LCS currents with time. This clearly demonstrates the validity of the analogue circuit requiring only the resistance of the LCS to change fairly rapidly with time and shows a consistent split of the current between the passive surface and the LCS. It also shows that if the behavior of the anode and cathode during localized corrosion can be de-

Fig. 8. Comparison between the observed and calculated LCS currents and specimen potential for transients 3 and 4 are shown in Fig. 2.

scribed in sufficient detail, the potential behavior can be predicted.

The equivalent circuit in Fig. 6b can also be used to analyze the open-circuit potential changes following initiation of the pit in Fig. 3. It becomes clear from the equivalent circuit that the capacitance of the passive surface is the component of major importance when the potential varies rapidly either immediately following changes in applied current or when pitting initiates. The equivalent resistances of the passive surface then play a minor role because of their high values. During the potential decrease in Fig. 3, the passive surface can be represented by a single capacitor. The equivalent circuit of the stainless steel is shown in Fig. 6c. The capacitance markedly retards the potential changes, with virtually no faradaic or net electrochemical reaction taking place. This was also noted when the applied currents were turned off and the current flowing from the LCS were far greater than those that could be produced by the oxygen reduction reaction.

The role of the capacitance is also extremely important during freely corroding conditions when pitting initiates. Considering Fig. 6c prior to pit initiation, the value of R is infinite. On initiation of localized corrosion, the presence of R leads to charging the capacitance. The amount of charge involved, Q , is given by the product of the potential change ΔE , and the capacitance, *i.e.*

$$Q = C\Delta E \quad [4]$$

In other words, the potential change observed in Fig. 3 when pitting initiated can, on one's knowing the magnitude of the capacitance, be used to estimate the amount of charge passed through the pit. From the charge, the amount of metal dissolved or the size of the pit can be calculated. Taking the capacitance as 25 μ F/cm², which is representative of the passive surface over a period of less than a few seconds, and a surface area of 1 cm², the transient in Fig. 3 of 230 mV results in a hemispherical pit size of about 5 μ m.

This approach can be extended to give information about the rate of growth of pits. Differentiation of Eq. [2] gives

$$i = C dE/dt \quad [5]$$

and indicates that the rate of pitting or pit growth can be determined from the shape of the rapidly decreasing portion of the curve in Fig. 3. This approach requires that the capacitance remains constant or its dependence with time be known. This approach was not developed in the present work but will be used in the future.

Following the repassivation of the pit, the value of R is again infinite and the potential changes are then controlled by the slow discharging of the capacitance via the high parallel resistances which are determined by passive surface polarization currents.

It may also be of interest to note that, because the capacitance increases with surface area of the stainless steel, this must have a bearing on pit propagation. From Eq. [5] and [4], increasing the capacitance decreases both the magnitude and rate of potential change. For both these reasons, increasing the surface area increases the likelihood of a pit's remaining active and not repassivating. Because of the greater charge available, the potential does not drop below any protection potential for the very small pits and the pit remains active. This analysis strongly suggests that the probability of forming a stable pit increases with area of stainless steel. The cause is related not to the statistics of initiation, as has been suggested, but to stabilizing propagation after initiation. The critical stages in producing a stable pit occur relatively rapidly and hence appear to be essentially independent of the rate of oxygen reduction and dependent on factors determining the interfacial capacitance.

Kinetics of the Low Temperature Hot Corrosion of Co-Cr-Al Alloys

Krishan L. Luthra*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Hot corrosion rates have been measured on many Co-Cr, Co-Al, and Co-Cr-Al alloys coated with 2.5 mg/cm² of Na₂SO₄ and exposed in O₂-0.15%(SO₂ + SO₃) at 750°C. The hot corrosion resistance of the binary alloys increases with the chromium and aluminum content of the alloys. However, the additions of aluminum to Co-Cr and of chromium to Co-Al alloys have deleterious effects. These results can be explained on the basis of a mechanism similar to one previously proposed in the literature (1, 2). Additional experiments have been conducted as a function of temperature and the (SO₂ + SO₃) content of oxygen to extend the proposed mechanism.

Sodium sulfate-induced hot corrosion problems have plagued the gas turbine industry for more than 30 years. Until about the mid nineteen-seventies, it was believed that these problems occurred only when liquid salts deposited on the surface of gas turbine components. However, since then, severe degradation of cobalt containing alloys and coatings has been observed at temperatures below the melting point of Na₂SO₄ (884°C). This corrosion is believed to be caused by formation of an Na₂SO₄-CoSO₄ eutectic and is identified in the literature as low temperature hot corrosion.

Many publications in the literature have been concerned with various aspects of low temperature hot corrosion (1-8). In earlier papers, we described the morphology

and mechanism of corrosion of cobalt-base alloys (1-3). While attempting to quantify further the corrosion rates of Co-Cr-Al alloys, some rather strange interactions were observed between the effects of chromium and aluminum, which ultimately led to the development of new coatings (9). This paper discusses these results and correlates them with the mechanism proposed earlier (1, 2).

Experimental

Hot corrosion studies were conducted on coupons of several cobalt-base alloys listed in Table I' by using laboratory-accelerated oxidation tests with 2.5 mg/cm² of Na₂SO₄. The coupon specimens (~12.5 × 6.3 × 1.0 mm) were obtained by machining small chill cast ingots pre-

pared from 99.9% pure elements. The salt coatings were obtained by spraying an aqueous solution of Na_2SO_4 with an air brush on prewarmed ($\sim 150^\circ\text{C}$) specimens. These samples were then exposed at 1 atm total pressure in an O_2 -0.15%($\text{SO}_2 + \text{SO}_3$) gas mixture at 750°C to simulate low temperature hot corrosion conditions present in engines. A platinum catalyst was used to ensure equilibrium in the gas mixture. During the course of the experiments, which usually lasted for about 24-72h, the samples were continuously weighed using a Cahn 1000 microbalance. Further details of the experimental arrangement are given elsewhere (1, 10).

Thermochemical Considerations

Thermodynamic calculations were performed to determine the minimum p_{SO_3} for which an Na_2SO_4 - CoSO_4 liquid can form on various cobalt oxides; the results are shown in Fig. 1. The details of calculations for CoO and Co_3O_4 , including the required minimum activity of CoSO_4 , were described in earlier publications (1, 10). These calculations will be extended to other oxides here.

The sulfation of any cobalt oxide can be considered as that of CoO existing at an activity of less than or equal to unity. Thus, the reaction for the formation of an Na_2SO_4 - CoSO_4 liquid can be represented by

where the underline indicates that CoO and CoSO_4 can exist at less than unit activity. From reaction [1], at any temperature

$$\frac{a_{\text{CoSO}_4}}{a_{\text{CoO}}p_{\text{SO}_3}} = \text{const.} \quad [2]$$

Thus, the SO_3 pressure needed to stabilize a liquid will increase inversely with a_{CoO} .

The equilibrium CoO activity in Co_3O_4 can be calculated from the equilibrium constant of the following reaction

Calculations based on JANAF Tables (11) show that at $P_{\text{O}_2} = 1$ atm Co_3O_4 is the stable cobalt oxide and the CoO activity in Co_3O_4 is less than unity below 947°C . Consequently, the SO_3 pressure required to form liquid Na_2SO_4 - CoSO_4 from Co_3O_4 in Fig. 1 is higher than that for CoO . The CoO activity may be even lower and the required SO_3 pressure even higher if cobalt exists only as CoCr_2O_4 or CoAl_2O_4 , which is possible on cobalt-based alloys containing high chromium or high aluminum, respectively. Under these conditions, the CoO activity can be calculated from the equilibrium constants of the following reactions

Fig. 1. Plots of the calculated SO_3 needed to form an Na_2SO_4 - CoSO_4 liquid from CoO , Co_3O_4 , a $\text{CoCr}_2\text{O}_4/\text{Cr}_2\text{O}_3$ mixture, and a $\text{CoAl}_2\text{O}_4/\text{Al}_2\text{O}_3$ mixture. The SO_3 values for Co_3O_4 decrease with $P_{\text{O}_2}^{1/6}$, and the values shown here are for $P_{\text{O}_2} = 1$ atm; all other curves are P_{O_2} independent. Also shown are the SO_3 pressures of an O_2 -0.15%($\text{SO}_2 + \text{SO}_3$) mixture at 1 atm (curve A) and of an O_2 -1%($\text{SO}_2 + \text{SO}_3$) mixture at 1 atm and 750°C (point B) (1, 10).

These calculations were performed using the free energy data for reactions [4] and [5] from Kubaschewski (12). The corresponding SO_3 pressures needed to stabilize the liquid phase are shown in Fig. 1. At present, it is not possible to ascertain errors associated with these SO_3 values because the errors associated with the SO_3 pressures for CoO in Fig. 1 and with the free energy data for reactions [4] and [5] are unknown.

Results and Discussion

Hot corrosion studies were conducted on several Co-Cr and Co-Al alloys. As shown in Fig. 2, the corrosion rates decreased with an increase in the chromium content of Co-Cr alloys. Macroscopic examination of the reacted samples showed that the Na_2SO_4 salt had melted on all alloys except on Co-40Cr, which corroded very slowly. Similar results were obtained on Co-Al alloys. As shown in Fig. 3, corrosion rates decreased with an increase in the aluminum concentration; again, the macroscopic examination of the reacted samples showed that the Na_2SO_4 salt did not melt on Co-15Al and Co-20Al, alloys that reacted very slowly.

An unexpected result was observed when aluminum was added to Co-40Cr. As shown in Fig. 4, even 1% aluminum significantly increased the corrosion rate. A purple Na_2SO_4 - CoSO_4 liquid was observed on the surface of the corroded samples containing aluminum. The detrimental effect of aluminum was also observed on other Co-Cr alloys, such as Co-35Cr (see Fig. 5), that normally formed a liquid and corroded significantly. However, comparison of Fig. 4 and 5 shows that the effect was less pronounced on Co-35Cr than on Co-40Cr. The detrimental effect of aluminum has been reported before (5). However, what has not been appreciated is that at a high enough chromium concentration (e.g., $\geq 40\%$ Cr) the liquid may not

Fig. 2. Effect of chromium concentration on the hot corrosion of binary Co-Cr alloys.

form and that under these conditions even a small amount of aluminum promotes the liquid formation and severely degrades the alloy. Figure 6 shows that the addition of 2, 5, and 20%Cr to Co-15Al, an alloy with excellent corrosion resistance at 750°C, also produced a detrimental effect.

These results show that the simultaneous presence of chromium and aluminum accelerates low temperature hot corrosion. The coatings used in industry (e.g., CoCrAlY) contain both of these elements because they

Fig. 3. Effect of aluminum concentration on the hot corrosion of binary Co-Al alloys.

Fig. 4. Effect of aluminum addition on the hot corrosion of Co-40Cr at 750°C.

are believed to be beneficial from the standpoint of hot corrosion at higher temperatures. Indeed, as shown in Fig. 7, chromium addition to Co-15Al and aluminum addition to Co-40Cr have beneficial effects at 900°C.

These results can be explained on the basis of an earlier mechanism (1, 2) that is based on the rapid dissolution of the more noble metal or metal oxide in liquid salts. An Na₂SO₄-CoSO₄ liquid forms on the surface of cobalt containing alloys by interaction of cobalt oxide, formed dur-

Fig. 5. Effect of aluminum addition on the hot corrosion of Co-35Cr at 750°C.

Fig. 6. Effect of chromium addition on the hot corrosion of Co-15Al at 750°C.

Fig. 7. Effect of chromium addition on the hot corrosion of Co-15Al and of aluminum addition on the hot corrosion of Co-40Cr at 900°C.

ing the transient oxidation, with the Na_2SO_4 salt and SO_3 present in the gas. Subsequent to the liquid formation, degradation is caused by the dissolution of cobalt and cobalt oxide.

Consider first the corrosion of Co-Cr alloys. The protection against corrosion is offered by formation of a $\text{CoCr}_2\text{O}_4/\text{Cr}_2\text{O}_3$ film and the exclusion of CoO and Co_3O_4 . With an increase in chromium content, the rate of growth of CoCr_2O_4 and Cr_2O_3 increases, in competition with CoO and Co_3O_4 formation, which thereby increases the corrosion resistance of alloys. For chromium levels $\geq 40\%$, the growth rate is presumably so fast that for all practical purposes the salt is in contact with only a $\text{CoCr}_2\text{O}_4/\text{Cr}_2\text{O}_3$ mixture; consequently, as expected from Fig. 1, the liquid phase would not form at 750°C in O_2 -0.15% ($\text{SO}_2 + \text{SO}_3$) and corrosion would not occur. The addition of aluminum must increase the corrosion rate of binary alloys by retarding the rate of growth of Cr_2O_3 and CoCr_2O_4 , which therefore makes the scales less protective. For alloys containing high chromium on which the liquid does not normally form ($\geq 40\%$ Cr), the effect would be most pronounced. If aluminum oxidation lowers the growth rates of Cr_2O_3 and CoCr_2O_4 , some cobalt may exist as Co_3O_4 during transient oxidation which would then promote the degradation of alloys by formation of an Na_2SO_4 - CoSO_4 liquid. The liquid formation was indeed observed on aluminum containing Co-40Cr alloys reported in Fig. 4.

The proposed mechanism of corrosion of Co-Al alloys is similar. With an increase in the aluminum content of alloys, the rates of growth of Al_2O_3 and CoAl_2O_4 increase, thereby making the oxide film more protective. At aluminum levels above about 15 weight percent, the protection is presumably markedly improved because cobalt exists only as CoAl_2O_4 which prevents the formation of the liquid phase. For such high-aluminum alloys, the chromium addition may retard the growth rate of an $\text{Al}_2\text{O}_3/\text{CoAl}_2\text{O}_4$ film and, thus, may promote the formation of the liquid, thereby increasing the corrosion rate. Indeed the liquid was observed on chromium containing Co-15Al alloys reported in Fig. 6. At present, it is not known whether the detrimental effect of chromium observed here is limited to the Co-Al alloys on which the liquid film does not form normally or whether it extends to lower aluminum alloys also.

A new conclusion in the mechanism proposed here compared to that previously proposed (1, 2) is that liquid formation on binary alloys containing high chromium and aluminum concentrations can be prevented by spinel formation. However, the presence of spinels has not been confirmed experimentally. The only oxide identified by x-ray diffraction on the Co-40Cr sample in Fig. 2 was Cr_2O_3 . This, however, provides no information about the formation of CoCr_2O_4 during the early stages of oxidation. The available literature on oxidation is also not helpful. At steady state, the formation of CoCr_2O_4 and CoAl_2O_4 has been reported on binary and ternary alloys in the Co-Cr-Al system at 1000°-1200°C (13-15). However, there have been no studies on transient oxidation of binary alloys containing high chromium and aluminum used in this study at 600°-800°C. According to the current theories of oxidation, some cobalt containing oxide should form on the surface during transient oxidation. It is, therefore, reasonable to expect that this oxide is a spinel on binary cobalt-base alloys containing high chromium and aluminum.

At present, it is not clear why additions of even small amounts of aluminum in Co-Cr alloys and of chromium in Co-Al alloys have such marked effects on the growth rate of $\text{Cr}_2\text{O}_3/\text{CoCr}_2\text{O}_4$ and $\text{Al}_2\text{O}_3/\text{CoAl}_2\text{O}_4$ films, respectively. These detrimental effects seem particularly surprising because at 1000°-1200°C addition of Cr to Co-Al promotes the formation of an Al_2O_3 film and addition of Al to Co-Cr alloys promotes a Cr_2O_3 film (15-16). As discussed above, these detrimental effects may be related to the oxides formed during transient oxidation. A more quantitative explanation is not possible without extensive studies on the transient oxidation of Co-Cr-Al alloys as a function of Cr and Al concentration at 600°-800°C, which are beyond the scope of this work.

Additional experiments were conducted to further prove the formation of spinels. Figure 1 shows that the SO_3 content of an O_2 -0.15% ($\text{SO}_2 + \text{SO}_3$) gas mixture at 750°C is slightly higher than the calculated value for formation of the liquid on a $\text{CoAl}_2\text{O}_4/\text{Al}_2\text{O}_3$ film. However, due to uncertainties associated with the calculated values, higher SO_3 values than in O_2 -0.15% ($\text{SO}_2 + \text{SO}_3$) or lower temperatures than 750°C might be necessary to form the liquid. Experiments were, therefore, conducted

Fig. 8. Hot corrosion of Co-15Al in O_2 -0.15%($SO_2 + SO_3$) at 600°C and in O_2 -1%($SO_2 + SO_3$) at 750°C, two conditions under which an Na_2SO_4 - $CoSO_4$ liquid can form even from a $CoAl_2O_4/Al_2O_3$ film. Also shown for comparison are the plots of results in O_2 -0.15%($SO_2 + SO_3$) at 750° and 900°C.

in O_2 -1%($SO_2 + SO_3$) at 750°C and in O_2 -0.15%($SO_2 + SO_3$) at 650°C. Liquid formation was indeed observed, and as shown in Fig. 8, significant corrosion rates were observed on Co-15Al for both sets of conditions. Figure 9 shows a plot of an average hot corrosion rate in O_2 -0.15%($SO_2 + SO_3$) as a function of temperature. A minimum in corrosion rate occurs at 750°C, where the liquid does not form. Higher corrosion rates are observed at 600°C, where low temperature corrosion occurs as a result of the formation of an Na_2SO_4 - $CoSO_4$ liquid, and at 900°C, where normal high temperature hot corrosion occurs.

Whereas a liquid can form at 600°C in O_2 -0.15%($SO_2 + SO_3$) on a $CoAl_2O_4/Al_2O_3$ film, it may not form on a $CoCr_2O_4/Cr_2O_3$ film because the SO_3 content of the mixture

Fig. 9. A plot of an average corrosion rate, obtained by dividing weight gain/area with time, over 24h as a function of temperature for corrosion of Co-15Al in O_2 -0.15%($SO_2 + SO_3$). The Na_2SO_4 - $CoSO_4$ liquid forms at 600° and 900°C, but not at 750°C. The curve connecting data points may not be smooth and is therefore shown dashed.

is close to the minimum required to form the liquid (see Fig. 1). Indeed, the liquid did not form, and the observed corrosion rate was very low on Co-40Cr. A weight gain of 0.6 mg/cm² was observed in 24h at 600°C, which is comparable to that observed at 750°C (0.5 mg/cm²) in Fig. 2.

These results show that, due to differences in the stability of $CoCr_2O_4$ and $CoAl_2O_4$, binary Co-Cr alloys can offer protection against low temperature hot corrosion up to higher SO_3 partial pressures in comparison to binary Co-Al alloys. It is known that due to solid-state diffusion effects the growth rates of Cr_2O_3 films are much higher than of Al_2O_3 films. Therefore, from the standpoint of kinetics also, the Co-Cr alloys should be superior to Co-Al alloys at lower temperatures.

This study shows that the simultaneous presence of Cr and Al is detrimental to low temperature hot corrosion. Traditionally, coatings developed for high temperature hot corrosion have been MCrAlY compositions containing 20-30% Cr, 6-15% Al, and a small amount of an active element, such as Y, to promote scale adhesion. But from the standpoint of low temperature corrosion, coatings of Co-Cr alloys containing $\geq 40\%$ Cr with a small amount of an active element should be good candidates for coating materials. Extensive studies conducted in our company show that coatings containing $\geq 37.5\%$ Cr provide excellent resistance to low temperature corrosion, at least an order of magnitude better than the current CoCrAlY coatings, and provide adequate resistance to normal high temperature corrosion, comparable to current CoCrAlY coatings (9). Figure 10 shows the results of a few such laboratory tests, where Co-40Cr coatings have been compared with CoCrAlY coatings normally used in marine engines. A patent application has been filed for these new, high-chromium cobalt-base coatings.

Conclusions

The degradation of cobalt-base alloys during low temperature hot corrosion is caused by formation of an

Fig. 10. Comparisons of the hot corrosion behavior of Co-40Cr and Co-22Cr-12Al-0.3Y coatings on Rene 80 substrate at 750° and 900°C. Clearly, the Co-40Cr is superior to the CoCrAlY coating. (The coatings were ~ 0.10 mm thick and were obtained by electron beam vapor deposition).

$\text{Na}_2\text{SO}_4\text{-CoSO}_4$ liquid that forms by interaction of cobalt oxide formed during the transient oxidation of alloys, with SO_3 in gas and Na_2SO_4 salt. Accelerated oxidation tests at 750°C show that the corrosion resistance of binary Co-Cr and Co-Al alloys increases with the Cr and Al content of alloys, respectively. This protection is offered by the rapid growth of $\text{CoCr}_2\text{O}_4/\text{Cr}_2\text{O}_3$ and $\text{CoAl}_2\text{O}_4/\text{Al}_2\text{O}_3$ oxides in comparison to CoO and Co_3O_4 . At high enough chromium ($\geq 40\%$) and aluminum ($\geq 15\%$) concentrations, the growth rates are so fast that the liquid does not even form; consequently, the corrosion rates are very low. The SO_3 pressures below which the formation of a liquid film can be prevented have been calculated.

Contrary to the experience at higher temperatures ($\geq 884^\circ\text{C}$), tests on Co-Cr-Al alloys indicate that the simultaneous presence of chromium and aluminum is deleterious to the resistance against low temperature hot corrosion resistance. It is proposed that the additions of aluminum to Co-Cr and of chromium to Co-Al alloys retard the growth rates of $\text{CoCr}_2\text{O}_4/\text{Cr}_2\text{O}_3$ and $\text{CoAl}_2\text{O}_4/\text{Al}_2\text{O}_3$ films, respectively, thereby reducing their corrosion resistance. Further work is, however, needed on transient oxidation of Co-Cr-Al alloys at $600^\circ\text{-}750^\circ\text{C}$ to confirm the mechanism of these deleterious effects.

A Mathematical Model for the Periodic Electrodeposition of Multicomponent Alloys

Mark W. Verbrugge* and Charles W. Tobias**

Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720

ABSTRACT

A mathematical model is presented for the electrodeposition of multicomponent alloys by an arbitrarily specified current source. The model takes into consideration transient, convective mass transfer to a rotating disk electrode, Butler-Volmer kinetics, and individual component activities in the electrodeposits. The model can be used to calculate current-potential relationships, ionic concentration profiles, and electrodeposits composition. Results for square-pulse, pulse-reversal, and triangular current waveforms are presented. An analogous model for potential-controlled electrolysis is also discussed.

The properties of alloys vary over a wider range than those of their parent metals, and thus can often be designed to better fulfill the mechanical and chemical requirements of our civilization. Electrodeposition offers several unique advantages for the formation of alloys. The superior control of the alloy composition, including the formation of nonequilibrium alloys, and the ability to prepare thin films are well documented. Brenner's encyclopedic monograph (1) reviews some practical methods for the electrodeposition of various alloys, and Gorbunova and Polukarov's treatment (2) outlines the fundamental principles involved. Srivastava and Mukerjee (3) review developments in the electrodeposition of binary alloys.

It has long been known that pulsing the current can profoundly affect the nature of single-component electrodeposits. Although the pulsed plating of alloys has re-

ceived comparatively little attention, it has been observed that the phase structure and morphology of alloy deposits can be altered by changing the characteristics of the pulsed-current waveform. This work presents a model for predicting the current-potential relationship and the composition profiles in the electrodeposits and the electrolyte.

Wan *et al.* (4) have presented a literature review dealing with the application of pulsed-plating techniques for single-component metal deposition. Avila and Brown (5) have cited the following advantages of pulsed plating over dc electroplating: (i) extremely dense and highly conductive deposits, (ii) a reduced need for plating additives, and (iii) increased plating rates. In reference to the last advantage, Cheh (6) has shown analytically that pulsed-current plating can never attain a higher average plating rate than dc plating at the diffusion-limited current. However, a higher average current density is often used in pulsed plating, relative to dc plating, since poor quality electrodeposits are often formed under dc condi-

tions near the diffusion limiting current. Lamb (7) has investigated the mechanical properties of single-component copper and silver electrodeposits obtained by current pulses in the microsecond range. Puipe and Ibl (8) studied the morphology of pulse-plated cadmium, copper, and gold electrodeposits. The influence of the off time, the pulse-current density, and the length of the pulse time were analyzed. Different morphological trends were observed and discussed for the different chemical systems. Ismail (9) investigated the periodic, reverse-current electroplating of copper from an alkaline-cyanide bath. The maximum brightness occurred at 0.27 Hz with a cathodic-current to anodic-current ratio of 2. Despic and Popov (10) examined the effect of a pulsating potential on the morphology of copper and zinc electrodeposits. Typical results illustrated that increasing the frequency led to a progressively smoother deposit. Popov (11) also has reviewed some approaches to the quantitative modeling of the surface-roughness amplification during an electrodeposition process. Sullivan (12) has reported that high-current-density pulsed plating of cobalt results in significantly stronger and harder electrodeposits.

The pulsed plating of multicomponent electrodeposits has received less attention than pure-component electrodeposition. Gelchinski *et al.* (13) electroplated chromium-cobalt alloys using a pulsed-potential source. Mirror-bright electrodeposits containing supersaturated solid solutions were obtained. It has been observed that the structure and the physical properties of the electrodeposited alloys can be very different from the thermally prepared alloys of similar composition. Gelchinski *et al.* also found that a change in the electrodeposition conditions can cause a marked change in the phase structure of the electrodeposit, even for those deposits of identical chemical composition. Burrus (14) has described various conditions where the pulsed plating of different metals and metal mixtures can be used advantageously. Leidheiser and Ghuman (15) used a pulsed-current setup to electrodeposit silver-tin alloys which could be easily polished to a high luster. Cohen *et al.* (16) have electroplated cyclic, multilayered, alloy coatings of varying silver and palladium composition with square-pulse and triangular current waveforms. They also report on periodic-potential plating studies of various multicomponent electrodeposits.

Mathematical Analysis

In considering the mathematical modeling for the electrodeposition of multicomponent alloys, it is convenient to divide the problem into three interrelated parts: the liquid phase containing the discharging ions, the electrolyte-electrodeposit interface, and the electrodeposited alloy.

The liquid phase.—One of the goals of this work is to quantitatively predict the ionic surface concentrations throughout the electrodeposition process. It has been well established that the ionic surface concentrations can greatly influence the electrodeposit composition and morphology (17, 18).

A theoretical analysis for single-component mass transfer in pulsed electrolysis was recently published by Chin (19). A stagnant (Nernst) diffusion layer was assumed valid in order to develop a comprehensive theory for pulsed electrolysis. Chin's paper includes a brief review of previous theoretical studies in single-component pulsed electrolysis.

Since our treatment uses a current-step solution and the method of superposition to derive a model for multicomponent mass transfer, we shall review some current-step solutions which can be used with this technique. The method of superposition is computationally very efficient, although the differential equations describing the process must be linear for this method to be applied. Therefore, migration effects are not included in this model. Double-layer charging is also not considered. Since practical plating baths usually contain an excess of supporting electrolyte, migration effects can often be ne-

glected. Double-layer charging effects can become important in an electrodeposition process if microsecond current cycles are used (20). Before proceeding, it should be mentioned that attempts have been made to qualitatively describe multicomponent, pulsed-current processes (21-24). Also, Cheng and Cheh have presented finite-difference models for the pulsed-current electrodeposition of copper with hydrogen evolution (25) and of lead-tin alloys (26).

The convective diffusion equation for the one-dimensional mass transport of species *i* is

$$\frac{\partial c_i}{\partial t} + v_y \frac{\partial c_i}{\partial y} = D_i \frac{\partial^2 c_i}{\partial y^2} \quad [1]$$

For high Schmidt numbers, the appropriate expression for the normal component of the fluid velocity to a rotating disk electrode (RDE) is (27, 28)

$$v_y = -0.51023 \omega^{3/2} \nu^{-1/2} y^2 \quad [2]$$

The radial variation of the ionic surface concentration is neglected in this treatment, as it would considerably complicate the problem (29-31). In a rigorous treatment for the RDE system incorporating both radial and axial variations, dimensionless groups arise which include the disk radius (29, 30). For small disks, it is appropriate to neglect radial variations in concentration and potential. Nanis and Klein (32) qualitatively address this assumption in their one-dimensional treatment for transient mass transfer to an RDE in the absence of kinetic resistance.

For the current-step problem, the initial condition and boundary conditions are

$$c_i(0, y) = c_i^b \quad [3]$$

$$c_i(t, \infty) = c_i^b \quad [4]$$

and

$$\frac{\partial c_i(t, 0)}{\partial y} = -\frac{i(0)}{n_i F D_i} \quad [5]$$

where the electrode reaction for metal deposition is

Krylov and Babak (33) have obtained an analytic series solution for the current-step problem stated by Eq. [1]-[5]. However, the solution does not converge for long times (34). Nisancioglu and Newman (35) numerically calculated an alternate series solution which is valid for long times and can be used in conjunction with a short-time, asymptotic series representation of Krylov and Babak's solution.

Nisancioglu and Newman's long-time solution is

$$c_i = c_i^b + \frac{i_i \delta_i}{n_i F D_i \Gamma(4/3)} \left\{ \int_0^\infty \frac{\Gamma(4/3) y}{\delta_i} e^{-x^3} dx - \sum_{k=1}^{\infty} B_k Z_k \left[\frac{y \Gamma(4/3)}{\delta_i} \right] e^{-\lambda_k D_i t \left[\frac{\Gamma(4/3)}{\delta_i} \right]^2} \right\} \quad [7]$$

The values of B_k , Z_k , and λ_k are given in Ref. (20) and (35).

The first few terms of the short-time, asymptotic series representation of Krylov and Babak's solution are

$$c_i = c_i^b + \frac{2i_i \sqrt{t}}{n_i F \sqrt{\pi} D_i} \left\{ 1 - \frac{\sqrt{\pi}}{16} \left[\frac{D_i t}{\left(\frac{\delta_i}{3^{1/3} \Gamma(4/3)} \right)^2} \right]^{3/2} + \frac{1}{420} \left[\frac{D_i t}{\left(\frac{\delta_i}{3^{1/3} \Gamma(4/3)} \right)^2} \right]^3 + \dots \right\} \quad [8]$$

In Eq. [7] and [8], δ_i is the Levich diffusion-layer thickness (36)

$$\delta_i = 1.612 \left(\frac{D_1}{\nu} \right)^{1/3} \left(\frac{\nu}{\omega} \right)^{1/2} \quad [9]$$

which is the characteristic distance for long times.

More approximate representations for the current-step problem have also yielded relatively accurate results. In a classic treatment, Rosebrugh and Miller (37) derived an analytic solution for the current-step problem by replacing Eq. [1] with the equation representing Fick's second law of diffusion and Eq. [4] by

$$c_i(t, \delta_i) = c_i^b \quad [10]$$

This solution is presented in the Appendix.

Rosebrugh and Miller used the method of superposition on their current-step solution to describe single-component mass transfer with a periodic current source (37). Cheh *et al.* (6, 38, 39) have made use of this solution by comparing it with some experimental results. Visawanathan and Cheh (40) and Hale (41) have presented numerical solutions to Eq. [1]-[5] and compared their solutions to that of Rosebrugh and Miller. [Hale actually compared his solution to Siver's solution (42), which Siver had in turn referenced to Rosebrugh and Miller.] The error was always less than 4%. Visawanathan *et al.* (43) numerically solved the system of Eq. [1]-[4], with a pulsed-current boundary condition in place of Eq. [5], and compared this to Rosebrugh and Miller's analytic solution for a pulsed-current source. The agreement between the two solutions was excellent.

Thus far, we have reviewed one analytical current-step solution (that assumes a Nernst diffusion layer) and three numerical solutions. For the problem we address in this paper, we require a current-step solution for short and long times. There is very little extra numerical effort involved in using Eq. [7] instead of Eq. [A-2], especially if only the surface concentrations of the discharging ions are required. For this reason, we have chosen to use Eq. [7] and [8], along with the method of superposition, to model the ionic mass transfer. This restricts our treatment to a RDE. The procedure to be used for other systems which can be modeled accurately with a Nernst diffusion layer is presented in the Appendix. A comparison between the two methods is shown in Fig. 2 for the RDE system.

Using the method of superposition on Eq. [7], the concentration expression for an arbitrarily specified current source is

$$c_i = i_{i,n} \Theta_{i,n} + \Psi_{i,n} \quad [11]$$

where

$$\Theta_{i,n} = \frac{\delta_i}{n_i F D_i \Gamma(4/3)} \left\{ \int_0^\infty \frac{y \Gamma(4/3)}{\delta_i} e^{-x^3} dx - \sum_{k=1}^{\infty} B_k Z_k e^{-\lambda_k D_i \left[\frac{\Gamma(4/3)}{\delta_i} \right]^2 (t-t_{n-1})} \right\} \quad [12]$$

and

$$\Psi_{i,n} = c_i^b + \frac{\delta_i}{n_i F D_i \Gamma(4/3)} \left\{ \sum_{j=1}^{\infty} i_{i,j} \sum_{k=1}^{\infty} B_k Z_k \left[e^{-\lambda_k D_i \left[\frac{\Gamma(4/3)}{\delta_i} \right]^2 (t-t_{j-1})} - e^{-\lambda_k D_i \left[\frac{\Gamma(4/3)}{\delta_i} \right]^2 (t-t_j)} \right] \right\} \quad [13]$$

The current source has been expressed as n discrete current steps. The method of superposition has been used previously for single-component, pulsed-current chronopotentiometry by Andricacos and Cheh (44), and there are a number of references in the literature which can be consulted to derive Eq. [11]-[13] (37, 45, 46).

For short times, the series in Eq. [12] and [13] will not converge. Equation [8] can then be used to express $\Theta_{i,n}$ and $\Psi_{i,n}$. For very short times, only the first term in Eq. [8] need be retained. Equation [8] then becomes the fam-

ilar Sand equation and δ_i drops out of the problem since there is no characteristic length for the semi-infinite linear diffusion problem. Equations [12] and [13] are then replaced by

$$\Theta_{i,n} = \frac{2\sqrt{t-t_{n-1}}}{n_i F \sqrt{\pi D_i}} \quad [14]$$

and

$$\Psi_{i,n} = c_i^b + \frac{2}{n_i F \sqrt{\pi D_i}} \sum_{j=1}^n i_j [\sqrt{t-t_{j-1}} - \sqrt{t-t_j}] \quad [15]$$

Equations [14] and [15] can also be used to solve the analogous problem of multicomponent mass transfer to a stationary electrode.

The liquid-electrode interface.—While a relatively accurate liquid-phase transport model can be developed, such an exacting and general approach is not as easily accomplished for the interface. In multicomponent electrolysis, the potential distribution across the double layer will be affected by the various discharging ions. However, in well-supported solutions, the discharging ions will not significantly influence the double-layer structure. The crystallization kinetics can also be changed, although this will not be considered in this paper. An excellent treatment of this problem can be found in the work of Fleischmann and Thirsk (47).

For the electrode reaction of component i , given by Eq. [6], a Butler-Volmer expression will be used to describe the electrode kinetics. Specific adsorption and chemisorption are not taken into account. Thus (48)

$$\frac{i_{i,n}}{n_i F} = k_{a,i} \alpha_{i,n} e^{(1-\beta) n_i f E_n} - k_{c,i} \frac{c_{i,n}^s}{\rho_0} e^{-\beta n_i f E_n} \quad [16]$$

where

$$E_n = V_n + \left[U_{re}^\theta - \frac{1}{n_{ref}} \sum_i s_{i,re} \ln \frac{c_{i,re}}{\rho_0} \right] - i_n r \quad [17]$$

The bracketed term in Eq. [17] represents the open-circuit potential difference between the reference electrode and a standard hydrogen electrode. The potential difference between the working electrode and the reference electrode is V_n . The last term in Eq. [17] accounts for the ohmic drop between the reference electrode and the working electrode. Hence, E_n is the potential difference between the working electrode and a standard hydrogen electrode, corrected for ohmic drop.

The individual currents can be obtained by substituting for $c_{i,n}^s$ in Eq. [16] using Eq. [11], evaluated at the surface, and solving for $i_{i,n}$

$$i_{i,n} = \frac{k_{a,i} \alpha_{i,n} e^{(1-\beta) n_i f E_n} - \frac{1}{\rho_0} k_{c,i} \Psi_{i,n}^s e^{-\beta n_i f E_n}}{\frac{1}{n_i F} + \frac{1}{\rho_0} k_{c,i} \Theta_{i,n}^s e^{-\beta n_i f E_n}} \quad [18]$$

The total imposed current must equal the sum of the m individual currents

$$\left(\sum_{i=1}^m i_{i,n} \right) - i_n = 0 \quad [19]$$

Equations [18] and [19] can be combined to yield a nonlinear equation in E_n , the electrode potential. The second-order Newton-Raphson algorithm (49) is used to solve the resulting equation for an arbitrary number of depositing metal ions.

Using Eq. [18] and [19], the function H_n is defined as

$$H_n = \left(\sum_{i=1}^m i_{i,n} \right) - i_n \quad [20]$$

For the correct value of the electrode potential, H_n will be equal to zero. H_n is given by

$$H_n = \left[\sum_{i=1}^m \frac{k_{a,i} a_{i,n} e^{(1-\beta)n_f E_n} - \frac{1}{\rho_0} k_{c,i} \Psi_{i,n}^s e^{-\beta n_f E_n}}{\frac{1}{n_i F} + \frac{1}{\rho_0} k_{c,i} \Theta_{i,n}^s e^{-\beta n_f E_n}} \right] - i_n \quad [21]$$

The value of E_n is found by iteration

$$(E_n)_{\text{new}} = (E_n)_{\text{old}} - \left[\frac{H_n}{\left(\frac{\partial H_n}{\partial E_n} \right)} \right]_{\text{old}} \quad [22]$$

The value of the derivative in Eq. [22] is

$$\frac{\partial H_n}{\partial E_n} = \sum_{i=1}^m \frac{\frac{k_{a,i} a_{i,n} (1-\beta)}{RT} e^{(1-\beta)n_f E_n} + \frac{k_{c,i} \Psi_i^s \beta_i}{\rho_0 RT} e^{-\beta n_f E_n}}{\left(\frac{1}{n_i F} + \frac{1}{\rho_0} k_{c,i} \Theta_i^s e^{-\beta n_f E_n} \right)^2} + \frac{\frac{1}{\rho_0} k_{c,i} \Theta_{i,n}^s k_{a,i} a_{i,n} \beta_i n_f e^{(1-2\beta)n_f E_n}}{\left(\frac{1}{n_i F} + \frac{1}{\rho_0} k_{c,i} \Theta_i^s e^{-\beta n_f E_n} \right)^2} \quad [23]$$

For each time step, the iteration scheme outlined in Eq. [20]-[23] must be completed. However, when the previous time step's value of E_n is used to start the iteration in Eq. [22], convergence is generally obtained within three or four iterations.

It should be noted that the partial currents can be obtained explicitly in terms of E_n in Eq. [18] because the electrochemical reaction was assumed to be first order in the concentration of the discharging metal ion concentration. This is usually the case in the electrodeposition of metals. If the reaction were not first order, it would still be relatively easy to solve numerically for the electrode potential and the partial currents.

Equation [18] is also valid for controlled-potential electrolysis. If the ohmic drop is neglected in Eq. [17], Eq. [18] yields the partial current explicitly for controlled-potential electrolysis. Since the ohmic drop can easily be subtracted out in one-dimensional systems, this does not present a major restriction.

The model we have provided for the liquid-phase mass transfer and kinetics could also be used to describe processes for the electrosynthesis of compounds by a periodic current source. Alkire and Tsai (50) have listed a number of references for the synthesis of compounds by a periodic current source.

The electrodeposit.—Two problems must be treated for a complete description of the solid-state alloy. The first problem concerns the dependence of the surface activity on the alloy composition. When experimental data are combined with the judicious choice of an activity model, the activities of the alloy components can be obtained. The second problem involves the actual number of monolayers in the electrodeposit which affect the surface activity, or the relevant surface-activity thickness (RSAT).

The first step in determining component activity coefficients is to choose a model for the molar excess Gibbs energy G^E . The excess properties are taken with reference to an ideal solution wherein the standard state for each component is the pure solid at the temperature and pressure of the mixture. Once the molar excess Gibbs energy is expressed, the activity coefficients γ_i can be found by (51)

$$RT \ln \gamma_i = \left(\frac{\partial(N_T G^E)}{\partial N_i} \right) \quad [24]$$

Since no general treatment has yet been developed to consider repulsion between ion cores or the interaction among cores and electrons at the Fermi surface, a useful approach is to treat the interaction between ions in a mixture by a pairwise model. The properties of such a system

are represented by the sum of interactions between neighboring pairs of ion cores, and the complications due to higher-order interactions are ignored. This quasi-chemical (or lattice theory) approach is outlined by Swalin (52) for regular solutions in which there is no excess entropy creation upon mixing, and any nonideality is considered in an enthalpy of mixing term. For the quasi-chemical approach, the activity coefficients for a binary, regular solution are given by (52, 53)

$$\ln \gamma_A = \frac{(1-x_A)^2 \Omega}{RT} \quad [25]$$

$$\ln \gamma_B = \frac{(1-x_B)^2 \Omega}{RT} \quad [26]$$

where Ω is an adjustable parameter.

Equations [25] and [26] bear close resemblance to the two-suffix Margules equation. Guggenheim (54) has extended the quasi-chemical approach to model systems which exhibit considerable deviation from randomness. For this case, the excess entropy of mixing is no longer zero and a short-range order parameter is introduced which may be determined in some cases by x-ray and neutron diffraction techniques (52).

Two other informative treatments of solid-state thermodynamics should be mentioned before presenting the theoretical aspects for the activity model we have chosen to use in this paper. Darken and Gurry's text (55) contains a great number of references with tabular thermodynamic data for numerous metal systems, as well as an informative description of solid-state physical chemistry. Lumsden's (56) monograph illustrates the usefulness of thermodynamics for the accurate correlation of various equilibrium properties in alloy systems.

Electrodeposited metals usually have a more fine-grained, amorphous structure than their pyrometallurgical counterparts. Hence, the simple quasi-chemical lattice model does not generally represent the true thermodynamic nature of electrodeposited alloys. The activity model proposed by Renon and Prausnitz (57, 58) is well suited to such a morphology. The authors define a local mole fraction x_{ij} representing the mole fraction of i in the vicinity of j . In a treatment similar to Guggenheim's extension of the quasichemical lattice theory, the local mole fractions are related to the overall mole fractions through Boltzmann factors

$$\frac{x_{ji}}{x_{ki}} = \frac{x_j}{x_k} \frac{\exp(-\alpha_{ij} g_{ji}/RT)}{\exp(-\alpha_{ik} g_{ki}/RT)} \quad [27]$$

The parameter α_{ij} ($\alpha_{ij} = \alpha_{ji}$) characterizes the tendency of components i and j to mix in a nonrandom fashion. The parameter g_{ik} ($g_{ik} = g_{ki}$) represents the energy of interaction between an i - k molecular pair. Scott's theory (59) is used to relate the extensive excess properties to the interaction energies and the local mole fractions. For a solution of m components, the molar excess Gibbs energy is

$$\frac{G^E}{RT} = \sum_{i=1}^m x_i \frac{\sum_{j=1}^m \tau_{ji} G_{ji} x_j}{\sum_{k=1}^m G_{ki} x_k} \quad [28]$$

where

$$\tau_{ji} = \frac{(g_{ji} - g_{ii})}{RT} \quad [29]$$

and

$$G_{ji} = \exp(-\alpha_{ij} \tau_{ji}) \quad [30]$$

Using Eq. [24] and [28], the activity coefficient of component i can be calculated (57)

$$\ln \gamma_i = \frac{\sum_{j=1}^m \tau_{ji} G_{ji} x_j}{\sum_{k=1}^m G_{ki} x_k} + \sum_{j=1}^m \frac{x_j G_{ij}}{\sum_{k=1}^m G_{kj} x_k} \left(\tau_{ij} - \frac{\sum_{l=1}^m x_l \tau_{il} G_{il}}{\sum_{k=1}^m G_{kl} x_k} \right) \quad [31]$$

One of the advantages of this activity model is that it can be extended to as many components as desired without any additional assumptions and without adding any constants other than those obtained from binary data. This treatment is applicable to partially miscible as well as completely miscible systems.

Equilibrium-potential measurements of binary solids in contact with an aqueous phase containing the corresponding ions represent a convenient method for obtaining activity data. For some alloy systems, the simpler quasi-chemical treatment may represent the activity data quite well. This approach, outlined by Eq. [25] and [26], can also be extended to model multicomponent systems. When Eq. [25] and [26] cannot be used to fit the data, the computer programs listed in Appendix K of Ref. (60) can be used to fit the parameters of Eq. [31].

For this general treatment, we have chosen to use Eq. [27]-[31] to describe the electrodeposition thermodynamics. However, the overall mole fractions in Eq. [27] must be adjusted to represent the surface, rather than bulk, composition. Though the activity model accounts for local composition, no characteristic length is associated with the range of applicability. Even for single-component electrodeposition systems, the surface plays a major role in the kinetics. Wranglen (61) observed that metals of low overvoltage grow by the lateral extension of layers 0.1-1 μm thick. It was also observed that changing the current density changes the relative growth rates between crystal faces as well as where the deposited layers begin to grow on the respective crystal faces. Wranglen's microphotographic study of growth layers contains results for a periodic current source, although no high frequency results are reported.

Underpotential deposition studies can yield some information about the RSAT. Kolb *et al.* (62) correlated the underpotential shift between the bulk deposit stripping peak and the first deposited monolayer stripping peak as a function of the difference in work functions between the substrate and the deposited material. The authors conclude that the work function of the first deposited monolayer may not differ greatly from that of the bulk electrodeposit, although the optical properties of such a monolayer are usually far from those of the bulk. Adzic *et al.* studied the underpotential deposition of Zn on Ag (63) and Zn on Cu and Au (64). For these reversible systems, the results support the work of Kolb *et al.* Approximately one monolayer of zinc was formed on the polycrystalline substrates prior to bulk deposition.

All of the work mentioned above indicates that the RSAT is about one monolayer. However, this may not be the case for all systems. Cadle and Bruckenstein (65) found that although only one monolayer of Bi is deposited on Pt by underpotential deposition, it is not until approximately five monolayers have been deposited that bulk deposition occurs.

Takamura and Kozawa (66) have reviewed a great deal of literature concerned with the use of optical reflectance methods to investigate an electrode-electrolyte interface *in situ*. They have found that, for a number of systems, the first few atomic layers do not have the same reflectance properties (67).

In general, higher current densities will shorten the RSAT. Setty and Wilman (68) have shown by electron diffraction experiments that high current densities promote the growth of a random, polycrystalline deposit growth which does not reflect the original electrode structure even during the initial stages of electrodeposition. Since most pulse plating processes make use of unusually high current densities, a highly random (or amorphous), polycrystalline deposit typically results. It has also been observed that the influence of a polycrystalline substrate with small crystallite grains ceases to exist at much earlier stages of deposition than that of the surface of a large single-crystal substrate (69).

Although there is a wealth of literature concentrating on epitaxy and morphology of electrodeposits, there is no clear *a priori* approach to estimate the RSAT. The work

reviewed in this paper dealt only with the early stages of electrodeposition. In pulse plating processes, the deposit usually has a random, polycrystalline structure, and the RSAT is probably much less than that of the initially deposited monolayer.

Optical studies seem to indicate that the RSAT can be greater than a monolayer. Conversely, the high current-density pulses often used in practical plating operations may lower the RSAT to about a monolayer. In light of the above considerations, it may be advantageous to weight the substrate's influence on the newly forming surface with a function that decays with depth (70, 71). For the purposes of this work, the following heuristic treatment will be used in estimating a relevant surface composition

$$x_i = \frac{\sum_{ml} \left[1 - \exp\left(-\sigma \frac{\text{RSAT} - d_{ml}}{\text{RSAT}}\right) \right] x_{i,ml}}{\sum_{ml} \left[1 - \exp\left(-\sigma \frac{\text{RSAT} - d_{ml}}{\text{RSAT}}\right) \right]} \quad [32]$$

where $d_{ml} \leq \text{RSAT}$.

In Eq. [32], the subscript ml refers to a monolayer, d_{ml} is the monolayer's distance from the surface, σ is a system-specific proportionality constant, $x_{i,ml}$ refers to the monolayer mole fraction of component i, and the bracketed terms are weighting functions for each monolayer. Monolayers that are deep below the surface make only a small contribution to the relevant surface composition. For $d_{ml} > \text{RSAT}$, no effect on the surface composition is taken in account. Equation [32] assures that the sum of the overall mole fractions is unity. It can also be seen that if σ is set to a very high value, then the weighting function for each monolayer within the RSAT will essentially be unity.

We can now formalize in the following algorithm the procedure for the implementation of the mathematical model.

For $t = t_1, t_2, \dots, t_n$, the procedure is as follows.

1. Obtain the total current i_n .
2. Solve for $\Theta_{1,n}^s$ and $\Psi_{1,n}^s$ (Eq. [12]-[15]).
3. Solve for H_n (Eq. [21]).
4. Solve for $(\partial H_n / \partial E_n)$ (Eq. [23]).
5. Solve for E_n by iteration (Eq. [22]).
6. Obtain the new surface composition from the individual currents according to Faraday's law (Eq. [18] and [32]).
7. Determine the new surface activity (Eq. [31]).

Results

We have chosen to model a three-component system to illustrate the flexibility of the algorithm. It is not possible to obtain the necessary parameters required for the model from the literature; for this reason, we are presently working on experiments that should yield the necessary data. We will discuss the experimental investigation and make a model comparison in a future publication.

The model inputs are listed in Table I. The values of the standard electrode potentials U_i^θ can be calculated from the rate constants. The values of U_i^θ are 0.3, 0.1, and -0.1V for components 1, 2, and 3, respectively. For each reaction, the rate constants have been chosen to yield an exchange-current density of 2 mA/cm² for $a_i = 1$ and $(c_i/\rho_0) = 1$ mol/kg. The transport properties for all components are equivalent since the diffusion coefficient and the characteristic length δ_i , which has been used to nondimensionalize the mass-transfer problem, were set equal for all ionic species.

For the base case, the current is pulsed to the total dc limiting current of the system. This current program is displayed in Fig. 1. In Fig. 2, the dimensionless surface concentrations are plotted for a system in which a Nernst diffusion layer is applicable (the dotted curves) and for the more rigorous solution outlined by Eq. [12] and [13] (the unbroken curves). It can be seen that the two solution techniques yield very similar answers, as would be expected from the close agreement of the respective current-step solutions. Due to the low bulk concentration

^a For component entries, component 1 is at the far left, followed by components 2 and 3, respectively.

and more noble character of component one, its surface concentration remains negligible throughout the electrodeposition process. The least-noble component 3 has the highest bulk and surface concentration. Figure 2 illustrates that the process reaches a uniform and sustained periodic state after about the fourth cycle.

The electrode-potential profile is portrayed in Fig. 3. The lower portions of the curve correspond to the on time. While deposition is occurring, the electrode potential is forced to more cathodic (negative) values since the discharging ion concentrations are decreasing. During the off times, the potential drifts in the anodic direction as corrosion reactions take place and metal ions are transported to the electrode surface by convection and diffusion.

One of the more practical aims of this work is to obtain the electrodeposition composition. A plot of the deposit composition is shown in Fig. 4. Though component 1 is the most noble component, its low bulk concentration limits its rate of mass transfer, thereby suppressing its deposit concentration. The opposite is true for component 3. About ten monolayers are deposited during the on time; thus, there is a considerable variation in the electrodeposition concentration during the on time. The corrosion currents also cause a change in the deposit mole fractions during the off time. At higher frequencies, there would be less variation in the deposit composition during a pulse.

In order to obtain the deposit mole fractions, the partial currents must be known. A plot of partial currents is

Fig. 1. Current source for the base case. The maximum cathodic current is the sum of the dc limiting currents of the discharging ions (-211 mA/cm^2).

Fig. 2. Dimensionless surface concentrations for the first five cycles. The current source is shown in Fig. 1. The dotted curve was obtained using the Nernst diffusion layer approximation. The surface concentration of component 1 remains near zero throughout the deposition process.

Fig. 3. Electrode potential relative to a SHE for the base case. The lower portion of the curve represents the on time.

shown in Fig. 5 for a pulse-reversal current source. A pulse-reversal current source is often used to produce smooth deposits, and it has a significant effect on the alloy composition and ionic surface concentrations. Due to the high bulk concentration of component 3, it carries most of the cathodic current. Figure 5 shows that components 1 and 2 incur mass-transport limitations during the on time. Component 3 also carries most of the anodic current due to its more negative standard electrode potential. At the end of the fifth cycle, the total deposit mole fractions are 0.028, 0.222, and 0.750 for components 1, 2, and 3, respectively. For the base case (Fig. 1-4) the analogous values are 0.021, 0.175, and 0.804. In addition, the pulse-reversal current source supports higher ionic surface concentrations due to the periodic deposit dissolution. A comparison of Fig. 2 and 6 illustrates this.

Some insight into multicomponent electrodeposition can be gained by examining the case of a triangular current source. The triangular current waveform in Fig. 7 reaches a cathodic current density 1.7 times the total dc

Fig. 4. Deposit mole fraction variation for the base case. Upper curve: component 3. Middle curve: component 2. Lower curve: component 1. At time zero, the electrode is pure 1.

Fig. 6. Dimensionless surface concentrations for the pulse-reversal current source. The surface concentrations are higher than those for the pulsed-current source depicted in Fig. 2.

Fig. 5. Component currents for a pulse-reversal current source. The current is reversed to 52.8 mA/cm^2 . The maximum cathodic current is the same as that shown in Fig. 1 (211.2 mA/cm^2).

Fig. 7. Triangular current source. The maximum current is 1.7 times the base case maximum cathodic current source shown in Fig. 1.

limiting current density displayed in Fig. 1. The nonlinear nature of the electrode kinetics is manifest in the electrode-potential profile in Fig. 8. The waveform in Fig. 7 was constructed to disallow the achievement of a periodic state. In Fig. 8, it can be seen that the minima reach more cathodic values for each succeeding period. At 0.20s, all three discharging metal ions reach a zero surface concentration. Directly after this another reaction would be forced to take place, such as solvent decomposition.

The influence of the individual solid-state activities can be seen by comparing Fig. 9 and 10 for the last off time displayed in Fig. 1. The partial currents for the base case are shown in Fig. 9. Component 1 carries its dc limiting current density throughout the process. Component 2 is also depositing during the off time, whereas component 3 dissolves. The partial currents sum to zero during the off time.

When the energy of interaction between components 1 and 3 and components 2 and 3 is attractive, the corrosion currents are reduced and the deposit is more stable dur-

ing the off time. This is depicted in Fig. 10. These concepts are important to the understanding of the corrosion of alloys. In particular, elements can be chosen to form a more corrosion resistant alloy. Though the partial currents are relatively low in Fig. 9 and 10, and the overall deposit composition will not change greatly because of the surface free-energy changes, situations can occur in which the individual solid-state activities could be very important. For instance, in pulse-reversal electrodeposition, where the magnitude of the anodic current is high, the surface activities will play an important role in determining the electrodeposit composition and the ionic surface concentrations.

Conclusions

This paper presents a mathematical model for the periodic electrodeposition of multicomponent alloys by an arbitrarily specified current source. An analogous model for potential-controlled electrolysis is also discussed. The method of superposition is used to solve this problem with an efficient numerical algorithm. This treatment ex-

Fig. 8. Electrode potential relative to the SHE for the triangular current source displayed in Fig. 7. For the specified conditions, a periodic state will not be achieved.

Fig. 10. Component currents during the fifth off time of the current source shown in Fig. 2. For this case, the activity coefficients deviate from unity. $G_{3,1} - G_{3,3} = G_{3,2} - G_{3,3} = -20,000$ J/mol. Component 3 is attracted to components 1 and 2 in the electrodeposit.

poses the large number of parameters the electroplater must consider for obtaining thin alloy films with the desired properties. If an accurate model is used by the electroplater, the different plating parameters can be intelligently varied to assist in manufacturing the desired electrodeposit.

APPENDIX

Rosebrugh and Miller's solution can be used to derive alternate expressions for Eq. [12] and [13]. The current-step solution is first required. Fick's second law

$$\frac{\partial c_1}{\partial t} = D_1 \frac{\partial^2 c_1}{\partial y^2} \tag{A-1}$$

with the initial condition and the boundary conditions given by Eq. [3], [5], and [10] outline the current-step problem. The solution is (37)

$$c_1 = c_1^b + \frac{i_1 \delta_1}{n_1 F D_1} \left[1 - \frac{y}{\delta_1} - \frac{8}{\pi^2} \sum_{j=1}^{\infty} \frac{\cos(m g_1 y)}{m^2} e^{-m^2 \alpha_1 t} \right] \tag{A-2}$$

where $m = 2j - 1$, $g_1 = \pi/2\delta_1$, and $\alpha_1 = \pi^2 D_1/4\delta_1^2$.

The similarity between Eq. [7] and [A-2] is evident. Retention of the velocity term in Eq. [1], the convective diffusion equation, tends to change slightly the eigenfunctions and the eigenvalues. The form and the behavior of the two current step solutions are very similar.

For short times, Eq. [A-2] can be reduced to the Sand equation. Thus, Eq. [8] bears a close resemblance to the asymptotic expression of Eq. [A-2] evaluated for short times and at the electrode surface.

When the method of superposition is used to obtain an expression for a varying current source, the concentration can be expressed by Eq. [11] and

$$\Theta_{1,n} = \frac{\delta_1}{n_1 F D_1} \left[1 - \frac{y}{\delta_1} - \frac{8}{\pi^2} \sum_{j=1}^{\infty} \frac{\cos(m g_1 y)}{m^2} e^{-m^2 \alpha_1 (t-t_{n-1})} \right] \tag{A-3}$$

and

$$\Psi_{i,n} = c_i^b + \frac{\delta_1}{n_i F D_i} \left\{ \frac{8}{\pi^2} \sum_{j=1}^{n-1} i_{i,j} \sum_{k=1}^{\infty} \frac{\cos(m g_i y)}{m^2} \left[e^{-m^2 \alpha_i (t-t_k)} - e^{-m^2 \alpha_i (t-t_{k-1})} \right] \right\} \tag{A-4}$$

The similarity between Eq. [12], [13], [A-3], and [A-4] is evident. This is especially true at the electrode surface where Z_k is unity. Equations [A-3] and [A-4] and Eq. [14] and [15] were used to model the solution-side mass transport in order to obtain the dotted curves in Fig. 2.

LIST OF SYMBOLS

- $a_{i,n}$ surface activity of component i at time step n
- $c_{i,n}$ concentration of species i during time step n (mol/cm³)
- c_i^b bulk concentration of species i (mol/cm³)
- $c_{i,n}^s$ surface concentration of species i during time step n (mol/cm³)

$c_{i, \text{re}}$	reference electrode compartment concentration of species i (mol/cm ³)
d_{ml}	monolayer thickness of electrodeposit (cm)
D_i	diffusion coefficient of species i (cm ² /s)
f	F/RT , (mol/V-eq)
F	Faraday's constant (96,487 C/eq)
g_{ij}	energy of interaction between components i and j (J/mol)
G^E	molar excess Gibbs energy (J/mol)
H_n	zeroing function (mA/cm ²)
$i_{i,n}$	current density carried by species i at time step n (mA/cm ²)
i_n	total current density at time step n (mA/cm ²)
$k_{a,i}$	anodic rate constant of component i (mol/cm ² -s)
$k_{c,i}$	cathodic rate constant of species i (kg/cm ² -s)
m	number of deposit components
M_i	symbol for chemical formula for species i
n	time step
n_i	number of electrons in the deposition reaction of species i
n_{re}	number of electrons in reference-electrode reaction
N_i	moles of component i
N_T	total moles
r	cell ohmic resistance (Ω -cm ²)
R	universal gas constant (8.314 J/mol-K)
RSAT	relevant surface-activity thickness (cm)
$s_{i,\text{re}}$	stoichiometric coefficient of species i in reference electrode reaction
t	time (s)
T	absolute temperature (K)
U_i^θ	standard electrode potential for reaction involving species i (V)
U_{re}^θ	standard electrode potential of the reference electrode reaction (V)
V_n	electrode potential referred to the reference electrode, during time step n (V)
v_y	normal velocity component to a rotating disk electrode (cm/s)
x_i	mole fraction of component i
y	normal distance from the electrode surface (cm)

Greek Symbols

α_{ij}	species interaction constant characteristic of the nonrandomness of the mixture
β_i	symmetry factor for component i
γ_i	activity coefficient of component i
$\Gamma(4/3)$	0.89298, the gamma function of 4/3
$\Theta_{i,n}$	concentration function (mol/A-cm)
$\Theta_{i,n}^s$	surface-concentration function (mol/A-cm)
$\delta_{i,n}$	Nernst diffusion layer thickness of species i (cm)
σ	exponential proportionality constant for the RSAT mole fraction
ν	kinematic viscosity (cm ² /s)
ρ_0	solvent mass density (kg/cm ³)
ρ_i	species i molar density (mol/cm ³)
ω	disk rotation speed (rad/s)
$\Psi_{i,n}$	concentration function (mol/cm ³)
$\Psi_{i,n}^s$	surface concentration function (mol/cm ³)

ABSTRACT

The recovery of gallium from dilute solutions is known to be slow and inefficient due to competing hydrogen evolution and the limitations of mass transport. Methods used to improve the process include pulse plating, inhibition of hydrogen evolution by suitable additives, increasing the pH, and conducting the process at temperatures above the melting point of gallium. In the present work, an alternative approach was taken employing microelectrodes to enhance the rate of mass transport and thus to increase the rate of gallium recovery. Potentiostatic plating and stripping experiments were performed using electrodes ranging in diameter from 1 cm down to 45 μm . The effect of electrode diameter on the rate and efficiency of the plating of gallium was studied at different potentials and under different conditions of mass transport. The effect of plating time was also determined, and the conditions for the optimum recovery of gallium in terms of the overall rate as well as the current efficiency were evaluated. Carbon fiber epoxy composites can serve as ensembles of microelectrodes. It was shown that, with a typical radius of 3-5 μm for the individual fibers, considerable enhancement of the rate of recovery of metals from dilute solutions can be expected.

Novel electrode designs have been suggested in recent years for the recovery of metals from dilute solutions, either as a means for purifying industrial waste, or as a method of primary recovery of the metal from low grade ore. Some well-known designs include the "Swiss roll" (1), the fluidized bed (2), the so-called "Eco cell" (3), as well as various types of porous electrode flow-through cells (4). Most of the above designs cannot be used efficiently for the recovery of gallium due to the low current efficiency caused by hydrogen evolution and because gallium tends to be soluble in the electrolyte used after it has been detached from the electrode surface and is no longer cathodically protected. An alternative electrode design, which has so far not been studied for this purpose, is a microelectrode or an ensemble of microelectrodes on a planar surface.

Recent interest in the electrochemical properties of microelectrodes is due to several possible applications of such systems. They can be considered for implantation in living organisms to follow the changes in concentration of biologically active molecules. The various future applications of microelectrodes were discussed in a recent symposium devoted to this subject (5). A number of theoretical papers have dealt with the calculation of the rate of mass transport to a microelectrode (6-11). In two recent studies (12, 13), the rate of mass transport to ensembles of microelectrodes was calculated, taking into account the interaction of the diffusion layers of adjacent electrodes. It was shown (13, 14) that an added advantage of ensembles of microelectrodes, as compared to large continuous electrodes, is the reduced ohmic potential drop. A number of experimental studies employing microelectrodes of

various types have been reported in recent years (15-23). Further possibilities for such experimental studies are enhanced by the advent of modern techniques of microelectronics and by the introduction of carbon fiber epoxy matrix composite materials as electrodes in certain applications (19, 24-26).

The inherent advantage of ensembles of microelectrodes for the recovery of metals from dilute solutions is the enhancement of mass transport, as compared to planar electrodes of equal total area. Since the partial current for metal recovery from dilute solutions will usually be limited by mass transport, enhancing the rate of mass transport should increase both the rate of metal recovery and the current efficiency for recovery (assuming that the competing reaction, which is typically hydrogen evolution, is not limited by mass transport). A possible drawback of microelectrodes is their tendency to be easily blocked by impurities and specifically by minute gas bubbles formed in the accompanying reaction of hydrogen evolution. This may lead to a significant scatter of experimental results in laboratory experiments, but should be of lesser importance in large-scale industrial operations in which flow rates of the solutions are typically high and large ensembles of microelectrodes will be used in any one reactor.

Theory

The limiting current density on a planar electrode following a potential step was given (8) for $(\pi Dt)^{1/2} \leq r$ as

$$I = nFCD \left[\frac{A}{\sqrt{\pi Dt}} + \frac{P}{2} \right] \quad [1]$$

*Electrochemical Society Active Member.

in which C is the bulk concentration, A is the area, and P is the circumference of the electrode. By setting $A = \pi r^2$ and $P = 2\pi r$, for a disk electrode this equation reduces to the well-known equation of the limiting current to a spherical electrode

$$I = nFCDA \left[\frac{1}{\sqrt{\pi Dt}} + \frac{1}{r} \right] \quad [2]$$

The first term in the brackets represents the classical Cottrell equation and is valid at short times when the diffusion layer thickness $\delta = (\pi Dt)^{1/2}$ is small with respect to the radius r of the microelectrode. If diffusion is the only mode of mass transport, the time-dependent term in Eq. [1] and [2] will approach zero at long times and the current will be governed by the radius of the microelectrode. This, however, is not a case of practical interest, since in any electrochemical reactor the diffusion layer thickness at steady state is governed by the conditions of flow near the electrode surface. Such steady state is reached when the naturally growing diffusion layer reaches the thickness enforced by electrolyte flow. If the latter is known, the time to reach steady state can readily be estimated from the relationship $t = \delta^2/\pi D$.

In the present work, the case studied was that in which the diffusion layer was determined by the method of stirring of the solution. In this case, one can define a capture area, shown in Fig. 1, as the envelope within which the concentration of the reactants and products significantly deviate from their respective bulk values. From simple geometrical considerations, it can be seen that the "capture area" A_c defined above is related to the diffusion layer thickness and the radius of the microelectrode. The ratio between the capture area and the area of the microelectrode is given by

$$A_c/A_e = 1 + \pi\delta/r + 2\delta^2/r^2 \quad [3]$$

This ratio may serve as a qualitative measure of the enhancement of mass transport to a microelectrode or to an ensemble of microelectrodes. For an infinitely large planar electrode, the above ratio is, by definition, equal to unity. As the ratio between the diffusion layer thickness and the radius of the microelectrode increases, the second and the third terms in the above equation become predominant. When the ratio is very large, the term involving the square of this ratio is most important. With this concept, the enhancement of the rate of diffusion is to an extent proportional to the ratio of areas of a circle having a radius equal to the diffusion layer thickness to the area of the microelectrode. A similar result was reached for an ensemble of microelectrodes assuming that the rate of mass transport was controlled only by diffusion, with no convective flow (13, 14).

Experimental

The cell and electrodes.—A rectangular cell constructed of polymethylmethacrylate was employed. The distance between the working and counterelectrodes was 8.5 cm, and a saturated calomel reference electrode (SCE) was situated in the compartment with and at a distance of 3.5 cm from the working electrode. All potentials shown in this

Fig. 1. The capture envelope

paper are with respect to the saturated calomel electrode. The counterelectrode and working electrode compartments were separated by a 125 μm Tyvek separator in order to prevent oxygen from getting to the working electrode when it was polarized cathodically. A 1 cm^2 copper plate was used as the continuous or plate electrode. Copper wires embedded in an epoxy matrix were used as the microelectrodes. The diameters of these electrodes were 1000, 510, 250, 100, 67, and 45 μm . For the three larger sizes, single electrodes were used. For the three smaller sizes, ensembles of electrodes having 6, 13, and 15 electrodes, respectively, were employed. The electrodes were situated at a relatively large distance from each other to ensure that their diffusion layers would not overlap during the experiment. Bonding of the microelectrodes to the embedding polymer initially posed some problems. These were overcome by the use of a silane coupling agent prepared by mixing 5 ml of organosilane ester (Union Carbide, A 176) with 5 ml acetic acid and diluting with 5 ml of distilled water.

After imbedding the copper wires into the polymer, the electrodes were polished to be flush with the surface. Polishing was performed with successively finer polishing materials, starting with 180, 320, 400, and 600 grit papers (3M Company), followed by 10 and 5 μm SiC papers (Mager Scientific Company). In the final polishing stage, 6 and 1 μm diamond pastes were used, followed by 0.05 μm alumina powder (Buehler).

Electrolyte and methods of stirring.—The electrolyte was prepared from reagent grade NaOH (Fisher Scientific, 283 g/liter) and anhydrous $\text{Ga}_2(\text{SO}_4)_3$ (Alfa Products, 2 g/liter, dissolved in distilled water). The molar concentrations were 7.07M hydroxide and 9.4 mM gallium, in the form of the gallate ion GaO_3^{3-} . The pH of the solution was 15.1 (27).

Two methods were used to agitate the solution. In initial measurements, a magnetic stirrer was employed. This was found to be unsatisfactory, since hydrogen bubbles sticking to the electrode surface were not removed. Much more efficient stirring was achieved by the use of an impinging jet of electrolyte, which was positioned 1.5 cm above and 0.5 cm away from the working electrode. The effective value of the diffusion layer thickness, estimated from measurements on the plate electrode (see Results and Discussion) was 68 and 19 μm for the two methods of stirring, respectively. The great advantage of the impinging jet was that it helped remove most of the hydrogen bubbles from the surface of the microelectrodes.

Procedure and apparatus.—At the start of each set of experiments, the solution was deaerated with pure nitrogen for 30 min. The working electrode was maintained at a potential of -1.4V to protect it cathodically. All experiments were conducted potentiostatically using a PAR Model 173 potentiostat. Plating was conducted for 10, 30, and 50s at potentials ranging from -1.70 to -1.90V . Anodic stripping was performed at a potential of -0.75V , until the anodic stripping current decayed to zero. The charge during plating and anodic stripping was measured with a bipolar computing coulometer (Electrosynthesis Company, Model 680). The amount of gallium stripped off was also measured in some of the experiments by determining the weight loss which varied from the coulometric determinations by no more than $\pm 5\%$.

A peristaltic pump (Cole-Palmer Instruments Company) was used to form the impinging jet. It provided a volume flow rate of 9.6 ml/s and a linear flow velocity of ca. 5m/s.

Results and Discussion

The rate of gallium deposition.—The average rate of gallium deposition is shown in Fig. 2 as a function of potential for microelectrodes of different size. In this figure, the current densities are based on the electrode conductors' apparent area with the data for the 1 cm^2 plate electrode shown for comparison. The results for the two largest microelectrodes studied here are not included in

Fig. 2. The effect of the diameter of the electrodes and the potential on the rate of deposition of gallium.

Fig. 2, since they are the same as for the plate electrode. The diffusion-limited current density for gallium deposition was estimated from the current density and the current efficiency measured in the range of potentials of -1.8 to -1.9 V. On the plate electrode, the value obtained in this manner was $i_L = 4.5$ mA/cm². This value was used to calculate the diffusion layer thickness δ , given here. The viscosity of the solution is approximately 6.0 cP, and the diffusion coefficient for the gallate ion is $D = 3 \times 10^{-6}$ cm²/s, significantly lower than in dilute aqueous solutions. Thus, the rate of gallium deposition was under mixed activation/mass-transport control on the plate electrode up to a potential of -1.80 V and switched to fully mass-transport control at more negative potentials. Due to significant enhancement of the rate of mass transport on the microelectrodes, the rate of gallium deposition was probably under mixed control throughout the range of potentials studied.

If we were to assume that the reaction is under mass-transport control for all electrodes at all potentials measured, it would be easy to calculate the difference between the current densities on the plate and on the microelectrodes, since

$$i_L(\text{micro}) - i_L(\text{plate}) = nFDC \left[\left(\frac{1}{\delta} + \frac{1}{r} \right) - \frac{1}{\delta} \right] = nFDC \left(\frac{1}{r} \right) \quad [4]$$

The differences calculated in this way amount to 3.8, 2.5, 1.7, and 0.7 mA/cm² for the 45, 67, 100, and 250 μm diam electrodes, respectively. The average values observed at the less negative potentials are 3.7, 2.5, and 1.7 mA/cm², respectively, the values for the 250 μm electrode being within experimental error of the value for the plate electrode. It is noteworthy, however, that this difference increases at more negative potentials. It is reasonable to assume that in this region the plate electrode is already completely under mass-transport control, while the rate of gallium deposition still increases slightly with increasing negative potential on the microelectrodes.

The solution resistance may play an important role in determining the rate of gallium deposition at the less negative potentials. Since the reversible potential for the deposition of gallium in the solvent is close to -1.70 V, a small difference in the potential across the interface, caused by an IR drop, may effect the rate of deposition of gallium in a major way. As pointed out above (13, 24), the solution resistance (for a fixed value of the current density) decreases with decreasing radius of the microelectrode. This may explain the relatively large difference in current density between the plate electrode and the smallest microelectrode observed in Fig. 2.

It should be noted that the condition $r \ll \delta$ did not exist even for the smallest microelectrodes employed in this

study. It was shown (12, 13) that for electroanalytical applications the radius of the microelectrodes in the ensemble should be 3 μm or less to have a significant advantage over large electrodes. However, the comparison in that case was done with pulse polarography, which is in itself one of the most sensitive electroanalytical techniques. The present results clearly show that when the radius is decreased below 50 μm , a definite advantage over large electrodes is observed and this advantage increases sharply with decreasing radius. Extrapolating the data in Fig. 2 to a radius of 3-5 μm would indicate a possible increase in the rate of recovery of gallium by one to two orders of magnitude compared to large continuous electrodes. This may be very significant technologically, since the radii of the fibers in graphite fiber epoxy composites are in that range. Thus, graphite fiber composites with relatively low graphite fiber loading may turn out to be very useful as ensembles of microelectrodes for the recovery of metals from dilute solutions.

Anodic stripping and alloy formation.—Anodic stripping was conducted following each plating experiment. The potential was held at -0.750 V until the anodic current decayed to zero, and the charge passed in this period was determined with the aid of a coulometer. Some typical anodic stripping curves are shown in Fig. 3. The longer the plating time, the longer the plateau during stripping. It should be noted that a Cu/Ga alloy was formed during longer periods of plating, leading to a somewhat complex form of the anodic stripping transient.

The formation of an alloy is indicated in Fig. 4. The lines shown represent consecutive cathodic plating transients, each followed by anodic stripping, as outlined above. The current density increases after each plating cycle and the current efficiency decreases, showing that the increase in current density is due to an enhancement of the rate of hydrogen evolution. The surface could be restored to its original form (*i.e.*, all the alloy could be removed) by setting the potential at a much more positive value of 0.00 V for a short time following anodic stripping at -0.75 V. It was not maintained at this potential for any length of time, since some anodic dissolution of copper could occur.

Current efficiency.—Plots of the average current efficiency for gallium deposition as a function of potential are shown in Fig. 5 for different sized microelectrodes. For the plate and the two largest microelectrodes, the efficiency is low at -1.70 V, has a broad maximum between -1.75 and -1.80 V, and decreases somewhat at higher negative potentials. This behavior is easy to understand. At the lowest negative potentials, one is close to the reversible potential of gallium deposition, and its rate is low and rising slowly (in a linear rather than exponential form) with potential. As the potential reaches -1.75 V, both the gallium deposition and the hydrogen evolution are in the Tafel region and the two partial currents increase to the same extent with potential, leaving their ratio, which is proportional to the current efficiency, essentially constant. It should be noted that the size of the

Fig. 3. Three cathodic deposition and following anodic dissolution transients.

Fig. 4. Consecutive cathodic deposition transients, each followed by anodic stripping. The average current efficiencies (%) were 1-27.6, 2-21.4, 3-17.4, 4-14.7, and 5-13.0.

electrodes has no effect in this range since their radii are large compared to the diffusion layer thickness under the present experimental conditions. The results shown for the smaller microelectrodes ($250 \mu\text{m}$ or less) are more difficult to reconcile with theory. *A priori*, one might have expected the efficiency to increase with decreasing radius of the microelectrode, since gallium deposition is under partial mass-transport control and its rate should increase with decreasing size, while hydrogen evolution is under activation control and hence should not be effected by the size of the electrode. This view, however ignores the effect of IR drop in solution. This can be estimated by considering the partial current densities for hydrogen evolution shown in Fig. 6. The apparent Tafel slopes observed are quite high, in the range of 0.20-0.25V. If one assumes that the correct Tafel slope should be 0.12V, the experimental data can be corrected by making $R_{\text{soln}} = 4.5 \Omega \text{ cm}^2$ for the plate electrode and $0.3 \Omega \text{ cm}^2$ for the microelectrode. While these numbers should only be considered as approximate, they show clearly the important effect of decreasing IR at microelectrodes. It should also be noted that a preliminary estimate of R_{soln} , based on the known geometry of the cell and the conductivity of the solution (0.38 mho cm^{-1}), yielded a value of $9.0 \Omega \text{ cm}^2$ for the plate electrode. For a spherical electrode of the same diameter as the microelectrode used here, a value of $0.011 \Omega \text{ cm}^2$ is calculated, significantly lower than found for the flat disk microelectrode, as expected.

The rate of gallium deposition is partially diffusion controlled and is hence little effected by the decrease in solution resistance. As the radius of the microelectrode is decreased, both partial current densities increase, although for different reasons. The diffusion-limited cur-

Fig. 5. The effect of the diameter of the electrodes and the potential on the average current efficiency for gallium deposition.

Fig. 6. Partial current densities for hydrogen evolution and for gallium deposition on a plate electrode and on the smallest microelectrodes used in this study ($r = 22.5 \mu\text{m}$). Dotted lines are obtained by assuming $R = 4.5$ and $0.30 \Omega \text{ cm}^2$ for the plate and the microelectrode, respectively.

rent density for gallium deposition increases as expected according to Eq. [1] and [2]. At the same time, the IR drop in solution is decreased (13, 14), leading to an increased rate of hydrogen evolution. The latter can depend on a number of factors, including cell geometry and the conductivity of the electrolyte. The results shown in Fig. 5 evidently indicate that in the present experiment the latter effect was predominant.

The large increase of current density for hydrogen evolution for the microelectrodes shown in Fig. 6 cannot be explained on the basis of the change in solution resistance alone. It is probably a catalytic effect occurring at the boundary between the metal and the surrounding epoxy matrix and silane binder. (It could be, for example, that gallium cannot wet this region, leaving a free copper surface on which hydrogen evolution can occur much faster). This effect has not been studied quantitatively.

It is of interest to consider the way in which the two partial current densities would change with a further decrease in the size of the microelectrode. When δ/r is very large, the partial current for gallium deposition increases as $1/r$ without limit, according to Eq. [2]. The solution resistance for unit area tends to zero under these conditions, but this can increase the hydrogen evolution rate only to the value corresponding to the Tafel line in Fig. 6. Thus one would expect that the current efficiency would go through a minimum at a certain value of the diameter of the microelectrode, and then increase with further decreases in diameter. The size of the microelectrode for which this minimum will occur depends on experimental conditions, as pointed out above. It is indeed possible that the smallest microelectrodes used in this study fall in the region of this minimum, since the radius of $22.5 \mu\text{m}$ was not sufficiently small, compared to the diffusion layer thickness, to cause a very large increase in diffusion-limited current density, as seen from Eq. [2].

Conclusions

Electrolytic recovery of gallium from dilute solutions in concentrated alkaline has been demonstrated experimentally. The rate of recovery (*i.e.*, the partial current density for gallium deposition) was found to be higher on microelectrodes than on large plate electrodes. This result is particularly significant in view of the fact that the microelectrodes were not really very small, the radius of the smallest being only $22.5 \mu\text{m}$, about the size of the diffusion layer thickness. It was shown recently (13, 27) that ensembles of microelectrodes would become very effective, compared to large electrodes, only when the radius of each microelectrode was of the order of $3 \mu\text{m}$ or even less. This is true when the ensemble is considered for

electroanalytical applications and its performance is compared to pulse polarography, which is itself a powerful tool in electroanalytical chemistry. For metal recovery, it was shown in the present work that the advantage of ensembles of microelectrodes becomes apparent already when the radius of each microelectrode is $50\ \mu\text{m}$ and their relative efficiency increases sharply as the radius decreases further. Carbon fibers used in fiber epoxy composites have radii in the range of $3\text{--}5\ \mu\text{m}$. Thus, a carbon fiber epoxy matrix composite with low fiber loadings (to comply with the requirement that the diffusion layers of adjacent electrodes will not overlap) could serve as a very good and relatively inexpensive ensemble of microelectrodes, which would be highly effective for the recovery of metals from dilute solutions. An effort to fabricate such composite electrodes or other types of ensembles of microelectrodes having even smaller radii of the individual microelectrodes is fully justified in view of their possible application for the recovery of metals and for the purification of industrial effluents containing heavy metal contaminants.

The decrease in current efficiency with decreasing diameter needs further investigation. If this is indeed due to a decrease of the IR drop in solution, as suggested above (12, 13), the current efficiency should reach a minimum, dependent on cell configuration and specific conductivity of the solution, and rise thereafter steadily with decreasing radius, after solution resistance has become insignificant. If the hydrogen evolution reaction is enhanced on the microelectrodes for some other reason (e.g., due to the reduction in the nucleation overpotential associated with hydrogen bubble formation at the edges of the microelectrodes), then an increase of the current efficiency with decreasing radius of the microelectrode may not be observed. In such event, one may still take advantage of the enhanced rate of gallium deposition on ensembles of microelectrodes, combined with suitable highly effective hydrogen inhibitors, to further identify conditions for high rate, high efficiency recovery of the metal from dilute solutions.

Performance Predictions for Solar-Chemical Converters Based on Photoelectrochemical I-V Curves

Department of Chemical Engineering, University of Texas, Austin, Texas 78712

ABSTRACT

Texas Instruments' solar energy system contains a solar-chemical converter (SCC) which converts solar energy into chemical energy via the electrolysis of hydrobromic acid (HBr) into hydrogen (H_2) and bromine (Br_2). Previous predictions of SCC performance have employed electrical dry-probe data and a computer simulation model to predict the H_2 generation rates. The method of prediction described here makes use of the photoelectrochemical I-V curves to determine the "wet"-probe parameters of V_{OC} , J_{SC} , FF, and efficiency for anodes and cathodes. The advantages of this technique over the dry-probe/computer simulation method are discussed. A comparison of predicted and measured H_2 generation rates is presented. Solar to chemical efficiencies of 8.6% have been both predicted and measured for the electrolysis of 48% HBr to hydrogen and bromine by a full anode/cathode array. Individual cathode solar to hydrogen efficiencies of 9.5% have been obtained.

Texas Instruments' solar energy system contains a solar-chemical converter (SCC) which converts solar energy into chemical energy via the electrolysis of hydrobromic acid into hydrogen and bromine (1-5). Figure 1 illustrates the various processes which occur in the SCC. Photons from the sun are absorbed by the spherical silicon solar cells either directly or by reflection and scattering from the SCC matrix. Hydrogen and bromine are simultaneously generated at metal electrodes deposited on the n/p (cathode) solar cells and on the p/n (anode) solar cells as electrons flow through the back-side conductor.

Previous evaluations and quality control required fabrication of completed arrays followed by actual hydrogen-generation tests. In most instances, either the anode cells or the cathode cells were limiting the performance of the SCC array. The hydrogen data alone were not sufficient to determine which electrode was in fact limiting. Predictions of SCC performance were then made based on dry probe data (V_{OC} , I_{SC} , and FF) of a small sampling of the cells and a complex computer simulation model (3, 5). The computer model included algorithms which described the relationships between the electrical characteristics of the individual solar cells, the assumed electrochemical behavior of the front-side electrodes, and the resistance parameters associated with the electrolyte, back-side conductor, membrane separator, and SCC panel geometry. This approach toward predicting the SCC performance was complicated by the difficulty encountered in measuring the electrical characteristics of a statistically significant number of solar cells and in estimating or measuring the area and activity of the electrodes on the solar cells. A prediction method is described where photoelectrochemical I-V curves are used with a simplified model to predict hydrogen generation rates and the performance of the SCC. This method also allows for the pairing of individual anode and cathode array sections in order to optimize the performance of a given anode/cathode combination for HBr electrolysis.

Experimental

The SCC arrays used in these experiments consisted of near-single-crystalline silicon spheres, each of 380-400 μm diam. Typically, SCC arrays are fabricated to include only anode cells or only cathode cells. The cells are cast and fired in a glass matrix with a center-to-center sphere spacing equal to 2.2 sphere radii, yielding more than 600 cells for each square centimeter of array area. The thin film electrodes on the front surface of the solar cells con-

sist of platinum/iridium alloy (7:3), sputter deposited as equatorially positioned bands around the individual solar cells. The electrode thickness is 100-400 \AA . The cores of the solar cells are interconnected on the back side of the SCC array with a thick, corrosion-resistant, sputtered tantalum film. For hydrogen-generation measurements, anode and cathode sections with a total area of 38-40 cm^2 were interconnected and mounted on a conductive substrate with conductive adhesive.

Hydrogen generation rate measurements for complete arrays which include both anode and cathode cells were accomplished by immersing the arrays in a quartz fixture which contains 48% hydrobromic acid. The fixture was illuminated with a solar simulator incorporating multiple ELH-type tungsten-halogen lamps. The insolation at the fixture was calibrated with a NBS traceable Si solar cell to air mass 1 (100 mW/cm^2). The spectral mismatch between the solar simulator and air mass 1 is less than 5% as measured with a LICOR 1800 spectroradiometer. Hydrogen was collected for 4 min, and the hydrogen generation rate was calculated from the gas volume.

The photoelectrochemical behavior of SCC array sections was determined with the test cell illustrated in Fig 2. Electrical contact was made to the back-side conductor by a clip along one edge of the array section. Selected areas of the array were masked off with photoresist. Typically, array areas of 5-10 cm^2 containing thousands of solar cells were evaluated with each determination. The three-electrode configuration included a hydrobromic

Fig. 2. Photoelectrochemical test cell

acid/bromine (6.9M/1.0M) reference electrode and a large platinum foil counterelectrode placed just outside the optical path of the multiple lamp solar simulator. Current-potential scans were obtained with a computer-driven ECO Model 555/B potentiostat at a scan rate of 40 mV/s in various hydrobromic acid/bromine mixtures (8.9 eq/liter). The electrochemical cell resistance was determined either by current interruption or from the slope of the current-voltage curve when the sections were strongly forward biased in the electrolyte (+10V for cathode cells, -10V for anode cells). Computer-plotted and -stored current-potential data were corrected for the photoelectrochemical cell resistance and normalized to the current density of the array section. The current density on the individual solar cell electrodes is typically ten times larger than the array section current density since the ratio of the electrode area to the projected array section area is approximately 1:10.

The condensed, normalized, and resistance-corrected data were transmitted to a main frame computer system for additional SCC system performance modeling. A simplified computer model calculated the SCC performance from the photoelectrochemical data and various re-

sistance parameters associated with the electrolyte, the back-side conductor, the membrane separator, and the panel geometry.

Results and Discussion

Typical photoelectrochemical behavior of SCC array anode and cathode sections in hydrobromic acid/bromine solutions is given in Fig. 3 and 4. From the photocurrent-potential curves, wet-probe parameters including open-circuit voltage, short-circuit current, fill factor, and efficiency are obtained for separate anode and cathode sections. These values are readily measured relative to the bulk electrochemical potential of the anolyte and catholyte. The potential values in these examples are -81 and -756 mV vs. the reference electrode for the anolyte and catholyte, respectively.

The increase in current observed on the cathode cells at potentials more negative than the electrochemical potential of the bulk catholyte results from a small number of leaky and shorted solar cells among the cathode cells of good quality. Analogous behavior is not observed on photoelectrochemical scans with anode sections. The poor quality anode cells have been selectively passivated. No attempt was made to passivate poor quality cathode cells, since they have little detrimental effect on the performance of the cathode section when used to reduce hydrobromic acid. Shorted or low V_{oc} cells among the anode cells can severely degrade the performance of the anode section, especially at high anolyte bromine concentration (> 300 mM), since they consume rather than generate bromine.

The observed photoelectrochemical response of a typical anode and cathode section is compared with the calculated response in Fig. 5. The calculated response was obtained with the previous computer simulation model which utilized dry-probe data for a multitude of individual solar cells (3, 5). The anode and cathode sections are readily matched to obtain the operating current density of complete arrays, which incorporate both section types. The operating current density is given where the anode and cathode photoelectrochemical response curves intersect. The calculated and observed response are in good agreement, especially along the current-limited regions of the photoelectrochemical curves and at the operating

Fig. 3. Photoelectrochemical behavior of anode SCC sections: array current density vs. potential of the back-side metal conductor. Electrolyte contains 0.05M bromine + 8.8M HBr.

point of the combined anode/cathode array. Some small error is observed in the calculated response along the voltage limited regions of the curves. The error primarily arises from two sources: the dry-probe sampling error and the error encountered in estimating the area and activity of the platinum/iridium electrodes on the individual solar cells. Typically, less than 1% of the individual cells are probed to obtain representative values of V_{oc} , I_{sc} , and FF.

Table I compares the hydrogen generation rates of several complete SCC arrays. The table includes the experimentally measured values, the values predicted from the photoelectrochemical behavior of the separate anode and cathode sections, and the values predicted from the dry-probe data/computer simulation model. Excellent agreement is found among the two prediction techniques and the observed SCC array performance. The best individual hydrogen generating cathode section fabricated had a

solar-to-chemical efficiency of 9.5%. The efficiency for individual array sections is defined as the product of the wet-probe J_{sc} , V_{oc} , and FF. In combination with the best bromine generating anode section, the best HBr electrolysis efficiency obtained was equivalent to a solar-to-chemical efficiency of 8.6%. In this case, the efficiency is defined as the product of the operating current density and the difference in the electrochemical potential of the bulk anolyte and the bulk catholyte divided by the incident light power (100 mW/cm^2).

The advantage of the photoelectrochemical method is that it encompasses the actual electrochemical activity of the front-side electrodes and the electrical characteristics of a multitude of individual solar cells in a single measurement. Consequently, sampling errors are reduced by this method. A larger number of solar cells are more readily characterized by the photoelectrochemical method since the dry-probe method requires that individual solar cells be probed. Anode and cathode SCC sections can be

fabricated and evaluated separately without the need to fabricate complete arrays incorporating both cell types and to measure the hydrogen-generation rate. Anode and cathode sections are readily matched by their photoelectrochemical behavior to obtain performance-optimized SCC modules. Additionally, the photoelectrochemical method can be used as a diagnostic tool to evaluate alternate SCC fabrication processes.

Although the dry-probe method is more difficult to use, the dry-probe technique itself serves as a useful diagnostic tool. It is particularly useful in distinguishing between array performance limitations associated with the electrical characteristics of the solar cells and those associated with the electrochemical activity of the front-side electrodes and the electrochemical process. In other words, the dry-probe method gives all the solid-state and electrical data and yields considerable information concerning array processing. It is a very good quality-control tool for the array-fabrication process. The photoelectrochemical measurements yield information on the electrode and electrochemical characteristics.

Conclusions

Performance predictions for solar-chemical converters are facilitated by investigations of the photoelectrochemical behavior of separate anode and cathode sections. The photoelectrochemical method encompasses the actual electrochemical activity of the front-side electrodes and the electrical characteristics of thousands of individual solar cells in a single measurement and minimizes sampling errors. This method allows for the separate optimization of the design and processing of anode and

cathode array sections. Anode and cathode sections can be evaluated separately and matched by their photoelectrochemical behavior to obtain performance-optimized SCC modules.

Use of the solar-chemical converter is not restricted to the hydrogen/HBr/bromine system. Different anolytes and catholytes can be examined independently for alternate systems. Likewise, electrodes of other materials can be fabricated on the anode or cathode cells and tailored for performance-optimized array sections. By changing the electrodes, electrolytes, or even the types of solar cell spheres (such as GaAs), a wide variety of photoelectrochemical systems can be investigated.

Investigation of Electroreduction Kinetics on Modified p-InP in Alkaline Electrolyte

Ronald L. Cook,* Patrick F. Dempsey, and Anthony F. Sammells*

Eltron Research Incorporated, Aurora, Illinois 60505

ABSTRACT

The electroreduction kinetics of surface modified p-InP were investigated. The surface was modified by electro-deposition of Co, Ru, Rh, Pt, Co/Pt, Ru/Pt, and Rh/Pt. Exchange current densities (i_0) for hydrogen evolution were obtained both in the dark and under 100 mW/cm² illumination. For sequentially deposited metals, i_0 values are lower compared to individually deposited metals during hydrogen evolution. Cathodic currents observed positive of the hydrogen-evolution region can be explained by electron-transfer processes involving p-InP surface states. In this latter potential region, i_0 values are higher for the sequentially deposited metals.

In optimizing the efficiency for light to chemical conversion for hydrogen evolving photocathodes such as p-InP, attention must be paid to two surface-related processes which can influence overall photoelectrochemical (PEC) performance. The first of these is the presence of extrinsic surface states which can act as recombination centers for the radiationless recombination of the photo-generated electrons and holes. If appropriate surface modification of the semiconductor is not performed to suppress the activity of such recombination centers, then there will be little opportunity for electron transfer to occur across the semiconductor/liquid junction to promote the desired hydrogen-evolution reaction. The second surface process relates to the electrocatalysis of the hydrogen-evolution reaction.

Clearly, the photogenerated electron, once successfully reaching the liquid junction interface, must find an appropriate catalytic site favoring this reaction. Here, the free energy associated with the formation and cleavage of the metal-hydrogen bond at the catalytic site plays a criti-

cal role in determining overall reaction kinetics. As is well documented, platinum group metals have metal-hydrogen bond strengths in the 15 kJ mol⁻¹ range which permits significant coverage of the catalytic site but does not impede cleavage of the M-H bond (1).

Here, the role of surface modification procedures on photoelectrodes should ideally fulfill the dual role of suppressing surface recombination sites and enhancing the kinetics for the desired photoelectrochemical (PEC) reaction.

For p-InP present in strong aqueous acids, a stable hydrated layer of In₂O₃ is present which can serve to effectively suppress electron-hole recombination (2, 3). Such oxide surfaces are not suited, however, for the promotion of the hydrogen evolution reaction. Hence, introduction of platinum group metals onto the p-InP surface favors the kinetics for this reaction (4). For Rh and Re, hydrogen evolution results in the formation of hydrogen alloys which can serve to increase the barrier of the modified p-InP, resulting in greater photopotentials and consequently larger overall solar efficiencies.

*Electrochemical Society Active Member.

The photoelectrolysis of strongly acidic aqueous solutions might introduce severe materials restraints, particularly at the oxygen evolution site. For this reason, we have recently started to investigate the PEC characteristics of p-InP in strongly alkaline electrolytes (5). For such electrolytes, however, the strategy of suppressing surface states via the *in situ* formation of a hydrated metal oxide, by analogy to the acid electrolyte case, is probably not valid. As a consequence, we have investigated various alternative approaches for both the simultaneous suppression of such surface states and enhancement of the electron-transfer step leading to hydrogen evolution. This work resulted in the identification of a 14.2% efficient p-InP photocathode (as calculated from power savings) after surface modification by the sequential electrodeposition of cobalt and platinum. Similar enhancements in PEC behavior have also been observed by us after surface modification with ruthenium/platinum and rhodium/platinum codeposits. Since in 6M KOH surface oxides can be expected to be largely absent from the p-InP surface, the question remains as to what is the apparent role of such surface modifications on the suppression of surface states. It has recently been shown from photocapacitance measurements (6) that the initial density of interface states present near the valence band can be significantly reduced after the sequential electrochemical deposition of cobalt and platinum and, in addition, introduces a surface state close to the conduction band associated with the metallic absorbate. This latter introduced state probably facilitates the electron-transfer step leading to hydrogen evolution during illumination.

If one of the roles of such bimetallic surface modifications is essentially electrocatalytic in nature for the hydrogen evolution process, then it is to be expected that there should be some correlation between exchange current density (i_0) as measured during hydrogen evolution and the nature of the metal introduced onto the p-InP surface. In addition, further electrode kinetic information relating to the presence or suppression of surface states might be obtained from steady-state measurements made on p-InP at potentials positive of the hydrogen evolution reaction. Such measurements can be made under cathodic bias conditions since the equilibrium potential of p-InP in alkaline electrolyte is significantly positive of that for the hydrogen evolution reaction.

In order to pursue this overall approach, we have measured exchange current densities on p-InP photocathodes both unmodified and modified with Co, Pt, Rh, Ru, Co/Pt, Ru/Pt, and Rh/Pt at potentials both positive and negative of the hydrogen evolution potential. These investigations were performed both with and without 100 mW/cm² ELH illumination. In the hydrogen evolution region, exchange current densities were obtained directly from the Tafel relationship. Cathodic processes occurring at potentials below the inception of hydrogen evolution may well be due to electron transfer via surface states involving metal oxides or hydroxides present at the liquid junction. In this second potential region, kinetic information was obtained via the use of the Allen-Hickling relationship (7)

$$\log \frac{i}{1 - \exp(nF\eta)} = \log i_0 - \frac{anF\eta}{2.3RT} \quad [1]$$

where i_0 is the exchange current density, and the other symbols have their usual significance. Here, by plotting $\log(i/[1 - \exp(nF\eta)])$ vs. η , i_0 can be obtained directly from the current axis intercept.

By comparing i_0 data for these two distinct electrochemical processes, some insight into the respective role of p-InP surface modifications on both the suppression of surface states and enhancement of the electron-transfer step leading to hydrogen evolution can be gained.

Experimental

p-InP was obtained from Varian Associates (VAIPC no. 109, Zn-doped, 1.27×10^{17} cm⁻³). Electrodes typically had

electrode areas of 0.06 cm². The (100) face was used in all experiments. Ohmic contact was performed by initially etching with concentrated HCl followed by rinsing with distilled water. To this was sequentially vacuum-deposited Au, Zn, and Au layers followed by annealing under hydrogen at 400°C for 1h. Current collection was achieved using a nickel wire contacted via silver epoxy and curing. Surface modifications of p-InP were achieved by electrodeposition from 1M solutions of the appropriate acidic chloride salt. Typical current densities varied between 0.09 and 0.11 mA/cm².

The electrolyte was 6M KOH in all experiments. A three-electrode configuration was used with platinized platinum as the counterelectrode and a SCE reference electrode connected via a salt bridge. The light intensity was 100 mW/cm² from a Sylvania 300W ELH bulb. The light intensity was measured with an Eppley 8-48 pyranometer. PEC measurements were made via the use of a Stonehart BC 1200 potentiostat and data recorded on a Linear Instruments 8036XY recorder.

Results and Discussion

Initial equilibrium potentials for single-crystal p-InP both with and without surface modification were initially in the range -500 to -600 mV vs. SCE after introduction into 6M KOH electrolyte. Following hydrogen evolution on the surface modified p-InP, rest equilibrium potentials were generally found to be in the -900 to -950 mV range. The cathodic shift in potential realized here after hydrogen evolution is probably a result of either formation of a metallic hydrogen alloy or surface adsorbed hydrogen species. In the absence of hydrogen evolution, the initial rest potential of ≈ -600 mV was shifted to ≈ -400 mV vs. SCE under 100 mW/cm² illumination. p-InP photocathodes were surface modified with Co, Pt, Rh, Ru, Co/Pt, Ru/Pt, and Rh/Pt by electrodeposition. Deposits were not uniform but more in the form of islands. Their nominal "thickness" was 100Å, however. These surface modified photoelectrodes were subjected to current-voltage measurements up to -1000 mV from the initial rest potential both with and without illumination.

A typical Tafel-type plot under illumination for ruthenium-modified p-InP is shown in Fig. 1. Here, the linear portion of the curve starts at an overpotential of -400 mV and corresponds to the hydrogen evolution region. Figure 2 shows a typical current-overpotential curve for platinum-modified p-InP in the dark. The i_0 data obtained here for these various modified photocathodes in 6M KOH are summarized in Table I. As can be seen, all

Fig. 2. Current-voltage curve for p-InP surface modified by 100Å Pt in the dark.

metallic surface modifications resulted in increased i_0 values for the hydrogen evolution region.

In the dark, currents were in the microampere per square centimeter range. Upon illumination, the minority carrier concentrations are substantially increased and the observed currents are in the milliampere per square centimeter range.

For p-InP, the increase in i_0 for hydrogen evolution on modification with platinum group metals appears to be essentially electrocatalytic in nature. For p-InP surface modified with individual metals, measured i_0 values for hydrogen evolution were found to be in the order $Rh > Rh \approx Pt > Co > \text{unmodified}$. For the sequentially surface modified p-InP, however, the exchange currents are similar or lower in value than those observed on p-InP modified by the individual metals. This is in contrast to the observed improvement in PEC performance for p-InP surface modified by sequentially deposited cobalt and platinum (5). This suggests that although photoelectrocatalytic phenomena are expected to have a dominant

role in influencing the photocurrent-voltage characteristics for hydrogen evolution on surface-modified p-InP, other factors such as the presence or absence of surface states might also be influential in dictating overall performance.

Differential capacitance studies on surface-modified and unmodified p-InP have indicated that the p-InP flatband potential remains relatively constant. Recent photocapacitance measurements have, however, shown that surface modification of p-InP with Co/Pt appeared to reduce the density of energy levels in the bandgap near the valence band and introduce new states near the conduction band (8). Such an observation could in part explain the improved fill factors found for Co/Pt modified p-InP by suppressing recombination at the semiconductor surface.

For p-InP surface modified with Co/Pt, Rh/Pt, or Ru/Pt, it appears that improved PEC performance may be influenced by both electrocatalytic and surface state recombination effects. Improvements in photocurrent-voltage behavior were observed for p-InP surface modified by Ru/Pt and Rh/Pt where increases of 20% were observed in fill factors on going from p-InP surface modified by single metals to sequential modification by two platinum group metals.

The large overpotential (with respect to the flatband potential) required for hydrogen evolution has been observed by others for p-InP (9), p-GaAs (10), and p-GaP (11). It has been suggested that surface recombination and trapping of electrons in these systems may be responsible for the large observed overpotential for hydrogen evolution (10). In view of photocapacitance results which indicate that surface-state recombination may be significantly suppressed by the sequential deposition of platinum group metals onto the p-InP surface, we have, in addition, investigated the photocurrent-voltage behavior of these electrodes at potentials positive of the inception of hydrogen evolution. In this potential region, cathodic currents may be explained by electron-transfer processes via surface states, possibly involving metal oxides or hydroxides present at the liquid junction.

Figures 3 and 4 show the current-overpotential curves for p-InP surface modified by Ru (illuminated) and Pt (dark). As anticipated from Eq. [1] plotting $\log(i/[1 - \exp(nF\eta)])$ vs. η is linear in the overpotential region 0-100 mV cathodic of the equilibrium potential. Table II gives i_0 values for p-InP modified with Co, Pt, Rh, Ru, Co/Pt, Ru/Pt, and Rh/Pt in this potential region (with respect to the flatband potential).

Here, i_0 values do not follow the same order seen in the hydrogen-evolution region. In general, the sequentially

Fig. 4. Allen-Hickling plot for p-InP surface modified by 100Å of platinum in the dark.

deposited metals give higher exchange currents than the respective single metals. The higher exchange currents observed for the sequentially deposited metals are consistent with other results observed on p-InP by us. On going from p-InP modified with Co, Ru, or Rh to the sequentially deposited metals (Co/Pt, Ru/Pt, Rh/Pt) an increase in the fill factor of $\approx 20\%$ can be generally observed. The higher exchange currents, fill factors, and the photocapacitance results are all consistent with an increased suppression of surface-state recombination when p-InP is modified by the sequential deposition of Co/Pt, Ru/Pt, and Rh/Pt.

For electron transfer via surface-state energy levels, the exchange current is given by (10)

$$i_{ss0} = k_s C N_t f \quad [2]$$

where k_s is the rate of electron transfer to the solution from the surface state, C the concentration of redox species in solution, N_t is the total number of surface states, and f the fraction of surface states occupied by electrons. If n_t is defined as the number of electrons in the surface state, then f becomes n_t/N_t , and

$$i_{ss0} = k_s C n_t \quad [3]$$

The change in the number of electrons in the surface state in terms of the schematic energy level diagram shown in Fig. 5 will be determined by (i) the rate of capture of electrons from the conduction band, (ii) the rate of hole capture from the valence band, and (iii) the rate of transfer of electrons to the solution redox species. Thus

$$\frac{dn_t}{dt} = k_n(n_s[N_t - n_t]) - k_p(p_s n_t) - k_s n_t C \quad [4]$$

where k_n is the rate of electron capture from the conduction band, n_s is the surface electron density in the conduction band, k_p and p_s are the rate of hole capture by the surface state and the concentration of holes in the valence band, respectively. At steady state ($dn_t/dt = 0$), Eq. [4] can be solved for n_t to give

$$n_t = N_t \left(\frac{k_n n_s}{k_n n_s + k_p p_s + k_s C} \right) \quad [5]$$

Equation [5] can be inserted into Eq. [3] to give the dependence of the surface state current i_{ss0} on the electron concentration in the conduction band and the hole concentration in the valence band. Thus

$$i_{ss0} = N_t \left(\frac{k_s C k_n n_{s0}}{k_n n_{s0} + k_p p_{s0} + k_s C} \right) \quad [6]$$

Fig. 5. Schematic energy level diagram representing electron transfer from p-InP to electrolyte via either the conduction band or surface states.

When the surface state is close to the conduction band, recombination may be negligible and the exchange current density would be determined by the electron density present in the conduction band, the concentration of the redox species at the interface, and the relative values of k_s and k_n . For surface modified p-InP in this work, it is not clear how k_s correlates with the observed exchange current in the low overpotential region. It appears, however, that for p-InP modified with Co/Pt, Rh/Pt, and Ru/Pt, the larger i_0 values are due to increases in k_n and a decrease in k_p . This may be due to the suppression of surface states near the valence band edge and introduction of a new surface state near the conduction band edge.

Although the exchange current densities for hydrogen evolution are smaller for the sequentially deposited metals than for the single metals on p-InP, the fill factors are increased for the sequentially deposited metals, leading to an overall increase in efficiency in these cells. It has been concluded (12) that improving the fill factor may play a larger role in increasing the efficiency than reducing the overpotential. Both our results and those obtained separately with a Co/Mo modified p-InP photocathode (13) are consistent with this conclusion.

ABSTRACT

Members of the title system were prepared by direct syntheses and studied by means of x-ray diffraction, electron microprobe analyses, and photoelectrochemistry. We found three new hexagonal phases in the low x region ($0.25 < x < 0.09$), all of which can be understood in terms of Se close packing. They provide indications for the occurrence of polytypism. Two of the three previously reported phases with cubic stacking were found in the less Cu-poor part. This region of cubic stacking extends from at least $x = 0.5$ to $x = 0.23$. CuIn_3Se_5 ($x \approx 0.25$) was found to be the end member of the cubic stacking region, and its frequent recurrence in various synthesis attempts indicates its stability. This compound, as well as all others identified in this study (e.g., $x = 0.15$), were photoelectrochemically active with some variability. Their optical bandgaps all fell between 0.9 and 1.3 eV. Two mixed sulfoselenides were prepared as well. One of them with $x = 0.55$ possessed the normal chalcopyrite structure and a direct optical bandgap that corresponded to what one would expect for such a mixed sulfide-selenide. Close to the nominal stoichiometry CuIn_5X_8 , we did not find the spinel phase as found for $X = \text{S}$; instead, we found two different polytype phases for the pure selenide and the sulfoselenide.

The compound CuInSe_2 is often regarded as a ternary analog of elemental Group IV semiconductors (e.g., Si, Ge) and of binary semiconductors (e.g., GaAs, ZnSe) (1). To support this point of view, the close relationship of its chalcopyrite structure to the diamond and sphalerite structures, from which it can be derived by simple unit cell doubling (because of cation ordering), is often mentioned. The promising photovoltaic and photoelectrochemical properties (2) of CuInSe_2 have stimulated extensive structural, optical, and electronic studies of this and related materials.

To some extent, this effort overshadows the fact that the material is also a member of a rather different family of interesting and versatile, but complicated, materials: the chalcogenides of transition metals, in particular, those of copper. This group of materials often displays a number of remarkable characteristics (3), such as broad homogeneity ranges, order-disorder transitions, strong d-p covalent mixing (4, 5), and fast ionic diffusion (6). Concerning the metal atoms, one often finds complicated structural characteristics, in contrast to a rigidly close-packed arrangement of the chalcogen atoms, albeit in various stackings.

This study represents a first step towards understanding the photovoltaic implications of the solid-state chemistry of CuInSe_2 , particularly where deviations from the 1:1:2 stoichiometry along the $\text{Cu}_2\text{Se-In}_2\text{Se}_3$ tie line are concerned. Results of measurements of some photoelectrochemical properties along this tie line are included as well.

The $(\text{Cu}_2\text{Se})_x(\text{In}_2\text{Se}_3)_{1-x}$ Pseudo-Binary System

From simple valence considerations, it is clear that changing the nonmolecularity parameter, x (7), of the $(\text{Cu}_2\text{Se})_x(\text{In}_2\text{Se}_3)_{1-x}$ system does not necessarily undo the semiconducting properties that are known for CuInSe_2 ($x = 0.5$). Rather, it is the nonstoichiometry parameter, y , describing the deviation of the total metal-to-nonmetal ratio from the ideal value of $2/(3 - 2x)$ that

will strongly affect sign and level of doping of a Cu-In-Se ternary (cf. Fig. 1). Although small variations in the parameter y were observed in our study, we shall limit our discussions to the x parameters.³

The phase diagram data that are used exclusively by the workers in the photovoltaic field covered only part of the title system (8), although recently some additional data have become available (9). The latter results refute the existence of a number of distinct stoichiometric phases purported to exist (10). This is in agreement with part of our own findings. The earlier data show that a two-phase region exists between Cu_2Se and the well-known chalcopyrite phase with x values slightly larger than 0.5. Other recent work (11) indicates that at elevated temperatures an additional phase Cu_5InSe_4 ($x = 0.84$) exists in the copper selenide-rich part of the diagram; unfortunately, its structure is unknown.

For the comparable sulfide system, Binsma and co-workers reported a tentative diagram (12) in which one other definite phase besides the chalcopyrite was identified, viz., the spinel phase CuIn_5S_8 ($x = 0.167$). This material has shown some photovoltaic merit (13). A narrow range of stoichiometry for the chalcopyrite phase (nominally $x = 0.5$) was suggested by Binsma *et al.* (12), although no specific experimental evidence was available. Similar inference was applied to the selenide diagrams (8, 9).

It seems clear that the phase relationships along x are not very well elaborated. Improvement of our knowledge on this subject can clearly be beneficial, particularly for the preparation of thin layer cells, where proper control of the x and y parameters is as important as it is difficult.

Experimental

Preparation.—Bulk polycrystalline samples were typically prepared from the elements in evacuated, sealed quartz ampuls. All starting materials used were 5N pure or better obtained from Cerac (Milwaukee, Wisconsin) or Spex (Metuchen, New Jersey) (Cu, In, Se, S). In_2S_3 and In_2Se_3 were 5N pure (Cerac). The reagents were heated to

³ Note that not all x, y combinations are equally likely from a structural point of view. For example, $x > 0.5$ and $y > 0.5$ are extremely unlikely to be single phase because it would involve overcrowding of the metal sites in the chalcopyrite lattice.

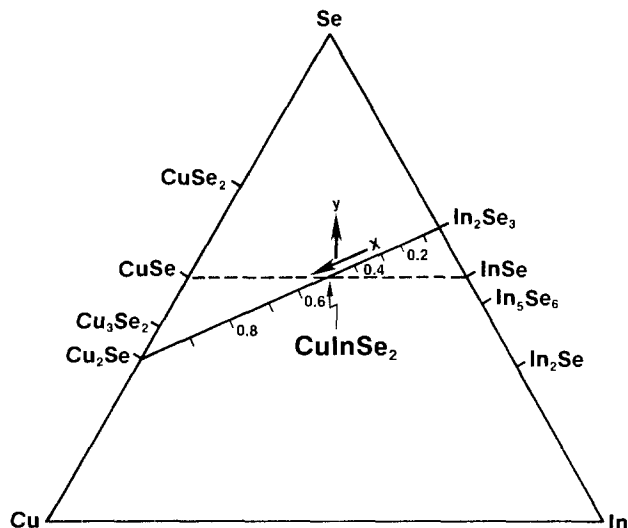

Fig. 1. The ternary Cu-In-Se system indicating the tie-line Cu_2Se_2 - In_2Se_6 along which runs the nonmolecularity (7) parameter x (from 0 to 1) and the nonstoichiometry (nonmetal excess or deficiency) ratio parameter y . Note that the two parameter axes are not perpendicular in this diagram.

temperatures of 600°-800°C, where they were held for several weeks. A pronounced tendency towards chemical vapor transport under their own vapor pressures (a slight excess of chalcogen was usually present) was observed. Even small accidental gradients in an otherwise well-controlled furnace were sufficient to produce this effect. The transport always took place towards the cooler end and the transported material, usually in the form of thin, at times brownish, translucent platelets, of hexagonal habit, always proved to be of significantly lower x than the bulk (x ranging from 0.18 to ~ 0.09). Often, the transported material did, however, contain Cu, which indicates that a species containing both Cu and In must be present in the vapor phase [Cu alone is not known to give this effect (29)]. Due to the transport effect, the samples obtained were often quite inhomogeneous in the sense that a gradient in x was obtained in conjunction with the temperature gradient that had been present. Since this made the information concerning the stoichiometry, as weighed in, worthless, we divided our samples in various parts, determined their stoichiometries by microprobe analyses, and correlated the obtained compositional data with structural data obtained from x-ray powder diffraction for each part.

Polycrystalline thin films were prepared by vacuum evaporation from the elements (2a, 14). The films were deposited on glass substrates. During deposition, the substrate temperature was held at 350°-400°C. The rates of evaporation of the three elements were determined empirically, so that the composition of the deposited films could be controlled by variations in one or more of the rates of evaporation of the elements. Film thicknesses varied between 3 and 5 μm .

Characterization.—X-ray diffraction.—All samples were characterized by powder x-ray diffraction using a powder diffractometer (Rigaku) with a rotating Cu anode source (Cu K_α). In one case, a Guinier-Hägg camera was used as well (Cu K_α).

Electron microprobe analyses.—All samples were analyzed by electron beam-induced wavelength dispersive x-ray fluorescence. A Cameca MBX electron microscope was used. The electron beam voltage was 20 kV; this voltage, which allows detection of the Se K_α line, was chosen because results obtained with it on a CuInSe_2 sample matched those of wet analyses most closely (30). The ZAF correction program (Tracor Northern) plus the following empirically derived multipliers (Cu:0.98; In:1.02; Se:0.99) were used. Except for very smooth samples, a defocused beam with 20 μm spot size and ca. 30 nA beam current

was employed. (We thank C. Herrington for these analyses.)

Optical spectroscopy.—Diffuse reflectance and scattered transmission spectra were obtained using a Beckman 5200 spectrophotometer. Thin film samples were used as prepared. Other samples were spread on a glass plate using double-sided tape or collodion.

Photoelectrochemical studies.—Electrodes were made from suitable crystals or oligocrystalline specimens, where possible, by mounting these on a small copper disk wetted with a liquid In-Ga alloy; a copper wire had been soldered previously to the back of the disk. The metallic parts and all but one face of the specimen were covered by insulating epoxy. In some cases, when only polycrystalline material was obtained, the powder was pressed onto tantalum foil, and a copper wire was attached to the back. A similar sealing procedure using epoxy was followed.

The photoelectrochemical measurements and analyses were accomplished using a computer-controlled apparatus. Its principal components were a 250W tungsten light source, a Jarrel-Ash Mark X monochromator fitted with a TTL-driven stepper motor, a PAR 92 light chopper (operating at 18 Hz), a PAR 174 polarograph, and a lock-in amplifier.

The Model 174 polarograph was used both as potentiostat and as current-to-voltage converter for output to the lock-in amplifier. The computer controlled the wavelength via the monochromator/stepper motor and measured the spectral response via the lock-in amplifier. Typically, a number of averages, ranging from 100 to 200, were taken at each wavelength depending on the sample response. The averaging was done on two time scales; a set of ten points was taken at 50 ms intervals, with each set of ten separated by 0.5s. Appropriate cutoff filters were used to eliminate second-order light from the monochromator. Lamp spectra was taken separately under the same conditions using a Dexter Research Model 2M thermopile with quartz window. The semiconductor response was corrected off line. The nature of the optical transitions was analyzed, as described in Ref. (15c), using a model first presented by Gärtner (15a) and subsequently applied to liquid junctions by Butler (15b). The true photocurrent, J , will be proportional to the absorption coefficient, α , for low values of α , if the conditions for this model are satisfied (15c). Then, if plots of $(Jh\nu)^n$ vs. $(h\nu)$ are linear, they will provide values for the energy of the direct ($n = 2; 2/3$) or indirect ($n = 1/2, 1/3$) transitions (16). Such an analysis can be incorporated in a general photoelectrochemical characterization procedure (31). Part of our goal in applying these analyses was to identify complications. In the course of our present study, two main sources of such complications were identified. The first is the interference of photoconductive effects; the second is the absorption in the IR by the electrolyte (particularly H_2O). A possible remedy for the first one is to apply a bias voltage when the spectral data are taken. This problem is encountered particularly for low doped samples. The second problem is relevant only if bandgap analyses are carried out over a region where the electrolyte absorbs significantly. For H_2O , this effect becomes important if data at wavelengths beyond ca. 925 nm need to be used for analyses. Possible remedies are reducing the optical pathlength through the solution to minimize absorption (in the case of H_2O , this may extend the useful wavelength region to about 1100 nm), correcting for the solution absorption (if the optical pathlength through the solution is known accurately), or using a different solvent (e.g., D_2O will not start to absorb significantly until ca. 1250 nm). Both kinds of complications were encountered, and their implications are discussed below.

The optical-transition analysis routine was written in FORTRAN IV.

Results

Compositions and structures.—For stoichiometries ranging from $x = 0.5$ to ca. 0.23, we typically find

reflections in the powder diffractograms corresponding to the cubic sphalerite sublattice together with superstructure reflections that can be indexed on the basis of a body-centered tetragonal cell with $c \cong 2a_0$. For values around $x = 0.5$, these additional lines obey the extinction rules of the chalcopryrite space group I42d. For $x = 0.23$, however, lines with indexes (114) and (118) are observed, indicating that the structure does not possess a diamond glide. In all cases, the tetragonal distortion c/a is at the edge of or beyond our detection limits. The tetragonal superlines were particularly weak or even absent for thin film samples, especially for those with low x values ($x \sim 0.3$). No stoichiometries between 0.23 and 0.18 were observed, and there appears to be a two-phase region between these limits. For values ranging from $x = 0.17$ to 0.09, we found three different new phases. Except for In₂Se₃, we did not investigate the $x < 0.09$ region. The three new phases were often found in heavily mixed form. Our evidence leads us to believe that their stoichiometries are quite comparable. As indicated above, these materials were often obtained as extremely thin, millimeter-size platelets of hexagonal habit. Their appearance suggests that they may have a layered structure, which is not unreasonable since the structures of α - and β -In₂Se₃ are also layered ones (17). The crystal habit leads to extreme preferential orientation when taking powder diffractometry data. In this particular case, this is helpful in identifying the phases because it reveals the periodicity in the direction perpendicular to the platelets. All three phases have one relatively strong reflection in common with each other and with the chalcopryrite phase. This line is indexed (112) in the latter case [or (111) in the corresponding sphalerite and diamond structures]. It is well known that the direction along which the close-packed Se layers are stacked corresponds to this lattice plane. The structure of the majority of chalcogenides can be described as having such a stacking of close-packed anion layers as its backbone (3). In the chalcopryrite case, the stacking occurs in a cubic fashion with a periodicity of three layers. For the low temperature phases of In₂Se₃, the stacking sequence is hexagonal (based on a twofold sequence). The most obvious approach to structurally identifying the new phases is therefore to treat them as possible mixed cubic/hexagonal stackings, *i.e.*, polytypes. Indeed it is possible to index most strong lines of the three patterns as (00 l) reflections after putting the line they have in common with the chalcopryrite ($d \cong 330$ pm) equal to (005), (006), or (007), respectively. On the one hand, this demonstrates that the new compounds are actually polytypes with stacking sequences of 5, 6, or 7 Se layers and makes it plausible that they are often obtained together. Kinetic effects are known to play an important role in the appearance of polytypes since their thermodynamic differences can be rather small (18). However, the extreme preferential orientation suppresses almost all information concerning directions other than the stacking direction.

Since for CuInSe₂ and In₂Se₃ the prefixes γ , δ , and α , β , γ , δ , respectively, are already in use, we will refer to the new phases as ϵ (7 layers), ζ (6 layers), and η (5 layers). They will be discussed in detail below. Figure 2 shows a tentative phase diagram as amended by integration of our results into the previous ones (8, 9).

The ϵ phase ($x \approx 0.14$ -0.17); [(112) chalcopryrite corresponds to ϵ (007) or (0014)].—We obtained a more complete picture of the lattice periodicity of this phase by combining powder diffractometry data with data from a Guinier-Hägg pattern. The preferential orientation effect for the latter is such that the two data sets are complementary. A hexagonal indexing based on a septuple axis (*i.e.*, seven close-packed Se layers) and an a axis corresponding to *ca.* $2\sqrt{3}$ times the shortest Se-Se distance in a close-packed layer was successful for both patterns. The refinements of the cell parameters were executed separately, and a slightly different c/a ratio was found for the two sets of data. Since the data were collected from adja-

Fig. 2. Tentative T - x diagram for the title system. It is based on our results, as discussed in the text, and data from Ref. (8-10, 18). Two endothermic thermal arrests were observed in a preliminary DTA run on an $x = 0.14$ sample at 610° and 645°C. These may indicate order-disorder transitions in the $\epsilon + \zeta$ mixed phase.

cent parts of the same sample, this could indicate that the phase possesses a certain width of homogeneity. A number of weak lines in both patterns remained unindexed. If we assume, however, that the c axis is double the septuple value, the lines in the diffractogram are easily indexed, mostly again as (00 l) reflections with l being odd. This may mean that a sevenfold stacking periodicity of the Se layers is to be combined with a twofold ordering of the metal atoms between them. Applying this doubling of the axis to the Guinier pattern provides an indexing of all lines, but since the resulting cell is quite big, we cannot consider this as additional evidence. It should be stressed that no attempt was made to find possible indexes with l being odd for lines that were successfully indexed with γ being even previously. Powder x-ray diffraction data for the selenide ϵ phase are given in Table I. These are the observed and calculated d spacings for both diffractometer and Guinier-Hägg data and their (common) indexing. The two patterns were refined independently and gave slightly different axes. The doubling of c explaining the few remaining hkl (l being odd) lines was applied afterwards. It should be noted that we find this phase to be the one closest to a nominal CuIn₂Se₈ stoichiometry ($x = 0.167$). No spinel phase as for the pure sulfide analog is found, while a mixed sulfoselenide with similar stoichiometry adopts another polytype structure (see η phase below).

The ζ phase ($x \approx 0.14$); [(112) chalcopryrite corresponds to ζ (006)].—Powder x-ray diffractometry data for the selenide ζ phase are given in Table II. The sixfold periodicity in the c direction is well documented, but the a axis only corresponds to a value that is comprehensible in terms of short Se-Se distances if we assume it to be $\sqrt{3}$ times the value found from the indexing. The pattern can be indexed on the basis of a hexagonal cell with $a = 913.9(7)$ and $c = 1964(4)$ pm. The c axis corresponds to a sixfold stacking (without doubling), but the a axis only shows a clear relationship to a short Se-Se distance if we take it to be $\sqrt{3}$ times as large. Since the amount of information on this axis contained in the pattern is limited, this assumption is plausible enough, especially since the resulting cell with $a = \sim 1600$ pm is identical to the cell of α -In₂Se₃. It should be noted, however, that no extinctions of (00 l) reflections, as imposed by the 6₃ axis reported for α -In₂Se₃ (17) are observed. A number of lines corresponding to the strongest (00 l) reflections of the ϵ phase are also observed in the pattern. It should also be noted that a phase with a cell like the one described here was reported by Gambarov *et al.* (10c). They claim, however, that its x value is 0.25.

The η phase ($x \approx 0.09$); [(112) chalcopyrite corresponds to η (005) or (0010)].—Just as what is found for the ϵ phase, there is evidence for doubling of the c axis and rather little information on the a axis. The pattern can be indexed successfully by analogy to the epsilon phase using an a axis that is $2\sqrt{3}$ times the shortest Se-Se distance and a tenfold stacking in the c direction. This indexing should be regarded as tentative in the a , b directions. One line corresponding to the strongest line of the zeta phase was also observed as a weak signal. Table III shows the powder x-ray diffractometry data for the selenide η phase. Both the basic fivefold periodicity in c and its doubling (cf. Table I) are well documented. The a , b indexing was adopted in analogy to the ϵ phase and is tentative. A slight

miscalibration rendered a refinement unreliable; instead, the cell parameters were based on an average over the high index reflections ($d < 200$ pm).

It should be mentioned at this point that crystals obtained by spontaneous vapor transport from a $\text{CuInS}_{0.8}\text{Se}_{1.2}$ bulk also proved to have a fivefold periodicity in the c direction. The measured stoichiometry corresponds to $x \sim 0.18$. (The remaining bulk had an x value ranging from 0.55 to 0.48).

The cubic stacking region ($0.5 \leq x \leq 0.24$).—As mentioned above, materials with cubic stacking and a tetragonal ordering were observed in the region $0.5 > x > 0.24$. The cell parameters do not change very much over this broad

range of homogeneity, and the tetragonal splitting remains at the edge of observability by ordinary diffraction means. We observed $a = 574.5(5)$ and $c = 1148(1)$ pm at the low x boundary [compared to 578.5 and 1157 pm for $x = 0.5$ (1)]. Diffractometry of a number of thin film samples deposited by multiple source evaporation according to the method described in Ref. (14) (at 400°C) showed the presence of monoclinic Cu₂Se for compositions with $x > 0.6$, and a tetragonal pattern without lines belonging to monoclinic Cu₂Se, for about $x = 0.6$ to $x = 0.45$; from $x = 0.45$ to $x = 0.3$, only the cubic substructure lines were observed. Obviously, the films do not achieve complete equilibrium under the deposition conditions. The (pseudo-cubic) cell parameter decreases slightly from 579 to 578 pm over this range. The homogeneity range at the high x side seems somewhat metastably broadened, whereas at the low x side the Cu/In or metal/vacancy ordering is not established. An interesting question relevant to photovoltaic applications in this respect is how long such unstable or metastable states may endure at room temperature. The samples we investigated were about one year old. The question is most likely to be answered in terms of years at least. We note that the detailed electron diffraction study by Manolikas *et al.* (19) also mentions freezing of the disordered state by quenching of the high temperature disordered state. It is claimed that above 700°C the symmetry is that of sphalerite (or even Li₂O). Unfortunately, the composition reported by these authors falls outside the range we find to be the region of existence of the cubic stacking. We assume, therefore, that this study was done on a sample corresponding to the lowest x limit (~ 0.24).

The precise nature of the Cu/In and metal/vacancy orderings for lower x values is far from clear. Whereas Manolikas *et al.* (19) claim an I4̄ thio-gallate structure, Djega-Mariadassou *et al.* (20) claim they observed, by careful x-ray work, that between $x = 0.34$ and $x = 0.31$ there is a cubic ordering P4̄3m, with a cell eight times the sphalerite cell and a tetragonal ordering from $x = 0.28$ to $x = 0.25$ with a "paracrystalline" (two-phase) region in between. Since both these and the chalcopyrite ordering stem from the same disordered sphalerite substructure, we have named them γ , γ' , and γ'' , respectively (Fig. 2). A group theoretical treatment showed the three orderings to be very closely related in terms of symmetry (21). Table IV summarizes the structural types encountered in the (Cu₂Se)_x(In₂Se₃)_{1-x} system for $x < 0.6$. (For $x > 0.6$, the monoclinic Cu₂Se is found, mixed with γ or δ .)

Photoelectrochemical experiments.—For the application of thin film Cu-In-Se materials to solar energy conversion, it is important to know how the structural complexity of the phase diagram relates to the performance of these materials in photovoltaic or photoelectrochemical cells. Since we obtained in the above structural study a number of samples that met with the rather modest requirements for photoelectrochemical characterization, we report here a number of relevant data obtained using this method.

The cubic stacking region.—Samples of only two of the stoichiometries encountered in this region were suitable for mounting as electrodes [except for the $x = 0.5$ chalcopyrite phases, *cf.* Ref. (2d)]. Figure 3 shows the current-voltage behavior with modulated white illumination for a sample with $x \approx 0.25$ in an acetonitrile solution of Co(bpy)₃(ClO₄) [see legend to Fig. 3 and Ref. (22)]. It is clear that the sample shows mainly a photoconductive effect. Similar results were obtained in aqueous polysulfide electrolyte. No significant photoactivity was detected in aqueous I⁻/I₃⁻. Using a lock-in technique, we were able to detect a small true n-type photoelectrochemical effect, probably superimposed on the photoconductive one. Figure 4 shows the wavelength dependence of what appears to be a true photovoltaic effect in deuterated polysulfide solution. By analyzing these data as explained in the Experimental section, we deduce a direct allowed optical transition of 1.15 eV and an indirect one of 0.87 eV. These numbers are in reasonable agreement with our reflectance data which indicate a lowest bandgap around 0.95 eV. Because the 0.87 eV value is

Fig. 3. Current-voltage characteristics in the dark and under illumination for hot-pressed layer of $x = 0.25$ (γ') on Ta foil (see Experimental section). The redox couple used was $0.1M$ $\text{Co}(\text{bpy})_3(\text{ClO}_4)_2$ in acetonitrile with $0.1M$ tetraethylammonium perchlorate as supporting electrolyte. This solution was developed by us for use in diagnostic tests on Cu-In-Se thin films (22).

significantly below the indirect gap values obtained for the other phases studied (see below), we should consider it with some caution, as it may be lowered artificially due to impurity bands. The second sample studied was a mixed sulfide/selenide (2:3) with a rather large x value of 0.55. Its photoelectrochemical effect (also n-type) in polysulfide electrolyte was harder to detect than that of the selenide phase with $x = 0.25$. Its spectral response shows a sharp bandedge at 1.18 eV. This value can be expected on the basis of linear interpolation between the reported values for the pure 1:1:2 ($x = 0.5$) sulfide and selenide (1). The value of 1.18 is also in excellent agreement with the value obtained from diffuse reflectance (1.17 ± 0.1 eV).

Because all thin film samples were on a nonconducting substrate (glass), no photoelectrochemical measurements were possible with them. From optical spectroscopic experiments, we could, however, deduce values for their optical bandgaps. All samples between $x = 0.35$ and $x = 0.84$ showed a bandgap of 1.0 ± 0.02 eV. The most Cu-poor ($x = 0.31$) sample gave a somewhat higher value of 1.05 ± 1.02 eV.

The epsilon phase.—Several platelike crystals of this phase ($x = 0.14$ -0.17) were suitable for use as electrodes. Figure 5 shows the current-voltage behavior under illumination and in the dark for one of these samples in aqueous polysulfide electrolyte. Although they exhibit reasonable n-type photovoltaic activity ($V_{oc} \approx 110$ mV), the figure shows clear evidence for some photoconductivity, too. Experiments in a $6M$ KI, $0.1M$ CuCl_2 solution (2d) showed an open-circuit voltage of some 300 mV, but the photoconductive effect was even more pronounced in

Fig. 4. The wavelength dependence of the photo effect of $x = 0.25$ (γ') at +50 mV bias vs. the redox potential of the deuterated polysulfide solution, $1.2M$ in Na_2S and $2M$ in S^0 , and $(Jh\nu)^n$ vs. $h\nu$ plots of these data to determine value of direct (...) and indirect (xxx) gaps.

latter solution was about ten times better than the best response obtained in the former. This is in contrast to results obtained from CuInSe_2 crystals (2). It is likely that the etch removes a partly rectifying layer from the crystal surface. Some of the photovoltaic response shown in Fig. 5 may be due in part to a heterojunction formed by this layer, which might be an indium oxide [cf. Ref. (2d)], as the most pronounced change was observed after a cathodic scan. This conclusion is in agreement with the observed decrease in dark current with time, after immersing a fresh electrode in the solution (suggesting a surface reaction) and the observed slight hysteresis in the C^{-2} -V plots. These plots suggested a donor density of ca. 10^{16} cm^{-3} .

The photoconductivity, alluded to above, was confirmed by spectral response data on a sample with $x \approx 0.15$ in D_2O -based polysulfide solution (cf. Fig. 6), which showed a pronounced peak around 1100 nm. This peak persisted also after etching the electrode, thus making it unlikely that it is due to surface effects such as surface recombination. It became more pronounced, when positive bias was applied and disappeared with sufficiently

Fig. 7. The photoresponse spectrum of $x \approx 0.15$ (ϵ phase) in the deuterated polysulfide solution of Fig. 6 at -300 mV vs. the solution redox potential. $(Jh\nu)^{1/2}$ vs. $h\nu$ plots to determine direct (...) and indirect (xxx) allowed transitions are shown as well.

Table V. Structural types and estimated optical bandgaps (E_g) of $(\text{Cu}_2\text{X})_x(\text{In}_2\text{X}_3)_{1-x}$

X S:Se	x	Sample ^a form	Structure	E_g^b

negative bias (cf. Fig. 7) (23). Also, the wavelength dependence of the resistivity of the cell showed a severalfold decrease around 1100 nm and the capacitance increased in this wavelength range (phenomena that can be ascribed to optical doping).

The data at -300 mV bias were analyzed for indirect and direct allowed optical transitions, as shown in Fig. 7. In this way, an indirect gap of 1.13 eV (1097 nm) was found, confirming the suggestion that the 1100 nm peak (Fig. 6) is due to photoconductivity. A direct gap of 1.31 eV was identified, as well. A sample with $x \approx 0.17$ showed similar photoconductivity behavior, with a peak at slightly longer wavelengths (1000-1050 nm), which could be suppressed at -100 mV bias. Then analysis of the data was possible only in terms of a direct forbidden transition, yielding a gap value of 1.0 eV. Similar analyses in H_2O -based electrolyte gave "evidence" for indirect and direct allowed transitions at 1.10 and 1.25 eV, respectively, illustrating the effect of H_2O absorption. Analyses of spectra that still showed the photoconductivity peak gave erroneously low results. The marked decrease in response at shorter wavelengths (Fig. 6) may indicate that surface recombination becomes a dominant de-excitation mechanism at higher energies.

The zeta phase.—This phase generally was not obtained in form pure enough to allow further study. The few samples that could be investigated showed complicated behavior, indicative of both bulk photoconductive and surface effects. Capacitance measurements indicate a n-type donor density similar to that observed for the ϵ samples (ca. 10^{16} cm^{-3}). A photoconductivity peak around 950 nm was seen in D_2O -based electrolyte. Note that such a peak would have been obscured in H_2O -based solutions. At slightly negative bias, spectra could be obtained that allowed analyses of the optical bandgaps. In this way, values of ca. 1.3 and 1.1 eV were deduced for direct and indirect gaps, respectively.

The eta phase.—While no pure selenide samples with this structure could be isolated, a mixed sulfoselenide with S/Se ≈ 0.8 , and $x = 0.18$, proved suitable for photoelectrochemical study. Crystals of this phase showed photoactivity of predominantly photovoltaic nature in various electrolytes: aqueous ferro/ferricyanide, in aqueous and deuterated polysulfide, in aqueous polyiodide, and in the previously mentioned (Fig. 4) organic electrolyte. Photovoltages up to 200 mV could be obtained in aqueous ferro/ferricyanide and polysulfide as well as in polyiodide, but in the last electrolyte this phase was grossly unstable. Capacitance-voltage plots in buffered aqueous nitrate solution indicated a donor density of 10^{15} - 10^{16} cm^{-3} and a flatband potential of -0.8V vs. SCE in this solution. Some evidence for surface recombination [from double-

Fig. 8. The photoresponse spectra of $x \approx 0.18$ (η phase) sulfoselenide (solid line) in the deuterated polysulfide solution of Fig. 6 under short-circuit conditions. Plots to analyze for direct and indirect allowed transitions are shown as well. For details, see Fig. 7.

illumination experiments, cf. Ref. (25)] and/or photoconductivity effects was seen in the spectral response data for one sample, but others showed straightforward n-type photovoltaic response (cf. Fig. 8). Analyses of the wavelength dependence of the photocurrent, both at 0 V bias (Fig. 8) and at +200 mV bias yielded values for direct and indirect allowed gaps of 1.34 and 1.11 eV, respectively. These values are surprisingly close to those obtained for the pure selenide, ϵ , and ζ phases discussed above. More experiments on pure samples are needed to confirm this anomaly.

In_2Se (δ).—For completeness' sake, we investigated briefly samples of In_2Se_3 on Ta. These samples were obtained from 5N pure In_2Se_3 which was heated at 780°C for several weeks, and subsequently hot pressed at 10^4 psi (69 MPa) and 350°C in a N_2 atmosphere for 60 min and held at this pressure during the 3h of cooling. Such samples showed appreciable n-type photoresponse in the acetonitrile (Fig. 4) electrolyte.

The wavelength dependence of the photoresponse was measured in aqueous ferro/ferricyanide solution, and its analysis showed the presence of a direct (allowed) transition at 1.7 eV, in fair agreement with the 1.6 ± 0.1 eV value obtained from diffuse reflectance. Further analysis of the photocurrent spectrum showed some evidence for an additional, indirect allowed transition at ~ 1.2 eV, which value agrees with the earlier reported⁴ one, obtained by optical absorption spectroscopy.

In_2S_3 .—We made some attempts to look at the other possible end members of the generalized series $(Cu_2X)_x(In_2X_3)_{1-x}$, where X stands for S or Se, in view of our success in preparing some mixed sulfoselenides and the obvious photovoltaic interest in such mixed chalcogenides. No significant photoelectrochemical activity was observed for Cu_2S or Cu_2Se (prepared as hot pressed pellets or layers on Ta). We had some success, though, with In_2S_3 . The electrode was prepared from 5N pure In_2S_3 powder, which was melted *in vacuo* at $\sim 1100^\circ C$ in an ampul and allowed to cool slowly. A slice was cut off the end of the resulting boule and mounted on a Ti plate. (We thank G. Hodes for this sample.)

This electrode was tested without further treatment, and showed appreciable n-type response in polysulfide electrolyte, extending far beyond the reported bandgap for In_2S_3 [2.03 eV, Ref. (26)], although a distinct discontinuity in the photoresponse was observed at ~ 2.02 eV.

⁴ Rehwald and Harbeke (26a) and Garlick *et al.* (26b) report a bandgap of 2.28 eV. Both these measurements were done on single crystals by optical absorption spectroscopy.

Analyses of this photoresponse revealed a direct, allowed, optical transition at 1.84 eV and an indirect, allowed one at 1.54 eV. (We did not note any photoconductive effect and the solvent absorption effect is minimal around these energy values.) The direct transition corresponds very closely to that reported for InS [27], 1.86 eV, although this value was obtained from thermal activation of electrical conductivity measurements. However, Diehl and Nitsche (28) report absorption edges for p- In_2S_3 (As) and p- In_2S_3 (Sb) of 1.88 and 1.44 eV, respectively, indicating that significant shifts of the absorption edge are possible by incorporation of small amounts of impurities. In view of the high purity starting material, and the likelihood of some S loss during the vacuum anneal, it seems reasonable to assume that the top layer was composed of a S-poorer indium sulfide. Indeed, after polishing off the top layer of the electrode and etching it in $Br_2/MeOH$, no significant photoresponse could be obtained anymore in polysulfide. This is easily understood because of the solution absorption. Subsequently, we tested this electrode in ferro/ferricyanide (0.1M $Fe(CN)_6^{4-}$; 0.01M $Fe(CN)_6^{3-}$) to which 1M K_2HPO_4 buffer was added (pH 8.8). Quantum yields up to 0.04 were obtained at 480 nm and 0.0 V vs. SCE and a photoresponse was obtained (Fig. 9) that yielded, after analyses, an indirect bandgap (allowed) of $1.99 (\pm 0.01)$ eV, in reasonable agreement with the 2.03 eV literature value, and a direct gap (allowed) of 2.33 eV, which corresponds to the 2.28 eV literature value (26).

Discussion

The pseudobinary system $(Cu_2Se)_x(In_2Se_3)_{1-x}$ presents a rich variety of structural complexities like so many chalcogenide systems. We can distinguish one common denominator: the fact that all structures are based on a close packed lattice of chalcogen atoms. Further, we can distinguish two or possibly three complicating structural features.

First of all, with decreasing x there is a change in the stacking of the close packed lattice from cubic via a number of mixed polytype-like stackings to hexagonal while at the same time the structures become more layerlike. Secondly, the Cu *vs.* In *vs.* vacancy ordering is quite varied in the region of cubic stacking. At high temperatures this region is very broad and a disordered structure is established; at lower temperatures there are indications for various types of order and the precise equilibrium phase boundaries are unclear; it is likely that at room

Fig. 9. Wavelength dependence of the short-circuit photocurrent of an etched In_2S_3 electrode (cf. text), in aqueous ferro/ferricyanide solution, phosphate buffered to pH = 8.8. The arrow indicates the onset of solution absorption.

temperature metastable (or unstable) materials can be obtained over the broad homogeneity range of the high temperature phase. A third feature is illustrated in the analogous sulfide system (12) where for lower x values the coordination of In changes from tetrahedral to octahedral. Although a spinel phase is not encountered in the selenide system, partial octahedral coordination is claimed for the α - and β -In₂Se₃ structures (17). Only a complete structure determination of the ϵ , ζ , and η phases can reveal if these structures are purely tetrahedral as the cubic stacked phases seem to be.

Our photoelectrochemical (PEC) survey has shown both the power and a number of complications of the PEC method as a characterization tool in solid-state chemistry. Because it only yields results if materials are obtained that answer to a number of requirements not always in control of the investigator (*e.g.*, specimens of suitable size, appropriate doping levels, mobilities and recombination rates, and suitable chemical behavior with respect to some electrolyte), a survey such as this is likely to be somewhat patchy. Nevertheless, useful information was obtained on a number of (new) materials which would not easily have been obtained otherwise and which allows us the following generalizations. The lowest bandgap of all the Cu-In-Se materials shows values that range only between 1.15 and 0.85 eV, even if the stacking is completely different. However, the rather subtle differences in the ratios of vacancies and Cu and In atoms and their orderings are able to destroy the good photoresponse of the chalcopyrite phase. It seems imperative, therefore, to monitor closely the value of x for any thin film material made and possibly the order parameter of the material can be of equal importance. For the former, x-ray diffraction will be of limited use since the lattice parameters change so little, but the intensities of the superstructure lines as opposed to those of the cubic sublattice may give at least some semiquantitative idea of the latter parameter. Of course, the details of the ordering(s) can only be elaborated on basis of detailed single-crystal x-ray, or, preferably, electron diffraction efforts.

Acknowledgments

Gas Permeation Properties of Solid Polymer Electrolyte (SPE) Membranes

Tetsuo Sakai, Hiroyasu Takenaka, Noboru Wakabayashi, Yoji Kawami, and Eiichi Torikai

Government Industrial Research Institute, Osaka Ikeda-shi, Osaka-fu 563, Japan

ABSTRACT

Gas permeation properties for Nafion membranes and their composites were investigated under various conditions. The permeability coefficients of Nafion depended greatly on the water content, the cation form, and the ion-exchange capacity. The gas permeation rate through a same sample varied with temperature, pressure, and membrane thickness. The permeability of hydrogen was about twice as great as that of oxygen. The electrocatalyst plated on the membrane did not serve as a barrier for gas permeation, but the structure of the catalyst layer played an important role in gas permeation during water electrolysis.

Perfluorosulfonic acid membranes (Nafion®), which has excellent chemical stability and high protonic conductivity, have received remarkable attention owing to their importance in electrochemical applications such as hydrogen-air fuel cells (1), chlor-alkali electrolysis (2, 3), and water electrolysis (4-6). In these electrochemical cells, catalytic electrodes are tightly bonded to the both sides of Nafion membrane to form an intimate electrode/electrolyte contact, and the membrane serves as both solid polymer electrolyte (SPE) and cell separator. It is well known that gas permeation through the SPE membrane causes a decrease in current efficiency. Recently, many studies on polymer structure (7-11) and ion transport (12-14) in Nafion membranes have been reported; however, detailed studies on gas permeability of the SPE membranes are few (15-17).

In this work, therefore, the effects of water content, cation form, ion-exchange capacity, and catalyst plating for Nafion membranes were examined on gas permeation. On the basis of the results, gas permeation during water electrolysis (18) was discussed.

Experimental

Membrane materials.—Measurements were made on Nafion 117 and 125 membranes (Plastic Department, du Pont) which have film thickness of 0.0185 and 0.013 cm and equivalent weight (EW) of 1100 and 1200, respectively. The EW is defined as the weight of acid polymer which neutralizes one equivalent of base and is given by

$$\text{IEC} = 1000/\text{EW} \quad [1]$$

where IEC is an ion-exchange capacity expressed in milliequivalents per gram of dry H⁺ form polymer.

Pretreatments of the purchased membranes were made as follows. They were thoroughly washed with acetone, then boiled in 2N HCl solution for 1h, and repeatedly washed with distilled water. The H⁺ form membrane obtained in this way was used as a starting material. Water absorption of the membrane was controlled by changing hydrothermal treatment temperature using an autoclave and expressed in weight percentage of water per 1g of dry polymer. The drying processes at 100°C in an air were repeated until a constant value was obtained. Potassium form membrane was obtained by immersing the H⁺ form membrane in 2N KOH solution for several days.

Nafion-electrocatalyst composites, which load metals in the range of 1-2 mg/cm², were prepared by an electroless plating of noble metal such as Pt, Rh, and Ir onto both sides of membrane (5). In order to improve adhesive property between the membrane and the plated metal, the surface of the membrane was roughened by a sand blasting machine (Daiichi Meteco Company). The thickness of the plated catalyst layer and the extent of the surface roughening were examined by means of a scanning electron microscope (Hitachi, S-430).

Measurement of gas permeation.—Gas permeability was measured with a volumetric method under high pressure

differences. The sample was sandwiched between stainless cells which have permeation area of 15.2 cm². In order to prevent the wet membrane from drying out during the experiment, filter paper soaked in distilled water was placed on the both sides of the membrane and penetrating gas was humidified by passing through distilled water in an autoclave. The penetrating gases such as H₂ and O₂ were introduced into the higher pressure cell after several flushings to replace the air. Gas permeation rate v (expressed in cubic centimeters per second), was measured by a precise gas flowmeter based on soap membrane (Standard Technology Company) in a steady state and converted to a STP (0°C, 1 atm) state of gas volume. The permeation rates under various pressures in the range of 1-30 atm were obtained at a constant temperature and plotted against the pressure differences (Δp). From the slope of the v vs. Δp plot, average permeability coefficient (P_m) expressed in cm³ (STP) · cm/cm² · s · cm Hg was derived from the following equation

$$P_m = \frac{(v/\Delta p)L}{A} \quad [2]$$

where L is the membrane thickness (in centimeters), A the permeating area (in square centimeters), and P the pressure difference (in cm Hg). The permeability values of H₂ and O₂ were obtained in the temperature range of 20°-90°C.

Results and Discussion

Table I shows characteristics of various kinds of Nafion membranes for gas permeation measurements. The water content of the membranes depended greatly on the treatment temperatures, equivalent weight, and salt form, as reported previously (19). Considerable loss of absorbed water occurred during gas permeation measurements for the highly swollen membranes, despite the existence of the wetted filter paper. By measuring permeability after a gas permeation for several hours, reproducible values of permeability coefficients (P_m) were obtained within ±5% on repeated runs. The existence of the wetted filter paper scarcely had influence on the permeation rate. We discussed the P_m values of the membranes on the basis of the values of water content and film thickness after the permeability measurements. Figures 1, 2, and 3 show Arrhenius plots of the P_m values of H₂ and O₂ for Nafion 117 (H⁺ form), 125 (H⁺ form), and 117 (K⁺ form) membranes with various water content, respectively.

Effect of water content.—The P_m values of H₂ and O₂ for all the types of membranes increased with increasing water content, suggesting that water contained in the membranes plays an important role in gas permeation. In order to discuss in more detail the influence of water on the P_m values, the permeabilities for Nafion 117 (H⁺) containing water less than 35 weight percent (w/o) and for Nafion 125 (H⁺) containing water less than 22 w/o were examined as follows. Immediately after the dry membrane was wetted with distilled water, the P_m value at

26°C was measured, and thereafter the water content was determined. The water content dependences of the P_m values of H₂ and O₂ at 26°C are shown in Fig. 4 and 5, respectively. The previous data by LaConti *et al.* (15, 16), which exhibited average values for three kinds of Nafion (H⁺ form) membranes with different ion-exchange

Fig. 1. Arrhenius plots of permeability coefficients (P_m) of H₂ and O₂ for Nafion 117 (H⁺) membranes with various water contents. Estimated values for water and previous values (22) for PTFE were shown for comparison.

Fig. 2. Arrhenius plots of permeability coefficients (P_m) of H₂ and O₂ for Nafion 125 (H⁺) membranes with various water contents.

capacities (EW = 1640, 1260, and 1090), are shown by the dotted line for comparison. Though both sets of values were very close in the range of low water content, previous values showed a more rapid increase than those in this work with increasing water content.

The water content dependences of permeability ratio, $P_m(\text{H}_2)/P_m(\text{O}_2)$, at 80°C for Nafion 117 (H⁺), 125 (H⁺), and 117 (K⁺) are shown in Fig. 6. The permeability ratio drastically decreased with increasing water content and became almost constant in the higher water content region. The constant $P_m(\text{H}_2)/P_m(\text{O}_2)$ value was approximately 2 at 80°C for Nafion 117 (H⁺) and 125 (H⁺). The $P_m(\text{H}_2)/P_m(\text{O}_2)$ values for the K⁺ form membrane had a tendency to come close to the values for the H⁺ form membranes with increasing the water content.

The structure of Nafion membrane has been proposed by Gierke *et al.* (7) based on the results obtained by small

Fig. 3. Arrhenius plots of permeability coefficients (P_m) of H₂ and O₂ for Nafion 117 (K⁺) membranes with various water contents.

Fig. 4. The influence of water content on permeability coefficients (P_m) at 26°C of H_2 for Nafion 117 (H^+), 125 (H^+), and 117 (K^+) membranes. Previous data by LaConti *et al.* (15, 16) on Nafion (H^+) membrane are shown by the dotted line.

angle x-ray scattering, mass-transfer experiments including hydraulic permeation and water diffusion, and electron microscopy. The structure model, so-called the cluster-network model, is as follows. Polymeric ions and absorbed water exist in approximately spherical domains as ionic clusters, separated from the polytetrafluoroethylene (PTFE) matrix. These clusters are assumed to be connected by short narrow channels which have a diame-

Fig. 5. The influence of water content on permeability coefficients (P_m) at 26°C of O_2 for Nafion 117 (H^+), 125 (H^+), and 117 (K^+) membranes. Previous data by LaConti *et al.* (15, 16) on Nafion (H^+) membrane are shown by the dotted line.

Fig. 6. The influence of water content on permeability ratios, $P_m(H_2)/P_m(O_2)$, at 80°C for Nafion 117 (K^+), 117 (H^+), and 125 (H^+) membranes.

ter of about 10Å. It was revealed that the cluster size grows with increasing amount of absorbed water; for example, a diameter of ionic cluster changed from 25.2 to 40.8Å when a water content increased from 5.4 to 19.4 w/o for 1200 EW membrane (8).

Since the swollen membrane was composed of both the PTFE matrix and the water absorbed in ionic cluster, its permeability properties are expected to depend strongly on those of their materials. The permeability coefficients (P_m) for water were estimated from the previous data (20, 21) of the diffusion coefficients (D) and the solubility (S) on the assumption that the equation $P_m = DS$ was applicable to the gas permeation in water. The P_m values estimated here for water and previously reported for PTFE (22) are plotted in Fig. 1 for comparison. The P_m values for Nafion dry membrane were very close to those for PTFE, while the P_m values for the wet membranes increased and approached those for water with increasing water content.

The water-content dependences of gas permeation properties can be explained in terms of the cluster-network model of Nafion structure. In a dried state, since only small amounts of absorbed water are accommodated in the clusters and these are isolated from each other, the water can scarcely influence the gas diffusion. When the membrane absorbs water and the narrow channels are filled with water, the gas diffusion through water would become predominant, causing the rapid change in the P_m and the $P_m(H_2)/P_m(O_2)$. With an increase of the water content, since an interaction between gas and polymer chains is reduced, the $P_m(H_2)/P_m(O_2)$ value would become almost constant.

Effect of equivalent weight.—A slight decrease of ion-exchange capacity from 0.91 meq/g (Nafion 117) to 0.83 meq/g (Nafion 125) is attended by a significant decrease of water absorption from 36 to 26 w/o (hydrothermal treatment at 100°C). This behavior is ascribed to the decrease in ion-cluster size with decreasing ion-exchange capacity as reported previously (8). When both the membranes were treated at a same temperature, the Nafion 117 had higher P_m values than the Nafion 125. In order to discuss whether the P_m is influenced by only the water content or by both the water content and the ion-exchange capacity, the P_m values of Nafion 117 (H^+) and 125 (H^+) were compared on the P_m vs. water content plots in Fig. 4 and 5. The P_m values of H_2 and O_2 for Nafion 117 drastically increased about six to eight times and then became almost constant in the water content range of 20-50 w/o, followed by a further increase in P_m in the higher water content range. On the other hand, the P_m values for Nafion 125 increased smoothly with the water content. The difference of behaviors of both the membranes may be explained by using the structure model of Nafion. Since the

amount of water which can be accommodated within a cluster in Nafion 117 is considerably greater than that in Nafion 125, their structures at the same water content would be different from each other. If we assume that Nafion 117 has a water content region where absorbed water is used only in the cluster growth and the channel diameter is kept almost constant, the occurrence of the constant P_m region can be understood.

The difference in the P_m values between Nafion 117 and Nafion 125 would be mainly ascribed to the difference in water content. The change in the ion-exchange capacity itself can affect the behavior of the P_m vs. water content plot.

Effect of cation form.—The change in cation forms influences the cluster size and therefore water content (8), resulting in the change in the P_m values. In order to discuss the effect of cation form itself on the permeability, the P_m values of the Nafion 117 (H⁺ form) and (K⁺ form) membranes were compared at the same water content in Fig. 4 and 5. The P_m values of H₂ and O₂ for the H⁺ form membrane were much greater than those for the K⁺ form one, suggesting that the K⁺ ions hinder the gas diffusion. Similarly, the $P_m(\text{H}_2)/P_m(\text{O}_2)$ values for H⁺ form membrane were less than those for the K⁺ form membrane (Fig. 6). Since the values of P_m and $P_m(\text{H}_2)/P_m(\text{O}_2)$ for the K⁺ form membrane have a tendency to come close to the values for the H⁺ form one with increasing water content, the influence of cations on the P_m seems to decrease with an increase of water content.

These results support the gas permeation model that gases diffuse through the part of the channels and the clusters which contain ions and water.

Effect of electrocatalyst plating.—The membrane-electrocatalyst composite, which was formed by plating noble metals on both the sides of Nafion, was used in a SPE water electrolysis cell. In order to discuss the decrease in current efficiency in terms of the gas permeation through the composite during water electrolysis, the permeability properties of the composites were examined and compared with those obtained for the original membrane (nonplating Nafion 117). The results were summarized in Table II. The Arrhenius plots of the P_m showed that the apparent activation energies were almost constant throughout all the samples. By the surface roughening treatment of the original membrane (OM), the surface was etched in the depth of 5-10 μm which corresponds to the 2-5% of the swollen membrane thickness, causing a little increase in the P_m . The OM-electrocatalyst composite with a catalyst thickness of 5-10 μm had a little greater permeability than the OM, indicating that the catalyst layer had a porous structure and did not serve as a gas barrier. The increase in P_m will be due to the effect of metal insertion into the membrane by which the path of

gas permeation is spread out. This behavior became more significant for the surface-roughened membrane (SRM)-electrocatalyst composites, where the maximum crack depth went to 18-22 μm after the metal plating. The increase in P_m , which was almost proportional to the increase in the depth of crack, was attended by an increase in the P_m ratio, $P_m(\text{H}_2)/P_m(\text{O}_2)$, suggesting an increase in the number of fine pores whose size is comparable to the molecular size of hydrogen.

It was revealed that the deposition of the catalyst layer on the membrane surface does not prevent gas permeation, but promotes it because the metal forms porous layer and is deeply inserted into the polymer.

When these composites were used for the water electrolysis, the current efficiencies in the range of 94-97% at 100 A/dm² and very high gas purities (greater than 99.999% for H₂, greater than 99.98% for O₂) were obtained as previously reported (18). The loss of current will be ascribed to the gas permeation through the membrane and recombination reaction of the permeating gas on the electrocatalyst. In terms of mass balance, the current efficiency can be related to the gas permeating rate as follows. When a part of generating hydrogen on the cathode permeates toward the anode at the rate of X_H (cm³/s · cm²) and approximately 100% of it undergoes recombination reaction on the anode, oxygen of 1/2 X_H will be inhibited to evolved. In the same manner, when a part of generating oxygen on the anode permeates toward the cathode at the rate of X_O (cm³/s · cm²) and undergoes recombination reaction on the cathode, hydrogen of 2 X_O will be inhibited to evolved. Therefore, the current efficiency (E) can be given by

$$E \text{ (cathode side)} = E \text{ (anode side)} \\ = (C_H - 2X_O - X_H)/C_H \quad [1]$$

where C_H is the hydrogen evolving rate predicted from the current density. The loss volume at 80°C ($P = 2X_O + X_H$) was plotted against the current density for samples no. 3, no. 4, and no. 6 in Fig. 7. The loss volume varied almost proportionally with the current density, suggesting that the evolved gas is disturbed to escape from the catalyst layer and induces a considerably high local pressure. If an individual permeation rate (X_H, X_O) is estimated, the values of the induced local pressures can be obtained by using the permeation rate vs. pressure difference relation shown in Fig. 8.

The permeation ratio, X_H/X_O , under water electrolysis will be given by

$$X_H/X_O = [P_m(\text{H}_2)/P_m(\text{O}_2)] [\Delta P_H/\Delta P_O] \quad [2]$$

where $P_m(\text{H}_2)/P_m(\text{O}_2)$ is the permeability ratio shown in Table II and $\Delta P_H/\Delta P_O$ the ratio of local pressure of hydrogen to oxygen. Since the local pressure has tendency to increase with increasing the gas generating volume, the $\Delta P_H/\Delta P_O$ is assumed roughly to be 2 according to the volume ratio of generating gases. From the X_H/X_O ratio estimated here and the loss volume ($P = 2X_O + X_H$), hydrogen permeation rate (X_H) was obtained and then the hydrogen local pressure was determined based on the permeation rate vs. pressure difference relation. The hydrogen local pressures at 80°C at 50 and 100 A/dm² for the composites are listed in Table III.

The local pressures of the SRM composites were lower than that of the OM composite by about 30% at 100 A/dm². Since the catalyst plated on the SRM has a more porous

structure for the evolved gas to escape than that plated on the OM, this result would be explained in terms of the difference in structure of the catalyst layer. On account of the above effects of electrode structure, the loss volume under water electrolysis increased in order of no. 4 (Pt/SRM/Rh), no. 3 (Pt/OM/Rh), and no. 6 (Pt/SRM/Pt), as shown in Fig. 7, despite the fact that the permeability coefficients of H_2 for no. 4 and no. 6 were higher than that for no. 3 by about 12% and 47%, respectively. Therefore, it is concluded that the mild surface roughening treatment, by which porous layer of catalyst is formed, is very effective for suppressing the gas permeation under water electrolysis.

Summary

The gas permeation measurements carried out in this work revealed the following matters. The permeability

coefficients (P_m) of the Nafion depend greatly on the water content, the cation form, and the ion-exchange capacity. The gas permeation rate through a same sample varies with temperature, pressure, and membrane thickness. The permeability of hydrogen is about twice as large as that of oxygen. Though the electrocatalyst plated on the membrane surfaces does not serve as a barrier for gas permeation, the structure of the catalyst layer is very important for gas permeation during water electrolysis. The porous structure facilitates the departure of the evolving gas, leading to the decrease in the induced local pressure and then the decrease in the gas permeating rate.

Further investigations are in progress in order to understand more completely the gas diffusion mechanism through Nafion membranes.

ABSTRACT

The feasibility of polyether-based all-solid-state cells has been assessed in a joint research and development program. At 80°-100°C, cells using TiS_2 or V_6O_{13} positive-electrode material and excess lithium show high material utilization at 0.5-1.0 mA/cm² and can be cycled more than 250 times. Furthermore, a new family of polyether electrolytes has been found that allows room temperature (26°C) operation at 3-20 $\mu\text{A}/\text{cm}^2$.

A joint research and development project ("ACEP¹ Project") between Société Nationale Elf Aquitaine (SNEA), Institut de recherche d'Hydro-Québec (IREQ), and ANVAR² acting for Laboratoire d'Énergétique Electrochimique (LEE) has been under way since 1980 to develop thin film solid-state batteries based on polyether complexes. The starting point for this project was Armand's pioneering work, which suggested the use of polymer electrolytes for high energy-density batteries (1). Albeit only slightly conducting, these materials can be obtained in a high surface-to-thickness ratio, and they also maintain a good contact with the electrode materials.

The main interest of SNEA and IREQ in this joint project is to develop a battery for electric vehicle (EV) application. Consequently, the work was organized along the lines of the main technical tasks identified an essential for success (Fig. 1).

Only two of the aspects of the project shown in Fig. 1 are dealt with in the present paper: the performance of TiS_2 and V_6O_{13} positive composite electrodes and their cycling properties vs. an excess-lithium negative electrode, and the ambient temperature project. To meet the power density requirements for EV applications (>80 W/kg sustained power) while using polyethylene oxide (PEO, Mw = 5×10^6 or 5M), the operating temperature was fixed at 80°-100°C for most of the tests. As shown below, PEO electrolytes have a very limited performance at temperatures below 40°C, which precludes their use in electrochemical cells working at ambient temperature. In the course of research, however, a family of improved electrolytes was developed that appears to be useful for ambient temperature applications. Initial results on primary and rechargeable cells at 26°C are presented to give an idea of the potential applications of this emerging technology.

Experimental

The experimental work described here was done using electrolyte and composite-electrode films obtained by solution casting techniques, as previously described (1, 2). Commercial PEO (5M and 0.9M) from Polyscience was used as received. The ratio between the number of monomer units ($\text{CH}_2\text{-CH}_2\text{-O}$) and the number of lithium in the salt (O/Li) was fixed at $\approx 8/1$ for both LiClO_4 (Ventron-Alfa Division) and LiCF_3SO_3 (Ozark-Mahoning) complexes.

The electrolyte thickness varied from 160 to 100 μm for small electrochemical cells and from 80 to 50 μm for

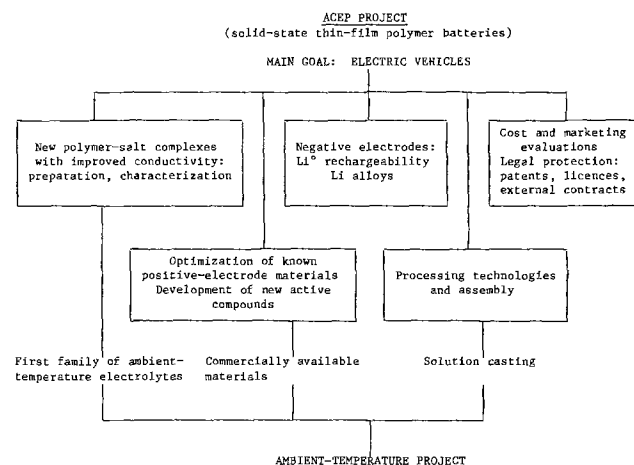

larger surface cells. The anodes were cut from freshly pressed Li° or from $\approx 100 \mu\text{m}$ lithium foils. The TiS_2 and V_6O_{13} (< 37 μm grain size) were prepared by in-house synthesis after adapting published procedures (6, 7).

Electrolytic MnO_2 (Trona Chemicals, Kerr-McGee Chemical Corporation) and MoO_2 (Ventron-Alfa Division) (< 15 μm grain size) were used after drying. The positive composite electrodes included the electrolyte (O/Li = 8/1), the active material (40-50 volume percent [v/o]) and acetylene black (≈ 10 v/o).

The 3.9 cm² cells were crimp-sealed button cells or the cell constituents were housed in containers such as illustrated in Fig. 2 and 3. As shown in Fig. 2a, a central Li° reference electrode was used on one side of the electrolyte, while in the configuration of Fig. 2b a LiAl-Al reference electrode was made by inserting a 10 μm aluminum strip during cell assembly and electrochemically charging it. The EMF of the latter reference electrode ranged from +400 to +360 mV vs. Li° between room temperature and 100°C (3).

Figure 3b shows a larger 70 cm² cell. Cells like this can be stacked in parallel for the scale-up tests described later. This design is convenient for laboratory tests. Optimization in terms of the energy density for future cells is presently under study.

The cycling mode used for this study is based on constant discharge and charge currents with high and low voltage limits.

Results and Discussion

The results presented here serve to establish the characteristics of experimental Li/PEO/TiS₂ and Li/PEO/V₆O₁₃ cells with respect to their performance on cycling. The achieved power and energy densities represent only a first step towards performance optimization based on presently known or commercially available materials. Although the present work is based on the results of a large number of cells, efforts have been made in this presentation to gather most of the studies into a limited number of cells. The results are then considered typical of the technology.

In the discussion of the cycling profiles, unless otherwise indicated, comparison is made between a discharge curve and the subsequent charge curve.

Li/PEO/TiS₂ cell cycling profiles.—Figure 4 illustrates the cycling profile of a 2.9 mAh cell, showing the number of coulombs measured during discharge and charge vs.

Fig. 3. a: Welded stainless steel cells with glass to metal seal. b: 70 cm² capacitor-type cell.

cycling. During the tests, several parameters such as T (°C) or the charge and discharge currents, J_c and J_d , were modified and/or systematically studied.

The changes (a to k on cycle number scale in Fig. 4) observed are listed below. They are also illustrated by additional figures.

a. At this point appears the effect of a lower discharging current on the number of coulombs followed by the effect of lower operating temperatures at constant current (Fig. 5).

b. This point shows charging/discharging at 70°C pursued for 14 cycles.

c. This marks the restorations, at 65°C, of the initial utilization of the TiS₂ electrode (previously observed at 100°C) by the reduction of currents J_d and J_c .

d. Here, cycling is continued at 44°C with a utilization lower than 10%. (Not shown here are some attempts at 26°C where, after a few hours, no current could be drawn from the cell.)

Fig. 4. Cycling profile of a 2.9 mAh TiS₂/Li cell: effect of temperature and cycling conditions on the number of coulombs observed on discharge (full lines) and charge (dotted lines). The discharge and charge currents, J_d and J_c , are represented as - and +, respectively.

Fig. 5. Effect of the temperature on percentage of utilization of TiS_2 at 0.27 mA/cm^2 during discharge. The number on each curve corresponds to the cycle number.

e. At this point is marked the appearance of dendrites on charge after 24 cycles at 44°C (50h), a phenomenon believed to be related to the onset of crystallization of the PEO/LiClO_4 complex. The test temperature is relatively close to a eutectic temperature in the PEO/LiClO_4 phase diagram presently under study (4).

f. The initial utilization of TiS_2 is restored when the temperature increases to $\approx 100^\circ\text{C}$.

g. This marks continuation of cycling under initial conditions.

h. At this point, the increase of the operating temperature to 122°C results in a high utilization but leads to inefficient and anomalous recharge plateaus (Fig. 6).

i. This point indicates a return to operating temperature of 100°C , which leads to initial utilization on discharge (Fig. 7) but to slightly less efficient recharge. (Possible damage resulted from previous high temperature cycles, (Fig. 6)).

j. A dendrite at the end of the 118th recharge plateau appears here (Fig. 6). This phenomenon was not observed in other experiments, not reported herein, when Li^+ was replaced by an LiAl alloy, which seems to confirm that lithium dendrite formation is involved.

k. This marks the return to stable performance of the cycle observed before the dendrite appearance; this suggests that (i) the dendrite is burnt by the Joule effect and (ii) no permanent damage results from occasional dendrites owing to the self-healing properties of the polymer electrolyte.

The second cycling profile (Fig. 8) also for a Li/PEO/TiS_2 cell with a 3.3 mAh capacity was used princi-

Fig. 6. Typical charge plateaus of TiS_2/Li^+ cell at different cycle numbers. C-102: Efficient charge plateau ($C = D$). C-106: Double-wave charge plateau of TiS_2 at 122°C . pally to establish the relations between the charge and discharge currents and the utilization of the TiS_2 electrode, especially for power and energy evaluation. The main observations are described below.

Points a, a', and a'' mark the appearance of occasional dendrites observed during charge, similar to cycle C-118 of Fig. 6.

Points b and b' indicate where several cycles are run at 100° and 80°C to establish a relation between the utilization of TiS_2 and the discharge current J_D (mA/cm^2) (Fig. 9 and 10). The results at 100°C (Fig. 9) show very good agreement with the theory of the insertion of an alkali metal in a composite electrode (5), which proves that the limiting mechanism at 100°C is the lithium diffusion in TiS_2 and not the polymer electrolyte conductivity.

Points c and c' mark improved utilization of the TiS_2 electrode at 80°C as a result of the lower charging current.

Point d shows the effect of a time delay (1h) between the end of a discharge and the next charge, indicating the presence of local concentration gradients in the Li/TiS_2 cell at 80°C .

Point e marks drop in utilization of the TiS_2 electrode resulting from a relatively high charging current (1 mA/cm^2).

Point f indicates cycling at $J_D = 0.5 \text{ mA/cm}^2$ and $J_C = 1.0 \text{ mA/cm}^2$ for more than 90 cycles without any evidence of dendrite formation or significant performance degradation.

Point g marks the appearance of a certain inefficiency of the charge half-cycle (5-10%) after 275 cycles (already illustrated for cycle C-112 in Fig. 6). This test was pursued under similar conditions for more than 450 cycles.

A third cycling profile illustrated in Fig. 11 is also based on a Li/PEO/TiS_2 cell of 3.7 mAh capacity. It is a study of the effect of uninterrupted deep-discharge/charge cycles on the cell performance at 100°C .

The area between a and a' is an area of stable performance of the cell and the balanced discharge and charge plateaus over the first 36 cycles.

At point b, $\approx 95\%$ overall energy efficiency (energy out at C/2)/(energy in at C/7) was observed at cycle 16 (Fig. 12).

The span from c to c' encompasses the appearance of a slight inefficiency of the charge half-cycle at cycle 31, increasing to $\approx 10\%$ at cycle 89.

At point d, a temporary reduction in the observed charge inefficiency took place through an increase in the charge current (cycles 90-100).

Point e shows the stabilization of the charge half-cycle inefficiency vs. cycling from cycles 100 to beyond 250.

Fig. 10. Utilization of $\text{TiS}_2\text{Li}^\circ$ cell vs. discharge current densities at 80°C .

Nature of the lithium salt.—All cells described so far were prepared with lithium perchlorate complexes (O/Li = 8/1) present in the electrolyte and in the TiS_2 composite electrode. However, other cells were prepared which contained lithium salt only in the electrolyte and not in the composite electrode (where only pure PEO was used) when they were assembled. The results presented in Fig. 13 and 9 (at 100°C and 0.5 mA/cm^2) afford the conclusion that there is no significant difference in performance whichever of the two methods of cell preparation is used.

Furthermore, if for a given cell LiClO_4 was replaced by LiCF_3SO_3 , the utilization of the TiS_2 electrode dropped from 80% to $\approx 15\%$ to 100°C and 0.5 mA/cm^2 . To obtain an equivalent performance with LiCF_3SO_3 , the operating temperature had to be increased to $>130^\circ\text{C}$ and the current density reduced by half. This large difference in the performance of LiClO_4 - and LiCF_3SO_3 -based cells at 100°C is expected considering that the conductivity of LiCF_3SO_3 8/1 complexes is much lower than that of LiClO_4 8/1 complexes (1.9×10^{-5} vs. $1.6 \times 10^{-4} \Omega^{-1} \text{ cm}^{-1}$ at 100°C); furthermore, the LiCF_3SO_3 -PEO phase diagram predicts the presence of crystalline phases in the electrolyte. An additional explanation could be a higher anionic transference number in PEO- LiCF_3SO_3 vs. PEO- LiClO_4 complexes.

Origin of the polarization.—The *in situ* LiAl-Al reference electrode described in Fig. 2b was used (3) on several occasions in the present study in order to determine

Fig. 12. Energy efficiency of Li/TiS_2 cell at 16th cycle

the origin of the polarization that limits the Li/PEO/TiS_2 cell performance. Figure 14 illustrates a test in which the cell potential is recorded simultaneously with the potential of the TiS_2 electrode vs. the LiAl reference electrode. It is clear from the similarity of the two curves at 100°C that the cell potential is largely controlled by the positive composite electrode. This behavior, typical of most of the present results, was obtained against a negative Li° electrode.

Li/PEO/ V_6O_{13} cells.— V_6O_{13} has many practical advantages as a positive-electrode material for EV application, namely, its light weight, high voltage, and number of lithium inserted per vanadium. These advantages compensate for the relatively sharp decrease in performance during the first few cycles (illustrated in Fig. 15 for a 2.42 mAh cell tested at 80°C). This behavior is typical of a high purity acicular $\text{V}_6\text{O}_{13}\text{-C}$ (x-ray diffraction). Up to 0.5 mA/cm^2 , the initial utilization of this positive-electrode material is close to 90-95% (vs. $\text{Li}_4\text{V}_6\text{O}_{13}$). However, in the subsequent cycles this value decreases and stabilizes at about 60% for a current density of 0.5 mA/cm^2 . These results are in agreement with those obtained by Murphy (6) for liquid organic electrolytes (0.7 Li/V). Under these conditions, V_6O_{13} electrodes appear to compare well with TiS_2 electrodes in terms of energy and power densities.

Larger cells (140 cm^2) made up of two 70 cm^2 units connected in parallel (represented in Fig. 3b) were assem-

Fig. 11. Cycling profile of a 3.7 mAh $\text{TiS}_2/\text{Li}^\circ$ cell: effect of uninterrupted deep-discharge/charge cycles. The discharge and charge currents, J_D and J_C , are represented as \ominus and \oplus , respectively.

Fig. 13. Utilization of Li/TiS₂ cells prepared without lithium salt in the composite electrode vs. a LiClO₄ (dotted line) or a LiCF₃SO₃ containing electrolyte (full line).

Fig. 14. Comparison of the Li/TiS₂ cell voltage with the signal of the same positive composite electrode vs. LiAl-Al reference electrode.

Fig. 15. Evolution of the discharge plateaus of a Li/V₆O₁₃-C cell during cycling at 80°C.

bled, one with V₆O₁₃-C, the other with a lower purity V₆O₁₃-B containing a small percentage of vanadium oxides such as V₂O₅. The performance of the 98 mAh V₆O₁₃-B cell, cycled at 100°C, presented in Fig. 16 is very close to that observed for small cells made with the same batch of V₆O₁₃. Except for the initial cycles, these experiments show a coulombic efficiency of about 100% between discharge and charge without any formation of dendrites.

Stabilized utilization, both for large and small cells, at high current drains (C/2.7 or C/1.5) depends on the quality of the V₆O₁₃: 60-65% for V₆O₁₃-C vs. 40% for V₆O₁₃-B at 0.5 mA/cm² for 140 cm² cells and 60-70% for V₆O₁₃-C vs. 50-60% for V₆O₁₃-B at 0.5 mA/cm² for 3.9 cm² cells.

ACEP Technology at 80°-100°C

Table I contains estimates of the power and energy densities along with other characteristics deduced from the present results obtained mostly on Li/TiS₂ cells. These estimates are based on experimentally determined values such as the utilization, the electrode thickness, etc. The only arbitrarily fixed values are the negative electrode capacity and a 10 μm provision for the current collector and the electrical insulation.

The power and energy densities presented in Table I correspond to a first step towards the optimization of the positive composite electrodes, but, already, they clearly demonstrate the power density of polymer-electrolyte batteries. This can be attributed to the polymer electro-

Table I. Present performance of ACEP technology based on positive-electrode-limited Li/TiS₂ cells

Calculations are based on 3.1 C/cm² Li/TiS₂ cell characteristics and performance: average discharge plateau voltage V, electrode composition, thickness, and utilization at 2, 1, and 0.5 mA/cm². Electrolyte thickness of 50, 100, and 150 μm. The anode capacity is three times that of the cathode. Provision of 10 μm is made for collectors and/or insulators.

	Energy density		Sustained power		Electrolyte thickness (μm)
	(Wh/kg)	(Wh/liter)	(W/kg)	(W/liter)	
0.5 mA/cm ² (C/1.7)	101	154	68	104	50

lyte's unique combination of solid-state characteristics with plastic behavior, which is particularly well suited to the power and cycling performance of positive composite electrodes.

The cycling values presented in Table I were obtained with excess-lithium electrode capacity and constitute indirect evidence of the efficiency of lithium redeposition from polymer electrolytes. However, systematic work with lithium-limited cells is under way and tends to confirm the high efficiency of the electrodeposition process. As for the dendrite problem, it appears to be an occasional phenomenon, dependent on the control of several technological parameters, which does not affect the cycling capacity of small or larger (70-140 cm²) cells built with lithium negative electrodes. Moreover, the polymer electrolyte appears to possess self healing properties since the dendrites do not seem to affect the following cycles.

The projected energy efficiency of large-scale practical Li/PEO/TiS₂ cells is notably higher than that found with existing rechargeable batteries. This will certainly contribute to the thermal management of large installations of thin film batteries.

Ambient Temperature Cells

As mentioned earlier, at room temperature the PEO conductivity is too low for this material to be used in practical cells, even at a very low drain (see first cycling profile in Fig. 4). In the ACEP Project, therefore, new polymer-salt complexes were developed with improved electrochemical and transport properties which allow operation of all-solid-state primary and secondary cells at ambient temperature.

Several cells have already been built and tested at low to moderate current drains. Figures 17 and 18 illustrate typical performances. The primary high voltage MnO₂ electrode and the reversible low voltage MoO₂ electrode both show utilizations in excess of 80% at rates up to C/37. In addition, nonoptimized MoO₂ cells have confirmed the feasibility of a large number of cycles: > 20 cycles at deep discharges (> 75%) have already been demonstrated at C/36, while 400 cycles have been obtained with the same cell but at rates between C/50 and C/10 at 27°C. Figure 20 shows that good electrochemical properties have been maintained at C/50 even after 300 cycles at C/10.

Moreover, the results presented in Fig. 19, based on a MoO₂/Li cell with a larger surface area (70 cm²), suggest that scale-up is possible and that the results obtained with small cells will be repeated.

Although the technology used for the construction of such ambient temperature cells has not reached a high level of development, a first attempt has been made to establish some of the characteristics of ACEP batteries at room temperature (see Table II). At the time these tests

Fig. 17. Utilization of primary Li/MnO₂ cell at 26°C

were conducted, the temperature observed in the glove box was $\approx 25^{\circ}\text{--}27^{\circ}\text{C}$. Based on more recent results, the authors consider that the performances presented here are still representative of ACEP technology at 20°C, for example.

The authors believe that this emerging technology based on polymer electrolytes is promising for microelectronic and other applications, especially those requiring a rechargeable power source.

Conclusions

In conclusion, the present work, although incomplete, suggests the feasibility of thin film polymer electrolytes in high energy- and power-density batteries for EV applications.

Projected energy densities of ≈ 100 Wh/kg were shown to be possible associated with a sustained power of ≥ 200 W/kg and peak power over 900 W/kg at half-charge and at

Other characteristics: (i) no self-discharge or performance losses after storage for 1 month at 71°C or > 6 months at ambient temperature; (ii) no liquid electrolyte (thus reducing sealing problems), and (iii) scale-up demonstrated at 70 and 150 cm ² .		

100°C. Also, an energy efficiency in excess of 90% and a cycling performance of ≥ 250 deep discharges (or 450 medium to deep discharges) have been demonstrated.

In the authors' opinion, the results obtained in the present study, especially in terms of power density, may be attributed mostly to the unique combination of solid-state properties with those of plastic materials, such as the deformability inherent in polymer electrolytes. This appears desirable as a means of maintaining the electrochemical integrity of the electrode/electrolyte interfaces, especially with respect to the cycling properties of composite electrodes.

In addition, it has been shown that polymer electrolyte cells can be operated at room temperature with lower rate capacities (C/15-C/300) for primary and secondary systems. These preliminary results appear very promising for small rechargeable applications.

The fact that recently the performance obtained on small cells has been successfully repeated at 100° and 26°C with cell areas greater than 100 cm² has led to the initiation of a demonstration program. In this program, the large-scale preparation techniques now used at both SNEA and IREQ will be adapted to the present manufacturing procedure in order to build a first generation of cells with capacities of 10-50 Ah. These cells will serve to establish realistic performances for the ACEP technology and to assess the scale-up problems and manufacturing costs.

These activities will be pursued in parallel with the research into new families of electrolytes and electrode materials and on performance optimization in particular by increasing the surface capacities of the positive electrode in order to improve the energy density yet maintain similar power densities.

Ionic Conductivity in Solid Solutions of the Na₃YSi₃O₉ Type

Chy Hyung Kim, Bingyi Qiu¹ and Ephraim Banks*

Department of Chemistry, Polytechnic Institute of New York, Brooklyn, New York 11201

ABSTRACT

Samples based on the Na₃MSi₃O₉ structure (M = Sm, Eu, Gd, Dy, Ho, Er, Tm, Yb, Lu, and Y) were prepared. A combination of phosphorus substitution and reduction of M³⁺ content permitted increasing sodium content, the maximum sodium content being 3.3. Conductivity of this sample, measured by pulse and two-terminal ac methods, was about 5.5×10^{-4} ($\Omega\text{-cm}$)⁻¹ at 320°C, compared to 9×10^{-8} ($\Omega\text{-cm}$)⁻¹ for Na₃YSi₃O₉ at the same temperature. Activation energies were slightly lowered with increasing sodium content, from 15 to 14 kcal/mol. In compositions with other rare earths, conductivity increased with increasing ionic radius of the rare earth ion. Lithium ions were introduced by ion exchange in molten LiNO₃. The conductivities were slightly lower than those of the corresponding sodium samples, but decreased with increasing rare earth radius.

The compounds of the type Na₃MSi₃O₉ (M = Y, Dy, Gd) were prepared by Shannon *et al.* (1). The sodium ion conductivity of Na₃YSi₃O₉ was reported to be 6×10^{-6} ($\Omega\text{-cm}$)⁻¹ at 300°C.

In our study of Na₃MSi₃O₉-type compounds, it was found that excess sodium could be introduced into the structure. Also, reduction of M³⁺ content (M = Y, Sm, Eu, Gd, Dy, Ho, Er, Tm, Yb, Lu) and substitution of small amounts of phosphorus for silicon without distortion of the Na₃MSi₃O₉ structure were possible, as evidenced by x-ray analysis. The conductivities of these modified com-

pounds improved with the values being in the range of 10^{-4} ($\Omega\text{-cm}$)⁻¹ at 300°C.

Experimental

Starting materials Na₂CO₃, SiO₂, and M₂O₃ of reagent grade were mixed and fired overnight at 900°-1100°C in covered platinum crucibles. The procedure of grinding and heating each of the samples was repeated to insure that the reactions were complete. The x-ray patterns were obtained on a Philips Diffractometer using CuK α radiation. The x-ray patterns of products obtained by quenching at the reaction temperature and by annealing were essentially the same.

The value in parentheses is the conductivity by ac method.

^a Does not belong to $\text{Na}_3\text{YSi}_3\text{O}_9$ phase.

To test the effect of each element on the magnitude of the conductivity, the electrical conductivity of the system $\text{Na}_{3+x}\text{Y}_{1-y}\text{Si}_{3-z}\text{P}_{9+(x-3y+z)/2}$ was measured for different values of x , y , and z in the range of existence of the $\text{Na}_3\text{MSi}_3\text{O}_9$ phase. The firing temperatures were decreased with decreasing yttrium and increasing phosphorus to avoid formation of amorphous phases, as described in Table I.

The compositions $\text{Na}_{3.2}\text{M}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$ were selected to compare the conductivity values for different rare earth elements. The firing temperatures were also adjusted depending on the sort of M_2O_3 . After sufficient firing was carried out, x-ray powder diffraction was used for phase analysis.

To synthesize $\text{Li}_{3.2}\text{M}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$, powders of $\text{Na}_{3.2}\text{M}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$ were treated with excess molten LiNO_3 at 300-350°C for about 30 min-1h and washed with warm water, filtered, and dried overnight at 150°C. X-ray diffraction of these phases showed a "halo" in the powder pattern, indicating the existence of amorphous material, probably due to the synthetic technique employed. No $\text{Na}_{3.2}\text{M}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$ could be detected. However, it is assumed that small quantities of impurity (< 5%) may not be detected in x-ray analysis.

Samples for the conductivity measurement were prepared as ceramic pellets. About 0.6g of powder was mixed with about 0.05g of recrystallized naphthalene as binder (more naphthalene was needed for making pellets of lithium compounds) and pressed into pellets at 3500-4000 psi. The pellets were heated at 250°C for 1h to drive off naphthalene, followed first by sintering at 800-1000°C for 15-20 min and then quenching in air. The lithium compounds were not sintered due to its undergoing a phase

Fig. 1. Variation of ionic conductivity with sodium content at different temperatures for $\text{Na}_{3+x}\text{Y}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.6+x/2}$.

change or reaction around 600-800°C, as evidenced by DTA and x-ray. Relative densities of the pellets were 64-83%.

After sintering, the pellets were coated by vacuum deposition of a thin layer of gold, which acted as electrodes for conductivity measurement (3). These are blocking electrodes, being irreversible to alkali metal decomposition. A thin layer of chromium was intercalated between the surface of the pellet and gold layer because gold itself does not adhere strongly to the surface of the pellet. A pulse method was used in combination with dc measurement, permitting the separation of ionic and electronic components of the conductivity (4). Voltage pulses of 3-7V in magnitude, a pulse width of 80 μs , and pulse repetition time 200 μs were used at 200°, 250°, 280°, and 320°C. For the dc measurement, 0.5V from a constant source was applied, but the electronic contribution was found to be negligible under the condition that the known resistance was 10 k Ω . Also, ac measurements were done at 10^2 - 10^5 Hz and at 1V in all cases; the results at high frequency agreed well with those of the pulse method.

Fig. 4. Dependence of ionic conductivity on yttrium content at various temperatures for $\text{Na}_{3.3}\text{Y}_{1-y}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{9.2-3y/2}$.

Results and Discussion

Table I shows the range of the $\text{Na}_3\text{YSi}_3\text{O}_9$ -type phase and the ionic conductivities at 320°C by pulse and ac method. The conductivities listed in the table are corrected for porosity under the assumption that the pores inside the sample are in the form of spherical cavities (4). Beyond the range of the $\text{Na}_3\text{YSi}_3\text{O}_9$ phase, one or more other phases such as $\text{Na}_5\text{YSi}_4\text{O}_{12}$, Na_3PO_4 , $\text{Na}_3\text{Y}(\text{PO}_4)_2$, $\text{Na}_3\text{YSi}_2\text{O}_7$, Y_2SiO_5 , and $\text{Y}_2\text{Si}_2\text{O}_7$ appeared. The table also shows the effect of each element on the magnitude of the conductivity. With increasing sodium concentration in the structure, the conductivities are seen to increase. This would appear to be due to the increase of mobile sodium ion concentration. Figures 1 and 2 show the variation in conductivity and activation energy calculated from the equation $\sigma = \sigma_0/T \exp(-E_a/kT)$ as functions of increasing sodium content in the $\text{Na}_{3+x}\text{Y}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.6+x/2}$ series. Figure 3 shows Arrhenius plots of the ionic conductivity as a function of temperature for the same system. The conductivities increase with decreasing yttrium concentration because vacancies in the structure are apparently

Fig. 8. Arrhenius plot of ionic conductivity for $\text{Na}_{3.2}\text{M}^{3+}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$

does not contribute toward improving the conductivity; instead, it decreases the conductivity and increases the activation energy (see Fig. 7). That is, $\text{PO}_{1/2}$ substitution for silicon increases the number of atoms and thereby interferes with ion transport. But experimentally we found that more sodium could be introduced into the structure by substitution of a very small amount of phosphorus ($z = 0.1$) for silicon (see Table D). For example, in $\text{Na}_{3+x}\text{Y}_{0.7}\text{Si}_{3-x}\text{O}_{8.55+x/2}$ and in the $\text{Na}_{3+x}\text{Y}_{0.7}\text{Si}_{2.9}\text{O}_{8.35+x/2}$ series, the x values were lower than 0.2 in spite of regrinding and reheating at 1040°C for 3 days. However, in the $\text{Na}_{3+x}\text{Y}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.6+x/2}$ series, which is the same as the former series except that a small amount of phosphorus is introduced, the x value could be increased (< 0.4) by heating at 1015°C for 24h. It appears that phosphorus has the effect of stabilizing the structure at higher sodium concentration, perhaps by

Fig. 9. Arrhenius plot of ionic conductivity for $\text{Na}_{3.2}\text{M}^{3+}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$.

enlarging the available sites, even though the increase of oxygen may induce a decrease in conductivity. At higher phosphorus concentrations, the appearance of other phases like $\text{Na}_3\text{Y}(\text{PO}_4)_2$ and Na_3PO_4 was observed by x-ray analysis.

Other rare earth compounds could be fabricated in the same way as described above for yttrium. In the case of $\text{M} = \text{Sm}$, more regrinding and reheating were needed to complete the reaction. The x-ray patterns of $\text{Na}_{3.2}\text{M}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$ showed that they are isostructural with $\text{Na}_3\text{YSi}_3\text{O}_9$. Only some shifts in the position of the peaks depending on the size of M^{3+} were observed. The orthorhombic $\text{Na}_{3.2}\text{M}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$ lattice constants were estimated using x-ray powder diffraction patterns (see Table II). The cell

Fig. 10. Variation of ionic conductivity with rare earth ionic radius for $\text{Na}_{3.2}\text{M}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$.

Fig. 11. Variation of ionic conductivity with rare earth ionic radius for $\text{Li}_{3.2}\text{M}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$.

volumes of these modified compounds were less than those of $\text{Na}_3\text{MSi}_3\text{O}_9$, as can be seen in Table III, mainly due to the reduction of M^{3+} and O^{2-} contents even though the sodium content was increased. However, the ionic conductivity was improved in modified compounds. Table IV and Fig. 8 and 9 indicate the conductivities and Arrhenius plots of $\text{Na}_{3.2}\text{M}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$ compounds. In general, with increasing size of the rare earth ion the conductivity increases, as shown in Fig. 10. If it is assumed that the $[\text{Si}_6\text{O}_{18}]$ rings are held together by sodium and rare earth ions, the amount of space between the rings will be influenced by the size of six coordinated M^{3+} . The larger the M^{3+} size, the larger the cell volume, which can probably provide more space in the structure. But in the $\text{Li}_{3.2}\text{M}_{0.7}\text{Si}_{2.9}\text{P}_{0.1}\text{O}_{8.7}$ series, the conductivity decreased with increasing size of the rare earth ion (see Fig. 11). It might be expected that the lithium ion size becomes smaller than the optimum size for ionic motion as the size of M^{3+} becomes larger.

Detailed structural analysis of $\text{Na}_3\text{YSi}_3\text{O}_9$ would help in understanding the mechanism of the conductivity. This will probably require the growth of single crystals, which has not yet been accomplished.

Solvent Effects on the Electrochemistry of Tetracyanoquinodimethane Polymer Modified Electrodes

Pal Joo¹ and James Q. Chambers

Department of Chemistry, University of Tennessee, Knoxville, Tennessee 37996-1600

ABSTRACT

The electrochemistry of tetracyanoquinodimethane (TCNQ) modified electrodes in contact with simple alcoholic solvents containing lithium salt electrolytes has been studied. Cyclic voltammetric responses characteristic of each alcohol are obtained for 0.1M LiCl/ROH solutions where R = CH₃, CH₃CH₂, CH₃CH₂CH₂, and CH₃CH₂CH₂CH₂. Film stability in the -2 oxidation state and persistence on the electrode were greatly improved in the alcohol solvents relative to the behavior in water. Based on the voltammetric responses, reversible and facile swelling of the polymeric TCNQ films was found when the electrodes were transferred between solvents and electrochemically cycled between the neutral and reduced forms. The effective diffusion coefficient for charge transport (D_{eff}) through the films decreases as the solvent size increases, but the product of the effective diffusion coefficient and viscosity was found to be approximately constant.

The modification of electrode surfaces with polymers has been pursued actively in recent years (1). Materials studied have included conducting metallic polymers such as polyacetylene (2) and poly(pyrrole) (3), ion-exchange polymers such as Nafion (4) and poly(vinylpyridine) (5), and polymers with fixed electron-transfer sites such as poly(vinylferrocene) (6), poly(bipyridine) metal complexes (7), and poly(nitrostyrene) (8). Judging by the many examples reported in a relatively brief time, it is evident that polymeric materials have great versatility for the chemical elaboration of the electrode/solution interface and mediation of concomitant redox processes.

We have recently synthesized a polyester that incorporates the electron-acceptor unit, tetracyanoquinodimethane (TCNQ), into the polymer backbone (9). Thin films of this polymer cast on metal substrates are electroactive and have been studied in contact with aqueous electrolytes. Aside from possible applications, these electrodes are of interest because the electron hopping charge-transport process through the films is markedly affected by chemical reactions in the polymer film phase. The rapid electron-transfer reactions of the TCNQ acceptor renders the films fully electroactive and permits the observation of the effects of coupled chemical reactions on the film electrochemistry. Association (10), protonation (11), and ion pairing (12) of reduced sites in the polymer phase have been documented in previous publications from this laboratory.

Solvent swelling of electroactive polymer films can be extensive, although the role of solvent in the film charge-transport process is difficult to establish. Film thickness increases of approximately 80% were reported by Leddy and Bard for electrodeposited poly(vinylferrocene) films in contact with acetonitrile (13). Earlier, in the case of plasma-polymerized vinylferrocene, Daum and Murray observed that the shapes of the cyclic voltammetric waves are solvent dependent and interpreted the differences by invoking solvent swelling effects (14, 15). A similar observation was reported by Shigehara and by Oyama and Anson for poly(vinylpyridine) ion exchange films (16). It is to be expected that solvent swelling will favor motions of electron donor and acceptor sites, migration of counterions in and out of the polymer film, and, accordingly, will promote electrochemical charge transport.

Herein we report on the electrochemistry of TCNQ polymer films in contact with aliphatic alcohol solvents

(ROH: R = CH₃, CH₃CH₂, CH₃CH₂CH₂, and CH₃CH₂CH₂CH₂). Cyclic voltammograms and spectroelectrochemical data characteristic of each solvent are observed. Since the TCNQ electrochemistry is well understood, both in solution (17) and in the polymer film state (10), the results provide some insight into the role of solvent on the polymer film electrochemistry experiment.

Experimental Section

The preparation of the TCNQ polymer has been described previously (9). Gel permeation chromatography analysis of material synthesized recently indicates that the molecular weight of the polymer is somewhat higher than that prepared initially (9). Voltammetric results in aqueous electrolytes were identical with previous reports. Analytical-grade LiCl and LiClO₄ (Fisher Scientific) were recrystallized and dried under vacuum prior to use. Methanol, ethanol, n-propanol, and n-butanol (all Fisher Scientific) were distilled and stored over 3A, 8-12 mesh molecular sieves (Aldrich).

The film electrode preparation procedures by spin coating and evaporation procedures using saturated tetrahydrofuran (THF) solutions of the polyester have been described (12, 18). Freshly distilled THF was used to prepare the solutions. The coated Pt button (Beckman, $r = 0.25$ cm) and Pt-on-quartz optically transparent disk ($r = 0.65$ cm) electrodes were usually baked for 5 min at 130°C in order to produce a stable, adherent coating.

An Ag/AgCl reference electrode and Pt auxiliary electrode were employed and immersed directly in the alcohol, 0.1M LiCl solutions. In order to correct for variation of the reference electrode potential in the alcohol solvents, the potential of the ferrocene/ferricenium "reference redox system" (19) was also measured at a bare platinum electrode in the solvents studied.

Results

Cyclic voltammetry.—Cyclic voltammograms (CV's) of (TCNQ)_x films adsorbed on platinum substrates in ROH (R = H, CH₃, CH₃CH₂, CH₃CH₂CH₂, and CH₃CH₂CH₂CH₂) are shown in Fig. 1-5. An initial observation is that the solvent markedly influences the qualitative voltammetric wave shapes, although all of the CV's display the basic EE behavior that has been reported previously for TCNQ polyester-modified electrodes. Solvent effects are found on the reversibility for the TCNQ^{0/-} and TCNQ^{-1/2-} processes, the effective diffusion coefficients for charge transport through the film, the film "break-in" process, and the stability of the film in the reduced state.

^a Volts vs. Ag/AgCl, unless stated otherwise. Sweep rate: 20 mV/s.

^b Peak width at $i = i_{peak/2}$.

^c Diffusion wave shape, E_{pw} , not measured.

^d Values in parentheses give $E_{1/2}$, volts vs. E_p^c for Fc^{+/0}; see text.

Peak potentials and $E_{1/2}$ values are collected in Tables I and II for the polymer film and TCNQ monomer, respectively. For the first wave in particular, good correspondence is found between the half-wave potentials for the film and monomer in solution. All of the $E_{1/2}$ values are positive relative to the values in water. This is especially true for the second wave, which is probably a reflection of stronger ion association between TCNQ²⁻ and Li⁺ ion in the alcohol solvents relative to water.

The half-wave potential vs. the ferrocene couple does not display any significant trends in the alcohol solvents. The ferrocene reference system was chosen in order to minimize variation of the reference electrode potential between solvents. Cyclic voltammograms were obtained for ferrocene at a bare platinum electrode in each solvent/electrolyte vs. an Ag/AgCl reference electrode. Unfortunately, the cyclic voltammograms of ferrocene in ROH/0.1M LiCl did not have the theoretical shape for a simple reversible one-electron transfer electrode reaction. The reverse cathodic peak was attenuated, indicating that the ferricinium ion was reactive in these alcoholic solvents, and the anodic wave was drawn out. Nonetheless, the ferricinium ion reduction wave was developed to approximately the same extent in all solvents studied and was used as a point of reference for the TCNQ waves.

The most dramatic solvent effect is seen on the stability of the film in the -2 oxidation state where protonation of the TCNQ²⁻ groups occurs in aqueous electrolytes (11). The film instability in water is seen in Fig. 1, which documents the effect of variation of the switching potential in the cyclic voltammetric experiment. When the potential sweep is extended into the region of the second wave in unbuffered aqueous media (on the second cycle in Fig. 1), the film dissolves as evidenced by the irreversible

Fig. 1. Cyclic voltammogram of a TCNQ film in contact with aqueous 0.5M LiClO₄. Sweep rate, 10 mV/s; current axis, 10 μ A/division; initial potential, 0.3V vs. Ag/AgCl. Cycles 1-3 are shown.

TCNQ^{-1/2-} wave ($E_p = -0.48$ V vs. Ag/AgCl), the greatly diminished TCNQ^{0/-} wave on subsequent cycles, and the appearance of the characteristic color of TCNQ and TCNQ⁻ in solution. By the third cycle of this voltammogram, only about 10% of the TCNQ sites remain in communication with the platinum substrate based on the charge under the TCNQ^{0/-} cathodic peak. This phenomenon has been ascribed to hydrolysis of the ester links in the TCNQ polyester by the OH⁻ ions formed by hydrolysis of the reduced acceptor sites (11).

In the alcohol solvents, the TCNQ polymer films are much more persistent in the -2 oxidation state. In CH₃OH, for example, well-developed reversible waves are observed for both the first and second electron-transfer steps which persist as the electrode is cycled between the 0 and the -2 oxidation states. With repeated cycling in CH₃OH/0.1M LiCl, however, the solution acquires the color of TCNQ monomer and the peak currents decrease, indicating that film dissolution does occur.

At slow sweep rates, the peak widths ($E_{pw} =$ peak width at $i = i_{p/2}$) and peak separations ($E_p^a - E_p^c$) are typical of reversible surface waves. At very slow sweep rates (less than ca. 5 mV/s), a prewave on the first wave becomes well developed in the CH₃OH voltammograms. This prewave is evident in the voltammogram shown in Fig. 2, where the sweep rate is 20 mV/s; at higher sweep rates, the prewave seems to merge into the first wave. The origin of this prewave is discussed below.

In the higher molecular weight alcohols, the stability and persistence of the TCNQ films increase. In addition, a rather different type of "break-in" phenomenon is observed. For thick films in contact with aqueous electrolytes, several potential sweep cycles are required to activate fully a TCNQ film as documented in the literature (12). In the voltammogram in Fig. 3 obtained in ethanol/0.1M LiCl, the peak current for the first wave decreases and a new wave, assigned to the TCNQ^{-1/2-} process, develops. Absorbance measurements at 720 nm on the TCNQ⁻ radical anion band support this assignment of the

Fig. 2. Cyclic voltammogram of a TCNQ film in contact with 0.1M LiCl/CH₃OH. Sweep rate, 20 mV/s; current axis, 5 μ A/division; initial potential, 0.4V vs. Ag/AgCl. Two cycles are shown.

developing wave to the TCNQ⁻²⁻ process. After several cycles, two waves with approximately equal peak currents are evident in the voltammogram. The value of $dAbs^{720}/dE$ decreases and reaches a minimum in the region of E_p^{cath} for the second wave in the CH₃CH₂OH/0.1M LiCl solution as would be expected for EE behavior (12). Careful inspection for the voltammograms in n-propanol and n-butanol reveals similar behaviors. In n-butanol (see Fig. 5), the current on the first negative going sweep is poorly defined, while subsequent cycles reveal a well-developed first wave and a steadily increasing second wave. The reason for this behavior is not fully understood. Virgin films achieve almost full electroactivity in the initial cycle in methanol and acetonitrile solvents, implying that the solvent swelling process occurs more readily in these solvents than in water.

Other implications of the role of solvent in these "break-in" phenomena can be seen in cyclic voltammograms obtained when a film is cycled in solvent A until a steady-state behavior is obtained and then transferred to solvent B for subsequent voltammetric experiments. For all of the solvents examined, the voltammetric pattern of a given solvent could be regenerated by potential cycling

Fig. 3. Cyclic voltammogram of a TCNQ film in contact with 0.1M LiCl/CH₃CH₂OH. Sweep rate, 20 mV/s; current axis, 10 μ A/division; initial potential, 0.4V vs. Ag/AgCl. Seven cycles are shown.

Fig. 4. Cyclic voltammogram of a TCNQ film in contact with 0.1M LiCl/H₂O (cycles 1 and 2) and transferred to 0.1M LiCl/CH₃CH₂CH₂OH (cycles 3-6). Sweep rate, 20 mV/s; current axis, 20 μ A/division; initial potential, 0.4V vs. Ag/AgCl.

through the TCNQ^{0/-} and TCNQ⁻²⁻ redox processes. An example is shown in Fig. 4 for the transfer of a TCNQ film from water to n-propanol. The first two cycles of this voltammogram are typical of the behavior observed in lithium salt electrolytes (9). Cycles 3-6 were obtained when the film was transferred to n-propanol/0.1M LiCl. Even on the first sweep in the alcoholic solvent (sweep number 3), the characteristic voltammetric curve in H₂O/0.1M LiCl is replaced with that in CH₃CH₂CH₂OH/0.1M LiCl. In this experiment, the potential was swept only into the foot of the TCNQ⁻²⁻ wave in n-propanol, but the definition and peak current for the oxidation of TCNQ²⁻ clearly increases as the electrode is cycled. After six cycles, the pattern is almost identical to that obtained on a virgin film that is broken in in CH₃CH₂CH₂OH/LiCl.

The striking feature of these voltammograms, and indeed all of the results of these transfer experiments, is that the voltammetric response characteristic of an alcohol solvent develops on the first cycle. The second wave,

Fig. 5. Cyclic voltammogram of a TCNQ film in contact with 0.1M LiClO₄/CH₃(CH₂)₃OH. Sweep rate, 20 mV/s; current axis, 10 μ A/division; initial potential, 0.4V vs. Ag/AgCl. Five cycles are shown.

in contrast to the observation in water (Fig. 1), has the appearance of a quasi-reversible one-electron surface wave. (The small asymmetry apparent in these voltammograms is probably due to uncompensated resistance in the electrochemical cell.) In water, film electroactivity is lost after the initial potential sweep into the region of the second wave; see Fig. 1.

In *n*-butanol also a noticeable break-in process is observed; see Fig. 5, which displays cycles 1-5 of a virgin film in *n*-butanol/0.1M LiClO₄. The perchlorate, and not the chloride salt, was used in this experiment in order to increase the solution conductivity. In *n*-butanol/0.1M LiCl, the same voltammetric features were evident, but the effect of uncompensated resistance was more evident. In the voltammogram of Fig. 5, the first negative going sweep is considerably drawn out. However, on subsequent cycles, the second wave develops at the expense of the first wave in a manner similar to the ethanol behavior of Fig. 3.

It is also clear that the electrochemical reversibility of the film redox processes is solvent dependent. There is an increase in the TCNQ wave peak separations in the sequence methanol to *n*-butanol. The peak separations, $E_p^a - E_p^c$, and peak widths are significantly larger in the higher molecular weight solvents. Quantitative measurements of "effective charge transfer rate constants" were not made from the peak separations owing to the difficulty of assessing the role of uncompensated resistance artifacts which will also contribute to the observed peak separations.

A final qualitative solvent effect is evident in the voltammograms obtained in methanol. In this solvent, even for virgin films, a split wave is seen for the first electron-transfer step. At even slower sweep rates, the separation and definition of the two components of this split first wave increase. Similar behavior is seen in acetonitrile solvents for the TCNQ films cast using the above procedures (20).

The TCNQ film reduction in CH₃OH/0.1M LiCl was studied in further detail by two spectroelectrochemical techniques, simultaneous electrochemistry and electron spin resonance spectroscopy, SEESR (21), and derivative voltabsorptometry (22). In the latter technique, absorbance measurements at 735 nm on the TCNQ^{•-} radical anion band showed that the prewave in the CH₃OH voltammogram was not due to reduction of the TCNQ units to the radical anion state. This experiment is shown in Fig. 6 for a thin (TCNQ)_x film on a platinum substrate. (Essentially identical patterns were obtained on gold substrates.) The value of dA_{735}/dE reaches a maximum in the region of the symmetrical wave at ca. 0.05V and a minimum at ca. -0.25V in the region of the second wave. This pattern is that expected for the TCNQ^{0/-2} redox chemistry undergoing EE reduction. Unfortunately, partially reduced TCNQ units, or the "mixed-valence species," do not absorb light in the visible or near-infrared spectral regions (12). Thus, it was not possible to monitor this state in a voltabsorptometry experiment. Accordingly, we turned to electron spin resonance techniques to study the process further.

The SEESR signal did not display a maximum in the region of the prewave at ca. 0.1V vs. Ag/AgCl as would be expected for formation of a paramagnetic "mixed-valence" species in a reduced film where extensive dimerization of the radical anion occurs (10). Only a slight increase (ca. 10%) over the residual ESR signal was noted in this potential region. However, stepping the electrode potential through the TCNQ^{0/-} wave at ca. 0.05V greatly increased the magnitude of the ESR signal and slightly increased the peak width from 4.7 to 5.2G. This can be understood if there is less dimerization of the radical anion sites in methanol than in water.

The redox process responsible for the prewave in 0.1M LiCl/CH₃OH is not clear. The addition of trace amounts of water or air to the cell had no effect on the voltammograms. Based on previous studies in water, it is possible that formation of partially reduced TCNQ units

Fig. 6. Cyclic voltammogram and derivative voltabsorptometry (obtained simultaneously) of a TCNQ film in contact with 0.1M LiCl/CH₃OH. Sweep rate, 5 mV/s; current axis, 5 μ A/division; dA/dE axis, 2×10^{-2} absorbance unit/V/division; initial potential, 0.4V vs. Ag/AgCl.

occurs in this region where the electron charge is delocalized into a semiconductor band formed by a superstructure of TCNQ units in the polymer film. Semiconductor and "organic metal" salts of partially reduced TCNQ monomers have been known for some time (23, 24).

Spectroelectrochemistry.—Absorption spectra of fully reduced films in ROH/0.1M LiCl solutions in the wavelength range, 300-750 nm, were qualitatively identical to spectra in aqueous LiCl solution (12). Upon reduction, bands for the radical anion ($\lambda_{\text{max}} = 720$ nm) and dimer dianion ($\lambda_{\text{max}} = 650$ nm) grow in intensity. The radical anion band is distinctly more prominent relative to the dimer band in the alcohol solvents than in aqueous solutions. The degree of dimer dissociation, $\alpha = [\text{TCNQ}^-]/C_T$, where C_T is the total concentration of acceptor sites in the polymer film, was found to be approximately 0.5 for all the alcohol solvents studied. This compares to $\alpha = 0.27$ found previously in aqueous solution. This result is consistent with the above cyclic voltammetric results which show that the anodic segment of the TCNQ^{0/-} process is less drawn out in alcohol than in water, indicating that oxidation of the radical anion dominates the anodic peak current for this process.

Another qualitative difference between the aqueous and alcoholic solvents is that reaction of the reduced film in the -2 oxidation state with oxygen is more rapid in the latter solvents. This is evidenced in the absorption spectra by the irreversible disappearance of all TCNQ bands, the appearance of a new band at $\lambda_{\text{max}} = 480$ nm, and a decrease of film electroactivity. It is likely, in view of the observation of Sushanski and Van Duyne (25), that the 480 nm band is due to the product reaction of the TCNQ²⁻ dianion with O₂.

In the previous studies in water, the potential region for the generation of the dianion was avoided due to the film dissolution process, and as a consequence, the O₂ decay product with $\lambda_{\text{max}} = 480$ nm was usually not observed. Furthermore, the previous derivative voltabsorptometric spectroelectrochemical studies (12) were conducted in the presence of aqueous CaCl₂ where the dianion and the TCNQ polymer films were relatively stable. However, even under these conditions, TCNQ films in the -2 oxidation state will undergo irreversible reaction in the presence of air to give a species with $\lambda_{\text{max}} = 480$ nm. Films that have been held in the -2 oxidation state in alcohol for ex-

tended periods of time ($> ca. 10$ min) no longer display the spectral characteristic of the TCNQ group. Potential sweeps in the region of $+0.4$ to -0.3 only revealed weak TCNQ redox processes and did not indicate the presence of any new waves.

Chronocoulometry.—In order to determine the “effective diffusion coefficient” for charge transport (D_{ct}) in the various solvents, potential step chronocoulometry was performed. Typical results are shown in Fig. 7 for 0.1M LiCl in each of the four alcohols studied. Based on the Cottrell slopes, there is approximately an order of magnitude decrease in D_{ct} in the sequence methanol through n-butanol. The following values ($D_{ct} \times 10^{12}/\text{cm}^2\text{s}^{-1}$) were determined: CH_3OH , 1.0 ± 0.1 ; $\text{CH}_3\text{CH}_2\text{OH}$, 0.4 ± 0.1 ; $\text{CH}_3\text{CH}_2\text{CH}_2\text{OH}$, 0.2 ± 0.1 ; and $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$, $ca. 0.1$. The values of D_{ct} in n-butanol, and to a lesser extent in n-propanol, were difficult to reproduce, owing in part to the high resistance of the 0.1M LiCl solutions in these solvents. In addition, the D_{ct} values in n-butanol appear to be strongly dependent on the film preparation procedures, i.e., baking time and temperature.

The viscosity of the alcohol solvents increases as the chain length increases (26). Not surprisingly, the product of the effective diffusion coefficient for charge transport and viscosity is approximately constant. At $ca. 25^\circ$, we find the following values for $D_{ct} \times 10^{12}/\text{cm}^2\text{s}^{-1}\text{cp}$: CH_3OH , 0.55 ± 0.06 ; $\text{CH}_3\text{CH}_2\text{OH}$, 0.44 ± 0.11 ; $\text{CH}_3\text{CH}_2\text{CH}_2\text{OH}$, 0.4 ± 0.2 ; $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$, 0.3 ; average, $ca. 0.4$.

Summary and Conclusions

These experiments have shown that the electrochemical behavior of TCNQ film electrodes is basically the same in a series of alcohol solvents as it is in water. Successive electron-transfer reactions (EE behavior) are observed in all solvents studied, including acetonitrile (20). The natures of the charge transport process, however, and the resulting voltammetric behavior are solvent dependent.

Cyclic voltammograms characteristic of each solvent are observed, and relatively facile transitions from the pattern of one solvent to that of another are found when film electrodes are transferred between solvents con-

taining the same supporting electrolyte. These results imply that solvent uptake by the film and film swelling occur readily. The break-in phenomena observed in these transfer experiments indicate that this solvent swelling process can be electrochemically driven. This conclusion is consistent with our observation (27) that coupling of platinum oxidation with the $\text{TCNQ}^{0/-}$ couple and penetration of water to the polymer/substrate interface take place in films that have been electrochemically cycled.

The approximately constant value of D_{ct}^{xn} suggests, but does not prove, that counterion migration balanced by a Stokes viscous force controls the charge-transport process in these TCNQ polymer films. Approximately constant D^{xn} values are predicted by the Stokes-Einstein relation for diffusion of particles of uniform size in viscous media (28). Polymer backbone segmental motions should also be diminished as the viscosity of the solvent increases. Both effects are likely to be involved in the electron hopping charge-transport process in electroactive polymer films (18).

Regardless of the detailed mechanism of the charge-transport process, however, it can be concluded that the solvent is intimately involved in the polymer film phase. Facile swelling is observed when the TCNQ electrodes are transferred and electrochemically cycled in different solvents. The voltammetric parameters reflect the swelling process. In the sequence from methanol to n-butanol, deviations from reversible surface wave behavior increase.

Semiconducting Characteristics of Galena Electrodes

Relationship to Mineral Flotation

P. E. Richardson* and C. S. O'Dell*

U.S. Department of the Interior, Bureau of Mines, Avondale Research Center, Avondale, Maryland 20782-3393

ABSTRACT

Electrochemical, interfacial capacitance, and surface photovoltage (SPV) measurements have been used in a study of oxygen reduction and xanthate chemisorption on *in situ* cleaved natural and synthetic lead sulfide crystals. Electrodes cleaved in nitrogen-sparged 0.1M sodium tetraborate assume the flatband potential, V_{FBP} , at the instant of cleavage, and thus the cleavage potential decreases with increasing bulk electron concentration. Highly n-type electrodes have a cleavage potential (V_{FBP}) of $\approx -0.6V$ (SCE), and highly p-type electrodes have a value of $\approx -0.2V$ (SCE). The space charge is readily varied by applied potentials in the range -0.2 to $-0.6V$. This Bureau of Mines, U.S. Department of the Interior, report discusses the effect of the variable space-charge layer on oxygen reduction and xanthate chemisorption.

The use of xanthates as flotation collectors for sulfide minerals is one of this century's more successful examples of applied surface chemistry, and their practical significance has stimulated extensive research on the reactions that confer hydrophobicity. The 1950's marked a major milestone when it was discovered by Plaksin (1) that oxygen was an essential reagent in the xanthate flotation of sulfides. Most sulfides are semiconductors, and Plaksin and Shafeev (2) suggested, in the case of galena, that oxygen chemisorption converted the surface from n- to p-type, energetically favoring the oxidation of xanthate anions to produce an adsorbed hydrophobic species

At about the same time, Salamy and Nixon (3) proposed a mixed potential model of sulfide flotation where xanthate oxidation to a hydrophobic surface species is compensated by the reduction of dissolved oxygen. The major difference between these two proposals is that the mixed potential model focuses on the solution side of the interface and assumes that the potential drop, V_h , between the surface and the outer Helmholtz plane, OHP, adjusts to make the rate of the anodic and cathodic reactions equal. In contrast, the semiconductor model focuses on the potential drop across the solid, which is assumed to control collector adsorption by changes in the Fermi level at the surface or by changes in the energetics of xanthate oxidation.

During the past decade, the mixed potential model has gained wide acceptance in flotation research. In the application of this model, semiconducting effects have been neglected by assuming sulfides behave as metals. For galena, it is assumed (4, 5) that there is no varying potential drop across the solid side of the interface so that the transfer coefficient has the same value as at metal electrodes, i.e., ≈ 0.5 . A transfer coefficient of 0.5 suggests that the Fermi level at the surface is pinned at a fixed value. However, Fermi level pinning at galena surfaces is inconsistent with a potential-dependent photovoltage (6), a Tafel slope of 225 mV, which has been reported for oxygen reduction at pH 9.2 (7), the influence of light on xanthate adsorption (8), nonuniform adsorption of xanthate and nonuniform deposition of copper, suggesting areas of

differing electrochemical potential (9), and the dependence of oxidation rate on light and stoichiometry (10).

In an attempt to reconcile the different viewpoints expressed in the two models and the conflicting experimental results, the present study on oxygen reduction and xanthate chemisorption on *in situ* cleaved galena electrodes was undertaken by the Bureau of Mines. *In situ* cleavage was selected to obtain unoxidized electrode surfaces having minimum mechanical damage in the surface region in order to avoid defect states that might pin the surface Fermi energy. Surface photovoltage and capacitance measurements were used to study variations in the space-charge potential.

Experimental

A conventional three-compartment quartz cell was used for xanthate chemisorption studies and a two-compartment cell for oxygen reduction studies. Potentials are reported with respect to a saturated calomel electrode connected via a Luggin capillary to the cells. A constant-current charging pulse with an amplitude of 0.1-1 mA/cm² and width of 15-20 μs was used to determine the capacitance. The electrode response of galena is characterized by a nearly vertical rise and fall in potential when the pulse is applied and terminated, a linear increase in potential during the on time of the pulse, and an exponential decrease in potential after the pulse is terminated. The surface photovoltage (SPV) was excited by illumination from a 200W xenon-arc lamp filtered to pass a 2000Å band near 8000Å, chopped at 86 Hz, and measured by a procedure described previously (6).

The electrolyte was 0.05 or 0.1M sodium tetraborate. The cell was sparged with ultrahigh purity nitrogen or with nitrogen containing known oxygen partial pressures ($pO_2 = 10^{-3}$ and 10^{-2} atm). Separate measurements on a platinum electrode in the cell used for oxygen reduction studies indicated that the diffusion current due to residual oxygen when sparging with nitrogen was $\approx 1 \mu A/cm^2$, which corresponded to a $pO_2 = 10^{-4}$ atm (11).

The electrodes were natural crystals of galena from Galena, Kansas, and Brushy Creek, Missouri, and synthetic crystals obtained from the Naval Surface Weapons Center, White Oak, Maryland. The semiconducting characteristics of the actual electrodes were determined from surface photovoltage (SPV) measurements (12-14), which are discussed in detail in the Results section. Based on the

*Electrochemical Society Active Member.

SPV, all of the natural crystals were highly n-type, possibly degenerate. Hall-effect measurements on a selected natural sample gave a bulk electron density, n_b , of $\approx 2 \times 10^{-18} \text{ cm}^{-3}$. The synthetic samples mounted as electrodes were from several different growth runs, and the SPV showed that they ranged from slightly n-type to highly p-type.

Electrodes were cleaved *in situ* in the electrochemical cell. Figure 1 shows an electrode prior to and after cleavage and illustrates the mounting technique. A platinum wire spot welded to the back surface prior to encapsulation in a nonconductive epoxy provided an ohmic contact. A sharp blow on a glass rod resting on the electrode resulted in (100) cleavage. Usually, the samples cleaved flush with, or just below, the surface of the epoxy so that the entire electrode area after cleavage was that of the freshly cleaved surface.

Results

Electrode potentials and photovoltages at cleavage.—All of the "as-mounted" samples had open-circuit potentials of -0.26 to -0.1V in oxygen-free borate. These potentials were dependent on dissolved oxygen but had no correlation with carrier densities. They are believed to represent the mixed potential of oxidation and/or dissolution reactions occurring on the surface. All electrodes except those found in subsequent studies (next section) to be highly p-type had positive photovoltages, indicating positive (electron-deficient/hole-rich) space charges.

Figure 2 shows the change in electrode potential and SPV for a typical natural mineral electrode as it is cleaved under borate. At cleavage, the electrode potential instantly decreases by several hundred millivolts and then slowly increases with time; simultaneously, the SPV instantly decreases to zero and then becomes increasing positive as the electrode potential increases. The behavior of the other electrodes at cleavage is qualitatively similar to the highly n-type, as shown in Table I. The zero SPV suggests that the electrodes all assume the flatband potential, V_{FBP} , at the instant they are cleaved, which will be substantiated in the next section. Since the flatband potential depends on the bulk carrier concentration through the well-known relationship (14)

$$V_{FBP} = \text{const.} - (kT/q) \ln(n_b/n_i)$$

the progressive increase in the potential at cleavage with decreasing electron concentration is also explicable by the assumption that the potential assumed at cleavage is equal to the flatband potential.

The increase in potential following cleavage represents a slow oxidation process, which gives rise to a positive SPV (upward band bending) on all electrodes except the

Fig. 1. Electrodes before and after cleavage

Fig. 2. Changes in electrode potential and surface photovoltage following cleavage of a natural galena electrode in 0.1M sodium tetraborate.

highly p-type. The latter is presumably close to degeneracy, preventing upward band bending at the surface due to an anodic process. Electrodes cleaved in oxygen containing solutions exhibit a much faster increase in electrode potential following cleavage. The increase in potential and the development of a positive space charge, therefore, can be plausibly attributed to an acceptor state associated with oxygen chemisorption. Alternatively, lead vacancies are known to act as acceptors in lead sulfide (15-16) and a dissolution reaction whereby lead is leached from the surface to produce a metal-deficient surface may also account for the development of a positive space following cleavage.

The behavior of the cleaved electrodes is in essential agreement with Plaksin and Shafeev's proposal (2) that an oxidation reaction increases the free hole concentration at the surface of galena, either by their mechanism of oxygen chemisorption or by a dissolution process that produces a lead-deficient surface.

Oxygen reduction and anodic oxidation reactions on cleaved samples.—The bottom and middle curves of Fig. 3-5 show the SPV and interfacial capacitance for two synthetic and one mineral electrodes. The SPV and capacitance curves exhibit the classical shape (12-14) characteristic of semiconductor electrodes, establishing qualitatively the existence of a polarizable space-charge layer. It can also be noted that variations in the SPV and capacitance occur over a potential range greater than the thermal bandgap, $E_g = 0.37 \text{ eV}$ (15), of lead sulfide. Therefore, changes in the Helmholtz potential cannot be neglected, and the usual Schottky-Mott plots (17) cannot be used to determine the flatband potential or the carrier densities of the electrodes. However, V_{FBP} can be determined from the SPV measurements for samples in which both the positive and negative branches are observed (Fig. 3 and 4).

Theoretically, the ratio of the saturation SPV's under strong anodic and cathodic bias should vary as the bulk electron-hole ratio, n_b/p_b (13). The ratio for the synthetic sample in Fig. 3 is close to unity, establishing that the sample is intrinsic. From the zero value of the SPV, the flatband potential, V_{FBP} , is at -0.375V , essentially the potential observed at cleavage. The equality of V_{FBP} deter-

Table I. Electrode potential, V_{E_r} and SPV of cleaved electrodes

Sample	Rest potential before cleavage		Potential at cleavage		Rest potential after cleavage	
	V_{E_r} V(SCE)	SPV	V_{E_r} V(SCE)	SPV	V_{E_r} V(SCE)	SPV
Highly n-type	-0.237	+	-0.540	0	-0.240	+
Slightly n-type	-0.232	+	-0.465	0	-0.225	+
Intrinsic	-0.137	+	-0.380	0	-0.137	+
Highly p-type	-0.260	0	-0.235	0	-0.225	0

Fig. 3. Surface photovoltage (bottom), interfacial capacitance (middle), and constant current polarization (top) for a synthetic PbS electrode in 0.1M sodium tetraborate.

mined from the SPV with the potential of the capacitance minimum provides further support of the intrinsic nature of this electrode (18).

The flatband potential of the synthetic sample in Fig. 4 is at -0.475V , again in agreement with the cleavage potential. The ratio of the saturation SPV's, after a small extrapolation of the negative branch, suggests this sample is slightly n-type with $5 < n_v/p_b < 10$. The slight shift of the capacitance minimum to potentials more positive than V_{FBP} , i.e., toward depletion, is in agreement with the expected theoretical shift (17) and provides further support for a slightly n-type sample.

Only the positive branch of the SPV is observable on highly n-type mineral electrodes (Fig. 5). Typically, at electrode potentials between -0.5 and -0.6V , the SPV of natural electrodes becomes less than the noise level ($\approx 0.05\text{ mV}$), and no photosignal is observed at potentials as low as -1.0V , suggesting that the bulk is degenerate p-type. Therefore, the surface Fermi level is at the conduction bandedge at V_{FBP} , preventing downward band bending even with strong cathodic polarization. The flatband potential cannot be determined precisely without reversal in the sign of the SPV, but it is apparently located at potentials $< -0.5\text{V}$. From the potential of several

natural electrodes at the instant of cleavage, it is believed to be between -0.54 and -0.69V (SCE). The capacitance minimum (Fig. 5) occurs $0.2\text{--}0.3\text{V}$ positive of the flatband potential, i.e., is shifted farther toward the depletion region, as expected for a highly n-type sample.

The uppermost curves of Fig. 3-5 show the constant-current polarization behavior of the electrodes. The oxygen reduction reaction (Fig. 4-5) is close to first order with respect to $p\text{O}_2$. The Tafel slopes are not constant but have approximate values of $\approx 0.21\text{V}$ for the intrinsic electrode, $\approx 0.16\text{--}0.22\text{V}$ for the slightly n-type electrode, and $\approx 0.2\text{V}$ for the highly n-type mineral electrode. A Tafel slope of 0.059V is usually anticipated (19) for cathodic reactions on semiconductors when the rate is dependent on the surface concentration of electrons, n_s , and changes in

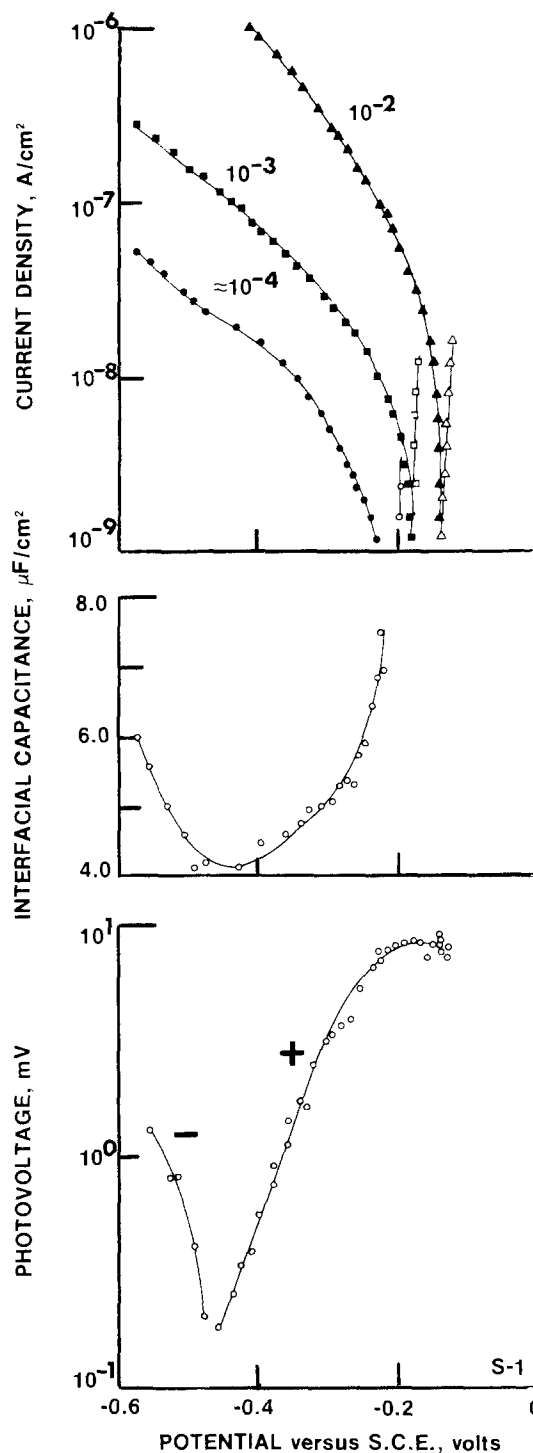

Fig. 4. Surface photovoltage (bottom), interfacial capacitance (middle), and constant current polarization (top) for a synthetic PbS electrode at oxygen partial pressures of 10^{-2} , 10^{-3} , and $\approx 10^{-4}$ atm in 0.1M sodium tetraborate.

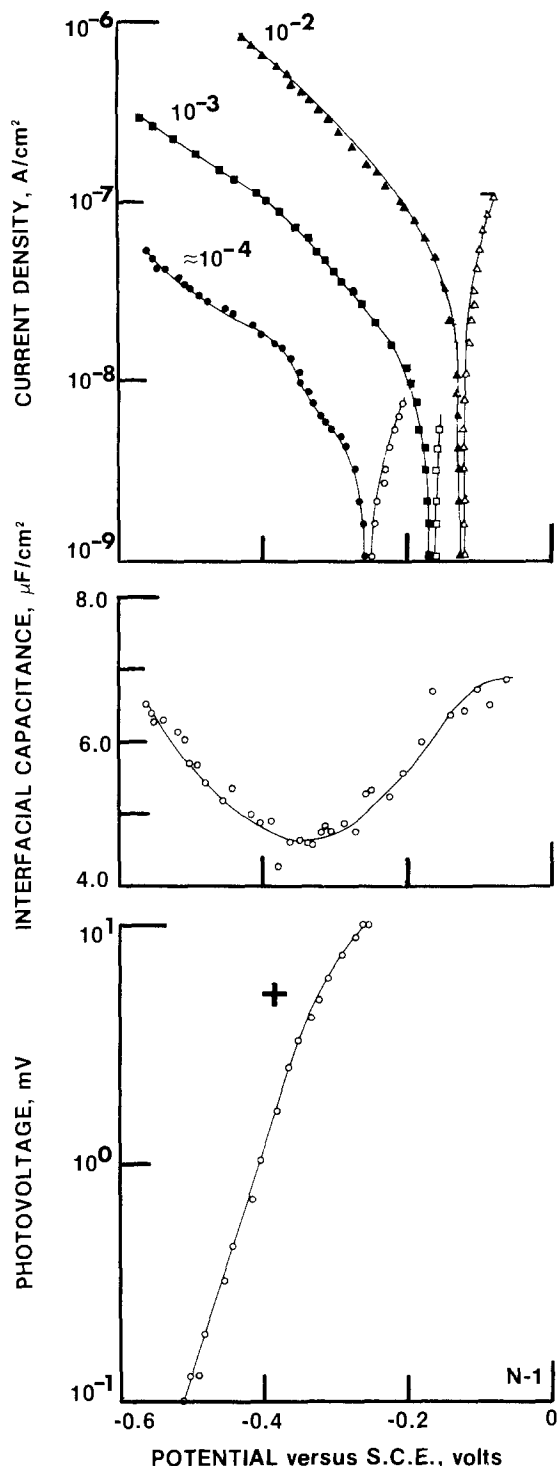

Fig. 5. Surface photovoltage (bottom), interfacial capacitance (middle), and constant current polarization (top) for a mineral galena electrode at oxygen partial pressures of 10^{-2} , 10^{-3} , and $\approx 10^{-4}$ atm in 0.1M sodium tetraborate.

electrode potential occur solely across the space-charge layer; whereas, an ideal Tafel slope of 0.118V is anticipated for the simplest one electron reduction reaction at metal electrodes. For the present electrodes with $n_b \geq n_i$ (n_i = intrinsic concentration), the rate of oxygen reduction is not dependent on n_s . In this case, any changes in potential across the space-charge layer should reduce the changes in overvoltage available in the Helmholtz layer for oxygen reduction, giving rise to the large apparent Tafel slopes. In the Appendix, the SPV has been used to estimate the partition of the potential between the solid and solution phases. The results indicate that over the range of potentials corresponding to the Tafel region for oxygen reduction, the potential is partitioned nearly

equally between the solid and solution phases. This suggests that Tafel slopes referenced to the change in Helmholtz potential have values approximately one-half as large as the experimental values, that is, ≈ 0.08 -0.12V.

These "corrected" Tafel slopes are not sufficiently accurate to warrant their use for a detailed analysis of the mechanism of oxygen reduction. The important point is that independent measurements of the SPV and capacitance establish the existence of a polarizable space-charge layer, which logically accounts for the large Tafel slopes observed experimentally on electrodes with $n_b \geq n_i$. It should also be noted that, on p-type electrodes, the rate of oxygen reduction conceivably could become limited by the rate of diffusion of electrons to the surface (19). However, the rate could only be less than at n-type electrodes. A slower rate is inconsistent with the semiconducting model of flotation reactions where p-type minerals are predicted to react more readily with anionic collectors than are n-type minerals (2). The results and the above argument suggest that a semiconducting limit of the rate of oxygen reduction should not be significant in galena flotation.

Xanthate chemisorption on cleaved electrodes.—

Ethylxanthate is known to chemisorb on galena, possibly as a 1:1 complex with surface lead (4, 20). Chemisorption is limited to a monolayer or less and accordingly does not give rise to steady-state currents but may be studied using transient methods such as voltammetry, after correcting for background effects. Figure 6 shows a background voltammetry curve at high current sensitivity for galena in 0.05M borate. The electrode was cleaved *in situ* while potentiostated near the flatband potential, a procedure selected to inhibit oxidation. The anodic and cathodic limits of the voltammetry scan were then gradually increased until an oxidation wave (O_I) and a reduction wave (R_{II}) became apparent at potentials $\geq -0.2V$ and $\leq -0.9V$, respectively. These waves are believed to produce second solid phases on the electrode, corresponding to $PbO + S^\circ$ at potentials $> -0.2V$ (6, 21) and to Pb° at potentials $< -0.9V$ (22). R_I and O_{II} appear only after prior oxidation at potentials $> -0.2V$ and reduction at potentials $< -0.9V$, respectively. For electrodes cleaved *in situ* and potentiostated in the range $-0.9 < V_E < -0.2V$, no gross compositional changes in the surface occur, and their behavior should be characteristic of lead sulfide and should not be influenced by other solid phases on the surface produced by oxidation or reduction.

In the presence of high concentrations of ethylxanthate, the currents between -0.6 and $-0.2V$ (Fig. 7) are much in excess of those occurring on the background voltammetry curve. The excess currents, therefore, are due to redox reactions between lead sulfide and ethylxanthate. The dotted voltammetry (Fig. 7) is in excellent agreement with voltammograms of Woods (4) and Gardner and Woods (23). The anodic prewave beginning

Fig. 6. Cyclic voltammogram of a cleaved natural galena electrode in 0.05M sodium tetraborate at 5 mV/s.

Fig. 7. Cyclic voltammograms of natural galena electrode in the presence of 0.01M sodium ethylxanthate/0.05M sodium tetraborate at 5 mV/s.

at -0.4V has been attributed to xanthate chemisorption to form a surface analogue of lead ethylxanthate (4), the wave at $\approx -0.2\text{V}$ to the formation of a mixed lead xanthate/sulfur/dixanthogen product layer (23, 24), and the reduction peak at $\approx -0.55\text{V}$ to the reduction of the mixed layer and any chemisorbed xanthate (23, 24).

When the anodic limit is kept slightly below the potential of mixed film formation, a distinct cathodic peak is observed at -0.35V that contains the same charge as the anodic chemisorption peak. A cathodic peak at as positive a potential as -0.35V , with distinct separation of this peak from that for $\text{PbX}_2/\text{S}/\text{X}_2$ reduction, has not been reported previously. It clearly represents the reduction and probably desorption of chemisorbed xanthate. It is also apparent that the chemisorption/desorption process is more reversible than reactions leading to $\text{PbX}_2/\text{S}/\text{X}_2$ products on the surface and their reduction. This result is not unexpected, since chemisorbed xanthate is an obvious intermediate in the formation of a $\text{PbX}_2/\text{S}/\text{X}_2$ layer and the formation of PbX_2 requires structural rearrangement at the surface.

From the standpoint of possible semiconducting effects, we are primarily interested in the chemisorption/desorption process occurring between -0.4 and -0.2V . Figures 8 and 9 show the xanthate chemisorption/desorption reaction and the SPV for a synthetic and natural mineral electrode. The SPV was obtained on the freshly cleaved surfaces immediately prior to xanthate addition. Only negative SPV's were observed on the synthetic electrode, establishing this electrode as highly p-type; only positive SPV's were observed on the natural mineral electrode, establishing it as highly n-type.

The flatband potentials of the electrodes (determined as the potentials at cleavage) are also indicated in Fig. 8 and 9. These provide reference potentials where the surface densities of carriers are qualitatively known; that is, the surface of the highly p-type electrode is highly p-type at $\approx -0.2\text{V}$, and the surface of the highly n-type is highly n-type at $\approx -0.6\text{V}$. Since at the semiconductor-electrolyte interface the Fermi level at the surface is independent of the bulk Fermi level (17), it follows that the p-type electrode has a highly n-type surface $\approx -0.6\text{V}$, and the n-type has a highly p-type surface at $\approx -0.2\text{V}$. The band configurations relative to a voltammetry curve are schematically illustrated in Fig. 10. The xanthate chemisorption/desorption process occurs between -0.4 and -0.2V , i.e., over the range of potentials where the space charge changes, suggesting chemisorbed xanthate may be represented by a surface state (donor-like) having an energy within the forbidden gap. The bandgap of PbS (15) is only $\approx 15kT$ (0.37 eV). With such a narrow gap, surface states are anticipated to be in equilibrium (facile charge exchange) with bandedge states, and with their occupancy determined by the location of the Fermi level at the surface. The occupied state corresponds to chemisorbed

Fig. 8. Cyclic voltammogram and surface photovoltage of a synthetic PbS electrode in 0.01M sodium ethylxanthate and 0.05M sodium tetraborate. V_{FBP} = potential at cleavage. Sweep rate 5 mV/s.

xanthate, probably in a 1:1 coordination with a surface cation, whereas the unoccupied (or reduced state) is rapidly desorbed to a xanthate anion in solution.

The results from the earlier cleavage experiments are also summarized in Fig. 10. The cleavage experiments establish that fresh surfaces of highly p-type galena assume a potential where ethylxanthate can spontaneously chemisorb; whereas highly n-type galena must undergo an oxidation or oxygen chemisorption reaction to lower the Fermi level at the surface to the point where it is thermodynamically favorable for xanthate to chemisorb. The inversion of the surface from n- to p-type by oxygen chemisorption is essentially in agreement with the original proposal of Plaksin and Shafeev (2) and explains the energetic changes that must occur at the interface before xanthate chemisorption. However, contrary to Plaksin and Shafeev, oxygen chemisorption alone cannot lead to significant, approximately monolayer, xanthate adsorption, for, as pointed out by Woods (25), an isolated surface cannot remain nearly neutral if the only processes are the anodic chemisorption of xanthate and oxygen chemisorption. The charge balance in this case simply represents the transfer of a negative xanthate ion and molecular oxygen to the surface and transfer of an electron from adsorbed xanthate to adsorbed oxygen, a process that would quickly lead to an electric field retarding further xanthate adsorption. To maintain electrical neutrality, it is assumed that oxygen must also be simultaneously reduced, as in a mixed potential model, to obtain a significant coverage with xanthate. The role of oxygen is apparently twofold with (i) oxygen chemisorption initially providing the energetic change that is thermodynamically

Fig. 10. Band diagrams showing flatband potentials of highly p- and n-type lead sulfide electrodes relative to the xanthate chemisorption/desorption reaction.

necessary before xanthate can chemisorb on n-type galena, in agreement with Plaksin and Shafeev, and (ii) oxygen reduction maintaining a "near"-neutral surface to sustain chemisorption to approximately monolayer coverage, in agreement with the mixed potential of Salamy and Nixon (3).

From the standpoint of flotation, the only significant difference that might be expected between p- and n-type galena is that the flotation of the latter may exhibit an induction period, following grinding, during which the potential increases to the point where xanthate chemisorption can occur. An induction period for the aqueous oxidation of n-type galena has been reported by Eadington and Prosser (10) and is explicable by the present work; that is, the potential of n-type electrodes must increase to the dissolution potential before measurable oxidation occurs. However, sulfide flotation circuits, excepting recent molybdenite practice, are operated with an infusion of air. With the abundant availability of oxygen, any induction period may be unobservable or insignificant.

Conclusions

Interfacial capacitance and surface photovoltage measurements have provided independent evidence of a polarizable space-charge layer on galena electrodes at pH 9.2, with the surface ranging from highly n-type at $\approx -0.6V$ (SCE) to highly p-type at $\approx -0.2V$. The flatband potential of galena decreases with increasing bulk electron concentration, consistent with the expected relation (14)

$$V_{FBP} = \text{const.} - (kT/q) \ln (n_b/n_i)$$

It has also been shown that galena surfaces instantly assume the flatband potential when cleaved in an electrolyte, with highly n-type galena having a cleavage potential (V_{FBP}) of $\approx -0.6V$ and highly p-type a potential of $\approx -0.2V$.

The Tafel slopes for oxygen reduction are larger than would be predicted from simple models of oxygen reduction at semiconductor or metal electrodes. The large slopes have been qualitatively explained by assuming the rate of oxygen reduction is not dependent on the surface concentration of electrons. The partition of changes in electrode potential between the solid and solution phases then simply reduces the Helmholtz overvoltage available for oxygen reduction.

Ethylxanthate has been shown to chemisorb and desorb over a narrow potential range between -0.4 and $-0.2V$. The chemisorption/desorption process is consistent with a semiconducting model in which xanthate chemisorption induces a donor-like surface state in the forbidden gap whose occupancy is determined by the Fermi energy at the surface. Ethylxanthate can spontaneously adsorb on freshly fractured, highly p-type galena, but the surface of freshly fractured, highly n-type galena must oxidize to increase the free hole concentration (lower the Fermi energy at the surface) to the point where xanthate can chemisorb.

APPENDIX

Taking into account lack of minority carrier effects (approximately equal current density-potential plots for the three electrodes and the negligible influence of steady illumination), the rate of oxygen reduction, I [see, for example, Ref. (18)] on electrodes with $n_b \geq n_i$ may be written

$$I = I_0 e^{-\alpha(F/RT)\Delta V_h} \quad [A-1]$$

where I_0 = exchange current density, α = transfer coefficient, ΔV_h = change in Helmholtz potential, and the other symbols have their usual meaning. Changes in electrode potential, ΔV_e , are assumed to be partitioned between the Helmholtz and space-charge layer, ΔV_{sc} , which can be expressed as

$$\Delta V_h = \gamma(V_e)\Delta V_e \quad [A-2]$$

$$\Delta V_{sc} = -(1 - \gamma)\Delta V_e \quad [A-3]$$

$$\Delta V_e = \Delta V_h - \Delta V_{sc} \quad [A-4]$$

where $\gamma(V)$ describes the partition of the potential across the two phases. The sign conventions are such that ΔV_h and ΔV_{sc} are both measured with respect to their bulk phases. To calculate the appropriate ΔV_h value from Eq. [A-2] for use in Eq. [A-1] a knowledge of $\gamma(V)$ under steady-state polarization conditions is required. Values of γ can be estimated from the SPV with appropriate assumptions.

Following the treatment of Frankl and Ulmer (26), the SPV in the absence of surface traps is given by

$$\text{SPV} = \frac{G_0 \tau (e^{\beta V_{sc}} + e^{-\beta V_{sc}} - 2)}{(1 + \epsilon) (1 + s^*/v) n_i \beta [e^{\beta \phi_b} (e^{\beta V_{sc}} - 1) - e^{-\beta \phi_b} (e^{-\beta V_{sc}} - 1)]} \quad [A-5]$$

where G_0 = light intensity, τ = lifetime, ϵ = absorption coefficient, s^* and v = surface recombination and diffusion velocities, respectively, n_i = intrinsic carrier concentration, $\beta = q/kT = RT/F$, and ϕ_b = bulk potential. If we assume a depletion barrier layer at the surface with $1 \ll |\beta V_s| \ll 2\beta \phi_b$ and that $s^*/v \ll 1$, Eq. [A-5] reduces to

$$\text{SPV} = -G_0 \tau \beta^{-1} n_b^{-1} (1 + \epsilon)^{-1} e^{-\beta V_{sc}} \quad [A-6]$$

which may be written using Eq. [A-4] as

$$\text{SPV} = -G_0 \tau \beta^{-1} n_b^{-1} (1 + \epsilon)^{-1} e^{\beta V_{sc}} e^{(1-\gamma)(F/RT)\Delta V_e} \quad [A-7]$$

If we also assume that $\gamma(V)$ is a slowly varying function of electrode potential, $\delta\gamma/\delta(\Delta V_e) = 0$, it can be shown from Eq. [A-7] that

$$\delta(\Delta V_e)/\delta \ln |\text{SPV}| = (RT/F)/(1-\gamma) \quad [A-8]$$

The $\log |\text{SPV}|$ vs. ΔV_e plots of Fig. 4 and 5 are fairly linear over the depletion region, in agreement with the exponential dependence suggested by Eq. [A-7]. The slopes are 125 and 110 mV per decade change in SPV, respectively. From Eq. [A-8] the slopes yield γ values of 0.53 (Fig. 4) and 0.46 (Fig. 5). These values suggest that Tafel regions for oxygen reduction vs. ΔV_h have slopes $\approx 50\%$ smaller than the experimental values determined from Fig. 4 and 5, i.e., Tafel slopes of 0.08-0.12V for the

slightly n-type electrode (Fig. 4) and 0.092 for the highly n-type electrode (Fig. 5).

Computer Modeling of Batteries from Nonlinear Circuit Elements

S. Waaben, I. Moskowitz, J. Federico, and C. K. Dyer*,¹

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Circuit analogs for a single battery cell have previously been composed of resistors, capacitors, and inductors. This work introduces a nonlinear circuit model for cell behavior. The circuit is configured around the PIN junction diode, whose charge-storage behavior has features similar to those of electrochemical cells. A user-friendly integrated circuit simulation computer program has reproduced a variety of complex cell responses including electrical isolation effects causing capacity loss, as well as potentiodynamic peaks and discharge phenomena hitherto thought to be thermodynamic in origin. However, in this work, they are shown to be simply due to spatial distribution of stored charge within a practical electrode.

Circuit analog models for the cell of a battery have typically been structured from resistors, capacitors, and inductors (1). This limited set of linear circuit elements cannot simulate many nonlinear cell characteristics such as transients, recovery from deep discharge and gassing effects.

The present work introduces a nonlinear circuit model for cell behavior. It is based on the PIN junction diode, whose time-dependent charge-storage behavior is related to that of electrochemical cells. The integrated circuit simulation computer program, ADVICE (2), is used to "painlessly" predict nonlinear responses from a circuit analog of the cell built directly by simply specifying the interconnection of components available from the circuit simulation program library.

Charge Sourcing, Transport, and Sinking

The basic features of a PIN diode and a cell are similar because their mechanisms of charge dynamics are analogous, as illustrated in Fig. 1. For charging a nickel-cadmium (NiCd) cell, the electrochemical reactions provide sourcing and sinking of charge carriers, OH⁻ ions, at the electrodes. Similarly, in a PIN diode under forward bias, negative charges (electrons) are injected by the N-type side into the I region, and negative charges are removed from the I region by the P side. Thus, there are analogies between the N-type side of the diode and the

negative electrode of the cell, the P-type side and the positive electrode, the I region and the electrolyte, and the diode space-charge regions and the interfacial regions in the cell. In brief, during the forward operation of both the diode and the cell, charge carriers are transported between interfaces; however, the time scales differ by many orders of magnitude (3-7).

Charge-Storage Diode Transients

The dynamic response of a minority carrier PIN junction charge storage diode is summarized in Fig. 2 (6, 7). The stored charge Q_s equals $I_F \bar{\tau}$ for the condition where the forward diode current I_F has been conducted for a period much longer than the minority carrier lifetime $\bar{\tau}$. It is significant to note that, as long as the diode contains substantial numbers of minority carriers, it remains forward biased even under reverse current conduction. Typical integrated circuit analysis packages like ADVICE (2) include minority carrier charge storage in the model for the circuit element "PIN diode." In cell circuit-analog modeling, by choosing an "infinitely" long minority storage lifetime for the diode, the basic charge-discharge cell response is obtained. The diode's minority carriers simulate the charge storage of the cell by chemical transformation and its discharge by the reverse chemical reaction. Changing the direction of the diode current produces a minor modulation of the voltage across the forward biased diode due to the voltage drop across the finite resistance of the diode (4-7). This small voltage ΔE can be expressed by the algebraic symbols $R_{\text{diode}}(I_F + I_R)$. The

Fig. 1. Ad hoc charge transport and accumulation in NiCd cell and PIN diode. a: NiCd cell. A forward current causes Cd(OH)₂ to produce Cd, injecting OH⁻ ions into the neutral solution across a charged double layer. The OH⁻ ions are transported through the electrolyte and absorbed at another charged double layer at the Ni(OH)₂ side, where NiOOH is formed by oxidation of Ni(OH)₂. Discharge involves the relaxation by reversal of the chemical and transport process that formed the Cd and the NiOOH: OH⁻ ions return to the Cd electrode, forcing current to flow in the external circuit. b: PIN diode. A forward current causes the N-type side to inject electrons into a neutral intrinsic region across a space-charge layer. The electrons are transported through this I region and absorbed across another space-charge layer at the P-type side, where they activate minority carriers. Discharge involves the relaxation reversal of the charge storage and transport process: stored minority carriers are returned to the side where they originated, forcing current to flow in the external circuit.

“double-layer” capacitance at electrode surfaces is here represented by a simple capacitor of constant value in parallel to the charge-storage PIN diode.

Electrochemical Turn-On Transients

After a NiCd cell has been completely discharged for a long period of time, the first application of a charging current produces a “turn-on transient.” This consists of a short-term rise in voltage associated with an initial phase change at the surface of the electrode (8). Similarly, a semiconductor PIN diode has a conductivity turn-on transient (4), but it is 6-8 orders of magnitude faster. In the case of the diode, the conductivity of the semiconductor is modulated by the injection of charge carriers into a previously uncharged region. Circuit simulation methodology using ADVICE circuits used as a function generator rather than sets of equations has been used for

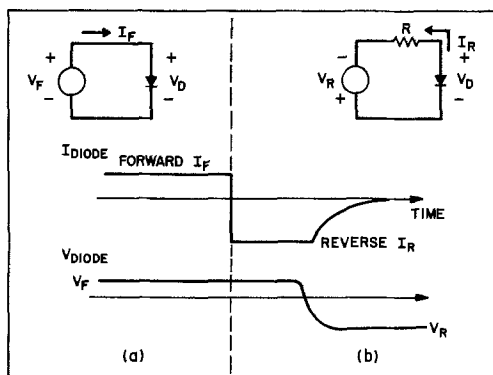

Fig. 2. Standard response of charge storage diode. a: During the forward current (charging) direction, semiconductor regions are filled with minority carriers; stored charge $Q_s = \int i_F dt$ for infinitely long minority carrier lifetime τ . For finite τ and $t \gg \tau$, $Q_s = I_F \tau$. b: During reverse conduction, the diode remains forward biased until the semiconductor regions are emptied of charge; then, the current and voltage decay. A correction ΔE is due to a voltage drop across the internal ohmic diode resistance.

Bottom: Circuit topology for ADVICE that simulates battery behavior shown in top of Fig. 3.

the simulation of PIN junctions (15). This subcircuit model method will be used for modeling the electrochemical turn-on transient of an electrochemical cell.

Electromagnetic Turn-On Transients: Series Resistance and Inductance

Figure 3 shows the measured two-terminal response of a small, charged, NiCd cell to a current pulse with risetime of about 1 μ s. For fast rising pulses, capacitors behave as short circuits. Therefore, Fig. 3 shows only an inductive spike, $E = L \Delta i / \Delta t$. Eventually, a steady-state voltage is reached which is proportional to the series resistance and the amplitude of the current pulse. The inductance is roughly that of a conductor of the geometrical dimensions of the cell, approximately 10^{-8} H in the present case. The resistance, about 10 m Ω , results from the combination of the metallic resistance of the electrode and the ionic conductance of the electrolyte. Figure 4 shows the basic circuit model for the cell: a PIN diode with a parallel capacitor, in series with an inductor, and a resistor.

Charging and Discharging

The cell overvoltage, η , can be defined as (3)

$$\eta = \text{nonequilibrium voltage} - \text{equilibrium voltage} \quad [3]$$

expressing that while a cell is being charged or discharged, there is a temporary increase or decrease, respectively, in the terminal voltage compared with the

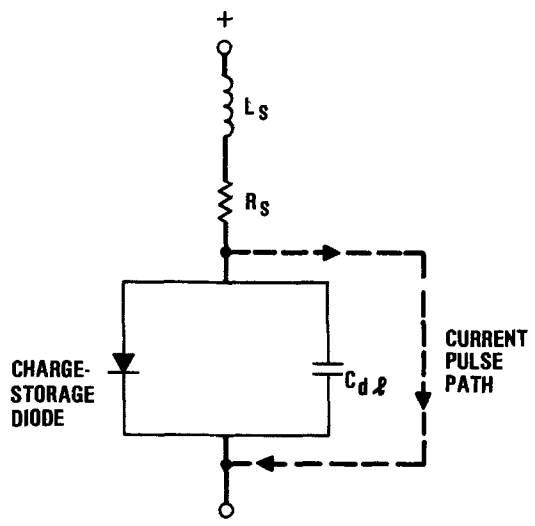

Fig. 4. PIN diode, double-layer capacitance (C_{dl}), series resistance, and series inductance interconnection topology.

Fig. 5. Overvoltage characteristics and modeling. a: Voltage response of a battery to constant current drive and subsequent open circuit. b: Plot of drive current i vs. η . c: Circuit analog model for overvoltage only.

open-circuit or equilibrium cell voltage. Typical overvoltage characteristics are shown in Fig. 5a (3). The overvoltage response curves are exponential for large currents and are linear for small currents (Fig. 5b). A circuit for implementing these responses is shown in Fig. 5c and consists of two diodes in parallel but in opposite directions, both in parallel with a resistor and a capacitor. These ADVICE model diodes are specified to have a relatively low barrier height of tens of millivolts to simulate typical low-load cell overvoltages.

The cell model with the overvoltage circuit section added is shown in Fig. 6. The internal node, "equilibrium voltage," marked in this figure is not physically accessible in an actual cell. Note that the PIN diode section contributes nearly all of the steady-state voltage developed across the two external terminals. For NiCd, this voltage is about 1250 mV, compared to overvoltages of only tens of millivolts. The measured overvoltage decays rapidly

Fig. 6. PIN diode, overvoltage section, and series resistance and inductance interconnection topology. Typical relative contributions to the overall battery voltage are indicated at the right.

when the external cell current flow is set to zero, as shown in Fig. 5a. Hence, in the ADVICE model, the minority carrier charge-storage lifetime for these overvoltage model diodes is short.

The queuing effect of charge carriers in a cell gives rise to a charge cloud at the electrode interfaces which is simplistically simulated by placing a fixed capacitor in parallel with the overvoltage diodes.

Charge Relocation in Grains

The voltage value to which the cell recovers after open circuiting depends in a very complicated way on previous cycling history. The circuit topology shown in Fig. 6 does not reproduce the open-circuit voltage "recovery" from deep discharge, open-circuit "charge loss," or "past history effects." A typical recovery from deep discharge is shown in Fig. 7.

Voltage recovery after deep discharge and "past history effects" are commonly assumed to be due to gradual charge relocation within the granular structure of the active material of the electrodes (9-12). In the case of the nickel electrode of a NiCd cell, for example, the nickel hydroxide grains at the spongy surface are converted to NiOOH by "absorbing" electrical charge. The internal sections of the grains are originally electrochemically uncharged, but can slowly absorb charge (9-12). The nonlinear circuit topology of Fig. 6 has been extended in Fig. 8 to model this relocation of charge by a nonlinear-diffusion mechanism, where the analytically complex responses can be directly computed using the ADVICE simulation program. In Fig. 8, the outermost diode and capacitor sections represent the interfacial reactions fed by exterior charge transport to and from the electrode. The charge storage and transport mechanism for a one-dimensional interior grain is modeled by a parallel combination of nonlinear storage sites represented by capacitors and PIN charge-storage diodes, where the diffusion of charge between the storage sites is modeled by adding 1 k Ω connecting resistors. When the circuit in Fig. 8 is first charged and then rapidly discharged, the overall voltage is mostly determined by the outer diodes and capacitors. The inner diodes and capacitors still retain much of their previous charge state due to the isolation provided by the 1 k Ω resistors; rapidly discharging the outer diodes leaves the charge within internal grains relatively untouched. However, on open circuiting, charge from the internal PIN diodes leaks back into the outer PIN diodes and causes the Fig. 8 circuit voltage to rise again, simulating the cell's recovery characteristic.

The inclusion of this grain model also reproduces the anomalous "bumps" in the final portion of the cell discharge curves observed when the load is a resistor (e.g., on the order of 100 Ω -1 k Ω depending upon the cell type and size). If we qualitatively assume that the internal diodes are all initially charged, say after operating at a continued constant voltage or "float," then, if at the end of a

Fig. 7. Measured voltage recovery of a NiCd battery after deep discharge at 200 mA.

Fig. 8. Circuit topology modeling the behavior of a one-dimensional granular electrode. Outer PIN charge-storage diodes simulate grain surface; internal diodes simulate internal grain charge storage mechanism.

discharge cycle of the outer diodes a resistive load on the order of 1 kΩ is applied, voltage divisions are caused by the progressive discharge of each internal diode through the 1 kΩ connecting resistors. Changing the size of the load resistor produces different plateaus in the simulated cell discharge curve, similar to the experimental observations. One may think of the cell as a nonlinear Thévenin-like source where the impedance of the charge source depends upon the charge state determined by the past history of operation, and Fig. 8 as the circuit model representation of such a distributed Thévenin source.

Gas Evolution during Overcharge

Continued charging to a high voltage triggers a gassing reaction when all active material at the grain surfaces is exhausted (11). For modeling simplicity, assume a constant voltage for the start of the gassing reaction. The circuit shown in Fig. 9 includes a mathematical function generator simulating the voltage climb for a nonsealed cell. The function generator circuit model works as follows. The outer charge storage diodes model the charge stored at the grain surfaces. When the surfaces are fully

charged (i.e., when the surface diode reaches a specified potential), it is disconnected from further charging by operating a switch. In the circuit of Fig. 9, from the beginning of charging, the switches (transistors) are "on," i.e., shorted, and the outer charge storage diodes receive charge. When these outer diodes reach the voltage of the transistor base supplies, the switches (transistors) turn off. The charging current is now routed to the internal diode string as well as to the gassing process; current through the 1 kΩ resistors to the grain causes the voltage to climb. The value of the transistor base supply thus simulates the gassing potential.

For generating the two-terminal response of a sealed cell, it can be of sufficient modeling precision to add the clamping diode shown in Fig. 9, which causes the rising voltage to level off, which occurs in sealed cells upon the buildup of gas pressure.

Computer-Generated Simulation

A variety of responses have been computed with the Fig. 9 circuit. The "user-friendly" ADVICE computer program analyzes circuits described by the node connections of circuit elements and their models. It should be noted that other standard circuit simulation computer programs, such as the commonly available SPICE program (2), can also be set up to compute the response of a given circuit. Since the ADVICE computer program is geared towards silicon integrated circuit simulations, such as 0.7V silicon diode junction drops, some *ad hoc* adjustments are required to scale the computer printout and plotting voltages up to values corresponding to cell voltages. Further, for Pb-acid simulations, a voltage source was for convenience placed in series with each charge storage diode to raise the overall cell voltage above 2V. This additional circuit complexity is due only to the restriction of "mathematical" access for ADVICE users to coefficients in the program's exponential expressions and may not exist for other circuit simulation packages. For NiCd, a judicious choice of the existing basic library diode parameters specified for the ADVICE user was sufficient to achieve the desired voltage magnitudes for plotting by the computer directly.

For "programming" simplicity, the circuit topology used was that of Fig. 9 for both NiCd and Pb-acid cells. There is no fundamental circuit difference in the responses of these two cell types on the level of precision of topology assumed here (14); only the quantitative parameter choices are different. For a particular cell, one set of device parameters was chosen, so that the computer-generated results matched the best available measurements. The NiCd measurements shown were performed on the GE GCR 1.0ST 1.0 Ah cell using an HP87 mini-computer in a laboratory experiment control and data gathering mode. The Pb-acid data were taken from the 1980 Gates Energy Products Battery Application Manual as well as from measurements on the Gates 2V, 5 Ah X-cell, PN 0800-0004.

Figure 10 shows a set of constant-current charge to open-circuit curves for the NiCd cell, starting from an initial equilibrium voltage of 1.290V. The differences between simulated and measured curves are less than 5 mV over a current range of nearly a decade.

Figure 11 shows constant-current charge-discharge open-circuit cycles for the NiCd cell, along with the simulations, for various current levels and initial voltages.

Figure 12 changes the time scale to microseconds and demonstrates the measured and model results for the inductive spike and series resistance.

Figure 13 shows an example of simulated recovery behavior. Values of the model's grain resistors can be selected to match the measured conditions.

Figure 14 shows simulated overcharge behavior after 600s.

Figure 15 exhibits simulated results under potentiodynamic conditions. In this simulation, an applied voltage is slowly ramped to the gassing overvoltage potential and down again. The computed current is plotted against

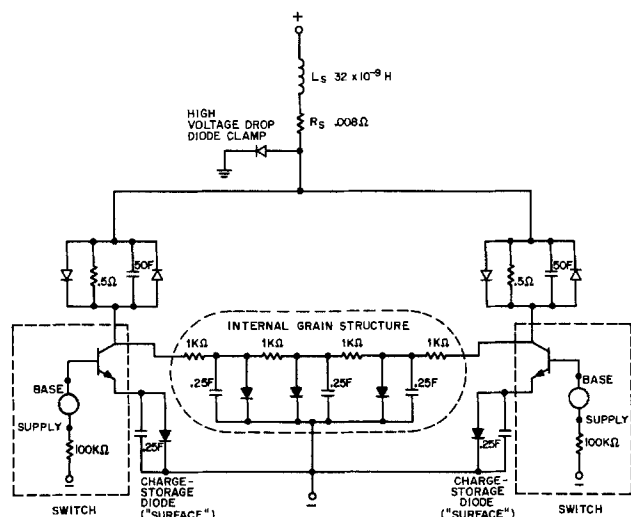

Fig. 9. Circuit analog topology for functional response simulation of gas-generation behavior. The battery's external charging current flow is switched from outer charge-storage PIN diodes to internal PIN diodes when the outer diode voltages reach that of the base supplies. (Simple ADVICE bipolar switches are used.) The clamping diode limits voltage rise to simulate sealed-battery behavior.

Interpretation of Cell Discharge Plateaus and Potentiodynamic Peaks

Common to several cells is the phenomenon of "capacity loss." That is, the coulombic storage capacity is significantly less than that which is theoretically available from the amount of electrochemically active material in the cell electrodes. In the case of NiCd and NiH₂ cells, a secondary discharge plateau is often measured at a lower voltage than that which is generally associated with the electrochemical couple. The magnitude and duration of the secondary plateau voltage is a very sensitive function of the discharge current such that the higher the current the lower the voltage and the shorter the plateau length. For example, for a threefold increase of discharge current there can be a 0.5V depression in voltage, while the primary plateau is only reduced by 30-50 mV (17). In the published literature, this phenomenon has been attributed to either (i) a different chemical phase, so that the lower voltage discharge plateau is due to different thermodynamics (18), (ii) a change in conductivity (decrease) due to removal of "defects" (17, 19), or (iii) reduction of adsorbed oxygen. The first direct experimental verification in favor of the second mechanism was reported recently (20) and showed undischarged regions of a Ni electrode electrically isolated from the conducting Ni grid by a lower conductivity phase, presumably Ni(OH)₂. Also, an additional mechanism of "capacity loss" has been identified as a loss of contact between the metal grid and the electrochemically active material (21).

The same basic circuit topology used above to simulate the electrical behavior of a single grain will now be used to model the electrically resistive connection of a group of individual grains or charge storage sites to the current collecting metal grid. The modeling of this physical situation involves the addition of resistive elements and a new choice for the value of resistors R_e in Fig. 9. Any of the capacity loss mechanisms mentioned above (20, 21) effectively interpose a resistor between each "internal" diode, representing a grain of active material, and the metallic contact or ground, as shown in Fig. 17. Secondary discharge plateaus similar to those observed in Ref. (17) can be produced from ADVICE by choosing equal values for each of the three resistors, R_b , in the range 0.1Ω (for 3A charges and discharges) to 10Ω (for 0.1A rates = C/10) (Fig. 18). This circuit simulation arrangements also shows high sensitivity to current amplitude. For example, for $R_b = 0.1\Omega$, tripling the current from 3A (3C rate) to 9A (9C rate)

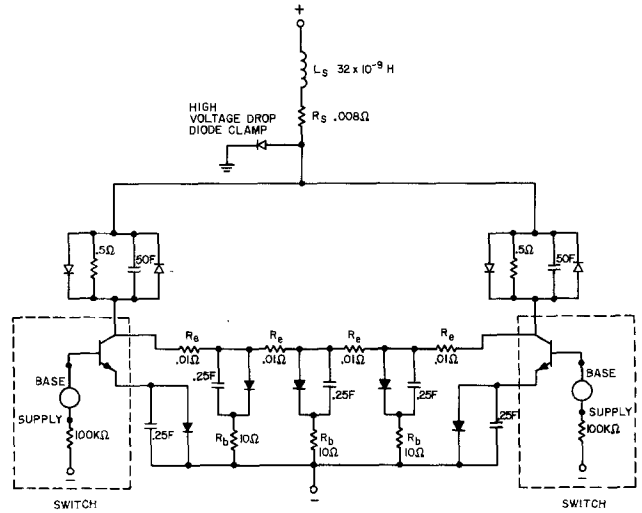

Fig. 17. Circuit analog topology for functional simulation of discharge plateaus.

depresses the secondary plateau from 1.1 to 0.7V. This is similar to the reported cell measurements (18). To calculate the electrolyte resistances R_e within the pore structure the following electrochemical data were used: solution resistivity (ρ) = 1.84 Ω-cm, 1 Ah electrode area (A) = 50 cm², the electrode thickness (t) = 0.030 in., porosity after impregnation (P) = 10%, and

$$R_e = (\rho t)/(4AP) = 0.01\Omega$$

The four series resistances R_e between each "grain" in Fig. 17 were chosen to be 0.01Ω for the computation shown in Fig. 18. Note that ohmic conduction and not a diffusion mechanism is modeled here. For increasing values of R_b , there is a greater depression computed in voltage of the secondary plateau, and for $R_b = 0$ there is no secondary plateau. However, an increase in the value of R_e while $R_b = 0$ can also produce secondary plateaus with similar dependences on current. For instance, a tenfold increase in resistivity or reduction in porosity such that $R_e = 0.1\Omega$ gives two secondary plateaus in the model. Although the general results of such calculations are possibly intuitively obvious, the model gives quantitative information for a particular design choice.

The model demonstrates that the effect of the inclusion of the resistances R_e and R_b is to produce additional potentiodynamic peaks which might otherwise have been misinterpreted as arising from new thermodynamic behavior such as the proposed appearance of new electrochemical phases in the case of the Ni electrode (18). Addi-

Fig. 18. Simulation of 11h charge at a current of $C/10 = 0.1A$, capacity = 1 Ah, discharge current = 0.1A, $R_e = 0.01\Omega$ and $R_b = 10\Omega$.

tion of R_b elements in the model topology to simulate the electrical isolation (20, 21) produces a second peak on reduction at scan rates lower than that shown in Fig. 15 where otherwise only one reduction peak would have appeared. This work corresponds to the second plateau under constant-current conditions. This second peak appears at lower potentials for higher values of R_b . A third peak appears on raising the scan rate from 0.3 to 3 mV/s. For negligible values of R_b , increasing R_e from 0.01 to 0.1 Ω or more also produces second and third peaks on potentiodynamic reduction.

Similar modeling of the Pb-acid system may also be used to interpret the observed relationship between electrolyte accessibility and composition within the porous electrode structure and the available discharge capacity (22). Recent work (22) shows that higher conductance of the electrolyte in pores gives higher delivered capacities, which is predicted from our model by lowering R_e .

Conclusions

The measured electrical behavior of NiCd and lead-acid cells can be simulated using a nonlinear circuit topology model based on the dynamic properties of the charge storage PIN diode and RLC circuit elements. A circuit-analysis computer program such as ADVICE (similar to SPICE) can be used to compute circuit responses directly from an interconnection description of the components. For a particular cell, one set of parameters accurately simulates a variety of measured data to within the precision of measurements. Charge-discharge, pulse response, deep discharge, turn-on transients, gas generation, cyclic voltammetry, and admittance characteristics all can be simulated by computer from the model. Since suitable circuit components for the cell model can be found to simulate both the spatially distributed electrochemical processes and the physical structure of the cell, the effects of a design change on performance can be simulated.

Application of the model shows that considerable care should be exercised in interpreting additional peaks during potentiodynamic scanning or additional plateaus during constant-current discharge. They may not be thermodynamic in origin, but may simply be the nonequilibrium response of spatially distributed electrochemical processes within the electrode structure.

Cell characteristics missing in the present model can be added by simply developing a physically reasonable circuit analog and including it in the present model through the use of a circuit simulation program.

Acknowledgments

Initial simulation runs on ADVICE were performed by N. Timmerman of Wells College, Aurora, New York. We would like to thank J. Broadhead, D. Maurer, B. Vyas,

and T. Willis of AT&T Bell Laboratories, Murray Hill, New Jersey, for many helpful discussions.

The Electrochemistry of Surface Oxidation of Chalcopyrite

T. Biegler and M. D. Horne

CSIRO Division of Mineral Chemistry, Port Melbourne, Victoria 3207, Australia

ABSTRACT

Linear sweep voltammetry with a freshly renewed surface of a chalcopyrite (CuFeS_2) mineral electrode shows a small anodic prewave in acid electrolytes. The main anodic reaction, with complete dissolution of copper and iron, occurs at more positive potentials. Experiments under nitrogen show that the prewave is not a consequence of atmospheric oxidation during surface preparation. The prewave represents a surface oxidation of chalcopyrite to form a thin passivating film. The charge passed in forming this film is around 2 mC cm^{-2} for a polished surface. The prewave reaction is identified with the initial phase of the oxidative dissolution or leaching of chalcopyrite. Contrary to the reported behavior at 80°C , the surface film is stable at 25°C for long periods at open circuit. Various evidence, including the relative charges passed in forming and then reducing the surface film, and the presence of dissolved copper, leads to the following suggested stoichiometry for the prewave reaction

The product layer containing CuS and S is about 3 nm thick.

The main interest in electrochemical studies of the mineral chalcopyrite (CuFeS_2) arises from the information such studies provide concerning the mechanism and kinetics of chalcopyrite dissolution in acidic oxidizing solutions. The dissolution, or leaching, process is a corrosion reaction, with anodic and cathodic half-reactions. The reaction in the oxidizing media most suited to practical use, such as acidic ferric chloride or sulfate solutions, is very slow. Since copper dissolution from chalcopyrite is the primary step in many hydrometallurgical processes for copper extraction, it is important to establish what determines this slow rate, especially from the viewpoint of the anodic process.

The recent work of Dutrizac (1-3) seems to have resolved some of the controversial issues in the kinetics of chalcopyrite leaching, such as the influence of temperature, iron concentration in chloride or sulfate media, surface area of the chalcopyrite particles, and locality of origin of the mineral sample. However, many different mechanisms have been proposed to explain the observed rates. Chemical leaching and electrochemical studies (4-12) show that a type of passivating surface layer limits the oxidation rate and causes the parabolic kinetics (rate $\propto t^{1/2}$) found under some conditions, particularly in sulfate media. The precise nature of this layer is in dispute. It has variously been described as sulfur (1, 7), a metal-deficient chalcopyrite-like sulfide (5, 12), a polysulfide (10), a solid electrolyte interphase (11), or precipitated iron compounds (1). Its effect on the oxidation kinetics has been explained in terms of physical blockage (1), solid-state diffusion of metal ions (5), electron-transport properties (7), passive film growth (12), or electrolytic conduction of metal ions (11).

How one could distinguish between some of these mechanisms, if indeed a distinction exists, is as yet unclear. An acceptable mechanism should also draw a clear line between reactions which form the passivating film and further reactions, such as film dissolution or transport through the film, which could continue when the film is complete. We believe that electrochemical studies will help to resolve some of these problems and to define these reaction stages.

The passivating reaction is a low potential electrochemical process (e.g., 0.7-0.8V vs. SHE at ambient temperatures) such as would occur when chalcopyrite is oxidized in a ferric solution. At higher potentials (1.0-1.2V vs. SHE), where there is continuous current, a number of studies agree [see Ref. (8)] that the reactions

and

both take place, in the proportion of around 6:1.

In this paper, we wish to present further evidence [see Ref. (8)] that an anodic prewave in voltammetry with a freshly prepared chalcopyrite surface represents the initial stages of chalcopyrite oxidation and gives information concerning the initial product layer. Other authors [e.g., Parker *et al.* (10)] have explicitly discarded "first sweep" results as spurious effects produced by surface oxidation during electrode preparation (grinding, polishing, washing). We are able to show that this view is incorrect and that the electrochemical results are representative of a clean chalcopyrite surface. Obviously, this conclusion has important implications for other kinds of surface studies on chalcopyrite, such as with Auger electron spectroscopy (13) or ESCA (14), where a knowledge of the initial state of the mineral surface is vital to interpretation of results.

Experimental

Electrodes suitable for rotation (Beckman variable-speed rotator) were prepared, as previously described (15), from high quality natural polycrystalline specimens of chalcopyrite showing no foreign inclusions under the microscope. Of the four electrodes used at various times, three (designated as A, B, and C) were cut from the same sample, from Moonta, South Australia, and the fourth (D) was from Mt. Lyell, Tasmania. The exposed areas were: A, 0.41 cm^2 ; B, 0.24 cm^2 ; C, 0.61 cm^2 ; D, 0.35 cm^2 . Two types of surface finish were used: ground surface, finished on fine silicon carbide paper (grit size: $15 \mu\text{m}$) and polished surface finished with $0.3 \mu\text{m}$ alumina on a polishing cloth.

A three-compartment glass electrolysis cell was used, with an isolated gold counterelectrode and a Luggin probe from the reference electrode compartment. Programmed voltammetry was carried out with conventional instrumentation (potentiostat, potential programmer, X-Y recorder). The reference electrode was a saturated calomel electrode (SCE), and all potentials are quoted with respect to the SCE. Measurements were carried out at 25°C in nitrogen-purged solutions prepared from doubly distilled water and reagent-grade chemicals.

Results and Discussion

Prewave shape and charge.—Figures 1 and 2 show the prewaves obtained for one specimen in different acid electrolytes and for different chalcopyrite specimens in the same electrolyte. These curves were all obtained by a similar procedure. The electrode was ground or polished, washed with a jet of distilled water, and quickly inserted into the deoxygenated electrolyte. Then, the potentiostat circuit was closed at or near the rest potential (which was usually drifting slowly at this stage) and the sweep started. The time between ending the surface preparation and starting the voltammogram was around 30-40s.

Fig. 1. First-sweep voltammograms on chalcopyrite electrode C; sweep rate 20 mV s^{-1} ; rotation rate 50 Hz . a: Polished surface; 1 M HCl (two cycles). b: Ground surface. Curve 1: 1 M HCl (two cycles). Curve 2: 1 M HNO_3 . Curve 3: $1 \text{ M H}_2\text{SO}_4$. Curve 4: 1 M HClO_4 .

These curves confirm and extend the limited results presented previously (8) for one specimen in $1 \text{ M H}_2\text{SO}_4$. The first anodic sweep shows a prewave, absent or, in 1 M HCl , greatly diminished on subsequent sweeps. The shape, position, and area (*i.e.*, charge) of the prewave depend on the mode of surface preparation (Fig. 1) but not much on the acid (Fig. 1) or the sample origin (Fig. 2). Stirring has little effect on the prewave itself but does influence associated phenomena as described in a subsequent section.

The prewave for a polished electrode (Fig. 1) shows two clear peaks at around 0.28 and 0.38 V vs. SCE . These vary in relative height from run to run and with different specimens. For a ground electrode, the major peak is more positive, at 0.55 – 0.59 V . The presence of two poorly defined shoulders on the rising branch of this peak leads us to suggest that it contains components corresponding to the peaks seen with a polished surface. An electrode which gave the prewave shown in Fig. 3 seems to have been incompletely polished after grinding; it shows the two characteristic peaks for a polished surface, plus a peak at 0.59 V . If we assume that peak position is a function of exposure of different aspects of the chalcopyrite

Fig. 2. First-sweep voltammograms for three chalcopyrite electrodes in 1 M HCl . Ground surfaces; sweep rate 20 mV s^{-1} ; rotation rate 50 Hz .

Fig. 3. First-sweep voltammogram on polished electrode C in 1 M HCl , showing residual peak for a ground surface.

lattice, then the surface fractures produced by polishing and grinding must be quite different. This behavior could result from the brittleness of chalcopyrite and its tendency to fracture unevenly. However, the peak shift with grinding is very large, and an explanation based on site exposure may not be adequate.

Prewave charges obtained by integrating the recorded curve from the foot of the prewave (0.15 V) to the current trough at around 0.55 or 0.7 V for polished or ground electrodes, respectively, are given in Table I. Most values represent the mean of several determinations, with a typical range of $\pm 10\%$. Charges for different specimens under the same conditions and for the same specimen in different acids are similar. The ratio between the charges for a ground and a polished surface is about 8. This ratio is a little less than the value of 11 reported previously (8) but still seems rather high to be explained by an increase in surface roughness. The dependence of prewave charge on sweep rate was similar to the previous finding (8), *e.g.*, for a ground surface in 1 M HCl , charges were 15.9 , 17.7 , and 11.3 mC cm^{-2} at sweep rates of 10 , 20 , and 50 mV s^{-1} , respectively.

In general, the observed behavior supports the earlier hypothesis (8) that the prewave represents a surface reaction involving oxidation of a thin layer of chalcopyrite. For complete oxidation to S , Cu^{2+} , and Fe^{2+} (see below for discussion of the oxidation state of iron), chalcopyrite would be consumed at a rate of $1.14 \text{ nm/mC cm}^{-2}$, based on true surface area, so that the prewave product layer can be no more than a few atoms thick (see below). The small dependence of prewave charge on sweep rate implies some influence of the kinetics of the prewave process on the amount of chalcopyrite oxidized.

Prewave in dilute acid electrolyte.—Prewaves in 1 , 0.1 , and 0.01 M HCl (the latter two with added 0.1 M NaCl) are shown in Fig. 4. The prewave seems not to shift with pH, but the main wave moves to less positive potentials with increasing pH and begins to obscure the prewave. This is presumably connected with the pH dependence of reaction [2], which involves protons. The results show that the prewave phenomenon exists at pH levels commonly

Table I. Prewave charges for various chalcopyrite electrodes and electrolytes at sweep rate 20 mV s^{-1}

Electrode	Electrolyte	Surface preparation	Charge (mC cm^{-2})
B	1 M HCl	Polished	2.2
C	1 M HCl	Polished	2.0
D ^a	1 M HCl	Polished	2.0
A	1 M HCl	Ground	16.1
B	1 M HCl	Ground	15.5
C	1 M HCl	Ground	15.6
D ^a	1 M HCl	Ground	17.0
C	$1 \text{ M H}_2\text{SO}_4$	Ground	14.5
C	1 M HNO_3	Ground	12.1
C	1 M HClO_4	Ground	14.3

^a Integrated with a steeper baseline than for other electrodes, with slope estimated from second and subsequent sweeps.

Fig. 4. First-sweep voltammograms on ground chalcopyrite electrode C in chloride electrolytes of different acidity. Sweep rate 20 mV s^{-1} ; rotation rate 20 Hz . Curve 1: 1 M HCl . Curve 2: 0.1 M HCl , 0.1 M NaCl . Curve 3: 0.01 M HCl , 0.1 M NaCl .

found in chalcopyrite leaching processes and is therefore relevant to the mechanism of those processes.

Surface preparation under nitrogen.—In view of the suspicions [e.g., see Ref. (10)] that first-sweep results may be influenced by exposure of the fresh chalcopyrite surface to air and to aerated water during preparation, it is important to establish what effect exclusion of oxygen has. We have attempted to do this by enclosing the cell, electrode assembly, and wash bottle in a glove box purged with nitrogen. No significant effect of the oxygen exclusion procedures was found. Indeed, prewave areas tended to be 10-20% greater than average, although this could easily be attributed to the different grinding technique required in the glove box and the likelihood of a different surface roughness.

We conclude, therefore, that the prewave is not a consequence of surface oxidation during electrode preparation. While this conclusion should be further substantiated under more rigorous conditions (fracturing chalcopyrite under oxygen-free electrolyte would be ideal), it is hard to accept arguments that the prewave is an artifact of prior exposure to oxygen. Preoxidation would surely tend to lower the anodic current, and this is not observed except after long exposure to air (8).

Effects of varying the potential program.—In Fig. 5, the normal prewave (program 1, solid curve) is compared with the voltammogram for an initial short sawtooth cycle to 0.45 V , immediate return to the starting potential, and a triangular cycle extending to 0.9 V (program 2, broken curves). In Fig. 6, a series of sawtooth cycles to 0.55 V is followed by a fifth cycle to 0.9 V . In both sets of curves, the diminishing currents on successive cycles are consistent with an accumulation of a prewave product layer.

Fig. 5. Initial voltammograms on ground chalcopyrite electrode A in 1 M HCl for the two potential programs indicated. Sweep rate 20 mV s^{-1} ; rotation rate 20 Hz .

Fig. 6. Initial voltammograms on ground chalcopyrite electrode A in 1 M HCl for the potential program indicated. Sweep rate 20 mV s^{-1} ; rotation rate 20 Hz .

Thus, the charge passed during the four sawtooth cycles in Fig. 6 is 17.9 mC cm^{-2} , of the correct magnitude for a complete prewave. On the fifth cycle, the prewave has essentially disappeared. Similarly, the charge in the second cycle of program 2 (Fig. 5) is diminished by about the charge passed during the first cycle. Note that the shoulder on the rising branch of the prewave appears only on the first cycle in such programs.

Figure 7 shows pairs of curves for potential programs which include a period at open circuit between two potential scans. The first scan for a fresh surface is interrupted at 0.45 , 0.55 , or 0.70 V , the potential decays at open circuit to 0.24 V . At this point, the second scan is started. As the potential of interruption increases, the charge passed on the second scan decreases, but the total charge remains constant; the full prewave charge (solid curve) in Fig. 7 is 13.3 mC cm^{-2} , and the sum of the charges is 13.3 mC cm^{-2} and 12.0 mC cm^{-2} for the pairs of curves with interruption at 0.55 and 0.45 V , respectively. Thus the complete surface layer can be formed in stages, unaffected by interruptions at open circuit.

Further experiments were carried out to test the stability of the prewave product at open circuit. After an initial sweep to give a complete prewave, the various treatments at open circuit were (i) leave electrode in the electrolyte (deoxygenated $1 \text{ M H}_2\text{SO}_4$) for 17h, (ii) withdraw electrode, rinse with water, and keep wet while exposed to air for 4

Fig. 7. "Interrupted" initial voltammograms on ground chalcopyrite electrode B in 1 M HCl without rotation. Sweep rate 20 mV s^{-1} . First scan is interrupted at X (0.7 V), Y (0.55 V), or Z (0.45 V). In each case, the potential is allowed to decay at open circuit to 0.24 V (approximate time taken is 5, 4, and 1 min, respectively). Then, a triangular scan from 0.24 to 0.7 V is started.

min, (iii) withdraw electrode, dry, and leave in air for 4 min, and (iv) withdraw electrode, rinse, and leave in deoxygenated water for 6h. In all cases, the first sweep from the new rest potential after returning to the cell gave no prewave.

Thus, the open-circuit reactivation phenomena observed by Parker *et al.* (10) at 80°C, which would be expected to lead to "regeneration" of the prewave, are not seen at 25°C. Any decomposition or solid-state diffusion processes tending to restore the initial surface composition must, therefore, be very slow at 25°C.

Effects of stirring—detection of a soluble product.—As noted above, stirring (by means of electrode rotation) does not significantly affect the prewave itself, but it does produce some interesting changes in other parts of the first and second cycles of triangular cyclic voltammograms (Fig. 8). Without stirring (solid curves), there are two small waves, marked A and B, on return sweep 1, and a peak C on sweep 2, which are all absent when the electrode is rotated (broken curves). The disappearance of these waves on stirring indicates that they involve a soluble species generated by the prewave process and dispersed by stirring.

Analogous results are found in the other acid electrolytes used, 1M H₂SO₄, 1M HNO₃, and 1M HClO₄, except that there is only a single cathodic peak on the first reverse sweep (Fig. 9, solid curve).

The obvious candidates for a reducible dissolved species are Cu²⁺ and Fe³⁺. Copper (5 × 10⁻⁴M) added to the electrolyte clearly enhances the waves shown in Fig. 8 and 9 (see, *e.g.*, the broken curve in Fig. 9). Iron (either Fe²⁺ or Fe³⁺) at a concentration of 5 × 10⁻⁴M has no effect on the voltammograms, consistent with the known irreversible nature, *i.e.*, the slow kinetics, of this redox system on chalcopyrite (10). In other words, iron as a soluble product of the prewave reaction would not be detected in voltammograms covering the potential range in Fig. 8 and 9. The cathodic waves are therefore due to dissolved copper, the presence of two waves A and B in 1M HCl presumably being due to the stability of a Cu(I) intermediate in chloride media. The size of the cathodic waves indicates that only a small amount of Cu²⁺ is released in the prewave reaction.

In establishing the nature of the process in the presence of Cu²⁺, we note that it seems to have a reversible potential (*e.g.*, at 0.16V in Fig. 9) well positive to the Cu²⁺/Cu⁰ potential for this copper concentration (around 0 V vs. SCE). This indicates formation of a sulfide rather than copper metal by reactions such as

Fig. 8. First and portion of second cyclic voltammograms for ground chalcopyrite electrode B, unstirred (solid curves) and stirred (50 Hz, broken curves), in 1M HCl. Sweep rate; 20 mV s⁻¹.

Fig. 9. First and portion of second cyclic voltammograms for ground chalcopyrite electrode C in 1M H₂SO₄ (solid curve) and 1M H₂SO₄ + 5 × 10⁻⁴M CuSO₄ (broken curve). No rotation; sweep rate 20 mV s⁻¹.

which has been demonstrated (16) for chalcopyrite reduction in the presence of Cu²⁺, or

Either of these reactions is feasible in the potential range of interest. If, as seems likely, Cu₂S is the solid product, the anodic peak on the second cycle would then represent reoxidation according to the reverse of reaction [4]

We shall discuss evidence below that the anodic peak position at 0.28V vs. SCE (Fig. 8 and 9) is characteristic for this reaction.

Effects of surface reduction—scanning to negative potentials.—Results considered so far have involved only the potential region positive to the initial rest potential, about 0 V vs. SCE. When cycling covers lower potentials (Fig. 10), the shape of the first cycle depends on the initial scan direction (see below) but subsequent cycles covering the full potential range (*i.e.*, at least +0.6 to -0.3V) give the main features shown in cycle 2 of Fig. 10. These features are a cathodic peak D centered around -0.22V and two anodic peaks, E and F, at 0.27 and 0.56V, the latter coinciding with the anodic prewave. Further cycling causes progressive small changes in these peaks. In each cycle (apart from the first), there is an approximate balance of the total anodic and cathodic charge passed.

The general behavior in 1M H₂SO₄ is similar to that shown for 1M HCl. With polished chalcopyrite, peak D is sharper and has no shoulder. In unstirred solution, extra peaks appear, indicating further reactions involving dissolved products of the main processes.

The first cycle (1a) of Fig. 10 starts in the positive direction from -0.03V and gives the anodic prewave expected with a freshly ground surface. At the positive limit, a surface layer of an as yet undetermined composition is present. The first return sweep (1c) gives the complex cathodic wave G in the region -0.1 to -0.3V. Wave G is found only on cycle 1 and clearly differs from D found from cycle 2 onwards. It also differs from the cathodic prewave (17), a single sharp peak at -0.10V found when the first scan with a fresh surface starts in the negative direction. Since this wave corresponds to the reduction of chalcopyrite itself, we conclude that wave G is characteristic for reduction of the surface layer formed during the anodic prewave.

The surface compositions at the end of the scans 1c and 2c must be very similar as their anodic oxidation characteristics in curves 2a and 3a are virtually identical. Since

Fig. 10. First (broken curve), second (solid curve), and segments of third cyclic voltammograms for ground chalcopyrite electrode B in 1M HCl, with starting potential $-0.03V$, initial scan in positive direction, and potential limits $+0.70$ and $-0.45V$. Rotation rate 50 Hz; sweep rate 20 mV s^{-1} .

peak E at $0.27V$ is in the region where an anodic peak for chalcocite oxidation is found (18), it can reasonably be assigned to reaction [5]. The reduced surface formed at $-0.45V$ is therefore chalcocite, or a similar sulfide. This is consistent with the known potential region of stability of chalcocite and related sulfide phases, which form through reactions such as

or

Various other phases, e.g., digenite $\text{Cu}_{1.78}\text{S}$, djurleite $\text{Cu}_{1.93}\text{S}$, and bornite Cu_5FeS_4 , are formed (19-21) by similar reactions and could be present with, or in place of, chalcocite in the reduced surface layer.

We now have to decide whether peak F at $0.55V$ on curves 2a, 3a, etc., represents the same reaction as the anodic prewave on curve 1a. The evidence on this point is contradictory. On the one hand, the two waves virtually coincide and are of similar heights. Furthermore, the size of wave E, but not of F, depends on the negative potential limit of the sweep. This is consistent with a surface-limited process of the prewave type and not with the other obvious possibility, that E and F are successive oxidation steps of the chalcocite layer. On the other hand, wave D is clearly different from wave G, which we have suggested is characteristic for reduction of the prewave product layer.

On balance, we favor the prewave process for wave F. This, of course, requires that fresh chalcopyrite surface is available, and we envisage that this occurs through the volume decrease in the solid phases formed during the electrochemical reactions. In the sequence $2\text{CuFeS}_2 \rightarrow \text{Cu}_2\text{S} \rightarrow \text{CuS}$, the total volume decrease is calculated to be about 77%.

At the positive potential limit of curve 2a, the surface contains a layer of CuS (formed in E) and prewave product (formed in F). These are reduced, together with more chalcopyrite, over the potential range -0.1 to $-0.45V$ in the next sweep 2c, and a quantity of Cu_2S is again formed. A charge of $2 F/\text{mol}$ of Cu_2S is passed through either reaction [6] or [7], while $2 F/\text{mol}$ of Cu_2S is also passed when Cu_2S is oxidized according to reaction [5]. This accounts for the observed approximate balance of charges in the

anodic and cathodic branches of these voltammograms from the second cycle onwards. At higher pH, charge balance in cyclic voltammograms is explained (22) by reversible transformations of phases within an immobile surface layer. Such explanations cannot apply here, where soluble products are formed and leave the reaction zone.

In summary, cyclic voltammograms which extend into a region where cathodic processes occur in a stirred solution show that the surface layer formed during the anodic prewave is reduced to Cu_2S (or a related sulfide), that reoxidation of this reduced layer to CuS occurs, that this sequence of reactions exposes fresh chalcopyrite surface, and that these processes continue for numerous cycles.

The prewave process.—The knowledge of the various processes in the voltammograms of Fig. 10 can be used to derive further details of the prewave reaction. We start with several assumptions as follows.

1. The only process occurring within wave G is the reduction of the layer of prewave product. The evidence for the lack of reduction of chalcopyrite itself in this region was discussed above, but is certainly not conclusive.

2. The solid reduction product is Cu_2S (see above); other products of the reduction process are taken to be Fe^{2+} and H_2S .

3. In the potential region of the anodic prewave, iron dissolves as Fe^{2+} . Given that the prewave extends over the range $0.2-0.7V$ vs. SCE and the E° for $\text{Fe}^{2+}/\text{Fe}^{3+}$ is $0.52V$ vs. SCE, this is a reasonable assumption for most of the prewave. The slow kinetics of Fe^{2+} oxidation at a chalcopyrite surface (10) would further favor this assumption.

4. The charge in wave G can be obtained by integration from $-0.08V$ to the current minimum at $-0.32V$. On this basis, the cathodic charge in wave G for a rotated electrode (at which any soluble reducible species have been dispersed) is around 1.3 times the anodic prewave charge.

Applying these assumptions, we write general reactions for the anodic prewave

and for cathodic reduction of the solid products

and

We can then determine whether there are stoichiometries consistent with the observed charge ratio 1.3.

Summing the charges in reactions [9] and [10] and taking this sum as 1.3 times the charge in [8], we obtain

$$8a + 3b = 6 \quad [11]$$

The only additional information is that a and b are both positive and no greater than unity. With these restrictions, we can deduce the possible ranges of values as $0.75 \geq a \geq 0.375$ and, correspondingly, $0 \leq b \leq 1$. Hence

$$4 \geq (1-b)/(1-a) \geq 0 \quad [12]$$

In other words, a series of equations in the form of reactions [8]-[10] can be written which satisfy the measured charge ratio of 1.3. In these equations, the ratio of dissolved iron and copper can lie anywhere in the range 0-4.

The small amount of Cu^{2+} detected as a prewave reaction product (see above) and the evidence from leaching studies (5, 23), that the $\text{Fe}^{2+}:\text{Cu}^{2+}$ ratio is at least 2:1 and perhaps as high as 6.6:1 in the initial stages of chalcopyrite dissolution, both point to an $\text{Fe}^{2+}:\text{Cu}^{2+}$ ratio close to the upper limit given by Eq. [12]. At this limit, the reaction stoichiometry would be

i.e., the product layer contains no iron. $\text{Cu}_{0.75}\text{S}_2$ is not a known phase, but is reminiscent of the metal-deficient polysulfide suggested by Parker *et al.* (10) as the composition of the passivating film on oxidized chalcopyrite. Since there are no restrictions on how sulfur appears on the right-hand side of this equation (c is eliminated when the charges in reactions [9] and [10] are summed), we can equally write reaction [13] in the form

in which the product layer contains the more familiar CuS and S.

With reaction [14] as the basis for the prewave reaction, the thickness of the reaction layer can be calculated from the prewave charge, estimated to be around 2 mC cm^{-2} for a smooth surface in 1 M HCl . This gives the thickness of chalcopyrite reacted as 3.7 nm and, from the molar volumes of CuS and S, a product layer thickness of 2.9 nm .

To summarize, the evidence from iron and copper ratios in chalcopyrite leaching, from copper dissolution during the anodic prewave, and from the charge passed in reducing the prewave product is consistent with a prewave reaction in which the product contains CuS and S, according to reaction [14]. The product layer is estimated to be about 3 nm thick.

Implications for chalcopyrite leaching and related studies.—The evidence from recent electrochemical studies shows that the initial stages of oxidative dissolution (*i.e.*, leaching) involve the formation of a copper-rich surface layer (10-12). The description of this layer is different in each study, depending on how the various authors view the way it inhibits the leaching process. Thus, it is described as a polysulfide layer (10), a solid-electrolyte interphase (11), and a passivating film (12).

The present contribution is to show that the formation of this material occurs in a voltammetrically distinct step, the anodic prewave, which can help characterize the product layer. Study of the prewave has not resolved the views of the inhibition mechanism. However, we see no compelling reason to go past the simplest view of the prewave reaction as an energetically favored process producing an ordered product layer which eventually covers the surface and blocks any further movement of iron and copper atoms. At ambient temperatures, the further reaction of this blocking layer is slow, but as the potential is increased the bulk oxidation process can be nucleated, with sulfate formation as the possible trigger (8). At elevated temperatures, decomposition of the blocking layer occurs at a measurable rate, as evidenced by the "reactivation" of the low potential process at open circuit (10).

Several authors have analyzed decaying current-time transients in the low potential region to derive the inhibition mechanism. Apart from the difficulty that the studies disagree on the experimental form of the transient (9, 11, 12), there seem to be inadequate criteria to allow such analysis to be diagnostic of any particular mechanism. A current decay with $t^{1/2}$ (9, 11) could be indicative of some form of transport control within a thickening product layer, but the conclusion that this passivating layer is an electrolytic and not an electronic conductor (11) seems unjustified. The evidence points to the contrary, as other authors (9, 10) have also concluded. One could also reasonably hope for more convincing $i - t^{1/2}$ data [compare the time scales used in Ref. (9), 0-100 min and Ref. (11), 0-16 ms] and more systematic temperature effects (11). Warren *et al.* (12) attach significance to their finding that the current decays according to $\ln i = b - mQ$ (where Q is the total charge passed and b and m are constants), which is characteristic of some passive film growth kinetics. This is simply the electrochemical form of the Elovich equation which is widely obeyed in surface chemical and electrochemical reactions (24) and reflects a linear increase in the activation energy of a reaction with coverage of the surface. It conveys limited mechanistic information.

Warren *et al.* (12) found large electrochemical reactivity differences between different chalcopyrite specimens which they attributed to the presence of impurities in some of the samples. As the differences they saw were in the same potential region as the prewave studied here, the properties of the prewave (shape, position, dependence on stirring, and sweep rate) established in this work should provide a method of determining whether a particular voltammogram is characteristic of chalcopyrite or contains contributions from, say, a more reactive sulfide impurity. One could then decide whether or not the differences were intrinsic to the chalcopyrite. This is important information in view of the continuing interest in reactivity differences of natural minerals (3, 8).

Two aspects of chalcopyrite electrochemical behavior have implications for spectroscopic studies (*e.g.*, photoelectron spectroscopy) of chalcopyrite surfaces [see, *e.g.*, Ref. (13, 14)]. First-sweep studies, both in the negative (17) and positive directions, show that a freshly prepared chalcopyrite surface is moderately stable to atmospheric oxidation, so that surface preparation in air before transfer to the instrument is feasible. Voltammetric characterization after spectroscopic examination should be a useful auxiliary tool. Further, the layer of initial oxidation product, which is formed during a suitable voltammetric scan, is also stable over periods of minutes or longer after withdrawal from the electrolyte, and this should provide an appropriate method of preparation of samples for studies of the composition of this layer, which has been one of the key problems in interpreting the leaching behavior of chalcopyrite.

Conclusion

The anodic prewave found on linear sweep voltammograms for freshly prepared chalcopyrite electrodes in acid solutions represents a surface oxidation process which is distinct in mechanism from the bulk oxidation of chalcopyrite observed at higher potentials. All indications are that it is a genuine reaction of a clean chalcopyrite surface and not a spurious process attributable to reaction with atmospheric oxygen prior to voltammetry. The significance of the prewave lies in the insight it provides into the mechanism of oxidative dissolution (leaching) of chalcopyrite, a reaction known to be progressively inhibited by formation of a thin surface film. This film is considered to be the same as the layer of product formed by the prewave reaction.

The main characteristic of the prewave is that its area is roughly independent of sweep rate and type of acid electrolyte used. The layer of product can be shown to accumulate progressively with a variety of potential programs and to remain stable for many hours at open circuit, even when the electrode is withdrawn from the cell. The prewave characteristics do not depend on specimen origin, implying that the initial reactivity with leachants such as ferric ion should also not depend on origin. The charge passed in forming the prewave product is about 2 mC cm^{-2} for a polished chalcopyrite surface.

The nature of the prewave reaction is deduced from information on the relative amounts of Fe^{2+} and Cu^{2+} which pass into solution and the relative charges associated with formation and reduction of the product layer. The latter comparison involves an arbitrary separation of the surface-layer reduction from other overlapping processes and an assumption of the composition of the reduced surface layer. A set of reactions is then obtained which satisfy the observations. The most plausible of these indicates a prewave reaction with Fe^{2+} and Cu^{2+} dissolving in the ratio 4:1 and a solid product of stoichiometry $\text{Cu}_{0.75}\text{S}_2$. If the phases in this layer are taken to be CuS and S, the layer is 2.9 nm thick and is formed from a 3.7 nm thick layer of chalcopyrite.

Electrochemistry of Prussian Blue Films on Metal and Semiconductor Electrodes

Alfred Viehbeck* and David W. DeBerry*

SumX Corporation, Austin, Texas 78758

ABSTRACT

The electrochemical properties of Prussian blue films on Pt and spark anodized n-type TiO₂ electrodes were investigated. Evidence for four redox states for Prussian blue was obtained. While the oxidation of Everitt's salt to Prussian blue involves the high spin iron atoms, the oxidation of Prussian blue to Berlin green and Berlin green to Prussian yellow involves the low spin hexacyanoferrate groups. The Prussian blue/Everitt's salt redox system ($E_0 = +0.2V$ vs. SCE) is the most stable and reversible couple. The diffusion coefficients for reduction and oxidation of this redox couple are 5.0×10^{-9} and 2.7×10^{-9} cm²/s, respectively. The photoelectrochromic behavior of Prussian blue on semiconductor TiO₂ electrodes is discussed. The films deposited on TiO₂ have short-circuit memory, and lateral color spreading through the film is slow. A light addressable electrochromic display is described.

In a previous communication, we demonstrated reversible photoelectrochromic imaging using a semiconductor electrode coated with an electrochromic material (1). The system consisted of a thin film of Prussian blue on an n-type TiO₂ electrode (both single crystal and anodized metal). Light absorbed by the semiconductor produced electrochromic reactions in the Prussian blue film at potentials negative of that measured at noble metals. Images resulted that were stable at open circuit but erasable upon reversal of potential bias. Other electrochemical photoimaging systems have been reported (2-6). Abruna and Bard (7) demonstrated the photoreduction of surface-confined poly(benzylviologen) on p-Si electrodes. Inganäs and Lundström (8) investigated the photoelectrochromic properties of poly(N-methylpyrrole) polymer on n-type silicon. And, recently, Itaya *et al.* (9) reviewed the photoelectrochemical properties of Prussian blue on single-crystal n-TiO₂ electrodes.

The present study is concerned with both the redox conductivity of Prussian blue films and their photoelectrochromic characteristics on spark-anodized polycrystalline TiO₂ electrodes. Spark anodization of Ti metal, as first reported by Sato *et al.* (10), yields n-type TiO₂ films with much-improved photoconversion efficiencies compared to anodic oxide films formed at low voltage. The various redox states of Prussian blue films on Pt and

TiO₂ electrodes are discussed. This work also examines the "short-circuit" memory (image retention) properties of the Prussian blue/semiconductor electrode. A prototype light addressable electrochromic display (LAED) device is described and an example of a light-pen-written image is shown.

Experimental

Polycrystalline semiconductor TiO₂ electrodes were made by high current-high voltage sparking of Ti metal (10). The anodic films were formed by applying 103V between a Ti electrode (0.25 mm thick) and a large-area Pt electrode in 1M Na₂SO₄ solution. During the anodization process, the Ti electrode exhibits various interference colors as the oxide film thickens with increasing voltage. Avalanche breakdown of the surface film occurred at ~85V as evidenced by the localized eruption of oxygen bubbles, followed by the visible generation of sparks at the surface. Sparking was maintained at 103V for 2 min. Following complete breakdown of the entire surface, the electrode has a uniform gray appearance. Scanning electron micrographs of the spark-anodized surface showed that the oxide film was quite porous in nature. Cross-sectional views allowed an estimate for the film thickness of ~15 μm. The sparked electrodes were etched in concentrated HCl for 2 min, then reduced at -1.0V for 2 min in 1M KCl solution. The quantum efficiencies of

$t^{-1/2}$ to test applicability of the Cottrell equation. Only at very short times, $t < 10 \text{ ms}$, are the plots linear with a zero intercept as expected for a semi-infinite diffusion-controlled process. The apparent diffusion coefficients for

Fig. 3. Cottrell plots for Prussian blue reduction and Everitt's salt oxidation transients of Fig. 2A and 2B, respectively.

the reduction and oxidation redox processes are 5.0×10^{-9} and $2.7 \times 10^{-9} \text{ cm}^2/\text{s}$, respectively. The deviation from Cottrell behavior at longer times indicates the transition from semi-infinite to finite diffusion boundary conditions (22-24). The kinetics of the Prussian blue/Everitt's salt redox process is reflected by the shape, relative position, and potential sweep rate behavior of the voltammetric response (23, 25). The excellent reversibility of this couple demonstrated by the small potential peak separation (see Fig. 1) is indicative of rapid electron-transfer kinetics. The linear relationship found for both the oxidation and reduction peak current density as a function of sweep rate (to 500 mV/s) further indicates that the diffusion-layer thickness quickly approaches the film thickness.

Concentration profiles during Prussian blue reduction are shown schematically in Fig. 4. The permeation of redox charge during the potential pulse is represented by the concentration profiles for Prussian blue sites in the film at time zero (solid line), relatively short time, $< 10 \text{ ms}$ (broken line), and at longer times (dot-dash line). Using the calculated diffusion coefficients and the onset time for thin layer behavior, the film thickness is estimated at 2000 \AA , in good agreement with the predicted thickness. As expected for a diffusion-controlled process, similar overall results are obtained for the experiments carried out in 0.1M KCl.

It is very interesting to note that the Cottrell slope ($D_{\text{app}}^{1/2}C$) for Everitt's salt oxidation is smaller than for Prussian blue reduction. This difference might be due to a change in the film resistance with a change in oxidation state of the film. However, this effect is also possibly the result of a change in the actual site concentration of the film due to film swelling during incorporation of counterions (20). Humphrey *et al.* (26) have recently investigated the charge-transport properties of nickel hexacyanoferrate derivatized nickel electrodes and found that D_{app} for oxidation was greater than for reduction. The redox conductivity of this system was interpreted in terms of time-dependent diffusion coefficients.

Prussian blue/semiconductor properties.—Figure 5 shows i/E curves for a Prussian blue-modified Pt electrode (A) and a Prussian blue-modified TiO_2 electrode (B) for comparing the potential regions of the various surface processes. Under dark conditions, Prussian blue reduction on the TiO_2 electrode occurs at $\sim -0.35\text{V}$ as shown (a), with no corresponding reoxidation of Everitt's salt form on the positive scan (b). Following reduction of the Prussian blue film, it remains in the Everitt's salt form on positive potential scan even at potentials above $+1.0\text{V}$ —in sharp contrast to its facile reoxidation on Pt. Such behavior is expected for an n-type semiconductor electrode on which dark oxidation reactions are inhibited. However, if this electrode, with its "Everitt's salt-coating," is illuminated with light having energy greater than the bandgap separation of the electrode, in this case

Fig. 4. Schematic representation of the Prussian blue form concentration profiles in the film during reduction at time zero (solid line), $< 10 \text{ ms}$ (broken line), and $> 10 \text{ ms}$ (dot-dash line).

Fig. 5. Cyclic voltammograms for a Prussian blue-modified Pt electrode (A) and a Prussian blue-modified TiO_2 electrode (B). Solid lines represent dark response; the dashed line represents under illumination with UV light. Scan rate = 50 mV/s.

UV ($\lambda < 400$ nm) light, an anodic photocurrent is exhibited on the positive-going scan at potentials above -0.35 V (dashed line). No difference in the photocurrent output was observed between the Prussian blue-modified TiO_2 and the bare TiO_2 electrode. Therefore, the photoresponse of this system is due to light absorption only by the TiO_2 electrode. The negative 0.5 V shift for photo-oxidation of Everitt's salt on TiO_2 as compared to the Pt electrode is due to conversion of light energy to electrochemical energy and consequent decrease in potential needed to drive the reaction. After photo-oxidation of Everitt's salt on TiO_2 , the negative going scan again shows the reduction of Prussian blue.

In our previous communication, we showed that the rate of Everitt's salt photo-oxidation depends on the semiconductor conversion efficiency, electrode potential, and light intensity (1). The ratio of the total quantity of cathodic reduction charge (Q_c) to anodic photocharge (Q_a) shows that the average charge storage efficiency is greater than 95% for Everitt's salt oxidation to Prussian blue. However, once the anodic photocharge exceeds the capacity of the Prussian blue form, the storage efficiency decreases and the subsequent reduction scan exhibits a separate peak at -0.20 V, as seen by comparing curves 2 and 3 in Fig. 6. The excess photocharge is then partially consumed by Prussian blue oxidation to Berlin green. On reduction, this doublet is due to the two-step process from Berlin green to Everitt's salt. Itaya *et al.* (10) recently confirmed the further photo-oxidation of Prussian blue to Berlin green on semiconductor electrodes.

Figure 7 shows the reduction response on TiO_2 following an extended potentiostatic hold at $+0.5$ V and electrode illumination with UV light. We postulate that the additional peak at -0.05 represents the reduction of the completely oxidized form of Prussian blue, *i.e.*, $\text{Fe}^{+3}[\text{Fe}^{\text{III}}(\text{CN})_6]_3$, the so-called Prussian yellow or Prussian brown form. This form seems to be less stable in aqueous solution as compared to the others.

The electrochemical characteristics of the semiconductor system can be explained using an energy-band model (27). For the n-type TiO_2 semiconductor under cathodic bias, the band bending makes electrons available at the electrode/Prussian blue interface for the reduction of any

Prussian blue form in the film. As shown in Fig. 5, the Prussian blue reduction process occurs at ~ -0.35 V. Under anodic bias, however, since no free carriers are available in the valence band, the oxidation process is inhibited. While the anodic photocurrent was linearly related to the UV light intensity, the potential of photocurrent onset was only slightly affected by intensity. The onset potential was used as an approximation for the flatband (E_{FB}) potential of -0.35 V (28, 29). This value for E_{FB} agrees well with those estimates obtained by capacitance mea-

Fig. 6. Cyclic voltammograms for a Prussian blue-modified TiO_2 electrode. Scan 1 done in the dark, scans 2 and 3 under UV illumination. Note: scan to higher positive potential 3, shows Berlin green and Prussian blue reduction peaks on the negative scan.

measurements in acidic solutions (30, 31). In this highly doped n-type TiO_2 material, the conduction band is usually within -0.2V of E_{FB} (32). Since the spectral response measurement of the spark-anodized TiO_2 bandgap gave a value of 2.95 eV, the valence band is therefore located positive of 2V. The potential of the photogenerated holes is sufficiently positive to oxidize Everitt's salt. Prussian blue, Berlin green, and electrolyte. The reduction of the more oxidized forms positive of E_{FB} is perhaps due to electron transport via intermediate surface states of the semiconductor to the redox centers in the film (33). The band bending must be reduced before electrons in the

conduction band fill the intermediate states. This accounts for the narrow potential range for the reduction of Prussian yellow, Berlin green, and Prussian blue just positive of the flatband potential as compared to the spacing for the reductions on a Pt electrode.

Electrochromic memory.—The ability to photogenerate a stable image on Prussian blue-modified TiO_2 electrodes indicates short-circuit memory because the imaged region of the electrochromic film is not in equilibrium with the reduced form of the rest of the surface coating. The redistribution of redox charge is suppressed by the semiconductor properties of the electrode substrate. Therefore, the effect of lateral charge transport within the film (involving self-exchange) is almost negligible for practical applications. For instance, if the lateral conduction is similar to the process normal to the surface (diffusion coefficient $\sim 5 \times 10^{-9} \text{ cm}^2/\text{s}$), it would require an estimated $1 \times 10^4 \text{ min}$ for an image to spread about 1 mm.

A metal-semiconductor electrode was fabricated to test the persistence of an image and the low degree of lateral self-exchange. This electrode had both an Au and a TiO_2 surface region with a Prussian blue coating over the combined electrode surface. It was made from a strip of Ti metal, first spark anodized, then partially etched and electroplated with gold. Front and cross-sectional drawings of the electrode are shown in Fig. 8. Figure 8 also gives i/E curves for the TiO_2 -Au/Prussian blue electrode in 1M KCl solution. The first scan (film in Prussian blue form) toward negative potentials (curve a) shows Prussian blue reduction on the Au surface at $\sim +0.2\text{V}$ and on the TiO_2 region at $\sim -0.4\text{V}$. On the following positive scan, only the film on the Au side oxidizes and turns blue, as depicted by the anodic peak at $\sim +0.3\text{V}$. The subsequent negative scan shows only reduction of the Prussian blue coating on Au (curve b). Thus, following total film reduction, the electrochromic process can then only proceed electrochemically (in the dark), on the Au substrate. However, as expected, the Prussian blue coating on TiO_2 can be photoelectrochemically oxidized under illumination with UV light at potentials positive of -0.3V . In this manner, only the TiO_2 side undergoes the electrochromic process, provided the overall electrode potential does not ex-

Fig. 8. Illustration of a combination Au/ TiO_2 electrode modified with Prussian blue, and cyclic voltammograms for this system. Scan rate = 50 mV/s

ceed +0.2V. These results illustrate the feasibility of using combination semiconductor/metal electrode segments side-by-side in a multiplexed, light-addressable display device.

Following complete reduction, then polarization to +0.4V, the Au film in the Prussian blue form and the TiO₂ film in the Everitt's salt form are stable at open circuit. However, in this condition, UV illumination of the TiO₂ portion results in a blue image with simultaneous loss of blue color on the Au side. In other words, this "short-circuited" semiconductor/metal system acts as a photobattery with Everitt's salt oxidation at the TiO₂ and Prussian blue reduction at the Au regions. This effect is due to the difference in "reversible potential" for the Prussian blue/Everitt's salt redox couple on these substrates. While photo-oxidation of Everitt's salt to Prussian blue on TiO₂ generates electrons with sufficient energy to reduce Prussian blue on Au, Prussian blue is not reduced by the oxidation of Everitt's salt on Au. A further demonstration involved an all-TiO₂ electrode containing a blue region. The charge (color) in this image can be transferred by illuminating a region containing Everitt's salt while under open circuit. Thus, the Prussian blue portion becomes the electron accepting region for open-circuit photo-oxidation of Everitt's salt at some other location.

Photoelectrochemical display operation.—A light addressable electrochromic display (LAED) based on a three-electrode configuration was developed. The photoelectrochromic electrode consists of a Prussian blue-modified spark anodized Ti sheet. A tin oxide-coated glass plate acts as both the counterelectrode and display window. This laboratory device has an Ag/AgCl reference electrode for allowing potentiostatic control. The display face measures ~30 cm² and the flat panel is ~0.5 cm wide. Figure 9 shows an example of a "light-written" image generated on the LAED. The image was written using the output of a fiber optic cable ("light-pen") connected to a UV light source (200W Hg lamp). The writing rate was ~1 cm/s. No noticeable spreading of the image occurred after 1h on open circuit. The image was completely erased by a cathodic voltage pulse, leaving no "ghost" images.

Conclusion

The photo-oxidation of Everitt's salt to Prussian blue on semiconductor TiO₂ electrodes occurs with better than 95% photocurrent conversion efficiency. The oxidation of the Prussian blue film leads to the Berlin green form involving the incomplete oxidation of the hexacyanoferrate (II) groups. A fourth oxidation stage of the film corresponds to Prussian yellow or iron (III) hexacyanoferrate (III). Cottrell slopes of the reduction of Prussian blue and the corresponding oxidation of Everitt's salt yield diffusion coefficients of 5×10^{-9} and 2.7×10^{-9} cm²/s, respec-

tively. For the PB-modified TiO₂ electrode, surface illumination with UV ($\lambda < 400$ nm) light at potentials positive of the flatband, $E_{FB} = -0.35$ V, can lead to oxidation of Everitt's salt to Prussian blue and Berlin green because of the high potential of photogenerated holes.

Spark anodization provides polycrystalline n-type TiO₂ electrodes with reasonable photoconversion efficiencies (5-15%). The n-type properties of the anodically formed electrodes allow a stable image to be produced since charge transport between different redox forms present in the same surface film via the electrode substrate is inhibited. A stable image further implies that lateral charge transport through electrochromic film itself is quite slow.

Transport Numbers in Molten Aluminum Chloride-1-Methyl-3-Ethylimidazolium Chloride Mixtures

Chester J. Dymek, Jr.,* and Lowell A. King

The Frank J. Seiler Research Laboratory (AFSC), United States Air Force Academy, Colorado Springs, Colorado 80840

ABSTRACT

The transport numbers of 1-methyl-3-ethylimidazolium (MEI^+), AlCl_4^- , and Cl^- ions were measured in equimolar and AlCl_3 -poor melts of AlCl_3 and 1-methyl-3-ethylimidazolium chloride (MEICl). The moving boundary method and a modified Hittorf method were used. The external transport numbers of the three ions in the equimolar melt were 0.70 ± 0.02 , 0.30 ± 0.02 , and 0, respectively. As AlCl_3 mole fraction decreases, the transport number for AlCl_4^- decreases, while that for Cl^- increases and that for MEI^+ remains the same. The internal transport number of the MEI^+ relative to Cl^- as the reference is 1.00 ± 0.02 .

Chloroaluminate melts have attracted great interest in recent years in connection with battery applications, as solvents for the stabilization of unusual oxidation states, as media for conducting inorganic and organic reactions, and in the Alcoa smelting process. In the most familiar chloroaluminate melts, which contain AlCl_3 in combination with an alkali chloride such as NaCl , the probable but never proven assumption generally made is that the alkali metal cation transports virtually all the charge passed through such a melt (1, 2). The fraction of the charge carried by an individual species during the passage of an electrical current is called the "transport number" of the species. The transport number is an "external" transport number when the flux of the transporting species is measured relative to some physical reference in the electrolytic cell, such as a porous separator or the wall of the cell. It is an "internal" transport number when the flux is measured relative to some other species present in the electrolyte.

If one makes the assumption that the cation is the principal charge carrier, and if charge transport actually is carried out by anions or shared between the cations and anions, serious errors may occur in calculating activities and equilibrium constants and in predicting concentration changes and voltage changes during discharge and charge of batteries utilizing these melts (3). The information on ion transport numbers may also be sufficient to rule out certain battery-design concepts at some electrolyte compositions. Conversely, knowledge of transport numbers may suggest the most promising designs to be investigated.

The assumption that only the cation transports charge may not be valid for a melt with an organic cation, which can be significantly larger than AlCl_4^- . In fact, in recent studies (4-6) of room temperature chloroaluminates, which contain AlCl_3 in combination with an organic salt such as a 1-alkylpyridinium chloride or a 1,3-dialkylimidazolium chloride, there was abundant circumstantial evidence that anions were important charge carriers. These melts with organic cations are liquid at and below room temperature for mixtures with apparent mole fractions of AlCl_3 , N , in the range $0.30 < N < 0.70$. The three most probable anions present in chloroaluminate melts in this mole fraction range are Cl^- , AlCl_4^- , and Al_2Cl_7^- . The anion fractions of all three vary with overall melt composition (see Fig. 1).

The first experimental verification that anions transport significant charge in chloroaluminate melts was made by Hussey and Øye (7). They studied mixtures of

AlCl_3 and 1-methyl-3-ethylimidazolium chloride (MEICl) in the composition range $0.507 < N < 0.670$. They used a classical Hittorf-like procedure, in which current was passed through a three-compartment cell. The compartments were isolated from each other by fine-porosity glass disks.

At the end of each experiment, the melt in each compartment was weighed, then dissolved in water, and the composition determined from absorption spectroscopic analysis of the 1-methyl-3-ethylimidazolium cation (MEI^+) in water. Their method yielded the external transport number of MEI^+ . Anion external transport numbers could also be extracted with lesser precision from the data. They obtained a value of 0.71 ± 0.05 for the cation and composition-dependent values for the two chloroaluminate anions. Chloride ion was present in negligible amounts in their composition range and was assumed to carry no charge.

Hussey and Øye also calculated the internal transport numbers for the MEI^+ cation and for aluminum atoms, relative to chlorine atoms as the internal reference. They found the internal transport number of the cation to be 1.0, and the corresponding value for aluminum to be 0.0. Notice that this result does not imply that the cation carries all the charge. Since in their treatment, by definition, chlorine was assigned a zero internal transport number, a zero value for aluminum atoms indicates that aluminum and chlorine are bound together in the same chemical

Fig. 1. Anion mole fractions vs. apparent mole fraction of AlCl_3 in $\text{MEICl}_3/\text{AlCl}_3$ melts. The basis for these calculated plots is described in Ref. (11).

* Electrochemical Society Active Member.

species, and the bare chloride ions carry no charge. The latter might be expected, since the concentration of Cl^- is extremely small in the composition range studied.

This report describes work done in equimolar melts using a moving boundary method and also work done in AlCl_3 -poor ($0.37 < N < 0.50$) melts, which do contain significant Cl^- concentrations, using a modified Hittorf method.

Experimental

Sample preparation.—The 1-methyl-3-ethylimidazolium chloride, MEICl , and its binary mixtures with AlCl_3 were prepared as described elsewhere (8). All sample preparation and handling (except in sealed apparatus) was conducted in an argon-filled glove box (Vacuum/Atmospheres Company dry box and Model MO-40 Dri Train) having a combined moisture and oxygen concentration less than 10 ppm. Borosilicate glassware was used.

Apparatus.—In both methods, electric current was supplied and monitored by a Princeton Applied Research Model 173 Galvanostat and Model 179 digital coulometer. The moving boundary cell was immersed in a silicone oil bath maintained at 93°C by a Haake constant-temperature circulator. This temperature is slightly above the melting point of MEICl . The modified Hittorf cell was kept at the ambient glove box internal temperature (ca. 30°C). Weighing was done in the dry box using a Mettler AE 163 electronic balance. Figures 2 and 3 show the main features of the two cells.

Moving boundary method.—The moving boundary technique for determination of transport numbers in molten salts depends on the maintenance of a sharp boundary between two liquid phases. The two phases should possess one common ion, in our case, MEI^+ , and differing counterions, Cl^- and AlCl_4^- . It is most convenient experimentally if hydrostatic flow is eliminated. This was accomplished in our cell by means of a very low porosity fritted disk through which all liquid transport must occur, and by filling the two arms of the cell to about equal heights. Use of such a cell for determination of transport

Fig. 2. Moving boundary cell

Fig. 3. Modified Hittorf cell

numbers in fused salts was previously reported by Duke and Cook (9).

The charge transporting ions will move when an electric current is passed across the boundary. The direction of electron flow is indicated by the arrow at the top of Fig. 2. If all the charge is carried by the common ion, MEI^+ , no movement of the meniscus will be observed because every MEI^+ crossing the meniscus into the pure MEICl phase will be "replaced" by a MEI^+ crossing the fritted disk. However, if the counterion in the melt in which the porous disk is located, *i.e.*, AlCl_4^- , carries charge, the effect of current passage is for the meniscus to move in the direction of the disk. In this case, an AlCl_4^- moving down through the fritted disk is not "replaced" by another from above the meniscus. As a practical matter, the leading counterion, AlCl_4^- , must possess a higher mobility than the trailing counterion, Cl^- . This will insure the maintenance of a sharp moving boundary between the two phases.

Moving boundary experiments were conducted in cells such as shown in Fig. 2. The fritted disks originally were fine through ultrafine porosity. They were partially fused during cell assembly to further reduce the possibility of significant hydrostatic flow during the course of an experiment. The capillary tubing used in the moving boundary cells was calibrated beforehand in volume per unit length with mercury in the conventional manner. The radius of the capillary we used was 0.104 cm. (We also used capillaries of 0.059 cm and 0.17 cm. The ohmic resistance of the former was too large to permit passage of a convenient current. A sharp meniscus was difficult to maintain in the largest radius capillary at the maximum currents the galvanostat could provide, given the total resistance of the cell.)

The moving boundary cell was filled inside the glove box in the following manner. Equimolar MEICl-AlCl_3 at ambient temperature was placed in the compartment opposite the capillary. The compartment was filled so that the melt was in contact with the porous separator. A several centimeter head was maintained until liquid could be seen on the capillary side of the disk (this required, as a minimum, 15h and insured that the disk was saturated with the equimolar melt). Then, more of the equimolar melt was added on the capillary side until the capillary was very nearly filled. Thus, the equimolar melt is the electrolyte in contact with both sides of the porous disk and therefore also the electrolyte in which the transport numbers are being measured. The addition was made with a Pasteur pipette inserted through the capillary to

exclude bubbles and to avoid wetting the wall of the compartment above the capillary. With another Pasteur pipette, pure MEICl from a reservoir maintained above its melting point was carefully added on top of the equimolar melt column.

The aluminum coils (Alfa Products, 99.999% Al) were quickly (but carefully, to minimize mixing at the liquid-liquid interface) immersed in the two compartments before the MEICl solidified. The capped cell was then removed from the glove box. When the MEICl was remelted in the oil bath, a distinct meniscus was evident between the two liquids. [The densities at 93°C of MEICl and of the equimolar melt are 1.1120 and 1.2395 g/cm³, respectively (6).] The meniscus became very sharp within a few seconds after the current was turned on. As indicated in Fig. 2, electron flow in the external circuit was from the right electrode to the left, and, consequently, negative ion conduction in the electrolyte would be from the left compartment to the right, or "down the capillary." A constant current of 20-30 mA was most convenient, and no dependence of calculated transport numbers on current was noted between 7.5 and 50 mA. The meniscus fell at about 1.4 cm/h at 20 mA. The meniscus movement was determined by measuring (using a cathetometer) the distance between the meniscus and an index mark on the capillary. Cathetometer readings of the meniscus location and index mark were made to a precision of ±0.05 cm.

When the current was turned on, the meniscus location and the total number of coulombs passed were recorded at periodic intervals. By the time the first reading was taken, the meniscus was sharp; the number of coulombs passed at that point was subtracted from all subsequent values. The corresponding meniscus location thus became the "zero" position for meniscus movement.

We evaluated the electrode reaction products and hydrostatic flow through the fritted disk for their possible effects on the melt composition and the meniscus position. Oxidation of aluminum at the anode (in the $N = 0.5$ melt) can be represented by the reaction

The acidic melt formed at the anode is well removed from the fritted disk. Also, since it is denser than neutral melt and mixes slowly, it is unlikely that significant Al_2Cl_7^- concentration builds up near the fritted disk. The cathode reaction (in the pure MEICl) must involve reduction of MEI^+ , but the products of the reaction have not been identified. The reduction does produce a distinct orange-brown color in the vicinity of the coiled aluminum cathode; however, the colored product does not appear to diffuse into the capillary. This observation, along with the constancy of the transport number obtained during a run (see Fig. 4 and related discussion), strongly support the

Fig. 4 Experimental results for Run 174,16 of moving boundary method. Equivalents of salt transported across the porous disk vs. charge passed.

assumption that the electrode reaction products do not significantly affect the calculated transport numbers.

In separate experiments (for each different porous disk used), enough equimolar melt was added to the capillary side of the cell to only half fill the capillary section. Motion of the meniscus was followed for 12-24h as a several centimeter head of melt was maintained on the other side of the porous disk. A typical hydrostatic flow rate was about 1% of the total flow rate observed during passage of a 20 mA current. Not even this hydrostatic flow rate would occur in an actual experiment, where the two liquid columns were at about the same height. Furthermore, a connecting tube between the vapor spaces of the two compartments prevented any unequal buildup of gas pressure from the electrode reactions. Accordingly, no corrections to the data for hydrostatic flow or pressure differences in the gas above the columns were deemed necessary.

Modified Hittorf method.—The cell was comprised of two concentric tubes, open at the top, and communicating by a fine-porosity glass disk, which was the bottom of the inside tube (see Fig. 3). Coils of aluminum wire (Alfa Products, 99.999% Al) were placed in each compartment. As with the other cell, the porosity of the glass disk was further reduced by partial fusion to reduce the possibility of hydrostatic flow between the compartments. This cell was filled and operated inside the glove box.

We call this technique a "modified Hittorf method" because there is a region defined by the porous separator in the cell in which the changes in species concentrations are measured and related to transport of ions into and out of the region. The inner compartment is such a region in our cell and it is also the anode, so the expected ionic motion during the passage of current is for MEI^+ cations to migrate out of this compartment and for anions to migrate into it. The composition and mass of the anolyte would be affected by both ion migration and the anodization of the aluminum electrode, i.e., $\text{Al} + 4\text{Cl}^- \rightarrow 4\text{AlCl}_4^- + 3e^-$. Thus, the mass and composition of the anolyte (before and after electrolysis), along with the charge passed through the cell, are required to determine how many moles of each species transported charge across the disk. Because of the unknown cathodic processes in basic ($N < 0.5$) melts (aluminum deposition does not occur to any significant extent), we did not attempt to relate the catholyte composition to any transport properties.

The hydrostatic flow rate was determined by monitoring the change in mass of the anode compartment for several hours while it was filled with sufficient melt to provide a 12 mm hydrostatic head above the frit. The leak rate was found to be 0.0012 g/h per mm of pressure head. In the cell assembly and operation, we estimate that the anolyte and catholyte levels can be maintained to within ± 2 mm, so our leak-rate error did not exceed ± 0.002 g/h. In a typical measurement, this leak-rate uncertainty contributes ± 0.006 to the overall uncertainty in the transport number.

The anode compartment (including the aluminum anode) was weighed empty of melt except for the amount of melt required to saturate the frit. This recorded tare weight also included a beaker used to hold the anode compartment during the weighings. The anode compartment was then filled with melt of a known composition and weighed again to obtain the initial mass of anolyte. Melt of the same composition then was placed in the cathode compartment. Next, the cell was assembled so that the anolyte and catholyte levels were at the same height. Finally, the cell was connected and a known charge passed at constant current of 50 mA. Then the anode compartment was removed, its outside surface was wiped clean, and it was weighed.

Since the method of wiping the outside frit surface can introduce serious error into the weight of the anolyte, the magnitude of this error was determined. The anode compartment containing melt was submerged in the catholyte for several minutes and then removed, wiped, and

weighed. Successive cycles of this process resulted in an uncertainty of $\pm 0.0005\text{g}$ for the more viscous basic melts ($0.33 < N < 0.40$). For the less viscous melts ($0.40 < N < 0.48$), the wiping process had to be done more gently to achieve an uncertainty of $\pm 0.001\text{g}$.

By correcting for the amount of aluminum anodized into the melt using the known anode reaction stoichiometry, the weight change of the melt can be combined with the composition change to obtain the number of moles of ions transported into or out of the anode compartment for a given passage of charge. The anolyte compositions before and after passage of a measured charge were determined by proton nuclear magnetic resonance (NMR) spectroscopy of aliquots removed from the anolyte compartment. Prior to obtaining the aliquots, the anolyte, which had already been weighed, was stirred to insure a uniform composition of melt in the anode compartment. NMR spectra were taken with a JEOL Model FX90Q NMR spectrometer. This procedure is the same as described elsewhere (10), except that a hexamethyldisiloxane external standard was used and the spectrometer was operated at 90 MHz in the present work.

This procedure was performed for several melts in the range $0.33 < N < 0.48$. Prior to each experiment, the frit was saturated with melt to be used in that experiment by placing some of the melt in the anode and letting it diffuse through the frit.

Results and Discussion

Moving boundary method.—For each ion moving in the vicinity of the boundary, a corresponding ion is moving through the porous disk. Thus, this experiment really measures the transport of ions through the disk. It follows that the transport numbers obtained are external transport numbers as described by Hussey and Øye. The transport numbers were calculated from

$$t_-(\text{AlCl}_4^-) = \frac{\text{equivalents of salt transported}}{\text{equivalents of current passed}} \\ = \frac{(\pi r^2 \Delta h) \rho / M}{Q/F}$$

where r is the capillary radius, ρ is the density of equimolar melt, Δh is the distance traveled by the boundary, M is the gram equivalent weight of the equimolar melt, F is the Faraday constant, and Q is the charge passed. The "equivalents of salt transported" down the capillary is equal to the equivalents of AlCl_4^- transported across the porous disk since the MEI^+ is the only cation in the two phases forming the boundary.

The results of the moving boundary experiments are given in Table I. The data from experiment 174,16 are also plotted in Fig. 4. The plotted data should be considered only representative; they are neither the best nor the poorest in terms of experimental scatter.

Since AlCl_4^- is, presumably, the only anion present in significant concentration in the $N = 0.50$ melt, the remainder of the charge will be carried by the imidazolium cation. If one assumes for the transport number of AlCl_4^- the overall value 0.30 ± 0.02 , given in Table I, the imidazolium ion transport number will be 0.70 ± 0.02 . This value is in agreement with the 0.71 ± 0.05 reported by Hussey and Øye (7) for acidic melts. Hussey and Øye claim their value is valid throughout the AlCl_3 composition range, $0.50 < N < 0.67$. The agreement is particularly gratifying in view of the two different experimental approaches taken.

It should be noted that Hussey and Øye worked at 28°C , while the present data were taken at 93°C . It is not known what, if any, effect the temperature has on the observed transport numbers.

Modified Hittorf method.—In this method, the measured mass, m , and mole fraction of AlCl_3 , N , of the anolyte were used to calculate the number of moles of MEICl and AlCl_3 before and after each passage of charge as follows

All data		0.299 ± 0.02	143	

$$\text{mol}(\text{MEICl}) = \frac{(1-N)m}{M_{\text{AlCl}_3}N + M_{\text{MEICl}}(1-N)}$$

and

$$\text{mol}(\text{AlCl}_3) = \frac{Nm}{M_{\text{AlCl}_3}N + M_{\text{MEICl}}(1-N)}$$

where the M is the formula weight of the subscripted species.

Since $\Delta \text{mol}(\text{MEICl})$ is the same as $\Delta \text{mol}(\text{MEI}^+)$ in the anolyte, we can calculate the mols of MEI^+ transported out of the anolyte. Similarly, $\Delta \text{mol}(\text{AlCl}_3) - Q/3F$ gives $\Delta \text{mol}(\text{AlCl}_4^-)$, or the number of moles of AlCl_4^- transported into the anolyte, since AlCl_4^- is the only Al containing anion present in the basic melt. The $Q/3F$ correction is required to account for AlCl_4^- formed by anodization of the Al anode by the reaction

Thus we have

$$t_+(\text{MEI}^+) = \frac{\Delta \text{mol}(\text{MEICl})}{Q/F}$$

$$t_-(\text{AlCl}_4^-) = \frac{\Delta \text{mol}(\text{AlCl}_3) - Q/3F}{Q/F}$$

and

$$t_-(\text{Cl}^-) = 1 - t_-(\text{AlCl}_4^-) - t_+(\text{MEI}^+)$$

The data recorded are tabulated in Table II with the runs listed in order of increasing AlCl_3 mole fraction of the melts used. The results using these data are listed in Table III with the same ordering of the runs. The initial tare weights listed in Table II include the weight of the beaker used to contain the anode compartment for the weighings. In Fig. 5, the transport numbers obtained by this method are plotted against the mole fraction of the melt used. Several runs were performed at $N = 0.37$, and the results at this point reflect the uncertainty in the data. Even considering this fairly large scatter in the results, it is clear that the transport numbers for the Cl^- and AlCl_4^- vary approximately with the concentrations of these species. When the transport numbers for these anions are plotted against their molarities in the melts (Fig. 6), it also becomes clear that the two anions have approximately the same mobilities. This may be rationalized by

noting that the smaller ionic radius of the Cl^- ions may be offset by its stronger associations with surrounding ions due to its larger charge/volume ratio. This dependence of the strength of ion associations on charge/volume ratio may also explain in part the large transport number of the MEI^+ relative to the smaller anions. However, further work, including molecular orbital calculations on the species in the melts and their interactions, is required for an understanding of the actual transport

mechanism, and such work is in progress at this laboratory.

Internal transport numbers.—The use of internal transport numbers to relate EMF data from concentration cells using these melts to thermodynamic data was described by Øye and King (3). In their paper on transport numbers in acidic melts, Hussey and Øye (7) reported that the internal transport number of MEI^+ (relative to Cl^- present in the chloroaluminate anions) is 1.00. Their external transport numbers for MEI^+ (t_R) and Al (t_{Al}) can be related to our external transport numbers for MEI^+ and $AlCl_4^-$ as follows

$$t_R = t_+(MEI^+)$$

and

$$t_{Al} = -3[t_-(AlCl_4^-)]$$

We can then use their Eq. [19] to calculate the internal transport number for MEI^+ (t'_R) from our data

$$t'_R = t_R + \frac{1-N}{2N+1}(1-t_{Al}-t_R)$$

The values of t'_R calculated from our data in this way are tabulated in Table III and plotted against N in Fig. 7. The mean value for t'_R in the basic melts we used is 1.00 ± 0.02

Fig. 6. External transport numbers for Cl^- and $AlCl_4^-$ vs. the molarity of the corresponding anion in the melt.

Fig. 7. Internal transport numbers of MEI^+ vs. mole fraction of AlCl_3 in the melt. Open squares: Modified Hittorf method. Circles: Moving boundary method.

(95% confidence limits). It thus appears that, over the entire range in which the $\text{MEICl}/\text{AlCl}_3$ melts are liquid at room temperature ($0.33 < N < 0.67$), the internal transport member for the MEI^+ is 1.00.

Conclusions

The external and internal transport numbers of species in basic and neutral $\text{MEICl}/\text{AlCl}_3$ melts obtained using the two methods reported agree with the values obtained for acidic melts by Hussey and Øye (7). The MEI^+ has external (relative to porous glass disks) and internal (relative to Cl in the melt) transport numbers of 0.70 and 1.00, respectively. The external transport numbers of the anions are roughly proportional to their concentrations in the melts.

Acknowledgments

The authors are grateful to Dr. John S. Wilkes and Dr. Armand A. Fannin, Jr., and to other associates at the Frank J. Seiler Research Laboratory (FJSRL) for many helpful discussions of this work. We are also grateful for the helpful and insightful evaluations of our work by Professors Harald A. Øye and Charles L. Hussey. Mr. Fred Kibler and Mr. Lloyd Pflug of FJSRL provided expert assistance in construction of the cells and in NMR analysis of the melts. Finally, we are grateful to Missy Landess for her expert typing and assistance in editing the manuscript.

Manuscript submitted Nov. 2, 1984; revised manuscript received Jan. 16, 1985.

The Air Force Office of Scientific Research assisted in meeting the publication costs of this article.

Technical Notes

Large-Scaled Polyacetylene Batteries

Takao Nagatomo,* Hidehiko Kakehata, Chiaki Ichikawa, and Osamu Omoto

Shibaura Institute of Technology, Shibaura, Minato-ku, Tokyo 108, Japan

Many detailed investigations on the electronic structure and the physical properties of $(\text{CH})_x$ film have been done since Shirakawa *et al.* proposed the synthetic method in the form of silvery films by a direct polymerization of acetylene on the surface of concentrated soluble catalyst solution in 1974 (1). Polyacetylene, $(\text{CH})_x$ film is the simplest conjugated polymer consisting of parallel chains of CH groups. It has recently been of considerable interest as the electrode active material of secondary batteries, with many superior features: (i) it contains an interwoven network of ca. 200Å $(\text{CH})_x$ fibrils; (ii) the electrical conductivity of $(\text{CH})_x$ films can be varied over 12 orders of magnitude from insulator to metal when suitably doped with donor or acceptor species; (iii) it is very stable chemically; there are other attractive features (2, 3). This battery promises to be lighter and has higher power and energy

densities as compared to conventional batteries such as lead-acid batteries.

We have reported the properties of the polyacetylene batteries (4-6). An $n\text{-(CH)}_x/\text{LiClO}_4 + \text{PC/p-(CH)}_x$ battery was investigated for 2600 charge-discharge cycles, although doping levels were shallow ($y = 0.002$). The maximum energy density obtained was 424 Wh/kg, based on the weight of the electrode active material (both electrodes; ~8 mg) under the charge-discharge conditions of the stored charge of 10.8C and the liberated charge of 4.52C (4-6). In this paper, we describe the charge-discharge characteristics of large-scaled polyacetylene secondary batteries with electrode areas of 20 ~ 54 cm².

The *cis*- $(\text{CH})_x$ films were polymerized by the Shirakawa technique (1). Care was taken to achieve pure $(\text{CH})_x$ starting material through extensive washing to remove all catalyst, with subsequent storage and handling in inert atmosphere to minimize oxygen content. All experiments

*Electrochemical Society Active Member.

for batteries were carried out in the absence of air and moisture in the argon atmosphere of a dry glass vessel as the electrical properties of $(\text{CH})_x$ films degraded on exposure to air and moisture. In our experiments, $(\text{CH})_x$ film on which 1000Å of gold had been evaporated on one side and aluminum foil ($\sim 100 \mu\text{m}$) were employed as the positive and negative electrodes on the doping and charging processes, respectively. Gold wire was attached to one end by pressed mechanical contact, and the $(\text{CH})_x$ with current collector of the evaporated gold film and aluminum foil electrodes were placed at ca. 3 mm distance in a 1.0M solution of LiClO_4 in the mixture of propylene carbonate (PC; 20%) and ethylene carbonate (EC; 80%) through a glass filter. The *cis*- $(\text{CH})_x$ film used as the electrode active material had the film thickness of 50 ~ 100 μm and the areas of 10 ~ 27 cm^2 . The battery was comprised of two $(\text{CH})_x$ cathodes and one Al anode, arranged in an alternating fashion with Al forming the inner electrode in the stack. Two types of batteries were fabricated for use in these studies: the first had a cathode area of 20 cm^2 (2 cm width \times 5 cm length \times 2 sides); the second had a cathode area of 54 cm^2 (3 cm width \times 9 cm length \times 2 sides). If the $(\text{CH})_x$ film and Al foil electrodes were attached to the positive and negative terminals, respectively, of a battery or dc power source (ca. 3.8V), perchlorate ions diffused into the positive electrode in a manner analogous to the way one would dope a semiconductor and lithium ions deposited on the negative electrode. The extent of doping was calculated from the weight of the $(\text{CH})_x$ film employed and the number of coulombs passed.

The course of the cell voltage of a $\text{p}(\text{CH})_x/\text{LiClO}_4 + \text{PC} + \text{EC}/\text{Al}$ battery during charge and discharge is illustrated in Fig. 1. These batteries had a cathode area of 20 cm^2 . A 1.0M solution of LiClO_4 in the mixture of propylene carbonate (PC; 20%) and ethylene carbonate (EC; 80%) was used as the electrolyte. These batteries were charged at constant currents of 10, 15, and 20 mA for 10 min and discharged at constant currents of 10, 15, and 20 mA to 2.5V immediately after charging, respectively. These charge and discharge rates in amperes per kilogram of $(\text{CH})_x$ (35 mg) are 286, 429, and 571, respectively. In these conditions, the charging voltage was gradually raised with an increase in charging current and was in excess of 4.5V at the charging current of 20 mA. The coulombic and power

Fig. 1. The course of the cell voltage of $\text{p}(\text{CH})_x/\text{LiClO}_4 + \text{PC} + \text{EC}/\text{Al}$ battery with a cathode area of 20 cm^2 during charging and discharging as a parameter of charge and discharge currents. Charge and discharge rates of $(\text{CH})_x$ (35 mg): 10 mA, 286 A/kg; 15 mA, 429 A/kg; 20 mA, 571 A/kg. The inset shows the coulombic and power efficiencies vs. the charging and discharging currents.

Fig. 2. The coulombic (η_c) and power (η_p) efficiencies of the charge-discharge cycle of $\text{p}(\text{CH})_x/\text{LiClO}_4 + \text{PC} + \text{EC}/\text{Al}$ battery with a cathode area of 20 cm^2 . Charge and discharge conditions: charging at 10 mA (286 A/kg) for 10 min; discharging at 10 mA to 2.5V.

efficiencies vs. the charging and discharging currents are illustrated in the inset. The coulombic and power efficiencies of charge-discharge cycle decreases with an increase in the charging and discharging currents. The loss of charge becomes gradually large, and can be caused by the chemical reaction of the electrolyte or by the reaction of impurities in the electrolyte with $[\text{CH}^+(\text{ClO}_4)_y]^-$ and Al, and by the degradation of $(\text{CH})_x$ and the decomposition of the organic solvent due to the excess amounts of charge and the large charging voltage. In addition, the loss of charge can be caused by the insufficient extraction of charge during the discharge to 2.5V. The problems of the degradations of $(\text{CH})_x$, such as the cross-linking reaction and the replacement of $(\text{CH})_x$ due to charging and discharging processes, and of the decomposition of the solvent are the subjects for a future study.

The coulombic (η_c) and power (η_p) efficiencies of the charge-discharge cycle of $\text{p}(\text{CH})_x/\text{LiClO}_4 + \text{PC} + \text{EC}/\text{Al}$ battery are shown in Fig. 2. This battery was charged and discharged for 30 cycles, each cycle consisting of a 10 min charge at 10 mA (286 A/kg) and a discharge at 10 mA to 2.5V. The coulombic and power efficiencies were 83 and 69%, respectively. No degradation of the charge-discharge characteristics was observed even after 30 successive charge-discharge cycles. This battery has a cathode area of 20 cm^2 as aforesaid. Although this battery had a cathode area ten times as large as that of the 2 cm^2 polyacety-

Fig. 3. The course of the cell voltage of $\text{p}(\text{CH})_x/\text{LiClO}_4 + \text{PC} + \text{EC}/\text{Al}$ battery with a cathode area of 54 cm^2 as a parameter of discharging current.

lene battery, the characteristics of the battery were by no means inferior to the 2 cm² battery.

The course of the cell voltage of the polyacetylene battery with a cathode area of 54 cm² during discharging is illustrated in Fig. 3 as a parameter of discharging current. These polyacetylene batteries were initially charged at 15 mA for 60 min (54C, doping level $y = 13.7\%$) and discharged at constant currents of 5, 10, and 15 mA to 2.5V immediately after charging. These discharge rates, in amperes per kilogram of (CH)_x (94.5 mg) are 52.9, 105.8, and 158.7, respectively. The energy density values obtained were: 5 mA, 114 Wh/kg; 10 mA, 110 Wh/kg; and 15 mA, 100 Wh/kg when the battery was discharged to 2.5V. As compared with the charge-discharge characteristics of 2 cm² polyacetylene battery, there was no significant difference between large-scaled polyacetylene battery (cathode area of 54 cm²) and 2 cm² battery. The coulombic efficiencies for the 5, 10, and 15 mA discharges in Fig. 3 are 48.7, 47.8, and 45.0%, respectively. As compared with the charge in short time (10 min) as shown in Fig. 1, the coulombic efficiencies are extremely low. This could be because, as charging time becomes longer, the (ClO₄)⁻ ions diffuse into the interior of the (CH)_x fibrils and the (CH)_x film. It is difficult to release completely their ions diffused into the interior of the (CH)_x fibrils and the (CH)_x film during discharging to 2.5V (6, 7).

Compared to conventional batteries, such as lead-acid battery, the polyacetylene secondary battery promises to be lighter and has high power density and energy density. However, there are several problem areas that must be resolved before use of polyacetylene electrode becomes a reality. Especially, although we did not deal with the polymer salt solvent combinations, these are serious problems. Further work is needed in this area. There is no significant difference between the charge-discharge characteristics of large-scaled polyacetylene battery (cath-

ode area of 54 cm²) and that of 2 cm² battery as mentioned above. Consequently, we consider that scaling up of the battery is not a serious problem.

Some Performance Characteristics of a Prussian Blue Battery

Vernon D. Neff

Department of Chemistry and the Liquid Crystal Institute, Kent State University, Kent, Ohio 44242

In the past, we (1-3) and Itaya *et al.* (4-6) have reported some of the thermodynamic and kinetic characteristics of the electrochemical oxidation and reduction of thin films of Prussian blue (PB) on various substrates. The purpose of this note is to point out the feasibility and to determine some preliminary performance characteristics of a Prussian blue battery. If PB is deposited on a substrate under controlled conditions, it is possible to reduce it to Everitt's salt (ES) according to (2)

or oxidize to Berlin green (BG) according to

In reaction [2] a definite compound is formed when only two-thirds of the ferrocyanide ions in the PB lattice have been oxidized (2). According to the voltammograms, a second oxidation occurs at ca. 1.1V vs. SCE and a yellow film is formed. We shall not be concerned with this second oxidation since the electrochemistry is not well understood and the film gradually deteriorates at potentials above 1.2V.

It is apparent that the two half-cells above could be combined to make a PB battery which, in the uncharged state, would consist of PB as both anode and cathode. The cell reaction would be

with a theoretical voltage of 0.68V.

An obvious disadvantage is the low energy density of such a cell. A pure PB electrode, based on the stoichiometric formula KFeFe(CN)₆, would have an energy density of only 95 mWh/cm³. Even so, there are good reasons for considering such a cell. First of all, the reactions [1] and [2] above are highly reversible (3). Second, the energy density, though small, is about five times greater than that for 1M redox couples in solution (such as the iron-chromium couple) which are being considered for off-peak power storage. Another advantage is that the PB cell requires no separator as do the redox solution cells. Finally, there is the advantage of the high chemical stability of these mixed valence hexacyanides in acid solutions. Judging from our experience (2) and that of others (7) concerning the cycling of carefully prepared thin films, it should be possible to develop a cell which is essentially indefinitely rechargeable.

Experimental

The electrodes consisted of PB electrochemically deposited on highly porous graphite. The graphite (PG-60) was obtained from the Union Carbide Corporation. This material has a density of ca. 1.2 g/cm³. The graphite was cut into blocks 2.5 × 2.5 × 0.6 cm with a volume of 3.75 cm³. The leads into the substrate electrodes were made

from 1/8 in. graphite rods press fit into holes drilled into the graphite blocks.

All chemicals used were reagent grade, and triply distilled water was used throughout. The deposition of PB was carried out from rapidly stirred 1 liter solutions which were 0.01M in $\text{Fe}_2(\text{SO}_4)_3$, $\text{K}_3\text{Fe}(\text{CN})_6$, H_2SO_4 , and 0.1M in K_2SO_4 . Since these bright red solutions are unstable over time, and gradually form a green suspension, they were replaced at 3h intervals. The PB was deposited at constant current of 1 mA with a PAR Model 173 potentiostat. The electrodes were removed periodically and drained on filter paper. During this process, a considerable amount of nonadherent PB came out of the electrodes. Deposition times varied from several hours to several days. After deposition, the electrodes were flushed extensively with 0.01N H_2SO_4 solution and finally with water and were allowed to dry in air for several days.

The amount of active PB on the electrodes was determined from the constant-voltage charging curves. Cathodes were prepared which had approximately one-third more PB (as determined by weighing) than the anodes. The electrodes were inserted in a 100 ml closed cell which could be purged with deoxygenated nitrogen. The cells were charged with a Sola OSV constant-voltage power supply. Cells were tested which had capacities varying between 10 and 40 mAh. The main cell characteristics studied were constant-voltage charging curves, discharge under constant load, and discharge at constant current. Preliminary measurements of voltage retention in the presence and absence of oxygen were also carried out.

Results and Discussion

In terms of oxidation and reduction, the mixed valence transition-metal hexacyanides which have been studied to date behave like solid solutions (2, 3, 8). In this sense, they most closely resemble redox polymeric films like the vinylferrocenes (9). It is instructive to consider the thermodynamic potential of the PB cell as a function of the amount (mole fraction) of PB in the electrodes. We have previously shown that, for the oxidation of PB to BG, the solid solution is approximately ideal so that activities can be set equal to mole fractions. This is apparently not the case for the reduction of PB to ES (2). For carefully prepared thin films, the voltammograms for the reduction are very sharp in 1N potassium ion solutions. One possible explanation of this observation is based on the assumption of a regular solution where the activity of PB is given by (2)

$$\alpha(\text{PB}) = x \exp W(1 - x^2)/RT \quad [4]$$

and that for ES is given by

$$\alpha(\text{ES}) = (1 - x) \exp Wx^2/RT \quad [5]$$

where W is a repulsive energy and x is mole fraction of PB. The general expression for the thermodynamic potential according to Eq. [3] would be

$$E = 0.68 - \frac{RT}{F} \ln \frac{\alpha(\text{PB, anode}) \alpha(\text{PB, cathode})^{3/2}}{\alpha(\text{ES}) \alpha(\text{BG})^{3/2}} \quad [6]$$

Substituting Eq. [4] and [5] for the activities at the anode, and setting activities equal to mole fraction x for ES and $(1 - x)$ for BG at the cathode, we can plot the thermodynamic potential for the discharge of the PB battery, as shown as the solid curve in Fig. 1. For this calculation, the repulsive energy parameter w/RT was set equal to 1.72, which was the value obtained for thin PB films on a platinum substrate (2). The solid circles in Fig. 1 represent the experimental cell voltage for the discharge of a 30 mAh cell at constant current of 1 mA in 1N K_2SO_4 . For these data, the mole fraction x of PB at time t was determined from $x = t/(t_d - t)$, where t_d is the time for complete discharge. Finally, the dashed curve in Fig. 1 represents the calculated potential for a cell in which activities are set equal to mole fractions for both anode and cathode. It is seen that the experimental cell voltages fall between the

Fig. 1. Solid curve: Calculated difference in potential $E - E^\circ$ as a function of mole fraction x of PB. The ES at the anode is assumed to behave as a regular solid solution with repulsive interaction $W/RT = 1.72$. Dashed curve: Calculated potential difference as a function of mole fraction assuming that both anode and cathode behave as ideal solid solutions. Solid circles: Experimental cell voltage minus E° for the constant current discharge of a 30 mAh capacity PB cell in 1N K_2SO_4 solution. The current was maintained as 1 mA, and the mole fraction x of PB was determined from $t/(t_d - t)$, where t is time and t_d is the time for complete discharge. $E^\circ = 0.68\text{V}$.

two calculated curves, indicating a situation intermediate between the thin film behavior and that for ideal solid solutions. The experimental data clearly illustrate the nernstian behavior and the highly reversible nature of the cell reactions. The underpotential at $x = 0.5$ is only ca. 10 mV below the theoretical value.

In Fig. 2, we have shown the constant voltage charging curve for a 30 mAh capacity cell in 1N K_2SO_4 solution. Under rapid charge, the electrode is subject to the combined effects of ohmic, concentration, and diffusion polarization. From the current in the initial stages of charge, the total ohmic resistance is estimated to be only ca. 3 Ω . The low initial resistance is attributed to the fact that the PB on the outside surface of the electrode is the first to react. Sectioning of the porous carbon showed a distinct gradient in the amount of PB from the outside of the electrode inward. Figure 2 indicates that, as charging proceeds, the current is dominated by the diffusion process. The diffusion process is complicated by the nature of the porous electrodes and by the fact that potassium ions must migrate into or out of the solid PB as well as in the solution. The curve appears to be more exponential than cottrellian, indicating that the diffusion in the PB, rather than in solution, is the primary limiting factor (3). When the cell is charged rapidly at potentials of 1V or greater, a yellow color develops gradually around the anode. The yellow color does not occur under conditions where the cell is charged slowly, and the current does not exceed 5 mA.

We also made some preliminary measurements with regard to the retention of charge. For good charge retention, it is necessary to exclude oxygen from the cell and to make sure that electrodes are well flushed of impurities.

Fig. 2. Constant voltage charging curve at 1.0V for a 30 mAh capacity PB cell in unstirred 1N K_2SO_4 solution.

We epoxy sealed a purged cell with a Lucite cap and slowly charged it to 1.0V. There was an initial voltage drop which leveled out to 0.93V within a few hours and remained constant for 10 days (the duration of the test). A second cell was charged to 1.0V and left open to the air. The voltage dropped to 0.74V within 24h. In this case, the voltage dropped due to the presence of molecular oxygen which reacts chemically with ES to form PB (2). Adsorbed ferric ions will also react with ES.

In these preliminary studies, we make no pretense with regard to having optimized conditions for a practical PB battery. One of the major problems we have encountered is the adherence of the PB deposit on the carbon substrate. In all cases, we observed a gradual loss of PB from

the electrodes after repetitive charging cycles. The PB comes out of the electrodes as a finely dispersed sol. The average rate of loss was ca. 5% capacity per cycle. The nature of the deposition reaction and the conditions for good adherence of the PB deposit are, at present, not well understood (2, 7). It is also obvious that a much more heavily loaded graphite or other substrate should be developed.

Finally, we should point out that it is not necessary to construct both electrodes from PB. There are a large number of insoluble, chemically stable, transition-metal hexacyanides which have not been studied electrochemically. For example, we have recently synthesized manganese blue films $[KFeMn(CN)_6]$ which can be electrochemically reduced to a colorless state at $-0.25V$ vs. the SCE. The details of this reaction will be discussed in a later communication.

Direct Observation of Voids and Cracks in the Barrier Oxide Layer of Composite Aluminum Oxide Films

K. Shimizu* and K. Kobayashi

Department of Chemistry, Faculty of Science and Technology, Keio University, 3-14-1 Hiyoshi, Yokohama 223, Japan

Composite aluminum oxide films, formed by the sequential process of the reaction with boiling water followed by anodic oxidation, have been widely used in the fabrication of electrolytic capacitors because of their excellent dielectric properties (1, 2). However, the barrier oxide layer of the composite oxide films frequently exhibits an electrical instability: losing the ability to sustain the original anodizing voltage after anodization. A reformation is needed to restore the barrier oxide to its original state. In an investigation of the electrical instability of the composite oxide films, Alwitt and Dyer (3) suggested that the instability is an intrinsic property of the films that arises from the presence, in the barrier oxide layer, of internal voids or cracks into which water can diffuse when the formation field is removed. A considerable amount of circumstantial evidence (4-6) has been accumulated supporting the mechanism proposed by Alwitt and Dyer. It was hoped that the presence of voids and cracks could be verified independently and directly. Thus, an attempt has been made, by Alwitt *et al.* (7), to detect the voids and cracks by transmission electron microscopy of

the stripped and subsequently ion beam thinned composite oxide films using defocus contrast. Phase objects have been observed in the barrier oxide layer of the composite oxide films and explained as representing discrete voids or cross sections of cracks which are thought to be responsible for the electrical instability of the composite oxide films.

Here, transmission electron microscopy of ultramicrotomed sections has been employed to reveal clearly the existence of voids and cracks in the barrier oxide layer of the composite oxide films.

Electropolished superpure aluminum sheets of dimensions of $50 \times 10 \times 0.2$ mm were immersed in boiling distilled water for 5 min and subsequently anodized to 300V in 0.1M ammonium pentaborate solution at 298 K with a constant current density of $50 A m^{-2}$.

Ultramicrotomed sections of the aluminum substrate and the composite oxide films were prepared in the now usual manner using a du Pont Sorvall MT2B ultramicrotome (8). In short, encapsulated specimens were trimmed initially with a glass knife and suitably thin sections, between 25-50 nm, were obtained finally by sectioning in a direction parallel to the metal/oxide interface with a dia-

*Electrochemical Society Active Member.

Fig. 1. Transmission electron micrograph of a cross section of the 300V composite oxide film.

mond knife. Ultramicrotomed sections obtained were examined in a Hitachi HU-12AS transmission electron microscope operated at 100 kV.

Transmission electron micrograph of an ultramicrotomed section of the aluminum substrate and the composite oxide film formed to 300V is shown in Fig. 1. The aluminum substrate is observed at the bottom of the micrograph and shows the darker bands or extinction contours that diffract at that particular orientation to the electron beam. Residual hydrous oxide layer is observed at the top of the micrograph as a fibrillar layer of varying thickness.

A barrier oxide layer separating the aluminum substrate and the residual hydrous oxide is clearly observed. The total thickness of the barrier oxide layer is about 290 nm, representing a nanometer-to-volt ratio of 0.97, which is considerably smaller than the 1.18 reported for conventional barrier anodic films formed under similar conditions (9). Within the barrier oxide, an amorphous layer between 70 and 110 nm thick is observed next to the metal. A crystalline region is present adjacent to the amorphous layer and is observed to extend near to the barrier/hydrous oxide interface. An electron diffraction analysis made recently by Alwitt *et al.* (7) has shown that the crystalline oxide within the barrier oxide layer of the composite oxide films formed under a condition similar to ours is γ' - Al_2O_3 . Numerous discrete voids, a few nanometers in diameter, and a network of fine cracks, a few nanometers wide, are observed clearly within the γ' -crystalline region. The voids and cracks could well be artifacts introduced during the sectioning. Our experiences in the ultramicrotomy indicate, however, that the cracks introduced during the sectioning appear generally as lines of differing widths running approximately perpendicular to the direction of the sectioning. In the present case, the

cracks introduced during the sectioning should appear as vertical cracks, since the direction of the sectioning is approximately parallel to the metal/oxide interface. No such cracks are readily apparent in the γ' -crystalline region of the composite oxide barrier layer. Therefore, our view is that the voids and cracks represent largely genuine features, although it is difficult to exclude totally the possibility that the original features of the voids and cracks might have been distorted to some extent during the sectioning operation.

It is interesting to note that the γ' -crystalline region, containing voids and cracks, is seen to be separated from the hydrous oxide layer by a thin barrier oxide layer, about 20 nm thick, which is not penetrated by the cracks and appears relatively featureless. The thin barrier oxide layer appears to prevent the penetration of water into the voids and cracks in the γ' -crystalline region and to also prevent the escape of O_2 gases known to be trapped within the voids and cracks under an extremely high pressure or even as a condensed state (5, 6).

In the fabrication of aluminum electrolytic capacitors, freshly anodized foils are usually given a short-time immersion in a boiling distilled water and then reanodized to the original anodizing voltage to obtain the composite oxide films of stable electrical property. It is readily understood that the role of the boiling water treatment prior to the reformation is to accelerate the complete conversion of the thin protective barrier oxide layer, separating the γ' -crystalline region and hydrous oxide into a nonprotective porous hydrous oxide.

In Situ X-Ray Diffraction of Surface Layers on Lithium in Nonaqueous Electrolyte

Gholamabbas Nazri* and Rolf H. Muller*

Lawrence Berkeley Laboratory, Materials and Molecular Research Division, Berkeley, California 94720

X-ray diffraction, combined with electrochemical techniques, has been used for the *in situ* identification of materials on electrode surfaces based on their crystal structure during the progress of electrochemical reactions. This approach avoids some long-recognized problems of *ex situ* measurements, which may not represent the na-

*Electrochemical Society Active Member.

ture of electrode materials because changes can occur upon transfer out of the electrochemical environment, when potential control is not possible (1-3). The combination of different *in situ* techniques has been reviewed by several authors (4-8).

Previous studies with x-ray diffraction from electrodes includes work by Salkind *et al.* (9), who obtained x-ray

patterns of iron electrodes during cycling in alkali using sealed polyethylene bags. Salkind and Bruins used *in situ* x-ray diffraction to study the Ni electrode in Ni-Cd cells during charge and discharge (10). Falk determined x-ray diffraction patterns of submerged positive and negative electrodes of Ni-Cd cells during charge and discharge (11). Recently, Fleischmann *et al.* used a position-sensitive proportional counter as x-ray detector to study the UPD of Pb on Ag and the adsorption of I_2 on graphite (12, 13). Fleischmann's work indicates that, with use of a sensitive detector, x-ray diffraction is capable to determine diffraction from a monolayer. Unlike LEED, Auger, and ESCA, for which the electrode must be removed

from the electrochemical environment and exposed to ultrahigh vacuum, the specimen can remain under electrochemical control during *in situ* x-ray diffraction. Another *in situ* x-ray technique is represented by the use of high intensity beams, usually provided by an electron storage ring for EXAFS electrode studies (14). EXAFS is able to provide information on short-range order such as distance and number of nearest neighbors and is particularly useful for amorphous compounds and clusters with short-range order.

In this work, *in situ* x-ray diffraction, using a conventional x-ray source and detector, has been applied to the

study of surface layers formed on lithium in nonaqueous electrolytes. The properties of these surface layers are important for the charge and discharge behavior of lithium electrodes in ambient-temperature batteries. Because of the high reactivity of lithium, use of *in situ* techniques for the characterization of surface layers is essential.

Experimental

The arrangement for *in situ* x-ray diffraction from electrode surfaces is illustrated in Fig. 1. A commercial diffractometer (Siemens Model D500) has been used. A collimated x-ray beam is directed toward the electrode surface at a fixed, glancing angle (6° from the surface), and the diffracted x-rays are measured by a rotating detector. In contrast to traditional x-ray diffraction, in which sample and detector are rotated, this arrangement enhances sensitivity for the surface region, although it does not detect monolayer films. The cell containing the electrode is shown in more detail in Fig. 2. The cell body was made of polypropylene and contained the working electrode of 1.9 cm diam in the center, surrounded by a 3 mm wide counterelectrode. A lithium reference electrode of 3 mm diam was located between working and counterelectrodes. Electrolyte could be injected and removed from the cell by the use of two syringes, which were connected to the cell with Teflon spaghetti tubing. Electrodes and electrolyte were separated from the atmosphere by a polyethylene or Mylar window 0.3 mm thick. The x-ray beam enters and exits through this window, which is sealed by use of an O-ring and a washer.

The cell is assembled in an inert atmosphere box where the nonaqueous solution (1.5M LiCl₄ in propylene carbonate) is also prepared. Permeation of water through the cell window in air over the time of the measurements was found to be negligible (no change in water concentration observed by cyclic voltammetry) (15, 16).

Results and Discussion

Results are illustrated by the formation of surface layers on lithium during its cathodic deposition at 1 mA/cm² from 1.5M LiClO₄ on a nickel substrate. Figure 3 shows a broad peak at low diffraction angle (20°), which is characteristic of polymeric compounds. This peak cannot be caused by adsorbed electrolyte because the present arrangement is not sensitive to monolayers. Also, the peak remains after evaporation of the electrolyte in vacuum. Figure 4 shows the much sharper diffraction peak characteristic of lithium carbonate. Both peaks increase with time. The identification of the two film materials agrees with earlier analyses by IR spectroscopy, SIMS, and ESCA (17). In the presence of trace amounts of water, the formation of Li₂O has also been observed. Use of a position-sensitive x-ray detector would make it possible to detect monolayer films and to collect diffraction data on a millisecond time scale, which would be of interest for mechanistic studies of nucleation, film formation,

and phase transformation during the application of potential or current pulses (18-21).

Kinetic Parameters of the Electro-Oxidation of Adsorbed Methanolic Fragments on Platinum in Acid Solution

D. Brynn Hibbert* and Foo Y. Y. Yon-Hin**

Department of Chemistry, Royal Holloway and Bedford New College, Egham Hill, Egham, Surrey, England

Several workers (1-3) have studied the properties of adsorbed methanol with a view to elucidating the mechanism of this potentially important fuel cell reaction (4). It is thought that the rapid adsorption of methanol occurs giving fragments having the formulas COH or COOH (5-8)

*Electrochemical Society Active Member.

**Electrochemical Society Student Member.

and, eventually, CO (9). The fragment (CHO⁺) has been detected after a platinum emitter was exposed to methanol vapor (10). At potentials below 0.6V (*vs.* SHE), the slow step in the oxidation is thought to be the reaction of the adsorbed fragment with an adsorbed hydroxyl radical (6). The work presented here has measured the rates of oxidation of adsorbed methanol at potentials between 0.6 and

1.0V and temperatures between 0° and 40°C by a potentiostatic step method and by steady-state current-voltage measurements. The oxidation of fragments from fully deuterated methanol has also been studied.

Experimental

Materials.—Spectroscopically pure methanol and 99.5%D CD₃OD were used without further purification. Sulfuric acid (0.5 mol dm⁻³) was prepared from AR-grade sulfuric acid and distilled, deionized water. Platinum foil electrodes (1 cm² Johnson Matthey 99.99% pure) were chemically cleaned (nitric acid, distilled water, tetrachloroethylene, distilled water) and then repeatedly cycled between -0.2 and +2.0V vs. SHE in the sulfuric acid electrolyte until the cyclic voltammogram was reproducible. The electrochemical surface area of the electrodes was measured by constant current charging curves (11).

Apparatus.—All electrochemical measurements were made in a nitrogen-purged, three-electrode cell against a dynamic hydrogen reference electrode (DHE). The DHE was found to be at a potential of -25 mV against a bubbling hydrogen electrode in the same electrolyte.

Method.—A platinum electrode was held at +0.15V vs. DHE in 0.5 mol dm⁻³ sulfuric acid for some minutes, after which it was dipped in methanol, dried for 2-3 min, and reintroduced into the cell, again at 0.15V. All solutions were thermostated ($\pm 0.2^\circ\text{C}$) at the working temperature and purged with nitrogen. The potential was then stepped to the working voltage (0.6-1.0V) and the current measured with time. Steady-state potentiostatic measurements were made on a 0.1 mol dm⁻³ methanol solution in 0.5 mol dm⁻³ sulfuric acid using a Thompson Associates potentiostat. In all cases, blank experiments in the absence of methanol were carried out and, where appropriate, results have had this background component subtracted from them.

Results

Steady-state current voltage data are shown in Fig. 1 for a range of temperatures. The data taken above 0.7V were fitted to an expression of the form

$$\ln i = \ln(A) + (E - \alpha FV)/RT$$

Fig. 1. Tafel plots for the oxidation of methanol (0.1 mol dm⁻³) in sulfuric acid (0.5 mol dm⁻³) at a platinum electrode. Open circles: $T = 290.0$ K. \times : $T = 298.5$ K. Closed circles: $T = 305.0$ K. +: $T = 314.2$ K.

Fig. 2. Current response on stepping a platinum electrode from 0.15 to 0.80V (vs. DHE) in 0.5 mol dm⁻³ sulfuric acid at 291.0 K. Full line: electrode with adsorbed methanol. Broken line: clean electrode.

with $\ln(A/A \text{ cm}^{-2}) = 15.31 \pm 0.07$, $E = 36.1 \pm 0.2 \text{ kJ mol}^{-1}$, $\alpha = 0.10 \pm 0.05$.

A typical transient current response on stepping a methanol-adsorbed electrode from 0.15 to 0.8V is shown in Fig. 2. The data quoted for the higher potentials have been corrected for the small oxidation current on a pure platinum surface. These data are plotted as $\ln(i_t - i_t^{\text{blank}})$ against t (Fig. 3) and the first-order rate constant (k) de-

Fig. 3. First-order plot of the transient current response on stepping a methanol-adsorbed electrode from 0.15 to 0.8V in 0.5 mol dm⁻³ sulfuric acid at 297.5 K.

Fig. 4. First-order plots of the transient current response of the oxidation of adsorbed methanolic fragments from CH_3OH (○) and CD_3OD (●). Voltage step 0.15-0.80V, $T = 299.5$ K. Electrolyte 0.5 mol dm^{-3} sulfuric acid.

terminated from the slope of the line. Data from such experiments conducted between 0.7 and 1.1V and 275.0 and 313.3 K (20 experiments in all) were fitted to

$$\ln(k) = \ln(A) - (E - \alpha FV)/RT$$

with $\ln(A) = 10.8$, $E = 39.2 \text{ kJ mol}^{-1}$, and $\alpha = 0.10$. The total charge passed during oxidation of the fragments was measured and compared with the charge required to oxidize the electrode surface in a galvanostatic experiment. In all cases, the coverage of the adsorbed species was less than 0.1. The oxidation of adsorbed deuterated methanol was measured between 0.8 and 1.0V and 292.0 and 311.0 K. No kinetic isotope effects were observed (that is, similar values of the rate constant k were measured at a given temperature and potential), as may be seen in Fig. 4. In all experiments, however, a greater coverage of the deuterated species was observed, the ratio of the coverages of normal and deuterated methanolic fragments being approximately 1:1.5.

Discussion

The current passed when a potential is applied to an electrode with adsorbed methanol shows an exponential decay, indicating a first-order oxidation of the adsorbed species

$$i/nF = dC_{\text{ads}}/dt = kC_{\text{ads}} \quad [1]$$

where C_{ads} is the concentration of the surface species. As-

suming an irreversible oxidation, the current is

$$\begin{aligned} i &= nFC_{\text{ads}}A \exp(-E/RT) \exp(\alpha F\eta/RT) \\ &= nFC_{\text{ads}}A \exp(-E'/RT) \exp(\alpha FV/RT) \end{aligned} \quad [2]$$

where E' is an activation energy at the zero of potential to which V is referenced. Comparison of Eq. [1] with [2] shows

$$k = A \exp(-E'/RT) \exp(\alpha FV/RT) \quad [3]$$

The solution of Eq. [1] is

$$C_{\text{ads}} = C_{\text{ads}}^0 \exp(-kt) \quad [4]$$

and, thus, combining Eq. [2] with Eq. [4]

$$i = nFC_{\text{ads}}^0 k \exp(-kt) \quad [5]$$

A plot of $\ln(i)$ against t yields k , the potential and temperature dependence of which allows the determination of E' and α . The measurement of current transients on stepping the potential gives useful information on the kinetics of the oxidation of surface species. The correspondence between the kinetics of the steady-state oxidation of methanol and the oxidation of adsorbed methanolic fragments suggest a similarity in the rate-determining step. This is consistent with the proposal of Bagotzky and Vassilyev (6) that

is rate limiting. This step is also consistent with the lack of isotope effect between CDO_{ads} (from CD_3OD) and OH_{ads} , the adsorbed hydroxyl coming from the normal electrolyte. Wiekowski (12) has found a kinetic isotope effect in the oxidation of methanol in H_2SO_4 and D_2SO_4 , which is also consistent with the proposed mechanism.

Bewick has shown that the ultimate species which is present at a platinum surface from several precursors is CO (9, 13). The oxidation of CO_{ads} would, of course, show no deuterium isotope effect. Considering the time scale of the experiments presented here, CO may indeed be the fragment which is oxidized. We note, however, that in recent studies of the oxidation of HCOOH and DCOOH on lead adatom covered platinum (14) a deuterium isotope effect of 2.6 was observed suggesting an initial rate-determining step involving the cleavage of the CH bond.

ABSTRACT

Cross-linked positive resists derived from copolymers of methacrylonitrile (MCN) and methacrylic acid (MAA) have been developed based on the theoretical formula which shows that a large $M_w \times G_s$ value is essential to improve the cross-linked positive resist sensitivity, where M_w is the weight-average molecular weight and G_s is the main chain scission efficiency. The cross-linked positive resist consists of P(MCN₉₂-MAA₈) with a viscosity-average molecular weight (\bar{M}_v) of 5.7×10^5 and tripropylene glycol diglycidyl ether (TPG) as a cross-linking agent. It has high sensitivity ($3 \mu\text{C}/\text{cm}^2$) and high dry-etch resistance, reflecting the large $M_w \times G_s$ value of the copolymer and the high dry-etch resistance of the MCN component. The resist is applied to a trilayer resist system as the top imaging layer. Submicron fine patterns delineated at $3.4 \mu\text{C}/\text{cm}^2$ are transferred to the thick organic layer, and high aspect ratio patterns are obtained.

Cross-linked positive resists were suggested to attain high sensitivity and good resolution (1-4). In cross-linked positive resists, linear polymers are cross-linked *in situ* on the substrate by heat or light to form an insoluble gel before the exposure. Only the exposed part is changed into a soluble material. The dose Q required to make the exposed part completely soluble is approximately written as

$$Q \cong \frac{200\rho N_A(\delta - 1)}{G_s A M_w}$$

where ρ is the polymer density, N_A is Avogadro's number, δ is the cross-linking coefficient, G_s is the G value for scission, A is the proportionality constant, and M_w is the weight-average molecular weight (5). This formula shows a large $M_w \times G_s$ value is essential to attain high sensitivity in cross-linked positive resists. On the other hand, dry-etch resistance is an inherent property of a resist material. Gokan *et al.* showed that the etch rate of the organic resist materials under ion bombardment condition had a linear dependence on the $N/(N_c - N_o)$ value, where N , N_c , and N_o denote the total number of atoms in a monomer unit, the number of carbon atoms in a monomer unit, and the number of oxygen atoms in a monomer unit, respectively (6). Since the polymers with the smaller $N/(N_c - N_o)$ value have the higher dry-etch resistance, a cross-linked positive resist derived from a polymer with a large $M_w \times G_s$ value and a small $N/(N_c - N_o)$ value is expected to be a positive resist with high sensitivity as well as high dry-etch resistance.

This paper reports the cross-linked positive resist consisting of methacrylonitrile (MCN) as a main constituent. MCN was selected because PMCN has a high G_s value [$G_s = 3.3$ (7, 8)] and high dry-etch resistance (9) because of its small $N/(N_c - N_o)$ value.

Molecular Design

In Table I, G_s values and $N/(N_c - N_o)$ values of well-known positive resists are listed with the qualitative estimates for their dry-etch resistance. PMCN and poly(α -

methylstyrene) (P α MeSt) have small $N/(N_c - N_o)$ values and high dry-etch resistance. Though P α MeSt shows the highest dry-etch resistance among investigated positive resists, its G_s value is too small. On the contrary, PMCN has a large G_s value while keeping high dry-etch resistance. Thus, MCN has been chosen as a main constituent for the cross-linked positive resist. Methacrylic acid (MAA) has been copolymerized with MCN to introduce a functional group which reacts with the cross-linking agent TPG. This cross-linking agent has been mixed with the copolymer so that the mixture contains equivalent quantities of epoxy and carboxyl groups.

Experimental

The copolymer of MCN and MAA has been synthesized by free radical polymerization. The viscosity-average molecular weights (\bar{M}_v) were measured using acetone as a solvent, assuming that the constants values in the Mark-Houwink equation relating η to \bar{M}_v were the same as those for PMCN. MAA content was measured by titration and elemental analysis. The \bar{M}_v values and MAA contents of the copolymers synthesized are shown in Table II.

Table I. G_s values and dry-etch resistance of positive resists

Polymer	G_s	$N/(N_c - N_o)$	Dry-etch resistance	Ref.
PMCN	3.3	2.5	Good	(7, 9)
PMMA	1.3	5.0	Fair	(14)
PMIPK	1.1	3.5	Fair	(15)
PMAAN	2.9	4.2	Fair	(7)
P α MeSt	0.3	2.1	Very good	(16)
PBS	11.0	4.7	Poor	(17)

PMCN: Poly(methacrylonitrile)
 PMMA: Poly(methyl methacrylate)
 PMIPK: Poly(methyl isopropenyl ketone)
 PMAAN: Poly(methacrylic anhydride)
 P α MeSt: Poly(α -methyl styrene)
 PBS: Poly(butene-1-sulfone)

Table II. Viscosity-average molecular weights and MAA contents of MCN-MAA copolymers

Sample no.	Polymer	$\bar{M}_v (\times 10^4)$	MAA content (m/o)
1	P(MCN ₉₁ -MAA ₉)	10	9.1
2	P(MCN ₈₅ -MAA ₅)	1.91	5.3
3	P(MCN ₈₉ -MAA ₁₁)	7.17	11.4
4	P(MCN ₉₂ -MAA ₈)	57.0	7.9
5	P(MCN ₉₁ -MAA ₉)	32.1	9.0

The mixtures of P(MCN-MAA) and TPG were dissolved in cyclohexanone (the polymer was 5-7 weight percent of the solution), spin coated on silicon wafers, and prebaked at 90° to 100°C for 1h in flowing nitrogen. Hiraoka *et al.* reported P(MCN-MAA) as a deep-UV resist (10). As shown in Fig. 1, this copolymer undergoes a cyclization reaction at temperatures over 120°C (11), which gives a broad UV-absorption band with the maximum at 246 nm. In the present experiment, a cross-linking agent TPG was added and prebaking condition was set to form cross-linkages without the formation of ring structures (Fig. 2). No infrared spectral change or color formation was observed by baking even at 110°C for 1h.

Electron beam exposures were carried out at 20 kV accelerating voltage with a JEOL JBX-5A electron beam exposure system. Sensitivity was measured on a 60 × 60 μm square pattern. The cross-linking coefficient δ was calculated from the gel fraction assuming that the molecular weight distribution of polymer follows a Poisson distribution and the weight-average molecular weight approximately equals the viscosity-average molecular weight. The gel fraction was estimated by measuring the thickness of the cross-linked polymer system before and after soaking in acetonitrile (MeCN) for more than 16h to wash out the sol fraction completely.

The resist-layer thicknesses were measured with a Taylor-Hobson Talystep instrument. Fine patterns obtained after the development were checked by an optical microscope and a scanning electron microscope.

Etching rates for P(MCN₉₁-MAA₉), PMCN, polystyrene (PS), polymethylmethacrylate (PMMA), and Shipley photoresist AZ-1350J were measured using Ar ion milling and CF₄ + H₂, CCl₃F + O₂, and CCl₄ + air reactive ion beam etching (RIE).

A Kaufman-type 3 in. ion gun (Veeco) and a 10 in. diffusion pumping system were used in Ar ion beam etching. The etching condition was 2 × 10⁻⁴ torr Ar pressure, 500 eV acceleration energy, and 0.83 mA/cm² ion current density. The RIE system was a parallel-plate reactor. The etching conditions are described in Table III. The target materials were polypropylene, quartz, and stainless steel for CF₄ + H₂, CCl₃F + O₂, and CCl₄ + air RIE, respectively.

Results and Discussion

Sensitivity.—The obtained sensitivity (Q_{exp}) for each molecular weight P(MCN-MAA) + TPG system with its theoretical sensitivity (Q_{theo}) is shown in Table IV. In a fine pattern fabrication, a MeCN and toluene (Tol) solution was used because it was found to be a good developer from the resolution standpoint. Except for the case when a strong developer is used to wash out the sol completely, the sensitivities measured are lower than the theoretical values. The explanation for this phenomenon will be given as follows. The M_w value is infinite at the gel point dose (D_g^1), and the M_w at a dose a little higher than

Fig. 2. Cross-linkage formation in a P(MCN-MAA) + TPG system

D_g^1 is quite high. The ultrahigh molecular weight polymer molecules that are almost insoluble in a developer exist in the exposed area. These ultrahigh molecular weight polymer molecules remained after the development in a 1:1 MeCN and Tol solution and are observed as remaining thicknesses. A practical electron exposure requires degradation of not only an insoluble gel but also ultrahigh molecular weight polymer molecules so that the smaller molecular weight molecules can be dissolved by the proper developer. Polymer 4 [P(MCN₉₂-MAA₈), $M_v = 5.7 \times 10^5$] showed the highest sensitivity among the systems developed with the practical developer. The exposure characteristics for the P(MCN₉₂-MAA₈) $M_v = 5.7 \times 10^5$ + TPG system are shown in Fig. 3. These exposure characteristics look unusual because of the surface roughness after development. The gel fraction of this sample is 52%. This means a large amount of sol is washed out in a developer leading to the surface roughness even though the moderate developer is used.

Resolution.—The development of the cross-linked positive resist is similar to that of the negative resist. The most important factor influencing the resolution is the swelling during the soak in a developer; therefore, to find the developer that minimizes the swelling is very important. Dimethylformamide, dimethylsulfoxide, benzonitrile, MeCN, and acetone were selected as good solvents, and Tol and isopropanol (IPA) were chosen as poor solvents. Good solvents and mixed solutions of a good solvent and a poor solvent were tried at various component ratios. As a result, a 1:1 MeCN and Tol solution was found to be a proper developer minimizing the swelling. It has been found that soaking in MeCN for 10 min to wash out the sol fraction before the electron exposure has a favorable effect on the resolution; that is, it prevents scum in the exposed area and improves the surface roughness in the unexposed area. This is because of two favorable effects: the initial resist thickness has been thinned and soluble materials washed out. Though this soaking procedure lessens the resist sensitivity [for example, from 3.0 to

3.4 $\mu\text{C}/\text{cm}^2$ for P(MCN₉₂-MAA₈) ($\bar{M}_v = 5.7 \times 10^5$) + TPG system] and increases the number of process steps, a fine pattern is delineated at 3.4 $\mu\text{C}/\text{cm}^2$ which is a high sensitivity among positive resists. Patterns obtained with P(MCN₉₂-MAA₈) ($\bar{M}_v = 5.7 \times 10^5$) + TPG are shown in Fig. 4.

Dry-etch resistance.—Etching rates for P(MCN₉₁-MAA₉), PMCN, PS, PMMA, and AZ-1350J under various etching conditions are shown in Table III. Though a quantitative relation between the etching rates and the chemical structures under the RIE conditions is not easily found, the sequences of etching resistance are the same under every etching condition. The sequence from the polymer with higher resistance is

This sequence is paralleled by the corresponding $N/(N_c - N_0)$ values from the lowest value to the highest. This shows that $N/(N_c - N_0)$ value can be taken as a criterion for the polymer's dry etching resistance. Very few positive resists are highly resistant to dry etching and highly sensitive at the same time. The dry-etch resistance of P(MCN₉₂-MAA₈) is almost the same as that of P(MCN₉₁-MAA₉), which is 1.4-1.8 times as high as that of PMMA. This resistance is good for a positive resist, considering the sensitivity of P(MCN₉₂-MAA₈) $\bar{M}_v = 5.7 \times 10^5$ + TPG system is 3.4 $\mu\text{C}/\text{cm}^2$, which is 35 times as high as that of PMMA.

Fig. 3. Exposure characteristics for P(MCN₉₂-MAA₈) + TPG. Development: MeCN/Tol = 1/1; 5 min. Rinse: IPA, 1 min.

Fig. 4. Scanning electron micrographs of resist profiles delineated in 0.3 μm thick P(MCN₉₂-MAA₈) + TPG as a top imaging layer in a trilayer resist system. The white bar represents 1 μm .

Fig. 5. Scanning electron micrographs of high aspect ratio patterns obtained by successive etching of organosilica film and AZ bottom layer. Fig. 5a (top) and 5b (bottom) correspond to Fig. 4 (top) and 4 (bottom), respectively.

Application to a trilayer resist system.—P(MCN₉₂-MAA₈) is so highly resistive to CF₄/H₂ RIE that it is etched only 60Å (7.5 Å/min), while an organosilica film is etched 2400Å (300 Å/min) when the etching condition is chosen properly (CF₄/H₂ = 10/2, 0.12 W/cm², 80 mtorr, 60 sccm, 8 min). An organosilica film is quite resistive to O₂ RIE and is etched only 163Å (16.3 Å/min), whereas AZ-1350J photoresist is etched 8500Å (850 Å/min) (O₂, 0.08 W/cm², 60 mtorr, 30 sccm, 10 min).

The cross-linked positive resist was applied as the top imaging layer in the trilayer resist system (12, 13). It consisted of a 1.0 μm thick AZ-1350J photoresist as a bottom layer, a 0.1 μm thick spin-coated organosilica film as an intermediate layer, and a 0.3 μm thick top imaging layer. The cross-linked positive resist was soaked in MeCN for 10 min to wash out the sol before exposure. The exposure dose was 3.4 μC/cm². The resist was developed in a 1:1 MeCN and Tol solution for 5 min, then rinsed in IPA for 1 min.

High aspect ratio patterns were obtained by successive etching of the organosilica film and the thick AZ-1350J photoresist layer. (CF₄/H₂ RIE: CF₄/H₂ = 10/2, 0.12 W/cm², 80 mtorr, 60 sccm, 8 min; O₂ RIE: 0.08 W/cm², 60 mtorr, 30 sccm, 12 min). The resultant profiles are shown in Fig. 5.

Conclusion

A highly sensitive cross-linked positive resist with high dry-etch resistance has been developed according to the two theoretical formulas which define the highest sensitivity attainable for cross-linked positive resists and the resist etching rate's linear dependence on the $N/(N_c - N_0)$ value. The resist consists of P(MCN-MAA) and TPG as a cross-linking agent.

A submicron fine-line pattern was obtained at 3.4 μC/cm² using P(MCN₉₂-MAA₈) ($\bar{M}_v = 5.7 \times 10^5$) + TPG cross-linked positive resist. The developed cross-linked positive resist has been applied to a trilayer system as the top imaging layer. High aspect ratio patterns were obtained by successive etching of an intermediate layer and a bottom layer.

Morphological Clue to a Pyrolytic Thin Film Growth Mechanism

Charles B. Greenberg*

PPG Industries, Incorporated, Glass Research and Development, Pittsburgh, Pennsylvania 15238

ABSTRACT

Methods for forming thin, transition metal oxide films pyrolytically from liquid spray vehicle are well known. On the one hand, there are the uniform and finely crystallized spinel-structured films grown from organic solutions of acetylacetonates; one of these is herein reviewed. A spectrally similar film grown from aqueous solution, of another spinel composition (1), is not so well formed. This film's relatively gross morphology is a clue to its growth mechanism. The morphology can be explained qualitatively by invoking a model for closely associated phenomena characteristic of spray drying (2). By this model, solid or partially molten metal-organic material approaches the hot substrate in the form of roughly spherical, porous, hollow shells. These remain after solvent evaporation from the droplets of the liquid spray. The hollow shells vaporize on the approach to the substrate, and the film grows by a CVD reaction at the substrate. Constituents which do not readily vaporize, such as impurities, impact the substrate and imprint a morphological pattern of collapsed shells. These comprise the rare clue for the analysis and for modeling film growth.

Thin, transparent, transition metal oxide films have been prepared by organic-based pyrolytic spray for many years. They are known to be very uniform and are often quite durable. The latter implies abrasion resistance as well as broad chemical stability. A cobalt-iron-chromium oxide film with these attributes is widely used architecturally in windows for its good solar attenuation (3). The film is grown on a hot, pristine soda-lime-silica float glass surface. It is deposited from a chlorinated hydrocarbon solvent containing acetylacetonates of the transition metal cations (4); a pneumatic spray traverses the moving glass normal to its path. The temperature of the glass $\approx 565^\circ\text{C}$. To preserve both the transparency of the film and its visual uniformity, primarily its freedom from iridescence, the physical thickness must be limited. The upper limit for the high cobalt oxide containing composition of particular interest is about 400\AA . This film is herein reviewed because it sets a standard for preferred morphology. By contrast, a film grown from an aqueous solution containing cobaltous acetate and methyltin chloride is of a less desirable morphology, which suggests the mode of film formation. This constitutes the real focus of discussion herein.

The Organic-Based Film

Film composition and morphology.—A typical composition for the organic-based film, as determined by atomic absorption analysis, is shown in Table I. Assuming a dense oxide structure, the film thickness is 400\AA , which is in agreement with interferometric measurements (5). The averaged composition and standard deviations are, in this instance, for six different 50 cm^2 samples of 3 mm thick glass. The spray solvent was a 1:1 mixture by volume of methylene chloride and trichloroethylene. The solution contained 125, 43, and 32 g/liter, respectively, of the acetylacetonates of trivalent cobalt, chromium, and iron; these were obtained from the Harshaw Chemical Company, Industrial Chemical Department. Figure 1 shows the characteristic microstructure for this film, obtained by using electron microscopy and C/Pt replication. The fine-grained morphology is accompanied by such low grain boundary porosity that the film blocks the otherwise instantaneous dissolution of underlying glass in 0.5% HF solution, at least for 5-10 min at room temperature. The film itself is generally slow to dissolve in various chemical agents, including the HF solution for 5-10 min and hot HCl, H_2SO_4 , NaOH, and NaCl solutions. Based upon the electron diffraction pattern's similarity to that of Co_3O_4 , the most probable film structure is that of a spinel; however, the individual transition metal ion valence states and unit cell sites are unknown.

Optical characteristics.—The curves in Fig. 2 show the reflectance and transmittance for a film in the 400-800 nm spectral range. The reflectance is high generally for an oxide. Values for the index of refraction and extinction

coefficient are given by $n-ik = 2.8 - i(0.5)$ at a wavelength of 550 nm. These values were calculated (6) from the optical data, corrected for substrate, and film thickness. The decimal precision in the calculated values is in large degree governed by film thickness, which is not known with better certainty than about $\pm 75\text{\AA}$.

The Aqueous-Based Film

Solution and film composition.—A Co-Sn-oxide film with virtually the same spectral properties is known from Michelotti and Ohlberg (1). Their spray formulation is an aqueous solution of cobaltous acetate (7) and methyltin chloride with the composition shown in Table II. The solution is acidic, with $\text{pH} = 4.4$, controlled by addition of acetic acid; the latter can be complexing for Co(II) (8). Sn(IV) is known to be very susceptible to hydrolysis with standing (9, 10), although perhaps it is inhibited by the carbon bonding in organotin halides. The possibility of hydrolysis is to be considered again in the interpretation of data. The electron diffraction pattern of the film indicates a spinel structure similar to Co_3O_4 , a result in common with the organic-based film. The ratio Co:Sn in the film is approximately that of the solution.

Cylindrical defect morphology at low magnification.—Generally, there are two ways in which cobalt oxide containing films prepared from aqueous solution, with or without Sn(IV), are of poorer uniformity. Aside from a tendency to be visually textured, they are susceptible to haziness, except where great care is taken to maintain solution purity. At least for the purpose of viewing in conditions that are not overly rigorous, the haze can be avoided. In Fig. 3 is an optical micrograph in pseudo-three-dimensional relief for a cobalt-tin-oxide film which exhibits no qualitatively discernible haze in normal viewing conditions. It was prepared with reagent grade cobaltous acetate and recrystallized methyltin chloride; distilled water was used for both recrystallization and preparation of the solution (11). The cylindrical and nearly cylindrical features, of comparatively low profile here, are projections above the plane of the film. Viguié and Spitz (12) showed a similar cylindrical feature in a pyrolytic iron oxide film prepared from an HCl solution of ferric chloride. While recognizing the spray droplet-to-

vapor pathway in general for uniform film growth, they did not expand on the defect's origin.

There are typically many more prominent cylindrical features at low optical magnification in films prepared from solutions of low purity. This is shown by the photo-

Fig. 2. Characteristic spectral curves for an organic solvent-based, spinel film. Data were obtained with a Beckman DK-2A Spectrophotometer, with an integrating sphere and angle of reflection of 8° . Transmittance was corrected with sufficient approximation by dividing by that for the uncoated glass at each wavelength.

Table II. Michelotti-Ohlberg aqueous solution (I)

Constituent	Concentration (weight percent)	Solute
Co(II)	4.8	$\text{Co}(\text{C}_2\text{H}_3\text{O}_2)_2 \cdot 4\text{H}_2\text{O}$
Sn(IV)	0.5	Methyltin chloride [80% $(\text{CH}_3)_3\text{SnCl}_2$ and 20% CH_3SnCl_3]
CH_3COOH	5.0	Glacial acetic acid

micrograph in Fig. 4, which suggests generally greater defect height above the plane of the film. Haze or light scattering is also very readily visible in the film.

Elevated defect relief is indicated from electron microprobe analysis of a cobalt oxide film that was prepared from aqueous solution of unspecified purity. In solution were cobalt acetate and acetic acid, approximately in the concentrations of Table II. Signal intensities for selected film and substrate constituents were normalized to the signal intensity for cobalt and were compared in and around high projections ($\sim 100\text{\AA}$); the more typical morphological features could not be resolved generally by microprobe counting. The normalized intensity for calcium, a major glass constituent, was typically $\sim 20\%$ less from within a defect than from substrate underlying defect-free film. This suggests in-defect masking of the substrate, that is elevated relief. Positive in-defect identifications were made for compounds of nickel and iron. The normalized in-defect probe signal for nickel impurity was typically approximately four times more intense than that for defect-free film; for iron the intensity was approximately two times greater. In general, nickel is a prin-

Fig. 3. Typical optical micrograph for the Co-Sn-oxide film prepared on a pristine glass surface from purified aqueous solution, showing characteristic raised features. Zeiss/Nomarski differential interference-contrast microscopy was used with reflected light. Background patchiness is associated with film texture.

Fig. 4. Typical Zeiss/Nomarski optical micrograph for a Co-Sn-oxide film similarly prepared from impure aqueous solution, showing the characteristic raised features even more distinctly. The metal compounds in solution were industrial grades; nickel is a major noncobalt impurity.

cial impurity in cobalt acetate, and iron is a minor one. In the impure cobalt acetate used for the cobalt-tin-oxide sample of Fig. 4, the nickel content is within 0.2-0.7% by weight. The iron content <0.01%. These are known from emission spectrographic analysis. This impure solution also contains ~0.2% fluoride as HF, an earlier batch constituent (1).

Morphological features such as those in Fig. 3 and 4 are not observable at all at low magnification in a Sn(IV)-free cobalt oxide film made from reagent-grade cobaltous acetate. This indicates that cobalt acetate by itself is not a significant contributor to defects, although the low profile defects in Fig. 3 suggest methyltin chloride may still be. Yet, in the aforementioned microprobe analysis, the signal for cobalt in-defect was greater than that of surrounding cobalt oxide film by about 25%. It is assumed that this is indicative of nonacetate impurities of cobalt. As the cobalt signal was approximately twenty times stronger within the defect than that for nickel, it was used for the indicated estimate of defect height for high projections. Apparently, the height of more typical defects above surrounding film <100Å, which is well below the typically micron-sized diameters in Fig. 3 and 4. These dimensions suggest a model.

The Charlesworth-Marshall model.—It is not necessary to invoke the impact of liquid droplets of aqueous spray to explain these particular features, even though physical appearances of the photomicrographs might suggest it. With such improbable collisions, it is likely that distinctly raised features would always occur at the points of impact, by instantaneous pyrolysis *in situ* (12). They do not occur with reagent-grade cobalt acetate. The same consideration very likely excludes the impact of a molten or

solid cobalt acetate droplet also. Rather, a reasonable explanation is to be found in the spray drying work of Charlesworth and Marshall for dissolved solids (2). These authors concerned themselves with vaporization of the solvent, not the solute. They showed the various configurations which an aqueous spray droplet takes when it is being dried, the most likely one of which is represented in Fig. 5 for the case at hand. Initially, while the coating droplet is in flight, and while receiving radiated energy from the glass, evaporation is from a free liquid surface. The droplet decreases in size at first, but then a solid, smooth, spherical or nearly spherical crust forms, with evaporation of liquid continuing from or through it. The crust is thus porous. In most cases observed by Charlesworth and Marshall, admittedly with relatively large droplets, the final particle was a hollow, thin, and nearly spherical crust. This was the result with a rigid but porous solid, as compared with one pliable and non-porous. By analogy, with the aqueous solution of Table II therefore, metal-organic vaporization and film growth proceed from a hollow solid crust after complete vaporization of the solvent. This situation is most likely to exist late in a droplet's flight, nearest the hot substrate.

If an impurity or a coating constituent, perhaps methyltin chloride, does not vaporize readily, it constitutes a part of a residual spherical skin that impacts the glass. The residual skins of the many spray droplets give the film its characteristic morphology at low optical magnification.

Vaporization and film growth.—It has been suggested that hydrolysis occurs first, and then the film grows by (13)

That, however, is not consistent with bulk simulations of the liquid in the droplet. With regard to the dry crust itself, its temperature will exceed that of the liquid boiling point, and hydrolysis of cobalt acetate is not likely (14). After refluxing a 500 cm³ volume of impure solution at about 90°C for 0.5h, there was no evidence for hydrolysis

Fig. 5. A Charlesworth-Marshall droplet approaching a hot substrate

beyond solubility limits on a 3 μm Millipore MF-type membrane filter. Not even when heated to dryness to 100°C was there any significant hydrolysis or oxidation of Co(II), nor any unmethylated Sn(IV) hydroxide or oxide. That is, there were no significant formations of insoluble materials left on 3 μm filter paper after redissolving the dried material in water. The metal oxides and hydroxides are generally insoluble in water. One might even speculate that impurity hydroxides present initially could be of shape and size to cause the defects in Fig. 3 and 4 without invoking the drying model. This was, however, not observed when impure solution was filtered in advance of these bulk simulation experiments.

With the loss of bound water at 140°C for $\text{Co}(\text{C}_2\text{H}_3\text{O}_2)_2 \cdot 4\text{H}_2\text{O}$, it is assumed that the crust thereafter contains, aside from impurities, the anhydrous acetate and unidentified methyltin compounds. Judging from the dried bulk, the methyltin compounds are water soluble, and perhaps undecomposed from the original, up to at least 100°C. For the major constituent in the dried solid shell(s)

and there are two possible routes to vaporization (14)

and/or

Sublimation has been reported with relatively slow heating in air and vacuum, and partial melting has been observed with decomposition at temperatures $\geq 255^\circ\text{C}$. Either way, pyrolysis and film growth may proceed on the hot surface from the gas phase, with the evolution of CH_3COOH , H_2O , and CO_2 (14). However, for the purpose of comprehending the morphology in Fig. 3 and 4, it is certainly more consistent to assume the validity of Eq. [2] than that of Eq. [3]. Otherwise, liquid surface tension works against a stable, hollow sphere.

It is appropriate to question whether an acetylacetonate particle is, prior to vaporization and pyrolysis, also in the configuration of a hollow, solid sphere. Even in the presence of known impurities, however, this has not been observed. Perhaps this relates in some way to the generally high vapor pressures of chlorinated hydrocarbons, relative to the less readily evaporated water. On the other hand, perhaps the relatively easy sublimation of acetylacetonate materials in general (15, 16) is an important difference. This matter is unclear in part because films grown from acetylacetonates lack the pronounced morphology that characterizes films prepared from aqueous solution.

Concluding Remarks

The method known as chemical vapor deposition, or CVD, is widely used for the growth of thin films of all sorts, particularly on a laboratory scale. As a typical example, acetylacetonates often are sublimed first and then carried to a hot substrate in a neutral gaseous vehicle. It is much less common, or at least not as well published aside from patent literature, to use a liquid carrier. Yet the latter, for many practical reasons, has lent itself best for coating substrates with thin, transparent films when the

emphasis has been on uniformity over a large area. It is most probable that morphologically good film formation with a liquid carrier, like other CVD, takes place entirely from the gas phase after vaporization. This view was expressed by Vigié and Spitz (12) and is reinforced by our own data. The liquid vehicle is, to a great extent, only a carrier. It is suggested herein that the aqueous vehicle in particular gives the in-flight, to-be-vaporized, metal-organic material its heretofore undisclosed shape as a hollow solid sphere, or nearly so. This follows from photomicrographic data, and microprobe scanning, for aqueous-based pyrolytic films and from a model by Charlesworth and Marshall (2) for spray drying of solutions. Finally, the analysis suggests that morphologically good films can also be grown from very fine metal-organic particles without liquid solvent, given proper dispersion in air and adequate momentum to the hot substrate. Various acetylacetonate-based systems have been described in recent patent literature to support this, which may well presage a technology in transition.

Acknowledgments

Several people have contributed to this work with their fine individual analytical efforts: H. R. Golob for electron microscopy and electron diffraction, J. M. Parsons for electron microprobe data, R. E. Robertson for atomic absorption analyses, and M. E. Helzel for spectrophotometry. I am grateful to J. O. Bookmyer and staff for helping with literature retrieval, and, as usual, to P. P. Harmon and N. Jauhar Seth for careful technical assistance. For the comments and constructive critiques of Dr. J. J. Finley and Dr. C. C. Lin, I am especially appreciative.

ABSTRACT

Tin oxide films were deposited by chemical vapor deposition on borosilicate and fused silica substrates using dibutyltin diacetate (DBTD) as tin feedstock and SbCl_5 or $\text{CCl}_3\text{-CF}_3$ as dopants. The film growth rate was measured as a function of dopant/DBTD ratio, temperature, and film thickness. Scanning electron microscopy and x-ray diffraction spectra of the films were used to determine the grain sizes and the preferential orientations of the crystallites in the film as a function of film thickness. Optical and electrical properties were measured. A model is proposed to elucidate the variation of transport properties of doped SnO_2 as a function of film thickness. It could be shown with this model that the thickness dependence of the conductivity of doped $\text{SnO}_2\text{:Sb}$ and $\text{SnO}_2\text{:F}$ films could be analyzed in terms of carrier concentration taking into consideration deep-level compensation. The number of carriers is decreased by electron trapping at Sb(III) or Sn(II) surface states when antimony or fluorine are used as dopant, respectively. The model based on results of the literature related to a single crystal with (110) orientation is extended in this work to other crystallite orientations. The present analysis indicates that deep levels appear only on the grain boundary surfaces with (110), (211), and (301) orientations, and not on the (200) and (400) ones. The concentration of free carriers can be calculated on the basis of x-ray diffraction spectra indicating an estimate of the relative fraction of the crystallites with each orientation as a function of the film thickness. The conductivities of the films can be computed using this model and taking a single value for the electron mobility of $19 \text{ cm}^2 (\text{V}\cdot\text{s})^{-1}$ for all film thicknesses and a total donor concentration of $2 \times 10^{20} \text{ cm}^{-3}$. All the obtained experimental data can be accounted for exclusively on the basis of film-thickness-dependent carrier concentration.

Tin oxide films have been extensively studied for their wide applications. Among these, they can be used in semiconductor-insulator-semiconductor solar cells (1) as a back contact in either CdS/Cu₂S structures (2) or photoelectrochemical devices (3). As well, such thin films deposited on silicon can protect it from photocorrosion in photoelectrochemical cells (4). For these applications, a high electrical conductivity and a high transparency, in the visible part of the spectrum, are required.

Tin oxide films have been prepared by various techniques. Detailed review papers have recently been published on the preparation and characterization of these layers (5-7). Chemical vapor deposition (CVD) of SnO_2 films using dibutyltin diacetate (DBTD) have been developed, and it was found that films with high conductivity and high transparency could be produced by this method (8-10). In these studies, antimony (V) chloride was used as a dopant. Recently, CVD of fluorine-doped SnO_2 films have been prepared using a Freon as a dopant (11).

The production of $\text{SnO}_2\text{:F}$ films doped with trichlorotrifluoroethane ($\text{C}_2\text{F}_3\text{Cl}_3$) is reported in this work. The latter compound has the advantage of being liquid at room temperature, so it can be transported through a saturator. It is also a cost efficient and noncorrosive chemical.

In the present paper, a systematic investigation for the thickness dependence of optical, structural, and electrical properties of antimony- and fluorine-doped tin oxide is reported. This work shows that structure, grain size, and optical and transport properties of the deposited layers are thickness dependent up to $1 \mu\text{m}$. For thicker films, transport properties become thickness independent, while structure, grain size, and optical properties of these layers undergo a continuous variation.

The electrical properties of the deposited layers were analyzed on the basis of a polycrystalline conduction model. It has been realized that the dominant crystal structure is of major importance in the elucidation of the

transport properties controlled by the grain-boundaries-generated trapping centers.

Experimental Procedures

The CVD setup consists of a resistance-heated Kanthal wire furnace (Lindberg, Model M-200) containing the reaction chamber made of a fused silica tube of 50 mm diam and 1.8 m long. An inner fused silica tube of 20 mm diam was used to bring the reactants in the middle of the reaction chamber separately from oxygen and nitrogen carrier gases. The substrates, being $2.5 \times 7.5 \text{ cm}$ borosilicate slides, were positioned at the downstream side of the reactor starting at about 8 cm from the end of the inner tube. Tin oxide films were prepared following the method of Kane and co-workers (8, 9) using DBTD (Kodak) as the tin feedstock and antimony (V) chloride (Alfa Products) or trichlorotrifluoroethane, Freon 113 (Dupont Canada, Incorporated) as a dopant. Nitrogen was bubbled through the saturators containing the tin feedstock and the dopant. The DBTD, SbCl_5 , and $\text{C}_2\text{F}_3\text{Cl}_3$ sources were maintained at temperatures of 100° , 25° , and 0°C , respectively, in order to obtain the required vapor pressure for each compound. Prior to deposition, the substrate was preheated for 5 min under a nitrogen gas flow which was equivalent to the total flow of the reactants during deposition. The typical deposition flow rates of gases were 400 ml/min nitrogen carrier gas, 550 ml/min oxygen, and 1.14 liter/min nitrogen through the DBTD saturator. Through the dopant saturator, the nitrogen flow rates ranged from 5 to 210 ml/min for SbCl_5 and from 25 to 280 ml/min for $\text{C}_2\text{F}_3\text{Cl}_3$, depending upon the chosen molar ratio.

After deposition, the sheet resistivity of the deposited films was measured with a four-point probe setup for a routine verification of the electrical properties of the deposited layers. Plates of 10 mm width were cut from the SnO_2 -covered slides. The clover leaf sample geometry was defined by photolithography followed by selective etching of the SnO_2 film by a mixture of zinc powder and dilute HCl (6M) (12). This procedure corresponds to the

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

van der Pauw technique (13). Film thicknesses were determined by a profilometer (Talysurf). Ohmic contacts to SnO₂ layers were obtained using Indium solder no. 3 (Indium Corporation). In the galvanomagnetic measurements, the Hall coefficient was verified to be field independent above 0.05T. Therefore, the reported data in this investigation were measured at 0.5T. The temperature dependence of resistivity and Hall coefficient were determined between 77 and 400 K.

The film structure has been analyzed by conventional x-ray diffraction ($\lambda = 1.544\text{\AA}$) and scanning electron microscopy (SEM). Transmission measurements were performed with a double-beam spectrophotometer using a borosilicate slide in the reference beam for substrate compensation. The transmission spectra were recorded between 400 and 750 nm for each sample. Average transmission in this region was calculated from measurements at every 25 nm.

Results

Film growth rate.—It has been found that the growth rate (film thickness divided by the deposition time) of doped SnO₂ films is a function of temperature, dopant/tin feedstock molar ratio, and film thickness. The maximum growth rates were obtained at 464° and 478°C for SnO₂:Sb and SnO₂:F films, respectively. These temperatures were used for the remainder of this study.

Figure 1 shows the growth rate variation of SnO₂:Sb and SnO₂:F films as a function of dopants/DBTD molar ratio. Growth rates were determined for 1-2 μm thick films. The maxima were found to be at two very different molar ratios: 0.1 for SbCl₅ doping and 27 for Freon doping. In the case of SnO₂:Sb films, the growth rate passes through a minimum at a molar ratio of 0.15. Catalytic effects of dopants on the growth rate of semiconductors have already been reported (14, 15). For example, B₂H₆ increases the growth rate of Si deposited by pyrolysis of SiH₄, but AsH₃ acts as a catalytic poison by impeding the adsorption of silane on the growing film. The decrease of the growth rate for SnO₂:Sb could be interpreted in these terms, but the presence of a minimum in the curve is difficult to understand if there is catalytic

Fig. 1. Growth rate of SnO₂:Sb (dark points) and SnO₂:F (open points) as a function of the dopant/DBTD molar ratio.

poisoning. Another rationalization of the growth rate behavior could be the preferential formation of Sb-O bonds. The formation of preferential P-O bonds was postulated to explain the SnO₂ deposition rate decrease in the case of doped SnO₂ deposited by CVD from tetramethyltin and PH₃ (16). In the present study, however, x-ray diffraction spectra did not reveal any antimony oxide phases in SnO₂:Sb films.

Figure 2 shows the film-thickness dependence of the growth rate. Depositions were made with a SbCl₅/DBTD molar ratio of 0.09 for SnO₂:Sb and with a Freon/DBTD molar ratio of 8 for SnO₂:F. These are also the deposition conditions used for the remainder of this study. Doped SnO₂ films of different thicknesses were obtained by varying the deposition time from 1 to 90 min. For both dopants, the growth rates decrease up to film thicknesses of about 1 μm . For thicker layers, it stabilizes at about 10 and 13 $\text{\AA}\cdot\text{s}^{-1}$ for SnO₂:Sb and SnO₂:F films, respectively. Growth rate was defined as film thickness d divided by the deposition time Δt . In Fig. 2, it can be seen that $d/\Delta t$ varies with the film thickness; therefore, the growth rate values reported in Fig. 1 were determined by the mean value obtained for 1-2 μm thick films.

X-ray diffraction.—X-ray diffraction spectra of SnO₂:F and SnO₂:Sb films, using a beam with $\lambda = 1.544\text{\AA}$, are depicted in Fig. 3 and 4. The deposited layers were found to be composed mostly of cassiterite with a tetragonal rutile structure (17, 18). Additional peaks at $2\theta = 24.5^\circ$ and 31.8° could be assigned to Sn₃O₄ (17, 19), and the peak at $2\theta = 19.0^\circ$ appearing only in SnO₂:F suggests the existence of an unknown tin oxide phase (Sn_xO_y) or a tin fluoride (SnF₂) phase.

These figures clearly show the thickness dependence of the crystallite orientations in the films. It can be seen that, with both dopants, the (110) plane is dominant for films thinner than 1 μm (Fig. 3a and 4a). Above 1 μm , however, the dominant plane becomes (200) (Fig. 3b and 4b). The distribution of the diffraction peaks are different for larger film thicknesses, depending on the dopant. For example, the plane (211) becomes dominant for thick SnO₂:Sb films (Fig. 4c). This peak also appears in the spectrum of SnO₂:F in addition to (301) and (400) ones. The occurrence of the plane (400) as a major crystallographic orientation for SnO₂:F films has previously been observed (6).

This switching from densely populated crystallographic planes for thin films to less densely populated ones for thicker films is reflected in the growth rate. It is indeed known that the fastest growth direction is perpendicular to the plane of the largest atomic density (20). The densely populated (110) crystallites appear to represent the dominant species with both dopants for films thinner

Fig. 2. Growth rate of SnO₂:Sb (open points) and SnO₂:F (dark points) as a function of film thickness.

Fig. 3. X-ray diffractograms of three thicknesses of $\text{SnO}_2\text{:F}$ films. a: $0.39 \mu\text{m}$. b: $1.65 \mu\text{m}$. c: $4.5 \mu\text{m}$.

than $1 \mu\text{m}$. The preferential orientation changes for thicker films, to other crystallographic planes such as (200), (211), (301), and (400) which are all characterized by a smaller tin surface density, compared to the one of (110), leads to a reduction of the growth rate.

Scanning electron microscopy.—Grain sizes at the outer surface were determined by scanning electron microscopy (SEM). Two types of grain structures were observed. In one structure (Fig. 5a), grains of different sizes grow either independently or are clustered in a cauliflower-like shape protruding from the surface of the film. For the other structure (Fig. 5b), large grains are surrounded by many smaller grains. Columnar growth structure was revealed from SEM observations of cross sections of thicker films, so the grain sizes measured only refer to those at the outer surface of the film. It is, however, difficult to deduce from cross sections of thicker layers whether they contain small grains, as do thin layers, close to the substrate.

In Fig. 6, the average grain size is plotted as a function of layer thickness. It can be seen that the grain size linearly increases with the film thickness. Such behavior has been observed for indium tin oxide deposited on zirconia in the same thickness range (21). It is usually found that the grain size saturates for a given thickness (22).

Fig. 4. X-ray diffractograms of three thicknesses of $\text{SnO}_2\text{:Sb}$ films. a: $0.31 \mu\text{m}$. b: $1.28 \mu\text{m}$. c: $5.1 \mu\text{m}$.

Fig. 5. SEM micrographs of A, $5.1 \mu\text{m}$, and B, $5.3 \mu\text{m}$ thick $\text{SnO}_2\text{:Sb}$ films.

However, in this study, there is no evidence of such a trend, at least up to a thickness of $5 \mu\text{m}$.

Optical properties.—Figure 7 depicts the variation of the optical transmission with the layer thickness. In the wavelength range of 400–750 nm, the transmission decreases as the thickness of SnO_2 layer increases. The ob-

Fig. 6. Grain size of $\text{SnO}_2\text{:Sb}$ (open points) and $\text{SnO}_2\text{:F}$ (dark points) crystallites as a function of film thickness.

tained values of the transmission are similar to those reported in the literature for fluorine-doped tin oxide (23, 24). In view of a possible application as transparent conductors, films thicker than $1 \mu\text{m}$ are not to be recommended due to their low transmission of the visible part of the spectrum.

Electrical properties.—Hall effect measurements indicate that $\text{SnO}_2\text{:Sb}$ and $\text{SnO}_2\text{:F}$ are n-type semiconductors. The variations of conductivity, σ , and Hall coefficient, R_H , with film thickness are illustrated in Fig. 8 and 9 for both dopants, respectively. From these data, it can be deduced that above $1 \mu\text{m}$, doped SnO_2 films have a charge carrier concentration $n \sim 2 \times 10^{20} \text{ cm}^{-3}$ and a mobility of $\sim 19 \text{ cm}^2 (\text{V}\cdot\text{s})^{-1}$.

For films thinner than $1 \mu\text{m}$, both carrier concentrations and mobilities decrease with decreasing film thicknesses. Such behavior has already been reported for the conductivity of undoped SnO_2 on Pyrex (25), doped $\text{SnO}_2\text{:F}$ on sheet glass (23, 24) and on Pyrex (23), and doped $\text{SnO}_2\text{:Sb}$ on sheet glass (26). In some instances, however, the conductivity of SnO_2 films remains constant down to very small thicknesses. These were found to be $0.05 \mu\text{m}$ for undoped SnO_2 on Si (27) and $0.1 \mu\text{m}$ for $\text{SnO}_2\text{:Sb}$ on Pyrex and on fused silica (26). The influence of the substrate in the experiments of this investigation

has been ruled out, since the same behavior of σ and R_H was obtained on both fused silica and borosilicate substrates.

In Fig. 10, the conductivity of three $\text{SnO}_2\text{:Sb}$ films of different thicknesses is plotted against the reciprocal temperature. Since the carrier concentration, characteristic of each film thickness, remains constant in the investigated temperature range, the change of the film conductivity as a function of the temperature reflects a similar variation of the mobility. The largest activation energy calculated from Fig. 10 is only $\sim 0.01 \text{ eV}$ for a $0.31 \mu\text{m}$ $\text{SnO}_2\text{:Sb}$ film in the high temperature region.

Discussion

Transport properties models.—It can be seen from the above results that SnO_2 films are polycrystalline. They are composed of crystallites joined together by grain boundaries which are transitional regions between differ-

Fig. 10. Conductivity of three thicknesses of $\text{SnO}_2\text{:Sb}$ films as a function of T^{-1} .

ent orientations of neighboring crystallites. Among polycrystalline semiconductors, polysilicon has been the most extensively studied material. Two existing models were employed to analyze the effects of grain boundaries on electrical properties of this material.

The first is a charge trapping model (15, 28-33) where it is assumed that grain boundaries contain lattice-defects-induced trapping states. These states compensate a fraction of the charge carriers of the ionized uniformly distributed dopants. This process creates a potential barrier across the depletion region, impeding the carrier motion from one crystallite to another. The influence of the grain size becomes very important when the depletion layer width becomes commensurable with the grain size of the crystallite. This treatment was applied to SnO_2 as well (34). In this model, the conduction mechanism is based on thermionic emission over the potential barrier. This, of course, requires a barrier energy larger than kT . As has been deduced from Fig. 10, the largest activation energy calculated from this figure is only ~ 0.01 eV for $0.31 \mu\text{m}$ SnO_2 :Sb film in the high temperature region. This is well below kT ; therefore, the model based on thermionic emission of carriers over an energy barrier at the grain boundary is not applicable to doped SnO_2 films.

The second is a dopant segregation model. In this case, the grain boundaries are assumed to act as sinks for preferential segregation of the dopants. Therefore, they become inactive in the boundary layers (35, 36).

In the following discussion, this model will be extended to analyze the conductivity variation of our SnO_2 :Sb or SnO_2 :F films with the layer thickness. In this compound semiconductor, it is to be recognized that the different crystal planes are having characteristic charge distribution to maintain specific neutrality conditions. This was not the case in elemental semiconductor discussed previously in the literature (28-36). In polycrystalline-doped SnO_2 films, based on the x-ray diffraction data (see Fig. 3 and 4), five dominant planes were considered. These are (110), (200), (211), (301), and (400). It will be discussed in the following that only three of these, (110), (211), and (301), are introducing deep lying trapping levels. These result in a compensation of free carriers of the crystallites. Consequently, the thickness dependence of the experimental carrier concentration is analyzed in terms of two factors. On the one hand, the specific effects of the crystalline orientations of the grains are examined. On the other hand, the total surface area of the grains is taken into account.

The extension of the segregation model has been based on the following results obtained from the literature. The maximum solid solubility of antimony in the rutile phase of SnO_2 is limited to an Sb/Sn ratio of $\sim 4\%$ (37). An investigation of polycrystalline material with this critical composition by Mössbauer spectroscopy indicated the presence of antimony (V) ions in the bulk together with antimony (III) ions at the surfaces of the grain boundaries (38). In order to investigate further the surface properties of SnO_2 , Cox *et al.* (39) studied undoped and doped SnO_2 (Sb/Sn = 3%) with surface sensitive techniques such as x-ray photoelectron spectroscopy (XPS) and ultraviolet photoelectron spectroscopy (UPS). Although the results of their investigation will be used in the present discussion, it is important to notice that their preparation method yielded single-crystal material in the (110) orientation for both undoped and doped SnO_2 .

It has been shown by XPS that a dramatic surface enrichment in antimony occurs. This was interpreted by the exchange of Sn cations by Sb at the surface of the bulk rutile structure. The normal $N(\text{Sb})/N(\text{Sn})$ bulk ratio is reestablished immediately beneath this monoatomic surface layer. Their UPS data indicated that the bulk free carrier concentration extends very close to this surface but surface antimony atoms do not contribute to the conduction. This suggests that free carriers may be trapped in these surface states which lie deep below the conduction band. In the literature, the surface states were identified to be Sb(III). These states also exist on the surface of

undoped materials where they are associated with Sn(II). In addition, Cox *et al.* (39) rationalized the stabilization of Sn(II) and Sb(III) on the surface of undoped and doped SnO_2 on the basis of electrical neutrality of the rutile structure. It is to be mentioned that although they recognized the strong tin oxygen covalency in SnO_2 , the ionicity of the covalent bond is used in their model.

Following the results of the literature, Fig. 11a shows the SnO_2 (110) surface without reduction of the top oxygen layer. The sequence of charged planes is $-2, +4, -2$. If the top oxygen plane with two negative charges is removed, the (110) surface terminates on the Sn(IV) containing plane, with four positive charges. To retain electrical neutrality, one Sn(IV) atom of this plane has to be reduced to Sn(II) as is depicted in Fig. 11b. Consequently, the sequence of charged planes at the surface will be $+2, -2$. This represents both undoped and fluorine-doped SnO_2 . In the antimony-doped films, however, the neutrality principle requires that all tin atoms should be exchanged by Sb(III) as is shown in Fig. 11c. Consequently, here as well, the sequence of charged planes at the surface remains $+2, -2$. This argument clarifies why, on doping (110) SnO_2 grains, part of the antimony is first used in the surface plane as Sb(III). Thus, this fraction of the antimony doping does not participate in the conduction mechanism.

The results obtained by Cox *et al.* (39) are used in the present investigation to extend the segregation model to other crystallographic orientations of interest. This is discussed in the following. Figure 12 shows the sequence of charged planes for a (200) surface. In contrast to the above-discussed (110) plane, no top oxygen plane has to be removed in this case in order to terminate the surface of a tin containing plane. Therefore, the (200) SnO_2 surface will only contain Sn(IV) atoms. Doping with antimony will substitute for some Sn(IV) Sb(V), which are acting as donors. Then, according to this treatment, there will not be any surface states as electron traps [e.g., Sb(III)], since surface atoms are either Sn(IV) or Sb(V).

The (211) planes, however, behave like (110) planes. Figure 13a represents the sequence of charged planes of a (211) surface without reduction. The charges are $-4, +16, -4$, and -8 considering four unit cells. If the top oxygen plane is removed (-4), then the (211) surface terminates on a tin containing plane with $+16$ charges. To retain electrical neutrality, two Sn(IV) atoms have to be reduced to Sn(II) as it is shown in Fig. 13b, decreasing the surface charge to $+12$. The sequence of charged planes in this case will be $+12, -4, -8$. This represents the case of undoped and fluorine-doped films. In the antimony-

Fig. 11. Crystallite surface of SnO_2 grown according to the (110) plane. a: Undoped SnO_2 with the outside oxygen layer. b: Undoped and F-doped SnO_2 after reduction. c: Antimony-doped SnO_2 after reduction.

Fig. 12. Crystallite surface of SnO₂ grown according to the (200) plane for undoped SnO₂. The symbols are described in Fig. 11.

doped SnO₂, however, the neutrality requires that all tin atoms in the top layer should be replaced by Sb(III), as it is shown in Fig. 13c, resulting in a surface charge of (+12). Then, the sequence of charged planes remains +12, -4, -8. As in the case of (110) orientation, part of the antimony is first used in the surface plane as Sb(III). This fraction of the antimony doping cannot participate in the conduction mechanism. In the case of undoped and fluorine-doped material, however, the compensating trapping center concentration will be given by the Sn(II) concentration in (110) and (211) grains.

Using this model, based on the crystallographic analysis of the SnO₂:Sb films prepared in this investigation, one can compute the variation of the carrier concentration as a function of film thickness. The results are summarized in Table I. Here, F_{110} , F_{200} , and F_{211} are the fractions of crystallites in the films having (110), (200), and (211) crystallographic orientations, collected for various film thicknesses. These fractions were obtained taking into consideration the relative amplitudes of the (110), (200), and (211) peaks of the x-ray diffraction spectra. It is assumed, as a first approximation, that the peak amplitudes are proportional to the relative amounts of the crystallites of the corresponding orientations. The above-mentioned three orientations are considered for SnO₂:Sb in this analysis.

The Sb(III) densities of the doped (110) and (211) crystallites, N_{110} and N_{211} , can be calculated for various film thicknesses as follows

Fig. 13. Crystallite surface of SnO₂ grown according to the (211) plane. a: Undoped SnO₂ with the outside oxygen layer. b: Undoped and F-doped SnO₂ after reduction. c: Antimony-doped SnO₂ after reduction. The symbols are described in Fig. 11.

$$N_{t110} = F_{110} \times N_{110} \quad [1]$$

where N_{110} is the number of tin atoms per cubic centimeter on the surface of (110) crystallites. N_{110} is calculated assuming columnar crystallites using the following equation

$$N_{110} = \left(\frac{2}{d} + \frac{4}{l} \right) \times A_{110} \quad [2]$$

where l and d are the diameter and height (film thickness) of the crystallite, respectively. A_{110} is the number of tin atoms per square centimeter on (110) plane. Since the lattice constants for SnO₂ are $a = b = 4.737\text{\AA}$ and $c = 3.185\text{\AA}$ (18), $A_{110} = 9.4 \times 10^{14}$ Sn at./cm². N_{211} can be obtained similarly using $A_{211} = 4.8 \times 10^{14}$ Sn at./cm².

Since Sb(III) replaces all tin atoms on (110) and (211) surfaces, N_{110} and N_{211} represent also the Sb(III) density of their respective crystallographic orientations. Then the total density of Sb(III) in the film, N_s , is given by

$$N_t = N_{t110} + N_{t211} \quad [3]$$

The obtained N_t values are collected in Table I and depicted in Fig. 14 (open triangle). Since, as has been discussed above, the Sb(III) act as trapping centers, the free carrier concentration can be computed as follows. If N_d is the donor concentration, antimony, in this case, the electron density in the conduction band for the (110) and (211) orientations will be $n = (N_d - N_s)$. This corresponds to the number of Sb(V) donors. However, for (200) orientation, the electron concentration in the conduction band will be equivalent to N_d since no Sb(III) are present on the surface of these crystallites. Therefore the total carrier concentration for SnO₂:Sb can be given by

$$n = (F_{200} \times N_d) + [(1 - F_{200}) \times (N_d - N_s)] \quad [4]$$

The calculated values of the free carrier concentration, n , for various film thicknesses are collected in Table I and shown as open circles in Fig. 14. N_d is an adjustable parameter, but its value must be very close to the experimental donor concentration for the largest crystallites. In this case, the effect of surface trapping becomes negligible. Thus, the value of $N_d = 2.0 \times 10^{20} \text{ cm}^{-3}$ has been used in these calculations.

From Fig. 14, it can be deduced that the contribution to charge carrier concentration, n , of the (110) and (211) crystallites begins for SnO₂:Sb films thicker than about 0.5 μm when the surface-state-introduced deep-level trapping center concentration, N_s , becomes less than the doping concentration N_d . For thinner films, all the carriers are coming exclusively from (200) crystallites, and their concentration increases with the increasing fraction F_{200} as a function of film thickness (see Table I). It is implicitly assumed in these calculations that an electric path exists between the (200) crystallites present in these films by direct contact between the (200) grains or, in the case of increasing dilution of these grains, by the formation of preferential conducting path according to the percolation theory (40).

In the case of fluorine doping, the Sn(II) surface states will behave as trapping centers. Therefore, the model can

Fig. 14. Total electron trap concentration N_t (Δ , \blacktriangle) and charge carrier concentration n (\circ , \bullet) calculated on the basis of x-ray diffraction spectra, for different thicknesses of $\text{SnO}_2\text{:Sb}$ (open symbols) and $\text{SnO}_2\text{:F}$ (dark symbols). The n curve represents a mean value through the calculated points.

be extended to analyze the transport properties of the fluorine-doped SnO_2 as well. This is treated in the following way. Five crystallographic planes ought to be considered as they become important at different thickness ranges. As far as Sn(II) surface states are concerned, the (400) planes can be treated like (200) planes; similarly, the (301) planes behave like the (110) or the (211) ones. This is shown in Fig. 15. Here, all Sn(IV) (full circles, Fig. 15a) must be reduced to Sn(II) (open circles, Fig. 15b) after the reduction of the oxygen layer to maintain the electrostatic neutrality. The total trapped electron concentration, N_t , corresponds, therefore, in the case of fluorine-doped SnO_2 , to the density of Sn(II). This can be given by the following equation

$$N_t = N_{110} + N_{211} + N_{301} \quad [5]$$

where N_{110} and N_{211} are obtained, as before, from the x-ray diffraction spectra. It is, however, to be noticed that, in this case, only half of the N_{110} and N_{211} concentrations deduced earlier have to be considered. In effect, examin-

Fig. 15. Crystallite surface of SnO_2 grown according to the (301) plane. a: Undoped SnO_2 with the outside oxygen layer. b: Undoped and F-doped SnO_2 after reduction. The symbols are described in Fig. 11.

ing Fig. 11b and 13b, one can see that only half of the Sn atoms contribute to the trapping density instead of all surface atoms, as in the case of antimony doping shown in Fig. 11c and 13c. For the (301) crystallites, $A_{301} = 4.0 \times 10^{14}$ Sn at./cm² determined from the unit cell parameters, is used to calculate N_{301} .

Finally, the free carrier concentration, in the case of fluorine doping, can be expressed as

$$n = (F_{200} + F_{400}) N_d + [(1 - [F_{200} + F_{400}]) \times (N_d - N_t)] \quad [6]$$

The calculated variation of n vs. the film thickness for $\text{SnO}_2\text{:F}$ is shown in Fig. 14 (full circles), along with N_t (full triangles). A single curve has been drawn through the calculated n values for both dopants. The experimentally determined fractions based on the x-ray diffraction spectra, for all the crystallographic orientations which have been taken into consideration, are collected in Table II.

Values from the calculated carrier concentration curve displayed in Fig. 14 can be used to determine a calculated Hall coefficient curve. This is shown as a full line in Fig. 9. Furthermore, assuming that the drift mobility is equal to the Hall mobility, the conductivity can be calculated. The result is displayed as a full line in Fig. 8. Here, a mobility of $19 \text{ cm}^2 (\text{V}\cdot\text{s})^{-1}$ has been used in the calculation for all film thicknesses. The fit of the calculated curves to the experimental points in Fig. 8 and 9 is quite reasonable.

Conclusion

It has been shown that the thickness dependence of the conductivity of doped SnO_2 films can be elucidated in terms of charge carrier concentration taking into consideration defect-induced deep-level compensation. Independently of the dopants used, the maximum charge carrier concentration in the films is decreased by electron trapping of Sb(III) or Sn(II) surface states when antimony or fluorine are used as a dopant, respectively. These deep lying trapping centers appear only on the surface of crystallites with (110), (211), and (301) crystallographic orientations.

The number of free carriers in the films can be calculated on the basis of x-ray diffraction spectra giving an estimate of the relative fractions of (110), (211), and (301) crystallites as a function of film thickness. The conductivity can be deduced from this model using a single

value for the electron mobility of $19 \text{ cm}^2 (\text{V}\cdot\text{s})^{-1}$ and a total doping concentration, $N_d = 2 \times 10^{20} \text{ cm}^{-3}$, for all film thicknesses. The computed values are in good agreement with the experimental data.

In this model, it is assumed that in the case of doping with antimony, for example, the dopant first substitutes all tin sites on the surface by Sb(III). This fraction of the antimony does not act as donor, but does introduce deep-lying trapping states. However, it is argued that only some of the crystallites with specific orientations participate in this trapping mechanism.

If this model is correct, very thin films ($\ll 1 \mu\text{m}$) dominated by (200) crystallites should have the same transport properties as thicker films ($> 1 \mu\text{m}$) where this crystallographic orientation prevails. As SnO_2 is used as a transparent electrode, the thinner the film, the better its transmission. Therefore, the production of very thin films with the same conductivity as thicker ones could be an asset if thin film technology of (200) dominant orientation can be developed.

LPCVD Oxide/LPCVD Nitride Stacks for Interpoly Dielectrics

Tiao-Yuan Huang,^{*,1} Donald J. Coleman, and James L. Paterson

Texas Instruments Incorporated, Semiconductor Process and Design Center, Dallas, Texas 75265

ABSTRACT

An LPCVD oxide/LPCVD nitride stack has been investigated as a possible substitute for the interpoly oxide in double-level-polysilicon VLSI processes. Results from capacitor lots show that 25 nm LPCVD oxide/25 nm LPCVD nitride stacks yield breakdown voltages greater than 25V with a tight distribution. The breakdown voltage can further be enhanced by depositing an additional LPCVD blocking oxide of 50Å thickness on the stack. Suitable thermal sealing oxides are also shown to be effective in enhancing the breakdown field strength. A further scaling of the stack thickness is also demonstrated.

The thermal oxide grown on polysilicon is known to be much leakier than the single-crystal counterpart. It is also well known that a higher oxidation temperature (> 1100°C) tends to smooth the asperities and yield better polyoxide (1, 2). However, such a high temperature treatment may be prohibitive in future VLSI process flows. On the other hand, the use of lower temperature (less than or equal to 1000°C) oxidation results in surface-reaction-controlled oxidation and, thus, a rougher polysilicon surface and a much leakier resultant polyoxide. An alternative dielectric deposited by LPCVD is a potential substitute for thermal polyoxide in VLSI processes.

Different combinations of thin LPCVD oxide and LPCVD nitride stacks (with equivalent SiO₂ thickness less than 500Å) have been demonstrated to yield good-quality, low defect density interpoly dielectrics suitable for VLSI EPROM/EEPROM applications (3, 4, 7, 8).

Experiments

P-type, (100) silicon slices at resistivity of 12-16 Ω-cm were used as the starting material. After growing a 400Å HCl-oxide, LPCVD polysilicon with nominal thickness of 3000Å was deposited; slices were then saturation POCl₃ doped at 1000°C. After stripping of the PSG grown during POCl₃ predeposition, different LPCVD oxide/LPCVD nitride stacks were then deposited (see Table I). For some splits, the oxide/nitride stacks were subjected to different postdeposition oxidation treatments to grow a suitable sealing oxide. A 4500Å polysilicon film was then deposited and saturation POCl₃ doped to serve as the upper electrode. The polyoxide capacitors were defined by photolithography and plasma etching. An additional 1000°C, 30 min heat-treatment and a 450°C hydrogen sintering were incorporated to simulate a full process flow. Breakdown and I-V characteristics were measured, with breakdown being defined as the voltage at which the current density exceeds 20 μA/cm² when a positive

voltage ramp is applied to the second-level polysilicon gate. The capacitor area is 0.0052 cm².

Results and Discussion

Figure 1 shows the histogram of a 25 nm LPCVD oxide/25 nm LPCVD nitride stack. With an equivalent electrical SiO₂ thickness (the thickness assuming a dielectric constant of 3.9 ε₀) of 37 nm, the stack shows a tight breakdown voltage distribution centered at 27V. The I-V characteristic of a typical 25 nm LPCVD oxide/25 nm LPCVD nitride stack is shown in Fig. 2. It can be seen that the low-field leakage is approximately 1 nA/cm² at 12V. Another feature of the oxide/nitride stack is that the I-V curves of the first (from a virgin sample) and second stresses fall almost upon each other, suggesting that a

Fig. 4. Histograms of breakdown voltage for 25 nm LPCVD oxide/25 nm LPCVD nitride film annealed at 1000°C in oxygen for 20 min (lower) and 90 min (upper).

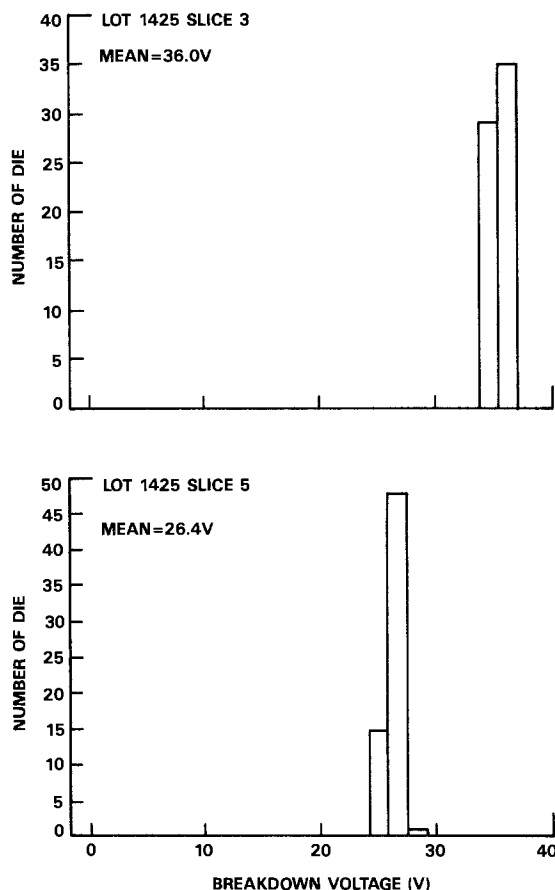

Fig. 5. Histograms of breakdown voltage for a 25 nm LPCVD oxide/25 nm LPCVD nitride film annealed in steam for 65 min at 900°C (lower) and 1000°C (upper).

Fig. 6. Histograms of breakdown voltage for 15 nm LPCVD oxide/15 nm LPCVD nitride film as grown (lower), with 1000°C, 90 min anneal in oxygen (middle) and with 5 nm LPCVD cap oxide (upper).

negligible amount of charge trapping occurred during the I-V measurements. This is contrary to what is found with a typical 1000°C, dry O₂ polyoxide that shows a significant shift of the I-V curve to lower values for the second stress, suggesting significant electron trapping.²

Figure 3 depicts the histogram of a 25 nm LPCVD oxide/25 nm LPCVD nitride/5 nm LPCVD oxide trilayer stack. The breakdown voltage is significantly improved to about 40V. This is not surprising, as it is well known in the metal-nitride-oxide-silicon (MNOS) field (5) that a suitable blocking oxide between the nitride and the silicon gate electrode will serve to increase the energy barrier heights (energy barrier height is 2.05 eV for an electron and 1.95 eV for a hole at the silicon nitride interface, while the barrier height is 3.1 eV for an electron and 3.8 eV for a hole at the silicon dioxide interface) between gate electrode and nitride, thus suppressing carrier interface injection from the gate electrode.

The effectiveness of a sealing oxide can also be achieved by treating the oxide/nitride stack in an O₂ or steam ambient, thereby forming a sealing oxide. Figure 4 shows histograms for stacks annealed in O₂ at 1000°C for

²At least an order of magnitude decrease in leakage current at low field (3 MV/cm) was usually observed for the dry thermal interpoly oxide grown at 1000°C, with otherwise the same growth condition.

Fig. 7. Histograms of breakdown voltage for 30 nm LPCVD oxide film (lower), 30 nm LPCVD nitride film as deposited (middle), and following 65 min anneal in oxygen at 1000°C (upper).

20 and 90 min. The 20 min anneal produced a mean breakdown voltage of 26.3V, which is comparable to an unannealed stack; the 90 min anneal, however, produced a mean breakdown voltage of 38.0V, a significant improvement. Figure 5 shows histograms for stacks annealed in steam for 65 min at 900° and 1000°C. The 900°C anneal has little effect, producing a mean breakdown

voltage of 26.4V; the 1000°C anneal, however, raises the mean breakdown voltage to 36.0V. The splits that received shorter time or lower temperature heat-treatments do not show any detectable enhancement in breakdown field strength, suggesting that a minimum sealing oxide thickness is required to act as a well-defined Si-SiO₂ energy barrier to enhance the breakdown voltage (6).

The stack has also been scaled in thickness to 15 nm LPCVD oxide/15 nm LPCVD nitride. Figure 6 shows histograms of breakdown voltage for this stack (lower), for a stack annealed in oxygen at 1000°C for 90 min (middle), and for a stack sealed with a 5 nm LPCVD oxide. The mean breakdown voltage increases from a value of 18.4V for the bilayer film to 35.2V for the trilayer film.

The characteristics of single-layer LPCVD films have also been explored. Figure 7 (lower histogram) shows a histogram of breakdown voltage for a 30 nm LPCVD oxide film; the distribution is tight with a mean value of the breakdown voltage of 13.4V. The 30 nm LPCVD nitride film (middle histogram) shows a mean breakdown voltage of 16.5V, and the 30 nm nitride film, annealed in oxygen at 1000°C for 65 min, shows a mean value of 26.3V.

Conclusion

The twelve different interpoly dielectric processes are compared in Table I. The total thickness of the LPCVD films varied from 30 to 55 nm. The anneals listed in the table are done prior to deposition of the second polysilicon film. The capacitors were stressed to 50V; the breakdown voltage was defined as the voltage at which the current density reached 20 $\mu\text{A}/\text{cm}^2$ (100 nA through capacitors of area 0.0052 cm²). A breakdown voltage of 26-27V results from either an unannealed 25 nm oxide/25 nm nitride film or a 30 nm nitride film which is sealed in oxygen at 1000°C. A 25 nm oxide/25 nm nitride film produces a breakdown voltage of > 35V when sealed with a 5 nm LPCVD oxide at 800°C or when sealed at 1000°C in steam for 65 min or in oxygen for 90 min. Note that the thinnest dielectric to achieve a breakdown voltage of 35V is the 15 nm oxide/15 nm nitride/5 nm oxide film, which is roughly equivalent to 28.5 nm of SiO₂.

Acknowledgments

The authors would like to thank the staff of Semiconductor Processing Laboratory for processing the material, especially Bruce Dudley for monitoring the lots, Wayne Caldwell for oxide/nitride stack depositions, and Sarah Poppenhouse for electrical measurements.

Evaluation of Diffusion Coefficients from Nonlinear Impurity Profiles

Dan Anderson and Kjell O. Jeppson

Department of Electrical and Computer Engineering, Chalmers University of Technology, S-412 96 Göteborg, Sweden

ABSTRACT

At high concentrations, impurity diffusion in semiconductors is governed by nonlinear diffusion processes. Using similarity analysis, a general expression for evaluation of the diffusion coefficient from experimental impurity profiles is derived for the case of redistributive diffusion of implanted impurities. This expression corresponds to the Boltzmann-Matano analysis for the case of diffusion with constant surface concentration.

Evaluation of diffusion coefficients from measurements of impurity profiles requires detailed knowledge of the diffusion conditions as well as the expected doping profile. Actually, only very few sources of diffusivity data in literature are reliable (1). For instance, Hu (2) has shown how fictitious diffusion coefficients have been obtained from junction depth and sheet resistivity measurements when the evaluation was based on a theory which was not appropriate for the diffusion conditions. Even when detailed impurity profiles are available from scanning ion mass spectroscopy (SIMS), erroneous diffusion coefficients may be obtained when Arrhenius-type expressions are fitted to diffusivity data that represent the sum of two diffusion mechanisms with different activation energies. Recently, *e.g.*, the diffusion coefficient of arsenic in silicon has been changed by a factor of two (1) after a reevaluation of the diffusion data.

In this paper, we will show that the conditions of diffusion for implanted impurities as arsenic and boron are important and will affect the evaluation of diffusion coefficients at high impurity concentrations. In particular, we demonstrate that for drive-in situations, where a constant predeposited high impurity dose is redistributed by means of nonlinear diffusion, the Boltzmann transformation is not valid. Consequently, diffusion coefficients derived from experiments involving high impurity concentrations of, *e.g.*, arsenic, must be viewed with considerable caution and perhaps even reevaluated.

In analytical studies of impurity diffusion, the use of the Boltzmann transformation (3) plays an important role and has greatly simplified the analysis by reducing the diffusion equation from a partial differential equation to an ordinary equation. This makes it possible to obtain simple explicit solutions for the impurity profile in a variety of different physical situations. Furthermore, it also provides a simple way to infer the diffusion coefficient from the observed impurity profiles. The corresponding Boltzmann-Matano analysis has become a standard procedure for the determination of diffusion coefficients (4).

Analysis

The diffusion of impurities in semiconductors is generally assumed to be governed by the diffusion equation

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x} \left(D \frac{\partial C}{\partial x} \right) \quad [1]$$

where $C(x)$ is the impurity concentration and D is the diffusion coefficient. The diffusion of substitutional im-

purities is a result of the interaction with vacant states in the semiconductor. This multiple-charge vacancy model has recently been summarized by Fair (1). The vacancies may be neutral or charged. Since the number of charged vacancies is dependent on the electron concentration, it makes the diffusion coefficient concentration dependent according to

$$D = h[D^0 + D^+(n/n_i) + D^-(n/n_i) + D^{=}(n/n_i)^2] \quad [2]$$

where D^0 , D^+ , D^- , and $D^{=}$ represent the effective diffusivities under intrinsic conditions for the neutral, positive, and negative singly and doubly charged states, n is the electron concentration

$$n = \frac{C}{2} \left\{ 1 + \left[1 + \left(\frac{2n_i}{C} \right)^2 \right]^{1/2} \right\} \quad [3]$$

and h the self electric-field enhancement factor

$$h = 1 + \frac{C}{2n_i} \left[1 + \left(\frac{C}{2n_i} \right)^2 \right]^{-1/2} \quad [4]$$

At low impurity concentrations ($C \ll n_i$), when the diffusion coefficient is independent of concentration, Eq. [1] becomes a linear differential equation and explicit solutions in terms of gaussians or erfc functions are easily found for different diffusion conditions using the Boltzmann transformation, *cf.* (3). However, if $C > n_i$, Eq. [1] becomes nonlinear, and analytical solutions are not as easily available.

In a previous paper (5), we have determined the characteristic impurity profiles, which appear as solutions of Eq. [1] in the case of strongly concentration-dependent diffusion coefficients ($D \sim (n/n_i)^{\gamma}$). This analysis clarified the limitation of the conventional Boltzmann transformation in situations where the nonlinear diffusion process involves a redistribution of a predeposited impurity. In such cases, the proper diffusion variable is not the Boltzmann variable $x/t^{1/2}$, but rather $x/t^{1/(\gamma+2)}$. This point has caused considerable confusion in previous works (6-8).

The purpose of the present work is to consider the important consequences of this result for the evaluation of nonlinear diffusion coefficients from the observed impurity profiles. The conventional interpretation of the diffusion data, in order to infer the diffusion constant, *e.g.*, the Boltzmann-Matano analysis, relies crucially on $x/t^{1/2}$ as the proper diffusion variable.

As shown in Ref. (5), similarity methods are a powerful tool for studying nonlinear diffusion equations. This implies that the solution of the diffusion equation, Eq. [1], is assumed to be of the form

$$C(x,t) = \frac{\phi(\xi)}{t^\alpha} \quad [5]$$

where the similarity variable, ξ , is given by

$$\xi = \frac{x}{t^\beta} \quad [6]$$

The unknown function, $\phi(\xi)$, as well as the parameters α and β , may be determined by insertion of the expressions in Eq. [5] and [6] into the diffusion equation and by using the appropriate boundary or initial conditions.

In the case of diffusion with a constant surface concentration, C_s , it follows that $\alpha = 0$ (cf. Eq. [5]), and by inserting Eq. [5] and [6] into Eq. [1], we obtain

$$-\frac{\beta\xi}{t} \cdot \frac{d\phi}{d\xi} = \frac{d}{d\xi} \left(D \frac{d\phi}{d\xi} \right) \cdot \frac{1}{t^{2\beta}} \quad [7]$$

where D now is a function of ξ . For the powers of t to match, $\beta = 1/2$ is required. (Note that the resulting diffusion variable is then the usual Boltzmann variable $\xi = x/\sqrt{t}$.)

Integration of Eq. [7] results in

$$-\frac{1}{2} \int_0^\phi \xi d\phi = D \frac{d\phi}{d\xi} \quad [8]$$

Substituting back to variables x and t and rearranging yields the diffusion coefficient

$$D(C_1) = \frac{1}{2t} \frac{\int_0^{C_1} x dC}{\left(\frac{dC}{dx} \right)_{x_1}} \quad [9]$$

where $C_1 = C(x_1)$. This is the well-known Boltzmann-Matano (4) expression for evaluation of concentration-dependent diffusion coefficients from experimentally determined impurity profiles. The accuracy of this method has been discussed (9).

However, for drive-in diffusion of a high dose of implanted impurities, the nonlinear character of the diffusion constant has important consequences for the similarity variable, ξ . At high impurity concentrations, one of the charged vacancies dominates the effective diffusivity, making

$$D = 2D_i \left(\frac{C}{n_i} \right)^\gamma \quad [10]$$

where D_i is the intrinsic diffusion coefficient, a good approximation of the concentration dependence of the diffusion coefficient. The parameter γ is equal to one for arsenic and boron diffusion, and γ is equal to 2 for phosphorus diffusion in the "flat region" (1).

In this case, instead of constant surface concentration, a constant amount of implanted impurities redistribute during diffusion. Thus, we require

$$\int_0^\infty C(x,t) dx = T^{\beta-\alpha} \int_0^\infty \phi(\xi) d\xi = Q_0 = \text{const.} \quad [11]$$

This obviously requires that $\alpha = \beta$, and the diffusion equation corresponding to Eq. [7] becomes

$$\frac{1}{t^{\alpha+1}} \alpha \frac{d}{d\xi} (\xi\phi) = \frac{d}{d\xi} \left(2D_i\phi^\gamma \frac{d\phi}{d\xi} \right) \frac{1}{t^{\alpha\gamma+2\beta+\alpha}} \quad [12]$$

Matching powers of t now requires

$$\alpha + 1 = \gamma\alpha + 2\beta + \alpha \quad [13]$$

i.e.

$$\alpha = \beta = 1/(\gamma + 2) \quad [14]$$

Integration of Eq. [12] yields

$$\alpha\xi\phi = 2D_i\phi^\gamma \frac{d\phi}{d\xi} \quad [15]$$

The diffusion coefficient may then be written

$$D = 2D_i \left(\frac{C}{n_i} \right)^\gamma = 2D_i \frac{\phi^\gamma}{t^{\alpha\gamma}} = \frac{\alpha\xi\phi}{t^{\alpha\gamma} \frac{d\phi}{d\xi}} \quad [16]$$

Substituting variables back to x and t yields the following expression for the diffusion coefficient

$$D(C_1) = -\frac{1}{\gamma + 2} \frac{x_1 C_1}{t \left(\frac{dC}{dx} \right)_{x_1}} \quad [17]$$

This equation implies a graphical method for determination of diffusion coefficients from experimentally determined impurity profiles. In this case, the evaluation is simplified as the graphical integration of the Boltzmann-Matano analysis for diffusion with constant surface concentration is eliminated. However, the degree of nonlinearity in the diffusion coefficient must be known in order to perform correct evaluations.

A further integration of Eq. [15] for $\gamma = 0$ yields the well-known gaussian profile. For nonlinear diffusion ($\gamma > 0$), the integration yields, after substitution of variables (5)

$$C(x,t) = C_s(t) \left(1 - \frac{x^2}{x_j^2(t)} \right)^{1/\gamma} \quad [18]$$

where the surface concentration is

$$C_s(t) = \left(\frac{\gamma}{4(\gamma+2)I_\gamma^2} \cdot \frac{Q_0^2 n_i^\gamma}{D_i t} \right)^{1/(\gamma+2)} \quad [19]$$

and the junction depth is

$$x_j = \left(\frac{4(\gamma+2)}{\gamma I_\gamma^\gamma} \cdot \frac{Q_0^\gamma D_i t}{n_i^\gamma} \right)^{1/(\gamma+2)} \quad [20]$$

I_γ is a numerical factor given by $I_1 = 2/3$ and $I_2 = \pi/4$ (5). For $\gamma \rightarrow 0$, this solution (Eq. [18]-[20]) gradually approaches the well-known gaussian profile.

Discussion and Conclusions

The impurity profiles given by Eq. [18]-[20] give excellent agreement with experimental data on impurity profiles for high concentration arsenic diffusion ($\gamma = 1$), see Ref. (5). Some of these data are repeated in Fig. 1.

Two points in relation to Eq. [18]-[20] should be emphasized.

1. The impurity profile is not a function of $x/t^{1/2}$, as was previously believed. Instead, the profile depends on $x/t^{1/3}$ in the case of arsenic and boron ($\gamma = 1$) and on $x/t^{1/4}$ in the case of phosphorus ($\gamma = 2$). The proper diffusion variable in these cases has caused considerable problems in previous investigations on nonlinear diffusion in semiconductors (6-8).

2. The inherent form of the impurity profile changes with increasing nonlinearity and tends to become more "rectangular." The high concentration region becomes more uniform and the descent toward low concentrations is steeper than for the linear profiles, cf. Fig. 1.

To evaluate the concentration dependence of the diffusion coefficient, the Boltzmann-Matano analysis (4) is used when diffusion is performed with constant surface concentration. The diffusion coefficient is then determined by

$$D = \frac{\int_0^{C_1} x dC}{2t \left(\frac{dC}{dx} \right)_{x_1}} \quad [9]$$

Fig. 1. Doping profile for shallow implanted arsenic ($\gamma = 1$) compared with experimental results from Hill (10). The gaussian profile for linear diffusion ($\gamma = 0$) is given for comparison.

as shown in the analysis. This method has been successfully used to evaluate the diffusion coefficient of several diffusants. The only condition is that the diffusion process must obey Fick's second law, on which the Boltzmann-Matano analysis is based. Hence, the analysis is invalid when other effects are involved, such as precipitation, clustering, or other nonequilibrium complex or vacancy formations. However, there are no restrictions on the concentration dependence of the diffusion coefficient.

In the case of a two-step diffusion process when an implanted or predeposited dose of impurities are redistributed during the drive-in diffusion step, detailed knowledge is needed about the diffusion process before the diffusion coefficient can be evaluated from the doping profile. First of all, as in the Boltzmann-Matano analysis, the diffusion process must obey the diffusion equation. Furthermore, the impurity profile should not contain residues of the originally implanted or predeposited profile, cf. Fig. 1. However, as shown in Eq. [17], detailed knowledge about the concentration dependence of the diffusion coefficient is also required. For arsenic and boron, with $\gamma = 1$, the diffusion coefficient may be evaluated from

$$D = - \frac{C(x_1, t)x_1}{3t \left(\frac{dC}{dx} \right)_{x_1}} \quad [21]$$

A similar expression has been used in the analysis by Fair and Tsai (7) giving the diffusion coefficient as

$$D = - \frac{C(x_1, t)x_1}{2t \left(\frac{dC}{dx} \right)_{x_1}} \quad [22]$$

However, this expression is based on the assumptions that the Boltzmann transformation is the proper variable and that the diffusion coefficient is a function of $C(x, t)/C_s = C(x, t)/C(0, t)$ (7, 8). This assumption is physically not realistic, and the expression is useful only for constant diffusion coefficients and gaussian profiles.

From this point of view, the evaluation in Ref. (7) should give values of diffusion coefficients that are 1.5 times too large. However, great care must be taken with the conditions under which the diffusion was performed. A gaussian profile is a well-known reference assuring that the diffusion was performed under linear conditions.

Fig. 2. Normalized impurity profiles for linear ($\gamma = 0$) and nonlinear ($\gamma = 1$) diffusion plotted together with experimental data for arsenic [from Fair and Tsai(7)]. For some lower doses of implanted arsenic an effective γ , $\gamma_{\text{eff}} = 0.5$, is the best approximation.

For nonlinear diffusion involving large doses of arsenic, the impurity profile is given by Eq. [18] as long as the concentration is so high that the nonlinear diffusivity is dominating. These two reference curves are shown in Fig. 2 together with experimental results from previous work by Fair and Tsai. Only the high dose implants agree with the theoretical curve, indicating a mixture of linear and nonlinear diffusion at lower doses. Only for the high dose implants may accurate evaluations of diffusion coefficients be performed using Eq. [21]. For the lower implant doses, approximate diffusion coefficient evaluations may be obtained from

$$D = - \frac{C(x_1, t_1)}{(\gamma_{\text{eff}} + 2)t \left(\frac{dC}{dx} \right)_{x_1}} \quad [23]$$

Fig. 3. Arsenic diffusivity vs. total concentration using Eq. [24] and [25]. The upper dots are experimental data from Fair and Tsai (7). The lower dots are the same experimental data reevaluated according to Eq. [21].

where γ_{eff} is an effective nonlinearity coefficient ($0 < \gamma_{\text{eff}} < \gamma$), which empirically accounts for the mixing of linear and nonlinear diffusion effects. Thus, before evaluating the diffusion constant by means of Eq. [17], the appropriate γ_{eff} has to be determined by fitting a curve of the form given by Eq. [18] to the available data points. This is different from the Boltzmann-Matano analysis, which is valid for arbitrary concentration dependence of the diffusion coefficient. In Fig. 2, the theoretical doping profile for diffusion with $\gamma_{\text{eff}} = 0.5$ is also shown.

To illustrate the validity of our theoretical analysis, we have plotted in Fig. 3 the arsenic diffusion coefficient as a function of concentration using the expression

$$D = h \left(D_0 + \frac{C}{n_i} D^- \right) \quad [24]$$

where h is given by Eq. [4] and D_0 and D^- by the today widely accepted (11) values of

$$D_0 = 0.066 \exp(-3.44/kT) \text{ and } D^- = 12 \exp(-4.05/kT) \quad [25]$$

In this figure, the experimental data of Ref. (7) for the diffusion coefficient evaluated from profiles of implanted impurities using Eq. [22] are also shown.

This experimental data generally seem to be too large compared with theoretical curves. On the other hand, if these experimental values are reevaluated using Eq. [21], as shown in Fig. 3, very good agreement with present day theory is obtained, especially for high concentrations when γ truly equals one. At lower concentrations, how-

ever, when γ becomes zero corresponding to linear diffusion, the evaluation of diffusion coefficients from Eq. [21] shows the best agreement with theory, as predicted by Eq. [17].

ABSTRACT

In this paper, the origins of the microscopic impurity inhomogeneity in Czochralski (CZ) silicon are reviewed. The relevance of impurity segregation behavior and microscopic growth rate variations to the impurity microfluctuations are analyzed and discussed. The nature of the oxygen microfluctuations is studied in terms of its segregation behavior and its effects on precipitation. Spatially resolved infrared absorption and spreading resistance are used to study the oxygen microfluctuations induced by the melt thermal asymmetry, isolated by a manually controlled crystal growth. It is shown that oxygen segregates microscopically in the same manner as arsenic in silicon, that is, $K_0 < 1$ for oxygen. A quantitative analysis yields a K_0 value in the neighborhood of 0.3 for oxygen, which agrees well with the previous result based on a macroscopic analysis. Heat-treatment experiments have shown that when CZ silicon exhibits microfluctuations in oxygen concentration the precipitation is not uniform; rather, the precipitation is enhanced in the high oxygen regions of the fluctuations. Such behavior can impede the formation of the denuded zone where the high oxygen regions meet the wafer surface, resulting in nonuniform denuded zone width across the wafer.

The microscopic inhomogeneity of impurity distributions in Czochralski (CZ) silicon crystals is, in general, a result of growth-rate fluctuations during crystal growth. The growth-rate fluctuations cause variations in the impurity incorporation levels. The lattice strain associated with local impurity concentration variations gives rise to the so-called "striation," as may be revealed by chemical etching. Severe microscopic dopant inhomogeneity corresponds to a large variation in carrier concentration, and is not desirable in silicon materials used for device fabrication, especially when such variation is comparable to the device feature size. This is an important consideration in VLSI fabrications. Large local fluctuations in oxygen concentration can result in preferential precipitation, of-

ten observed as concentric ring patterns in etched wafers following heat-treatments.

Several recent works have addressed impurity incorporation in CZ silicon crystals and the effects associated with inhomogeneous impurity distribution (11, 12). Here, we have grown crystals with very regular impurity striation patterns so that a more quantitative analysis of the causes and consequences of microscopic inhomogeneity can be made. The main focus of our work is upon oxygen incorporation and striation.

This paper is organized as follows. First, the sources of impurity concentration fluctuation are reviewed briefly. Next, the growth and characterization of a specially grown crystal with widely spaced, regular impurity stri-

tions are described. From the measured impurity distributions, the segregation behavior of oxygen in silicon is determined. Finally, a number of effects associated with oxygen precipitation in inhomogeneous crystals are shown very clearly in our samples that have regular striation patterns.

Microscopic Inhomogeneity in Czochralski Silicon

In Czochralski silicon growth, there are several sources of microscopic growth rate variations.

Noncentral symmetric thermal distribution in silicon melt.—In large melt silicon growth systems, finite thermal asymmetry exists about the center of the melt. During crystal growth, as the crystal is rotated about the growth axis, the interface will experience slightly different temperatures at different positions of the melt. Therefore, the growth rate of a given crystal element parallel to the crystal axis would fluctuate periodically, as illustrated schematically in Fig. 1. In general, the fluctuation is most pronounced in the crystal elements furthest from the crystal center. The periodicity of the fluctuation is determined by the average growth rate \bar{f} , and crystal rotation rate ω , as \bar{f}/ω . Corresponding to the growth-rate variations, there are variations in the impurity incorporation level. When the equilibrium segregation coefficient (K_0) of the element involved is less than unity, the fluctuation in impurity incorporation level is in phase with the growth rate fluctuation. If $K_0 > 1$, the two fluctuations will be out of phase. This is also illustrated in Fig. 1. The relationship may be realized readily by examining equation of Burton *et al.* (1).

Thermal convection-related temperature fluctuations.—These fluctuations are mostly random in nature and etched striations are characteristically aperiodic (2). When thermal convection is significant, the microstriations would bear the signature of high frequency fluctuations, on the order of tens of hertz.

Automatic diameter control-induced perturbations.—Growth rate fluctuations can be further perturbed by the automatic diameter control mechanism (ADC) commonly employed in silicon growth. The crystal pull rate is slaved by optically monitored crystal diameter variations in order to maintain a preset diameter. The pull rate adjustments are both "instantaneous" (a few seconds) and "long-term" (minutes). The long-term pull rate adjustment determines average growth rate. The instantaneous pull rate adjustment imposes modifications on the microscopic growth-rate fluctuations resulting from thermal asymmetry and thermal convection. The net effect is to smear the periodic nature of the impurity fluctuation resulting from the melt thermal asymmetry.

Microscopic Analyses and Crystal Growth

In this study, the microfluctuations of oxygen were measured directly by spatially resolved infrared absorption near $9 \mu\text{m}$,¹ and indirectly by spreading resistance (SR) following an oxygen donor activation treatment at 450°C .

Our apparatus for making spatially resolved IR measurements is based upon a Hughes Model 3802H-L line tunable CO_2 waveguide laser. The laser could be tuned (4.6) to $9.17 \mu\text{m}$, near the maximum of the well-known $9 \mu\text{m}$ IR absorption band that is used routinely to characterize the concentration of oxygen in silicon. The laser spot diameter (FWHM) at the focus was measured to be less than $200 \mu\text{m}$.

Silicon samples were ground wedge shaped (surfaces 6° off parallel) to eliminate the multiple-reflection interference effects that give rise to large interference fringes for uncoated plane parallel surfaces. Samples were then polished to a mirror finish on both sides. We chose wedge-

¹The earliest microscale measurement of $[\text{O}_i]$ we are aware of was performed by McDonald (3). Recent microscale measurements have been reported by Ohsawa *et al.* (4, 5) and by Rava *et al.* (6). Our measurement system is most like that described by Rava *et al.*

Fig. 1. Schematic illustration of growth-rate fluctuation and its relationship with microscopic impurity fluctuation in CZ crystal. f and ω are growth rate and crystal rotation rates, respectively.

shaped rather than antireflection-coated samples because it was more convenient to perform heat-treatments and remeasure absorption spectra on uncoated specimens. Our system was carefully checked with float-zone (oxygen-free) silicon to ensure that interference effects and surface imperfections had indeed been eliminated. We also measured the spatially resolved IR spectrum for our Czochralski-grown samples at $9.6 \mu\text{m}$ (off the oxygen absorption band) to determine transmission fluctuations not due to oxygen striation. Such nonoxygen-related fluctuations of the transmitted beam were $\sim 0.3\%$ of the transmitted signal.

The spreading resistance measurements were performed on a Solid State Measurement Model ASR210 SR probe. The probe spacing used was $150 \mu\text{m}$.

To understand the nature of the microscopic oxygen inhomogeneity induced by the various mechanisms of growth-rate fluctuations during the crystal growth, it is helpful to isolate the major contribution. For this purpose, a $\langle 100 \rangle$ crystal was grown under a constant pull rate of 90 mm/h to avoid the effect of forced pull-rate variations of the ADC mechanism. The crystal was grown from a relatively small charge, 5 kg , to minimize the thermal convection effect. The crystal was lightly doped with arsenic to serve as a reference. A slow crystal rotation rate of 2 rpm was used in order to maximize the periodicity of the rotational striations and to facilitate SR and IR measurements. After growth, (110) longitudinal slices, 1.4 mm thick, were prepared from near the center of a crystal section 75 mm from the seed. Slices were polished on both sides. The average $[\text{O}_i]$ of these slices were measured by FTIR to be 19 and 17 ppma (7) at the center and near the crystal edge, respectively.

Figure 2 shows IR absorption scans along the growth direction, 8 mm from both crystal edges (labeled sample A and sample B). The observed periodic oxygen concentration fluctuations are well resolved. The average spacing measured is 0.76 mm , consistent with the constant pull rate and crystal rotation rate used. The large absorptions at the ends of the scans are due to reference scratch markers. From the change in transmission, the change in absorption coefficient, about the mean and the percent change in the interstitial oxygen concentration can be deduced. An analysis of ten periods gives an average fluctuation of 4.4% about the mean. Under growth without forced pull-rate variations, these well-resolved fluctuations in microscopic oxygen incorporation rate are due to

Fig. 2. $9 \mu\text{m}$ IR absorption scans on crystal's longitudinal slice at positions A and B and C, in as-grown condition. Insert shows sample positions with respect to the experimental crystal. Horizontal segments on the sample represent scratch markers.

melt thermal asymmetry. The relatively symmetrical waveform of the fluctuations indicates that the thermal asymmetry consists of hi-lo temperature regions approximately 180° apart across the melt center. Since the "instrument width" of the laser beam was measured to be narrower than $200 \mu\text{m}$, far less than the periodicity of the oxygen fluctuation, the instrument convolution and smearing effect is insignificant. Therefore, the measured amplitude of the oxygen fluctuations are very close to the actual magnitude. However, some details in the microfluctuation are not resolved by the laser beam, but can be detected by high resolution SR measurements.

Variations in oxygen concentration are observed in the IR scans near the crystal center, (such as position C in Fig. 2) along the growth direction. The fluctuations are small ($\leq 3\%$ peak to valley) and are not periodic in nature. They are mainly due to thermal convection-related growth-rate fluctuations.

Microfluctuations of oxygen were also measured by SR after sample A was annealed at 450°C for 4h to convert some of the interstitial oxygen to electrically active donor complexes (8). Figure 3a shows the SR profile measured at the same sample location as the laser scan, 8 mm from

Fig. 3. Spreading resistance profiles measured along growth direction after the as-grown slice was heat-treated at 450°C for 4h (a), and additional 700°C for 2h followed by quenching (b). The spacing of the data points is $20 \mu\text{m}$.

the crystal edge, after the donor heat-treatment. The higher resistance corresponds to lower oxygen concentration. When the scratch marks are aligned in the laser and SR scans, it may be seen that the fluctuations are well matched. It is noted that some of the fine features detected by SR are not resolved by the laser IR. Since the oxygen donor formation kinetics are proportional to fourth power of the $[\text{O}_i]$ (9), the donor profile measured would give a larger fluctuation than the actual magnitude. A SR measurement at the same sample position after an oxygen donor elimination treatment would reveal dopant fluctuations, in this case arsenic, due to exactly the same growth-rate fluctuations that oxygen experienced during the growth. Figure 3b shows such a SR profile after sample A was annealed at 700°C for 2h followed by fast cooling to room temperature. The average arsenic concentration measured is on the order of 2.5×10^{14} . This is in a good agreement with the four-point probe measurement on the neighboring bulk crystal samples after 700°C donor-elimination treatments. The measured arsenic fluctuations can be discerned and have a periodicity of 0.76 mm . With the scratch marks aligned between profiles in Fig. 3a and 3b, it is seen that the periodic fluctuations are in phase. This demonstrates that oxygen segregates in the same manner as arsenic ($K_o = 0.3$) and that K_o for oxygen is also smaller than unity.

Oxygen Segregation

It is realized that under constant-pull-rate growth (or nominally constant average growth rate), the fluctuations in impurity incorporation level, such as have been observed, are the result of impurity segregation and microscopic growth-rate fluctuations about the average growth rate. It is possible to deduce the magnitude of the growth-rate fluctuation when K_o is known, or vice versa. An analysis of the microscopic arsenic fluctuation yields an average of 5.1% about the mean. Figure 4 shows graphically the effect of growth-rate fluctuations on the impurity-incorporation level. In this plot, the percent change in K_{eff} is computed as a function of the percent growth-rate change about the nominal value used in the present experiment, i.e., $\bar{f} = 90 \text{ mm/h}$, for the K_o values of interest. The computation assumes an oxygen diffusion coefficient $D = 10^{-4} \text{ cm}^2/\text{s}$ and a diffusion boundary layer, δ , of 0.04 cm (10). From the figure, the observed $\Delta K_{\text{eff}}^{\text{As}}$ corresponds to a growth-rate fluctuation of 11% about the nominal growth rate. With this range of growth-rate fluctuations, the 4.4% microfluctuation observed in oxygen incorporation would correspond to a K_o value of slightly greater than 0.3. This value may be compared with the previously determined value of ~ 0.25 by a macroscopic

Fig. 4. Percent change in K_{eff} as a function of growth rate fluctuations about a nominal growth rate of 90 mm/h for equilibrium segregation coefficients 0.2-0.5.

analysis (10). Considering the difference in the methods used and the measurement errors involved, the two results are in a good agreement. Our results from direct crystal growth experiments with both macroscopic and microscopic analyses have yielded similar results. The equilibrium segregation coefficient of oxygen in silicon is considerably smaller than unity. The K_0 value is in the neighborhood of 0.3.

Effect on Oxygen Precipitation

In order to examine the effects of microscopic oxygen fluctuations on precipitation behavior, two neighboring samples from the experimental crystal with different thermal history were further heat-treated at 1050°C for 5h. Sample A was previously heat-treated at 450°C for 4h and 700°C for 2h for the study described above. Sample B was in the as-grown condition. After the heat-treatment, the $[O_i]$ measured at 8 mm from the crystal edge in sample A was 10 ppma, a decrease of 6 ppma from the as-grown concentration of 16 ppma. In other words, about 38% of the original interstitial oxygen was precipitated. A similar measurement in sample B showed the corresponding $[O_i]$ decrease was only 2 ppma. The low temperature treatments preceding the 1050°C treatment in sample A clearly enhanced precipitation.

Microstructural analyses of these samples indicate that the precipitation is not uniform. Rather, preferential precipitation takes place in the originally high oxygen regions of the microfluctuations. Figure 5a shows the etched surface of sample A after 1050°C treatment, 8 mm from the crystal edge. The striking microstructure shows periodic bands of oxygen precipitation which extend to the silicon surface. There appears to be no defect-free volume (denuded zone) under the surface in the precipitation band regions. The vertical scratch reference marks are shown at each end. The original SR trails parallel to the growth direction can be vaguely seen among the random scratch damage due to sample handling. With reference to the SR tracks and scratch marks, the precipitation

bands in Fig. 5a may be matched with the SR profile shown in Fig. 3a to show that the heavy precipitation bands correspond to the originally high oxygen regions. The precipitation density in the low oxygen regions appears to be insignificant. However, relatively small precipitates can be seen under high magnification microscopy. These observations suggest that when there are microfluctuations in oxygen distribution, in the present case ~ 4.4% about the mean, enhanced precipitation can occur in the high oxygen regions. Furthermore, the fact that the precipitation occurs at the sample surface suggests that no denudation takes place in the banded precipitation regions. Apparently, the oxygen out-diffusion near the sample surface is suppressed by a fast nucleation/growth mechanism in the high oxygen regions. Such effects are especially pronounced in the case where precipitation was assisted by low temperature nucleation treatments. These preferential precipitation bands would correspond to concentric ring patterns in the crystal's transverse cross sections, *i.e.*, normal wafer slices. It is believed that the preferential oxygen precipitation mechanism associated with microscopic oxygen fluctuations is the cause of the concentric rings often observed in oxidized or heat-treated CZ wafers, following chemical etching. Figure 5b shows etched striated micrograph in sample A near the crystal edge after 1050°C treatment. There is no preferential precipitation taking place due to low oxygen concentration at the crystal edge. The average periodicity of the striations, ~ 25 μm , corresponds to a high frequency fluctuation of 1 Hz associated with melt thermal convection.

Our data indicate that the oxygen precipitation kinetics in CZ silicon with microfluctuations is not strictly proportional to oxygen concentration. Several factors for such preferential precipitation may be speculated. It is likely that the preferential precipitation of oxygen in the high $[O_i]$ regions reflects the number of nuclei formed during the low temperature heat-treatments. Our SR measurements show that, following 450°C heat-treatment, the

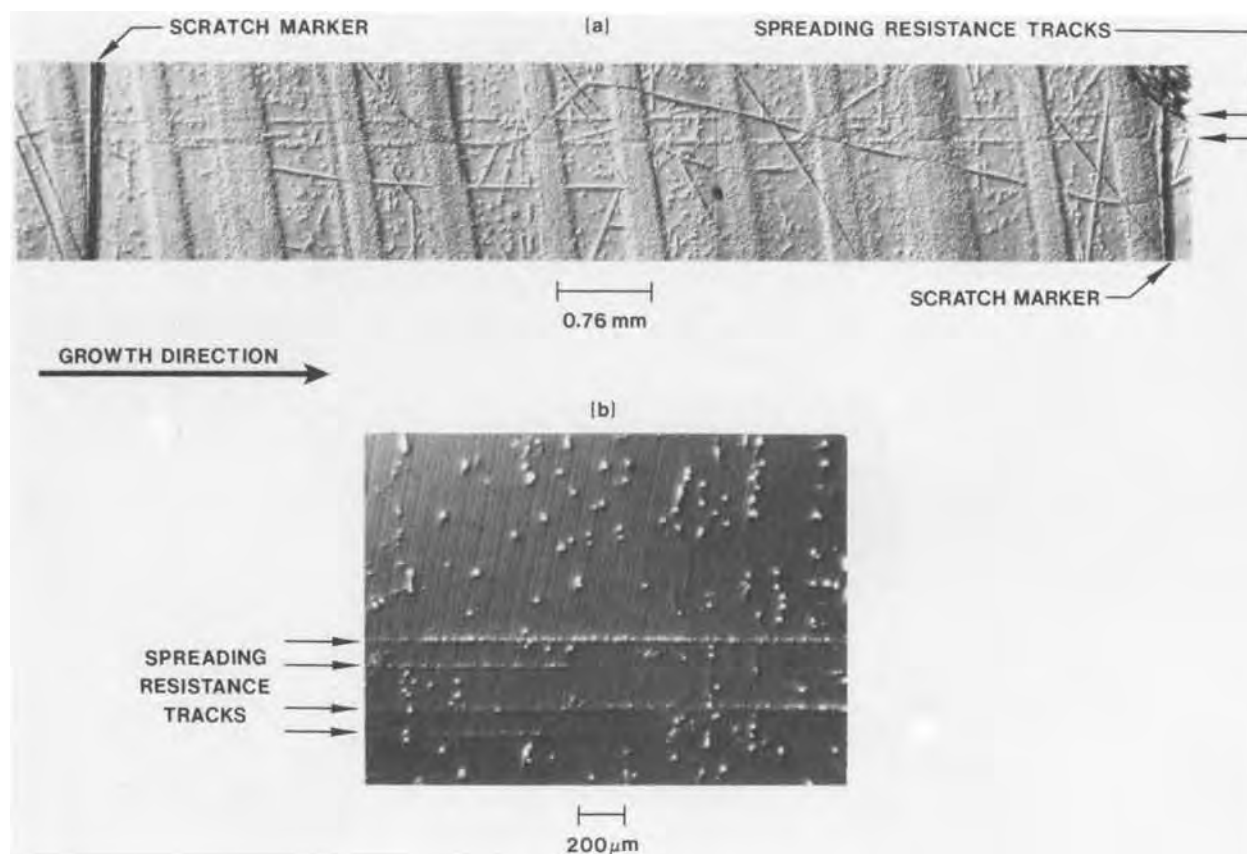

Fig. 5. a: Micrograph of Secco-etched sample A showing preferential oxygen precipitation at high $[O_i]$ regions after 1050°C, 5h treatment. b: Microstriations near the crystal edge (of sample A) showing average periodicity of 25 μm . The heat-treatment condition is same as in a.

distribution of thermal donors reflects $[O_i]$ distribution but with greater fluctuation amplitude. We have not measured directly the distribution of nuclei following 700°C treatment, but the precipitation behavior at 1050°C would seem to indicate a large fluctuation amplitude for the concentration of nuclei also.

Another postulated mechanism for inhomogeneous precipitation behavior involves the preferred nucleation and growth of oxygen precipitation at microdefect centers introduced during crystal growth. Such defects, ranging from several hundred angstroms to tenth of a micron in size, have been related to temperature oscillation and remelting occurring at the growing crystals' solid-liquid interface (13, 14). The defect centers would provide convenient nucleation sites for oxygen precipitations at a preferential rate. The remelting phenomenon is closely related to growth conditions where thermal asymmetry exists.

Remelting can occur when the rotating crystal's interface changes from low to high temperature fields such that a negative instantaneous growth-rate results. In the present sample, this condition would correspond to the low growth-rate portion of the microfluctuations. That is, logically, if remelting-related microdefects exist in the current sample, they are likely to occur in the low oxygen regions, not the high oxygen regions. This is not consistent with the current observation of the enhanced precipitation, which occurs in the high oxygen regions. Furthermore, the present SR measurements and microstructures do not give a sufficient indication that a correlation exists between the microdefects and enhanced precipitation in the present crystal. The possible role of the microdefects in enhanced precipitation needs to be further investigated.

One of the strong characteristics observed in the precipitation band regions is that oxygen outdiffusion at the surface is being suppressed such that precipitation extends to the surface with no "denuded zone." In comparison, much weaker precipitation effects have been observed in CZ silicon with similar $[O_i]$, but much better microscopic uniformity when receiving identical heat-treatments. In the latter case, the precipitation-free depth region near the surface is not zero, but 10 μm or so. Thus, CZ silicon wafers fabricated from crystals with significant microfluctuations would be likely to display nonuniform precipitation and denuded zone width across the wafer. This phenomenon has often been observed (15). The degree of nonuniformity in the denuded-zone width would depend on the amplitude and periodicity of the fluctuations, the crystal's interface curvature, and the thermal history of the wafer prior to the precipitation process. The significant implication of such behavior is that, when the crystal with $[O_i]$ microfluctuations is fabricated into wafers, the formation of the wafer surface-denuded zone may be impeded where high oxygen regions of the fluctuations meet the surface.

Summary and Conclusions

In this paper, the origins of the microscopic impurity inhomogeneity in Czochralski silicon have been reviewed. The relationship of impurity segregation behavior and microscopic growth-rate variations to the impurity microfluctuations is analyzed and discussed. The observed microfluctuations in large diameter CZ silicon crystals are characteristically a result of convoluted growth-rate fluctuations due to melt thermal asymmetry, thermal convection, and forced pull rate variations induced by automatic diameter control.

In general, the effect of the oxygen microfluctuations may be minimized by reducing the periodicity of the fluctuations, via increased crystal rotation rate during crystal growth. However, a more fundamental approach would be to improve the melt thermal symmetry. In a side-heated Czochralski growth system, it is essential that

good contact be maintained between the entire crucible wall and surrounding graphite susceptor for uniform and symmetrical heating. The forced pull-rate variations induced by the automatic diameter control can be reduced by proper adjustment in the control electronics. More recent diameter-control designs based on advanced optical sensors coupled with a microprocessor offer smoother control. Thermal convection-induced temperature oscillations can be suppressed by using either small melt growth, such as a double crucible (16) or low aspect ratio approaches, or by applying magnetic field (17).

The nature of the oxygen microfluctuations is studied in terms of its segregation behavior and its effects on precipitation. High resolution laser IR absorption and spreading resistance are used to study the oxygen microfluctuations induced by the melt thermal asymmetry, isolated by a manually controlled crystal growth. It is shown that, microscopically, oxygen segregates in the same manner as arsenic in silicon, that is, $K_0 < 1$ for oxygen. The quantitative analysis yields a K_0 value in the neighborhood of 0.3 for oxygen, which agrees well with the previous result based on a macroscopic analysis (10).

Heat-treatment experiments have shown that when CZ silicon exhibits microfluctuations in oxygen concentration, the precipitation is not uniform; rather, the precipitation is enhanced in the high oxygen regions of the fluctuations. Such behavior can impede the formation of the denuded zone where the high oxygen regions meet the wafer surface, resulting in nonuniform denuded zone width across the wafer.

Process-Induced Leakage Current in a Low Noise GaAs MESFET

P. A. Folkes, C. C. Chang, and E. Lane

Bell Communications Research, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The cause of a process-induced leakage current in low noise GaAs MESFET's has been traced to conduction along the semi-insulating buffer surface surrounding the mesas that contain the active elements of the device. The ion milling process, which we used to define the mesas, is responsible for inducing large, variable increases in surface leakage. For a fixed voltage between the gate and source pads of 1V the induced leakage current ranged from 5 nA to 10 μ A at 23°C. We compared the effects of several commonly used etches for cleaning GaAs. A buffered peroxide solution did not reduce the induced leakage current. By contrast, a concentrated aqueous NH_4OH solution reproducibly reduced the induced leakage current to below 1 nA. Auger analysis revealed a correlation between high surface leakage and the presence of a surface Ga oxide layer. We were unable to definitively identify the cause of the leakage, but suggest two possible mechanisms that are consistent with our data: (i) band bending due to charges in the surface oxide, or surface state effects, and (ii) conduction through a thin layer of elemental As located between the surface oxide and the GaAs.

GaAs MESFET's are receiving increasing attention because of their use as preamplifiers in light wave receivers (1). There is interest in understanding and minimizing the leakage current in GaAs FET's, since at low bit rates the receiver sensitivity is limited by shot noise, which is proportional to the leakage current.

The data shown in Fig. 1 illustrate that, if special precautions are not taken, a tremendous variation is observed in the gate leakage current of GaAs MESFET's from similarly processed wafers. Measurements of the resistivity of the GaAs substrates showed no difference in substrate resistivity, suggesting that the large leakage current variation was induced by processing. We focused on the following aspects of this problem: (i) location of the leakage current, (ii) the processing steps responsible for inducing leakage, (iii) the physical mechanism involved, and (iv) techniques to reduce leakage. We show below that we succeeded with the first, second, and fourth aspects. Although we were unable to definitively identify the third, we suggest two candidates that are consistent with our data.

Experimental

GaAs FET structure.—A schematic cross section of the transistor structure is shown in Fig. 2. The substrate is high resistivity chromium-doped GaAs. An epitaxial high resistivity chromium-doped GaAs buffer layer (3-5 μm thick) separates the substrate from the n-type active layer, which is only 0.4 μm thick. An n^+ layer grown over the active layer facilitates the formation of ohmic contacts. All epitaxial layers were grown by chemical vapor deposition.

Figure 3 shows a top view of the FET. The active region of the device is enclosed by the heavier dashed line. The shorter dashed lines delineate the gate metal. Isolation between different devices is achieved by the creation of mesas using an ion milling process (Ar ions at 300 $\text{\AA}/\text{min}$). Milling is preferred over chemical etching because of undercutting around mesa edges and other problems. The region outside the heavier dashed line in Fig. 3 is the surface of the high resistivity GaAs:Cr buffer that is exposed by the ion milling. The source, drain, and gate bonding pads, which are deposited onto the buffer surface, are indicated in the diagram by the letters S, D, and G, respectively. Typical dimensions are, for mesa length 75 μm , for S and G pads $50 \times 100 \mu\text{m}$, for G to mesa spacing 40 μm , for gate width 250 μm , and for gate length 1 μm .

Electrical measurements.—In order to identify the processing steps responsible for inducing the leakage current, the current-voltage (I-V) characteristics of wafers were monitored at several stages during processing. The I-V characteristics were measured as a function of the applied voltage between the gate and source pads with the drain floating. We demonstrate below that the current being measured was the current flowing between the gate

pad and the entire mesa. Typically, each wafer was characterized by measuring the leakage current of eight devices from different sections of the wafer. Unless otherwise noted, the leakage current was measured at an applied gate voltage of 1V. A computer-controlled measurement system, consisting of a Hewlett-Packard HP-85 computer, an HP Model 3497A Data Acquisition/Control Unit, an HP-6002A programmable power supply, and an HP-7245 plotter/printer, was used. The devices were accessed using an Electroglas Model 131 wafer prober. The processing steps of interest, in sequential order, are: 1, growth of buffer and n-type active layers, 2, mesa definition by ion milling followed by PA etching (using a

solution of 30% hydrogen peroxide in deionized water buffered to a pH 7.2 with ammonium hydroxide), 3, ohmic metal deposition and alloying, 4, gate notch etch and gate metal (Al) deposition, 5, final metal deposition, and 6, dicing. Wafers were evaluated after processing steps 3, 4, 5, and 6, as well as before and after alloying of ohmic metal. Only a small number of devices was measured after dicing, owing to the long sorting time required to find specific devices. In order to investigate the effects of processing steps 1 and 2 on leakage, wafers were grown with no n-type active layer on top of the high resistivity buffer layer. Each wafer was then cleaved into several samples. The surfaces of some of these samples were ion milled in separate runs and had metal deposited on them for ohmic contacts, while others had metal deposited on them without any ion milling. The leakage currents of these samples were then measured.

The ion miller was a Technics Model TLA-20, operated at an ion beam energy of 500 eV with the substrate temperature held at 60°C by use of a water-cooled wafer holder. It is important to note that the machine and the procedure for this ion milling is very different from those used in the Auger apparatus (described below) for depth profiling and surface cleaning.

Surface etching.—The wafers were treated with a variety of etchants to determine whether the leakage current path is at the surface and to develop a technique to reduce the leakage. The PA etch of processing step 2 and an aqueous NH_4OH solution were used primarily in these experiments; however, the effects of a $\text{H}_2\text{SO}_4:\text{H}_2\text{O}_2:\text{H}_2\text{O}$ (1:1:200) and a 0.05% bromine-methanol solution were also investigated.

The NH_4OH etch, when used in conjunction with a prior anodic oxidation of the GaAs surface, can produce an essentially stoichiometric and contaminant-free GaAs surface (2). We used a 1:1 solution of NH_4OH in deionized water with a pH of 12.7. Wafers were etched for 2-10 min, rinsed with deionized water, and blown dry with filtered nitrogen. The etch rates were measured using a Talystep 1 instrument.

Auger electron spectroscopy.—The chemical nature of the GaAs buffer surface was studied by Auger electron spectroscopy (AES) using a PHI 590A system. The experimental system and analysis conditions have been described elsewhere (3). For depth profiling and surface cleaning, a PHI Model 04-303 differentially pumped ion gun was used, operated at an ion energy of 3-4 keV (Ne), and milling rates of 50-100 Å/min. The main objective of the AES analysis was to look for any correlations between the chemical nature of the GaAs surface and the leakage current. This information is important in understanding the mechanism responsible for the leakage current.

Electrical Measurements

Effects of processing steps 3-6 on leakage.—Figure 4 shows typical leakage current vs. voltage curves for two devices from different wafers which were measured after (i) formation of ohmic contacts, (ii) gate deposition, and (iii) deposition of final metal. Most of these data were taken with the gate biased negatively with respect to the

Fig. 4. Typical set of I-V characteristics after ohmic metal, gate, and final metal.

source, after we had established that the leakage current is insensitive to the polarity of the gate. Note that at the ohmic contact and gate formation steps the leakage current varies linearly with voltage over the voltage range 0.1-12V, whereas after final metal the current is ohmic up to 7V and then increases steeply with increasing voltage. This sharp increase in current is indicative of space-charge-limited current flow caused by the injection of electrons into the semi-insulating buffer from the ohmic metal (4). Measurements of over 200 devices showed that the threshold voltage for the transition from ohmic to space-charge-limited current flow lies in the range of 6-10V. The operating voltage of the device is only about 2V, which is well below this space-charge-limited threshold. This fact, along with Fig. 4, indicates that the variation in leakage current is not related to space-charge-limited current flow but is due to variations in the resistivity of a conducting region in the buffer. Figure 5 shows the broad distribution of wafer average leakage current (at 1V) measured at room temperature shortly after formation of ohmic contacts.

Figure 4 also shows that the processing steps subsequent to the formation of ohmic contacts have little effect on the leakage current. Measurements on 40 additional wafers supported this observation. Table I lists the aver-

age leakage current at room temperature of some of these wafers after processing steps 3, 4, and 5. Most wafers showed no significant change in leakage, and approximately 20% changed by a factor of 2-3. A limited amount of data from devices measured after dicing showed that this process does not affect leakage. As illustrated by Table II, alloying of the deposited ohmic metal does not increase the leakage. These results suggest that at least one of the processes which precede the deposition of ohmic metal is responsible for inducing an increase in the leakage current.

Effects of ion milling on leakage.—Measurements of the leakage current, I_g , in the unmilled high resistivity buffer were carried out using wafers without any n-type active layer. I_g ranged from 0.1 to 1 nA, as shown in Table III.

The ion-milled samples from these same wafers show a large variable increase in the observed leakage current. In particular, one wafer, labeled "Tester" in Table III, was cleaved into eight samples, three of which were measured as unmilled samples. For the ion-milled samples, I_g ranged from 2 nA to 10 μ A, as shown in Table III; these were milled in separate runs. For the unmilled samples, I_g was consistently equal to 1 nA.

These results prove that the ion milling process is responsible for inducing large variable increases in leakage

current. They are also an indication that the leakage current path is located at (or very near) the buffer surface since the 500 eV ion milling process (with the wafer surface temperature maintained at approximately 60°C) is not expected to damage the GaAs material well below the surface (5).

PA etching effects.—An experiment to evaluate the PA etch is shown in Table IV. The wafers were ion milled and then cleaved into several samples. Before the formation of ohmic contacts, half of these samples were PA etched for 1 min using a freshly prepared solution each time, while the other set was not etched. The results show that, except for wafer 1485, there is no significant difference in the measured leakage current of the etched and unetched samples. It should be pointed out that this set of samples happened to have uniformly low leakage currents. Similar results were obtained on samples with higher leakage currents (see Fig. 6 and 7).

Repeated PA etching of the buffer surface can even lead to increased leakage, as shown in Fig. 6. The initial

Fig. 6. Effect of repeated PA etching on leakage

Fig. 7. Effects of NH_4OH and PA etching on the leakage current of the ion-milled sample Tester 1.

I-V curve is shown by the solid line. After three 2 min PA etches the leakage current increased by a factor of 2. A Talystep measurement showed that the PA etch removed 6000\AA from the buffer surface. A subsequent 15 min 100W oxygen plasma "cleaning" of this wafer surface reduced the leakage by a factor of 4. We tried a few more experiments with oxygen plasma cleaning and became convinced that the slight reduction in leakage current did not warrant further investigation of this approach; these surfaces were not Auger analyzed.

Further evidence of the erratic nature of the PA etch can be seen in Fig. 7. The solid line is the leakage I-V curve for the ion-milled sample, Tester 1. This sample was cleaved into two pieces after ion milling. One half was etched with the PA etch for 1 min, while the other was etched with the NH_4OH solution. After the PA etch, the leakage current, which was initially $10\ \mu\text{A}$, decreased to $4\ \mu\text{A}$. A Talystep measurement showed that the PA etch removed less than 30\AA of material from the surface; it appears that, in this case, the PA etch did not remove any GaAs.

The sample which received the PA etch was cleaved in two and each piece etched in either $\text{H}_2\text{SO}_4:\text{H}_2\text{O}_2:\text{H}_2\text{O}$ or the bromine-methanol solution. Both treatments increased the leakage current nonuniformly across the wafer.

NH_4OH etching effects.—Figure 7 shows much more favorable results for the other half of Tester 1, which was etched several times in the NH_4OH solution. The first NH_4OH etch, which lasted for 1 min, reduced the leakage current from $10\ \mu\text{A}$ to $140\ \text{nA}$. Subsequent etches of the same sample resulted in a steady decrease in the leakage current. After the fourth etch, corresponding to a total etch time of 6 min, the leakage current decreased to $0.4\ \text{nA}$. Similar results were observed on all the other ion-milled wafers irrespective of the magnitude of the initial leakage current. Figure 8 shows the leakage current of four different wafers, which were etched in NH_4OH , as a function of etch time.

Talystep measurements of these NH_4OH -etched wafers show that in all cases less than 100\AA of material was re-

Fig. 8. Leakage current, I_g (at 1V) as a function of length of time of etch in the 1:1 NH_4OH solution for four different samples.

moved from the surfaces after 6-8 min of etching. Because the etch rates are so small, a more careful measurement of the NH_4OH etch rate was made using a wafer on which no active layer was grown. After ion milling, the samples were cleaved from this wafer and etched in the NH_4OH solution for various periods of time using electroplating tape as an etch barrier to create a step. Figure 9 shows that the etch rate of ion-milled buffer surface is approximately $10\ \text{\AA}/\text{min}$. These results confirm that the leakage current path is located at the GaAs buffer surface.

Use of the NH_4OH etch in processing.—Table V shows the average leakage current at room temperature of wafers from nine device lots which received an 8 min NH_4OH etch after mesa definition. The first three wafers were measured after processing steps 3, 4, and 5; the others were measured only after processing steps 3 and 5. The average gate leakage current of devices from three wafers operating at 85°C (with $V_{ds} = 1.5\text{V}$ and $V_{gs} = -0.25 \pm 0.05\text{V}$) were 17, 9, 13 nA, respectively.

Surface chemical analysis.—Surface chemical analyses were performed using Auger spectroscopy. Typical Auger spectra are shown in Fig. 10-12; these were taken under identical experimental conditions (3 keV incident electrons at 1 μ A current) and are all displayed at the same vertical magnification scale (except Fig. 11c) so that the relative sizes of the Auger peaks can be directly compared. The Auger data are summarized in Table VI, in which the height of the oxygen Auger peak (labeled O Peak in Table VI in arbitrary units), the As/Ga peak height ratio (As/Ga), the height of the GaAs plasmon loss peak of the Ga spectra (plasmon, normalized to the 1067 eV Ga peak height), and the "symmetry factor" (explained in the table) are shown.

The buffer surface immediately after mesa delineation by ion milling was examined before PA etch (top row of Table VI). Auger data from this surface are shown in Fig. 10a. From these spectra, we estimate that there is a surface Ga oxide containing less than 5 atom percent of As. Note the small value of the GaAs plasmon loss peak height in Table VI, top row, indicating that the surface oxide is sufficiently thick to almost completely attenuate the plasmon loss signal from the GaAs substrate. The oxide was then milled off while monitoring the O, Ga, and As signals, in order to determine the oxide thickness. The oxide was found to be about 60Å thick, as shown by the Auger data in Fig. 10b, which were taken after milling off 60Å. The milled thickness was estimated assuming the milling rate for SiO₂. In the figure, the Ga and As signals from the substrate are strong, and the oxygen signal is almost gone, indicating that the data were taken at the interface between the oxide and the GaAs buffer layer (the rate of oxygen readsorption in our Auger system was negligible).

The escape depth of oxygen Auger electrons (at 507 eV) is about 10Å; we estimate that an oxygen signal of 4 in Table VI should correspond to an oxide 10 ± 5 Å thick. A

Table VI. Analysis of Auger data

Sample	O Peak	As/Ga	Plasmon	Symmetry ^a
Ion milled (mesa)	7.0	0.05	0.05	0.75

Low leakage (PA)	3.8	0.57	0.12	0.56
NH ₄ OH etched	2.8	0.84	0.15	0.53
"Clean" GaAs ^b	0	0.67 ± 0.07	0.19	0.53 ± 0.03

^a Symmetry = Pos/Neg, where Pos/Neg is the ratio of the positive excursion to the negative excursion of the Ga (1067 eV) peak plotted in the "derivative" mode.

^b Ion mill cleaned in the Auger apparatus.

more quantitative analysis would become somewhat involved, because the peak shape (which affects the peak height) is chemistry dependent (6). The oxide thickness is not linear with the oxygen signal, but increases very rapidly with the oxygen signal above about 4 (6).

The thicknesses of the oxides on both PA etched surfaces are small, about 10Å for the low leakage, and 17Å for the high leakage surface (see Table VI). This thicker-oxide conclusion is supported by the smaller GaAs plasmon loss peak and greater symmetry of the Ga (1067 eV) peak from the high leakage surface than from the low leakage surface. The Auger spectra from these surfaces are given in Fig. 11a and 11b. The plasmon loss peak for the Ga (1067 eV) peak of Fig. 11b is shown more clearly in Fig. 11c. The GaAs plasmon loss peak and the asymmetry of the Ga peak are signatures of the GaAs substrate. Auger data from a thick oxide show no GaAs plasmon loss peak and very symmetric Ga peak shape (symmetry factor about 0.8). The decreasing plasmon signal and increasing Ga peak symmetry with increasing oxygen intensity in Table VI are due to attenuation of signals from the substrate by the surface oxide (6).

The oxide on the high leakage PA etched surface is As deficient because of the small As/Ga peak height ratio (Table VI). The true As deficiency in the high leakage oxide is probably greater than indicated by the As/Ga ratio because the leaky surface should have a thin As-rich layer under the As deficient oxide, according to the literature (2, 7). Because these compositional changes occur in a depth of only about 10Å, useful data can only be generated using the lowest energy (below 100 eV) Auger transitions; unfortunately, such peaks are difficult to quantify. A large amount of such data were taken and analyzed, but the only definitive conclusion we could draw was that we could not exclude the existence of the interfacial As layer.

Fig. 10. a (left): Auger spectra from the surface oxide produced after mesa definition by ion milling. The vertical axis is the "derivative" Auger peak intensity in arbitrary units. The same vertical magnification has been maintained in Fig. 10-12 (except Fig. 11c), so that relative intensities can be compared from figure to figure. b (right): Spectra after 60Å were removed from the same sample used in Fig. 10a.

Fig. 11. a (top left): Auger spectra from the buffer surface of a PA-etched, high leakage wafer. b (above): Auger spectra from the buffer surface of a PA-etched, low leakage wafer. c (left): Detail of the Ga Auger peak of Fig. 11b, showing the plasmon loss peak.

We conclude that the high leakage PA-etched surface has a thicker oxide that contains mostly Ga oxide, and that there can be a thin As layer between this oxide and the semiconductor.

Auger data from a surface etched in NH_4OH are displayed in Fig. 12. The O peak is smaller and the As peak is larger than that from the low leakage PA-etched surface; therefore, the NH_4OH etched surface is even closer to the "Clean GaAs" (Table VI) surface than the low leakage PA etched surface. The clean GaAs surface of Table VI was ion-mill-cleaned in the Auger apparatus until no contaminants could be detected. This surface is As deficient (2) by about 7%, a negligibly small quantity compared to the much larger As deficiencies we encountered in this work.

Finally, there are certain perverse situations in which the above quantitative results will not be valid because of diffraction effects in the single-crystal substrates; we did not observe any suspicious variations in our data, but we made no systematic studies of angular dependencies of the peak heights. Possible difficulties from chemical shifts and diffraction are the reasons why we tabulated four properties in Table VI instead of just the oxygen peak height. Since all four columns of data agree, there does not appear to be any significant experimental artifacts.

Discussion

We have found a direct correlation between the amount of surface (As-deficient) Ga oxide and the leakage cur-

rent. The failure of the bromine methanol etch to reduce the leakage is consistent with this correlation because bromine methanol leaves just such a surface oxide (2). A mechanism that would explain the large leakage current variations must take the following factors into considera-

Fig. 12. Auger spectra from an NH_4OH -etched surface

tion: (i) the leakage current is a near-surface phenomenon, (ii) the range of leakage current is large, from 0.5 nA to over 10 μ A, (iii) it operates in the environment of the semi-insulating substrate, and (iv) leakage can be controlled by an oxidized surface layer only about 10-60Å thick.

A mechanism consistent with the above is the surface band bending due to fixed charges in the surface oxide or surface states. Band bending could lead to either accumulation or inversion at the buffer surface with the associated increase in surface conductivity (8). The variation in leakage could then be explained by variations in the buffer surface potential (amount of charge in the oxide) or the type and degree of carrier compensation (buffer layer quality).

Another possible mechanism for current leakage is conduction along an elemental As layer at the interface between the oxide and the semiconductor; the large range of leakage current then results from the thickness variation and degree of continuity of the As layer. It is possible that both mechanisms control the leakage current. The first mechanism is especially interesting because it should be less effective in wide-gap (uncompensated) semi-insulating GaAs.

The composition (almost pure Ga oxide) and thickness (only about 60Å) of the surface oxide created by ion milling for mesa delineation indicate that the poor performance of the PA etch in controlling leakage is caused by the inability of the pH-adjusted PA etch to reproducibly remove this oxide. However, it is not a simple problem of slow or variable etch rate, since, if that were the case, the leakage current should eventually come down after a sufficiently long etch time (which is not the case). We propose that the basic problem is not the oxide etch rate, but rather the competition between the oxide etch rate and growth rate. According to the literature (9), the solubility of Ga oxide is lowest in a neutral solution and increases with both acidity and alkalinity. This is consistent with our finding in this work that the etch rate of GaAs with a Ga oxide surface layer in our neutral PA etch can be very fast or slow (PA etching effects section). It is also known that the oxidation rate of GaAs in the PA etch can be relatively fast because of the presence of the peroxide. Therefore, the slow attack of GaAs can be explained by the growth of a slowly etching oxide during PA etch when the initial surface layer is a passivating oxide. When steady state is established, the surface is covered with a thicker oxide than when the NH_4OH etch is used; in the NH_4OH case, the Ga oxide is dissolved rapidly because of the high pH. However, the PA etch can attack GaAs rapidly if the initial passivating oxide is absent because the rapid oxidation of the unpassivated surface results in the growth of more nonpassivating oxide. According to our data, one criterion of a passivating oxide is its low As content.

Conclusion

We have shown that the leakage current is due to conduction along the semi-insulating buffer surface outside the active area of the device. We have also shown that the ion milling process used to define mesas is responsible for inducing the leakage and that the PA etch does not

consistently reduce the induced leakage current. A concentrated aqueous NH_4OH solution will remove the surface oxide rapidly but will etch the GaAs very slowly and reproducibly reduce the induced leakage current to below 1 nA.

Auger spectroscopy results indicate that ion milling for mesa delineation results in a surface oxide layer which is mostly Ga oxide. Wafers which were ion milled and then PA etched also have an As-deficient surface oxide, probably with a thin As-enriched layer underneath it. We propose that the leakage current phenomenon can be explained by one, or a combination, of the following mechanisms: (i) band bending due to charges in the surface oxide and surface state effects, and (ii) conduction through a thin interface layer of elemental As.

No investigation is ever complete, and neither is this one. A more definitive verdict on the existence of the As layer (perhaps by use of ion scattering spectrometry), electrical measurements of the effect of charges in the Ga oxide layer, and the dependence of the surface etch rate on pH, NH_4OH concentration, solution temperature, As content of the surface oxide, and semiconductor doping level would certainly contribute to better control of the surface leakage problem. Future experiments using pure (uncompensated) semi-insulating GaAs should be especially illuminating with respect to our band bending model. Finally, it is truly surprising that an unpassivated semiconductor surface can be simply etched chemically in such a way that the leakage current can be reproducibly reduced to below 1 nA, and at times by as much as five orders of magnitude.

Acknowledgments

We would like to acknowledge the many informative and helpful discussions with S. H. Wemple, and with H. M. Cox, who was also responsible for the CVD epitaxial growth of the GaAs wafers used in this study. We would also like to thank G. E. Mahoney and P. F. Sciortino for providing processing information and supervision of the experimental wafers in the device processing line.

Substrate Orientation Dependence of the In-Ga-As Phase Diagram for Liquid Phase Epitaxial Growth of $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ on InP

Kazuo Nakajima and Jiro Okazaki

Fujitsu Laboratories Limited, Atsugi Laboratories, 1677 Dannoki, Ono, Atsugi, 243-01 Japan

ABSTRACT

The liquidus isotherms of the In-Ga-As system were determined at 600° and 700°C by the improved seed dissolution technique. From the results of the liquidus isotherms and the lattice-constant measurements, the substrate orientation dependence of solution compositions to grow lattice-matched $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ layers on the (100), (111)A, and (111)B InP substrates by liquid phase epitaxy (LPE) was exactly obtained in the temperature range 600°-790°C. The solution compositions of Ga for the (111)A and (111)B faces are always larger than those for the (100) face over the entire temperature range 600°-790°C. The solution compositions of As for the (111)A and (111)B faces are always smaller than those for the (100) face over the entire temperature range 600°-790°C. In order to study effects of the surface free energy on the In-Ga-As phase diagram which was determined by using the LPE method, the In-Ga-As phase diagram was calculated, for the first time, by adding the surface free energy to the chemical free energy of the $\text{In}_{1-x}\text{Ga}_x\text{As}$ solid phase. According to the calculated phase diagram, the composition of Ga in the solution to obtain the (111) oriented $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ is smaller than the composition of Ga in the solution to obtain the (100)-oriented $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$. This tendency of the calculated results is contrary to the experimental results. That is to say, the difference in the surface free energy is not a main reason for the substrate orientation dependence of the In-Ga-As phase diagram.

The liquid phase epitaxial (LPE) growth of lattice-matched $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ on InP is important especially for infrared photodetector (1-3) and FET (4-6) applications. It has been reported that the solution composition for the growth of lattice-matched $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ strongly depends on the orientation of InP substrates (7-10). However, the growth temperature dependence of the difference of the solution compositions for the growth of lattice-matched $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ on (100) and (111)B InP substrates is different according to each author. Antypas *et al.* (7) studied the temperature dependence of the incorporation of Ga during LPE growth of $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ on (100) and (111)B InP in the temperature range 621°-650°C, and they reported that there was a cross point at 629°C, at which the solution composition for the growth of $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ on both faces of InP are equal. On the other hand, Pearsall *et al.* (8) and Nakajima *et al.* (9) reported that the composition of Ga in the solution for the growth of $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ on (111)B InP is always larger than that on (100) InP in the temperature range 600°-670°C. Recently, it was reported by Hsieh (10) that the difference between the solution compositions for the growth of $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ on (100) and (111)B InP decreased with increasing temperature, and above about 700°C the solution compositions for both faces were the same. In order to yield clues to these inconsistent results and to understand the LPE growth mechanism of multicomponent systems, it is very important to study the temperature dependence of the solution composition in detail and to make clear the origin of the substrate orientation dependence of the solution composition.

The equilibrium phase diagram is not completely adequate for describing the LPE growth of $\text{In}_{1-x}\text{Ga}_x\text{As}$ on InP because of the strong perturbing effects of the substrate orientation on the phase diagram. It has been generally discussed that these perturbing effects of the substrate orientation presumably result from the attachment kinetics at the growth interface or from a difference in surface energy (8-10). However, the origin of the substrate orientation dependence of the phase diagram has not been made clear until now because no one has calculated the phase diagram by adding these effects to the chemical free energy of the solid phase or confirmed how the phase diagram was influenced by the addition of these effects. Therefore, the influence of these effects on the phase diagram must be investigated in order to develop a theoretical model for calculating the phase diagram which is adapted to the LPE growth.

In this work, the liquidus isotherms of the In-Ga-As system were experimentally determined using an improved seed dissolution technique (9). The results of the

phase diagram and the lattice-constant measurements were used to obtain the solution compositions for the growth of lattice-matched $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ layers on the (100), (111)A, and (111)B InP substrates. From these results, the substrate orientation dependence of the solution compositions and the distribution coefficients were exactly obtained in the temperature range 600°-790°C. The surface free energy was obtained for the (100)- and (111)-oriented $\text{In}_{1-x}\text{Ga}_x\text{As}$ layers. The In-Ga-As phase diagram was calculated, for the first time, by adding the surface free energy to the chemical free energy of the $\text{In}_{1-x}\text{Ga}_x\text{As}$ solid phase. The origin of the substrate orientation dependence of the phase diagram was studied by the calculation.

Experiments and Results

Liquidus isotherms.—The accurate liquidus isotherms of the In-Ga-As system were determined at 600° and 700°C by the improved seed dissolution technique, which had been used previously to obtain the 650°C liquidus isotherm of the ternary system (9). A ternary In-Ga-As solution was brought into contact with an InP seed at 600°C (or 700°C) and kept in contact at this temperature for 30 min. If the As concentration in the ternary solution was below the solubility limited at 600°C (or 700°C), the initially undersaturated solution became saturated with P, and the P solubility could be calculated from the weight loss of the seed after removal of the solution. If the As concentration in the solution was just at or above the solubility limit, P could not dissolve from the InP seed, and no weight loss could be detected. Therefore, the accurate ternary solution compositions just saturated at 600°C (or 700°C) could be known by measuring P solubility as a function of As concentration. In this improved seed dissolution technique, a very thin epitaxial film of the ternary alloy was formed on the surface of the InP seed in contact with the saturated ternary solution. The thin film protected the InP seed from further dissolution. Therefore, the ternary solution was in equilibrium with the ternary thin film when the solution was saturated.

The ternary solution was made from semiconductor-grade In, InAs, and GaAs. The InP seeds were semiconductor-grade polycrystals. The experimental apparatus consisted of a horizontal furnace system and a conventional sliding graphite boat. Pd-purified H_2 was flowed through the fused silica tube set in the furnace.

Figure 1 shows the P solubility in solutions at 600°C as a function of X_{As}^1 at several X_{Ga}^1 , where X_i^1 represents the atomic fraction of an element i in the solution. At constant X_{Ga}^1 , X_{P}^1 decreases with increasing X_{As}^1 . X_{P}^1 becomes zero at a certain value of X_{As}^1 , and X_{P}^1 remains zero when X_{As}^1 is above that value. The value of X_{As}^1 at which X_{P}^1 be-

Fig. 1. P Solubility, X_P^I , at 600°C in In-Ga-As-P quaternary solutions as a function of X_{As}^I as determined by the seed dissolution technique.

comes zero is the As solubility in the ternary In-Ga-As solution just saturated at 600°C. Figure 2 shows the P solubility in solutions at 700°C as a function of X_{As}^I at several X_{Ga}^I . The value of X_{As}^I at which X_P^I becomes zero also corresponds to the As solubility in the ternary In-Ga-As solution just saturated at 700°C. From the results shown in Fig. 1 and 2, the accurate liquidus isotherms at 600° and 700°C were determined as shown in Fig. 3. The liquidus isotherm at 650°C was quoted from our previous work (9). The data reported by Wu and Pearson (11) and Liu and Peretti (12) are also shown in Fig. 3. In the temperature range 800°-900°C, much available data have been reported (11-15). Figure 4 shows the liquidus isotherms at 800°, 850°, and 900°C, which were derived from the previously reported data.

Lattice-matching.—In_{1-r}Ga_rAs ternary layers were grown from solutions with compositions on the liquidus isotherms at 600°, 650°, 700°, and 790°C shown in Fig. 3 and 4. The (100), (111)A, and (111)B oriented InP single crystals were used as substrates. No supersaturated solutions were used in the growth. In_{1-r}Ga_rAs layers were grown at a constant cooling rate of 0.5°C/min by the ramp cooling technique. The lattice constants of In_{1-r}Ga_rAs were mea-

Fig. 2. P Solubility, X_P^I , at 700°C in In-Ga-As-P quaternary solutions as a function of X_{As}^I as determined by the seed dissolution technique.

Fig. 3. Liquidus isotherms at 600°, 650°, and 700°C in the In-Ga-As ternary system, including points from this work (○), Ref. (9) (●), Ref. (11) (□), and Ref. (12) (■).

sured by the double-crystal x-ray diffraction technique. The precise diffraction angles of the ternary layers were determined from the (333) Cu-K α_1 or (400) Cu-K α_1 reflection by using the substrate reflection as an internal standard.

The lattice constant is displayed as a function of X_{Ga}^I in Fig. 5 and 6. The dashed line represents the lattice constant of InP. They are lattice constants of the epitaxial lattice perpendicular to the wafer surface. The lattice constant of a layer grown on a (111)A substrate is larger than that of a layer grown on a (100) substrate from a solution with the same composition, and the lattice constant for the (111)A face is smaller than that for the (111)B face. The solution compositions required to grow lattice-matched layers on InP substrates with various orientations can be exactly known from these results.

Substrate orientation dependence of solution compositions and distribution coefficients as a function of growth temperature.—Figure 7 shows the compositions of Ga in the In-Ga-As ternary solutions for the LPE growth of lattice-matched In_{0.53}Ga_{0.47}As on the (100), (111)A, and (111)B InP substrates as a function of the growth temperature, which are derived from Fig. 5 and 6 and our previous work (9, 16). The data reported by other authors are also shown in Fig. 7. The data for the (100) and (111)B faces at 620°C were reported by Pearsall et al. (17) and the data for the (100) and (111)B faces at 600°, 691°, and 714°C

Fig. 4. Liquidus isotherms at 800°, 850°, and 900°C in the In-Ga-As ternary system, including points from Ref. (11) (●), Ref. (12) (●), Ref. (13) (●), Ref. (14) (●), and Ref. (15) (●).

Fig. 5. Lattice constants of the $\text{In}_{1-x}\text{Ga}_x\text{As}$ ternary alloys grown on (100), (111)A, and (111)B InP substrates at 600°, 650°, and 700°C. Broken line represents the lattice constant of InP.

were reported by Hsieh (10). Hsieh's data imply that the solution compositions of Ga for the (100) and (111)B faces are the same above about 700°C. However, it is apparent from our present data in Fig. 7 that the solution compositions of Ga for the (111)B face are always larger than those for the (100) face over the entire temperature range 600°-790°C. It is also apparent that, over the entire temperature range, the solution compositions of Ga for the (111)A face are always somewhat larger than those for the (100) face and are always smaller than those for the (111)B face. These results also make it clear that there are not any cross points as reported by Antypas *et al.* (7).

Figure 8 shows the solution compositions of As in the In-Ga-As ternary solutions for the LPE growth of lattice-matched $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ on the (100), (111)A, and (111)B InP substrates as a function of the growth temperature. These results are derived from Fig. 3-6. The data reported by Pearsall *et al.* (17) and Hsieh (10) are also shown in Fig. 8. Hsieh's data show that the solution compositions of As for the (100) and (111)B faces are the same above about 700°C. However, it is apparent from our present data in Fig. 8 that the solution compositions of As for the (111)B face are always smaller than those for the (100) face over the entire temperature range 600°-790°C. It is also apparent that, over the entire temperature range, the solution compositions of As for the (111)A face are always somewhat smaller than those for the (100) face and are always larger than those for the (111)B face. The degree of the difference between the solution compositions for the three orientations is almost constant and is independent of the growth temperature, as shown in Fig. 7 and 8.

Fig. 6. Lattice constants of the $\text{In}_{1-x}\text{Ga}_x\text{As}$ ternary alloys grown on (100), (111)A, and (111)B InP substrates at 790°C. Broken line represents the lattice constant of InP.

(17) (\bullet , \blacktriangle), and Ref. (10) (\bullet , \blacktriangle).

Fig. 9. Distribution coefficient of Ga for the LPE growth of lattice-matched In_{0.53}Ga_{0.47}As on the (100), (111)A, and (111)B InP substrates as a function of the growth temperature, including points from this work (○, △, □), Ref. (17) (●, ▲), and Ref. (10) (●, ▲).

substrates as a function of the growth temperature. These results are derived from Fig. 8. The distribution coefficient of As for the (100) face is always smaller than those for the (111)A and (111)B faces over the entire temperature range.

Substrate orientation dependence of growth rate.—In order to study whether or not the growth rate of In_{1-x}Ga_xAs layers has influence upon the substrate orientation dependence of the liquid-solid phase data for the LPE growth, the substrate orientation dependence of the growth rate was studied over the temperature range 650°–790°C. In_{1-x}Ga_xAs layers were grown on the (100) and

Fig. 10. Distribution coefficient of As for the LPE growth of lattice-matched In_{0.53}Ga_{0.47}As on the (100), (111)A, and (111)B InP substrates as a function of the growth temperature, including points from this work (○, △, □), Ref. (17) (●, ▲), and Ref. (10) (●, ▲).

(111)B InP substrates by the ramp cooling method. Epitaxial layers were grown at the same time on two substrates with different orientations using the same solution. This technique was used in our previous work (18). In the ramp cooling growth, a constant cooling rate of 0.5°C/min was used. The temperature interval cooled from the starting growth temperature, 650°, 700°, and 790°C, was 6°C.

Figure 11 shows the ratio of the thickness on the (100) face, $d_{(100)}$, to the thickness on the (111)B face, $d_{(111)B}$, as a function of the growth temperature. When the growth temperature is 650°C, the ratio, $d_{(100)}/d_{(111)B}$, is about 3, and when the growth temperature is 700° or 790°C, $d_{(100)}/d_{(111)B}$ is less than 2. In spite of the dependence of $d_{(100)}/d_{(111)B}$ on the growth temperature, the degree of the difference between the solution compositions for the (100) and (111)B faces is almost constant and is independent of the growth temperature as shown in Fig. 7 and 8. Therefore, the difference of the growth rate does not play an important role in determining the orientation dependence of the liquid-solid phase data for the LPE growth.

As shown in Fig. 11, the growth rate of In_{1-x}Ga_xAs layers grown on the (100) InP substrates is larger than that on the (111)B InP substrates. Therefore, the depletion of solute Ga in the solution near the interface between the solution and the substrate is stronger for the growth on the (100) face than for the growth on the (111)B face. Because of the different depletion effect on the substrate orientation, the solution composition of Ga, X_{Ga}^l , required to grow In_{0.53}Ga_{0.47}As layers on the (100) face must be larger than that on the (111)B face. However, as shown in Fig. 7, the experimentally determined X_{Ga}^l required to grow In_{0.53}Ga_{0.47}As layers on the (100) face is always smaller than that on the (111)B face. These results indicate obviously that the different growth rates on the different orientations do not have important influence on the orientation dependence of the liquid-solid phase data for the LPE growth. Pearsall *et al.* also reported that kinetic effects in the solution or growth-rate differences played an unimportant role in determining the orientation dependence of the distribution coefficient data (8). Our results are in good agreement with theirs.

Theory and Calculation

Surface free energy.—The effect of substrate orientation on the solidus data cannot be ignored and must be considered in the calculation of the solid composition of epitaxial layers on substrates in equilibrium with the liquid solution. It is considered that this effect presumably results from a difference in surface free energy (9, 10) or from the attachment kinetics at the growth interface (10). However, no one has calculated the phase diagram by

Fig. 11. The ratio of the thickness on the (100) face, $d_{(100)}$, to the thickness on the (111)B face, $d_{(111)B}$, as a function of the growth temperature.

considering the surface free energy or the attachment kinetics and has confirmed how these factors influence the phase diagram until now. In this section, it is described how the surface free energy influences the substrate orientation dependence of the In-Ga-As phase diagram for the LPE growth of $\text{In}_{1-x}\text{Ga}_x\text{As}$ layers.

On the surface between the vapor and solid phases, the surface free energy, $\gamma_{\text{surf}(v,s)}$, can be given approximately by

$$\gamma_{\text{surf}(v,s)} = (1 - w/u)\Delta H_{v0}N_0^{2/3} \quad [1]$$

where u is the number of nearest neighbors of an atom in the bulk of the solid and w is the number of neighbors in the solid of an atom on the face in question, ΔH_{v0} is the enthalpy of evaporation of the material at 0 K, and N_0 is the number of atoms per unit volume (19). The argument used is that the surface free energy is the energy to break all of the nearest neighbor bonds across a given plane. The number of atoms per unit area, N_s , can be related to N_0 as follows

$$N_s = N_0^{2/3} \quad [2]$$

For III-V zinc-blende-type compound, N_s for the (111) and (100) faces can be given by

$$N_s = \frac{4}{\sqrt{3}a^2} \quad [3]$$

for the (111) face, and

$$N_s = \frac{2}{a^2} \quad [4]$$

for the (100) face, where a is the lattice constant of the III-V compound (20).

For growth from solution, such as the LPE growth, however, the enthalpy of dissolution per one atom, ΔH_d , must be used instead of ΔH_{v0} in order to calculate the surface free energy on the surface between the liquid and the solid, $\gamma_{\text{surf}(l,s)}$. ΔH_d is given by the enthalpy of dissolution per mol, ΔH , as follows

$$\Delta H_d = \Delta H/2N_A \quad [5]$$

where N_A is Avogadro's number ($N_A = 6.023 \times 10^{23}$). Therefore, from Eq. [1]-[5], $\gamma_{\text{surf}(l,s)}$ for the (111) and (100) faces can be written as follows

$$\gamma_{\text{surf}(l,s)} = \frac{\Delta H}{2\sqrt{3}a^2N_A} \quad [6]$$

for the (111) face, and

$$\gamma_{\text{surf}(l,s)} = \frac{\Delta H}{2a^2N_A} \quad [7]$$

for the (100) face.

In order to obtain the surface free energy per mol, ΔG_{surf} , it was assumed that all atoms per mol were arranged on the surface. The obtained area, A , on each face is given by

$$A = \frac{\sqrt{3}N_A a^2}{2} \quad [8]$$

for the (111) face, and by

$$A = N_A a^2 \quad [9]$$

for the (100) face. Then, ΔG_{surf} can be written as follows

$$\Delta G_{\text{surf}} = \gamma_{\text{surf}(l,s)} A = \Delta H/4(\text{cal/mol}) \quad [10]$$

for the (111) face, and

$$\Delta G_{\text{surf}} = \Delta H/2(\text{cal/mol}) \quad [11]$$

for the (100) face. The method to derive the equation of ΔH is described in the Appendix.

Surface energy per mol is affected by a solid-liquid interface shape because orientation of interfaces and total

surface area can be varied according to the solid-liquid interface shape. The calculation of the surface energy for the LPE growth which is performed on a surface of substrates is a special case of the calculation of the surface energy. In this case, all atoms per mole grow on the surface of the substrate and then on each surface of each epitaxial layer as they are arranged successively on each surface of each layer. Therefore, the surface energy per mole for the LPE growth just corresponds with the surface energy for arranging all atoms per mole on a wide plane. In this case, the solid-liquid interface shape is considered to be a wide plane.

Expressions to calculate the ternary phase diagram influenced by the surface free energy.—The following expressions can be used to calculate the phase diagram of the III-V A-B-C ternary system in which there are a liquid solution of elements A, B, and C and a solid of the binary compounds AC and BC (22)

$$RT \ln \gamma_{AC} + RT \ln x = RT \ln \frac{\gamma_A \gamma_C}{\gamma_A^{\text{sl}} \gamma_C^{\text{sl}}} + RT \ln 4X_A^{\text{I}} X_C^{\text{I}} + \Delta S_{AC}^{\text{F}}(T_{AC}^{\text{F}} - T) \quad [12]$$

and

$$RT \ln \gamma_{BC} + RT \ln (1 - x) = RT \ln \frac{\gamma_B \gamma_C}{\gamma_B^{\text{sl}} \gamma_C^{\text{sl}}} + RT \ln 4X_B^{\text{I}} X_C^{\text{I}} + \Delta S_{BC}^{\text{F}}(T_{BC}^{\text{F}} - T) \quad [13]$$

where γ_{AC} and γ_{BC} are the activity coefficients of the AC and BC compounds in the solid, respectively, γ_i is the activity coefficient of an element i in the ternary liquid solution, x is the mole fraction of AC in the solid, ΔS^{F} and T^{F} are the entropy of fusion and the temperature of fusion of the indicated pure binary compound, respectively, R is the gas constant, and T is the absolute temperature. The superscript "sl" indicates the stoichiometric liquid. When the surface free energy is considered to calculate the phase diagram, the terms of $RT \ln \gamma_{AC}$ and $RT \ln \gamma_{BC}$ in Eq. [12] and [13] are influenced by the surface free energy. The total excess free energy of the solid, $\Delta G_{\text{total}}^{\text{rs}}$, can be given by

$$\Delta G_{\text{total}}^{\text{rs}} = \Delta G_{\text{m}}^{\text{rs}} + \Delta G_{\text{surf}} \quad [14]$$

where $\Delta G_{\text{m}}^{\text{rs}}$ is the excess free energy of mixing of the solid. On a basis of a simple solution model, $\Delta G_{\text{m}}^{\text{rs}}$ can be written using Eq. [A-8] (see Appendix) as follows

$$\Delta G_{\text{m}}^{\text{rs}} = \Delta H_{\text{m(ABC)}}^{\text{rs}} = \Delta H_{\text{m(ABC)}}^{\text{s}} = x(1-x)\Omega_{AC-BC}^{\text{s}} \quad [15]$$

where $\Delta H_{\text{m(ABC)}}^{\text{rs}}$ is the excess enthalpy of mixing of the ternary solid. $RT \ln \gamma_{AC}$ and $RT \ln \gamma_{BC}$ are given by

$$RT \ln \gamma_{AC} = \Delta G_{\text{total}}^{\text{rs}} + (1-x) \left(\frac{d\Delta G_{\text{total}}^{\text{rs}}}{dx} \right) \quad [16]$$

and

$$RT \ln \gamma_{BC} = \Delta G_{\text{total}}^{\text{rs}} - x \left(\frac{d\Delta G_{\text{total}}^{\text{rs}}}{dx} \right) \quad [17]$$

$RT \ln \gamma_{AC}$ and $RT \ln \gamma_{BC}$ for the (111) and (100) faces can be obtained by using Eq. [10], [11], [14]-[17], and [A-12] (see Appendix) as follows. For the (111) face

$$RT \ln \gamma_{AC} = \frac{3}{4} (1-x)^2 \Omega_{AC-BC}^{\text{s}} + \frac{1}{4} \Delta S_{AC}^{\text{F}} T_{AC}^{\text{F}} - \frac{1}{16} \Omega_{AC}^{\text{I}} - \frac{1}{8} H_A^{\text{I}} - \frac{1}{8} H_C^{\text{I}} + \frac{1}{4} \alpha \quad [18]$$

and

$$RT \ln \gamma_{BC} = \frac{3}{4} x^2 \Omega_{AC-BC}^{\text{s}} + \frac{1}{4} \Delta S_{BC}^{\text{F}} T_{BC}^{\text{F}} - \frac{1}{16} \Omega_{BC}^{\text{I}} - \frac{1}{8} H_B^{\text{I}} - \frac{1}{8} H_C^{\text{I}} + \frac{1}{4} \alpha \quad [19]$$

and for the (100) face

$$RT \ln \gamma_{AC} = \frac{1}{2} (1-x)^2 \Omega_{AC-BC}^s + \frac{1}{2} \Delta S_{AC}^F T_{AC}^F - \frac{1}{8} \Omega_{AC}^l - \frac{1}{4} H_{A^i}^l - \frac{1}{4} H_{C^i}^l + \frac{1}{2} \alpha \quad [20]$$

and

$$RT \ln \gamma_{BC} = \frac{1}{2} x^2 \Omega_{AC-BC}^s + \frac{1}{2} \Delta S_{BC}^F T_{BC}^F - \frac{1}{8} \Omega_{BC}^l - \frac{1}{4} H_{B^i}^l - \frac{1}{4} H_{C^i}^l + \frac{1}{2} \alpha \quad [21]$$

where

$$\alpha = X_A^l X_B^l \Omega_{AB}^l + X_A^l X_C^l \Omega_{AC}^l + X_B^l X_C^l \Omega_{BC}^l + X_A^l H_{A^i}^l + X_B^l H_{B^i}^l + X_C^l H_{C^i}^l \quad [22]$$

The III-V A-B-C ternary phase diagram which is influenced by the surface free energy can be calculated by using Eq. [12], [13], and [18]-[22].

Calculated results.—The parameters to calculate the In-Ga-As ternary phase diagram are listed in Table I. Figure 12 shows the enthalpy of dissolution per mole, ΔH , which was obtained from the phase diagram calculation and Eq. [A-12]. In this calculation, X_{As}^l takes a constant value of 0.5. In Fig. 12, curve a represents ΔH obtained from the phase diagram calculation in which the influence of the surface free energy was not considered, and curves b and c represent ΔH for the (100) and (111) faces, respectively. ΔH of InAs is the smallest, as shown in Fig. 12. When a small amount of InAs is mixed into GaAs, ΔH for the (111) face increases slightly and decreases, but ΔH for the (100) face decreases monotonously. ΔH is nearly in proportion to the strength of bonds in In_{1-x}Ga_xAs solids. Therefore, when the weak bonds of InAs are mixed into the strong bonds of GaAs, the strength of the bonds weakens. ΔH for the (111) face is larger than ΔH for the (100) face, that is to say, the energy to dissolve the In_{1-x}Ga_xAs film from the (111) oriented In_{1-x}Ga_xAs surface into the In-Ga-As solution is larger than the energy to dissolve the film from the (100) oriented In_{1-x}Ga_xAs surface into the solution.

Figure 13 shows the surface free energy of the (111) and (100) oriented In_{1-x}Ga_xAs surface, which was calculated at $X_{As}^l = 0.2$ and 0.5. As a matter of course, the surface free energy depends on the composition of the solutions. The surface free energy for the (100) face is larger than for the (111) face. Therefore, the (111) surface is more stable than the (100) surface. As shown in Fig. 13, the surface free energy of In_{1-x}Ga_xAs which is in contact with the solution of $X_{As}^l = 0.2$ is larger than the surface free energy of In_{1-x}Ga_xAs which is in contact with the solution of $X_{As}^l = 0.5$. That is to say, the surface in equilibrium with the solution of $X_{As}^l = 0.2$ is more unstable than the surface in equilibrium with the solution of $X_{As}^l = 0.5$.

Table I. Thermodynamic input data for the calculation of the In-Ga-As phase diagrams

Input data	
$T_{GAs}^F = 1511$ K	$T_{InAs}^F = 1215$ K
$\Delta S_{GAs}^F = 16.64$ cal/mol K	$\Delta S_{InAs}^F = 14.52$ cal/mol K
$\Omega_{GAs}^l = 5160 - 9.16T$ cal/mol	$\Omega_{InAs}^l = 3860 - 10.0T$ cal/mol
$\Omega_{GAs}^s = 1060$ cal/mol	$\Omega_{GAs-InAs}^s = 3000$ cal/mol
$H_{GAs}^l = -63,353$ cal/mol	$H_{In}^l = -55,909$ cal/mol
$H_{As}^l = -73,166$ cal/mol	

T_{AB}^F and ΔS_{AB}^F are the temperature and entropy of fusion of the AB compound, respectively (22). Ω^l and Ω^s are the interaction parameters in the liquid solution and solid, respectively (22). H_i^l is the enthalpy of the pure i melt (23).

Fig. 12. The calculated enthalpy of dissolution per mole, ΔH (cal/mol), from In_{1-x}Ga_xAs to solutions with $X_{As}^l = 0.5$ as a function of x in In_{1-x}Ga_xAs.

The calculated In-Ga-As phase diagrams which are influenced by the surface free energy are shown in Fig. 14, 15, and 16. Figure 14 shows the solution composition of Ga, X_{Ga}^l , in the In-Ga-As ternary solution in equilibrium with the (100)- and (111)-oriented In_{0.53}Ga_{0.47}As, which are represented by the curves a and b, respectively. The experimental results for the (111) and (100) faces are also shown by the broken lines of curves f and g, respectively. The calculated X_{Ga}^l of the solution in equilibrium with the (100)-oriented In_{0.53}Ga_{0.47}As is larger than the calculated X_{Ga}^l of the solution in equilibrium with the (111)-oriented In_{0.53}Ga_{0.47}As. This tendency of the calculated results is contrary to the experimental results as shown in Fig. 14. Figure 15 shows the solution composition of As, X_{As}^l , in the In-Ga-As ternary solution in equilibrium with the (100)- and (111)-oriented In_{0.53}Ga_{0.47}As, which are represented by the curves a and b, respectively. The experimental results for the (111) and (100) faces are shown by the broken lines f and g, respectively. The calculated X_{As}^l of the solution in equilibrium with the (100) oriented In_{0.53}Ga_{0.47}As is larger than the calculated X_{As}^l of the solu-

Fig. 13. The calculated surface free energy (cal/mol) of the (111) and (100) oriented In_{1-x}Ga_xAs surfaces in equilibrium with solutions with $X_{As}^l = 0.2$ and 0.5 as a function of x in In_{1-x}Ga_xAs.

Fig. 14. The solution composition of Ga, X_{Ga}^I , in the In-Ga-As ternary solution in equilibrium with the (100) and (111)-oriented $In_{0.53}Ga_{0.47}As$ as a function of the growth temperature. The solid lines are the calculated results and the broken lines are the experimental results.

tion in equilibrium with the (111)-oriented $In_{0.53}Ga_{0.47}As$. This tendency is in agreement with the experimental results shown in Fig. 15. Figure 16 shows the composition of Ga in $In_{1-x}Ga_xAs$ in equilibrium with solutions of $X_{As}^I = 0.2$ as a function of X_{Ga}^I . The curves a and b show the calculated results for the (100) and (111) faces, respectively. Obviously, X_{Ga}^I of solutions in equilibrium with the (100)-oriented $In_{0.53}Ga_{0.47}As$ is larger than X_{Ga}^I of solutions in equilibrium with the (111)-oriented $In_{0.53}Ga_{0.47}As$.

Fig. 15. The solution composition of As, X_{As}^I , in the In-Ga-As ternary solution in equilibrium with the (100)- and (111)-oriented $In_{0.53}Ga_{0.47}As$ as a function of the growth temperature. The solid lines are the calculated results and the broken lines are the experimental results.

Fig. 16. The composition of Ga, x , in $In_{1-x}Ga_xAs$ in equilibrium with solutions of $X_{As}^I = 0.2$ as a function of X_{Ga}^I , which is calculated by adding the surface free energy effects.

Discussion

The experimental results indicating that the solution compositions of Ga in equilibrium with the (111)-oriented $In_{0.53}Ga_{0.47}As$ are larger than those in equilibrium with the (100)-oriented $In_{0.53}Ga_{0.47}As$ cannot be explained by the effect of the surface free energy only as shown in Fig. 14. The results calculated by adding the surface free energy to the chemical free energy of the solid phase are contrary to the experimental results. These results imply that other effects must be considered to explain the substrate orientation dependence of the In-Ga-As phase diagram for LPE growth of $In_{0.53}Ga_{0.47}As$ on InP.

In Fig. 14, 15, and 16, the curves e show the results calculated by the conventional simple solution model (21), which is not influenced by the surface free energy. The results calculated by adding the surface free energy which are shown by the curves a and b are very much apart from the calculated results shown by the curves e. This is mainly caused by overestimation of the surface free energy per mole, ΔG_{surf} . In order to obtain ΔG_{surf} , it was assumed that all atoms per mole were arranged on the surface. However, in the actual LPE growth, it is naturally considered that, prior to the growth, Ga-As or In-As pairs are made in the liquid solution due to large ionicity of III-V compounds (24, 25). Much of these pairs seems to exist within the region between the grown surface and the liquid solution as shown in Fig. 17, because the crystal structure must be rapidly knitted using the elements in the solution. Therefore, it is only natural that the crystal is grown using these pairs in the solution. That is to say, in order to obtain ΔG_{surf} , it can be assumed that, instead of each atom, Ga-As or In-As pairs per mole were arranged on the surface. Then, ΔG_{surf} can be written under this assumption as follows

$$\Delta G_{surf} = \Delta H/8 \text{ (cal/mol)} \quad [23]$$

for the (111) face, and

$$\Delta G_{surf} = \Delta H/4 \text{ (cal/mol)} \quad [24]$$

for the (100) face. In the actual In-Ga-As ternary solution, it is more natural that bigger pairs (for example, $Ga_2In_2As_4$, $GaIn_3As_4$, or $InAs_4$) than Ga-As or In-As pairs are made and exist within the region between the grown surface and the liquid solution as shown in Fig. 18. Therefore, ΔG_{surf} must be written as follows

$$\Delta G_{surf} = \Delta H/\beta \text{ (cal/mol)} \quad [25]$$

where β is the value which depends on the size of pairs in the solution.

The calculated In-Ga-As phase diagrams which are influenced by the surface free energy of Eq. [25] with $\beta = 16$ for the (111) face and $\beta = 8$ for the (100) face are shown

Fig. 17 Schematic representation of the interface between the In_{1-x}Ga_xAs solid and the growth solution with Ga-As or In-As pairs.

in Fig. 14, 15, and 16 by the curves c and d, respectively. This case corresponds to the ternary solution with pairs of Ga₂-In₂-As, Ga-In₃-As, Ga-As₄, and In-As₄ near the growth surface. The curves c and d are closer to the curves e calculated by the conventional simple solution model and the experimental curves f and g than the curves a and b calculated by Eq. [10] and [11]. These results imply that the crystal is grown using some pairs in the solution.

In the calculation of the surface free energy, the difference of the (111)A and (111)B faces cannot be explained. The nature of bonding on (111)A and (111)B surfaces of III-V compounds was qualitatively described by several authors (20, 26). According to them, the Group V atoms of the B surface are triply bonded to the lattice and have an unshared pair of electrons. The (sp³) tetrahedral configuration of the bulk is thus retained. On the other

Fig. 18 Schematic representation of the interface between the In_{1-x}Ga_xAs solid and the growth solution with complex pairs.

hand, the Group III atoms of the A surface are also triply bonded to the lattice but have no dangling electrons. Consequently, it is proposed that these atoms tend toward a planar (sp²) configuration. It is not clear how the difference between the configurations reflects the surface free energies of the (111)A and (111)B faces. In order to understand the difference between the phase diagrams for the LPE growth on the (111)A and (111)B faces, it seems that the attachment kinetics at the (111)A and (111)B growth interfaces must also be considered.

Summary and Conclusion

The liquidus isotherms of the In-Ga-As system were determined at 600° and 700°C by the improved seed dissolution technique. From the results of the liquidus isotherms and the lattice-constant measurements, the substrate orientation dependence of the solution compositions to grow lattice-matched In_{0.53}Ga_{0.47}As layers on the (100), (111)A, and (111)B InP substrates was exactly obtained in the temperature range 600°-790°C. The solution compositions of Ga for the (111)A and (111)B faces are always larger than those for the (100) face over the entire temperature range 600°-790°C. The solution compositions of Ga for the (111)A face are always smaller than those for the (111)B face over the entire temperature range. The solution compositions of As for the (111)A and (111)B faces are always smaller than those for the (100) face.

The In-Ga-As phase diagram was calculated, for the first time, by adding the surface free energy to the chemical free energy of the In_{1-x}Ga_xAs solid phase. According to the calculated phase diagram, the compositions of Ga in solutions to obtain the (100)-oriented In_{0.53}Ga_{0.47}As is larger than the compositions of Ga in solutions to obtain the (111)-oriented In_{0.53}Ga_{0.47}As. This tendency of the calculated results is contrary to the experimental results. The difference in the surface free energy for both faces is not a main reason for the substrate orientation dependence of the In-Ga-As phase diagram. Other effects must be considered to explain the experimental results. The surface free energy can be estimated more accurately by considering complex formation in the growth solutions.

APPENDIX

ΔH corresponds to the enthalpy change accompanying the transfer of one mole of solid A_xB_{1-x}C to the ternary A-B-C solution with which it is in equilibrium at the growth temperature, T . The enthalpy of the ternary solid, H_{ABC}^s , is given by

$$H_{ABC}^s = \Delta H_{m(ABC)}^s + xH_{AC}^s + (1-x)H_{BC}^s \quad [A-1]$$

where $\Delta H_{m(ABC)}^s$ is the enthalpy of mixing of the ternary solid, and H_{AC}^s and H_{BC}^s are the enthalpy of the pure AC and BC binary compounds, respectively. The enthalpy of the ternary solution, H_{ABC}^l , is given by

$$H_{ABC}^l = \Delta H_{m(ABC)}^l + X_A^l H_A^l + X_B^l H_B^l + X_C^l H_C^l \quad [A-2]$$

where $\Delta H_{m(ABC)}^l$ is the enthalpy of mixing of the ternary solution, X_i^l is the atomic fraction of an element i in the ternary solution, and H_i^l is the enthalpy of the pure i melt, that is to say, H_i^l corresponds to the heat of evaporation of the pure i melt. The enthalpies of the pure A-C and B-C binary melts, H_{AC}^l and H_{BC}^l , are given by

$$H_{AC}^l = \Delta H_{m(AC)}^l + H_A^l/2 + H_C^l/2 \quad [A-3]$$

and

$$H_{BC}^l = \Delta H_{m(BC)}^l + H_B^l/2 + H_C^l/2 \quad [A-4]$$

where $\Delta H_{m(AC)}^1$ and $\Delta H_{m(BC)}^1$ are the enthalpies of mixing of the pure A-C and B-C binary melts, respectively. The enthalpies of fusion of the pure AC and BC binary compounds, ΔH_{AC}^F and ΔH_{BC}^F , are given by

$$\Delta H_{AC}^F = H_{AC}^1 - H_{AC}^{s} \quad [A-5]$$

and

$$\Delta H_{BC}^F = H_{BC}^1 - H_{BC}^{s} \quad [A-6]$$

The enthalpy of dissolution per mole, ΔH , can be written using Eq. [A-1]-[A-6] as follows

$$\begin{aligned} \Delta H = & H_{ABC}^1 - H_{ABC}^s = \Delta H_{m(ABC)}^1 \\ & + X_A^1 H_A^1 + X_B^1 H_B^1 + X_C^1 H_C^1 \\ & - \Delta H_{m(ABC)}^s + x \Delta H_{AC}^F + (1-x) \Delta H_{BC}^F - x \Delta H_{m(AC)}^1 - x H_A^{1/2} \\ & - (1-x) \Delta H_{m(BC)}^1 - (1-x) H_B^{1/2} - H_C^{1/2} \quad [A-7] \end{aligned}$$

The enthalpies of mixing can be written using a simple solution model (21, 22) as follows

$$\Delta H_{m(ABC)}^s = x(1-x) \Omega_{AC-BC}^s \quad [A-8]$$

$$\Delta H_{m(ABC)}^1 = X_A^1 X_B^1 \Omega_{AB}^1 + X_A^1 X_C^1 \Omega_{AC}^1 + X_B^1 X_C^1 \Omega_{BC}^1 \quad [A-9]$$

$$\Delta H_{m(AC)}^1 = \Omega_{AC}^1/4 \quad [A-10]$$

$$\Delta H_{m(BC)}^1 = \Omega_{BC}^1/4 \quad [A-11]$$

where Ω_{AC-BC}^s is the interaction parameter in the ternary solid $A_x B_{1-x} C$, and Ω_{ij}^1 is the interaction parameter of the ij pair in the ternary solution. ΔH can be given using Eq. [A-7]-[A-11] as follows

$$\begin{aligned} \Delta H = & X_A^1 X_B^1 \Omega_{AB}^1 + X_A^1 X_C^1 \Omega_{AC}^1 + X_B^1 X_C^1 \Omega_{BC}^1 \\ & - x(1-x) \Omega_{AC-BC}^s + x \Delta H_{AC}^F + (1-x) \Delta H_{BC}^F \\ & - x \Omega_{AC}^1/4 - (1-x) \Omega_{BC}^1/4 \\ & + X_A^1 H_A^1 + X_B^1 H_B^1 + X_C^1 H_C^1 - x H_A^{1/2} \\ & - (1-x) H_B^{1/2} - H_C^{1/2} \quad [A-12] \end{aligned}$$

For the growth from the solution such as the LPE growth, ΔH can be calculated by Eq. [A-12].

Electrochemical Characteristics of n-Doped Polyacetylene

R. Huq and G. C. Farrington*

Department of Materials Science, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

Polyacetylene can be electrochemically reduced in tetrahydrofuran containing dissolved LiClO_4 to form compositions of the type, $(\text{Li}_y\text{CH})_x$. The reduction occurs with high coulombic efficiency for doping levels of $y < 0.10$. Reduced polyacetylene in this composition range appears to be quite stable in this particular electrolyte. The potential of $(\text{Li}_y\text{CH})_x$ is 0.5-1.5V positive of that of Li. Compared with Li as a nonaqueous battery negative electrode, $(\text{Li}_y\text{CH})_x$ has considerably lower gravimetric and volumetric energy densities and a higher electrochemical potential.

Polyacetylene $[(\text{CH})_x]$ is a simple conjugated polymer with unusual electrochemical properties. It can be electrochemically reduced or oxidized to compositions which are n- or p-type electronic conductors (Eq. [1a] and [1b]) (1). Nigrey *et al.* (2) have proposed using polyacetylene as an electrode material for nonaqueous electrolyte batteries. They found that cation-doped (n-type) polyacetylene can function as a negative electrode and anion-doped (p-type) polyacetylene can as a positive electrode. Since their pioneering work, the various forms of polyacetylene have received considerable attention as potential electrode materials (3-7).

*Electrochemical Society Active Member.

MacDiarmid *et al.* (2, 3) have reported that the p doping process is electrochemically reversible with high coulombic efficiency. Other authors (5-7) have confirmed that polyacetylene can be reversibly oxidized to doping levels of $y = 0.09$ and less with near 100% coulombic efficiency. The same researchers (5-7) have also shown that only about 50% of the charge stored in oxidized polyacetylene at a current density of 0.05 mA/cm² can be recovered at a discharge rate comparable to (1-10 times) the charging rate. The remainder of the charge can be recovered, but

only upon extended (10-20h) controlled potential discharge at far lower ($10 \mu\text{A}/\text{cm}^2$) current densities. Several cyclic voltammetry and polarization studies (8, 11) have suggested that electrochemical p doping involves a slow diffusion process, presumably that of the dopant species within the polymer.

The few studies of n doping that have appeared include those of Kaner *et al.* (9) and Shacklette *et al.* (10). Kaner *et al.* (9) concluded that polyacetylene can be reduced to dopant concentrations of $y = 0.06$ with excellent stability and reversibility. The reduction/oxidation coulombic efficiency ($Q_{\text{out}}/Q_{\text{in}}$) was found to be about 99% at Li^+ , Na^+ , and $(\text{Bu}_4\text{N})^+$ dopant concentrations up to $y = 0.06$. Shacklette and co-workers (10) observed considerable swelling of polyacetylene when it was reduced in tetrahydrofuran (THF) with Li^+ as the doping ion. They reported that unreduced, neutral polyacetylene did not swell in the presence of THF.

Our goals in the present work were to examine the general electrochemical characteristics of the n doping reactions of polyacetylene in order to evaluate its attractiveness as a battery electrode. The lithium electrode was chosen as the standard of comparison, since it has received the most investigation as an electrode material for high energy density, nonaqueous electrolyte batteries. Our studies have included measures of the coulombic efficiency, rate capability, stability, and electrode potential as a function of doping level.

Experimental

Electrochemical measurements were carried out in a miniature glass cell having three compartments separated by glass frits. The polyacetylene film electrodes (approximately 1 cm^2 in area and 0.01 cm thick) were sandwiched in Pt mesh and housed in the central compartment of the cell. The lithium reference and counterelectrodes were located in the two side compartments. About 1 ml of electrolyte was required to fill all three compartments. The electrolyte used was $0.8\text{-}1.0\text{M}$ LiClO_4 in THF.

Electrolytes were prepared from Burdick and Jackson tetrahydrofuran, which was distilled and percolated through neutral activated alumina (Woelm). The LiClO_4 (Anderson Physics) was dried at 180°C in vacuum before use. After the salt was dissolved, the electrolyte solution was purified by a second percolation through activated alumina.

All experimental procedures were performed in an argon-atmosphere dry box (Vacuum Atmospheres). Standard electrochemical equipment was used for carrying out the cyclic voltammetry and constant current/potential experiments.

The polyacetylene films used in these experiments were prepared by the technique first described by Shirakawa (12). They were graciously provided to us by the research group of Professor A. MacDiarmid of this university.

Results and Discussion

Controlled potential studies.—Cyclic voltammetry.—Cyclic voltammetry experiments used samples of polyacetylene which had areas of $0.3\text{-}1.0 \text{ cm}^2$ (single side) and weighed approximately $0.00475 \text{ g}/\text{cm}^2$. Cyclic voltammograms were recorded between 0.5 and $2.5 \text{ V vs. Li/Li}^+$ under the following conditions. (i) Pt mesh electrode in fresh electrolyte; (ii) fresh polyacetylene in fresh electrolyte; (iii) reduced polyacetylene; and (iv) polyacetylene after various reduction/oxidation cycles. The results are shown in Fig. 1-3.

Cyclic voltammograms on the Pt mesh electrode without polyacetylene were carried out to monitor the level of background current and the stability of the electrolyte. Fresh electrolyte (Fig. 1a) showed a window of stability from 2.5 to 0.6 V that was interrupted by only a few small peaks. The electrolyte decomposition rate increased at potentials less than 0.5 V . A Pt electrode in the same solvent after 11 reduction/oxidation cycles on a polyacetylene sample (Fig. 1b) showed essentially identical cyclic

Fig. 1. a (top): Cyclic voltammogram of a Pt mesh electrode in fresh $\text{LiClO}_4\text{-THF}$ electrolyte. Scan rate of 20 mV/s . b (bottom): Voltammogram of same Pt mesh electrode in same solution after eleventh reduction/oxidation cycle of a polyacetylene film. Scan rate of 20 mV/s .

voltammetry behavior. No evidence of soluble electrolyte degradation products was observed over this number of cycles.

The rest potential of fresh polyacetylene was about $2.2 \text{ V vs. Li/Li}^+$. Repeated cyclic voltammograms of a fresh sample of polyacetylene (Fig. 2a) showed that both the reduction and oxidation peaks increased with cycling. For polyacetylene reduced to $y = 0.047$ (Fig. 2b), both the reduction and oxidation peaks were broader and the maximum current densities were $10\text{-}15 \text{ mA}/\text{cm}^2$.

After six cycles (Fig. 3a), the voltammogram was similar to that for fresh polyacetylene, although the peak currents had decreased. After the eleventh cycle (Fig. 3b), the peak current decreased dramatically, and the shape of the voltammogram indicated that the reaction had become less reversible. Since there was no change in the cyclic voltammogram of a Pt electrode in the electrolyte after the eleventh cycle (Fig. 1b), it is reasonable to conclude that the decreased peak current and reversibility were the result of changes in the polyacetylene electrode itself.

Controlled potential reduction of polyacetylene.—Samples of polyacetylene were reduced and then reoxidized in two different controlled potential experiments. In the first, the potential was decreased in 100 mV steps from 2.2 V (approximately the rest potential) to 0.7 V . At each point, the current was allowed to decrease to a steady value of about $20\text{-}25 \mu\text{A}/\text{cm}^2$. When the series of reduction steps was complete, the potential was stepped to 2.5 V to oxidize the film.

The results are shown in Fig. 4, which plots the cumulative doping level, y , as a function of the controlled potential. The points on the curve are not the true maximum doping levels that could be attained, since the current was not allowed to decay below $20\text{-}25 \mu\text{A}/\text{cm}^2$. However, they are quite close to the maxima that would be observed after exhaustive reduction.

As Fig. 4 shows, very little doping took place between 2.2 and 1.3 V ; but, from 1.2 to 1.0 V , the rate of doping in-

Fig. 2. a (top): Voltammogram of a fresh polyacetylene sample in $\text{LiClO}_4\text{-THF}$ electrolyte. Scan rate of 20 mV/s. The starting potential was the potential of zero current. b (bottom): Voltammogram of polyacetylene sample reduced to $y = 0.047$ in $\text{LiClO}_4\text{-THF}$ electrolyte.

creased rapidly. By 0.7V, the maximum doping level of 0.09-0.10 was reached. It may be possible to achieve higher levels by decreasing the potential below 0.7V. Un-

Fig. 3. a (higher): Voltammogram of polyacetylene after sixth reduction/oxidation cycle. Scan rate of 20 mV/s. b (lower): Voltammogram of same electrode after eleventh reduction/oxidation cycle. Scan rate of 20 mV/s.

Fig. 4. Reduction level, y , as a function of controlled reduction potential in 100 mV steps.

fortunately, below 0.6V, the electrolyte was increasingly unstable and the reduction process was inefficient.

In the second set of experiments, the polyacetylene was electrochemically cycled by reduction at either 1.1 or 0.7V followed by oxidation at 2.5V. The oxidation was considered complete when the current decayed to about $0.5 \mu\text{A}/\text{cm}^2$. The current decay curves during controlled potential reduction at 1.1V showed an interesting evolution with increasing cycle number (see Fig. 5). The current levels upon initial polarization were typically 4-5 mA/cm^2 , based on the geometric area of one side of the electrode, regardless of the cycle number. In the earlier cycles, the current decreased to a plateau ($0.75\text{-}1.2 \text{ mA}/\text{cm}^2$) after which it decayed to much smaller values. High current densities were only observed in early cycles, and the magnitude of the current plateau decreased steadily with cycling. By the tenth cycle, the current plateau was in the range of $200 \mu\text{A}/\text{cm}^2$.

Because the average reduction current decreased dramatically with cycling, longer and longer times were required to reach the same doping level at a potential of 1.1V. For example, reduction times of 60 min in the second and fifth cycles yielded 3.32 and 3.2% doping, respectively. However, by the tenth cycle, the same reduction time produced only 2% doping. Not only did the doping time increase with cycling, it became necessary to decrease the reduction potential to achieve the same doping levels. For example, 3.8% doping was achieved at 1.1V during the second cycle, but the potential had to be decreased to 0.8V to reach the same doping level during the tenth cycle. All of these results are consistent with the cyclic voltammogram study, which showed a significant decrease in the peak reduction current by the tenth cycle.

Controlled potential oxidation of polyacetylene at 2.5V.—In this series of experiments, polyacetylene was cycled by

Fig. 5. Curves 1, 2, and 3 are current decay curves for the second, fifth, and tenth constant potential reduction cycles, respectively.

Fig. 6. Curves 1 and 2 are current decay curves for the second and tenth constant potential oxidation cycles, respectively. Curves 1' and 2' show the coulombic efficiencies (Q_{out}/Q_{in}) upon immediate oxidation for 3.8% reduced polyacetylene for the second and tenth cycles, respectively.

first reducing it to $y = 0.038$ under appropriate conditions of controlled potential and then exhaustively oxidizing it at a controlled potential of 2.5V. The variation of the oxidation current with time for the second and tenth cycles is shown in Fig. 6. For each oxidation, a high current in the range of 10 mA/cm² was observed upon initial polarization. The current then decreased at a quasi-exponential rate. Over the first two to ten cycles, about 30-50% of the charge initially passed during reduction was recovered at current densities greater than 1 mA/cm². After 1h, the oxidation current level had decayed to less than 0.1 mA/cm², and the fraction of charge recovered was 60-70%. After exhaustive oxidation until the current level was less than 2 μ A/cm², which typically required 40-60h, the apparent coulombic efficiency, Q_{out}/Q_{in} , was 0.93 or greater.

Controlled current studies.—Constant current reduction.—In these experiments, samples of polyacetylene were reduced at a constant current of 0.1 mA/cm² until a desired doping level was reached. They were then oxidized at 1 mA/cm² until the cell potential reached 2.5V. Oxidation was then continued but at a controlled potential of 2.5V.

Figure 7 shows the cell potential for $(Li_yCH)_x$ during reduction and the open-circuit potential after a 1 min current interruption for the second and eleventh cycles as a function of the doping level, y . The electrode established

Fig. 7. Open circuit and cell potential of $(Li_yCH)_x$ as a function of y for the second (1, 2) and eleventh (3, 4) reduction/oxidation cycles. See text for more complete description of experimental conditions.

Fig. 8. Change in open-circuit potential with time after the twelfth reduction/oxidation cycle. The polyacetylene was reduced to 3.5%.

a reasonably flat voltage plateau in the second cycle. But, by the eleventh cycle, it decreased sharply with increasing doping level. If 0.5V is considered a cutoff point for efficient reduction, it is clear that the capacity (y) of the polyacetylene electrode that could be efficiently cycled decreased with cycling and was about 0.04 by the eleventh cycle.

In addition, the overvoltage for the reduction process was considerably greater in the eleventh cycle than in the second cycle. The rate at which the open-circuit potential rose after current interruption demonstrates this point. In the third cycle, the current was interrupted at the 4% doping level. The open-circuit potential gradually rose 120 mV over 17h. When the current was interrupted at 4% doping during the twelfth cycle the potential rose about 300 mV within 5s and then gradually rose another 200 mV over 12h.

These observations are consistent with the results of the cyclic voltammetry and constant potential experiments previously discussed. They indicate that the electrochemical characteristics of the polyacetylene electrodes changed upon electrochemical cycling. The behavior of polyacetylene evolved from that which resembles a redox couple with an extended voltage plateau, behavior that is desirable for a battery electrode, to a state in which the potential decreased steeply with increasing charge, a characteristic that is undesirable in a battery electrode. The gradual decrease of the open-circuit potential of polyacetylene doped to 4% as function of cycle number (Fig. 9) severely limits the electrode capacity that can be efficiently cycled.

Constant current oxidation.—Constant current oxidation experiments showed that the rate at which Li⁺-doped

Fig. 9. Open-circuit potential as a function of cycle for a 4% reduced polyacetylene sample.

polyacetylene could be oxidized decreased as the material was cycled. In initial experiments, samples of polyacetylene were cycled by reduction to an n doping level of $y = 0.04$ - 0.06 at 0.1 mA/cm^2 and oxidized at 1 mA/cm^2 until the potential reached 2.5 V . The amount of charge that could be extracted before the potential reached 2.5 V decreased with cycling. In the third and fourth cycles, about 60% of the charge could be extracted before the potential reached 2.5 V . By the eleventh cycle, only about 40% of the charge could be recovered in this way. In each case, the remaining charge could be almost completely recovered by an extended (40-60h) oxidation at a controlled potential of 2.5 V .

The total coulombic efficiency for the reduction/oxidation process was measured by reducing polyacetylene to various doping levels at 0.1 mA/cm^2 , and then reoxidizing, first at a constant current of 1 mA/cm^2 and then exhaustively at a controlled potential of 2.5 V . Table I summarizes the results obtained in one set of experiments over 15 cycles.

Polyacetylene reduced to $y = 0.04$ maintained a coulombic efficiency of nearly 100% to the fifteenth cycle. The reactions were very efficient despite the obvious decrease in the open-circuit potential of the reduced polyacetylene at the $y = 0.04$ doping level. If this gradual decrease in open-circuit potential were to continue, the potential would ultimately enter the region of solvent instability, and the coulombic efficiency of the reduction reaction would decrease.

Reduction to levels higher than $y \approx 0.04$ and allowing the sample to stand on open circuit both decreased the fraction of charge which could be recovered upon oxidation, as Fig. 10 demonstrates. When reduction was followed by immediate oxidation, a coulombic efficiency of nearly 100% was maintained to doping levels of about $y = 0.06$. It then declined sharply, and reached about 80% at $y = 0.09$. An 18-20h stand on open circuit after reduction decreased the overall coulombic efficiency at doping levels above about $y = 0.04$. For example, for polyacetylene doped to $y = 0.07$, the coulombic efficiency dropped from 93% upon immediate discharge to 76% after an 18h delay.

Conclusions

The most important concerns regarding the attractiveness of polyacetylene as an alternative to the lithium electrode for high energy density, rechargeable battery technology are its stability, potential as a function of doping level (y), and volumetric and gravimetric capacity. Our results provide insight into each of these issues.

The stability of Li^+ -doped polyacetylene is quite good. At the reduction levels of $y < 0.10$ investigated in this work, reduced polyacetylene electrodes with Li^+ as the dopant appear to be quite stable in $\text{THF}/\text{LiClO}_4$ toward short-term loss of capacity. Polyacetylene that has been n doped under these conditions is far more tolerant of impurities in the electrolyte and extended storage in contact with the electrolyte than its rather fragile p-doped counterpart (4).

However, we found that the electrochemical characteristics of polyacetylene gradually changed as the material

was cycled from $y = 0$ to $y = 0.04$ - 0.06 ten or 20 times. The electrochemical reduction process grew less reversible, and the cyclic voltammetry peaks corresponding to the reduction/oxidation processes became more diffuse.

The rate capability of polyacetylene electrodes also decreased with cycling. The current levels observed during reduction and subsequent oxidation grew smaller. A careful study of the current/time curves for the reduction of polyacetylene films at 1.1 V showed that a fresh sample had an initial reduction current of 4 - 5 mA/cm^2 , which decayed within 30 - 60 s to a plateau of about 0.7 mA/cm^2 . If the sample was then oxidized to restore the value of y to nearly 0 , and then rereduced at 1.1 V , the initial reduction current was about the same as in the first reduction, but the magnitude of the plateau current decreased. The trend continued through subsequent cycles until the plateau disappeared entirely.

The open-circuit potential of reduced polyacetylene also changed with cycling. At a constant value of y , the potential gradually shifted toward that of Li as the number of cycles increased. For example, during the second reduction/oxidation cycle, the potential of $(\text{Li}_{0.01}\text{CH})_x$ was 1.27 V . It established a plateau of about 1.2 V between $y = 0.01$ and 0.05 and then decreased sharply at higher reduction levels. By the eleventh cycle, the potential at $y = 0.01$ was 1.38 V , but it decreased to 0.84 V at $y = 0.04$. Because the electrolyte was increasingly unstable below 0.5 V , the reduction of polyacetylene to high doping levels was increasingly inefficient.

All of these observations indicate that the electrochemical characteristics of polyacetylene in this electrolyte deteriorate markedly after a few cycles. It becomes increasingly difficult to achieve high reduction levels ($0.06 < y < 0.10$) efficiently. It takes longer to reduce and oxidize the film, because the reduction/oxidation current densities at controlled potential decrease with cycling. Whether this deterioration continues beyond 10 - 15 cycles is not known. It is also not clear whether the degradation is peculiar to the electrolyte used in these experiments. Perhaps more stable behavior would be observed in another electrolyte.

The gravimetric and volumetric energy densities of polyacetylene that has been n doped with Li^+ to the maximum level of $y = 0.10$ that was achieved in this investigation are rather low. The equivalent weight of $(\text{Li}_{0.10}\text{CH})_x$ is 137 g ; that of Li is 6.9 g . The equivalent volume of $(\text{Li}_{0.10}\text{CH})_x$ is about 190 cm^3 ; that of Li is 12.9 cm^3 . In addition, the potential of polyacetylene doped with Li^+ to $y < 0.10$ in $\text{THF}/\text{LiClO}_4$ is 0.5 - 1.5 V positive of that of Li , a substantial penalty in ultimate cell voltage.

All of our results indicate that reduced polyacetylene can serve as a negative electrode in a nonaqueous electrolyte battery in the traditional role of lithium. However, with the $\text{THF}/\text{LiClO}_4$ electrolyte used in this study, it suffers from significant degradation in electrochemical

characteristics upon cycling, a low to moderate gravimetric energy density, low volumetric energy density, and restricted rate capability. Naturally, its performance may be better in other solvent/electrolyte salt combinations.

Our findings do not suggest that n-doped polyacetylene is an attractive alternative to Li for high energy density, rechargeable, nonaqueous battery electrodes. However, it is critical that fundamental studies of the electrochemical reactions of this material be continued. We need to learn whether the electrochemical characteristics observed for n-doped polyacetylene in this study represent ultimate limitations on its performance or are artifacts of, for example, the polymer morphology or the solvent/electrolyte salt combination. If the maximum doping level of $(Li_xCH)_x$ could be increased by a factor of 3-4 and a larger fraction of the stored charge could be recovered at high current densities, n-doped polyacetylene might be an attractive electrode for some applications. However, at present, it appears to be more of an intriguing electrochemical curiosity than a material with immediate technological applications in high energy density batteries.

Method for Reducing Metal Salts Complexed in a Polymer Host with a Laser

A. Auerbach

The BOC Group, Incorporated, New Providence, New Jersey 07974

ABSTRACT

We describe a novel method for generating fine metal lines with a laser. The laser radiation is focused onto the surface of a nonconductive silver nitrate-doped polymer film to reduce silver. By translating the surface relative to the laser beam, a highly conductive silver line is formed. The measured resistance agrees well with the computed value for a silver conductor of comparable dimensions.

In the past few years, the application of lasers to a wide variety of technologies has occurred. Among the factors contributing to this are the laser's versatility and ability to provide localized photons and/or heat. In no area is this more evident than microelectronics. Pulsed xenon laser systems have been available for some time as ablation tools for the localized removal of thin metals or polymer films from a substrate (1, 2). Laser machining and welding applications have also been investigated and applied (3).

Recently, lasers have been used to deposit or remove conductors. Applications of these kinds include work done by Raffel *et al.*, who used laser radiation to form carbon conductors in polyimide film by graphitization (4). Since the resistivity of carbon is high compared to metal, these conductors are generally not useful. Another application reported by von Gutfeld *et al.* (5) involves laser-assisted electroplating. The laser makes possible rapid electrodeposition of dense and crack-free gold by providing localized heating of the substrate. Laser-assisted electroless gold and platinum deposition from so-

lution was investigated by Karlicek *et al.* (6). Tsai *et al.* have described an etching application where a laser is used to remove aluminum under an ambient bromine atmosphere (7).

In the area of photochemical metal deposition, UV-visible lasers are being used to enhance the deposition of metals and semiconductors (8-10). While this technique shows good promise for producing thin film conductors, exotic and highly toxic organometallics are often required. Also, to accomplish bond scission with a single photon, large and expensive UV lasers are required.

This paper describes a new approach for generating highly conductive metal lines by laser-assisted thermal reduction of metal salts dissolved in a polymer host. The technique is especially promising, since very low cw laser power (10-30 mW) is required. For the silver system described below, we have achieved conductivities on the order of pure silver. Future publications will describe other metal salt/polymer systems which can be used to form copper or gold conductors.

Experimental

Reagent-grade solvents were used. The polymers were purchased from Amoco Chemical Corporation and du Pont Specialty Coatings Division. The AI-10 polyamic acid (Amoco) came as pellets which had to be dissolved in a suitable solvent. The du Pont materials, PyraLN 2540, 2560, and PyraMIL 5057, are polyamic acid solutions, and were further diluted with either *N*-methyl pyrrolidone or *N,N*-dimethyl formamide.

Silver nitrate salt (AgNO_3 , 99.9%) was purchased from Metron, Incorporated. ULTEM™ sheets (1.5 mm thick) were provided by the Specialty Polymers and Plastics Division of General Electric.

Films were cast from solution with a Headway Research spin coater (Model 1EC101-R485). They were dried and baked in a Blue M oven. A programmable X-Y translator stage (Anorad Corporation Model 170) was used in conjunction with an argon ion laser (Spectra Physics Model 171). The output of the laser was focused through a 10× planar convex microscope objective. The focal region was viewed and displayed with a solid-state camera and television.

Resistance measurements were made with a multimeter. The linearity (I-V) of the conductors and the quality of connection to the contacts were investigated using a curve tracer (Tektronix, Incorporated, Type 576). The curve tracer was also used to determine the electric current carrying capacity of the conductors. A scanning electron microscope (Hitachi Corporation Model 5-520LB) and PGT 4 x-ray analyzer were frequently used.

Results

The present study was undertaken after previous work had shown that highly conductive polymer films result when silver nitrate doped polyamic acid films are processed in an oven at 300°C (11, 12). Resistivities as low as $10^{-3} \Omega\text{-cm}$ (pure silver = $1.6 \times 10^{-6} \Omega\text{-cm}$) were achieved. We decided to investigate the possibility of using a laser to accomplish the reduction in a localized region.

The first attempt at thermal reduction using a laser was successful. A mixture consisting of 1.5g of silver nitrate dissolved in 10g of polyamic acid solution (PyraML 5057) was prepared and cast onto a glass substrate. The film thickness depends both on the viscosity of the solution and the spin speed; for the above formulation and a spin speed of 3000 rpm, a 0.75 μm thick film resulted as measured after a 30 min bake at 150°C. The sample was placed on the Anorad translator stage and translated relative to the laser beam focused onto its surface. Using low output powers, and a 300 $\mu\text{m/s}$ translating speed, conductive silver lines were written. One series of lines formed in this manner is shown in Fig. 1. These conductors were written using laser powers between 10 and 40 mW. Pyrolysis of the undoped polymer, which is transparent in the visible, does not occur at these low powers; it is only after

Fig. 1. Laser-reduced silver conductors on glass substrate 10 mW, 20 mW, 30 mW, 40 mW, 40 mW (100 $\mu\text{m/s}$). Film thickness: 0.75 μm .

the silver ion is incorporated in the polymer matrix that sufficient absorption occurs to allow the rapid heating and reduction. Figure 2 compares the absorption spectra in the 200-800 nm spectral range for doped and undoped AI-10 polyamic acid films. The prominent adsorption band centered at 450 nm is present only for the doped polymer film. This band results from complexation between the nitrogen containing imide moiety and the silver ion. The rate of complexation is temperature dependent, and the absorbance increases with temperature and time. This is shown in Fig. 3, where the absorbance at 450 nm is plotted against the sample dry temperature. The reason for the high efficiency with which the reduction occurs (as shown below, approximately 100% of the Ag is reduced) is a direct consequence of this temperature dependence. As the laser radiation is adsorbed, heating occurs increasing the absorbance until reduction occurs. Since the polymer is a poor thermal conductor, the reduced volume remains localized.

Initial work using a glass substrate showed that a continuous metal conductor results when the film is translated relative to the focused laser radiation. The resistance of these conductors was measured by forming them between InSnO_2 contacts patterned on glass substrate. Contact metals including aluminum, gold, or silver were

also evaluated. A variety of AgNO₃ doped polyamic acid solutions (see Table I) were formulated and evaluated. Good connection between the laser-reduced silver and the different contact metals was achieved. As the thickness of the contact metal is increased, higher output powers are required to achieve good electrical connection, since the metal is thermally more conductive than the glass substrate.

A variety of polymer substrates were also evaluated. Among these, the thermoplastic ULTEM worked best because of its high heat deflection temperature (~200°C). Squares (2.54 × 2.54 × 0.120 cm) were cut from ULTEM sheet and laminated with 56g copper foil, (Gould, Incorporated). The copper was patterned using conventional printed circuit board processing. Afterwards, a relaminating step was performed to planarize the surface. This is done to present a uniform surface topography so that no refocusing is required. Figure 4 shows one such patterned substrate coated with mixture no. 3 (see Table I). Also shown is a laser-reduced silver connection between the two copper conductors. The measured resistance between the contacts was 60Ω. This is remarkably low for the silver line 1 cm long by 40 μm wide. As is shown below, the calculated resistivity agrees well with that of pure silver.

Although laser writing directly on a polymer substrate is straightforward, forming good electrical connection to patterned metal laminated on the polymer surface is more difficult, since the metal is inherently thick, and, to achieve good connection, a high laser power is required; too high a power can melt the polymer underneath. Excellent connection between the reduced silver and copper- or gold-plated copper contact metals has been achieved by using one power level for writing on the ther-

Fig. 4 Laser-written silver connection between two patterned copper conductors on Ultem.

moplastic (10-20 mW) and a power 10 times greater (approximately 100-200 mW) to form connections to the metal. Using this approach, we have formed connections having contact resistance below 1Ω. This is shown in Fig. 5, where the I-V characteristics of one such conductor is investigated with a curve tracer. The trace is linear to 20 mA. The current carrying capacity of the silver line is excellent; a 20 μm by 1 cm long conductor can pass 20 mA (at 3V) continuously. This is equivalent to 1 mA/μm, and agrees with the power-to-width specification for standard VLSI conductors having a comparable thickness (see below). Also shown in the figure is a closeup of the contact region. A higher power was used to form the low resistance connection. These conductors were formed using a scan rate of 1 cm/min (0.2 mm/s). Since scan speed and laser power are interdependent, it is expected that faster scan rates are possible.

Discussion

We have shown that during laser reduction enough silver forms to generate highly conductive lines. The simple calculation which follows predicts almost 100% conversion and agrees both with the measured resistivity and optical SEM results. The calculation is based on mix 5 (see Table I) and a film thickness of 2 μm. Two assumptions are made: first, all solvent evaporates during the casting and oven drying; second, the density of the doped film is approximately double that of undoped film, since

Fig. 5. Laser-written silver lines connecting patterned aluminum conductors to an aluminumized silicon square imbedded in Ultem. A: SEM close-up of silver conductors showing the smooth (not granular) silver deposit. B: The contact region. C: I-V trace of one silver conductor. The linearity is indicative of little contact resistance.

AgNO₃ has a molecular weight comparable to that of an Al-10 unit¹.

The mass of silver nitrate contained in the volume occupied by a typical laser-scribed conductor (1 cm × 20 μm × 2 μm) can be calculated, since the polymer volume is ~4 × 10⁻⁷ cm³ and the density of the doped film is approximately 2.5 g/cm³. The mass of AgNO₃ in this volume is 1 × 10⁻⁶g, and since the mole ratio is approximately 1:1 (Al-10 unit to AgNO₃) the mass of Ag⁺ is 108/200 × 1 × 10⁻⁶g or 5 × 10⁻⁷g. Assuming all the Ag⁺ is reduced to the metal during the laser writing, then the volume of reduced silver is mass (Ag)/density(Ag) or 5 × 10⁻⁸ cm³. For a conductor 1 cm long by 20 μm wide, this implies a silver thickness of ~0.25 μm. Using this value and the tabulated resistivity of silver (1.6 × 10⁻⁶ Ω-cm), the resistance of the 1 cm long by 20 μm by 0.25 μm conductor is

$$R = r \frac{1}{A} \sim 32\Omega \quad [1]$$

Since this value agrees well with resistance values which have been measured, the reduction is very efficient. Also, it is expected that the contact resistance between the reduced silver and the contact metallization is small. This is in agreement with the linear I-V character observed on the curve tracer Fig. 5.²

An important consideration is that these laser-written conductors be durable. Although at the present time no careful study has been undertaken, it has been determined that, once formed, the silver has little tendency to be oxidized if protected with an epoxy or polymer overcoat. This is equally true in the region where the silver contacts the substrate metal. Unprotected contacts tend to open (*i. e.*, electrical connection is lost) with time in the presence of humidity. This is because reaction occurs between the silver, nitrate ion, and substrate metal. The problem is severe with copper; substrate metals such as aluminum, gold, and molybdenum are less reactive. Once encapsulated in epoxy, both the contact region and conductors exhibit good stability under ambient conditions (25°C and 40-80% relative humidity).

Finally, as the silver is reduced on the polymer substrate, it forms in the polymer melt pool, and becomes imbedded into the thermoplastic material as it cools. This means that intimate attachment to the polymer occurs.

¹This assumes that the silver ion occupies a much smaller volume than the polyamic acid repeat unit.

²Contact resistance would appear as nonlinearity in the V-I plot at low voltage (and current).

We have observed that moderate flexing of the substrate does not detrimentally affect the electrical conductivity of the conductor.

Conclusion

It has been shown that, under appropriate conditions, the output of a laser can be used to supply thermal energy for the oxidation reduction reaction between polymer and dopant salt to occur. By translating the substrate relative to the laser beam, highly conductive lines can be generated. Since sufficient heating occurs mainly in the localized region of the focused laser radiation-beam waist 10 μm-fine lines result.

There are a variety of applications for this technique. One which we have begun to investigate is to write connections between the bonding pads on a chip to external conductors on a printed circuit board. Briefly, this involves laminating copper to the surface of a thermoplastic polymer, then patterning and gold plating the copper. A chip is laminated into the thermoplastic so that the patterned conductors surround it. The polymer/salt solution is cast onto the surface, and electrical connection between the bonding pads on the chip to the conductors is made by laser writing. Initial results look very promising (13).

Near-Surface Damage and Contamination after CF₄/H₂ Reactive Ion Etching of Si

G. S. Oehrlein,* R. M. Tromp, J. C. Tsang, Y. H. Lee,* and E. J. Petrillo

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Silicon surfaces which had been exposed to CF₄/40%H₂ reactive ion etching have been characterized by x-ray photoelectron emission spectroscopy, He ion channeling, H profiling, and Raman scattering techniques. Plasma exposure of a clean Si surface leads to the deposition of a thin (~30-50Å thick) C,F containing film. The near-surface region (~30-50Å) of the Si substrate is heavily disordered ("amorphized"), as found by ion channeling and Raman scattering. A modified, less damaged Si region extends from about 30-50Å from the surface to a depth in excess of 250Å. This layer contains a high concentration (~5 atom percent) of H as shown by hydrogen profiling techniques. From the observation of Si-H and Si-H₂ vibrational modes by Raman scattering, it has been shown that the H is bonded to the Si lattice. In ion scattering, the extended modified Si layer appears to cause a strongly enhanced background in the energy spectra. Results of Monte Carlo range calculations are reported and compared with the damage depth found experimentally.

Fine-line pattern transfer in very large scale integrated (VLSI) device processing is achieved by anisotropic dry etching techniques (1). Presently, the most widely used directional etching techniques are reactive ion etching (RIE) and ion beam sputtering. The directionality of these etching techniques is based on energetic ion bombardment of the etched surface (2). The low energy ion exposure of electronic materials can result in bombardment damage, which can affect the device applicability of these materials in a detrimental way. Indeed, a large number of reports has appeared in the literature, where detrimental side effects of dry etching techniques on semiconductors were reported and related to dry etching-induced damage in the semiconductor substrates (3-5). In the case of silicon, the following effects have been observed: a degradation of the minority carrier lifetime (6), changes in the barrier height and of the ideality factor of Schottky barriers formed on dry etched Si (7), high contact resistance in contact hole etching (8), and a deterioration of the oxide quality (interface state density, dielectric strength) of thermal SiO₂ films grown on dry-etched substrates (4, 6). The physical and chemical origins of these effects are at this time poorly understood.

An interesting property of the dry etching-induced "damage" is the depth to which it appears to penetrate into the Si substrate. Several investigators report that in order to recover the original electrical properties of a Si wafer, about 500Å of modified Si had to be removed by wet etching techniques (4, 9). This finding was assumed to imply that the "damaged" region would extend 500Å from the free surface into the bulk of the semiconductor.

Another key feature of a dry etching process is the selective etching of one material *vs.* another material. An important problem in Si technology is selective etching of SiO₂ over Si. Addition of H₂ to CF₄ has been found to increase the SiO₂-to-Si etch-rate ratio (10). There are indications that this selectivity is in part due to the deposition of an involatile carbon containing residue onto the Si surface once the SiO₂-Si interface is reached during dry etching (11). It is clear that the formation of surface residues during etching will affect the electrical properties of structures or layers formed on so-contaminated surfaces. By electrical measurements alone, it would be difficult to identify the origin of modified electrical behavior as either surface contamination or displacement damage in the substrate. This differentiation is, however, important in the search for suitable post-RIE cleaning or annealing procedures.

In the present paper (12), we report results of studies aimed at identifying the structural and chemical changes of the surface and near-surface properties of Si caused by reactive ion etching. A number of surface and near-surface sensitive techniques were employed to characterize as-etched room ambient-exposed Si. Although for sur-

face characterization, *in situ* analysis would be more desirable in order to exclude further contamination by room ambient exposure, the results of the present study are of direct technological interest.

Sample Preparation

500Å layers of thermal oxide were grown on chemically cleaned 2 Ω cm, B-doped, <100> 3.25 in. diam Si wafers. The oxide was subsequently completely removed either by dry etching or, in the case of control samples, by wet etching in buffered HF. The dry etching experiments were performed in a single-electrode RIE reactor, *i.e.*, in a configuration where the sample is placed on the powered electrode. The etching conditions were 0.178 W/cm² RF power density applied using a CF₄/40%H₂ gas mixture. A self-bias voltage of about -425V developed at the powered electrode during etching. The gas flow was 40 sccm, and the chamber pressure 25 mtorr. The etch rate of SiO₂ under these conditions was 400 Å/min, while the etch rate of Si was ~15-20 Å/min [see also Ref. (10)].

In order to study the effect of different overetching conditions on the quality of the exposed Si, the etching times were varied. The etch end point was determined by laser interferometry at the center of a Si wafer. In one case, the RIE was stopped once the whole SiO₂ layer had been etched away (denoted by "no" overetching). In other cases, the RIE conditions remained unchanged for various times up to 10 min after complete etching of the SiO₂ film. In those experiments, the Si surface was therefore exposed for the length of the overetching time to the CF₄/40%H₂ plasma.

In reactive ion etching, the maximum energy of impinging ions at the Si surface is given by the difference of the self-bias voltage developed at the powered electrode and the plasma potential [both potentials measured with respect to ground, *i.e.*, in the present case, the numerical values add (1)]. In our experiments, the maximum ion energy was about 450 eV. (We assume that the density of doubly ionized species is negligible.) Collisional processes in the sheath region can lower this energy. As a result, ions and neutrals with a great spread of energies, ranging from the maximum energy listed before to no energy, bombard the etched surface during the discharge.

From the cathode current the ion flux at the Si surface was estimated to be 1.6×10^{15} ion/cm² s (ignoring unknown corrections, such as secondary electron emission). For specimens overetched for 10 min, the total ion dose is therefore of the order of 1.0×10^{18} ion/cm².

After completion of the RIE treatments, the Si specimens were removed from the plasma chamber. The as-etched and room ambient-exposed surfaces were characterized using x-ray photoemission spectroscopy (XPS) and high resolution He ion scattering/channeling techniques. The presence of hydrogen in the near-surface region of the Si specimens was detected by the ¹H + ¹⁵N nu-

*Electrochemical Society Active Member.

clear reaction technique (13). Raman scattering was used to detect the presence of disorder in the Si lattice and to observe vibrational Si-H modes.

Experimental Results

Photoemission measurements.—In Fig. 1 and 2, XPS survey spectra are shown for dry-etched Si samples and Si samples etched in buffered HF (BHF). Magnesium $K\alpha$ radiation was used for the excitation of the photoelectrons. In Fig. 1 (250–800 eV binding energy range), we notice O Auger, O 1s, and C 1s peaks due to the native oxide on the control (BHF-etched) specimen. The native oxide was 20Å thick, as determined by ellipsometry. The carbon contamination is caused by exposure to room atmosphere. A Si sample where the SiO_2 had been dry etched with no overetching shows additional peaks due to F at the surface. The oxygen intensity is decreased, while the C intensity is increased. The changes are more dramatic for a Si specimen which had been 1 min overetched: the F- and C-related peaks are further increased, while the O-related lines are much weaker than those for the control. The F, C, and O photoemission signals of a specimen which had been overetched for 10 min are very similar to the sample which had been overetched 1 min.

The buildup of dry etching-related F, C contamination on the surfaces of processed Si specimens is reflected in the intensity of the photoelectron peaks from the underlying Si substrate. This is shown in Fig. 2. For the dry-etched samples, the Si-related photoelectron peak height is decreased as compared to the BHF control. The peaks are weaker for the 1 min overetched Si than for the no overetched sample, implying a greater amount of surface contamination with longer overetching time. This trend is not continued during prolonged overetching. The 10 min overetched specimen in Fig. 2 shows stronger Si related peaks than the 1 min overetched sample, which can be interpreted as being due to less surface contamination.¹

¹The escape depth of Si 2s and 2p electrons excited with Mg $K\alpha$ x-rays in polymeric materials is about 30Å (14). This XPS-derived thickness of the C, F layer is in agreement with an estimate based on the ion channeling measurements.

Fig. 1. XPS survey spectra (250–800 eV binding energy range) of control and $\text{CF}_4/40\% \text{H}_2$ dry etched Si samples. With no overetching, a sample is denoted where the RIE was stopped when the SiO_2/Si interface had been reached during etching.

Fig. 2. XPS survey spectra of the 0–250 eV binding energy range of control and dry-etched Si specimens. Note that the Si 2s and 2p peaks are stronger after 10 min overetching as compared to 1 min overetching, indicating less C, F film contamination after 10 min overetching.

The atomic percentage of the surface contaminants for the different Si specimens together with their processing histories is summarized in Table I. The table verifies the trends apparent in Fig. 1 and 2 concerning Si and C. It also shows that there is a monotonic increase in F concentration with longer overetching time.

In Fig. 3 the C 1s fine structure of a sample which had been overetched for 3 min in CF_4/H_2 is shown. On the high binding energy side of the regular C 1s peak, one can recognize three chemically shifted weaker components. A comparison of the binding energy positions of these weaker components with published CF , CF_2 , and CF_3 spectra (15, 16) shows that the energy positions found here agree very well with the literature values. One concludes that the carbon, in addition to being bonded to H and C, is primarily bonded to one, two, or three F neighbors. The relative concentration of the various bonding states depends on the parameters of the particular "etching" process and on the length of the plasma exposure.

Ion scattering and channeling studies.—In order to see whether subsurface damage was introduced by RIE, several samples were studied with He^+ scattering and channeling techniques. The initial energy of the He^+ ions was 120 keV. High surface sensitivity was achieved by performing the experiments in a double-alignment geometry (17). Here the incident and the (detected) scattered particle beam are aligned with respect to channeling and blocking crystal directions, respectively.

In Fig. 4, the intensity of backscattered particles vs. backscattering energy is shown for some representative

Table I. Atomic concentration of Si surface contaminants as measured by x-ray photoelectron emission spectroscopy

Sample	Atomic concentration (%)			
	F	O	C	Si
HF control	—	24.1	20.4	55.4
No overetching	7.3	26.1	31.1	35.6
1 min overetching	15.0	14.8	63.4	6.8
10 min overetching	35.4	11.3	40.8	12.5

Fig. 3. High resolution XPS spectrum of the C 1s region of a Si sample which had been overetched for 3 min in a CF₄/40% H₂ plasma. The chemically shifted weaker components on the high binding energy side correspond to the indicated bonding states.

experiments. The bottom curve in Fig. 4 is for the wet-etched control sample. At 99 keV, a pronounced random peak due to scattering from Si at the surface is observed. Additional peaks due to oxygen and carbon (from the native oxide layer) occur at 85.5 and 75.9 keV. No other major features appear in the spectrum. The background level is very low.

The second curve from the bottom is for a dry-etched Si specimen where no overetching was applied during RIE, *i.e.*, the plasma was immediately turned off once the SiO₂-Si interface had been reached. The Si surface peak is larger than for the control sample. Furthermore, the background level is higher and an additional F peak at about 90.3 keV is just noticeable. The next curve is for a specimen which had been overetched for 1 min. Strong peaks due to C and F are present in this spectrum. The oxygen peak appears weaker and is shifted to somewhat lower energy. The Si surface peak is also shifted to lower energy, except for a small fraction which remains at 99 keV. The energy shift in the Si and O peaks is caused by the C,F overlayer. The small Si peak remaining at 99 keV indicates that the C,F film is not continuous. The back-

Fig. 4. High resolution He ion scattering and channeling spectra of control and dry-etched Si samples.

ground level is clearly higher than for the HF control in the present case. The upper curve of Fig. 4 is the RBS spectrum for a specimen which had been overetched for 10 min. In this case, most features are similar to the 1 min overetched sample. Notable differences are that no Si peak is remaining at 99 keV (signifying a continuous C,F film) and that the background to the left of the large Si surface peak is about twice that measured for the 1 min overetched sample. For the 10 min overetched sample, the Si surface peak occurs at slightly higher backscattering energy than after 1 min overetching, which is consistent with a thinner C,F layer on top of the Si.

Hydrogen profiling experiments.—The presence of H in the Si lattice was detected using a nuclear reaction profiling technique (13) based on the reaction

A complete description of the application of this technique to the analysis of H in Si can be found in Ref. (19).

Hydrogen concentration depth profiles for the specimens previously studied with XPS and RBS techniques are shown in Fig. 5. For the control (HF-etched) sample, the H concentration close to the surface exceeds 15 atomic percent (a/o). The H arises in this case from a moisture contamination of the native oxide (13). The H concentration drops off rapidly at increasing Si depth, and at about 200Å away from the surface a constant background level is reached. The Si specimens which had been etched in CF₄/H₂ display a much greater H concentration near the surface and deeper into the bulk. The greater H concentration close to the surface is most likely caused by the C,F surface films ("C,F polymer") present on these samples. The 1 and 10 min overetched Si samples, which according to XPS and RBS had about the same thickness of C,F-film contamination, show also nearly the same concentration of H close to the surface. At greater Si depths the H concentration is markedly different for the two samples. The 10 min overetched sample displays consistently a higher H concentration. From this comparison of the 1 and 10 min overetched specimens, it is clear that the substantial H concentration observed in the bulk, *e.g.*, 250Å away from the surface, is not caused by a measurement artifact, *e.g.*, due to a higher H surface concentration, but reflects a H concentration increase in the near-surface region of the 10 min overetched Si caused by the CF₄/H₂ RIE process.

Fig. 5. Hydrogen depth profiles of control (BHF-etched) and dry-etched Si wafers. Note that, for the 1 and 10 min overetched specimens, the H surface peaks are the same (due to similar C,F film contamination), while deeper in the bulk the H concentration of the 10 min overetched sample is higher.

Raman scattering analysis.—Raman spectroscopy can probe several hundred angstroms deep into a Si sample. By observing vibrational excitations of impurities, direct information about the chemical bonding can be obtained (20). The Raman spectrum of amorphous Si shows no sharp lines at frequency shifts larger than 200 cm^{-1} , but does show a broad continuum which peaks at about 480 cm^{-1} (21). The Raman spectrum of crystalline Si consists of a single sharp line at $\sim 520\text{ cm}^{-1}$. The difference arises from the fact that for α -Si no translational symmetry exists as a result of which the selection rules for Raman scattering are relaxed (21). Therefore, all vibrational modes of the amorphous material can take part in the scattering process and a continuum reflecting the density of vibrational states results. These favorable characteristics of Raman scattering have been used to study properties of hydrogenated α -Si (21, 22).

In Fig. 6, Raman spectra of heavily disordered Si which had been produced by several methods are shown. The top curve was obtained with a 60 \AA thick amorphous Si film which had been deposited onto a single-crystal Si substrate at 225°C by decomposition of SiH_4 in a glow discharge. (The contribution of the single-crystal Si substrate has been subtracted, causing the negative excursion of the Raman intensity near 522 cm^{-1} .) The Raman spectrum agrees with the reported spectrum for α -Si (21). The second curve from the top was obtained with a $\text{CF}_4/40\%\text{H}_2$ reactive ion etched Si sample (10 min overetching). The Raman spectrum is similar to the one obtained with the deposited α -Si film. This result demonstrates (in agreement with the RBS findings) that a heavily damaged or amorphized Si layer has been produced by the RIE processing. The two lower curves in Fig. 6 were obtained with single-crystal Si samples which had been implanted with 500 eV Ar^+ ions or 1000 eV H^+ ions to a dose of $1.0 \times 10^{18}\text{ ion/cm}^2$. We notice that these processing steps also introduce Raman scattering similar to the one observed for α -Si.

In Fig. 7, Raman spectra for the same samples are shown at a Raman shift corresponding to Si-H vibrational modes in α -Si ($\sim 2000\text{ cm}^{-1}$) (22). The top curve in Fig. 7

Fig. 6. Raman scattering spectra of amorphous Si layers on top of single-crystal Si. (The Raman spectrum of the crystalline Si substrate has been suppressed in the figure.) The disordered Si layers were either produced by SiH_4 decomposition in a glow discharge, 10 min overetching of a Si sample in a $\text{CF}_4/40\%\text{H}_2$ RIE, 500 eV Ar^+ ion bombardment, or 1000 eV H^+ ion implantation.

Fig. 7. Raman scattering spectra of Si-H vibrations in $\text{CF}_4/40\%\text{H}_2$ RIE Si (no overetching), a, 10 min $\text{CF}_4/40\%\text{H}_2$ overetched Si, b, 60 \AA of hydrogenated amorphous Si on top of single-crystal Si, c, and 1000 eV H^+ ion-implanted Si, d.

was obtained with a $\text{CF}_4/40\%\text{H}_2$ dry-etched sample without overetching. The spectrum is flat, which indicates a low density of Si-H active modes. The second spectrum from the top was obtained with a sample which had been overetched for 10 min in $\text{CF}_4/40\%\text{H}_2$. In this case a very pronounced double peak is visible. The peak at $\sim 2050\text{ cm}^{-1}$ corresponds to a Si-H vibration, while the band at $\sim 2200\text{ cm}^{-1}$ is due to a vibrational mode of Si-H_2 (22). Figure 7 shows for comparison also Raman spectra of a 60 \AA thick hydrogenated α -Si film on single-crystalline Si and a H^+ -implanted single-crystalline Si target (1000 eV H^+ , $1.0 \times 10^{18}\text{ ion/cm}^2$) in the same wave number region. A more complete description of the Raman scattering experiments and discussion of the results will be published in a separate paper (23).

Monte Carlo range calculations.—We have performed Monte Carlo range calculations utilizing a program developed by Ziegler *et al.* (24). Several elements typically used in RIE (C, F, and H) and an amorphous Si target were employed. The initial energies of the ions were varied from about 100 eV to 2 keV . The following (possibly important) effects were ignored in the range calculation: physical sputtering of the target by the bombarding ions and the influence of damage on the sputter yield; diffusion of already implanted species caused by the high ion flux; and channeling of ions.

The energy dependence of the mean range (projected range) of the ions found in these calculations is displayed in Fig. 8. Despite the many effects which were not considered in the calculation, the following conclusions can be drawn from Fig. 8: (i) the mean range of ions such as F and C is of the order $20\text{--}30\text{ \AA}$ or less for typical ion energies encountered in reactive ion etching; (ii) the mean range of about 150 \AA or less for hydrogen is significantly larger. The depth of the damaged or modified Si layer should roughly correspond to the ion range.²

²In several investigations of H-implanted single-crystal Si, it has been found that the H profile coincided with the damage profile (25a). For electrically active dopant ion implantation, it has often been found that the damage distribution peaks at about 10% closer to the surface than the dopant distribution (25b).

Fig. 8. Projected range of C, F, and H as calculated by a Monte Carlo simulation on an amorphous Si target as a function of the ion energy. Possible ion energies encountered in RIE processing are indicated.

Discussion

Surface contamination.—The surface contamination caused by direct exposure of a Si surface to CF₄/40%H₂ RIE consists mainly of a C,F layer [Ref. (34) describes a similar XPS study of freon-etched Si]. Immediately on top of the Si surface, there is a O-rich transition layer. It is likely that this transition layer is formed upon exposure of the reactive ion-etched sample to room ambient. X-ray photoelectron spectroscopy data (which are not presented here) show that the thickness of the C,F film reaches a maximum after about 3 min overetching and decreases slightly in thickness after overetching times in excess of 3 min. After even longer overetching times (~10 min), it appears that a steady-state situation is reached, where the deposition of new C,F material is equal to the amount removed by the RIE.

We did not verify in our experiments that the Si etch rate of 15-20 Å/min was constant during overetching. However, the quoted etch rate had been determined with the same RIE tool and using the same RIE parameters (10). Silicon etching implies a dynamic 30-50Å thick C,F film on Si, which will change its composition during overetching due to different simultaneous processes: silicon etching and transport of reaction products through the C,F-film; deposition of new C,F-material; physical sputtering of the deposited film; and chemical etching of the C,F-film by F species, which will form C-F bonds, produce volatile fluorocarbon molecules, and desorb. One expects, therefore, that the composition of the C,F film will depend on the overetching duration, which is borne out by Table I.

The C-, F-, and O-related information obtained by the ion scattering experiments is in agreement with the XPS-derived information as regards trends in atomic percentage vs. processing history, C,F layer thickness, etc. The ion scattering results also indicate near-surface damage in the dry-etched Si substrates.

Near-surface disorder.—The increase of the Si surface peak for the no, 1, and 10 min overetched samples indicates that Si atoms close to the surface have been displaced from regular lattice sites as a result of the RIE processing. The width and the area of the surface peak are both a measure of the depth at which the surface damage occurs. The energy resolution in the present experiment of 400 eV for 100 keV ions (31) corresponds to a depth resolution of 6Å and is high enough to enable a determination of the depth of the heavily damaged near-surface layer. In the first two columns of Table II, we list the thickness of the disordered surface region as inferred from the width of the surface peak and the number of Si

Table II. Silicon surface peak width and area (at./cm²), and background intensity (as a percentage of the intensity obtained with random beam incidence) for the He⁺ ion scattering spectra of Fig. 4

Sample	Surface peak		Background (%)	
	Width (Å)	Area (at./cm ²)	Measured	Calculated
HF control	17	4.7 × 10 ¹⁵	0.8	0.0
No overetch	27	8.9 × 10 ¹⁵	2.2	0.1
1 min overetch	34	9.7 × 10 ¹⁵	7.5	0.4
10 min overetch	37	14.4 × 10 ¹⁵	16	0.6

atoms per square centimeter present in this disordered region as determined from the surface peak areas. Both the width of the disordered region and the number of surface atoms displaced from a regular lattice site increase with increasing etching time. Between 1 and 10 min, the width increases less than the number of displaced atoms. This indicates that the surface region gets more heavily disordered, although the depth of the disorder does not change much any more. The thickness of this saturation disorder depth is ~35Å.

This heavily damaged layer is most likely created by the heavier ions in the plasma, which give rise to collision cascades. In particular, polyatomic species such as CF₃⁺ can be critical for damage production since the deposited energy density in the collision cascade has been found to be important in terms of damage creation and retention (29). The extent of the heavily disordered region is roughly in agreement with the maximum projected range of ~25 and ~30Å found for F and C in the Monte Carlo calculations. It is possible that this heavily disordered region contains trapped F and C.

Hydrogen penetration.—One of the surprising results of initial RIE-damage investigations was the "damage depth" of ~500Å (4, 9) caused by the low energy ion bombardment in a glow discharge. The data presented in the previous paragraph showed that there is a heavily disordered region very close to the surface (~35Å). The energy spectra of backscattered He ions, however, do not only show an increase in the surface peak width and area, but also an increase in the background intensity at lower energies and a buildup of a C,F contamination film. The increase in background intensity can be because of two reasons. The first reason is that the ion beam loses its angular definition when it passes through the amorphous film in the surface area before it enters the underlying single crystal. Due to this angular straggling, channeling of the ion beam cannot be as good as for a well-collimated beam, and the background intensity is higher. Alternatively, the region immediately below the heavily disordered surface area may contain a certain concentration of defects, giving rise to an increased background intensity, due either to direct scattering or dechanneling. We have calculated the increase of background intensity caused by dechanneling of the ion beam in the amorphous overlayer, which consists of the heavily disordered Si surface region and the C,F contamination film, if present. These Monte Carlo calculations were performed by following the trajectories of many ions through the amorphous overlayer and the underlying crystal. The background intensity was calculated by evaluation of the nuclear encounter, probability between ion and substrate atoms along the trajectory, and averaging over a large number of trajectories (32). This method only takes dechanneling by nuclear interaction into account. Since the inelastic energy losses are small, we believe this to be a good approximation.

Columns 3 and 4 in Table II show the measured and calculated background intensities as a percentage of the scattering intensity when the beam enters the crystal in a random direction. For the BHF sample, the measured and calculated intensities agree quite well. (A 1% deviation is not surprising, since the calculation assumes the incident beam to be perfectly collimated. In the experiment, the beam has an angular spread of 0.1°-0.15°.) For the RIE-

etched samples, the measured intensities are consistently much higher than the calculated intensities. This can only be explained by the presence of defects. Thus, on the basis of these results and the H profiling experiments, we attribute the increased background (especially observed for the 10 min overetched Si sample) to the presence of H and possibly H-related secondary defects in the Si lattice. The suggested origin of the increased background appears to be in good agreement with a transmission electron microscopy analysis of H₂ plasma-treated Si (3), where centers which compressed the Si lattice and dislocation loops were found in the near-surface region. It is known (18) that dislocations are ineffective in scattering and can be observed primarily by dechanneling effects. Hydrogen-related secondary defects are indicated by the observation of SiH and SiH₂ vibrational modes, since, presumably, the occurrence of SiH bond formation requires that initially broken Si-Si bonds are present, *i.e.*, disorder.

According to the H profiling experiments, even at depths in excess of 250Å there exists a substantial H concentration for the 10 min overetched sample caused by the reactive ion etching. The Monte Carlo calculations found a projected H range of ~150Å for the maximum ion energy possible in our plasma conditions. According to the modeling results, a substantial H concentration can therefore exist at distances in excess of ~200Å from the Si surface for H⁺ ion energies of about 500 eV. We have no experimental data on the actual ion energy distribution at the Si surface for our RIE experiments, and it is possible that due to collision processes the "average" ion energies are much lower than the maximum ion energy and the H range would accordingly be reduced. However, channeling effects can be important, and, additionally, diffusion effects can occur during the ion bombardment. It appears that the diffusion coefficient of H in Si is not well known at room temperature. If diffusivity values determined by tritium diffusion at about 500°C (26) are extrapolated to room temperature, a diffusion distance of ~300Å is obtained. An atomic H diffusivity value determined at about 900°C (27) gives a diffusion distance orders of magnitude larger (~2.0 × 10⁴Å). Recent H diffusion determinations based on compensation of a Au donor level in Si with H by deep level transient spectroscopy (28) gave diffusion values close to the tritium diffusion results. Therefore, the possible H diffusion distances during the plasma processing times used in our experiments should be significant (~300Å). [We ignored here the fact that during reactive ion etching the Si wafer temperature can rise by as much as 30°C (30). The conceivable H diffusion distances could, therefore, be even greater.] We conclude that the observed depth of the H-"modified" layer is not inconsistent with the projected H range and a possible profile redistribution brought about by H diffusion occurring concurrently with the plasma treatment.

Overetch time dependence of damage.—The question arises of how long overetching can proceed before a steady-state damage profile has been reached. Upon exposure of the free Si surface to the CF₄/H₂ plasma, there will be accumulation of damage in the Si substrate. At the same time, reactive ion etching of the Si substrate is occurring which will consume the damaged layer. Initially, the degree of disorder near the Si surface will increase with overetching time. The conditions for obtaining steady state are different for the heavily damaged near-surface layer which has an extent of ~30-50Å and H-modified Si, which has an extent in excess of 250Å.

A simple, approximate³ way to estimate the times to reach steady state in terms of damage production or accumulation of trapped impurities is given here. We assume that the effects of different ions on the Si substrate are in-

dependent and simply add. The erosion of the target and the creation of damage and trapping of ions in the substrate are treated as occurring simultaneously but independently. We assume that the damage profile and the impurity profile coincide (25) and that the impurity profile is given by a gaussian. With $n(x,t')$, the ion concentration at position x introduced in the time interval dt' at time t' is denoted. The surface is located at $x = 0$ initially but moves with a velocity v to the right ($v =$ etch rate). A point in the Si substrate located at a distance x from the original surface will receive an ion density $n(x,t') dt'$ at time t' in the interval dt'

$$n(x,t') dt' = \frac{Q}{\sqrt{2\pi}\Delta R_p} \exp \left[-0.5 \left(\frac{(x - vt' - R_p)^2}{\Delta R_p^2} \right) \right] dt' \quad [2]$$

with Q being the dose rate per square centimeter, R_p the projected range of the impinging ions, and ΔR_p the straggling. The ion (or damage) distributions $n(x,t')$ of all time intervals dt' up to time t will add up to give a resulting ion (or damage) distribution $N(x,t)$

$$N(x,t) = \frac{Q}{\sqrt{2\pi}\Delta R_p} \int_0^t \exp \left[-0.5 \left(\frac{(x - vt' - R_p)^2}{\Delta R_p^2} \right) \right] dt' \quad [3]$$

which gives

$$N(x,t) = \frac{Q}{\sqrt{2\pi}v} \left[\operatorname{erf} \left(\frac{x - R_p}{\sqrt{2}\Delta R_p} \right) - \operatorname{erf} \left(\frac{x - vt - R_p}{\sqrt{2}\Delta R_p} \right) \right] \quad [4]$$

A point x_1 fixed with respect to the actual surface will have coordinates $x_1 + vt$ at time t with respect to the original coordinate system. The ion (or damage) distribution $N(x_1, t)$ is, therefore, given by

$$N(x_1, t) = \frac{Q}{\sqrt{2\pi}v} \left[\operatorname{erf} \left(\frac{x_1 + vt - R_p}{\sqrt{2}\Delta R_p} \right) - \operatorname{erf} \left(\frac{x_1 - R_p}{\sqrt{2}\Delta R_p} \right) \right] \quad [5]$$

For a given location x_1 from the Si surface, $N(x_1, t)$ will have reached its maximum possible value to within 1% after a time t (33)

$$t \geq \frac{2.69\Delta R_p + R_p - x_1}{v} \quad [6]$$

In our experiments, the etch rate of Si was about 15-20 Å/min and the maximum range of C and F are about 30Å. For the sake of simplicity, we assume that the range straggling equals the numerical value of the projected range. The heavily damaged Si (as measured with ion channeling at $x_1 = 0$) will have reached its maximum value after about 5-7 min. Consistent with this time estimate for reaching steady state, the RBS spectra show that the Si surface peak due to displaced Si atoms increases from no overetching to 1 min overetching. However, it is nearly the same for the 1 and 10 min overetched specimens. The intensity (or extent) of the heavily damaged near-surface layer should have reached the maximum possible value possible for the experimental RIE conditions used prior to 10 min overetching.

The overetch time required to measure the maximum H concentration in the H-modified Si is ~18-30 min (taking into account the maximum range and a measurement location x_1 of about 50Å from the surface). Consistent with this much greater time to reach steady state, we measured a large increase in H concentration for the 10 min overetched sample as compared to the 1 min overetched specimen. It is likely that the H concentration obtained after an even longer overetching time, *e.g.*, 20 min, would be greater than the concentration which we measured after 10 min overetching.

Conclusions

Our experimental data allow us to summarize some of the effects which direct exposure of a Si surface to CF₄/40%H₂ RIE has on the Si surface properties as follows (see also Fig. 9): (i) a C,F containing film is deposited

³A full treatment would require knowledge of the energy distribution, mass, and partial flux of the bombarding species, the way in which physical sputtering and chemical reactivity interact and result in a net removal rate of material for each species, the effect of accumulated "damage" and impurities on the various reactive ion sputtering coefficients, etc.

Fig. 9. Schematic diagram of changes of Si near-surface region caused by CF₄/H₂ reactive ion etching.

onto the Si, the thickness of which is limited to less than 50Å; (ii) a layer of ~30-50Å thick heavily damaged Si is formed as a result of the energetic particle bombardment; (iii) hydrogen is implanted to depths in excess of ~200Å. This layer is less damaged than the Si layer immediately adjacent to the surface. In ion channeling studies, these defects give rise to a strongly enhanced background in the energy spectra. At least some of the H bonds to the Si lattice and gives rise to SiH and SiH₂ vibrational modes observable by Raman spectroscopy.

Since, at present, the energy and particle flux distributions impinging upon the Si substrate are unknown, the data were discussed mainly in terms of maximum possible ion energies. The results of Monte Carlo range calculations for F⁺, C⁺, and H⁺ are roughly in agreement with the damage depths or impurity ranges found experimentally.

Acknowledgments

The authors would like to thank Dr. L. E. Gulbrandsen of the Physical Electronics Laboratory for assistance in obtaining some of the XPS data. Professor W. Lanford of SUNY (Albany, New York) is acknowledged for helping us to measure the H depth profiles and stimulating discussions. We are also grateful to Dr. J. F. van der Veen of the FOM Institute for Atomic and Molecular Physics (Amsterdam, The Netherlands), for giving us time and equipment to perform the He ion scattering experiments. We furthermore thank Dr. J. F. Ziegler, Dr. M. R. Polcari, and Dr. R. Kalish for helpful discussions.

An Empirical Oxidation Rate Law for Thin Oxides

S. Aptekar and M. Fernandes

ABSTRACT

An oxidation rate law for thin oxides, as suggested by Hu (2, 3), has been found to correlate very well with experimental data. The growth law, although not based on any interface reaction mechanism, has been formulated to be consistent with the observed power-law pressure dependence of the linear rate constant through the use of a dummy parameter, p . The higher oxidation rate observed at thin oxides has been taken into account by an exponentially decaying term. The analysis assumes that p varies linearly over the thickness of the oxide. Values of the other parameters in the rate law have been taken from available data.

In the process of miniaturization of metal-oxide-semiconductor field-effect transistors (MOSFET's), the gate oxide is being reduced to below 300Å. In case of oxidation under wet oxygen conditions, and for large oxide thickness grown in dry oxygen, the Deal-Grove expression (1) predicts oxide growth accurately. However, oxide growth for thin oxides in dry oxygen conditions has an anomalously high oxidation rate, the mechanism of which is yet not fully understood.

With increasing need to obtain thin oxides, it has become necessary to predict oxide thickness for oxidation in dry oxygen. In this work, therefore, an attempt has been made to correlate an oxidation rate law, suggested by Hu (2, 3), with known experimental values (4). The new law takes into account the power-law dependence of the interface reaction rate. It is therefore not based on any interface reaction mechanism, and is independent of whatever mechanism might give rise to that pressure dependence. In our analysis, we have only assumed an oxide thickness of 700Å over which a dummy parameter $p = p_i/p_o$ (ratio between the oxygen pressure at the Si-SiO₂ interface and that in the ambient) varies linearly over the thickness of the oxide. Values of other parameters in the rate law have been taken from available data. Excellent correlation with experimental values at two different temperatures has been obtained up to 300Å, above which the Deal-Grove expression should be used.

Theory

The classical Deal-Grove relationship, widely used to describe the growth kinetics of oxidation of silicon, is given by

$$X^2/B + X/(B/A) = t + \tau \quad [1]$$

where X is the oxide thickness, t is the oxidation time, B and B/A are the parabolic and linear rate constants, respectively, and τ is a correction parameter for the presence of any initial oxide X_i . The Deal-Grove model suggests that molecular oxygen goes through the gas boundary layer, diffuses through the oxide, and reacts with the silicon substrate. The expression is based on the assumption of three fluxes in steady state: the flux of oxidant from the gas ambient to the gas-SiO₂ interface; the diffusive flux of oxidant through the SiO₂ film; and the flux representing the oxidation reaction at the Si-SiO₂ interface.

By equating the three fluxes and by integrating from time zero to time t , and from an initial thickness X_0 to a final thickness X , one can obtain

$$X = \frac{A}{2} \left[\left(1 + \frac{t + \tau}{A^2/4B} \right)^{1/2} - 1 \right] \quad [2]$$

Equation [2] reduces to

*Electrochemical Society Active Member.

$$X \cong \frac{B}{A} (t + \tau) \cong \frac{KC^*}{N_i} (t + \tau) \text{ for } (t + \tau) \ll \frac{A^2}{4B} \quad [3]$$

where N_i is the number of oxidant molecules to form a unit volume of oxide and C^* is the maximum oxidant concentration for a given pressure. The other limit is

$$X \cong (Bt)^{1/2} \cong \left(\frac{2DC^*t}{N_i} \right)^{1/2} \text{ for } t \gg \frac{A^2}{4B} \quad [4]$$

Hence, for short oxidation times (and therefore for thin oxides), the oxide thickness is linearly proportional to the surface reaction rate constant. For long oxidation times (and hence for thick oxides), oxide thickness is determined by the diffusion constant D . It also follows that B/A , the linear rate constant, is a more important factor for thin oxides than the parabolic rate constant, B .

The oxidation rate can be obtained from Eq. [1]

$$\frac{dX}{dt} = \frac{(B/A)B}{2(B/A)X + B} = \frac{B}{2X + A} \quad [5]$$

The oxidation rate obtained from the Deal-Grove expression is dependent on both the linear rate constant (B/A) and the parabolic rate constant (B). However, by Eq. [3] and [4] it is clear that for very thin oxides the linear rate constant is a more important factor. The growth-rate law suggested by Hu (2, 3) is for very thin oxides and therefore does not depend on the parabolic rate constant B .

To account for the high oxidation rate for thin oxides in dry oxygen, various models have been suggested which differ significantly from each other. Adams *et al.* (5) believe that the best fit for their data is parabolic. Irene (6), Haas and Gray (7), and van der Meulen (8) suggest that thin oxide grows linearly with time. Kamigaki and Itoh (9) show that a different law is obeyed when the oxidation ambient pressure is varied.

Hu's model (2, 3) proposes a general law which encompasses the Deal-Grove linear parabolic growth law and Blanc's law (10) as two special cases. The law assumes that the intermediate step in the oxidation reaction is the chemisorption of oxygen molecules. The chemisorbed molecular oxygen may directly oxidize the silicon or it may dissociate into atomic oxygen, which then rapidly oxidizes the silicon. Hu suggests that the Freundlich isotherm fits data very well and uses this isotherm to derive the general equations for oxide thickness (X) and time (t) (2)

$$X = 1/2 a (p^{-m} - p^{1-m}); 1 > p > 0$$

$$t = 1/4 b (2m - 1)(2m - 1)p^{-2m}$$

$$+ 2(1 - m)p^{1-2m} - 1]; m \neq 1/2$$

$$t = (1/4 b)(p^{-1} - 1 - \log p); m = 1/2 \quad [6]$$

where a and b are related to B/A and B as follows

Fig. 1. Temperature dependence of the linear rate constant, B/A , for $\langle 100 \rangle$ and $\langle 111 \rangle$ oriented silicon. See Ref. (11).

$$a = (B/A)/B$$

$$b = (B/A)^2/B$$

m lies between 0.6 and 0.8; p defined as $p = p_i/p_0$ can be regarded as a dummy parameter running from $p = 1$ ($X = 0$) to $p = 0$ ($X \rightarrow \infty$). When $m = 1$, the above set of equations reduces to linear parabolic law, and, when $m = 1/2$, the set reduces to Blanc's growth law (10).

Massoud *et al.* (11) suggest that their data can be fitted by

$$\frac{dX}{dt} = \frac{B}{2X + A} + C_1 e^{-X/L_1} + C_2 e^{-X/L_2} \quad [7]$$

where the characteristic length L_1 slowly increases with temperature and C_1 has a break-in activation energy at $\approx 900^\circ\text{C}$ (11). The first added exponential term represents the fast growth observed at the onset of oxidation and up to about 50\AA (11). By neglecting the first exponential term, one arrives at errors of less than 5% in fitting the experimental data (11). The oxidation rate could therefore be rewritten as

$$\frac{dX}{dt} = \frac{B}{2X + A} + C_2 e^{-X/L_2} \quad [8]$$

The decay length L_2 is approximately independent of temperature and is equal to $\approx 70\text{\AA}$ (12). C_2 is a singly activated function of temperature with an activation energy of 2.35 eV for $\langle 111 \rangle$ and $\langle 100 \rangle$ orientations (12). The physical origin of these parameters is now known, but Ho *et al.* (12) claim that implementation of Eq. [8] in SUPREM III has produced good simulation capabilities for the thin oxide region.

The linear rate constant B/A has been found to have a $p^{0.6} - p^{0.8}$ pressure dependence (4, 8). B/A was also observed to have a $p^{0.7} - p^{0.8}$ pressure dependence in a high pressure oxidation study by Lie *et al.* (13). Massoud's data (11) show that oxidation rate in the thin oxide regime has a high pressure dependence of $\approx p^{0.8}$, which is in agreement with other data.

To take into account this pressure dependence, Hu (2, 3) suggests a different equation for oxidation rate which takes into account this pressure dependence. The

Fig. 2. Temperature dependence of the pre-exponential constant C_2 for the oxidation of $\langle 100 \rangle$ - and $\langle 111 \rangle$ -oriented silicon in dry oxygen. See Ref. (11).

equation is given by

$$\frac{dX}{dt} = \frac{B}{A} p^m + C_2 e^{-X/L_2} \quad [9]$$

where the exponentially decaying term is similar to that in Eq. [8]. Although the equation takes into account the pressure dependence, the physical reason of the non-linear pressure dependence is unknown at this time. It probably reflects the relative contributions of atomic and molecular O_2 reactions at the interface as suggested by van der Meulen and Ghez (8, 14). It should therefore be emphasized again that the new growth law is not based on any interface reaction mechanism.

Results

In our analysis, we have used Eq. [9] to satisfactorily predict the oxidation rate for thin oxides. The calculated oxidation rates have been compared with the data of Hopper *et al.* (4). Hopper *et al.* (4) obtained oxidation rates for $\langle 111 \rangle$ -oriented silicon oxidized at 760 torr oxygen at temperatures of 870° and 930°C . The linear rate constant, B/A , has been determined by Deal and Grove (1), besides oth-

Fig. 3. Fitting of the new growth law (dots) with the data of Hopper *et al.* (4).

Table I. Effects of changing values of m and L_2 on the calculated values of dt/dX (s/Å) at 930°C

	Oxide thickness (Å)	$m = 0.8$ $L_2 = 67\text{Å}$ dt/dX (s/Å)	$m = 0.7$ $L_2 = 67\text{Å}$ dt/dX (s/Å)	$m = 0.6$ $L_2 = 67\text{Å}$ dt/dX (s/Å)	$m = 0.8$ $L_2 = 70\text{Å}$ dt/dX (s/Å)
$T = 930^\circ\text{C}$	10	3.5	3.5	3.5	3.5
	200	10	10	10	10
	300	13	12	12	13
$T = 870^\circ\text{C}$	10	10	10	10	10
	200	26	25	25	26
	300	33	32	31	33

ers, but we have used the values for B/A , C_2 , L_2 , and m as determined by Massoud *et al.* (11).

B/A and C_2 are known to be dependent on temperature. The variations of these parameters as a function of temperature are shown in Fig. 1 and 2 (11). From Fig. 1, the values of B/A at 870° and 930°C are 2.76 and 7.17 Å/min, respectively. The value of C_2 at 870° and 930°C is 3.72 and 11.87 Å/min (see Fig. 2). L_2 has been determined to be independent of temperature (11, 12). We have chosen a value of 67Å which is near to the value of 70Å suggested by Ho *et al.* (12). m lies between 0.6 and 0.8 (4, 8, 11, 13), but in our analysis a value of 0.8 has been used (11).

Although only particular values of m and L_2 have been used, using different reported values of m and L_2 have a small effect on the results. As can be seen in Table I, taking $m = 0.6$ or 0.7 instead of 0.8, and L_2 as 70Å instead of 67Å, changes the results by a small percentage.

Hence, the only parameter which is not available from literature is p . In our analysis, we have assumed that p varies linearly from $p = 1$ ($X = 0$) to $p = 0$ ($X = X$) over an oxide thickness X . Taking $X = 700\text{Å}$, a perfect fit of calculated values with Hopper's data has been obtained at both 870° and 930°C. Taking X to be between 600 and 800Å gives an error of dt/dX (s/Å) of less than 5% up to an oxide thickness of 200Å. The experimental and calculated values of the inverse of oxidation rate *vs.* oxide thickness are shown in Fig. 3.

Calculated values show that a good correlation exists at both temperatures up to an oxide thickness of about

300Å. Beyond 300Å, the calculated and experimental values deviate from each other. Oxide growth can therefore be broken up into two regimes. Up to 300Å, the new oxidation law can be used. For thicknesses greater than 300Å, the Deal-Grove equation (Eq. [1]) is suitable.

Conclusions

An oxidation rate law, which incorporates the pressure dependence of oxidation rate, has been shown to correlate very well with experimental data up to an oxide thickness of 300Å. Values of the various terms in the equation are available from literature. The only assumption made by the authors is that the parameter p varies linearly between 0 and 1 over an oxide thickness of 700Å.

Effect of Cu on the Kinetics and Microstructure of Al_3Ti Formation

M. Wittmer,* and F. Le Goues

ABSTRACT

Impurities and structural defects have a strong influence on the kinetics of thin film reactions. We have investigated the effect of Cu on the kinetics of formation and microstructure of Al_3Ti in the temperature range of 375°-450°C. We found that the presence of 1 weight percent Cu in the Al changes both the activation energy and the pre-exponential factor of the growth law. At the same time, the Cu influences the microstructure of the growing Al_3Ti phase and smoothens the reaction interface. The results are discussed in terms of possible diffusion mechanisms in Al_3Ti .

There is a continuing interest in the interdiffusion and interaction phenomena of thin metal films for two reasons. First, such phenomena occurring in thin film diffusion couples may be very different from those observed in bulk diffusion couples. In contrast to bulk specimens, thin films contain a lot more interfaces and surfaces. In addition, the film thickness is usually limited to a few thousand angstroms. These structural differences are of

*Electrochemical Society Active Member.

ten responsible for the particular behavior of thin film diffusion couples (1, 2). Second, many areas of thin film technology require a detailed understanding of interdiffusion and interaction in thin metal films. Particularly, microelectronics makes use of multilayer metal films for electrical contacts and interconnects. Aluminum alloys are widely used for metallization of integrated circuits, and, consequently, studies of the reaction of aluminum with transition metals are of great interest.

Interdiffusion and intermetallic compound formation in binary aluminum-transition metal thin film systems have been reviewed by Baglin and Poate (3). In the case of the Al-Ti thin film reaction, it was found that the intermetallic compound Al_3Ti is formed with an activation energy of 1.85 ± 0.05 eV (4). Recently, it has been reported that copper, which is often added to Al for improved electromigration resistance, retards the growth of Al_3Ti and increases the activation energy (5, 6). We have studied the influence of Cu in the Al-Ti thin film reaction in detail by comparing the changes in the kinetics with the concomitant changes in the microstructure of the films.

Experimental

Oxidized silicon wafers were used as a substrate throughout the course of this study. Bilayers of Ti and Al were prepared by sequential deposition of a 1500Å thick Ti layer, followed by a 6300Å thick Al-Cu layer with a Cu content varying from 0 to 4.5 weight percent (w/o) (all percentages are given in weight percent). The layers were evaporated with an electron gun in a diffusion-pumped vacuum system. The base pressure of the system was about 7×10^{-5} Pa. Care was taken to prevent oxygen contamination of the Ti film by first evaporating a thin layer of Ti onto the walls of the vacuum system while the substrates were protected with a shutter. The oxygen content in the Ti film was measured with Auger depth profiling technique and found to be less than 0.1 atom percent (a/o). The Al-Cu films were evaporated from an alloy source of proper composition. Subsequently, the wafers were cleaved and small samples of the thin-film couples were annealed in forming gas ($\text{N}_2:\text{H}_2 = 9:1$) in the temperature range of 375°-450°C for various times.

The kinetics of the Al-Ti reaction were investigated with Rutherford backscattering spectrometry (RBS) and electrical resistivity measurement. A commercially available four-point probe was used for the resistivity measurements. Compound formation was examined with glancing angle x-ray diffraction on selected samples. The microstructure of the films was studied with a Philips scanning transmission electron microscope (STEM) on flat-on as well as cross sections of the bilayer thin films.

Results

Kinetics of phase formation by RBS.—The interaction of Al and Ti was analyzed with RBS at an energy of 2 MeV. The superposition of two RBS spectra from an Al(1%Cu)/Ti sample are shown in Fig. 1. The solid line presents the analysis of the as-deposited sample and the dotted line shows the results of the same sample after a heat-treatment at 400°C for 16h. The vertical arrows in Fig. 1 indicate the energy of $^4\text{He}^+$ particles scattered from the surface position of the corresponding element.

We have chosen to deposit first Ti, the heavier metal, and then the Al alloy, which is the lighter metal. The reason was to protect Ti from oxidation during heat-treatments. As a result, the signals of the Al and Ti overlap in the RBS spectrum because the Ti signal, which would otherwise be at higher energies, is now shifted to lower energies due to the energy loss of the $^4\text{He}^+$ particles in the overlying Al-alloy film. The leading edges of the Al and Ti signal coincide in the spectrum of the as-deposited sample. Shown in Fig. 1 is also the Cu signal which is magnified by a factor of 10. Finally, the RBS signals from the SiO_2/Si substrate make up the low energy part of the spectra in Fig. 1.

The heat-treatment at 400°C caused a partial intermixing of Al and Ti. This can be seen in Fig. 1 from the steps occurring simultaneously at the trailing edge of the Al signal and the leading edge of the Ti signal. The relative composition of the intermixed layer can be calculated from the heights of the Al and Ti signals in that layer, as is shown in Fig. 1. The atom ratio is found to be Al:Ti = 3:1, indicating the formation of the compound Al_3Ti . Positive phase identification was made by glancing-angle x-ray diffraction using a Seeman-Bohlin camera. Figure 2 presents the diffraction pattern obtained

Fig. 1. 2.0 MeV $^4\text{He}^+$ RBS spectra of Al(1%Cu)/Ti samples following deposition of the layers and subsequent heat-treatment at 450°C for 16h. The vertical arrows mark the surface position of the corresponding elements. The heights of the Al and Ti signal near the Al interface indicate a composition of Al:Ti = 3:1 in the intermixed layer.

with Cu $K\alpha$ radiation of an Al(4.5% Cu)Ti sample which has been annealed at 450°C for 6h. The diffraction lines confirm unambiguously the formation of the compound Al_3Ti . This result agrees well with those published in the literature (4-6) and demonstrates that 4.5% Cu dissolved in the Al does not affect the nucleation and growth of the Al_3Ti phase.

The copper distribution observed with RBS in the as-deposited sample is very uniform, as can be seen from Fig. 1. Even after the heat-treatment, the Cu backscattering yield in the Al_3Ti layer is unchanged. A slight reduction of the yield of the Cu signal is observed near the surface at an energy of 1.5 MeV. This is due to the fact that the spectra of Fig. 1 were taken from two different samples which had a slight variation of the Cu content in the surface region of the Al film. In conclusion, we find that the heat-treatment does not disturb the copper distribution in the bilayer thin film. It should be noted that the RBS results present an average over an analysis area of 1 mm². It will be shown that TEM analysis finds many Al_2Cu precipitates. But, from RBS, we know that these precipitates are uniformly distributed in the alloy film.

The thickness of the Al_3Ti layer can be calculated from the width in energy of either the Al or the Ti step in Fig. 1. By assuming bulk density for the compound Al_3Ti and

Fig. 2. Glancing angle x-ray diffraction pattern obtained with a Seeman-Bohlin camera and Cu $K\alpha$ radiation of a Al(4.5%Cu)/Ti sample after annealing at 450°C for 9h.

Fig. 3. Growth kinetics of the compound Al_3Ti for pure Al films at four different temperatures.

by using the surface approximation in evaluating the stopping cross sections, we find a thickness of 1950Å. In the same fashion, we analyzed a large number of samples annealed for various times in the temperature range of 375-450°C to obtain the growth kinetics of Al_3Ti . The results are presented in Fig. 3, 4, and 5 for three cases, Al without Cu, with 1% Cu, and with 4.5% Cu, respectively.

A common characteristic of the plots in Fig. 3-5 is that the data points can be fitted to straight lines. It is evident from Fig. 3 that the straight lines do not intercept the origin of the plot. A finite thickness of Al_3Ti exists for zero annealing time. The reason for this peculiarity is twofold. First, the annealing time has been measured as the time

Fig. 4. Growth kinetics of the compound Al_3Ti for Al-1% Cu films at four different temperatures.

Fig. 5. Growth kinetics of the compound Al_3Ti for Al-4.5% Cu films at four different temperatures.

which the samples spent in the center of the annealing furnace. The time for the manual loading and unloading of the samples has not been taken into account. Thus, the measured annealing time is slightly shorter than the actual annealing time. Second, it will be shown in the Microstructural analysis section that the $\text{Al}_3\text{Ti}/\text{Al}$ interface is rough, which leads to a certain ambiguity in the determination of the actual interface location and, thus, to an uncertainty in the measurement of the Al_3Ti thickness by RBS. The samples with 1% and 4.5% Cu solute have a smooth $\text{Al}_3\text{Ti}/\text{Al}$ interface. Consequently, the straight lines in Fig. 4 and 5 intercept the axes close to the origin of the plot.

Since the abscissa in Fig. 3-5 is calibrated in square root of time, the growth of Al_3Ti obeys a parabolic law. This behavior is independent of Cu solute and characterizes a diffusion-limited reaction process. Thus it is possible to determine the chemical interdiffusion constant from the slopes of the straight lines in Fig. 3-5.

The logarithm of the interdiffusion constant D is plotted as a function of reciprocal temperature $1/T$ (Arrhenius plot) in Fig. 6. Straight lines can be fitted again to the data points. It appears from Fig. 6 that the growth kinetics of Al_3Ti with 1% and 4.5% Cu solute are the same, but differ from those without Cu. Thus the growth of Al_3Ti is thermally activated in all cases, but with different activation energies E_a and preexponential factors D_0 . The parameters E_a and D_0 were obtained from a fit of $D(T) = D_0 \exp(-E_a/kT)$ to the straight lines in Fig. 6 and are listed in Table I. The addition of 1% Cu to the Al increases the activation energy from 1.6 to 2.05 eV and the pre-exponential factor by three orders of magnitude.

Table I. Effect of Cu on the kinetics of Al_3Ti growth as determined from Rutherford backscattering (RBS) and resistivity (Res.) measurements

Cu concentration (%)	E_a (eV)		D_0 (cm ² /s) RBS
	RBS	Res.	
0	1.60 ± 0.10	1.50 ± 0.10	3.4 × 10 ⁻³
1	2.05 ± 0.10	2.00 ± 0.10	2.9
4.5	2.05 ± 0.10	2.00 ± 0.10	2.9

Fig. 6. Arrhenius plots of the chemical interdiffusion coefficients calculated from the data of Fig. 4-6. The addition of Cu to the Al alters both the activation energy and the pre-exponential factor.

Electrical resistivity measurement.—Provided that the Ti has a limited solubility in Al and that the Al film has a low resistivity, then any change in resistivity can be ascribed to the formation of an Al-intermetallic compound layer if the reaction interface is planar. We will show in the next section that this assumption holds in Ti/Al thin film couples. Thus, a time-dependent parameter, β , can be defined which measures the increase in resistivity as a result of the progressing interaction between Al-Cu and Ti, according to

$$\beta \equiv \frac{1}{\rho_0} - \frac{1}{\rho}(t) = \frac{\rho(t) - \rho_0}{\rho_0 \rho(t)}$$

ρ_0 being the electrical resistivity of the as-deposited thin film assembly and $\rho(t)$ the resistivity after annealing the assembly for time t at a given temperature.

It has been shown that the resistivity of a Al(Cu)/Ti bilayer film first decreases rapidly after very short annealing at an elevated temperature, due in large extent to the precipitation of Al_2Cu particles, and then increases monotonically due to the formation of an Al-intermetallic compound (6). Thus, a minimum in resistivity is observed for short anneals of a bilayer film where a certain amount of Cu has been added to the Al. We have chosen this minimum in resistivity to represent the value of ρ_0 .

The parameter β calculated from the measured resistivities of samples with various Cu contents is plotted in Fig. 7 as a function of the square root of the annealing time at 400°C. As shown in Fig. 7, β varies linearly with $t^{1/2}$, except for short annealing times where departure from the parabolic behavior cannot be explained at present. The effect of Cu on the reaction rate is also clearly illustrated in Fig. 7. These results are consistent with those obtained by RBS.

The correlation between the resistivity increments due to compound formation and the compound layer thicknesses measured by RBS is shown in Fig. 8. The results were obtained from samples with pure Al and Al with 1% and 4.5% Cu which were annealed at 400°C for various

Fig. 7. β vs. annealing time at 400°C for Al(Cu)/Ti bilayer films with various Cu contents.

times. It can be seen in Fig. 8 that the resistivity increments vary linearly with the compound layer thicknesses measured by RBS. The better linear correlation for the Al (1%Cu) and Al (4.5%Cu) samples suggests that the compound layer formed in the presence of Cu has a more planar interface, because the resistivity analysis assumes a planar layer growth. This point has been confirmed by cross-sectional TEM observation as discussed in the next section.

The slopes of the curves in Fig. 7 determine the reaction rate constants, which, if obtained at several annealing temperatures, can be used to calculate the corresponding activation energies. The results are listed in Table I. It is not surprising that, due to the linear correlation, the activation energies determined from the resistivity data are in good agreement with those obtained with RBS.

Microstructural analysis.—It is well known that solutes influence the microstructure of thin metal films. An indication of the effect of Cu on the microstructure of the Al_3Ti compound can be obtained from a careful RBS analysis. In Fig. 9, we present 2.3 MeV RBS spectra of two samples, one with 1% Cu and the other without Cu solute in the Al, following a heat-treatment at 425°C for 2h. The retardation of the Al_3Ti formation can immediately be seen by the difference in widths of the steps at the trailing edges of the Al signals and leading edges of the Ti signals. Besides a difference in widths, there is also a difference in slopes of the signals at these steps. The sample with 1% Cu dissolved in the Al exhibits steeper slopes at these steps than the sample without Cu solute. This points to a smoother and/or laterally more homogeneous interface between the Al_3Ti compound and the Al layer. Since RBS cannot distinguish between the two possibilities, a TEM analysis is needed.

Fig. 8. Correlation between resistivity measurements and thickness of the Al_3Ti compound determined by RBS.

Fig. 9. 2.3 MeV $^4\text{He}^+$ RBS spectra of two samples with Al layers containing 1% Cu and no Cu following simultaneous heat-treatment at 425°C for 2h. The contribution of the Al signal to the overall spectra is indicated by the dashed line.

Figures 10 and 11 show micrographs of cross sections of samples which have been annealed at 450°C for 30 min and 4h, respectively. The micrographs of Fig. 10 were obtained from samples with a pure Al layer, and those of Fig. 11 from samples with a Al-1% Cu layer. The labeling distinguishes the different layers in Fig. 10 and 11. The thickness of the Al_3Ti is much larger for the samples without Cu. Also, without Cu, there is a marked penetration along the Al grain boundaries, where the Al_3Ti compound formation is more advanced. In contrast, the growth of Al_3Ti in the presence of 1% Cu solute in Al is independent of the Al grain boundaries. As a result, the $\text{Al}_3\text{Ti}/\text{Al}$ interface is rough in the samples without Cu, while the samples with Cu exhibit a smooth interface. Finally, it should be noted that the grain size of the Al is larger when Cu is added than without Cu.

Discussion and Conclusion

The above results show that Cu has a significant effect on the formation kinetics and microstructure of Al_3Ti . The presence of 1% Cu in the Al increases the activation energy for the growth of Al_3Ti to 2.05 ± 0.10 eV. This value is in good agreement with that found by Huang and Wittmer (6) and Tardy and Tu (7) but is lower than the value of 2.4 eV published by Krafcsik *et al.* (5). Higher Cu concentrations do not increase the activation energy fur-

ther. Without Cu we found an activation energy of 1.60 ± 0.10 eV, which also agrees well with those published by Huang and Wittmer (6) and Tardy and Tu (7), but is again lower than both the value of 1.8 eV reported by Krafcsik *et al.* (5) and the early value given by Bower (4). A possible explanation for the difference in activation energies found by the different groups could be that in the preceding work Ti was contaminated by some impurities, notably oxygen. Titanium is well known for its oxygen gettering capability, and in many cases Ti thin films contain a small but measurable amount of oxygen.

The growth of Al_3Ti necessitates a continuous supply of Al and Ti atoms to the reaction interface. Each atom species can be supplied by diffusion through the growing Al_3Ti layer. The parabolic growth of the Al_3Ti , which has been observed in all studies on Al-Ti thin film reactions, indicates that the rate-limiting step is the interdiffusion through the growing Al_3Ti layer and not the interfacial reaction at the metal-compound interface. Tardy and Tu (7) have carried out marker experiments to determine which atom species, Al or Ti, is the predominant diffusing species. They found that the diffusivity of Al is about ten times faster than that of Ti in the temperature range of 350°-450°C, irrespective of the presence of a small amount of Cu in the Al. Thus, it appears that the growth kinetics of Al_3Ti are governed mainly by the diffusivity of Al through the growing Al_3Ti layer.

In determining the role of Cu on the microstructure of Al_3Ti , we recall that Cu is known to precipitate as θ -phase particle (Al_2Cu) on surfaces and interfaces of the Al film (8, 9). Without Cu solute in the Al, the Al grain boundaries are preferential nucleation sites for the formation of Al_3Ti , because grain boundary diffusion is faster than bulk diffusion. The presence of Cu in the Al layer causes the formation of θ particles and, probably, Cu segregates at the grain boundaries. Both prevent a significant diffusion of Ti along the Al grain boundaries. Consequently, the growth of Al_3Ti occurs more uniformly at the Al-Ti interface, which results in improved smoothness of the interface.

Other factors influence the smoothness of the Al-Ti interface. In the absence of Cu, the Ti diffusing along the Al grain boundaries impedes the growth of the Al grains. However, in the presence of Cu, not only is the grain boundary diffusion of Ti inhibited, but also the Cu promotes the grain growth of the Al (10). The difference in Al grain size is evident from a comparison of Fig. 10 and 11. With larger Al grains, the Al-Ti interface becomes smoother, independent of the nucleation process of the Al_3Ti .

It is consistently found that the Cu slows the growth of Al_3Ti . With Al being the dominant diffusing species, Krafcsik *et al.* (5) proposed that segregation of Cu on the

Fig. 10. Cross-sectional TEM micrographs of Al/Ti samples following a heat-treatment at 450°C for (a) 30 min and (b) 4h

Fig. 11. Cross-sectional TEM micrographs of Al(1%Cu)/Ti samples following a heat-treatment at 450°C for (a) 30 min and (b) 4 h

Al_3Ti grain boundaries retards the diffusion of Al along these fast diffusing paths and shifts the transport of Al atoms more to bulk diffusion. Unfortunately, this segregation model cannot be corroborated with solid solution data of Cu in Al_3Ti because the latter are not known. From our investigation, however, we find an increase in the diameter of the Al_3Ti grains by a factor of 3 to 4 in the presence of Cu, which means that the areas of the fast diffusing paths are reduced by a factor of about 10. This could account for the reduced growth rate of Al_3Ti in the presence of Cu, if grain boundary diffusion is the principle transport mechanism of the Al atoms.

The effect of Cu on the Al-Ti reaction kinetics can also be due to the formation of phases which are different from Al_3Ti . At low Cu concentrations, a (Al_3Ti , Cu) solid solution is likely to be formed. With higher Cu concentrations, however, one may expect from the Al-Cu-Ti ternary phase diagram (11) the formation of $\text{Al}_{23}\text{Ti}_9$ or $\text{Al}_{11}\text{Ti}_5$, whose phase fields extend to ternary alloys of $\text{Al}_{70}\text{Cu}_5\text{Ti}_{25}$ composition. It is also possible that the ternary compound Al_4CuTi_2 forms and is stable in contact with Al(Cu) and Ti. Unfortunately, the crystal structure of $\text{Al}_{23}\text{Ti}_9$, which is the only one known, is so close to that of Al_3Ti that it is difficult to determine unambiguously which one is formed in our Al(Cu)-Ti reaction couples. Therefore, more work is needed to clarify the Al-Cu-Ti ternary system near the Al_3Ti intermetallic compound. In conclusion, the role of Cu in the Al-Ti reaction kinetics is a difficult one and may not be explained by a simple segregation model.

ABSTRACT

We have investigated the silicide-silicon interface during the oxidation of titanium silicide on polysilicon. We find that during oxidation the polysilicon layer under the silicide is consumed inhomogeneously and that at the same time the titanium silicide moves into the polysilicon layer. Oxidations were carried out both in wet and dry O_2 with similar results. This nonuniform consumption of the polysilicon layer appears to be related to the condition of the silicide-silicon interface prior to the oxidation step. This effect can result in the reduction of the dielectric breakdown strength of underlying gate oxide in titanium silicide/polysilicon/oxide/Si structures.

The application of refractory metal silicides to interconnects in VLSI has been the subject of many investigations in the last few years (1-6) because of their low resistivity and ability to withstand high temperature processing. Of the four refractory metal silicides, WSi_2 , $TaSi_2$, $MoSi_2$, and $TiSi_2$, that are commonly considered, $TiSi_2$ has the lowest resistivity (15-25 $\mu\Omega\text{-cm}$), and from this point it appears very attractive. However, one of the desired features of any interconnect material which is to be used in place of polysilicon is the ability to grow a passivating layer of oxide over it. Silicides by themselves do not have this feature. Moreover, it is desirable to maintain the work function of the gate at the value for doped polysilicon in order to retrofit existing processes that utilize polysilicon gates. For this reason, the use of a silicide layer on top of a doped polysilicon layer (polycide) has gained wide acceptance. It has been shown that, during oxidation, silicon from the underlying polysilicon layer diffuses through the silicide layer and provides the silicon necessary to grow the silicon dioxide layer (2). It has been found for $MoSi_2^3$ and WSi_2^3 films and $TaSi_2^4$ that the thickness of the polysilicon layer (pad poly) underneath the silicide has to be kept larger than a certain minimum thickness in order to maintain the gate integrity after oxidation of the polycide structures. The requirement of a minimum pad poly thickness may be related to the degradation of the silicide-silicon interface after oxidation. It has been shown in the case of WSi_2 polycides that the presence of a native oxide on the polysilicon can lead to silicon being consumed from only a few points in the polysilicon, thus causing voids to be formed at the silicide-silicon interface (5). These voids, besides affecting the MOS properties, can also cause loss of adhesion between the silicide and polysilicon. In this paper, we report on the effects of oxidation of $TiSi_2$ polycide structures on the gate oxide integrity. We show that this is closely related to the structural changes that occur at the silicide-polysilicon interface during oxidation. The effect of the cleanliness of the initial interface is investigated with the aim of preventing the degradation of the silicide-polysilicon interface and maintaining gate oxide integrity. The consequences of these results on the use of $TiSi_2$ polycides for process applications will be discussed.

Experimental Details

The starting wafers for the MOS capacitor studies were n-type (100) having a resistivity of 3-5 $\Omega\text{-cm}$. Standard 500Å gate oxides were grown and annealed. Polysilicon films with thicknesses ranging from 500 to 2500Å in steps of 500Å were deposited on these oxides by low pressure chemical vapor deposition (LPCVD) and were doped N^+ using $POCl_3$ at 1000°C for 15 min. The sheet resistance of a 2500Å thick polysilicon layer was 28 Ω/\square after the

*Electrochemical Society Active Member.

doping. Two wafers with a 2500Å polysilicon layer were kept as controls; the rest of the wafers were coated with a 2000Å layer of titanium silicide, which was sputtered from a cold-pressed $TiSi_{2.2}$ composite target (Varian, CPVS grade) in a CVC Model 601 sputtering system. In addition, two wafers with only the gate oxide also received the 2000Å layer of titanium silicide. The sheet resistance of the silicide film after deposition was 20 Ω/\square and decreased to 1.2 Ω/\square after an anneal at 950°C in ultrahigh purity (UHP) argon for 30 min corresponding to a resistivity of 24 $\mu\Omega\text{-cm}$. One group of wafers was subsequently oxidized in dry O_2 for 60 min at 950°C. The oxide grown on top of the silicide was removed using a dry plasma etch. In order to simulate realistic devices, both groups of wafers, oxidized and unoxidized, were coated with 1 μm of Al/1% Si and patterned using wet etching into 10 mil diam dots to form capacitors. The back of each wafer was coated with aluminum to ensure good ohmic contact. A voltage ramp of 1 V/s was applied to 100 capacitors on each wafer, and the voltage necessary to reach 1 μA was recorded.

In order to study the oxidation process in more detail, a second set of wafers was also prepared. In this set, the gate oxide was replaced by a 4000Å thermal oxide layer. A 2500Å layer of LPCVD polysilicon was deposited and doped, followed by a 2000Å layer of titanium silicide. Silicide films of the same thicknesses were also deposited on bare Si wafers. This set of wafers was oxidized either in dry O_2 at 950°C or in O_2 bubbled through water at 96°C. This was done to study the growth rate and oxide quality in each case. Prior to turning on the O_2 , the wafers were annealed in dry N_2 for periods of time ranging from 10-60 min.

Auger depth profiles of the annealed samples revealed no detectable oxygen in the films, and the stoichiometry estimated from Auger and x-ray dispersive spectroscopy was that of $TiSi_{2.1}$. X-ray diffraction confirmed that the main phase existing in the films after the anneal was the disilicide.

The oxide thickness on top of the silicide was estimated using values obtained by the sputtering rate in our Auger system, where the oxide sputtering rate was known. The wafers were also examined by SEM. The interface between the silicide and polysilicon film was studied by etching the oxide and silicide film in buffered HF, which does not etch polysilicon or single-crystal silicon substrates.

Results and Discussion

The measured breakdown field strength of the inert ambient-annealed polycide capacitors is plotted in Fig. 1 as a function of the pad polysilicon thickness t_p . The polysilicon thickness was measured prior to doping. The inert ambient annealing was done at 950°C for 30 min in

Fig. 1. Breakdown field strength for polycide capacitors as a function of pad poly thickness, when the silicide layer was inert ambient annealed in Ar (not oxidized) and oxidized at 950°C in wet oxygen for 30 min.

UHP Ar. For t_p ranging from 500 to 2500Å, the gate oxide field strength remains at approximately 9 MV/cm, which is the breakdown field strength measured for the control polysilicon capacitors on gate oxide. However, when the silicide is in direct contact with the gate oxide, the field strength drops to about 5 MV/cm. This shows that even for an inert ambient anneal, a TiSi_2 layer cannot be placed directly on the gate oxide without compromising the gate oxide integrity.

This reduction in gate oxide field strength may be the result of an interaction between the titanium silicide film and the SiO_2 layer during which the SiO_2 layer is partially consumed (6). This thinning of the gate oxide may be the cause of the observed lowering of the breakdown voltage.

The polycide films that had been annealed in Ar or N_2 at 950°C for various lengths of time ranging from 10 to 60 min had the top layer of silicide stripped away with BOE to investigate this phenomenon with respect to the silicide-polysilicon interface integrity. The interfaces were examined by SEM and were found to be smooth with no indication of any reaction between the polysilicon and titanium silicide.

In contrast, when the polycide was subjected to either dry or wet oxidation, the gate oxide field strength decreased to approximately 5 MV/cm even with an initial 2500Å thick layer of pad polysilicon underneath (Fig. 1). This indicated that the process of oxidation appeared to cause deterioration of the gate oxide integrity even in a polycide structure. This phenomenon has been observed in other polycide structures using Ta, W, and Mo silicide (3, 4). To further investigate this deterioration of the gate oxide during oxidation of the polycide structure, the silicide-polysilicon and silicide-single-crystal silicon interfaces were examined in detail under various oxidation conditions.

Since wet oxidation of gate structures is common in IC processing, the polycide structures on 4000Å field oxide layers were subjected to wet oxidation at 950°C for various intervals of time. The Auger profiles of the polycide structures which were subjected to wet oxidations for 10, 30, and 60 min at 950°C are shown in Fig. 2. The depth of the profiles extends to the lower portions of the polysilicon layer. As expected, the thickness of the silicon dioxide grown on top of the polycide increases with time and was estimated to be 600, 1500, and 2200Å for 10, 30, and 60 min, respectively, based on Auger sputtering rates. These oxide thicknesses on top of the silicide are consistent with the literature (7, 8). Visually, the films became progressively cloudier as the oxidation time progressed, indicating increasing surface roughness. The Auger profiles show that in all three cases the interface

Fig. 2. Auger depth profiles of polycide structures oxidized at 950°C in wet O_2 for 10 min (a), 30 min (b), and 60 min (c).

between the oxide and the silicide is very sharp, that is, the thickness of the oxide layer is uniform over the scanned area, even though the surface morphology is not smooth. In contrast, the interface between the silicide and polysilicon is less sharply defined, with the Ti signal tailing into the polysilicon. This interface broadens with increasing oxidation time such that in the 60 min oxidation case, the silicide and polysilicon are intermixed.

The silicide-polysilicon interface was examined by stripping the oxide and silicide over half the sample using buffered HF. SEM pictures of the samples are shown in Fig. 3. The top half of each micrograph shows the oxide surface, while the lower half shows the exposed surface of the polysilicon. The polysilicon layer, in all cases, is pitted, and the size of the pits increases with increasing oxidation time. The Auger results suggest that these pits were filled with silicide before the HF etch, and confirmation of this is provided by cross-sectional SEM pictures of the 30 min wet oxidized sample shown in Fig. 4. Prior to delineation in BOE, no voids are seen between the silicide and the polysilicon (Fig. 4a). After silicide delineation by dipping the sample in BOE for 10s, the result is shown in Fig. 4b. It is clear that the silicide filled the pits seen earlier in Fig. 3. Note that the oxide layer is very uniform in thickness and that the oxide-silicide interface is abrupt. In contrast, the silicide layer is no longer uniform but is very thick in some places and thin in others. The silicide spiking into the polysilicon reduces the effective pad polysilicon thickness and, therefore, allows the

Fig. 3. SEM micrographs of polycide samples that were oxidized at 950°C in wet O₂. The upper half of each picture shows the surface of the oxide film, the lower half the exposed surface of the polysilicon after a BOE etch. a: 10 min oxidation. b: 30 min oxidation. c: 60 min oxidation.

reduction of gate oxide integrity. This is evident in the Auger profiles, where the range over which the silicon and titanium signals are flat (indicating uniform silicide) decreases with increasing oxidation time. On the basis of Auger and SEM results, it is possible to show the progression of the various layers with increasing oxidation, as shown in Fig. 5. This mechanism has also been cited in Ref. (4) as the cause of the gate oxide breakdown field strength reduction in TaSi₂/polysilicon structures.

In order to study the effect of the rate of oxidation, the polycide structure was also oxidized in dry O₂ at 950°C for 30 min to grow about 200Å of oxide. On stripping the oxide and silicide, pits similar in size to the wet oxidation which produced the same oxide thickness were once again observed in the polysilicon layer. Thus the rate of oxidation does not appear to be the critical factor in causing the deterioration of the silicide-polysilicon interface. The 950°C, 30 min dry O₂ oxidation was used as a test for all subsequent attempts to improve the oxidation characteristics of the polycide structures.

The effect of different anneal times in nitrogen prior to oxidation was investigated. The function of the anneal is

Fig. 4. SEM cross sections of the titanium silicide/polysilicon structure after 30 min oxidation in wet O₂. a: Before delineation of silicide layer. b: After delineation of the silicide layer by dipping the wafer in buffered HF for 10s.

Fig. 5. Schematic representation of the change in the silicide-polysilicon interface with increasing oxidation time.

to crystallize the silicide, to allow it to reach its equilibrium stoichiometry, and to let the silicon distribute uniformly throughout the film so that free Si is readily available at the time of oxidation. The time of the anneal prior to a 30 min dry oxidation at 950°C was varied from 10 to 60 min. Increasing the time of preanneal appeared to decrease the extent of pitting seen in the polysilicon layer but did not remove it entirely.

All the results indicated that the thermal cycle during the oxidation process was not the critical factor causing the silicide penetration into the silicon. In the case of WSi₂⁵, the interfacial oxide between the silicide and polysilicon was shown to be responsible for the formation of voids at the silicide-polysilicon interface during oxidation. The effect of an interfacial oxide that could cause localized consumption of silicon was investigated by trying different cleaning techniques prior to the titanium silicide deposition. The initial technique of cleaning the wafers in HF just prior to silicide deposition was not successful. *In situ* sputter etching of the polysilicon prior to silicide deposition was also attempted but appeared to aggravate the problem, possibly due to redeposition of impurities onto the polysilicon surface. In a third cleaning method, the wafers were given a slight etch in CF₄ + O₂ in a barrel plasma reactor to remove some of the native oxide and about 100Å of polysilicon immediately prior to silicide deposition. The silicon was again consumed nonuniformly, but the pits appeared to be shallower than in the case of an HF dip and rinse prior to deposition. Whenever the pits are shallow, their areal density is higher than when they are deep, which is to be expected because the same amount of Si is consumed in both cases. Finally, high dose ion implantation of heavy ions was considered as a means of dispersing interfacial oxides (9, 10). It has been shown in the case of the direct reaction of Ti films with silicon that the implantation of Si or P ions through the films not only facilitates the diffusion of Si into the Ti, but also leads to the more uniform consumption of silicon (11). Since the oxidation of silicides requires the transport of Si across the silicide-polysilicon interface, ion implantation should prevent localized penetration of the titanium silicide. The thickness of the silicide film was reduced to 1000Å because of the limitations imposed by the highest energy limit of 200 keV in the ion implanter. The film was implanted with 170 keV phosphorus ions to a dose of 1×10^{16} ion/cm². At this energy, the phosphorus penetrates into the polysilicon and the

Fig. 6. SEM micrograph of the polysilicon surface after the polycide was implanted with 170 keV P ions at a dose of 1×10^{16} ion/cm², annealed at 950°C in dry O₂ for 30 min, and the oxide and silicide top layers stripped away in BOE.

damage peak should be located at the silicide-polysilicon interface. After oxidation for 30 min in dry O₂ at 950°C and stripping the oxide and silicide, pits were once again observed in the polysilicon layer. However, the pits were more widely distributed and formed a distinctive pattern, as shown in Fig. 6.

It is possible that the doped polysilicon layer may be responsible for the degradation of the interface. Any effect of the polycrystalline nature of the underlying silicon layer and any effect of heavy doping were removed by repeating the oxidation experiments with silicide deposited on undoped single-crystal silicon substrates. Wet oxidations at 950°C were carried out simultaneously with the polycide samples discussed earlier. The oxide thicknesses were the same as for the polycide samples. Figure 7 shows the surface and the silicide-silicon interface of wet oxidized films at 950°C for 10, 30, and 60 min. As in the case of the polycides, nonuniform consumption of silicon occurs from the underlying silicon substrate. Several points of distinction are to be noted between the polycide case and the silicide-single-crystal silicon case. First, the shape of the pits is different. Second, in the case of the single-crystal silicon, the top surface of the oxidized film shows a network which is distinctive of grain boundaries and is not seen on polysilicon. We believe this relates to the titanium silicide grains. The shape of the depressions observed in the silicon substrate match the silicide grains. Numerous voids also appear between the grain-like structures extending into the oxide layer which are not observed in the polycide case (Fig. 4). Similar penetration of

Fig. 8. a: SEM micrograph of the top surface of titanium silicide layer on single-crystal silicon, implanted with 15.0 keV Si to a dose of 1×10^{16} ion/cm² and oxidized in dry O₂ at 950°C for 30 min. b: Same sample as in a, but with the oxide and silicide layer stripped away.

TiSi₂ is noticed when the silicide on single-crystal silicon is oxidized in dry O₂ at 950°C for 30 min.

To further examine the silicide-single-crystal silicon case, the effect of ion implantation interface mixing was also investigated. The implantation consisted of a 150 keV implant of Si ions to a dose of 10^{16} ion/cm². Si was used instead of P to rule out any doping effects, but the masses of the two ions are so close that the ion implantation-related effects should be similar. These films were then oxidized in dry O₂ at 950°C for 30 min following a 15 min N₂ anneal. The top surface of the film (Fig. 8a) shows a pattern resembling grain boundaries and a pitted silicide single-crystal silicon interface (Fig. 8b). It should be noted that some grains appear raised in Fig. 8a and that the distribution and shape of these grains match the pits seen at the interface. This seems to indicate that some of the grains in the silicide film grow perpendicular to the surface both upwards and downwards into the silicon. This takes place only during oxidation, as films annealed in N₂ for the same length of time show a very smooth surface. Faint traces of grain boundaries can be seen in the single-crystal silicon following the anneal with size of the grains being similar to those seen in oxidized films. This grain growth is expected in titanium silicide at 950°C, and the removal of silicon underneath the silicide due to oxidation allows the grains to grow vertically downwards. However, the fact that only some grains of the silicide grow vertically confirms that the silicon is being consumed very nonuniformly from the underlying silicon layer.

Conclusions

It is known that during the oxidation of refractory metal silicides on silicon the silicon required to form the SiO₂ diffuses through the silicide to the top surface from the underlying silicon. As the silicon is consumed, the silicide layer is depressed into the silicon. We have shown that this silicon consumption is nonuniform, as silicon is consumed only from selected sites. In the case of a polysilicide, the uniformity of silicon consumption was shown to be dependent on the condition of the silicide-polysilicon interface. In the case of silicide on single-crystal silicon, the titanium silicide grain boundaries also affected silicon consumption. In addition, we have shown that the titanium silicide fills the areas where the silicon is consumed, and hence, instead of voids, isolated pockets of silicide penetrate into the underlying silicon.

We propose that the presence of a nonuniform silicon diffusion barrier at the silicide-polysilicon interface results in localized silicon consumption. We have attempted to clean this interface by HF etching, plasma etching, *in situ* bias sputter etching, and ion-beam mixing without success. None of the methods described was successful in completely removing the titanium silicide penetration. The best that could be achieved was to reduce the depth of the penetration. The technique that gave the best results was the plasma etching prior to the titanium silicide deposition. Thus, the key to maintaining the gate oxide integrity is to use a pad poly of sufficient thickness to prevent the silicide from spiking through the poly and reaching the gate oxide. This is necessary, since the titanium silicide was shown to have a deleterious effect on

the integrity of the gate oxide when in contact with it. We have shown that the silicide spiking problem is exacerbated with increasing oxidation, and, therefore, a thicker pad poly would be needed with increasing oxidation.

Low Temperature Oxidation of Silicon in a Microwave-Discharged Oxygen Plasma

Shin-ichiro Kimura, Eiichi Murakami, Kiyoshi Miyake, Terunori Warabisako, Hideo Sunami, and Takashi Tokuyama*

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

Silicon dioxide growth in an oxygen plasma is investigated using newly developed microwave discharge equipment with electron cyclotron resonance. It is found that the plasma oxidation kinetics can be explained by the Cabrera-Mott model, in which the drift motion of ions is assumed, rather than by the Deal-Grove thermal oxidation model. The drift motion of oxygen ions across the oxide film under the influence of self-bias in the plasma is considered to be the plasma oxidation mechanism. Infrared absorption and etch-rate measurements reveal that the physical properties of plasma oxidized SiO₂ at 600°C are structurally quite comparable to those of thermally oxidized SiO₂.

Low temperature film formation techniques have recently been considered a key process for realizing forthcoming VLSI's. This is because such conventional high temperature processes as thermal oxidation, chemical vapor deposition, or damage annealing of implanted areas have given rise to defect formation and impurity redistribution which seriously damage a VLSI's performance.

Plasma oxidation, utilizing a highly activated oxygen plasma, is one of the low temperature techniques used to grow dielectric films on semiconductor surfaces. This plasma oxidation is usually divided into two categories. One is plasma anodization, in which the specimen to be oxidized is positively biased to enhance the diffusion of oxygen or substrate atom ions through the oxide film, and the other is plasma oxidation without external bias.

The most extensively investigated technique is the former, because with it a considerably higher oxidation rate is obtained. For example, an oxidation rate of about 1 μm/h has been reported (1-3) at 600°C for Si oxidation. This rate is equivalent to that of thermal oxidation in an H₂O atmosphere at 1200°C.

Plasma anodization has several disadvantages, as pointed out by Ray *et al.* (4). For example, since the two electrodes used to apply a bias to the specimen are directly immersed in the plasma, it is difficult to avoid contamination caused by electrode sputtering. Also, heavy damage by irradiation of charged particles and UV light is unavoidable (5).

On the other hand, plasma oxidation has not been as intensively investigated as plasma anodization, since it is difficult to obtain high oxidation rates (6). One of the exceptions is the very thin oxide film formation on lead or niobium for Josephson junctions (7).

However, as the thickness change of the gate oxide in MOS transistors clearly shows, the gate oxide becomes increasingly thinner in accordance with the decrease in device geometry (8). This means that plasma oxidation has potential uses in place of plasma anodization, because the above-mentioned disadvantages of anodization can be avoided.

In this paper, the newly developed plasma oxidation equipment using a microwave discharge is first described (9) along with an investigation of oxygen plasma characteristics. Second, plasma oxidation kinetics are dis-

*Electrochemical Society Active Member.

cussed based on the oxidation mechanisms proposed by Deal and Grove, Tiller, and Cabrera and Mott. The physical properties of the oxide film, such as infrared absorption and etch rate, are also described.

Plasma Oxidation Equipment and Experiments

Several kinds of plasma anodization and/or oxidation equipment have been reported, utilizing dc [Chesler *et al.* (10) and Gourrier *et al.* (11)], RF [Ho, *et al.* (2, 3)] and microwave [Ligenza (1), Kraitchman (12), and Bárdoš *et al.* (13)] discharge plasmas.

The plasma oxidation equipment used in this study is similar to the plasma stream transport system initially proposed by Tsuchimoto (14) for Si_3N_4 film deposition and later developed by Suzuki *et al.* (15) for plasma etching. A schematic diagram of the equipment is shown in Fig. 1.

A 2.45 GHz microwave generated by a magnetron is guided through the waveguide to the quartz discharge tube filled with oxygen gas (99.99%). The vacuum chamber can be evacuated to 6×10^{-6} Pa using a turbomolecular pump.

The diameter of the discharge tube is 100 mm. The oxygen gas is supplied directly from an oxygen cylinder to the discharge tube, and the oxygen pressure in the chamber is controlled by a leak valve. No special purifying system such as a liquid nitrogen trap is provided. The discharge tube is surrounded by three magnetic coils, and the magnetic field is set to meet the electron cyclotron resonance (ECR) condition.

When the electrons rotating spirally absorb the microwave under the ECR condition, a high density oxygen plasma is easily obtained even at a low oxygen pressure ($< 1 \times 10^{-2}$ Pa). This is the characteristic phenomenon of a microwave discharge with a magnetic field which no other discharge system can achieve.

The plasma is then transported to the specimen confined by the magnetic field, as shown in Fig. 2. The silicon substrate to be oxidized is placed on the quartz holder with two halogen lamps to heat it. The oxygen plasma irradiates the specimen at almost normal incidence. The characteristics of this oxidation equipment are summarized as follows.

1. A high density oxygen plasma is easily obtained by ECR discharge.

Fig. 1. Schematic diagram of microwave plasma oxidation equipment and distribution of magnetic flux density, B .

Fig. 2. Side view of oxygen plasma. The plasma is confined by a magnetic field and transported to the specimen.

2. An oxygen plasma with little contamination is obtained, because the plasma is kept away from the chamber wall and sputtering is avoided.

3. Independent temperature control of the specimen is accomplished by separating plasma generation from the specimen.

The physical properties of the oxide film grown using this equipment were investigated. Fourier transform infrared (FTIR) is applied to investigate the IR absorption peak of the oxide. Etch rate measurement using the P etch solution ($\text{HF}:\text{HNO}_3:\text{H}_2\text{O} = 1.5:1:30$) is carried out to evaluate the densification of the oxide film.

Emission Spectrum from Oxygen Plasma

It is well known that plasma characteristics are influenced by factors such as gas pressure and flow rate. The emission spectrum and electron temperature, therefore, were measured to obtain the optimum oxidation condition. The optical emission spectrum from the microwave discharge oxygen plasma is shown in Fig. 3. The ox-

Fig. 3. Emission spectrum from microwave discharge oxygen plasma. The oxygen pressure is 2.7×10^{-2} Pa. The microwave power is 140W. Spectra from oxygen atoms (OI) and molecular oxygen ions (O_2^+) are observed.

xygen pressure is 2.7×10^{-2} Pa, and the microwave power is 140W.

Very sharp spectra from oxygen atoms at 394.7, 436.8, 532.9, and 615.8 nm and somewhat broader spectra from molecular oxygen ions at 525.1, 559.7, 597.3, and 635.1 nm are clearly observed in this figure. These peaks show that highly excited species such as O and O_2^+ exist in the plasma. Dzioba *et al.* (16) have already reported the emission spectra from a microwave (without ECR) oxygen plasma, where the oxygen pressure was 13 Pa. They observed emission not only from O and O_2^+ , but also from O^+ . However, the emissions from O_2^+ were weak compared with the present results. In addition, they observed a peak from Na^+ , which was not observed in this experiment.

Figure 4 shows the oxygen pressure dependence of the relative peak height of O (436.8 nm) and O_2^+ (525.1 nm). The peak height reaches a maximum near 5×10^{-2} Pa. Additionally, in the pressure region below 5×10^{-2} Pa, the O_2^+ peak is higher, while above this pressure, the peak heights are reversed. Taking the dissociation energy (5 eV) and the ionization energy (13 eV) (17) of the oxygen molecule into consideration, it is likely that dissociation rather than ionization occurs in the high pressure region, since the electron energy is low due to frequent collision. However, in the low pressure region, the electron energy is high enough to preferentially give rise to ionization.

Since peak height is related to the concentration of excited species in the plasma, an oxygen pressure of 2.7×10^{-2} Pa, which gives a nearly maximum peak height, was selected for the oxidation experiment.

In order to investigate the electron temperature of the plasma, a probe current measurement was conducted. Figure 5 shows the probe current and applied bias. From the semilog plot of the probe current and positively applied bias, an electron temperature of 5-7 eV was obtained (18). In addition, from the negative bias at which the net current of the probe became zero, the potential of the specimen held electrically floating in the plasma can be evaluated as -15V. The floating potential of the microwave plasma is small compared with that of the conventional dc or parallel-plate-type RF discharge plasma, since the bias is not directly applied to the specimen. This small floating potential in the microwave plasma is one of the advantages useful in the prevention of irradiation damage.

Results and Discussion

Plasma oxidation kinetics.—In order to discuss the plasma oxidation kinetics based on the proposed oxidation model, the time and temperature dependences of oxide growth were investigated. The thickness of the SiO_2 film was measured by an ellipsometer, assuming a re-

Fig. 4. Oxygen pressure dependence of emission intensity from OI (436.8 nm) and O_2^+ (525.1 nm).

Fig. 5. Current of the probe immersed in the microwave discharge argon plasma. The electron temperature of the plasma is about 6 eV. The floating potential is -15V, which is small compared with that of the conventional dc or parallel-plate-type RF discharge equipment.

fractive index of 1.47. Also, since the thickness varied about 10% from one point to another owing to the plasma distribution, the average of measurements taken at nine points near the center of the specimen was used.

Figure 6 shows the relation between thickness and oxidation time as a function of temperature. The result from thermal dry oxidation (700°C at 1 atm) is shown as a dashed line for comparison. Since an oxide thickness 30 times as large is obtained by plasma oxidation even at 640°C, it is obvious that the oxygen plasma enhances the oxidation considerably.

Fuller *et al.* (19) demonstrated that oxide thickness (x) and oxidation time (t) can be expressed by the power law relation, *i.e.*

$$x^n = kt \quad [1]$$

where n and k are constant. Deal and Grove (20) reported that the constant n varied from 1 to 2 according to a change of the mechanism from the linear rate region in a thin oxide to the parabolic rate region in a thick oxide.

The results in Fig. 6 are replotted according to the power law relationship in Fig. 7. It is obvious that the values of n obtained from the slope of the curves exceed 2, in contrast to Deal and Grove's results.

In the thermal oxidation mechanism of Deal and Grove (DG model) (20), the relation between oxide thickness and

Fig. 6. Oxide growth as a function of oxidation time. The dashed line shows thermal oxidation at 700°C and 1 atm.

Fig. 7. Plot of oxide thickness (x) and oxidation time (t) using a power law relation. Every n obtained from the slope of the lines exceeds 2.

oxidation time is expressed by the linear-parabolic equation

$$X^2/B + X/(B/A) = t + \tau \quad [2]$$

where B/A , B , and τ are constants which include the reaction rate constant at the Si/SiO₂ interface, diffusion of oxygen through SiO₂, and the time representing oxide thickness present at the beginning of oxide growth, respectively. All the constants can be obtained by fitting the data in Fig. 6 to Eq. [2] by the least squares method. The results are shown in Table I. Every $1/(B/A)$, which contains the reaction rate constant at the Si/SiO₂ interface, becomes negative.

According to a modified DG model proposed by Tiller (21), it is shown that B/A can become negative if migration of oxygen ions is considered. The results shown in Table I indicate that the plasma oxidation mechanism may be explained by a model in which oxygen ion migration is assumed. In Tiller's model, a linear-parabolic oxidation rate equation similar to the DG model is essentially obtained, although the effect of field-aided ion migration enters B/A , B , and τ . The reason why every n in Eq. [1] exceeds 2 in the present experiment is thus not explained by Tiller's model.

However, Fehlner (22) reported that the Cabrera-Mott model (23) (CM model) is valid for explaining the oxidation under low temperature or low pressure conditions. Kamigaki *et al.* (24) and Horiuchi *et al.* (25) reported that the CM model rather than the DG model was adequate for explaining the kinetics of thermal oxidation under low partial pressures, in which diluted oxygen is used to grow very thin oxide films of less than 10 nm for MNOS non-volatile memory devices. Furthermore, Yamasaki *et al.*

640°C	-62.63	-4.86	0.122

Deal-Grove model $t + \tau = \frac{1}{B} X^2 + \frac{1}{B/A} X$

(26) proved that the plasma anodization of GaAs was also well explained by the CM model.

In the model, it is assumed that the electric field originating in the contact potential difference between the metal and the adsorbed oxygen ions decreases the activation energy for ion movement, resulting in the rate equation

$$dx/dt = 2U \sinh (X1/x) \quad [3]$$

where $X1$ and U are a characteristic distance and velocity, respectively. $X1$ is linearly proportional to the contact potential difference, and U contains the activation energy. Moreover, Fehlner *et al.* (27) concluded that the same equation could be applied to both cation and anion movement.

When $X1 \gg x$, Eq. [4], which produces the parabolic rate law, can be derived as

$$dx/dt = 2U(X1/x) \quad [4]$$

However, when $X1 \ll x$, Eq. [5], which was discussed above in connection with previous reports, can be derived as

$$dx/dt = U \exp (X1/x) \quad [5]$$

In the present experiment, it is reasonable to directly use Eq. [3] rather than Eq. [5], since the oxide thickness is much larger than the results obtained from Kamigaki *et al.* (24) and Horiuchi *et al.* (25).

The oxidation rate, *i.e.*, dx/dt at an arbitrary oxide thickness, can be estimated by differentiating Eq. [1] ($dx/dt = k/\eta x^{n-1}$) using the n and k obtained in Fig. 7. U and $X1$ from Eq. [3] are determined using this dx/dt , applying the repetition method. The results of the analysis are indicated in Fig. 8, which includes values determined for U and $X1$. The measured oxidation rate (closed circles) coincides well with the calculated curve.

It is found that the present plasma oxidation results can be readily explained by the CM model. However, characteristic distances, $X1$, obtained here (20-40 nm) are much larger than those found in previous results (< 10 nm) (24, 25). These details will be discussed later.

The characteristic velocity, U , in Eq. [3] is closely related to the activated process such as diffusion or solution of substrate atoms in the oxide. The Arrhenius plot of U

Fig. 8. Plot of reciprocal oxide thickness ($1/x$) vs. oxidation rate (dx/dt) using the Cabrera-Mott equation. Solid lines are calculated curves. The characteristic distance ($X1$) and characteristic velocity (U) are obtained simultaneously by fitting the experimental data to the Cabrera-Matt equation.

is shown in Fig. 9. Although it is peculiar that the data obtained at 560°C are larger than those of 640°C, a very small activation energy (0.40 eV) is obtained. This activation energy is much smaller than the previous results for 1-2 eV (24, 25). In addition, this activation energy is also smaller than the value obtained in thermal oxidation (20).

The kinetics of plasma oxidation can be more readily explained by the CM model and partially by Tiller's modified DG model than by the DG model. It is also found that plasma oxidation is quite similar to low pressure oxidation. Distinguishing differences have appeared, however, between plasma and low pressure oxidation with respect to activation energy and characteristic distance, X_1 .

Since X_1 in the CM model is proportional to the potential across the oxide, the reason it becomes larger in the present experiment as compared with the low pressure oxidation can be considered as follows. The specimen to be oxidized is held electrically isolated in the plasma. Therefore, more mobile electrons can arrive at the specimen surface faster than ions, resulting in a floating potential around the specimen. The electrons on the specimen surface also apply a negative bias across the oxide film. Since this negative bias is considered to be larger than the contact potential assumed in the CM model, it is almost certain that the characteristic distance, X_1 , in plasma oxidation becomes larger.

The second question is the very small activation energy obtained in this experiment. Kamigaki *et al.* (24) obtained 2 eV, which coincided with the bond breaking energy of Si during low pressure oxidation. Additionally, the activation energies obtained by Deal and Grove (20) in the diffusion dominant region were 1.24 eV in a dry atmosphere and 0.71 eV in a wet atmosphere. They concluded that these activation energies were equivalent to the diffusion of O_2 and H_2O in quartz. However, the activation energy (0.40 eV) obtained here is quite small.

The CM model assumes the diffusion of substrate atoms toward the oxide surface in contrast to the oxygen diffusion of the DG model. In order to investigate the diffusing species of this plasma oxidation, oxidation in a tracer ambient and depth profile analysis using SIMS were carried out.

Briefly, the specimen was first oxidized in a $^{16}O_2$ atmosphere at 640°C for 25 min. This oxidation condition grew a 25 nm thick oxide layer, as shown in Fig. 6. Next, the same specimen was reoxidized in a 20% $^{18}O_2$ atmosphere

Fig. 9. Arrhenius plot of characteristic velocity (U). The activation energy of plasma oxidation is 0.4 eV.

at the same temperature over 2.5h. The total thickness was therefore 50 nm. Following this oxidation, a depth profile analysis of ^{18}O and ^{16}O was conducted using SIMS with Cs^+ as the primary ion. The results are shown in Fig. 10. The closed circles represent the intensities from ^{18}O and ^{16}O , and the open circles represent the ratio $^{18}O/^{16}O$. In the ratio curve, it is found that ^{18}O exists throughout the oxide film. These results clearly indicate that oxygen diffuses during plasma oxidation, in contrast to the results obtained from plasma anodization of Si (3) and GaAs (26), in which diffusion of substrate atoms is also observed. In addition, the ratio in the bulk of the oxide is equivalent to the tracer content in the atmosphere. Rochet *et al.* (28) report that most of the tracer appears at the Si/SiO₂ interface in the case of thermal oxidation. The existence of the tracer in the bulk of the oxide in Fig. 10 may imply that oxygen exchange takes place during plasma oxidation, similar to oxidation of Si in wet ambient (29) and plasma anodization of silicon through thin ZrO₂ films (30, 31). Studies are in progress to examine such oxygen exchange phenomena during plasma oxidation.

From these results, we can discuss the plasma oxidation mechanism as follows.

As suggested by Hu (32), the diffusing species are considered to be oxygen ions (O^-). The O^- ion is produced in the plasma by dissociation of oxygen molecules followed by electron attachment. Formation on the oxide surface is also possible, since the specimen is covered with electrons from the plasma.

The diffusion process should involve ion drift, since there is a built-in potential across the oxide. This originates in the potential which exists around the specimen held electrically floating in the plasma. Also, since this built-in potential is considered to be larger than the contact potential assumed in the CM model, it is likely that a large X_1 (characteristic distance) can be experimentally obtained.

Moreover, since the O^- ion is smaller than the oxygen molecule in size, the activation energy is expected to be smaller in plasma oxidation. Ray *et al.* (4) also reported a considerably smaller activation energy (0.16 eV) in their RF discharge plasma oxidation. However, the details are subject to further investigation.

Fig. 10. Depth profiles of ^{16}O and ^{18}O in plasma grown SiO₂. The specimen was first oxidized in $^{16}O_2$ atmosphere and then reoxidized in a 20% $^{18}O_2$ atmosphere. Open circles show the ratio of ^{18}O to ^{16}O .

Physical properties of plasma oxidized SiO₂ films.—Infrared absorption properties.—As there have been several reports concerned with the IR absorption properties of SiO₂ films grown by various methods, it has become well known that absorption peaks vary to a large extent with physical properties such as the density of strains in the film.

Figure 11 shows the IR absorption peaks of microwave-plasma-oxidized SiO₂ films as a function of oxidation temperature. The result from a thermally dry-oxidized films (curve a) is also given for comparison.

The absorption peaks of SiO₂ grown above 500°C (curves b and c) are very similar to that observed in thermally oxidized SiO₂. In addition, the absorption peak coincides well with previous results. On the other hand, the peaks of SiO₂ films grown below 500°C (curves d and e) are shifted slightly (15 cm⁻¹) toward greater wavelengths.

Dylewski *et al.* (33) investigated the properties of SiO₂ films formed by oxygen ion implantation using IR absorption techniques. They reported that the absorption peaks of heavily implanted films shifted toward greater wavelengths. It was concluded that this shift can be attributed to strain in the Si and O bonds. Pliskin (34) observed the same peak shift of SiO₂ films made by a sputtering technique.

These results indicate that SiO₂ films made by a low temperature method, when compared with thermally oxidized films, can differ in structural or physical properties due to large strains in the film. However, since even thermally oxidized SiO₂ films show a peak shift when they are very thin, it is difficult to judge whether the shift IR

Fig. 11. Relation between infrared absorption peak and plasma oxidation temperature. Curve a is SiO₂ thermally oxidized at 1000°C, which shows the absorption peak at 1076 cm⁻¹.

absorption peaks in the plasma oxidized SiO₂ film below 500°C is attributable to strain.

Etch-rate measurement.—The etch rate using P etch solution (35) has been occasionally used as a parameter to indicate the degree of densification of SiO₂ films. Figure 12 plots the relation between etch rate of the present films and oxidation temperature. The dashed line indicates the etch rate of thermally oxidized SiO₂ at 1000°C for comparison.

Although no peak shift is observed in the plasma-oxidized SiO₂ grown above 500°C, the etch rate is slightly larger than that of the thermally oxidized film. In addition, the lower the plasma oxidation temperature, the larger the etch rate.

Conclusion

Microwave plasma oxidation equipment using electron cyclotron resonance has been developed. An oxygen plasma is ignited under ECR conditions, and optical emissions from oxygen atoms and oxygen molecular ions are observed. The intensities of both emissions depend on the oxygen partial pressure. Below 5×10^{-2} Pa, the emission from the oxygen molecular ion is stronger. However, the emission from the oxygen atom becomes stronger above this pressure.

It is found that plasma oxidation kinetics can be explained using the Cabrera-Mott model rather than the Deal-Grove model. However, there are two differences in the present results compared with previous reports in which the CM model was applied to explain the oxidation kinetics of the low pressure thermal oxidation of Si. One difference is a large characteristic distance (X_1). Since X_1 is proportional to the potential across the oxide film, the floating potential is taken to be the cause of the large X_1 . The other difference is a small activation energy, which may imply that the diffusing species is small in size. Moreover, the depth profile analysis of the oxygen isotope clarifies that the diffusing species is oxygen, similar to the case of thermal oxidation.

From these results, the diffusing species is concluded to be the O⁻ ion produced in the plasma or on the substrate surface. In addition, the O⁻ diffusion is enhanced by the potential across the oxide, which originated in the floating potential existing around the specimen held electrically floating in the plasma.

The physical properties of plasma-oxidized SiO₂ are comparable to those of thermally oxidized SiO₂ with respect to IR absorption. However, the etch rate is a little faster than that of the thermally oxidized SiO₂.

Acknowledgments

The authors express their gratitude to Dr. M. Horiuchi and Dr. M. Naito for useful discussions. They also thank Dr. E. Mitani for his cooperation in the SIMS analysis.

Planar Deposition of Aluminum by RF/DC Sputtering with RF Bias

Yoshio Homma and Sukeyoshi Tsunekawa

Hitachi, Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

Planarization of multilevel interconnection is most effective for achieving a higher packing density. However, it is shown by computer simulation that degradation of metallization step coverage becomes serious as the via aspect ratio increases. Conventional deposition methods, in which emitted particles flow onto the substrate and usually do not migrate, are shown to be inadequate for maintaining sufficient step coverage. A new deposition technique, RF/dc sputtering with RF bias for metal, is developed and found to provide sufficient step coverage and, moreover, planarity. In an application of the technique to aluminum film deposition, the existence of a resputtering effect was confirmed. Aluminum particles were found to deposit primarily near the bottom of the depressions and to fill up the depressions completely, through sputtering at a high bias. Steep, deep grooves and vias with aspect ratios up to 3 were found to be completely filled with the aluminum film by deposition at resputtering rates higher than 50%. It was also found that substrate biasing has a decisive effect on giving aluminum films an almost complete (111) crystallographic texture.

Highly packed, multilevel interconnection has become one of the most fundamental and indispensable technologies for improving VLSI packing density. Planarization of interlevel insulation layers has been most effective for achieving finer patterns of overlapping metallization layers. For use in interlevel insulation planarization, etchback planarization (1), polyimide insulation (2), and bias sputtering (3, 4) have been developed. Planar SiO₂ films, e.g., those obtained by a planar magnetron bias sputtering technique, have been applied to a two level interconnection for a 1 Mbit dynamic random access memory, and have proved effective in improving the packing density (5).

However, the insulation layer has to be somewhat thicker than in ordinary structures in order to planarize the insulation layer on the very jagged substrate surface produced by fabrication of devices and underlying metallization. This leads to higher aspect ratio vias, through which the upper layer metallization has to be connected with the under layer. This may limit the packing density of interlevel connection in future VLSI's, due to severe degradation of step coverage of the upper layer metallization around the vias.

This paper first discusses step coverage degradation of the metallization layer around such vias. Then a newly developed aluminum film deposition technique is introduced (6). It is shown that this technique can improve aluminum step coverage drastically, and, furthermore, fill up and planarize the fine vias for multilevel interconnection. These effects are obtained by film deposition using RF/dc sputtering with RF bias. The effects of substrate biasing on film quality are also described.

Experimental

Step coverage evaluation.—Coverage of metallization layers around jagged steps on LSI surfaces has been an important measure of reliability. Much research has been reported on improving the metallization step coverage (7, 8). However, it seems that the concept of step coverage has been treated ambiguously.

The step coverage dependence on metal deposition conditions and underlying groove profiles is investigated systematically utilizing a computer simulation which follows Blech's model (9, 10). In the model, particles are assumed to impinge onto the substrate surface isotropically within designated maximum incident angles, $\pm\omega_{\max}$, cor-

responding to the geometrical structure of the deposition systems. The sticking coefficient of the deposited particles is assumed to be 1, and no surface migration effect is taken into account. The step coverage factor was defined as the ratio of the minimum film thickness around the grooves to the nominal film thickness (equal to the groove depth), since the factor changes according to deposited film thickness as well as groove aspect ratio and ω_{\max} .

Aluminum bias sputtering.—A high rate bias sputtering technique, employing both a planar magnetron cathode instead of a conventional cathode and RF substrate biasing during deposition, was developed to deposit planar SiO_2 films at a higher deposition rate (4). This technique was introduced for metal deposition.

The bias sputtering system is shown schematically in Fig. 1. Either dc or RF power can be applied to the cathode, while the application of RF power to the water-cooled substrate electrode causes the resputtering effect necessary to achieve planarization (3). The magnetron cathode was chosen to achieve a high deposition rate of aluminum at low substrate temperatures. The cathode was 122 mm, and the distance between the cathode and the substrate electrode was normally 35 mm. The background pressure of the system was 0.13 mPa.

First, the influence of substrate biasing on the film deposition rate was examined to determine the resputtering effect. Second, the influence of biasing on film quality was investigated by SIMS and x-ray diffractometry. Finally, the effects of substrate biasing on the film step coverage were shown.

Results and Discussion

Step coverage degradation around fine vias.—Customarily, it has been thought that step coverage is mainly determined by film deposition conditions such as maximum incident angles. It is believed that methods for wider deposition incident angles, such as sputtering, provide better step coverage than those with narrow maximum incident angles, such as vacuum evaporation (8, 11). The effects of underlying surface topography have not really been taken into account.

However, these conventional ways of evaluating and improving step coverage were found to be inadequate for future VLSI metallization. For example, the step coverage factor of the second-level metallization layer has been evaluated using isolated steps, as shown in Fig. 2a. The underlying projected line was produced by depositing CVD PSG (phosphosilicate glass by chemical vapor deposition) film on a dry-etched first level metallization. The second-level metallization layer was deposited by a conventional magnetron sputtering system. Around such isolated steps, conventional sputtering technique can achieve good step coverage. On the other hand, Fig. 2b shows an example where the step coverage of the second-

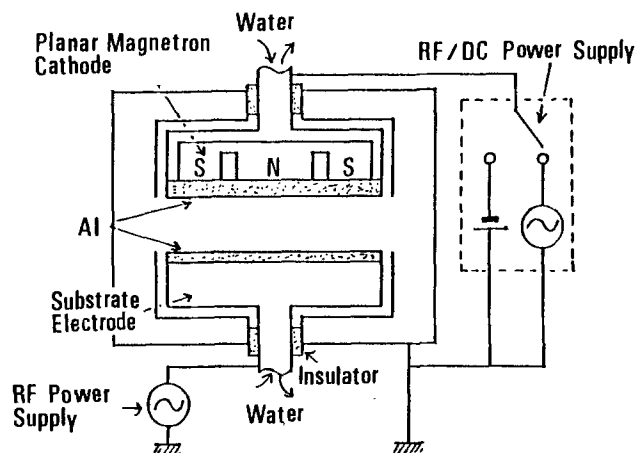

Fig. 1. Aluminum bias sputtering apparatus

Fig. 2. Influence of underlying step density on second-level metallization step coverage. a: Step coverage around an isolated step. b: Step coverage around dense steps.

level metallization shows extreme degradation around narrow and deep depressions, though the metal deposition conditions are the same as those in Fig. 2a.

The influence of the aspect ratio of vertical grooves on step coverage was investigated by computer simulation. The model is two dimensional and is insufficient for discussing step coverage problems around "three-dimensional" vias. However, the simulation is effective enough for showing qualitatively the seriousness of the problems. The step coverage factor was measured from the calculated figures, as shown in Fig. 3. As shown in Fig. 3, the particles are assumed to flow onto the substrate isotropically through a sliced hemisphere surface within the angular range $\pm\omega_{\max}$. Figures 3b and 3c show examples for a sloped and a vertical groove, respectively. These results are shown together in Fig. 4. The groove aspect ratio was changed from 0.33 to 2.0, i.e., the groove width was changed from three times to one-half of the depth. This figure shows two things. First, the step coverage factor shows extreme degradation as the aspect ratio increases. Second, film deposition under wider ω_{\max} does not necessarily provide better step coverage, especially around grooves of larger aspect ratio. Almost the same results have been reported for steep grooves (slope angle $\theta = 80^\circ$) with dc magnetron sputtering (12).

Next, the effects of maximum incident angles, ω_{\max} , on film step coverages are shown in Fig. 5. The slope angle, θ , of groove side walls is used as a parameter. It can be seen from Fig. 5 that the change of step coverage factor is roughly divided into three parts. The step coverage factor is constant, irrespective of ω_{\max} , and is dependent only on the θ , in region A. In region B, where ω_{\max} exceeds $(90 - \theta)^\circ$, the step coverage factor increases and reaches a maximum. Then, in region C, the step coverage factor decreases as ω_{\max} increases.

As the slope angle, θ , increases, region A becomes narrower, and disappears when θ reaches 90° . Region A corresponds to where there is no shadowing effect. In region B, the effect of step coverage improvement due to ω_{\max} increment is larger than the degradation due to the shadowing effect. In region C, the coverage degradation due to

Fig. 3. Examples of calculated figure following Blech's model. a: Definition of the particle incident angle ω_{max} . the self-shadowing effect becomes the major effect. The situation for actual vias would become much more severe, since the results are for two-dimensional grooves and the influence of the self-shadowing effect increases more around three-dimensional vias.

It can be concluded from these results that conventional deposition methods, in which particles simply flow on to and stick on the substrate, cannot achieve adequate step coverage around fine vias for future VLSI metallization. Thus, new deposition methods, such as

Fig. 4. Influence of groove aspect ratio on film step coverage

Fig. 5. Influence of groove profile on film step coverage. The aspect ratio of the grooves is 1.

those using surface migration or surface reaction effect, appear to be necessary.

Resputtering effect in aluminum bias sputtering.—Bias sputtering for metals has been mainly used for improving film quality (13). The existence of the planarization effect in metal bias sputtering due to resputtering effect had not been documented (11). We first tried to confirm the existence of the resputtering effect by utilizing the planar magnetron bias sputtering system (6). It was recently reported that the aluminum film step coverage was improved by using an MRC 603 bias sputtering system (14). However, the improvements were slight and it could be argued that the effects were due to surface reflow or a

migration effect caused mainly by an increase in substrate temperature. Such an interpretation is possible because the resputtering effect was not confirmed in the work, and substrate heating as reported in the work could improve surface migration effect and step coverage.

The influence of substrate biasing on the aluminum deposition rate is shown in Fig. 6. Though a strict measurement of the resputtering rate is difficult, it can be defined practically as follows

$$\text{Resputtering rate} = \frac{D_N - D_B}{D_N}$$

where D_N and D_B are deposition rates without and with substrate biasing, respectively, under the same cathode RF power (15).

The figure shows that the aluminum deposition rate decreases when RF power is applied to the substrate electrode. This reduction of the deposition rates corresponds to the resputtering rates from 50 to 70% as the cathode RF power is varied, while the substrate RF power is kept constant. It is reasonable that such an extreme reduction in deposition rate was caused by the resputtering effect rather than the substrate temperature increase due to biasing. The resputtering rates when aluminum films were deposited under Ar pressure of 0.13 Pa were larger than those under 6.7 Pa. Similar effects were observed when the films were deposited with dc power to the cathode and RF power to the substrate electrode.

Effects of deposition conditions on film quality.—The effects of substrate biasing on film crystalline structure were investigated utilizing x-ray diffractometry. It was previously reported that substrate biasing gives aluminum films a (111) texture (16). However, in that report, the influence of substrate temperature increase due to substrate biasing on crystalline structure was overlooked. Therefore, it was not determined whether the texture was the result of the resputtering effect or the substrate temperature increase due to biasing during deposition.

Four kinds of test samples were prepared, as shown in Table I, to clarify this point. Samples a and b were made through normal dc sputtering without substrate biasing, and, in both samples, films were deposited under almost identical sputter conditions with the exception of sub-

Fig. 6. Effects of substrate biasing on aluminum deposition rate

strate temperature. A comparison of these two samples shows the influence of substrate temperature during deposition on the film crystalline structure. Samples b and c were made under nearly the same deposition rate and substrate temperature conditions but without and with RF substrate biasing, respectively. Thus, a comparison of these two samples shows the influence of substrate biasing on film crystalline structures. Sample d was made with a higher resputtering rate to show the effect of an increment in resputtering rate.

Measurements made with conventional x-ray diffractometry are shown in Fig. 7, and a standard ASTM diffraction pattern is also shown for comparison. The other four figures represent the results for each sample. Sample a, deposited normally at low deposition temperature, shows no special preferred orientations. On the other hand, sample b, deposited normally at a higher temperature, shows a strong (111) texture, although some amount of other orientation textures still remain. Higher deposition temperatures strongly influence aluminum film toward a (111) texture.

However, samples c and d, deposited through bias sputtering, show almost complete (111) texture. Furthermore, although the deposition temperature for sample d was lower than for sample c, there was little difference be-

Fig. 7. Influence of aluminum deposition conditions on film crystalline structure. Cu K_{α} x-rays were used.

Table I. Aluminum deposition conditions in crystalline structure evaluation

Sample no.	Ar pressure (Pa)	Cathode dc power (W/cm ²)	Substrate RF power (W/cm ²)	Resputtering rate (%)	Deposition rate (nm/min)	Substrate temperature (°C)
a	0.67	1.74	0	0	176	23
b	0.67	1.73	0	0	175	173
c	0.67	1.88	0.6	17	158	~150
d	0.67	0.82	0.6	38	50	~100

tween results for these two samples. From these results, it can be concluded that substrate biasing has a decisive influence in giving aluminum film structures an almost complete (111) texture, and that this phenomenon is caused by the resputtering effect rather than substrate temperature increase during deposition. The influence of substrate biasing on impurity concentration in the film was also investigated by SIMS, but no significant difference could be observed.

Planarization effect in bias-sputtered aluminum film.—The influence of substrate biasing on aluminum step coverage was evaluated by depositing the films on vertically dry-etched SiO₂ grooves, as shown in Fig. 8. The films were deposited at temperatures lower than 250°C. Both the width and the depth of the grooves are 1.5 μm. The aluminum was deposited on these substrates, and the cross sections were observed by etching the front sides of the aluminum films.

Fig. 8. Cross-sectional comparison of aluminum films deposited on vertical grooves. a: Resputtering rate of 0%. b: Resputtering rate of 40%. c: Resputtering rate of 50%. d: Resputtering rate of 70%. The aspect ratio of the grooves is about 1.

Fig. 9. Change of bias-sputtered aluminum film as a function of deposition time. a: 3 min. b: 6 min. c: 9 min. d: 18 min. The resputtering rate is about 50%.

A cross section of the normally sputtered aluminum film on the vertical grooves is shown in Fig. 8a. The step coverage factor of the film is estimated to be less than 0.2, due to the self-shadowing effect, as shown in the figure. However, the cross sections of aluminum films deposited with substrate biasing show an extreme change. As shown in Fig. 8b, the film deposited at about 40% resputtering rate connects the aluminum film surfaces on top of the grooves to each other, but small crevices can be seen in the middle of the grooves. As the resputtering rate exceeds 50%, the grooves fill up completely with aluminum, and the degree of film surface planarization improves with the rate increase, as shown in Fig. 8c and 8d. The film surface, deposited at about a 70% resputtering rate, was planarized almost completely. In the cases shown in c and d, the conventional term "step coverage" has no meaning. "Filling factor" or "surface planarity" may be more suitable.

The change in film cross section around the grooves as a function of deposition time is shown in Fig. 9. These SEM micrographs illustrate how the bias-sputtered aluminum films fill up the vertical grooves of aspect ratio 1. The resputtering rate in this experiment was about 50%. As can be seen from these micrographs, the bias-sputtered aluminum particles deposit first primarily near the bottoms of the vertical sidewalls. As the film grows, the grooves become shallower and are finally filled up completely. This suggests that some portion of the aluminum particles deposited around the upper edges of the grooves is etched by Ar ions and is deposited inside of the grooves again. Thus, the particles fill up the grooves without the influence of the shadowing effect.

Via filling up with bias-sputtered aluminum.—The aluminum bias sputtering technique was applied to fill up small, high aspect ratio vias. Figure 10a shows an SEM micrograph of $2.5 \mu\text{m}$ deep, $2 \times 2 \mu\text{m}^2$ vias formed in a bias-sputtered SiO_2 film. The aspect ratio of the vias is about 1.2. The SEM micrograph in which the aluminum film was deposited normally is shown in Fig. 10b. In the figure, a significant shadowing effect can be observed which results in poor step coverage. In contrast, by depositing aluminum film at about a 50% resputtering rate, the vias were filled up completely, and only very gently sloped, shallow depressions remained on the film surface, as shown in Fig. 10c.

Cross sections of these test samples were observed utilizing cross-sectional polishing, as shown in Fig. 11. Via sizes in the SEM micrographs are 2×2 , 1.5×1.5 , and $0.8 \times 0.8 \mu\text{m}^2$, respectively. From these micrographs, it

Fig. 10. Via filling with bias-sputtered aluminum film. a: Vias produced through dry etching in bias-sputtered SiO_2 . b: Normally sputtered aluminum surface. c: Surface of bias-sputtered aluminum deposited at about 50% resputtering rate.

can be seen that even a $0.8 \times 0.8 \mu\text{m}^2$ via, whose aspect ratio is about 3, can be completely filled up with aluminum by bias sputtering. It can be seen from these results that bias sputtering for metals should become a very effective technique for near-future VLSI interconnection.

Summary

A new metal deposition technique, i.e., RF/dc sputtering with RF bias for metal, was developed to solve the step coverage problem in VLSI multilevel interconnection. An application of the technique to aluminum film deposition confirmed the existence of the resputtering effect. Through sputtering at a high bias, aluminum

Fig. 11. Cross section of vias filled up with bias-sputtered aluminum. a: Via of aspect ratio 1.2. b: Via of aspect ratio 1.8. c: Via of aspect ratio 3.

particles were found to be deposited primarily near the bottom of the depressions and to fill up the depressions completely. By deposition at resputtering rates higher than 50%, the aluminum film was found to fill up steep, deep grooves and vias, even when the aspect ratio was as high as 3. It was shown that substrate biasing has a decisive effect on giving aluminum films an almost complete (111) crystallographic texture. It was also confirmed that these effects were obtained by the resputtering effect itself rather than by the substrate temperature increase associated with substrate biasing.

Evaluation of the Phosphorus Concentration and Its Effect on Viscous Flow and Reflow in Phosphosilicate Glass

R. A. Levy,* S. M. Vincent, and T. E. McGahan

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

This study describes the use of x-ray fluorescence as an analytical tool for determining phosphorus concentration in phosphosilicate glass. By comparison with other available methods, we shall demonstrate that this direct measurement technique is accurate, simple, fast, reproducible, and nondestructive. With the use of this technique, flow and reflow profiles of phosphosilicate glass will be illustrated at different phosphorus concentrations and representative thermal cycles.

Low pressure chemical vapor deposited phosphosilicate glass (PSG) serves a variety of important functions in the fabrication of semiconductor devices (1). It is widely used as a dielectric to insulate gate interconnects from metallization, as a getter of sodium and other rapidly diffusing metal ions, as a material that undergoes viscous flow to provide a planar topography, as a passivation overcoat to provide mechanical protection, and as a solid diffusion source of phosphorus in silicon. Since the properties of the PSG, which make it useful in a given application, are directly related to the phosphorus concentration, a technique which can offer an accurate, nondestructive, fast determination of the composition becomes very desirable in an IC processing line. Many techniques have been used to measure phosphorus concentration in phosphosilicate glass. These include wet chemical analysis (2, 3), neutron activation (4, 5), Auger electron spectroscopy (6), electron microprobe (7), energy dispersive x-ray spectrometry (8, 9), x-ray fluorescence (10-12), infrared absorption (13), refractive index determination (5), etch rate variation (2, 4, 14, 15), and diffusion techniques (4, 16). Although tedious and time consuming, wet chemical analysis, which is independent of film thickness, phosphorus content, or any variation in phosphorus throughout a wafer, is considered by the industry as the primary standard. Neutron activation, Auger electron spectroscopy, electron microprobe, and energy dispersive x-ray spectrometry all require sophisticated and expensive equipment, skilled engineers, lengthy sample preparation procedures, and destruction of the specimens. Infrared absorption, index of refraction determination, etch-rate variation, and diffusion techniques are relatively simple but lack the required accuracy and reproducibility. In this study, we describe the use of x-ray fluorescence as an analytical tool for determining phosphorus concentration in phosphosilicate glass. We shall demonstrate that this direct bulk measurement technique is simple, fast, accurate, reproducible, and nondestructive. However, as is typical of all other analytical techniques which yield relative results, it requires proper standardization. Based on a compilation of x-ray fluorescence data and results gathered on the identical PSG films with electron microprobe and energy dispersive x-ray (EDS) analysis, a correlation among all three techniques will be established. We shall then proceed to examine the effect of phosphorus concentration on the viscous flow and reflow profiles of PSG at representative thermal cycles.

Electrochemical Society Active Member.

Principles of X-Ray Fluorescence Analysis

In the x-ray fluorescence technique, electrons accelerated within the system generate, by collision with a metal target, x-rays which are directed toward the sample. These primary x-rays activate orbital electrons within the sample that cause emission of secondary x-rays which are analyzed. The principles governing the operation of the electron microprobe are quite similar, with the exceptions that no target is used and that the electrons, in this case, are directly accelerated toward the sample. Since x-rays cannot be focused and are more penetrating than

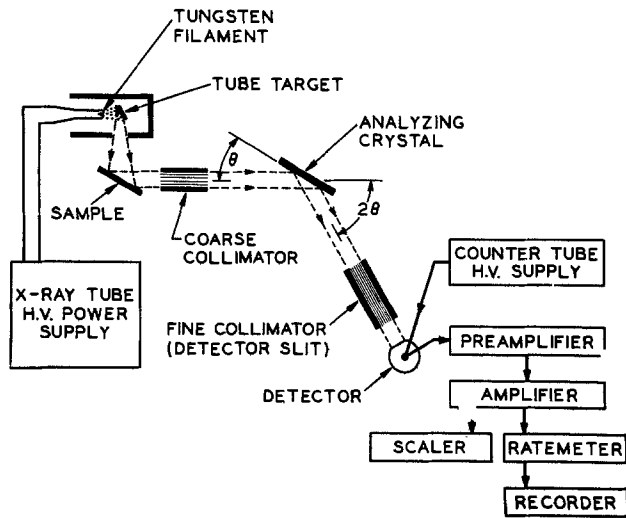

Fig. 1. Schematic representation of the x-ray fluorescence apparatus

electrons, the fluorescence technique represents more of a bulk measurement than the microprobe. That could be an advantage if large local fluctuations in phosphorus concentration exist across the sample.

A schematic representation of the x-ray fluorescence apparatus used throughout this investigation is shown in Fig. 1. The mode of operation includes three basic functions, namely, excitation, detection, and analysis. The excitation system consists of an EA 75 dual target (Cr-W) tube driven by a General Electric XRD-6 power supply operated at 50 kV and 60 mA. The analyzing system utilizes a coarse collimator, a graphite crystal with a 2d spacing of 6.704 Å, and a 250 μm Soller slit. In order for the Bragg equation to be always satisfied for a given x-ray wavelength, the graphite crystal is coupled to the detector and detector slit through a spectrogoniometer which automatically rotates the detector and its associated slit by 2θ while the crystal rotates by θ. The detection system includes an Ar-10%CH₄ flow proportional counter operated at 1480V and assorted electronic modules to amplify the pulses and display the count rate.

For thin films, the observed intensity at a given wavelength is related to film thickness and the concentration

of the corresponding element emitting the radiation, through the equation (17, 18)

$$I = \frac{AP}{B} (1 - e^{-BT}) \quad [1]$$

where I is the emitted radiation in normalized counts, T the film thickness in units of angstroms, P is the concentration of the element emitting the radiation (in this case, phosphorus), and A is a parameter that includes the five separate factors involved in the excitation process, which are, as stated by Jenkins and De Vries (17): (i) the number of primary photons striking the sample surface per unit time; (ii) the attenuation of this intensity by the absorbing matrix; (iii) the efficiency of the actual excitation of characteristic radiation; (iv) the proportion of these photons which are accepted by the collimator; and (v) the attenuation of the characteristic radiation by the sample matrix. B is a parameter that depends on the mass absorption coefficient and density of the sample matrix as well as

x-ray path correction factors. Since both A and B are functions of the density of the sample matrix, the assumption that these parameters will be constant can only be valid over a limited range of phosphorus concentrations.

Measurement Procedure

With a stabilized power supply to the x-ray tube and proportional counter, and with the goniometer set at an angle of 133.33° to satisfy the Bragg equation for phosphorus $K\alpha$ radiation, the measurement procedure is initiated by placing the standard wafer onto an aluminum mask with a $\frac{1}{4} \times \frac{1}{8}$ in. window in the experimental chamber. The x-ray shutter is open and the ambient gas in the chamber flushed out with He to minimize absorption of phosphorus radiation. After an equilibration time of about 30s, the counter is activated and P $K\alpha$ counts are taken, typically, at a fixed 100s interval. This procedure is repeated after removal of the standard and insertion of the test sample. A sequence of up to ten measurements

can be taken before reintroducing the standard wafer for calibration purposes. The elapsed operation time which includes loading, equilibration, and measurement periods has been estimated to amount to less than 3 min/wafer, proving x-ray fluorescence analysis to be one of the fastest available techniques for determination of phosphorus concentration in phosphosilicate glass. Furthermore, the fact that whole wafers can be accommodated in the system with no pre- or postsample preparation qualifies x-ray fluorescence as a nondestructive technique. Possibilities of radiation-induced damage to the device become nonexistent after the subsequent high temperature flow or reflow processing steps. From values of normalized intensity, I , given by the ratio of test wafer count rate to standard wafer count rate, and film thickness, the phosphorus concentration in PSG is determined for known constant values of A and B . These constants were calculated from a systematic investigation of a set of ten PSG samples (to be referred to as "standards") with various phosphorus concentrations and film thicknesses. The PSG films were deposited directly onto p-type (1-10 Ω -cm) silicon wafers in a low pressure CVD (LPCVD) reactor using SiH_4 , O_2 , and PH_3 as source materials. The PH_3 gas flow or deposition time was adjusted in each run to achieve the desirable phosphorus concentration or film thickness, respectively. Half-wafers from this set of standards were forwarded to Balazs Analytical Laboratory¹ for chemical analysis, with the corresponding halves undergoing x-ray fluorescence measurements in adjoining parts of the samples. Table I identifies the samples investigated with their characteristic thickness, phosphorus concentration expressed in at./cm³ and weight percent (w/o) P, and count rate normalized to a selected sample (P37) which was midrange in phosphorus concentration. A computer program with a nonlinear curve fitting routine was then used to calculate the values of A and B from the best fit of the data to Eq. [1]. (A summary of the program logic is described in the Appendix.) The value of A was determined to be equal to

¹ Balazs Analytical Laboratory, Mountain View, California 94043.

Fig. 6. Graphical representation of degree of correlation between energy dispersive spectrometry and x-ray fluorescence.

$4.5874 \times 10^{-26} \text{ cm}^3/\text{at}\cdot\text{\AA}$ and that of B equal to $7.5331 \times 10^{-4} \text{ \AA}^{-1}$. In Table II, a comparison between calculated and measured values of normalized intensities yielded a percent deviation less than $\pm 2.5\%$, confirming the validity of the theoretical model used in the derivation of Eq. [1].

In wet chemical analysis, the percentage of P in PSG is determined from accurate measurements of the mass of the film. That is accomplished from an evaluation of sample weight loss due to dissolution of PSG in an HF-based mixture. The samples are then run against known standards of the same species using colorimetric spectrophotometry. From measurements of the mass and those of the corresponding test area, the density of PSG has been calculated with the results summarized in Table III. For samples with up to 9 w/o P, the average density, ρ , of LPCVD phosphosilicate glass exhibits a value of $2.06 \pm 0.05 \text{ g/cm}^3$, in excellent agreement with the reported value (10) of 2.00 g/cm^3 for atmospheric pressure CVD films with phosphorus in the range of 1.31-9.00 w/o. At ~ 10 w/o P, our results indicate an increase on the order of $\sim 7\%$ in the value ρ , pointing to a potential loss in accuracy for the x-ray fluorescence technique at these higher concentrations. For consistency's sake, a value of $\rho = 2.0 \text{ g/cm}^3$ has been systematically used in all calculations.

Figure 2 illustrates the calculated curves of relative intensity vs. w/o P for films of constant thickness. As expected, the linear curves intercept the origin and exhibit in the limit as $T \rightarrow \infty$ a slope equal to the ratio A/B . In Fig. 3, the calculated curves of relative intensity vs. film thickness are shown for phosphorus concentrations in the operating range of 5-9 w/o. The results, in this case, convey the message that at film thicknesses as high as $2 \mu\text{m}$, a saturation regime has yet to be reached.

Correlation of Results

From the group of standards, representative samples with phosphorus concentrations of 7.42, 8.32, and 9.93 w/o were selected to investigate the etch-rate and substrate sheet resistivity variations of densified PSG films. Densification of these films was performed in the center zone of a diffusion furnace at 1100°C for 20 min in a $99\% \text{N}_2$ - $1\% \text{O}_2$ ambient. The etching experiments were carried out at room temperature (22°C) in a 30:1 buffered HF solution (30 parts $40\% \text{NH}_4\text{F}$ to 1 part $49\% \text{HF}$ by volume). The film thickness was measured with an interferometer after 1 min intervals in the etch bath. A total of five readings was taken for each of the samples so as to extend the analysis down to depths of over 4000 \AA . Figure

4 exhibits the observed dependence of etch rate ($\text{\AA}/\text{min}$) on w/o P over this investigated range of concentrations. A linear fit through the data emerges with a perfect correlation factor ($R^2 = 1.000$) and a variation in etch rate, as calculated from the slope of the curve, of $92 \text{ \AA}/\text{w/o P}$. However, the scatter in the data, reflecting the slower etch rate at the surface, appears to widen with higher phosphorus concentration. Predictably, as a consequence of Henry's law (19), this is caused by higher phosphorus evaporation, from the surface of samples with a higher phosphorus content, during densification. Following these etch-rate experiments, the samples were stripped in an HF solution down to the bare silicon substrate surface and the sheet resistivity measured with a four-point probe at four sites across each sample. The average sheet resistivity together with its associated standard deviation is plotted in Fig. 5. The substrate sheet resistivity is observed, here, to increase with lower w/o P in the PSG film reflecting the decrease in substrate surface free carrier concentration. The rate of variation, calculated from the slope of a linear fit of the data, yields in this limited range of phosphorus concentration a value of $-2.1 \Omega/\square/\text{w/o P}$.

Since electron microprobe (EM) analysis and energy dispersive x-ray spectrometry (EDS) are routinely used in the determination of phosphorus, a comparative analysis of the standards becomes a prerequisite in establishing a cross correlation among EM, EDS, and x-ray fluorescence. The selected standards for this experiment are listed in Table IV with the corresponding results of chemical analysis, electron microprobe, and energy dispersive spectrometry. The EM analysis was conducted in a Cameca MBX system at a 6 keV accelerating potential with Si, O, and P $K\alpha$ lines being examined. Intensity corrections were made to account for atomic number, fluorescence, and absorption effects. GaP was used as a standard for P and thermal oxide (SiO_2) as a standard for both Si and O₂. Samples coated with carbon yielded, apparently because of poor conductivity, marginal results relative to both chemical analysis and EDS. Other samples coated with Al achieved a better correlation with the chemical analysis results. Each of the EM results represents an average of five data points per sample. The EDS analysis was carried out at 5 keV in a scanning electron microscope interfaced to an Ortec EDS detector. The intensity ratio of P/Si was measured at two points on the carbon-coated samples with the results averaged. Such ratio measurements render the dependence on good conduction to be not as crucial as in case of electron microprobe analysis. The EDS system was calibrated against EM standards. Examination of Table IV reveals excellent agreement between the EDS technique and wet chemical analysis, over the investigated range of P concentrations, with recorded percent deviations typically of the order of $\pm 2\%$ for most samples. The EM results on the carbon-coated samples exhibited strong deviations, from both the chemical analysis and EDS data, most likely caused by surface charging effects. On the other hand, the

results on the Al-coated samples are within $\pm 1.5\%$ of the standards up to 9 w/o P, but start diverging at the higher P concentration, possibly due to the influence of matrix density changes.

These previous results lead to the next step of establishing a direct correlation between EDS and x-ray fluorescence. For that purpose, LPCVD films of phosphosilicate glass typically 10,000Å thick were deposited directly onto p-type Si wafers. The phosphorus concentration was varied from run to run by sole adjustment of the PH_3 gas flow in the LPCVD reactor. X-ray fluorescence measurements were conducted at the center of each of the wafers, followed by EDS analysis in corresponding carbon-coated areas of the sectioned wafer. Table V identifies the run number as of the tested wafer in the reactor and also lists the results and percentage of deviation between these two techniques. It is interesting to note that except for the sample with the lowest P concentration (4.96 w/o) where limitations of the EDS technique have been recognized, the results from all other samples agree to within 5%, with a majority of cases being closer to 1%. A graphical representation of the degree of correlation between these two techniques is shown in Fig. 6 where a slight trend toward systematically lower values for the EDS technique is noted. However, in view of the otherwise excellent agreement achieved, such trends in either direction are judged to be insignificant. Finally, with regard to reproducibility, x-ray fluorescence measurements gathered on the standard wafer (P37) at many interval periods in a lengthy sequence of runs have never been observed to deviate more than $\pm 1\%$.

Having established the viability of x-ray fluorescence as an analytical tool, we shall, now, use it in illustrating the effect of phosphorus concentration on the viscous flow and reflow characteristics of phosphosilicate glass.

Effect of Phosphorus on Viscous Flow and Reflow of PSG

The effect of P concentration on the viscous flow and reflow of PSG has been investigated, by SEM examination of cross sections of both monitor and patterned wafers, at representative thermal cycles. The selected monitor wafers were from runs made to generate the standards and consisted of PSG films with average P concentrations of 7.34, 8.93, and 10.19 w/o deposited directly onto p-type silicon substrates. The patterned wafers used were fabricated with a $\sim 6000\text{\AA}$ TaSi_2 over polysilicon step (20). Preceding PSG deposition, a $\sim 1000\text{\AA}$ LPCVD undoped oxide layer was deposited on all patterned wafers. The PSG deposition proceeded with the PH_3 gas flow adjusted from run to run to yield P concentrations over a range of 6.59-11.83 w/o. The P concentration of each of the product wafers was deduced from x-ray fluorescence measurements of the adjoining monitor wafer. A comparison of P concentrations on several sets of monitors positioned back to back in a given slot yielded the percentage of deviation ($\approx 2\%$) within the accuracy of the measurement technique.

Following deposition, both sets of monitor and patterned wafers underwent several high temperature processing steps. In the case of monitor wafers, samples with the three considered P concentrations were cross sectioned for SEM examination after undergoing reactive sputter etching (RSE) of windows, window reflow, and

Fig. 7. Series of SEM cross sections of windows at RSE step for PSG films deposited on silicon monitors. Tilt angle was (A) $\sim 60^\circ$, (B) $\sim 90^\circ$.

aluminum metallization. In Fig. 7, a series of SEM micrographs, shot at angles close to 60° and 90° , reveal the window profile at the RSE step, following a high temperature flow ($1000^\circ\text{C}/90 \text{ min}/\text{N}_2$) and phosphorus gettering ($950^\circ\text{C}/30 \text{ min}/\text{PBr}_3$) cycles. The sharp edges and steep walls, characterizing windows of all samples, reflect the anisotropic nature of the plasma etch and are considered, at that stage, unsuitable for metal coverage with present line-of-sight deposition techniques. It is interesting to note in all samples the presence of a step extending $\sim 1000\text{\AA}$ upward from the bottom of the window. There is the possibility that the rounded bottom of the RSE contour can, due to a dry etch-rate difference at the PSG/Si interface, produce that step. A series of micrographs taken, again after window reflow ($1000^\circ\text{C}/30 \text{ min } \text{N}_2$), are shown in Fig. 8. For samples with an average P concentration of 7.34 w/o, the window edges appear adequately rounded and suitable for metal coverage. At 8.93 w/o P, there is a significant change in window geometry reflected here by the excessive rounding of the edges and sloping of the sidewalls. At 10.19 w/o P, the windows are shown to have severely receded, but no signs of a re-entrant angle are noted on any of the windows at this higher P concentration. With a remnant undoped layer on top of the PSG, the reflow is shown in Fig. 9 to be hampered, and, furthermore, due to etch-rate differences between undoped and PSG films in HF, a ledge is formed on the top surface which may disrupt continuity of the metal coverage. SEM micrographs taken on monitor wafers at the aluminum metallization step are shown in Fig. 10. The step coverage, calculated from the ratio of the aluminum thickness along the window sidewalls to that along the PSG top surface, varies, in extreme cases, from $\sim 23\%$ for samples with 7.34 w/o P to $\sim 41\%$ for samples with 10.19 w/o P. Improvements in step coverage of that magnitude for such dramatic differences in window profile emphasizes the inherent limitations, in this case, of In Source Al or similar line-of-sight deposition techniques, in providing the conformal coverage needed for further horizontal or vertical integration of devices.

Fig. 8. Series of SEM cross sections of windows at reflow step for PSG films deposited on silicon monitors. Tilt angle was (A) $\sim 60^\circ$, (B) $\sim 90^\circ$.

The effect of bypassing the flow and gettering steps so as to minimize the thermal cycle and achieve shallower junctions was also investigated on monitor wafers with average phosphorus concentrations of 7.34, 8.93, and 10.19 w/o. The wafers were, in this case, patterned directly after PSG deposition and underwent a reflow cycle of 1000°C for 30 min in N_2 . SEM cross sections revealed window profiles similar to those of wafers which received the additional flow and gettering step. The observations emphasize the higher order dependence of viscous flow on phosphorus concentration and temperature over time.

The influence of surface topography on the viscous flow and reflow characteristics of PSG films was determined from examination of SEM cross sections of patterned wafers. The phosphorus concentration was varied, in this case, in steps of typically 0.5 w/o over a range of 6.59–11.83 w/o. Following PSG deposition, these wafers underwent, prior to aluminum deposition, several high temperature steps. Parts of each wafer were cross sectioned after reactive sputter etching the windows, after window reflow, and after a 2 min 30:1 buffered oxide etch. Figure 11 shows a series of SEM micrographs of the combined $\sim 1000\text{\AA}$ undoped oxide and PSG structure over a polycide runner after a flow ($1000^\circ\text{C}/90\text{ min}/\text{N}_2$) and gettering ($950^\circ\text{C}/30\text{ min}/\text{PBr}_3$) cycles for films with phosphorus concentrations of 6.59, 7.07, 7.34, 8.14, 8.48, and 9.09 w/o. The films are observed to exhibit profiles over steps that get progressively smoother with higher phosphorus concentration reflecting the corresponding enhancement in viscous flow. Samples from the same wafers examined after reflow yield, as shown in Fig. 12, a further reduction in topography for films with low phosphorus concentrations; however, at 7.34 w/o P or above the films are notably similar to those at the RSE step (i.e., prior to reflow). Consistent with previous observations on monitor wafers and published results (21), the window edges become, as seen in Fig. 13, progressively rounded with higher phosphorus concentration while the window sidewalls increase correspondingly their tapering angle. Inspection of the same wafers after a 2 min 30:1 buffered oxide etch did

Fig. 9. SEM micrographs revealing window profile at reflow with a remnant undoped oxide on top of the PSG.

not reveal noticeable changes in the step or window profile of any of the considered phosphorus concentrations.

It is interesting in this context to point out that SEM cross sections of a patterned wafer with a measured phosphorus concentration of 11.83 w/o yielded a step and window profile, shown in Fig. 14, characteristic of PSG films with <6 w/o P. This appears to have been common amongst all wafers which exhibited a preponderance of

droplets on the wafer surface. A litmus test on these wafers turned in color, confirming the presence of an acid, presumed here to be phosphoric acid. The tendency of as-deposited PSG films with phosphorus concentrations higher than 8 w/o to be hygroscopic has been well documented (22-28) and recognized as the source of aluminum corrosion. However, the work of Nagosima *et al.* (22), as well as that of Levin (23), have also shown that the effect of densification, at temperatures of 700°C or above, is to shift the threshold concentration from ~8 w/o P to ~12 w/o P. The delamination of the PSG film structure over steps at the higher P concentration (11.83 w/o) is assumed to be the result of a phase separation of the glass into a primary $\text{SiO}_2\text{-P}_2\text{O}_5$ (with $P < 6$ w/o) phase and a hygroscopic, water soluble P_2O_5 phase. Since the stress of as-deposited PSG films has been determined to be tensile (1, 29, 30), further increases in thermal stress due to a mismatch in thermal expansion coefficient of the PSG/ SiO_2 film and silicon substrate ($\alpha_{\text{PSG}} < \alpha_{\text{Si}}$) coupled with lack of viscous flow of the low phosphorus primary phase could account for the observed film delamination.

Conclusion

In this study, we have examined the use of x-ray fluorescence as an analytical tool for determining phosphorus concentration in phosphosilicate glass. By comparison with other available methods, we have demonstrated that this direct measurement technique is accurate, simple, fast, reproducible, and nondestructive. Using this technique, we have illustrated the effect of phosphorus concentration on the viscous flow and reflow of PSG at typical thermal cycles. For a given heat-treatment, both

Fig. 14. SEM micrographs of step and window profile of PSG with 11.83 w/o P. Film is presumed to have phase separated.

flow and reflow profiles were observed to be dependent on changes in the phosphorus concentration of the glass.

Acknowledgments

The authors wish to thank J. F. Roberts for deposition of some of the LPCVD PSG films; D. R. Wonsidler and M. D. Patterson for the electron microprobe and energy dispersive spectrometry work; L. APPENDIX

Starting from a set of measurements of phosphorus concentration, thickness, and normalized intensity (P_i, T_i, I_i) $i = 1, 2, \dots, n$, the purpose, here, is to fit this data to an equation of the form

$$I = \frac{AP}{B} [1 - e^{-BT}]$$

in a least squares sense to I . Thus, we want to find A and B which minimize

$$R(A, B) = \left[\sum_{i=1}^n \left[\frac{AP_i}{B} (1 - e^{-BT_i}) - I_i \right]^2 \right]^{1/2}$$

By setting $A/B = C$ and the i th component of the vector \bar{M} to

$$M_i = P_i [1 - e^{-BT_i}]$$

then the least squares problem reduces to finding C and B such that

$$R(C, B) = \|\bar{M}(B)C - \bar{I}\|_2$$

[A-1]

is minimized.

In this problem, C appears linearly and B nonlinearly, which means that if the optimal B is known, call it B' , the optimal C is given as

$$C = [\bar{M}(B')^T \bar{M}(B')]^{-1} \bar{M}(B')^T \bar{I} \quad [A-2]$$

It has been shown (31) that Eq. [A-2] can be substituted into Eq. [A-1] and that B' also minimizes the one variable function $S(B)$ defined by

$$S(B) = \|(\bar{M}(B)\bar{M}(B)^T \bar{M}(B))^{-1} \bar{M}(B)^T \bar{I}\|_2$$

where \mathbf{I} is the identity matrix.

A one-dimensional problem that has a unique local minimum in a given interval is much simpler to solve than a two-dimensional problem. We chose to solve Eq. [A-1] by applying Brent's algorithm (32) to minimize $S(B)$ and then use Eq. [A-2] to determine the optimal C . Brent's algorithm does not require derivatives of $S(B)$ and uses a combination of golden section steps guaranteed to yield a terminating algorithm and parabolic interpolation steps to speed convergence. It is superlinearly convergent.

Si Epitaxial Growth of Extremely Uniform Layers by a Controlled Supplemental Gas Adding System

T. Suzuki,* Y. Inoue, T. Aoyama, and M. Maki

Hitachi Limited, Hitachi Research Laboratory, Hitachi, Ibaraki 319-12, Japan

ABSTRACT

A new approach to uniform growth, which directly modulates and controls the reactant gas concentration distribution within a reactor, has been proposed. A rotary disk (pancake) type reactor with a controlled supplemental gas adding system for regions of insufficient epitaxial layer thickness was designed and fabricated after consideration of gas flow patterns and reaction gas concentration distribution within the reactor. Simulation and control methods were developed to optimize the parameters of the multiple supplemental gas nozzles so that a uniform layer thickness distribution over a large range of susceptor radial directions could be achieved. Experiments using three supplemental nozzles showed that this system and control method could achieve deviations in thickness of less than $\pm 1\%$ both within a wafer and within a growth lot.

The chemical vapor deposition of epitaxial layers of silicon is a widely used process in the semiconductor industry. In this process, there is a requirement for better accuracy in growth control of the layer thickness, both to improve device production yield and to allow use of larger diameter wafers. As the diameter of the silicon substrate wafers becomes larger, the size and capacity of the growth reactor are inevitably scaled up to maintain the wafer charge number per growth lot. However, reactor scale-up reduces uniformity in the layer-thickness distribution, since more variation occurs in the growth rate along the gas stream due to depletion of the silicon source gas concentration. Therefore, it is important to consider how high uniformity can be achieved over a large growth area within larger reactors.

Chemical and transport phenomena in the epitaxial reactor have been studied by a number of investigators to obtain the optimal reactor design and operating conditions which ensure higher uniformity. A number of models, describing the growth-rate distribution along the gas stream in horizontal reactors have been studied (1-6). Other groups (7-8) have reported on quantitative models which describe the deposition-rate distribution in vertical cylinder reactors. More recently, another model has been presented which describes growth-rate distribution along the reactor deposition zone (9). Although these models have proven to be useful in optimization of the growth process conditions, they do not give any clue to how to overcome the fundamental problem of reactant gas depletion along the gas stream at reasonable gas flow rates. Unless some basic change is made in the present reactor construction, this problem cannot be avoided and limitations will continue to be placed on realization of extreme uniformity. Therefore, it is necessary to develop a new approach such as direct modulation of gas conditions within a reactor or to utilize a quite different reactor construction. With respect to the latter approach, Ban (6) reported on a novel reactor with a significantly large wafer capacity. This reactor, however, has the disadvantage of mechanical complexity and it has not achieved a thickness uniformity higher than that of conventional reactors.

In this paper, first, gas flow conditions and reaction gas concentration distributions within a rotary disk (pancake) type reactor were observed by means of gas flow pattern visualization and quadrupole mass spectrometric monitoring in order to understand transport and chemical phenomena. After consideration of the observation re-

sults, a practical, new approach to uniform growth, which directly modulates and controls the reactant gas concentration distribution within a reactor, was proposed and investigated. In this approach, supplemental reactant gas is added using multiple auxiliary gas nozzles in regions of poor thickness distribution according to a correction factor supplied from data for the preceding growth lot. The growth results for the extremely uniform layers obtained by using this supplemental gas control method are also shown.

Growth Reactor

Figure 1 is a schematic drawing of the rotary disk-type reactor used in our experiments. The diameter of the graphite susceptor was 12 in. The main gas inlet nozzle, positioned at the center, had an alternating vertical row arrangement of three and two holes for gas emission, spaced at an angle of 60° . A special feature of this reactor was the supplemental gas system used in addition to the conventional main gas system. The former had its own gas control system, inlet nozzle, and position regulator. The reactor had an *in situ* reaction gas concentration measuring system which consisted of a quartz capillary, position regulator, and gas concentration monitor (quadrupole mass spectrometer). This monitoring system and measurement method were the same as used previously (10). Deviations in the concentration measurements were less than $\pm 10\%$ within the concentration range studied.

Figure 2 defines the coordinate axes x and y and angle θ that are used in the following description. The arrows depicted around the center inlet nozzle indicate the direction of gas emission. The thick arrows show the direction of gas emission from the three vertically rowed holes and the smaller arrows show the two holes. The angle θ is defined as the angle from the direction shown by a thick arrow.

The epitaxial films were deposited by the hydrogen reduction of tetrachlorosilane (SiCl_4). Typical growth conditions were as follows: total gas flow rate (F_0) = 27 liter/min; SiCl_4 concentration (C_0) = 2.1 mole percent (m/o); and silicon substrate temperature (T_s) = 1200°C (corrected). The radial temperature distribution of the susceptor surface was almost constant within $\pm 10^\circ\text{C}$. Impurity doping gas was not used. The substrates used were mirror-polished CZ silicon wafers 3 in. in diameter with (111) orientation (off angle: $3^\circ \pm 1^\circ$). The rotation rate of the disk pedestal was kept constant during all experiments at 20 rpm.

Transport and Chemical Phenomena in Reactor

Deposition and uniformity in CVD reactors are functions of chemical and transport phenomena. Although a few theoretical studies of transport phenomena in rotating disk reactors have appeared previously (11-13), little experimental work using a rotary disk-type, multiwafer reactor has been reported. Only Duchemin (14) has presented results dealing with the mechanism of silicon deposition based on analysis of gas concentration profiles.

In our study, first, gas flow patterns in the reactor were observed. In order to visualize the gas flow, monosilane (SiH_4) gas mixed with helium gas was introduced through the main inlet nozzle to produce a smoke streamline. Flow patterns on a selected reactor cross section were observed by projecting collimated parallel light through a slit onto the transparent quartz reactor. The disk temperature and total gas flow rate in the following two experiments were 800°C and 27 liter/min, respectively. Photographs of the gas flow pattern were taken

Fig. 2. Definition of coordinate axes x and y and angle θ

1-5s after opening the valve for introduction of tracer gas ($\text{SiH}_4 + \text{He}$) since the pattern became unclear after that.

Figure 3 shows typical streamline results observed on two different vertical cross sections where θ equals (a) 0° and (b) 30° . Streamlines of the emission flow toward the outer circumference of the susceptor, as well as the ascending flow caused by thermal convection, could be seen on the vertical cross section where $\theta = 0^\circ$. Interestingly, streamlines flowing backwards, toward the center nozzle, could also be seen on the vertical cross section where $\theta = 30^\circ$.

Fig. 3. Typical gas streamlines observed on two different vertical cross sections where (a) $\theta = 0^\circ$ and (b) $\theta = 30^\circ$. $T_s = 800^\circ\text{C}$ and $F = 27$ liter/min.

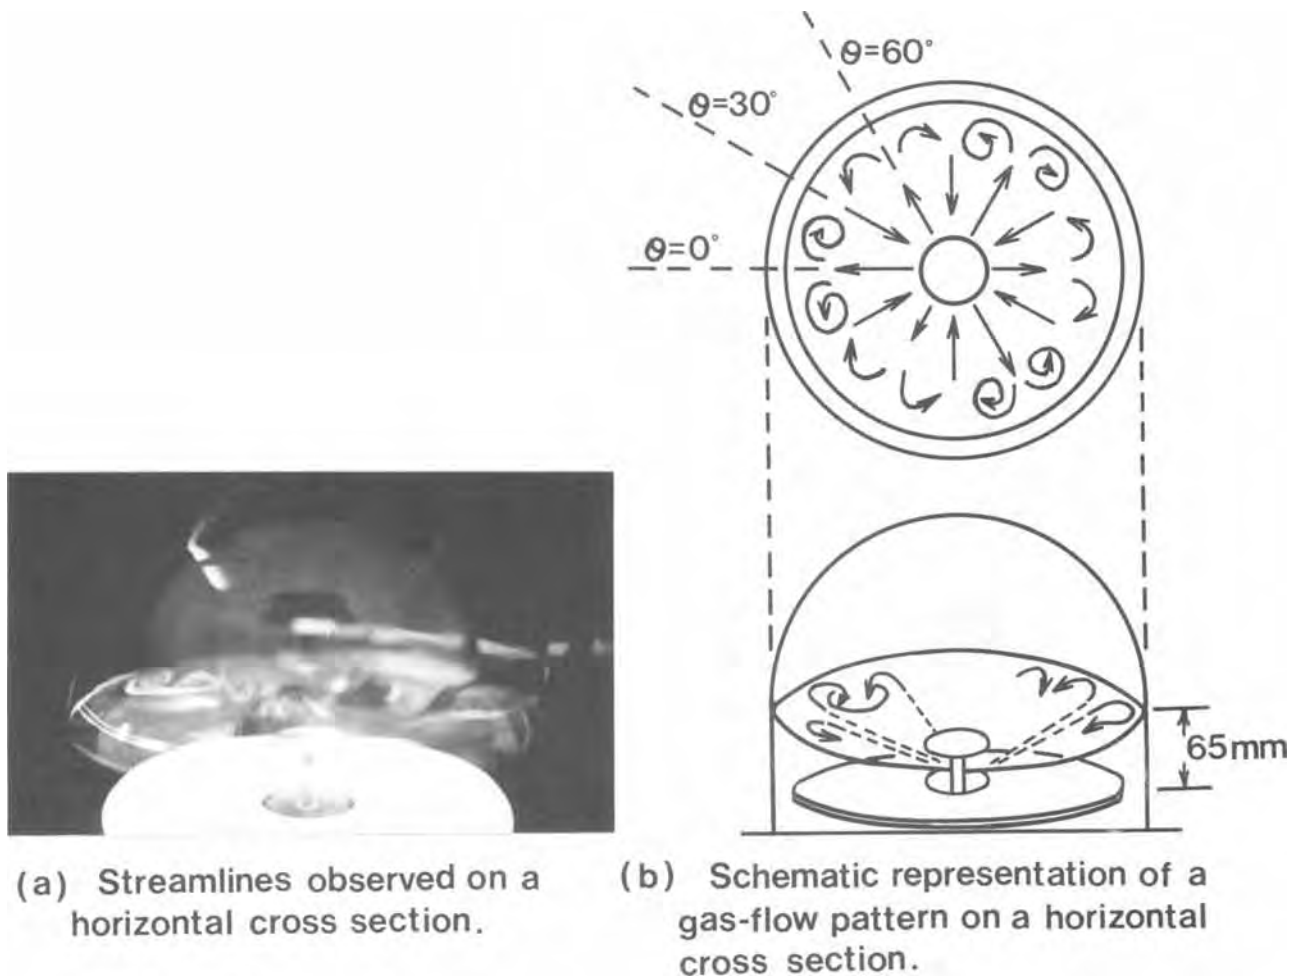

Fig. 4. Typical observed gas flow pattern on a horizontal cross section. $h = 65 \text{ mm}$; $T_s = 800^\circ\text{C}$; and $F = 27 \text{ liter/min}$

Figure 4 shows typical streamline results observed on the horizontal cross section at a height 65 mm above the susceptor. Some gas streams, emitted from the center

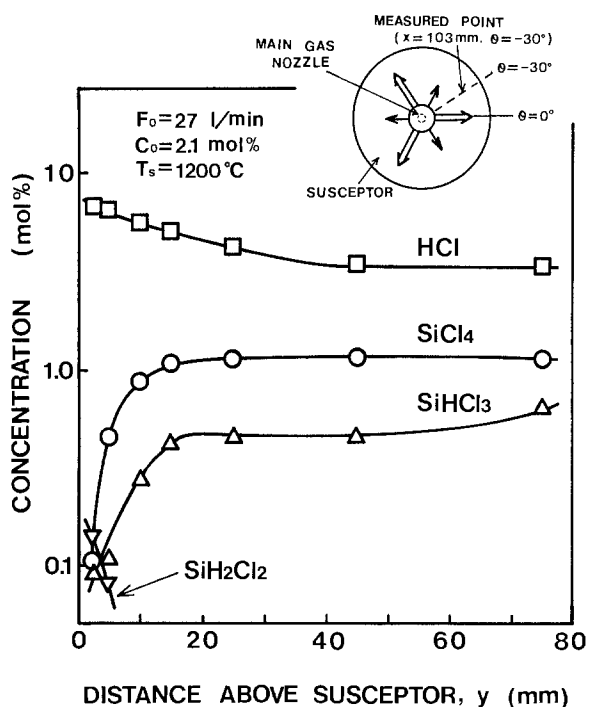

Fig. 5. Concentration profiles for the reactants measured along a distance above susceptor at the position defined by $x = 103 \text{ mm}$ and $\theta = -30^\circ$.

Fig. 6. SiCl_4 concentration profiles measured on a curved plane where the radial distance $x = 103 \text{ mm}$ at various heights of y above the susceptor.

Fig. 7. SiCl_4 concentration profiles measured along the radius of the susceptor at various heights y above the susceptor on two different cross sections where (a) $\theta = 0^\circ$ and (b) $\theta = 30^\circ$.

nozzle which struck the bell jar wall were then turned back in the opposite direction (along the line of the angle $\theta = 30^\circ$) to make an eddy streamline (Fig. 4b). At the same time, the ascending convection flows from the susceptor caused by heating were added to these lateral flows to give a very complicated gas flow pattern.

Next, the gas concentration distribution in the reaction chamber was measured by means of *in situ* mass spectrometry measurements. Figure 5 shows an example of concentration profiles for the reactants measured along a distance above the susceptor at a position defined by $x = 103$ mm and $\theta = -30^\circ$. Trichlorosilane (SiHCl_3), dichlorosilane (SiH_2Cl_2), and hydrogen chloride (HCl) were present, in addition to silicon tetrachloride (SiCl_4) as reactant species. Silicon dichloride (SiCl_2) was not observed. Profiles of SiCl_4 and SiHCl_3 had a concentration gradient in the area between the susceptor surface and a height of about 15 mm, indicating that these species diffused toward the silicon substrate surface and contributed to heterogeneous silicon growth reaction. HCl diffused upwards.

In the upper region of the reactor, the concentration profiles of the reactant gases were fairly constant. The concentration of SiCl_4 at the upper part was about 1.1 m/o, and this value was smaller than the concentration value of 2.1 m/o initially introduced into the reactor as the source gas. This indicated that the SiCl_4 fed into the reactor was extensively decomposed to other chlorosilanes such as SiHCl_3 and SiH_2Cl_2 . From these results, it seemed that the heterogeneous reaction directly related to the deposition of silicon was not only the reduction of SiCl_4 , but also the reduction of other related compounds such as SiHCl_3 . This kind of complicated heterogeneous reaction has also been described for a horizontal reactor by Nishizawa and Saito (1) and the authors, (10).

Figure 6 shows a typical example of SiCl_4 concentration profiles measured on a curved plane at various heights, y , above the susceptor. The radial distance x from the center nozzle to the plane was 103 mm. Although there

was not such a significant variation in SiCl_4 concentration in the upper region of the reactor ($y = 45$ mm), there was a noticeable variation in the lower region near the susceptor surface ($y = 5, 10$ mm). The concentration peak at $\theta = 0^\circ$ corresponded to the gas flow emitted from the center nozzle, and the peaks at $\theta = \pm 30^\circ$ corresponded to the gas flow being turned back towards the center from the bell jar wall.

Figure 7 shows SiCl_4 concentration profiles measured along the radius of the susceptor at various heights y from the susceptor surface. Figure 7a indicates the profiles measured on a section where $\theta = 0^\circ$, and Fig. 7b where $\theta = 30^\circ$. Quite complicated profiles were seen in both cases. The disturbed profiles in the neighborhood of the susceptor circumference could probably be attributed to the gas flow striking the bell jar wall.

As mentioned above, it was seen that the gas conditions in the actual growth reactor were very complicated. The thickness distributions resulted from the interactions of the various gas reactions and gas conditions such as the flow pattern and concentration and temperature distributions. Accordingly, it was thought that, at present, the *in situ* (real time) control of thickness uniformity with such accuracy as $\pm 1\%$ could not be done by a method based on monitoring certain gas parameters within the reactor, especially in a large-scale production facility. Therefore, we took another approach in our investigation.

Supplemental Gas Control Method

It was found in the preliminary experiments that growth rate could be increased locally by adding supplemental reactant gas into the midst of the main gas flow. Using this effect, a new approach for realizing extremely uniform distribution which directly modulated and controlled the reactant gas distribution within a reactor was investigated.

In this approach (Fig. 8), additional reactant gas is introduced through the supplemental gas nozzle to regions of insufficient thickness distribution as determined by a

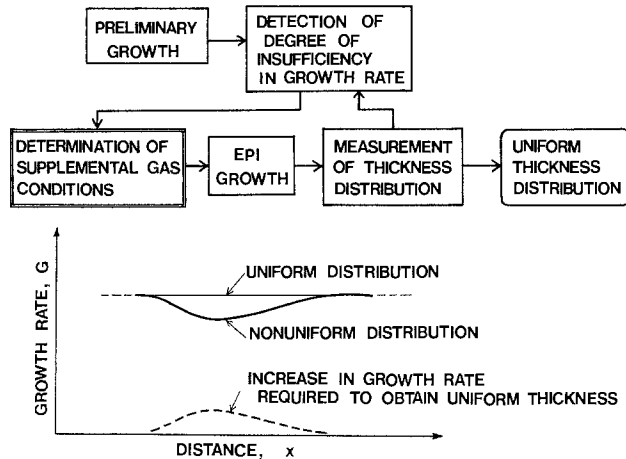

Fig. 8. Concept of thickness uniformity control by supplemental gas addition method.

correction factor supplied from data for the preceding growth lot. That is, preliminary growth is needed first, and then the difference between the uniform and nonuniform distribution is detected. The supplemental gas conditions required to form a uniform distribution are determined. Then, epitaxial layers are grown by applying these conditions to achieve a uniform thickness distribution. If necessary, this revision process can be repeated.

In order to control the uniformity with this method, calculations must be made which simulate the effects of gas supplements on the growth-rate distribution. Therefore, these effects were investigated in detail.

Figure 9 shows the configuration of the supplemental gas nozzles used in the experiments and defines the parameters related to the nozzles (c_i is the SiCl_4 concentration, x_{Ni} the distance from the susceptor center, and h_{Ni} the nozzle height, where i indicates the nozzle number). These supplemental gas nozzles are used to widen the area affected by the supplements. These nozzles are arranged between the emitted streamlines, where the gas velocity is relatively slow, as observed before.

First, the effects of gas supplements using a single nozzle were examined. The nozzle was positioned at $x = 100$ mm. Figure 10a shows the effects of supplemental gas concentration c on the growth-rate distribution along the susceptor radius. As the concentration was increased, the peak height of the growth rate curve increased, although the position and general shape of the peaks were almost unchanged. Figure 10b shows the effect of changes in

nozzle height h_N . As the nozzle height was increased, the peak height of the growth rate curve decreased, while the width of the distribution increased. At the same time, the peak position shifted toward the center of the susceptor. This may be due to the gas flow being turned back towards the susceptor center from the bell jar wall.

As could be seen from these figures, the increase in the growth-rate curve, using a gas supplement, has the same appearance as that of a typical normal distribution function. Therefore, we approximated the increase in growth rate $\Delta G(x)$ as follows

$$\Delta G(x) = A \exp \left\{ -\frac{(x - x_p)^2}{2\sigma^2} \right\} \quad [1]$$

where A is the peak height, σ is the standard deviation corresponding to the width of the peak, and x_p is the distance of the peak from the susceptor center. Using this expression, the effects of supplemental gas parameters, c , h_N , and x_N on the shape and position of the distribution of the increase in growth rate curve, A , σ , and x_p , were examined further and summarized in Fig. 11. These plots showed that the distribution shape could be controlled by using the three nozzle parameters. The shape of the distribution of the increase in growth rate was also influenced by the flow rate f of the supplemental gas. Our experiments showed that, as the flow rate f was decreased, the peak height A decreased, and, at the same time, the peak distance from the susceptor center x_p became less, because the supplemental gas flow was carried away by the main gas stream flowing toward the susceptor center. This fourth nozzle parameter f , however, was kept at a constant value of 1.5 liter/min in the following experiments in order to simplify the supplemental gas control.

Next, we considered a method for calculating the normal distribution functions of the individual supplemental gas nozzles. This was necessary to achieve a uniform distribution from a given nonuniform distribution when multiple supplemental gas nozzles were used. It was assumed that the resultant increase in growth rate using multiple supplemental gas nozzles could be expressed by the simple superposition of the increase in growth-rate curves for individual gas nozzles. Then the normal distribution functions of each supplemental gas nozzle necessary to achieve a uniform distribution from a given nonuniform distribution were obtained as the solution of A_i , σ_i , and x_{pi} in the following equation

$$\sum_j A_j \exp \left\{ -\frac{(x - x_{pj})^2}{2\sigma_j^2} \right\} = T - G_0(x) \quad [2]$$

Fig. 9. Configuration of three supplemental gas nozzles and definitions of their parameters

Fig. 10. Effects of changes in supplemental gas conditions on growth rate distribution along the susceptor radius

where j is the number of supplemental gas nozzles, T is the uniform growth rate distribution (constant), and $G_0(x)$ is a given nonuniform distribution of the growth rate. Although an analytical solution of Eq. [2] could not be ob-

tained, an approximate solution was possible using the Newton method in which reasonable values of A_j , σ_j and x_{pj} were given as initial values. Figure 12 shows an example of calculated distribution functions of the growth rate

INCREASE IN GROWTH RATE:

$$\Delta G = A \exp \left\{ - \frac{(x - x_p)^2}{2\sigma^2} \right\}$$

- A : PEAK HEIGHT
- σ : STD. DEVIATION
- x_p : PEAK POSITION

Fig. 11. Relation between supplemental gas conditions and parameters of normal distribution function (increase in growth rate)

Fig. 12. An example calculation of the distribution functions of the growth rate supplement which are required to make the nonuniform distribution $G_0(x)$ uniform, assuming the use of three nozzles.

supplement which are required to make the nonuniform distribution $G_0(x)$ uniform, assuming the use of three nozzles.

Since the growth-rate distribution functions of each supplemental nozzle could be calculated by solving Eq. [2], it was now possible to control the thickness uniformity by applying the supplemental gas control method shown in Fig. 13. This figure shows a flow diagram for thickness uniformity control by the supplemental gas method. First, preliminary growth was needed to detect the difference between uniform and nonuniform thickness distribution. Then the distribution functions of the growth-rate supplement of each nozzle required to realize a uniform distribution were calculated. After this, the supplemental gas conditions of each nozzle c_i , h_{Ni} , x_{Ni} could be calculated approximately by using calibration data between the distribution functions of the growth-rate supplement and the supplemental gas conditions. Applying these conditions, epitaxial layers were then grown, and the resulting thickness distributions were measured. However, growth rate (or thickness) distribution as uniform as initially planned (for example, $\pm 1\%$) could not always be achieved at once due to errors in the calibration curves and approximations made in the calculations. If the obtained uniformity was insufficient, then the supplemental gas conditions were corrected by comparing the actual distribution functions of each supplemental gas nozzle with the initial ones. The actual supplemented distribution functions after epitaxial growth could be calculated by applying the method which was used for obtaining the distribution of the growth rate supplement required to achieve a uniform distribution. By repeating such growth and correction procedures as needed, the desired uniformity in thickness distribution was achieved.

Results and Discussion

Figure 14 shows an example of the transition to uniform thickness distribution along the susceptor radius on

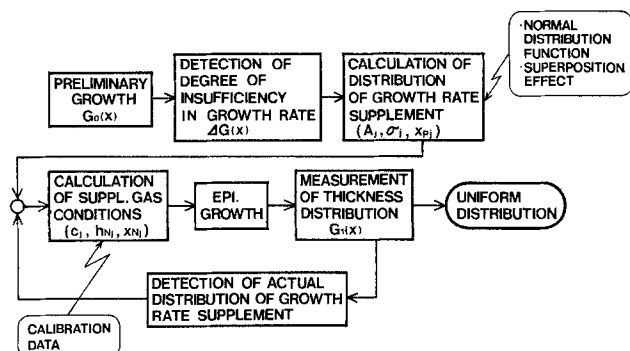

Fig. 13. Flow diagram of thickness uniformity control by supplemental gas method.

Fig. 14. Example of the transition to uniform thickness (growth rate) distribution along susceptor radius by the application of the supplemental gas control method. Three supplemental gas nozzles were used.

application of the developed supplemental gas control method. Three supplemental gas nozzles were used in this case. The variation in thickness (or growth rate) distribution before the gas supplement was $\pm 6.9\%$. By repeating the correction, the uniformity was enhanced until a deviation of only $\pm 0.7\%$ was achieved, on the third growth, within a 3 in. wafer.

Figure 15 shows an example of the transitions of uniformity within a growth lot when a similar repetition of growth was performed. In this case, six 3 in. wafers were charged per lot. The thickness deviations of less than $\pm 1\%$ were obtained and maintained from the third growth.

Thus, it was demonstrated that a thickness uniformity deviation of less than $\pm 1\%$ both within a wafer and within a growth lot could be obtained by applying the supplemental gas control method. Application of the same control method, it is believed, should make possible the same extremely uniform growth by widening the effect of the gas supplement for each nozzle or by increasing the number of supplemental gas nozzles. Furthermore, automated computer control of the process is possible, since the conditions for the gas supplement can be calculated.

Summary and Conclusions

Gas flow conditions and reaction gas concentration distributions were observed by means of gas-flow-pattern visualization and quadrupole mass spectrometric monitoring in order to understand transport and chemical phenomena of silicon epitaxial growth within a rotary disk-type reactor. After consideration of these observa-

Fig. 15. Example of the transitions of uniformity within a growth lot with the application of the supplemental gas control method. Six 3 in. wafers were charged per lot.

tions, a practical, new approach to uniform growth, which directly modulated and controlled the reactant gas concentration distribution within a reactor, was proposed and investigated.

A rotary disk-type reactor with a controlled supplement gas system for adding reaction gas to regions of insufficient layer thickness distribution was designed and fabricated. Simulation and control methods were developed to optimize the parameters of the multiple supplemental gas nozzles so that a uniform thickness distribution over a large area of the susceptor radial direction could be achieved. In this method, the resultant increase in growth-rate distribution by multiple supplements was simulated by superposition of the individual increase in growth-rate curves, with each single gas supplement being approximated by the normal distribution function. The supplemental gas conditions of each nozzle were determined using calibration data and corrected by comparing resultant distribution functions after growth with the initial ones. Experiments using three supplemental nozzles showed that this system and control method could yield a thickness uniformity deviation of less than $\pm 1\%$, both within a 3 in. wafer and within a growth lot.

It is believed that the same extremely uniform growth can be achieved in a scaled-up reactor and that automated, computer control of the process is possible.

Acknowledgments

The authors wish to express their sincere thanks to Professor J. Nishizawa, Dr. M. Okamura, and Dr. H. Kato for

their guidance and encouragement in this work. They also would like to thank Dr. M. Tanuma for his helpful discussions.

Physical Properties of Sputter-Deposited Titanium Silicide as a Function of Substrate Temperature

M. Tanielian and S. Blackstone

Gould Research Center, Rolling Meadows, Illinois 60008

ABSTRACT

The resistivity, composition, and microstructure of sputtered titanium silicide films from a composite $\text{TiSi}_{2.1}$ target were investigated as a function of substrate temperature T_s in the range of $T_s \approx 25^\circ\text{--}600^\circ\text{C}$. We find that there are essentially three distinct regimes of properties, for $T_s \approx 25^\circ\text{--}200^\circ\text{C}$, $T_s \approx 200^\circ\text{--}450^\circ\text{C}$, and $T_s \approx 450^\circ\text{--}600^\circ\text{C}$. The oxygen incorporation, oxidation sensitivity, and resistivity of the films decrease as the substrate temperature increases. The most notable observation was that the physical properties of the films in the temperature range of $450^\circ\text{--}600^\circ\text{C}$ are similar to fully reacted titanium disilicide films formed in a furnace anneal at 900°C , and, in addition, they are oxygen free. In order to explain this result, we had to assume that the surface substrate temperature was several hundred degrees higher during sputtering than what the macroscopic measurements of the bulk substrate temperatures would indicate.

The preparation and processing of the refractory metal silicide films such as TiSi_2 , TaSi_2 , MoSi_2 , and WSi_2 have been the topic of many investigations (1). Their importance arises from their usefulness as low resistivity interconnection materials in VLSI circuits. Films of these refractory metal silicides have been deposited using all types of conventional thin film deposition techniques, such as sputtering from a single composite target, co-sputtering, coevaporation, and CVD. Each method provides different advantages in terms of purity, step coverage, and stress. However, one aspect all these methods share in common is that the formation of the fully reacted, low resistivity disilicide phase can only be achieved after a high temperature sinter, typically in the range of $850^\circ\text{--}1000^\circ\text{C}$, subsequent to the thin film deposition. One exception to this process is in the case of plasma-enhanced chemical vapor deposited titanium silicide films where it appears that only a 650°C anneal is necessary to get fully reacted films.

Of all the refractory metal silicides, TiSi_2 has the lowest resistivity, which makes it an attractive candidate as a VLSI interconnection material. However, it also presents

some special problems, since the unreacted (room temperature as-deposited film) has a high affinity for oxygen. For instance, during deposition, some oxygen may be incorporated into the film; also, during sintering, a thick oxide may grow on the film, unless the sintering is done in vacuum or in an inert ambient.

Here, we report that the sintering step is not necessary when the titanium silicide films are sputtered at elevated substrate temperatures, because the high substrate temperature films appear to be fully reacted. In the case of titanium silicide sputtered from a cold-pressed composite target, this range of substrate temperatures (2, 3) is $450^\circ\text{--}600^\circ\text{C}$. In fact, there appear to be three distinct regimes in the properties of sputtered titanium silicide films as they relate to the substrate temperature.

Experimental

The films were sputtered in a small glass bell jar chamber which was fitted with two 2 in. dc magnetron sputter guns. The target was a cold-pressed target from Varian with a nominal composition of $\text{TiSi}_{2.1}$. The system was pumped down to 3×10^{-7} torr before each deposition and

then backfilled with ultrahigh purity argon to a pressure of about 3 mtorr. Before the deposition of the film, the target was presputtered for approximately 1h with the shutter closed, in order to clean the target and getter any background oxygen in the system. The substrates were (111), 10 Ω -cm, bare silicon wafers. The heating of the wafers was done using a Mo resistor fabricated on the oxidized back of the wafers. This heating technique was chosen because it minimized the heating of other parts and fixtures in the sputtering chamber, which could degas and produce unwanted background gases. Using this technique, we could reproducibly heat the wafer between ambient and 650°C. The substrate temperature was measured on the front side of the wafer using a thin wire thermocouple via a spring contact. The sheet resistance of the films was measured using a four-point probe and the thickness was obtained from a Dektak II stylus probe. The Auger signals were calibrated using TiSi_2 powder samples. The sintering step was carried out in a furnace tube in argon at 900°C for 30 min.

Results

The room temperature resistivity of the films both before and after a 900°C, 30 min Ar anneal was measured as a function of substrate temperature over the range of 25°-600°C. The results, shown in Fig. 1, indicate that there are three distinct regions. Presumably, these correspond to three distinct phases of titanium silicide.

Phase I: $T_s \approx 25^\circ\text{-}200^\circ\text{C}$.—This is the range of substrate temperatures conventionally used for sputtering. The Auger analysis of a film deposited at 25°C which is typical of this range (3) is given in Fig. 2. The as-deposited film contains 5-7 atom percent (a/o) oxygen throughout its thickness. No carbon or Ar signals were detected (3).

When annealed, the top third of the film was converted to a mixture of Si, Ti, and their respective oxides. It is worthwhile to observe that the amount of oxygen incorporated in the annealed film decreases to some extent after the high temperature anneal. This effect has been seen before (4) and has to do with the thermodynamic

Fig. 1. The resistivity as a function of substrate temperature of titanium silicide films both before and after anneal. As one can see, the resistivity of the films deposited at $T_s > 450^\circ\text{C}$ is unchanged after a 900°C, 30 min argon anneal.

Fig. 2. Auger depth profile of a film deposited at $T_s = 25^\circ\text{C}$. a: As deposited. b: After a 900°C, 30 min argon anneal.

equilibrium of this ternary system (5, 6). The x-ray diffraction trace from this film shows that the as-deposited film is amorphous, and it crystallizes after the high temperature anneal, as shown in Fig. 3. SEM pictures of the surface of the film are shown in Fig. 4. They reveal a grainy structure with a typical grain size of about 1000Å both before and after anneal. These grains cannot be related to the crystallite size in these films, since the x-ray data show that the as-deposited film is amorphous while the annealed film is polycrystalline.

Fig. 3. X-ray diffraction data of a film deposited at $T_s = 25^\circ\text{C}$. a: As deposited. b: After a 900°C, 30 min argon anneal. The peak corresponds to the (004) peak of TiSi_2 .

Fig. 4. SEM micrographs of the surface texture of a film deposited at $T_s = 25^\circ\text{C}$. a: As deposited. b: After a 900°C , 30 min argon anneal. The surface morphology remains unchanged although the film crystallized.

Fig. 5. Auger depth profile of a film deposited at $T_s = 300^\circ\text{C}$. a: As deposited. b: After a 900°C , 30 min argon anneal.

Phase II: $T_s \approx 200^\circ\text{--}450^\circ\text{C}$.—In this range of substrate temperatures, we find that the titanium silicide films are partially reacted. A fully reacted film in this case is defined as a film that has properties similar to a film which has undergone a 900°C , 30 min, argon anneal. This characterization is based on the fact that these films share some features of a fully reacted film. For instance, the surface layer oxide is made of SiO_2 with no Ti or TiO_x species mixed in, which is typical of a fully reacted film. This layer remains unchanged after annealing. The Auger analysis of a film deposited at $T_s \approx 300^\circ\text{C}$ which is typical of this range is shown in Fig. 5. The reason these films are referred to as partially reacted relates to the resistivity of the films in this range which, although lower than the resistivity of the films in Phase I, is still higher than the value of the fully reacted film. Further justification for the term “partially reacted” is based on TEM studies (10) where it was found that the $T_s \approx 300^\circ\text{C}$ film was comprised of two silicide phases, the equilibrium titanium silicide phase (C54 structure), and a metastable TiSi_2 phase (C49, ZrSi_2 structure) which is a precursor to the equilibrium phase. It is interesting to note that the amount of oxygen incorporated into the film in this phase is about 2–4 a/o. This is lower than the amount present in the films deposited in Phase I, and, again, it decreases somewhat after annealing. These films are also less oxidation sensitive than those in Phase I, as seen by a comparison of the Auger depth profile of the as-deposited and annealed films. SEM examination of the surface of these films in Fig. 6 reveals that the grain size is very small. The films appear quite smooth before and after anneal. This is somewhat surprising, since at higher T_s one expects a higher surface mobility and, therefore, larger grains.

Phase III: $450^\circ\text{--}600^\circ\text{C}$.—This range of substrate temperatures is normally unavailable in commercial sputtering systems. Our special heater design allowed us to heat the wafer without heating any other fixtures in the sput-

Fig. 6. SEM micrographs of the surface morphology of a $T_s = 300^\circ\text{C}$ film. a: As deposited. b: After a 900°C , 30 min argon anneal.

Fig. 7. X-ray diffraction of a film deposited at $T_s = 500^\circ\text{C}$. a: As deposited. b: After a 900°C , 30 min argon anneal. The x-ray diffraction trace remains unchanged. It is interesting to note that the (004) peak present is the same feature present at the $T_s = 25^\circ\text{C}$ film which was annealed (Fig. 3).

tering system and thus reduced the amount of degassing taking place. The resistivity of the as-deposited films in this temperature range is the same as for the fully reacted films as seen in Fig. 1. X-ray diffraction of a film

Fig. 8. SEM micrographs of three films deposited at (a) $T_s = 450^\circ\text{C}$, (b) $T_s = 500^\circ\text{C}$, and (c) 600°C . The grain size in this phase is a strong function of substrate temperature.

deposited at $T_s = 600^\circ\text{C}$ in Fig. 7 shows a single peak (004) of the equilibrium type of TiSi_2 (orthorhombic, C54 structure) indicating that the film is crystalline. The absence of other strong peaks suggests that there is a preferred orientation in these films. This feature is unchanged after a 900°C , 30 min argon anneal. TEM studies showed this film to be exclusively of the C54 structure in agreement with the x-ray data. The surface grain size of the films is large, typically $0.6\text{--}0.8\ \mu\text{m}$ and is a strong function of temperature. The higher the temperature, the larger the feature size, as seen in Fig. 8 for $T_s = 450^\circ, 500^\circ,$ and 600°C films. An Auger depth profile of a film deposited at $T_s = 500^\circ\text{C}$ and representative of films in this regime is depicted in Fig. 9. The oxygen incorporation in the as-deposited film is very low and is unchanged after a 900°C , 30 min anneal in argon. The only oxygen present is in the form of SiO_2 on the surface. These films, then, have all the desirable characteristics of a fully reacted film and, in addition, are oxygen free.

Discussion

From the results we have described in the previous section, it is apparent that when we refer to substrate temperatures we are referring to a macroscopic measurement which does not take into account the actual kinetics present on the substrate surface during the sputtering process. The reason is that the formation of fully reacted titanium disilicide films at 500°C is several hundred degrees below typical furnace-reacted, sputter-deposited films. It has been suggested (7) that the high temperature furnace anneals are necessary because of the incorporation of oxygen in the film, which slows down the formation reaction. However, since the system in which these depositions were done had a fairly high oxygen background, as evidenced by the Auger analysis of the low substrate temperature films, the only explanation that could account

Fig. 9. Auger depth profile of a film deposited at $T_s = 500^\circ\text{C}$. a: As deposited. b: After a 900°C , 30 min argon anneal. The striking feature of these films is the absence of oxygen incorporation in the film.

for the observed results is that the surface temperature of the wafer was actually much higher, perhaps several hundred degrees higher, than the macroscopically measured bulk temperature of the wafer. This hypothesis is supported by experiments done on the direct reaction kinetics of a Ti film on Si. It was found that for partially reacted titanium silicide phases there may be a significant amount of oxygen present in the silicide film. As the film is annealed at about 900°C or above, the oxygen is segregated (6) and pushed to the surface (4), where some of it is lost in the form of SiO₂. The remaining oxygen forms an SiO₂ layer on the surface of the TiSi₂ film. As one can see in a comparison of Fig. 2, 5, and 9, the amount of oxygen incorporated in the as-deposited film decreases with increasing substrate temperature. Assuming that the background amount of oxygen stayed constant, the results can be explained on the basis that *in situ* formation of the TiSi₂ excludes the oxygen from the growing film. This is in accordance with results found by other workers (4-6).

It is well known (8) that the species deposited during sputtering have, on the average, higher kinetic energies than in other vacuum deposition techniques such as evaporation or chemical vapor deposition. Furthermore, this kinetic energy is a function of the forward power applied during sputtering. When the sputtered species arrive at the substrate surface, they will transfer part of that kinetic energy to the substrate surface and the chemical species present there. Increased substrate temperature acts in a similar way by increasing the mobility and diffusivity of the substrate surface species. The combination of the two parameters gives rise to an enhanced surface temperature process which we call TEPSI (thermally enhanced plasma surface interaction), which may have consequences for a number of material systems where high bulk substrate temperatures are not desirable.

Further evidence to support the TEPSI hypothesis comes from a different set of experiments. When a titanium film was deposited onto a Si wafer at a substrate temperature of 515°C in the same system, the results was not a Ti film on Si, but a fully reacted titanium silicide film (9), free of oxygen, with a resistivity of about 15 μΩ-cm. This could only be explained using the above TEPSI model. Similar results were seen for Ta and Mo films deposited at T_s = 600°C. We believe that this technique of sputtering films at high substrate temperatures could be used in a variety of other thin film systems.

Summary and Conclusions

We have studied the substrate temperature dependence of titanium silicide films, sputtered from a composite target in the range of T_s = 25°-600°C. We found that at high substrate temperatures, T_s ≥ 450°C, there is enough energy available to the species on the substrate surface to promote the formation of fully reacted titanium silicide films. To explain these results, we hypothesize that the surface temperature of the wafer, during sputtering, is much higher than what the bulk substrate temperature would indicate, and this effect can be used in other material systems where high bulk temperatures are not desirable.

ABSTRACT

Single crystals of BaFX:Eu²⁺ phosphors have been prepared. Optical absorption spectra and stimulation spectra measured with polarized light are in good agreement with each other. The experimental ESR spectra of the F⁻-rich and X⁻-rich undoped BaFX powder phosphors which have been x-rayed coincide with the calculated spectra of F(X⁻) and F(F⁻) centers, respectively. In addition, the decrease of the ESR signal intensity with light exposure is substantially in agreement with the stimulation spectra for each case. It is concluded that the PSL of BaFX:Eu²⁺ phosphors is caused by the liberation of electrons trapped at F centers created by the x-ray exposure.

A new system of computed radiography, Fuji computed radiography (FCR), has been developed. It is based on new concepts and the latest computer technology. This system can eliminate the drawbacks of the conventional film-screen radiography. The basic principle of the system is the conversion of x-ray energy patterns into digital signals utilizing a He-Ne laser scanning of the imaging plate, which consists of photostimulable phosphors (1).

The photostimulated luminescence (PSL) phenomenon was discovered in the middle of the nineteenth century, but it has been almost ignored because of a lack of industrial applications. We have found some materials which exhibit strong PSL (2), of which the europium-activated barium fluorohalide materials, BaFX:Eu²⁺ (X = Cl, Br, I), have the most favorable characteristics for the FCR system. Some characteristics of these are as follows (1).

The PSL emission peaks are located between 385 and 405 nm, while the main peaks of the stimulation spectra are found between 430 and 630 nm. These peaks shift to longer wavelengths as the halogen ion is changed from Cl to I. The response of the PSL intensity to the exposed x-ray energy shows good linearity in the more than 10⁵ range of x-ray dosage.

The lifetimes of these phosphors are listed in Table I. Because of their fast response characteristics, the scanning readout system (like FCR) can be realized.

It is well known that BaFX crystals have the tetragonal structure as PbFCl (P4/nmm;D_{2h}⁷) and that in BaFCl two types of color centers, F(F⁻) and F(Cl⁻), can be created corresponding to trapped electrons in F⁻ and Cl⁻ ion vacancies, respectively (4). The relation of F centers and PSL in these phosphors has not been investigated yet.

In this paper, we show, using the results of optical and ESR measurements, that the PSL of BaFX:Eu²⁺ is caused by the liberation of the electrons trapped at F centers.

Results

Preparation of single crystals.—The single crystals were prepared by the horizontal Bridgman method. Packed in a graphite boat, Eu²⁺-activated BaFX (X = Cl, Br) was heated to 1070°C in a nitrogen atmosphere. The material was then cooled at the rate of 0.2°C/min to 800°C and 1.0°C/min to room temperature. Because of the neighboring halogen ion planes, it is easy to cleave the crystals perpendicular to the c axis, and so it is difficult to make a thick sample. In preparing single crystals, only stoichiometrically F⁻-rich ones were grown well.

Optical measurements.—Optical absorption spectra of an irradiated BaFCl:Eu²⁺ single crystal are shown in Fig. 1a. In the case of the c axis perpendicular to the electric vector **E** of the incident light, the absorption band peaks at about 550 nm. If the c axis is parallel to **E**, the absorp-

Table I. The lifetimes of BaFX:Eu²⁺ phosphors

Sample	Lifetime (PSL) (μs)	Lifetime (UV) (μs)
BaFCl:Eu ²⁺	7.4 ^a	5.7 ^b
BaFCl _{0.5} Br _{0.5} :Eu ²⁺	2.0	1.1 ^b
BaFBr:Eu ²⁺	0.8 ^a	—
BaFI:Eu ²⁺	0.6 ^a	—

^a See Ref. (1).

^b See Ref. (3).

tion peak stands at about 440 nm. These absorption spectra coincide with those of F(Cl⁻) centers in BaFCl single crystals (4). Stimulation spectra of the same sample are given in Fig. 1b, the peaks of which are in good agreement with those of the absorption spectra. In a BaFBr:Eu²⁺ single crystal, the same results have been obtained (see Fig. 2a and 2b).

ESR investigations.—ESR studies on undoped BaFX (X = Cl, Br) powder phosphors have been made to show that color centers created by x-rays are F centers. Undoped materials were used because ESR signals of trapped electric charges become undetectable in the presence of ESR signals of Eu²⁺ ions. The undoped BaFX powder phosphors also show PSL emission whose stimulation spectra are similar to those of BaFX:Eu²⁺ phosphors, although in this case PSL emission was thought to

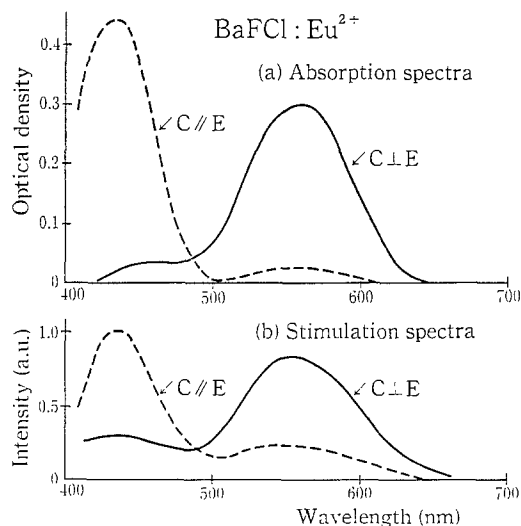

Fig. 1. Optical absorption spectra (a) and stimulation spectra (b) of the x-ray-irradiated BaFCl:Eu²⁺ single crystal.

be due to a trace of contaminated Eu²⁺ ions. Four samples, whose BaF₂/BaX₂ charged ratios are 95/105 and 105/95, X = Cl and Br, respectively, have been prepared to investigate the effect of the chemical composition in BaFX phosphors. In spite of deviating from the 1:1 ratio between BaF₂ and BaX₂ by as much as 10%, the x-ray diffraction patterns of these materials show that they are still substantially single phase (see Fig. 3). The ESR measurements on heavily x-rayed BaFX powder phosphors have been carried out at Q band using a Varian E-109 spectrometer. The ESR spectra of BaFCl (F/Cl = 95/105), BaFCl (F/Cl = 105/95), BaFBr (F/Br = 95/105), and BaFBr (F/Br = 105/95) are shown in Fig. 4 (curves A). These spectra, which decrease under the visible rays, are not observed in BaFX powder phosphors until they are irradiated by x-rays. The decrease of the ESR signal intensity with the light exposure was also measured. The results are shown in Fig. 5 (curves A) for the above samples.

Discussion

In case of F centers in BaFX, only the hyperfine interaction between the electron trapped at the F center and the nearest neighbor barium nuclei should be taken into account. The hamiltonian spin can be written as

$$\mathcal{H} = \beta_e \mathbf{H}(g)\mathbf{S} + \mathbf{I}_k(T_k(\text{Ba}))\mathbf{S}$$

where $(T_k(\text{Ba}))$ and \mathbf{I}_k are the hyperfine tensor and the nuclear spin of the k th Ba nucleus, respectively [k ranges from 1 to 4 for F(F⁻) and from 1 to 5 for F(X⁻)]. Barium has two isotopes of nuclear spins with 3/2, ¹³⁵Ba($g_1 = 0.555$) and ¹³⁷Ba($g_1 = 0.621$), whose natural abundances are 6.6% and 11.3%, respectively. The two other isotopes, ¹³⁶Ba and ¹³⁸Ba, have no nuclear spins (4).

Experimental ESR spectra can be simulated supposing that the hyperfine interaction terms with fluorine and

Fig. 4. The experimental ESR spectra of the x-ray-irradiated BaFCl(F/Cl = 95/105), BaFCl(F/Cl = 105/95), BaFBr(F/Br = 95/105) and BaFBr(F/Br = 105/95) powder phosphors (curves A), and the calculated ones of F(F⁻) centers in BaFCl, F(Cl⁻) in BaFCl, F(F⁻) in BaFBr, and F(Br⁻) in BaFBr, respectively (curves B).

other halogen nuclei will only contribute to the broadening of the hyperfine lines and that microcrystals are oriented in all directions with equal probability in powder samples. The results of the calculation are shown in Fig. 4

Table II. The ESR parameters used to calculate the simulated spectra of F(F⁻) and F(X⁻) centers in BaFX (X = Cl, Br)

Parameter	Phosphor F center	BaFCl		BaFBr	
		F(F ⁻) center	F(Cl ⁻) center	F(F ⁻) center	F(Br ⁻) center
g_{\parallel}		1.985	1.983	1.988	1.980
g_{\perp}		1.970	1.970	1.966	1.980
Linewidth		12G	12G	50G	50G
$A_{\parallel} (^{135}\text{Ba}, k = 1 - 4)$		69G	37G	73G	39G
$A_{\parallel} (^{137}\text{Ba}, k = 1 - 4)$		69G	41G	73G	43G
$A_{\perp} (^{135}\text{Ba}, k = 1 - 4)$		78G	34G	82G	30G
$A_{\perp} (^{135}\text{Ba}, k = 1 - 4)$		78G	38G	82G	34G
$A_{\parallel} (^{135}\text{Ba}, k = 5)$		—	41G	—	43G
$A_{\parallel} (^{137}\text{Ba}, k = 5)$		—	45G	—	48G
$A_{\perp} (^{135}\text{Ba}, k = 5)$		—	38G	—	36G
$A_{\perp} (^{137}\text{Ba}, k = 5)$		—	42G	—	40G

Fig. 5. The decrease spectra of the ESR signal intensity with the light exposure (curves A) and the stimulation spectra (curves B) in the BaFCl(F/Cl = 95/105 and 105/95) and BaFBr(F/Br = 95/105 and 105/95) powder phosphors. I : ESR signal intensity from F centers after the light exposure. I_0 : ESR signal intensity from F centers before the light exposure.

(curves B), and the ESR parameters used in the calculation are listed in Table II, where A_{\parallel} (c axis/magnetic field) and A_{\perp} (c axis \perp magnetic field) represent the hyperfine constant measured at 9.1 GHz. The values for BaFCl were obtained by the simulation based on the data of Yuste *et al.* (4).

Table III. The types of color centers created in BaFX by x-ray exposure

Phosphor	BaFCl (X = Cl)		BaFBr (X = Br)	
	F/X atomic ratio	Color center	F/X atomic ratio	Color center
	95/105	F(F ⁻)	95/105	F(F ⁻)
	105/95	F(Cl ⁻)	105/95	F(Br ⁻)

The coincidence between the experimental spectra and the calculated ones in Fig. 4 implies that color centers created by x-ray exposure in BaFX phosphors are such centers as listed in Table III.

It is shown in Fig. 5 that these centers decrease effectively under the visible radiation that gives rise to efficient PSL. Because of the difference between the exposures of light in the PSL measurement and the ESR, the spectral correlations of these data are not so good. Thus, in BaFX:Eu²⁺ phosphors, PSL emission is caused by the liberation of the electrons trapped at F centers.

Conclusion

In photostimulable BaFX:Eu²⁺ phosphors, F centers can be created by x-ray exposure. When these are irradiated by the visible rays in the F center absorption band, they liberate the electrons and show PSL emission.

Automatic End-Point Detection of Spray Etching in Application to Mask Making

Fumio Mizuno, Makoto Kato, Tooru Koizumi, Yoichi Takehana, and Katsuro Sugawara*

Hitachi Limited, Device Development Center, Kodaira, Tokyo 187, Japan

Keiji Mori

Hitachi Limited, Production Engineering Research Laboratory, Totsuka-ku, Yokohama 244, Japan

The development of high performance LSI's has increased the requirement for precise control of mask making in addition to that of wafer processing. One method for obtaining precise control is "in-process" end-point detection. End-point detection methods have previously been devised for thin film formation, such as thickness control of SOS (silicon-on-sapphire) epitaxial layers (1), homoepitaxial layers (2), and for plasma etching (3). In mask making, "wet etching" has been used due to thin Cr film deposited on mask blanks and to flat surface in comparison with the wafer fabrication. In this note, a novel method of the end-point detection used for the mask making will be reported; it is quite different from that used for the "dry etching."

A schematic diagram of the end-point detection apparatus is shown in Fig. 1. The specimen used in this experiment was an electron-beam resist coated mask blank with a Cr film of 800Å thick and was developed by the spray method. This apparatus consisted of (i) a light source, (ii) a reflector, "corner cube," which reflected the incident light, (iii) a photodetector which detected the reflected light and transduced it to the electric signal, (iv) a photosensor which had a disk with a slit in order to generate a timing signal synchronized with the incident light, and (v) a control circuit which decided the end point by receiving the electrical signal converted from the reflected light. The light source and the photodetector were installed above the mask. The corner cube was used as the reflector to separate the incident and the reflected light. The disk with the slit was attached to the mask holder; the slit was adjusted to be located just above the photosensor when the corner cube was rotated just under the light source. The signal from this photosensor produced the timing signal for the control circuit. The reflected light was converted by the photodetector to an electrical signal, synchronized with the timing signal, and the electrical signal was used to detect the end point.

Figure 2 is a block diagram of the control circuit. The signal generated by the reflected light was first amplified, then sampled at the rate of once per revolution, synchronized by the timing signal, and transferred to an A-D converter. The signal was converted to the digital signal through the A-D converter and processed by an 8 bit microcomputer. Thus, the microcomputer, which judged the end point, gave the control signal to the spray etching apparatus and stopped the etching.

There was approximately 10% fluctuation in the output of the A-D converter at the end of the etching unless further signal processing was done. Therefore, a novel algorithm was devised to obtain accurate end-point detection as shown in Fig. 3. The first step was the moving average process. The output value of the signal, TN_n , at a certain time, n , is given by

$$TN_n = \sum_{i=1}^n V_n/i \quad [1]$$

where V_n is the value of the n th signal before the process and i is the sampling number of data to average, ordinarily 16. Thus, the signal of the reflected light became smoothed. The next step was the differential process. The essential object was to increase the judging accuracy. In our method, the end point was defined as the point at which the reflected light signal reached saturation, and was where the signal difference reached 0. That is, the n th signal converted after the differential process, T_n , is expressed as

$$T_n = (TN_n - TN_{n-1})/\Delta t_j \quad [2]$$

Fig. 1. Schematic diagram of the apparatus to detect the end point during the spray etching of Cr mask.

*Electrochemical Society Active Member.

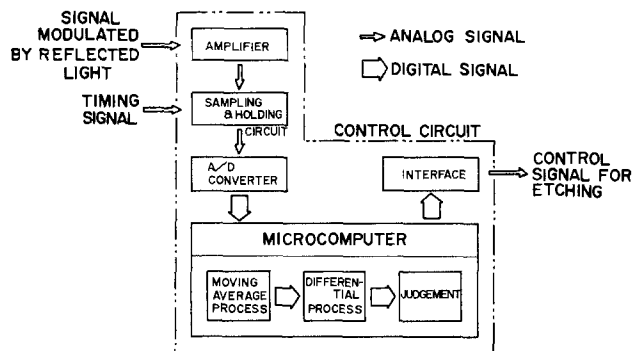

Fig. 2. Block diagram of the control system to judge the end point during the spray etching.

Fig. 3. Data flow to judge the end point during the spray etching

where TN_n and TN_{n-1} are the data after the moving average process at the n th and the $(n-1)$ th signal, respectively; j is the sampling number to be used for the process, and Δt is the interval of the timing signal. Figure 4 shows examples of the data thus treated. Figure 4a is the signal generated by the reflected light, Fig. 4b is the smoothed signal which was treated after Eq. [1], and Fig. 4c is the signal to judge the end point after the differential process using Eq. [2]. The pattern in Fig. 4c shows the sharp peak, which fell to 0 after a few seconds. The spray etching was stopped just after the 0 signal of the end-point detection was sent to the etching apparatus.

For accurate control of mask making using spray etching, a novel method using reflected light from a corner cube to detect the end point of the etching precisely, after smoothing the signal and increasing the accuracy by means of both a moving average process and differential process, was developed. Using this method, the variation of the Cr mask critical dimension after etching could be improved from ± 0.2 to $\pm 0.1 \mu\text{m}$.

Characterization of Epitaxial Layers and Substrate Wafers by Surface Topographic Observation

K. Kugimiya*

Matsushita Electric Industrial Company, Limited, Semiconductor Research Center, 3-15 Yagumonakamachi, Moriguchi, Osaka 570, Japan

The characteristics of polished Si wafer surfaces (1) have been recognized as being very influential to the properties and yields of IC's for a long time. Characterization is carried out by, for instance, Newton ring observation (2), x-ray analyses (3, 4) and optical methods (5, 6). Yet, because of many difficulties, only a few quantitative observations have been made. The optical observation method (7, 8) derived recently from the "Makyo concept" (observation of projected images of mirror surface contours reflecting the surface waviness) has been a very

*Electrochemical Society Member.

powerful tool for the analyses of the topological nature of wafer surfaces. It is a nondestructive, instantaneous, and visual observation method, although a qualitative one. Some of the recent applications, the in-line monitoring of IC processes, and the improvement of the wafer surface quality, are herein briefly summarized.

Experimental

The in-line monitoring (7) was done using a surface monitor ZX-5100 (Matsushita Industrial Equipment Company, Limited) at our laboratory and the production lines. (100) and (111) Si wafers were purchased commercially

from several vendors. After the initial examination of the surfaces, single and cyclic thermal processes (9, 10) were carried out to detect crystal defects hiding behind the apparent deformation at the surfaces. Defects were delineated by the Secco etchant.

The monitor was further applied for optimizing epitaxial Si growth conditions in a barrel-type reactor. Slip lines were observed by the monitor. It was also applied for the improvement of wafer surface quality.

Results and Discussion

Figure 1 shows the various surface deformations of as-received wafers observed by the monitor over a few months. Bright lines and areas correspond to surface concavity and dark lines and areas to surface convexity. Most of observed deformations are polishing/lapping marks (Fig. 1, parts 2, 3, 5, 7, 8), dimples (Fig. 1, parts 1, 5, 9), and back-side damage irregularities (Fig. 1, part 1) and a few scratches (Fig. 1, parts 8, 9), orange peels, protrusions, and some unknown deformations (Fig. 1, parts 2-4, 6, 8). Scratches appearing as dark lines (Fig. 1, parts 8, 9) were made at the front sides (7). The diameters of wafer images indicate the flatness of wafers. A specimen in Fig. 1, part 5 is fairly flat, while a specimen in Fig. 1, part 1 shows concavity and those in Fig. 1, parts 2 and 9 convexity. Skews are also observed in the images. Most of the deformations were clearly made during the processing by wafer vendors, possibly because of the difficulty of achieving perfect process control, *e.g.*, cloths and powders in polishing, dust and air bubbles in pasting, etc. (11).

X-ray topographs of the deformation showed that back-side damage irregularities, scratches, and some of unknown deformations were accompanied by a slight lattice deformation and thus by the residual stresses. However, optical microscopic observation of oxidized and etched wafers showed that most of the deformations were proved to be harmless and some were related with crystal defects (12). A typical example of the stacking fault formation after the dry oxidation at 1000°C for 1h is shown in Fig. 2. Stacking faults revealed by the Secco etching are shown by dots, and their distribution as shown by two gray bands in Fig. 2B is in a fair agreement with lapping marks in Fig. 2A. This clearly indicates that some lapping marks are accompanied by latent mechanical damage. Some specimens with the residual strains, Fig. 1, parts 1, 2, 9 showed an unusual denuded zone formation after cyclic annealing (Fig. 3B). For a wafer with an interstitial oxygen concentration of about $10^{18}/\text{cm}^3$ as used in this

Fig. 1. In-line monitoring of as-received Si wafers. Parts 1-3: left column, top to bottom, respectively. Parts 4-6: middle column, top to bottom, respectively. Parts 7-9: right column, top to bottom, respectively.

experiment, no denuded zone nor microprecipitate formation is usually observed even after the heat cycle of 1100°C O₂ 1% 4h/800°C N₂ 16h/1000°C N₂ 6h (9). Stress-enhanced precipitate formation by Si₃N₄ or poly-Si layers has been observed (13). These stress effects are obviously different and ambiguous, *i.e.*, precipitates are formed with the relaxation of the residual stress in the former while the stresses are present all through the heat cycle in the latter.

The in-line monitoring of the epitaxial Si growth process has been very successful. In a usual technique, slips are, for instance, delineated and observed after etching, a destructive and time consuming process. An abnormal wafer as shown in Fig. 4 clearly reveals the presence of numerous slip lines without destruction. One of the large slip lines is revealed and shown in the circle in Fig. 4 after angle lapping and staining. The surface profiles also shown in the figure clearly point out numerous small steps. Some are of less than 100Å. These small steps of surface curvatures result in dark and bright line images as shown in the figure.

Minor modification and some improvement of polishing and pasting methods in the wafer process resulted in better quality, as shown in Fig. 5. In-line monitoring could still readily pick up any slight change in the wafer process.

GaAs wafers were generally of a very poor surface finish, worse than those shown in Fig. 1. Large residual stresses and distortion were generally observed. The improvement of the wafer process using a surface monitor is now in progress.

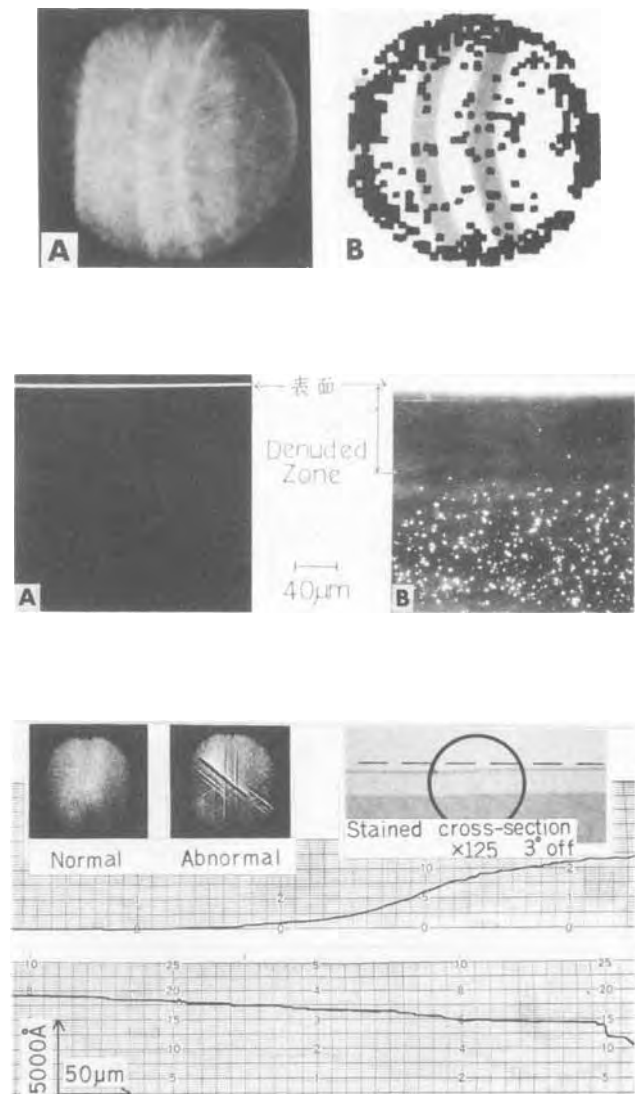

Fig. 4. Monitoring of slip lines formed in the epitaxial process

Fig. 5. Surface regularity after the minor modification in the wafer process. Processes A, B, and C.

Conclusion

It has been shown that the optical method derived from the Makyo concept is simple and nondestructive, and thus suitable for the in-line monitoring of wafers and IC processes. The monitoring could effectively stabilize the wafer surface quality and the epitaxial process. It could also eliminate abnormal wafers with unusual residual stresses. The method can be further applied to minimize slip lines in heat processes and also to analyze mirror surfaces and even lenses.

Since the method can pick up surface deformations, which other flatness testers using the scanning laser or Moire methods can barely detect, the method is complementary to the others. Thus, combined analyses will result in the better characterization of the wafer surface.

Acknowledgments

The author would like to express his thanks to A. Nishikawa for the in-line monitoring of as-received wafers and

M. Matsumoto of Matsushita Electric Industrial Company Limited for the wafer and the yield evaluations in the IC production lines.

Sulfation of CeO₂ and ZrO₂ Relating to Hot Corrosion

R. L. Jones,* S. R. Jones,¹ and C. E. Williams

Naval Research Laboratory, Chemistry Division, Washington, DC 20375-5000

The reactions of SO₂-SO₃ (SO₂ + 1/2 O₂ ⇌ SO₃) with ceria (CeO₂) are of interest in the development of materials for resisting hot corrosion in gas turbine engines. Addition of CeO₂ as a dispersed oxide phase in the metal reduces sulfidation-oxidation attack on nickel-based turbine blade super alloys presumably by reducing the sulfur activity through formation of Ce₂O₃S (1). Ceria appears also to promote hot corrosion resistance in ZrO₂-based ceramics. In material tests for MHD channels, CeO₂-ZrO₂ has shown good resistance to 1200°C K₂SO₄-K₂CO₃ melts (2). And, of more immediate relevance to hot corrosion in gas turbines, plasma-sprayed CeO₂-ZrO₂ has been patented as protecting super alloys against attack by vanadium and SO_x impurities in turbine gas (3).

Ceramic coatings of Y₂O₃-ZrO₂ have been considerably studied as thermal barrier coatings for gas turbines and diesel engines, and reaction with molten vanadates is known to "leach" Y₂O₃ from the ceramic, with resultant rapid degradation of the coatings (4). Perhaps less well known is the fact that the concurrent action of Na₂SO₄ and SO₃ can also cause Y₂O₃ depletion and ceramic degradation under SO₃ partial pressures, e.g., as low as 700 Pa (7 × 10⁻³ atm) at 700°C (5). In a recent investigation of Y₂O₃ and HfO₂ sulfation, we have confirmed the high re-

activity of SO₃ with Y₂O₃ and determined the equilibrium SO₃ partial pressure for the initial sulfation reaction, Y₂O₃(s) + SO₃(g) ⇌ Y₂O₂(SO₄)(s), to be approximately 1.5, 2.5, and 3.5 Pa at 850°, 900°, and 950°C, respectively (6). Mixed sulfates of Y₂(SO₄)₃-Na₂SO₄ were formed when Na₂SO₄ was present, with the system exhibiting a eutectic in the vicinity of 25 mole percent (m/o) Y₂(SO₄)₃ which melted below 800°C. Pure hafnia was strongly resistant to sulfation, and although liquid phase mixed sulfates could be produced by sulfation of 50 m/o HfO₂-Na₂SO₄ mixtures at 700°C, SO₃ partial pressures in excess of 1500 Pa were required.

In the experiments reported here, we have applied the techniques of our Y₂O₃-HfO₂ investigation to study the sulfation behavior of CeO₂ and ZrO₂. Our goals were to determine if CeO₂ is more resistant to SO₃-Na₂SO₄ reaction than Y₂O₃, and if ZrO₂, like HfO₂, is strongly resistant to sulfation (Hf and Zr commonly show similar chemical behavior). The first finding could help to confirm whether CeO₂- or Y₂O₃-stabilized zirconia should be best against molten sulfate hot corrosion, while the second would aid in defining the corrosion resistance of zirconia itself.

Experimental

Our experiments were conducted using controlled gas atmosphere furnaces, described previously (7), wherein

*Electrochemical Society Active Member.

¹Member of the Naval Research Laboratory Ensign Program.

the pure oxides and oxide-Na₂SO₄ mixtures were exposed to low concentrations of SO₂ or equilibrated (over Pt at temperature) SO₂-SO₃ in air at temperatures of 650°-800°C. The incoming SO₂ concentrations were controlled by electronic mass flow controllers, and the furnaces were fitted with analytical trapping systems which allowed determination of the SO₂, SO₃, and SO_x (SO_x = SO₂ + SO₃) concentrations in the exhaust air. Gas control and analyses were within ± 10%, except at high SO₃ partial pressures (> 500 Pa) where sulfuric acid mist formation and SO₃ polymerization reduced accuracy substantially. Furnace temperatures were maintained within ± 5°C.

The specimens were exposed in porcelain boats using 100 mg samples of the oxides and 250 mg samples of the oxide-Na₂SO₄ mixtures which were of 50 m/o composition and taken from thoroughly ground and mixed master stocks. The reagents were of high purity as indicated: CeO₂ (99.9%, Alfa Ventron), ZrO₂ (99.998%, Alfa Ventron Puritronic), Na₂SO₄ (reagent grade, Fisher), and SO₂ (99.98%, Matheson).

Results and Discussion

Catalytic activity of CeO₂.—To understand sulfation reactions, one must know whether the metal oxide reacts predominantly with SO₃, or with SO₂ + 1/2 O₂. Our studies with Co₃O₄, NiO, and ZnO indicate that the 700°C sulfation of these oxides proceeds by reaction with SO₃ (7). This is somewhat difficult to discern with Co₃O₄ and NiO, since both oxides catalyze the reaction, SO₂ + 1/2 O₂ ⇌ SO₃, and sulfation can occur (although at higher SO_x partial pressure) even when the furnace gas contains only SO₂. With ZnO, which is not catalytic, the effect is readily evident, and sulfation occurs essentially only when an external catalyst is present. This can be important, as illustrated, for example, in a study of the sorption of SO₂ from synthetic flue gas by metal oxides where ZnO was found not to sorb SO₂ (*i.e.*, sulfate), even though the thermodynamics were favorable (8).

The catalytic activity of CeO₂ was tested by passing low concentrations (< 30 Pa) of SO₂ in air at 200 ml/min over 100 mg samples of the oxide contained in porcelain boats at 650°C, and analyzing for the SO₂ and SO₃ concentrations in the furnace exhaust air. The SO₃/SO₂ ratio after passing over the CeO₂ was approximately 0.6, whereas with all the conditions the same, except for CeO₂'s absence, the SO₃/SO₂ ratio was near 0.08. Clearly, therefore, CeO₂ catalyzes the SO₃ ⇌ SO₂ reaction.

Equilibrium SO₃ partial pressure for CeO₂ sulfation.—The equilibrium SO₃ partial pressure for the initial sulfation reaction of CeO₂ at 650°, 700°, and 750°C (Fig. 1) was determined following a procedure employed previously (7). By this technique, the weight gain after 24h exposure for individual 100 mg samples of CeO₂ was determined for increasing concentrations of SO₃, and these data points were then plotted and extrapolated to zero weight gain, as shown in Fig. 1, to define the equilibrium SO₃ partial pressure for the reaction. To verify that equilibrium SO₃ was in fact obtained, the sulfated specimens were re-exposed at SO₃ partial pressures below the equilibrium value and shown to revert to the oxide.

The equilibrium P_{SO_3} values obtained in Fig. 1 are 30, 100, and 230 Pa at 650°, 700°, and 750°C, respectively. Assuming the initial sulfation product to be CeOSO₄ (see below), and that there is negligible intersolubility, the standard free energy of the sulfation reaction

can be calculated from $\Delta G^\circ = -RT \ln K$, where taking the solid phase activities as unity, $K = (1/P_{SO_3})$. Estimating the probable error in temperature to be ± 5°, and in SO₃ equilibrium partial pressure to be ± 20%, the standard free energies were calculated as being -62.2 ± 2 , -55.9 ± 2 , and -51.7 ± 2 kJ/mol at 650°, 700°, and 750°C. No standard free energy for reaction [1] exists in the literature for comparison with these values. However, the calculated free energies can be fitted (to within less than the experimental

Fig. 1. Determination of the equilibrium SO₃ partial pressure for sulfation of CeO₂ at the temperatures indicated.

error) over the investigated temperature range to the expression $\Delta G = \Delta H - T\Delta S$, where $\Delta H = -160$ kJ/mol and $\Delta S = -0.105$ kJ/mol-deg. The ΔS so derived can then be compared to data compiled, *e.g.*, by Turkdogan (9) where ΔS ranges from -0.105 for $\text{K}_2\text{O}(\text{s}) + \text{SO}_3(\text{g}) \rightleftharpoons \text{K}_2\text{SO}_4(\text{s})$ to -0.186 for $\text{CdO}(\text{s}) + \text{SO}_3(\text{g}) \rightleftharpoons \text{CdSO}_4(\text{s})$. The ΔS in these reactions presumably results mainly from the incorporation of 1 mol of SO₃ that occurs. The agreement in ΔS thus tends to support the postulated CeOSO₄ sulfation reaction and the measured SO₃ equilibrium partial pressures.

Test for the criticality of SO₃ in CeO₂ sulfation.—Although "equilibrium SO₃ partial pressures for sulfation" were determined above, it cannot be unequivocally shown that the reaction involves SO₃ solely. For non-catalytic oxides such as ZnO, the relative roles of SO₂ and SO₃ can be evaluated by comparing the sulfation behavior with and without the platinum catalyst in the gas stream. When the catalyst is removed, the SO₃ concentration at the oxide surface is greatly reduced and, unless the oxide reacts with SO₂, it will not sulfate even though the total SO_x concentration is as high (or higher) as when sulfation occurred when the Pt catalyst was present. This behavior was clearly evident with ZnO (7).

Conversely, the weight gain (sulfation) with CeO₂ could not be seen to be affected by the presence or absence of the external catalyst even at SO_x partial pressures near the equilibrium value (Fig. 2). This implies either that

Fig. 2. Sulfation of CeO₂ at 650°C with and without the external Pt catalyst present (as a test of whether the sulfation proceeds principally by SO₂ or SO₃ reaction; see text).

CeO₂ reacts as readily with SO₂ as with SO₃, or more likely, that SO₂-SO₃ equilibrium is achieved at the catalytic CeO₂ surface (at least in the initial stages of sulfation) with sulfation then actually proceeding by SO₃ reaction. Unfortunately, however, neither possibility can be proved within the context of the present investigation.

Identification of the CeO₂ sulfation product.—In studies of CeO₂ for desulfurization of hot gases, the sulfation product has been variously identified as CeO₂O(SO₄)₃ (10) or Ce(SO₄)₂ (8). Cerium sulfate has also been proposed (11) to decompose in eutectic sulfate melts according to

and then at higher temperature

To identify the sulfation product in the present experiments, 500 mg samples of CeO₂ were sulfated over long times, with periodic grinding, at 650° and 750°C under SO₃ partial pressures only moderately above the equilibrium SO₃ pressure for sulfation. In each case, the weight gain approached a limiting value of approximately 220-240 mg, as shown in Fig. 3. The theoretical weight gains for total conversion of the CeO₂ to CeOSO₄, to Ce₂O(SO₄)₃, and to Ce(SO₄)₂ are 233, 349, and 465 mg, respectively. Therefore, the gravimetric data indicate that the initial product in the sulfation of pure CeO₂ is most likely CeOSO₄. At higher SO₃ pressures, of course, other sulfates including Ce₂O(SO₄)₃ and Ce(SO₄)₂ could be formed, which might explain the different CeO₂ sulfation products reported.

The sulfation product produced in these experiments gave a characteristic x-ray diffraction pattern having numerous lines (Table I). The pattern is presumably that of CeOSO₄, but no reference pattern for CeOSO₄ exists in the JCPDS Powder Diffraction File or in other x-ray diffraction literature to our knowledge to allow this to be confirmed. The JCPDS file contains a pattern for CeOSO₄ · H₂O (card 12-89) which, like the Table I pattern, exhibits numerous lines, but there appears to be no simple relationship between the two patterns.

Sulfation of 50 m/o CeO₂-Na₂SO₄ mixtures.—Under hot corrosion conditions, Na₂SO₄ is normally found on turbine blades, and sulfation of CeO₂ in the presence of Na₂SO₄ (50 m/o mixtures were chosen arbitrarily) provides a better measure of the potential hot corrosion performance of CeO₂ containing coatings than simply the sulfation of pure CeO₂. Many sulfates form low melting

Fig. 3. Long-term sulfation of CeO₂ at 750°C under an SO₃ partial pressure of ~ 300 Pa. (Powder removed from boat and reground in mortar and pestle at points labeled "Ground.")

mixed sulfates with Na₂SO₄, with phase diagrams that show for temperatures above the eutectic melting point and starting at 100 m/o Na₂SO₄, first a single-phase region of MSO₄-Na₂SO₄ solid solution, then a narrow region of solid solution-liquid solution coexistence, and then a single-phase region of MSO₄-Na₂SO₄ liquid solution. The single-phase regions have two degrees of freedom, and therefore, at fixed temperature the solution composition will be a function of the SO₃ partial pressure.

Figure 4 shows representative results from experiments where 50 m/o CeO₂-Na₂SO₄ specimens were exposed over

Fig. 4. Equilibrium Ce(SO₄)₂-Na₂SO₄ compositions obtained in the 700° and 800°C sulfation of 50 m/o CeO₂-Na₂SO₄ at the SO₃ partial pressures indicated. Note that liquid sulfate phases were produced at 800° but not 700°C.

long periods (some > 168h) until they reached constant weight (equilibrium composition) at the temperatures and SO₃ partial pressures indicated. Since hot corrosion is generally considered to become aggressive only when molten sulfates are formed, attention was focused on determining the conditions under which molten phases were generated in the CeO₂-Na₂SO₄ sulfation. [Note: although not determined by analysis, Ce(SO₄)₂ is assumed to be the CeO₂ sulfation product in Na₂SO₄ by analogy with other systems (6, 7) where direct oxide sulfation yields the oxysulfate, but sulfation in Na₂SO₄ gives the sulfate.] No molten phases were observed at 700°C for compositions up to 39 m/o Ce(SO₄)₂. The large composition change for small increase in P_{SO₃} shown by the first two 700°C data points may indicate transition across a region of coexistence of two solid phases; there is (at constant temperature) a fixed equilibrium P_{SO₃} for such a region, and even slight increases above this P_{SO₃} will cause the sulfate composition to change from the lower to upper limit of the region. At 800°C, molten phases were clearly visible when the specimen boats were withdrawn from the furnace in the runs giving 21 and 31 m/o Ce(SO₄)₂ formation (Fig. 4). It appears, therefore, that Ce(SO₄)₂-Na₂SO₄ forms a eutectic which melts below 800°C (but probably above 700°C) and has a composition somewhat greater than 20 m/o Ce(SO₄)₂.

The Y₂(SO₄)₃-Na₂SO₄ system exhibits a similar eutectic melting below 800°C and with a composition of ~ 25 m/o Y₂(SO₄)₃ (6). For Y₂O₃ vs. CeO₂ hot corrosion performance, however, the important point is not so much the composition of the eutectic, or even the identity of its components, but rather the SO₃ partial pressure required for molten phase generation. As Fig. 4 shows, this is 100-150 Pa of SO₃ for CeO₂-Na₂SO₄ at 800°C whereas Y₂O₃-Na₂SO₄ forms liquid phases under > 5 Pa of SO₃ at the same temperature (6). Assuming other factors to be equal, CeO₂ thus should be significantly superior to Y₂O₃ as the stabilizer in ZrO₂ coatings intended to withstand SO₃-Na₂SO₄ hot corrosion.

Sulfation of 50 m/o ZrO₂-Na₂SO₄ mixtures.—Zirconia alone, like HfO₂ (6), was found to resist sulfation at 700°C at SO_r partial pressures as high as 3000 Pa (N.B., the partial pressures are reported here as SO_r because of the difficulty in analyzing for SO₃ at such high concentrations; the external Pt catalyst was used, however, and the SO₃ concentrations should presumably be near equilib-

rium, i.e., ~ 1/2 of SO_r). In the presence of Na₂SO₄, ZrO₂ could be sulfated and liquid phases formed, although high SO_r partial pressures were required (Fig. 5). The sulfation behavior in Fig. 5 is very similar to that shown with 50 m/o HfO₂-Na₂SO₄ (6). Both the HfO₂- and ZrO₂-Na₂SO₄ systems are noteworthy in that while they each yield mixed sulfates with eutectic melting below 700°C, the extent of sulfation appears not to become significant (at 700°C) except above SO_r partial pressures of ~ 1000 Pa. This suggests that ZrO₂ (and HfO₂) should have good inherent resistance to hot corrosion by SO₃-Na₂SO₄ attack.

Conclusions

With increasing P_{SO₃}, the first sulfation reaction of CeO₂ with SO₃ is

with ΔG° for reaction over the temperature range 650-750°C given by ΔG° = -160 kJ/mol - T (K) (-0.105 kJ/mol-deg).

Sulfation of CeO₂ in the presence of Na₂SO₄ yields a Ce(SO₄)₂-Na₂SO₄ mixed sulfate system with a eutectic melting below 800°C. An SO₃ partial pressure of 100-150 Pa is required for liquid sulfate phase formation in the Ce(SO₄)₂-Na₂SO₄ system at 800°C.

The sulfation behavior of Y₂O₃ vs. CeO₂ may be compared to indicate their potential 650-850°C hot corrosion resistance when used as stabilizing additives in ZrO₂-based ceramic coatings for gas turbine blades. Extrapolation of the thermodynamic data for Eq. [1] predicts the equilibrium SO₃ partial pressure for sulfation of CeO₂ at 850°C to be ~ 1200 Pa, whereas for Y₂O₃ it is only ~ 15 Pa (6), or nearly 10³ lower. Similarly, the SO₃ partial pressure for liquid phase formation in the sulfation of Y₂O₃-Na₂SO₄ at 800°C is < 5 Pa (6), or approximately 10² lower than for liquid phase production with CeO₂-Na₂SO₄ at the same temperature. Thus, all other factors being equal, CeO₂ should be superior to Y₂O₃ for improving the hot corrosion performance of zirconia coatings.

Zirconia is substantially more resistant to SO₃-Na₂SO₄ attack than either Y₂O₃ or CeO₂ and remains essentially unsulfated at SO_r partial pressures of 1000 Pa (~ 500 Pa of SO₃) at 700°C. The limiting factor in hot corrosion performance appears therefore to lie not with ZrO₂, but rather with the elements used for stabilizing additives.

Acknowledgments

This research was sponsored under the NAVSEA Program for Development of Advanced Marine Gas Turbine Materials, and the support is gratefully acknowledged. We wish also to thank Dr. C. Vold of NRL who aided us in the x-ray diffraction study of the CeO₂ sulfation product.

Interest in III-V compound semiconductors has increased rapidly in recent years due to the advances in both optoelectronics and GaAs IC technology. In contrast to silicon technology, where dislocation-free substrates are available, III-V technology suffers from the lack of homogeneous, dislocation-free substrates. To study the fabrication and growth processes of such materials, it is, therefore, necessary to characterize the distribution of crystalline defects, especially dislocations in the GaAs or InP substrates. Many methods are available for defect characterization, including x-ray topography and preferential etching. However, x-ray topography requires long exposure times, and is, therefore, time consuming. Preferential etching is destructive since it destroys the surface of the substrate and often exhibits artifacts not representative of crystalline imperfections. Another particularly elegant technique to study dislocations is cathodoluminescence (1, 2). Dislocations are revealed by cathodoluminescence due to the presence of nonradiative centers at the dislocation. The cathodoluminescence efficiency varies for the different positions of the electron beam on the sample.

The experimental apparatus usually used for cathodoluminescence (CL) consists of an electron-emission system and a monochromator for analysis of the wavelength of the emitted light, with corresponding photon counting electronics (1, 2). The disadvantage of this experimental setup is that it exhibits poor sensitivity, and therefore requires very high primary beam currents and/or low temperature stage to increase the nonradiative lifetime. Recently, silicon photodiodes have been placed inside the chambers of a scanning electron microscope (SEM) to serve as a wavelength integrating detector (4-6). In this paper, we present an improved detection scheme utilizing a photodiode located in the position usually occupied by a solid-state backscattered electron detector in the SEM. This detection scheme offers very high collection efficiency. Consequently, low primary beam currents can be used at room temperature for satisfactory CL images. These advantages thus make cathodoluminescence easy to use and increase the fields of potential application.

Experimental

The detection arrangement utilized in the present experiment is shown in Fig. 1. A donut-shaped Si detector is positioned on the pole piece of the objective lens in the SEM. The detector consists of a single-crystal silicon wafer with a 5 mm hole drilled in the middle to allow the passage of the electron beam. The wafer is then masked, and a p-n junction is diffused to act as a photodetector. The mask is designed in a way to fabricate four separate diodes in a quadrand arrangement. A similar detector is commercially available from GW Electronics, Incorporated

(Norcross, Georgia), for backscatter imaging. However, the surface of the backscatter detector is coated with aluminum in order to reject cathodoluminescence. A disk-shaped glass cover with a 5 mm hole in the center is attached in front of the cathodoluminescence detector to reject any backscattered electrons. This is necessary, since the backscattered electrons of the primary beam energy would penetrate the silicon, and create a signal by scattering and creation of electron-hole pairs. The backscatter signal would obscure the CL signal. The glass protection is coated with approximately 50 nm of sputtered indium-tin oxide to prevent charging and subsequent deterioration of the resolution. The output of each diode is amplified separately, summed to the other signals, and displayed on the CRT.

For amplification and summation, we used a standard Type 30 Backscatter Electron Detector System manufactured by GW Electronics, Incorporated. The output of the detector is connected directly to the auxiliary CRT input of the microscope. The capacitance of the detector diodes is small enough to allow operation at 2 MHz, half of the TV rate. Due to the geometrical arrangement of the detector, most of the light emitted into the upper hemisphere can be detected.

Results

Figure 2a represents an enlargement of a reflection x-ray topograph of a semi-insulating GaAs wafer grown by the liquid encapsulated Czochralski (LEC) method. Dark regions correspond to disruptions of the periodic lattice, *i.e.*, dislocations or dislocation clusters. Figure 2b is the cathodoluminescence image of the same area imaged with the above-described detector. The image is recorded at a working distance of 15 mm and a sample cur-

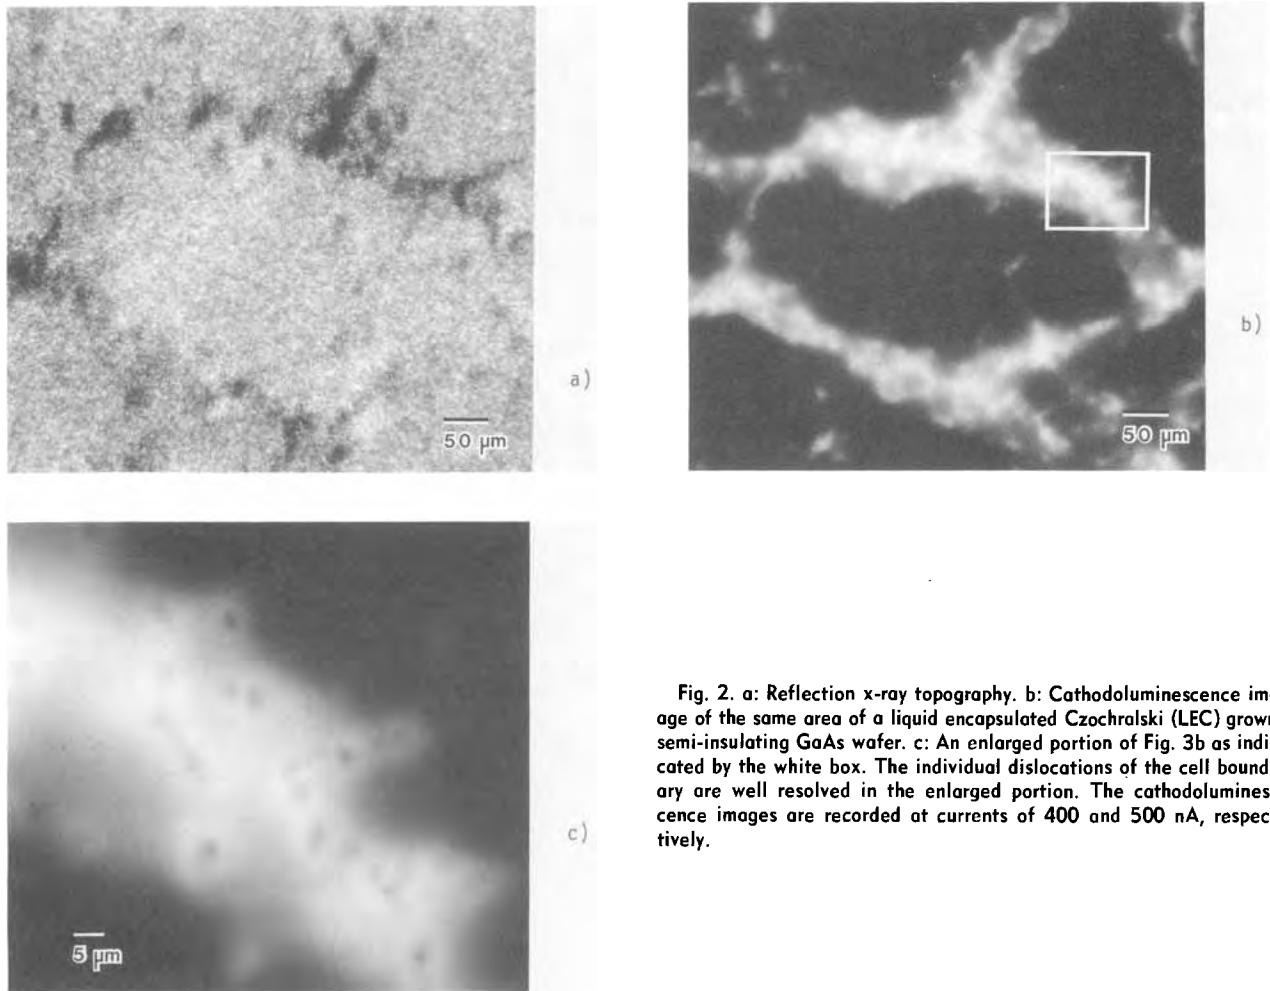

Fig. 2. a: Reflection x-ray topography. b: Cathodoluminescence image of the same area of a liquid encapsulated Czochralski (LEC) grown semi-insulating GaAs wafer. c: An enlarged portion of Fig. 3b as indicated by the white box. The individual dislocations of the cell boundary are well resolved in the enlarged portion. The cathodoluminescence images are recorded at currents of 400 and 500 nA, respectively.

rent of 400 nA. No degradation of the sample is observed at this current level. The cathodoluminescence signal shows excellent correlation to the structure revealed in the topograph. The dislocations are clustered in cell walls, leaving almost dislocation-free cell interior (5, 7). The dislocations in cell walls are clearly resolved, as an enlarged portion of the cell structure reproduced in Fig. 2c demonstrates. These images suggest that the dislocations and dislocation clusters getter the nonradiative impurities through the Cottrell effect in the adjacent volume. Every dislocation is therefore surrounded by a

bright Cottrell cloud (7). For LEC, GaAs cathodoluminescence yields better resolution than reflection x-ray topography. At the same time, the image collection is much more rapid than x-ray topography. SEM images are recorded within minutes, while the x-ray topography technique requires several hours.

As a second example, a cathodoluminescence as well as quasi backscatter image of an AlGaAs double-heterostructure are reproduced in Fig. 3. The quasi backscatter image is obtained by switching off the accelerating voltage of the scintillator. The quasi backscatter image re-

Fig. 3. a: Quasi backscatter electron image of slip dislocations in a AlGaAs heterostructure grown by LPE. b: Cathodoluminescence image of slip dislocations in a AlGaAs heterostructure grown by liquid phase epitaxy. Both images are recorded at the same position of the sample and the same beam conditions. The specimen current is 3 nA.

veals only a diagonal wavy structure of the surface due to the growth by liquid phase epitaxy (LPE) as well as some remaining debris. The cathodoluminescence image in Fig. 3b exhibits a dense array of dislocations. The image pair of Fig. 3 is recorded on a part of the sample close to the wafer edge. Slip dislocations are introduced probably by the thermal stress. The penetration depth of electrons in GaAs at 30 keV is approximately $3 \mu\text{m}$ (8). The cathodoluminescence signal originates in the volume defined by the penetration depth and the diffusion length of the excited carriers in the semiconductor. The dislocations therefore appear diffused. Any surface debris is imaged very sharply in contrast to the defects inside the material. This difference in the image formation mechanism is specially observed in the middle of the lower part of the image, where five particles of debris align very closely. At 30 kV accelerating voltage, a specimen current of only 3 nA is needed to obtain such contrast.

Conclusions

In summary, a new detection scheme for cathodoluminescence has been presented which utilizes a large area photodiode attached to the objective pole piece of the scanning electron microscope. Due to the geometrical arrangement, the emission in almost all of the upper hemisphere is detected. Cathodoluminescence images at room temperature are recorded at specimen currents as low as 3 nA in the case of AlGaAs heterostructures. The detector

operates at half of the TV rate resulting in good visual images. The high collection efficiency should enlarge the application possibilities of cathodoluminescence to include materials with low cathodoluminescence efficiency and/or high electron beam sensitivity.

Lithium Insertion in $V_3Nb_9O_{29}$. A Wadsley-Roth Type Phase

E. Wang, N. Kimura, and M. Greenblatt

Department of Chemistry, Rutgers, The State University of New Jersey, New Brunswick, New Jersey 08903

Compounds which can reversibly incorporate lithium atoms into their structure are of interest because of their potential use as cathode materials in secondary batteries. Recently Cava et al, reported on the lithium insertion reactions of Wadsley-Roth type phases (1-3). These compounds are oxide crystallographic shear structures which form with stoichiometries between MO_3 and MO_2 . The structures can be described in terms of blocks of corner sharing MO_6 octahedra which are finite in two out of three dimension, and are joined to adjacent blocks by edge sharing. Thus there are $n \times m \times \infty$ ReO_3 -type units, where n and m are the length and width of the blocks. The structures display open tunnel like regions (which can accommodate small cations) bound by extensive MO_6 octahedra edge sharing. It has been shown that some crystallographic shear is required to stabilize ReO_3 -type structures upon lithium insertion (4).

$V_3Nb_9O_{29}$ is made up of $4 \times 3 \times \infty$ ReO_3 type blocks (Fig 1) with relatively large

Figure 1. Idealized projection of the $4 \times 3 \times \infty$ block structure of $V_3Nb_9O_{29}$ along the $[010]$ direction. Shaded and unshaded octahedra are centered at $z = 1/2, 0$ respectively, resulting in edge sharing along the block perimeters.

proportion of ReO_3 like regions. This suggested a good combination of structural stability and sufficient interstitial volume for reasonable lithium insertion stoichiometries.

EXPERIMENTAL

$V_3Nb_9O_{29}$ was prepared by heating stoichiometric mixtures of V_2O_5 , VO_2 and Nb_2O_5 powders in sealed, evacuated quartz tubes at $1000^\circ C$ for 1 week. Chemical lithiation of the product was carried out by treatment with $\sim 1.5N$ n -butyllithium (n -BuLi) in hexane. The amount of lithium inserted was determined by acid base titration of the excess n -BuLi and by plasma emission spectroscopy of the lithiated product. Delithiation reactions were carried out on the lithium inserted compound with $\sim 0.1N$ iodine in acetonitrile (I_2/CH_3CN). The amount of I_2 reacted was determined by titration of the excess with standard thio-sulfate solution.

$V_3Nb_9O_{29}$, its lithium-inserted and delithiated analogues were identified by powder X-ray diffraction using Ni filtered Cu radiation.

Small electrochemical test cells (5) were fabricated using $V_3Nb_9O_{29}$ mixed with 15 weight percent graphite as cathode, Li metal foil as anode and $1M LiClO_4$ in propylene carbonate (PC) as electrolyte.

RESULTS AND DISCUSSION

Chemical lithiation of $V_3Nb_9O_{29}$ (brown) by treatment with n -BuLi/hexane for \sim a week with mechanical stirring yielded $Li_{13.6}V_3Nb_9O_{29}$ (black); ~ 1.2 Li/metal. The electrochemical reaction yielded stoichiometries similar to that obtained by the n -BuLi reaction. Open circuit voltages of a test cell as a function of lithium composition (x), is shown in Fig. 2.

Powder X-ray diffraction patterns of the lithiated compound and the starting material are quite similar as shown in Table I, but with substantial changes in the unit cell parameters. The cell parameters of

$\bar{2}03$	3.577	3.577	50	3.521	3.522	100
600	3.402	3.401	60	3.438	3.438	100
112	2.977	2.972	20	2.858	2.863	25
$\bar{7}12$	2.880	2.880	20	2.746	2.744	50
$\bar{1}13$	2.799	2.802	15	2.712	2.701	45
800	2.548	2.551	20	2.576	2.579	20
$\bar{1}006$	2.361	2.353	25	2.301	2.304	20
$\bar{1}007$	2.050	2.050	25	2.058	2.056	40
1000	2.042	2.041	95	2.015	2.013	45

$V_3Nb_9O_{29}$ are: $a = 28.3\text{\AA}$, $b = 3.81\text{\AA}$, $c = 14.1\text{\AA}$ and $\beta = 133.2^\circ$ (Ref.4), compared to that of $Li_{13.6}V_3Nb_9O_{29}$: $a = 28.68\text{\AA}$, $b = 4.118\text{\AA}$, $c = 14.35\text{\AA}$ and $\beta = 134.6^\circ$, which was obtained by least-squares fit to the observed powder x-ray data. There is a significant (8.4%) increase in the b axis, parallel to the infinite dimensions of the ReO_3 type blocks; similar results have been observed in other Wadsley-Roth phases on lithiation (1-3). It is probable that part of the observed unit cell dimension increase on lithiation is associated with increase in the effective ionic radii in reducing Nb^{5+} to Nb^{4+} and V^{5+} to V^{4+} and V^{3+} . The similarity of unit cell dimensions and x-ray powder pattern intensities of the lithiated and host materials respectively, suggest that there has not been extensive distortion of the host lattice on Li insertion. Delithiation of the fully lithiated phase by I_2/CH_3CN restores the

Figure 2. Open-circuit voltage vs x for $Li|1M LiClO_4, PC|Li_xV_3Nb_9O_{29}, graphite$.

original color and X-ray pattern of the host compound. Furthermore, the shape of the emf curve Fig 2. also supports occurrence of topotactic lithium insertion and suggests a continuous homogeneous single phase region at least up to $x = 13$ in $Li_xV_3Nb_9O_{29}$. One cycle of the electrochemical test cell showed very small difference in the emf between charge and discharge curve indicating good reversibility of lithium insertion.

Qualitative measurement of the electrical resistivity at room temperature on pressed powder pellets showed a drastic decrease of resistivity from $\sim 1M\Omega$ for $V_3Nb_9O_{29}$ to $\sim 40\Omega$ for $Li_{13.6}V_3Nb_9O_{29}$. The significant increase in the conductivity of the lithiated phase is most likely due to the presence of small concentrations of mixed valent V^{4+}/V^{5+} , V^{4+}/V^{3+} , Nb^{5+}/Nb^{4+} transition metal ions that facilitate charge hopping.

The theoretical energy density of the $Li/V_3Nb_9O_{29}$ cell based on the n-BuLi stoichiometry of 1.2 Li/metal is approximately 441 Whr/kg which is comparable to those of other cells that are considered for application for lithium secondary batteries.

In summary, $V_3Nb_9O_{29}$ a Wadsley-Roth type phase undergoes lithium insertion reversibly to $Li_{13.6}V_3Nb_9O_{29}$ at room temperature and shows promise as a feasible electrode material for secondary lithium batteries.

A Percolation Model for Electrocatalysis on Microparticle Electrodes

D. C. Wright and D. Stroud

Department of Physics, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

We present a general percolation model for electrocatalysis by microparticles dispersed in a nonconducting film on a conducting substrate. The model addresses the problem of charge transfer between microparticles and the requirement of large effective catalytic surface. A characteristic peaked curve of effective catalytic surface area per microparticle *vs.* the microparticle concentration is found in computer simulations. The behavior of the electrode as a function of various experimental parameters is discussed.

Recent work has shown it is possible to improve significantly the efficiency of certain redox reactions by coating the electrode surface with thin films of microparticles dispersed in a supporting matrix. Examples include platinum and palladium microparticles suspended in nonconducting polymer films or clay colloids on metal and glassy carbon electrodes (1-5) and in polymer films on p-type semiconductor photocathode surfaces (6-10). Because of their high catalytic activity and stability, these systems appear promising for various practical applications, such as fuel cells.

The microparticles in these systems are believed to act as catalytically active centers for the reaction. This means they must be accessible to the electrolyte and be in electrical contact with the electrode supporting the film. An optimum catalytic system would then maximize the surface area of the microparticles, with the constraint that a large fraction of them form part of a conducting pathway to the electrode.

We present here a simple model for microparticle electrodes with nonconductive supporting matrix, based on a variation of the standard percolation picture (11-13), which includes two important aspects of the problem: charge transfer to the microparticles from the electrode and the amount of effective catalytic surface. We investigate the optimum loading of microparticles and the optimum thickness of the film, both of which are important experimentally.

The model does not depend on details of the supporting matrix, and should therefore be generally applicable to a range of systems with minor modifications. We do assume that the microparticles are roughly spherical and are distributed randomly throughout the film, and that the limiting factor for the reaction is the amount of effective catalytic surface area and not the rate of chemical transport through the film. In particular, we are concerned here with the geometrical restrictions imposed by the requirements of electrical conductivity through the microparticles. We believe it is essential to understand these effects before transport effects are considered in detail (although transport effects will doubtless also be important and should be included in a complete theory).

Another, somewhat related example in which connectivity and surface area are important is porous Vycor glass. Porous Vycor is made by embedding small grains of a soluble material in liquid glass and then chemically leaching out the grains after the glass has solidified. This

process leaves a convoluted network of pores throughout the system. If a large fraction of the pores intersect to form a pathway connected to the exterior of the glass, this process results in an extremely large surface area which is available for adsorbing gases, etc. This example is in a sense the complement of the first, since the microparticles in the microparticle electrodes play a similar role to that of the pores in Vycor.

For definiteness, we will specifically consider the case of platinum (Pt) microparticles (or "crystallites"), which provided the original motivation for this work. The ideas underlying the microparticle electrode are quite simple. A nonconducting film of thickness t is laid down on a supporting electrode and is seeded with Pt. The seeding is presumed to occur at random positions throughout the polymer. The seeded regions are then allowed to accrue Pt by electroreduction of platinum salts until the microparticles have grown to the desired size.

The redox reaction can take place only if electrons can reach the Pt from the electrode, and if the reactants can reach the Pt from the electrolyte solution above the film. Electron transfer between the microparticles presumably occurs in two ways: by direct contact between crystallites, and by hopping between crystallites which are sufficiently close. Those crystallites sufficiently near the bottom of the film are in electrical contact with the electrode. All crystallites which are electrically connected to the electrode by at least one route are said to belong to the "effective network." Since electron transfer from the electrode is necessary for the reaction to occur, only the surface area of the Pt crystallites belonging to the connected network is available for catalysis. We shall refer to that surface area simply as the "effective surface" of the system.

The catalytic properties of the system are maximized by maximizing the total effective surface of the platinum. However, since Pt is expensive, the more relevant figure of merit for the electrode is the "effective dispersion," or the effective catalytic surface per particle

$$D = S/M \quad [1]$$

where S is the effective surface and M is the total mass of Pt in the supporting film. D differs from the usual quantity known as "dispersion" only in that S includes only that surface area electrically connected to the electrode, rather than the total surface. Optimum efficiency of the catalyst system is expected near the percolation thresh-

old, since at that concentration of metal a large fraction of the crystallites becomes part of a conducting cluster, while the cluster contains many branches giving a large surface area per volume of Pt added. At higher Pt concentrations, the cluster becomes less branched and D is expected to decrease.

We turn now to the body of the paper. The following section gives a qualitative picture of how the catalytic efficiency is expected to vary with experimental parameters, based on these ideas. We then present a specific lattice model and in the final section describe the results of computer calculations using this model.

Review and Application of Percolation Theory

Some of the main features of the microparticle electrode can be understood from percolation theory, the relevant results of which we briefly review here. [For a more extensive review, see, e.g., Ref. (11) and (12).] We also discuss below how these results are modified when surface area is relevant.

To illustrate the main results of percolation theory, we consider a regular lattice, whose sites can be "occupied" or "unoccupied" at random with probabilities p and $1 - p$, respectively. Each occupied lattice site is considered to be connected to all occupied nearest neighbor sites. (This version is known as "site percolation," to be distinguished from "bond percolation," in which the bonds are occupied or empty at random.) Groups of occupied sites which are connected together are called "connected clusters," and percolation theory is concerned, among other things, with the growth of these clusters as p increases. At low p , the clusters are small and isolated from one another. In the limit of a system which is very large in all directions, the "percolation threshold" p_c is defined by the appearance of a connected cluster which reaches from one edge of the lattice to the opposite edge, the so-called "incipient infinite cluster" (IIC). Various properties associated with the formation of the IIC are characterized by power law dependence (13) on the variable $(p - p_c)$; this behavior accounts for much of the interest in the subject.

For example, $P(p)$, the fraction of all occupied sites which belong to the infinite cluster when the occupation probability is p , is found to vanish at $p = p_c$; while for p just greater than p_c , $P(p)$ is found numerically to vary as

$$P(p) \propto (p - p_c)^\beta \quad [2]$$

where β is a critical exponent which is independent of lattice type and is the same for site and bond percolation. It is also the same for nearest neighbor or farther neighbor percolation models. (It does, however, depend on whether the underlying lattice is two or three dimensional.) The value of β in three-dimensional samples is about 0.2, indicating that just above p_c the fraction of grains belonging to the infinite cluster grows very rapidly from zero.

In contrast to β , the value of the percolation threshold p_c is not universal, but depends on details of the model. For most three-dimensional lattices, p_c is surprisingly low, typically between 0.1 and 0.2; p_c is even lower if connections are allowed between a central site and further neighbors.

The behavior of connectivity described by percolation theory is clearly important in the catalysis problem because of the requirement of electrical connectivity between the Pt microparticles. "Connected" thus translates to "electrically connected" for the electrode case. However, in the catalysis problem, the quantity of interest is not the fraction of Pt particles in the infinite cluster, which connects opposite faces of the sample, but rather the total number of particles connected to one face (the electrode).

The qualitative behavior of the effective surface per microparticle (the effective dispersion D) can be deduced from the percolation results. At low Pt concentrations, most crystallites are isolated and cannot contribute to the effective surface. When the microparticle concentration increases, the crystallites begin to form connected clus-

ters and more of them become connected to the electrode. As the concentration increases above the infinite sample percolation threshold p_c , the effective surface area is expected to increase abruptly as a large fraction of the crystallites becomes part of the connected network. However, the effective surface per crystallite soon begins to decrease for two reasons. First, as p (the filling fraction of metal) increases beyond p_c , more and more grains intersect, obscuring each other's surface area. The connected network, in other words, becomes less and less highly branched. Second, at sufficiently high p , the supporting matrix will begin to form isolated pockets which are entirely surrounded by platinum and therefore cannot be reached by the reactants (that is, the concentration begins to approach the percolation threshold of the matrix). The Pt surface bounding this trapped pocket cannot take part in the reaction and becomes ineffective.

Thus, the Pt concentration must be sufficiently large that many crystallites belong to the connected network, but not so large that the effective surface is decreased by excessive contact between neighboring crystallites, or by the formation of isolated pockets of matrix. The effective surface area per Pt microparticle viewed as a function of Pt concentration is, therefore, expected to be fairly sharply peaked just above the percolation threshold of the crystallites.

Although this picture is constructed for a particular geometry, namely a solid electrode with a microparticle-film catalyst above it, similar effects are expected in quite different contexts. For Vycor, the percolation threshold once again plays an important role in determining the surface activity. Clearly, enough pores must be present to form a large connected network, but if the pore volume fraction is too large, the pore cluster will become less convoluted and the available area of the glass will fall dramatically. For Vycor, however, it is probably the total effective surface area, rather than D , which is relevant.

Lattice Model

To demonstrate the effects just described, we model the supporting matrix as a three-dimensional lattice of N layers, each of $R \times R$ sites, which can be occupied randomly by Pt crystallites (see Fig. 1). While the Pt microparticles in the actual electrode obviously do not sit on a lattice, the presence of the underlying regularity is expected to have little effect on our results (14). In our model, the sites are assumed to be occupied with probability p , and a rule is imposed to determine if nearby occupied sites are to be considered electrically connected. Another rule is neces-

Fig. 1. Schematic of composite film geometry discussed in the text. The film is shown in an edge view. In this schematic, it is four layers thick, and is modeled as a set of cubes, which may be occupied either by Pt (darkened squares) or polymer, randomly distributed on the sites of a periodic lattice, as shown (other models are discussed in the text). The carbon substrate acts as a donor of electrons, which can be transported through those metal particles which are electrically connected to the substrate as discussed in the text. The polymer is assumed permeable to the electrolyte, so that chemical reactions can take place on the polymer-Pt interface.

sary to determine by how much the presence of nearby crystallites reduces the surface available for catalysis. This reduction is assumed to result from direct contact between crystallites. Specifying these rules is equivalent to assuming a size and shape for the crystallites. For convenience we assume that all crystallites throughout the sample have the same size and shape; in particular, we take them to have the shape of the Wigner-Seitz cell for that lattice. (The Wigner-Seitz cell is the polyhedron bounded by planes which perpendicularly bisect lines drawn from a lattice point to all other lattice points). The results of the model are independent of the crystallite size, which is determined by the lattice spacing.

The simplest lattice we have considered is simple cubic (SC), which leads to cubic crystallites (six faces). This is a somewhat unappealing choice for a realistic composite, in which the grains probably more closely approximate spheres, since the number of possible n th nearest neighbors a grain can have is a rather important property in models of connectivity, and is considerably smaller for cubes than for spheres. We have, therefore, carried out most of our calculations on face-centered-cubic (FCC) lattices, whose rhombic dodecahedral crystallites (12 faces) more closely approximate spheres. We have considered connections not only between nearest neighbors, but also, in some of our calculations, between second and third shells of neighbors. These further neighbor connections model the physical fact that electron transfer may occur between microparticles which are sufficiently close to one another but are not in direct physical contact, and which therefore do not reduce the effective surface. While the actual composite is certainly more complicated than our idealized model, the model does include the two effects we believe to be of principal importance: connectivity between microparticles and the reduction of effective surface by the presence of neighbors.

Modeling the crystallites to have flat faces permits us to calculate the reduction of effective surface area in a direct way. If two nearest neighbor sites are occupied, we assume the crystallites are in contact along a face, so that the common faces are rendered unavailable for catalysis. If we allow more distant neighbors to be in electrical contact, we assume that no surface area is obscured by this contact. (The Wigner-Seitz cells of second and further neighbors have, at most, an edge in common.) We shall find that the effective surface area per microparticle is rather insensitive to the assumed crystallite shape.

The occupied sites in the lowest layer of the film are taken to be in electrical contact with the electrode on which the film sits. All microparticles electrically connected to one or more of these sites form the effective catalytic network (the "connected network"). The surface area of the connected network is found by summing up the effective surface areas of all the crystallites in the network.

The relevant figure of merit for this reaction is the quantity D (the lattice version of D), defined as the ratio of the total effective surface of the connected network, S , to the total number of occupied sites, whether or not they are part of the connected network. In addition, it is convenient to divide by the surface area per crystallite. This ratio is clearly appropriate, since the catalytic potential depends on the effective surface, while the cost is proportional to the number of occupied Pt sites.

Results

The results of computer simulations on an FCC lattice with N layers of 40×40 sites are shown in Fig. 2-4. We plot here D , the average fraction of surface area per crystallite which is available for catalysis. In all three cases, the sites of the lattice are occupied at random. These plots show the results of individual runs on the computer; details of the curve shapes may vary slightly from run to run. The size of the lattice was chosen to minimize such statistical fluctuations while giving reasonable run times on the computer. Values of D_{\max} and p_{\max} vary by, at most, a few percent between runs. In Fig. 2, only occupied

Fig. 2. Computer results on an FCC lattice with $N = 2, 4,$ and 8 layers of 40×40 sites. The horizontal axis is the fraction of sites occupied by Pt grains, and the vertical is the fraction of surface per grain available for catalysis. Electrical connections are only allowed between nearest neighbor sites, i.e., one shell of neighbors.

nearest neighbor sites are assumed to be in electrical contact, while, in Fig. 3 and 4, electrical contact is assumed to extend to second and third nearest neighbors, respectively.

In all three cases shown, the curves have the same characteristic shape. D increases sharply at the percolation threshold, reflecting an abrupt rise in the fraction of particles belonging to the connected network. This increase becomes sharper as the number of layers increases and the percolation transition approaches that of a bulk sample. Little change in the curves occurs as the number of layers N increases above 4, except for some further narrowing of the peak. The curves shown for $N = 8$ are thus probably very similar to those for $N = \infty$ (bulk). Slightly

Fig. 4. Results for FCC lattice with electrical connections allowed to first, second, and third nearest neighbor sites, i.e., three shells of neighbors. Other details are the same as in Fig. 1.

above p_c , all the curves reach a maximum and begin to fall as the connected network becomes less extensively branched.

As we increase the number of near neighbor shells assumed to be in electrical contact with a central crystallite, the peak concentration p_{max} decreases. This decrease reflects a decrease in the percolation threshold p_c when second and third neighbors are allowed. Furthermore, the effective surface area per crystallite increases because more electron transport can take place without obscuring surface area.

The results of this model depend on two effects: connectivity, or the total number of neighbors to which a crystallite can be connected; and the obscuring of surface area, which depends only on the number of nearest neighbors. In order to test the model dependence of our calcu-

Fig. 5. Results for SC lattice with electrical connections allowed to first and second nearest neighbor sites. Other details are the same as in Fig. 1.

lation of obscured surface, we ran computer simulations for an SC lattice with second nearest neighbor connections (see Fig. 5), since (by coincidence) when second neighbor connections are allowed, a crystallite in both the SC and FCC lattices can be connected to 18 neighbors. Because the number of connections is the same in both cases, we expect the purely connective aspects of the problem to be the same. However, since the number of nearest neighbors is not the same in the two lattices, the degree of surface obscured by nearest neighbors may be quite different in the two cases.

We find that both the models give nearly identical results for $N = 4$ and $N = 8$ layers ($N = 2$ is too far from bulk behavior). In both cases, the maximum efficiency occurs at $p \sim 0.24$, and the fraction of effective surface area per crystallite is 0.74 ± 0.02 . Thus, the most important feature of the model in determining reaction efficiency is the number of possible connections, and not the grain shape. The very weak dependence of the results on details of the grain shape strongly suggests that the results of the simulations presented here are applicable to the physical samples, in which grain shapes may differ from the obviously idealized shapes assumed here.

The correction arising from the presence of isolated pockets of matrix (i.e., a portion of the matrix which is not part of the connected matrix network) can be estimated.¹ It is found to be completely negligible (of order 0.01%) in the neighborhood of the peak in efficiency. This result is reasonable, because the peak occurs at matrix concentrations much above the matrix percolation threshold, so that the fraction of matrix sites which belong to the connected matrix cluster is very nearly unity.

In view of these results, we display in Table I the maximum in effective surface area per grain (\bar{D}) as a function of the principal experimental parameter of importance: the number of potential connections. The value of this

¹If the Pt and matrix are both distributed randomly, the percolation problem for the matrix is the same as that for the Pt, but with p replaced by $(1 - p)$. From our simulations, we therefore automatically know the fraction of matrix sites which are in isolated pockets (i.e., not in the connected matrix network) at any value of p . If we assume that the exposed surface per matrix site is the same in the pockets as in the connected cluster (a quantity we have calculated), then we can estimate the total exposed surface of the matrix in the pockets from the total amount of matrix in pockets. This equals the amount of platinum surface surrounding the pockets, which is therefore available for catalysis.

Table I. Results of computer simulations. N_{conn} is the number of neighbors to which a grain can be connected; it is varied by allowing electrical contact between further neighbors. N_{layer} is the number of layers of points in the lattice. \bar{D}_{max} is the maximum fraction of surface area per microparticle available for catalysis. p_{max} is the critical Pt concentration at which \bar{D}_{max} occurs. The final column tells which lattice was used for the calculation. Most of the values shown are averages over more than one run. Variations in \bar{D}_{max} and p_{max} between runs are, at most, a few percent

	4	0.15	83	
	8	0.12	84	

maximum increases with the number of connections, as would be expected. The concentration at which the maximum occurs likewise shows a monotonic decrease. For a reasonable number of connections (ten or more) this concentration is surprisingly low, indicating that even at a relatively low filling fraction of Pt, most of the crystallites are indeed able to participate in the chemical reaction.

Our results appear to have several experimental implications. If the percolation model is applicable to a given reaction, then a relatively low filling fraction of microparticles will maximize the catalytic efficiency or effective dispersion (as defined above). Also, it appears that catalytic efficiency mainly depends on the number of potential electrical connections between microparticles, rather than on particle shape. We speculate that the same results would hold for a porous electrode in which the microparticles are characterized by a distribution of shapes (or sizes).

The Passivation of Zinc in Alkaline Solutions

B. Aurian-Blajeni* and Micha Tomkiewicz*

Department of Physics, Brooklyn College, Brooklyn, New York 11210

ABSTRACT

We report on the behavior of zinc electrodes in stirred alkaline solutions saturated with soluble zinc species. Based on the application of the differential effective medium theory for the interpretation of frequency dispersion spectra of the impedance, a mechanism is proposed for the growth of the passive layers on zinc electrodes in batteries. It was concluded that a principal role, during the growth of the passive layer, is played by the diffusion of the electrolyte across a porous layer and that, after passivation, the film becomes more compact, with grains approaching spherical shapes.

Zinc is one of the most important materials being used for electrodes in battery applications. The properties of zinc are the subject of numerous studies. For comprehensive reviews, see Ref. (1-3); many useful references to recent literature are also given in Ref. (4), and recent developments are summarized in Ref. (5).

Under anodic bias, zinc electrodes passivate with formation of zinc oxide layers (4, 6, 7). The mechanism of formation of these layers in alkaline solutions is by a solution-precipitation path. This results in a wide morphological variety, depending on the growth environment. Basically, the passive layers are described in terms of a duplex structure with a thin compact component underneath a porous one, although it was shown that little morphological difference exists between the two layers (8).

Since we shall make use of concepts from the model described in Ref. (7), a short description of that model follows. The passivation of zinc electrodes by a solution-precipitation mechanism occurs by growth and merger of crystallites. The development of an anodic passive film would proceed in a series of steps: a quasiequilibrium state formed immediately after the switching on of the perturbation, which corresponds to a charging of the double layer; and development of a transport region, followed by polymerization. These steps are succeeded by the actual formation of the film by nucleation and growth of

the nuclei, growth of the oxide, and densification. The last stage is a peeling off of the film by buckling and folding.

The aim of the present study is to get some insight about the anodic behavior of zinc electrodes in alkaline solutions by investigating the frequency dispersion of the impedance as a function of various electrochemical parameters such as current density prior to passivation and amount of charge passed after passivation. Although studies using impedance techniques were carried out for zinc electrodes, most of them involved the active regime (9, 10).

Experimental

The experiments were performed in a three-compartment cell. The anodic compartment was separated from the cathodic one by means of a strongly acidic Nafion membrane, in order to repel the zincate ions and to avoid zinc plating on the counterelectrode during discharge. Prior to mounting into the cell, the membrane was soaked in 5M KOH for 24h at room temperature. All the potentials were measured vs. a saturated calomel reference electrode. A 7 cm² platinum foil was used as a counterelectrode. The working electrode was a zinc rod (0.08 cm² exposed area) (Fisher), pressure fitted in a Teflon holder. During the experiments, the exposed area was kept in vertical position. Before each experiment, the exposed area was polished down to 4/0 grid and then etched in concentrated hydrochloric acid for about 10s (9)

* Electrochemical Society Active Member.

and rinsed in purified water (18 M Ω). The 5M KOH solutions were prepared from purified water and analytical-grade potassium hydroxide (Fisher).

The experimental setup is shown in Fig. 1. A typical experiment comprised two kinds of measurements, which were performed alternately. During the experiments, a dc voltage was applied across the whole circuit by means of a dc power supply (Hewlett-Packard HP 6111A). In the first type of measurements, the electrode potential and the current were monitored with a Keithley 192 dmm and a Keithley 177 dmm (measuring the potential drop across a 66.5 Ω resistor), respectively. This type of measurement enabled us to observe the time evolution of the process of passivation of zinc in alkaline solution (Fig 2). At various time intervals (shown by arrows in Fig. 2), impedance measurements were made according to the procedure described in Ref. (11) in order to characterize the layers formed up to a certain moment. The ac source was a Hewlett-Packard HP 3325A synthesizer/function generator, supplying a 5 mV amplitude signal at frequencies between 1 Hz and 1 MHz. The phase angle and the modulus of the ac response were measured with a Hewlett-Packard HP 3575 gain-phase meter. During the impedance measurements, all the voltmeters were disconnected, as was the magnetic stirrer, which was used during the passivation stage of the experiments. Since hydrodynamic control is important in the passivation process (12, 13), the use of a stirrer is the major flaw of our experiments and it is kept responsible for the scatter of the data. Nevertheless, we tried to minimize the errors (or at least make them systematic) by keeping the same stirring regime (except for voltage fluctuations) during all the ex-

periments. The whole setup was controlled by a Hewlett-Packard HP85 desktop computer, which was used also for data collection.

The key feature from the experimental point of view is obtaining a stable layer of zinc oxide. Owing to the high solubility of zinc oxide in alkalis, the passive layers are unstable on smooth electrodes. However, the porous electrodes for which the passivating layer is stable have exceedingly complex impedance characteristics. This problem was overcome by using an extra zinc electrode. Before starting the actual experiments, the solution in the anodic compartment was prepared *in situ* (14). A current was passed between the platinum electrode and this fourth electrode until qualitative turbidimetry showed that the solution was saturated in zinc species. This procedure was necessary to prevent (or slow down) the dissolution of the zinc oxide species formed on the surface of the electrode, based on the fact that electrolytically formed zinc oxide is more soluble than the one externally added [e.g., Fisher (dry process), certified ACS] (1). Moreover, our experimental setup allowed impedance measurements to be performed while the electrode was kept in the passive state.

Results

The layer formed at the surface of the electrode is dark for the first half-hour after exposure to air. It whitens afterwards, and its texture changes. This fact was previously observed and associated with an excess of zinc (15).

The typical behavior of the electrode potential and current density as a function of time is shown in Fig. 2. From Fig. 2, one can see that, following a region of almost constant current and potential, a sudden change occurs. This change is followed by an increase in current density (decrease in electrode potential), and a second, slower, decrease follows. The characteristics of the curves of the type shown in Fig. 2, relevant for the present study, are: the initial current density (I); the initial electrode potential (V_i); the final electrode potential (V_f); and the time of passivation, considered to be the time corresponding to the major change in current density (electrode potential). Passivation experiments were carried out for various values of the initial current density in the range 60-160 mA \cdot cm $^{-2}$.

The impedance measurements reported in this paper are made for the electrode under steady-state conditions, since the frequency dispersion spectra recorded before passivation exhibited no structure in the range of measurement.

In Fig. 3, we show typical experimental results obtained for the impedance of a zinc oxide layer anodically grown.

In Fig. 4, we show the evolution of the frequency dispersion spectrum of the imaginary part of the impedance for the same passivation experiment as a function of the charge passed after passivation.

Discussion

The advantage of using a potentiometric setup is that it is closer to battery operating conditions than a constrained system, in which either constant current or constant electrode potential are imposed. Moreover, it allows the observation of the evolution of the system under charge.

Before passivation, the process is in an ohmic (linear) regime, as shown in Fig. 5, in which the current density is represented as a function of the electrode potential.

Figure 6 shows the change in electrode potential with the total potential drop across the cell. It is noted that the initial electrode potential does not change much with voltage, while the slope of the final electrode potential as a function of voltage is close to one. We interpret this as follows: after passivation, the main potential drop occurs across the passivating layer. In other words, passivation in our case occurs not because a "passivation potential" is reached, but because the overpotential is too small at the reaction interface, because of increased potential drop across the oxide layer. If the potential drop across the cell

is calculated (cf. Fig. 5 and 6), it is observed that, before passivation, the potential drop has a constant value of $0.350 \pm 0.03V$, which compares well with $0.415V$ predicted for the reaction $Zn + H_2O = ZnO + H_2$ (16) and an internal resistance of the cell of $55 \pm 10\Omega$. The value of the series resistance of the cell is consistent with the value obtained from impedance measurements (the high frequency plateau of the real part of the impedance spectrum in Fig. 3b).

The frequency-dependent impedance may be expressed as

$$Z = R + iX = il(\gamma A \omega \epsilon) \quad [1]$$

where l is the thickness, γ is the roughness factor, A the area of the sample of material under consideration (l is parallel to the electric field), ω the angular velocity, and ϵ the complex dielectric constant of the composite. From Fig. 4, one can see that the slope in the low frequency region is not only different from 1 (as for a passive RC element) or $1/2$ (corresponding to a Warburg- or de Levie-type impedance), but increases monotonically as a function of the amount of charge passed.

During the growth of oxide layers at the surface of zinc electrodes, electrolyte solution is also imbedded. The dielectric properties of the resulting layer are not a linear combination of the dielectric characteristics of the components (i.e., oxide and solution), but are affected by other cross-term effects as well (17). One of the ways of describing the dielectric behavior of composites is the effective medium approximation (18, 19). Among the most

Fig. 4. Change of the dispersion spectrum of the imaginary part of the impedance as a function of the quantity of charge. Data from Fig. 2.

Fig. 5. Initial current density as a function of the initial electrode potential.

used forms of this approximation are the Maxwell-Garnett, the Bruggeman, and the self-similar or differential form. The Maxwell-Garnett approximation for a two-component system is valid whenever a distinction may be made between a "host" and a "guest" component in the composite material. This limitation is not present in the Bruggeman version, which applies for spherical inclusions in a homogeneous medium consisting from the two

Fig. 6. Variation of the initial electrode potential (V_i) (top) and the final electrode potential (V_f) (bottom) as a function of the potential drop across the cell.

components. The refinement of this latter approximation, the self-similar or differential effective medium theory, allows for any form of inclusions in media in which the conductive phase remains interconnected for any ratio of the components.

We used this interpretation of the frequency dispersion of the impedance based on the SEM data in Ref. (7) and the fact that the behavior of the impedance can be predicted by neither equivalence to a passive circuit nor by Warburg-type impedance (Fig. 4).

The form of the effective medium approximation used by us was developed for the description of the dielectric characteristics of sedimentary rocks (17, 18, 20). In its closed form, for a composite consisting of a porous insulator saturated with electrolyte solution, the equation for the porosity is as follows

$$P = \frac{\epsilon - \epsilon_d}{\epsilon_w - \epsilon_d} \left(\frac{\epsilon_w}{\epsilon} \right)^m \quad [2]$$

where P is the porosity; ϵ , ϵ_w , and ϵ_d the complex dielectric constants of the composite, solution, and insulator, respectively; and $0 < m < 1$ is a screening factor (depolarization factor) dependent on the shape of the grains in the composite (18, 19). The forms encountered in the literature use a limited number of fixed values of the parameter m . We extended the model for the continuous variation of m in the interval $[0, 1]$ (21).

The complex dielectric constant, at frequencies lower than 10^7 Hz, may be written as

$$\epsilon = k + i(4\pi/\omega)\sigma \quad [3]$$

with k is the real dielectric constant, ω the angular velocity, and σ the dc conductivity.

The dissipation spectrum of the impedance will be dependent on the geometric factors of the sample (l , γ , and A), the dielectric characteristics of the components (ϵ_w and especially ϵ_d , their ratio and microstructure (P and m)). The results predicted by the effective medium theory are compared with the experimental values in Fig. 3. Some of the parameters used were taken from the literature as $k_w = 70$ (12), $k_d = 9$ (22), $\sigma_w = 0.500$ ($\Omega\text{-cm}$)⁻¹ (1). The adjustable parameters are the thickness to roughness ratio l/γ (one parameter), the conductivity of zinc oxide σ_d (depending on the nonstoichiometry of the anodically formed zinc oxide), the porosity P , and the depolarization factor m . The adjustable parameters were fit by least mean squares fitting for nonlinear models. Fitting was performed only for the imaginary part of the impedance (Fig. 3, top). As a check for the consistency of the model, the values obtained for the parameters were fed into the expression for the real part of the impedance and the results were compared with the experimental data (Fig. 3, bottom). Thus, some of the characteristics of the passivating layers were derived from impedance measurements: the porosity, the depolarization factor, the thickness to roughness ratio, and the conductivity of the insulating phase.

Figure 7 shows the evolution of the parameters of the system from Fig. 4 and 2 as a function of the quantity of charge passed after passivation. From Fig. 7a, which represents a typical set of data after passivation, a jump in porosity is observed. We associate this jump with the phase transition mentioned by Dirkse (14) and postulated by McKubre and Macdonald (4), probably related to the transformation from polyhydroxide to oxide (7). After this transition is finished, the porous layer considered to comprise zinc oxide and solution becomes more compact, as seen from the decrease in porosity. The decrease of the depolarization factor (Fig. 7b) toward values characteristic for spheres suggests that densification occurs by the grains becoming more and more spherical and, according to Ref. (7), finally merging. This process is accompanied by a decrease in conductivity of the insulating phase (zinc oxide) (Fig. 7c). The number of free carrier concentration derived from conductivity data (10^{16} cm⁻³ as compared to 10^{-11} cm⁻³ for the intrinsic material) is consistent with the

Fig. 7. Change of the parameters derived from the application of the effective medium theory to data in Fig. 4, as a function of charge passed after passivation.

excess of zinc in the passive layer (15). The decrease in conductivity may be due either to migration of impurities in the high field across the layer or to electrochemical reaction inside the layer. After the above parameters reach roughly their steady-state values, the layer continues to grow (Fig. 7d). This conclusion is based on the assumption of constant roughness (the initial decrease in the thickness-to roughness-ratio is probably due to the fact that this assumption is not valid at that stage).

The terms used in Ref. (7) to describe the passivation

Fig. 8. Variation of the amount of charge passed before passivation (top) and of the initial porosity (bottom) as a function of initial current density.

Fig. 9. Initial current density as a function of the reciprocal square root of the passivation time.

are "polymerization" and "densification," where the processes occur successively. We believe that they occur concomitantly and that the ratio of their rates is dependent on the current density. This is better illustrated by Fig. 8, in which are represented the dependence of the amount of charge before passivation (top) and of the initial porosity obtained from impedance measurements (bottom) as a function of the initial current density. The picture suggested by Fig. 8 is that the lower the current density, the "fluffier" the layer formed, since with an increase in current density less charge is necessary for passivation and the passive layer is less porous. In other words, at low current density the polymerization is rapid, while at high current density the densification is rapid. This may be interpreted as a diffusion-controlled mechanism in which the diffusing species is the electrolyte. That the passivation process is a diffusion-controlled one is indicated by Fig. 9, in which the initial current density is seen to be linear with the reciprocal square root of the passivation time. That this is a realistic possibility is also indicated by the observation that, if a passive electrode is left at open circuit, it is "reactivated" after a certain period of time (23). An alternative explanation invokes dissolution. Under the present conditions, we do not believe this to be the case, since the solution is electrolytically saturated in zinc species. Moreover, chemical dissolution would not explain the fact that the time of passivation of the "reactivated" electrode is shorter than that for initially active electrodes. In view of our model, the passivated electrode is just reflooded with electrolyte and again repassivated, with diffusion of the electrolyte becoming more difficult, as the porous layer becomes thicker.

A word about the implicit assumptions involved in this analysis is called for. One is that the passive layer is considered homogeneously porous. The effect of removing this assumption is currently under investigation in our laboratory. Another assumption is that the passivating layer comprises only two components: zinc oxide and solution. Other assumptions are more drastic; namely, that the effects of the high field in the passive layer were neglected, as well as the random orientation of the grains [although the latter assumption is justifiable for an electrolytically grown layer (15)].

Conclusions

The study of vertical flat zinc electrodes in alkaline solutions electrolytically saturated with soluble zinc species has led us to the following conclusions.

1. The passivating layers under these conditions are composite layers comprising both oxide and solution.
2. The growth of the layers and electrical passivity/activity of the electrodes are dictated by the diffusion of the electrolyte across these layers.

3. After passivation, the characteristics of the passive layers change as a function of the amount of charge passed after passivation. These changes are summarized as follows: the passive layer becomes more and more compact with grains approaching a spherical shape; after a certain porosity and conductivity of the insulating layer is reached, the thickness of the layer increases.

Second-Order Harmonic in the Current Response to Sinusoidal Perturbation Voltage for Lead-Acid Battery

An Application to a State-of-Charge Indicator

S. Okazaki, S. Higuchi, and S. Takahashi

Government Industrial Research Institute, Osaka, Midorigaoka 1, Ikeda, Osaka 563, Japan

ABSTRACT

Distortion of the current response to sinusoidal alternating perturbation voltage has been quantitatively measured as a function of state of charge for commercially available lead-acid batteries. The input amplitude adopted here was greater than those used for ordinary impedance measurement. The distortion is represented as a power spectrum. Among higher order harmonics, that of the second one was selected for the parameter of a state-of-charge indicator. Excellent linearity was observed for the state of charge. It was also clarified that, compared to other parameters of the indicator, such as terminal voltage, impedance of fundamental tone, and concentration of sulfuric acid, this parameter is less influenced by other factors during practical operation, such as discharge current and rest time.

Many types of state-of-charge indicators have been proposed for use in primary and secondary batteries. In particular, interests have been directed to lead-acid batteries, which are very popular as SLI batteries, emergency power supplies, and electric vehicle power sources. For the last case, especially, a state-of-charge indicator serves as a fuel meter and plays an important role in the system. As for the SLI batteries, though state-of-charge is presently not monitored, it is hoped that its indication can be incorporated into the car's indicator system for the sake of convenience.

Recently, special efforts have been made to develop various advanced secondary batteries for vehicular and load leveling applications. In consideration of their operational conditions, a correct understanding of the state-of-charge is very important. Consequently, the need for the development of indicators of high accuracy at low cost now becomes greater and greater.

Most indicators proposed so far are based in principle on terminal voltage (1), impedance (2), and especially the concentration of sulfuric acid in the case of lead-acid batteries. Density (3), refractive index (4), and saturated humidity (5) have been studied as physical properties representing the concentration of sulfuric acid. The state-of-charge can also be obtained from integrated current. To measure these physical quantities accurately, simply, and automatically in packed batteries, many devices have been proposed (1-5). Still, many problems remain, and only a few devices have proved good enough to be of practical use. For example, when sulfuric acid concentration is selected as a parameter, a large time delay exists between the change of residual charge and the corresponding concentration at the probe. Thus, real-time monitoring is not possible in this case. Terminal voltage takes different values in the absence and in the presence of a load. If this difference is corrected according to current, the device will be very complicated and costly. Finally, fundamental wave impedance is largely dependent on rest time for lead-acid batteries (6). An attempt is now being made to apply it to primary cells before use (2).

Thus, a new parameter closely correlated to the residual charge of a battery should be proposed. For this purpose, the distortion of output current from a single sinusoid generated by alternating input voltage, represented as a power spectrum quantitatively, has been investigated. Among higher-order harmonics, that of the second one is adopted as such a parameter. The second harmonic was discussed first by Smith with reference to ac voltammetry (7). Using the apparatus stated in the Experimental section, it is possible, in principle, to analyze it more directly. This quantity provides important information about reaction kinetics. Our discussion here is limited to the application of the second harmonic to the state-of-charge indicator, i.e., to phenomenological treatment. More fundamental treatment and application of this pa-

parameter to reaction kinetics will be carried out in the near future.

Experimental

When a sinusoidal alternating voltage

$$V(\omega, t) = V_0 \sin \omega t \quad [1]$$

is superimposed on an inherent terminal voltage, V_b , of a battery as input, the current response is represented as a Fourier series expansion

$$I(\omega, t) = I_0 + \sum_{n=1}^{\infty} I_n \sin(n\omega t + \phi) \quad [2]$$

where $\omega = 2\pi f$ (f : frequency) and ϕ are the angular velocity of the imposed sinusoidal voltage and phase deviation of the response, respectively. The direct current I_0 corresponds to faradaic rectification effect, and I with the subscripts $n = 1, 2, 3, \dots$, are amplitudes of the fundamental tone, second-order harmonic, third-order harmonic, \dots , respectively. In order to evaluate the m -order wave component, $m = 1, 2, 3, \dots$, the distorted wave $I(\omega, t)$ is treated as follows. First, $I(\omega, t)$ is integrated with $\cos m\omega t$ and $\sin m\omega t$ from 0 to the period T . Then

$$I'_m = \int_0^T I(\omega, t) \cos m\omega t dt = \frac{T}{2m} I_m \sin \phi \quad [3]$$

and

$$I''_m = \int_0^T I(\omega, t) \sin m\omega t dt = \frac{T}{2m} I_m \cos \phi \quad [4]$$

The amplitude I_m is obtained from equation

$$I_m = \frac{2m}{T} \sqrt{I'^m{}^2 + I''^m{}^2} \quad [5]$$

Of course, I_0, I_1, I_2, \dots , are functions of ω and V_0 . In the ordinary chemical impedance measurement, V_0 must be selected so that direct current and higher-order harmonics may be neglected. In such a case, a perturbation voltage of a few millivolts is usually employed.

In order to carry out the above measurements, a new system was constructed similar to those used for impedance measurements. This system is controlled by a microcomputer having a potentiogalvanostat to provide a perturbation voltage (or current) to the battery and to charge and discharge it.

The terminal voltage is monitored by a digital multimeter connected to the computer, according to which the offset voltage, V_b , is determined. This device is also used to detect the cutoff voltage of discharge in capacity tests. The main block of the system is FRA S-5720 manufactured by NF Electronic Instruments Company and analyzes distorted waves.

The computer automatically controls charge, discharge, and rest period of the cell, carries out capacity tests according to the defined cutoff voltage, provides perturbation and offset voltage, and performs analysis of response wave forms.

A commercially available pasted-type lead-acid battery with nominal voltage and capacity of 6V and 12 Ah, respectively, was used. The battery was placed within the thermostat at $25 \pm 1^\circ\text{C}$.

The influence of rest time on the parameter was evaluated first. This test concerns not only rest time, but also the difference in behavior of the parameters in the presence and absence of a load. The effect of the discharge current magnitude was then clarified. For this purpose, the battery was treated in the following way.

After a 15-20 min discharge, its terminal voltage was perturbed by an external power supply immediately or after a 15-120 min rest. In the former case, the offset voltage V_t was polarized, *i.e.* a closed-circuit voltage, where three kinds of discharge rates were adopted, *i.e.* 10, 8, and 5 HR, respectively. In the latter case, the rest times were 20 and 120 min for the 10 HR and 15 min for the 5 HR discharge. This procedure was repeated until the terminal voltage dropped to a cutoff voltage defined as 5.4V for the 10 and 8 HR and 5.25V for the 5 HR discharge. The state-of-charge is available from integrated discharge time at each measurement and capacity obtained at the end of discharge.

Results and Discussion

Nonlinear current response.—Rigorously, current response to sinusoidal voltage input does not consist of a single sinusoid as stated in the previous section. It does so only when the low field approximation is valid in the Butler-Volmer equation. Figure 1 shows practical wave forms of current response for a fully charged lead-acid battery with an open-circuit voltage of 6.498V. The ordinate and abscissa scales are arbitrary. When the input is 10 mV rms, the output is nearly sinusoidal and the ratio of the amplitude for the second harmonic to the fundamental tone is less than a few percent. When the amplitude of the input is as much as 30 mV rms, the output wave becomes somewhat distorted and the content of the second harmonic is about 10%. It is evident from the figure that there is a barely distinguishable shoulder at the very center of each of the two sharp peaks for 100 mV rms. This corresponds to the existence of a large second harmonic and the ratio becomes as much as $\sim 20\%$. Thus, the larger

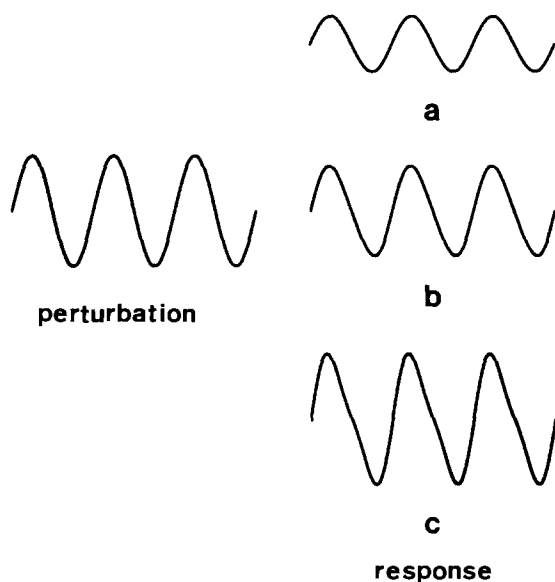

Fig. 1. Wave forms of input perturbation voltage and current responses for fully charged lead-acid battery. The response wave forms are those for three kinds of input magnitudes: a, 10 mV rms, b, 30 mV rms, and c, 100 mV rms. Amplitude scale is arbitrary.

the amplitude of the perturbation voltage, the greater the distortion of the current response.

Wave distortion should be discussed in some detail here. First, we shall consider the ratio as a function of perturbation frequency. The ratio is plotted against the logarithm of frequency in Fig. 2, where $V_0 = 30$ mV rms. It is clear that, although at higher frequencies the system contains only a negligible second harmonic, it increases abruptly at low frequencies less than a few hertz. In spite of the small ratio, 1 or 2% at high frequencies, it is 10% at 1 Hz and exceeds 20% at 0.1 Hz. These frequencies belong to the Warburg region in a usual complex plane analysis for the lead-acid battery. Figure 2 also shows plots against the amplitude of perturbation voltage V_0 , where the frequency is 1 Hz. When V_0 is as small as that used in an ordinary impedance measurement, ~ 3 mV rms, $I_{n=2}/I_{n=1}$ is less than 1%. In this case, even at a lower frequency, the low field approximation may be considered valid.

A linear relation is observed between $I_{n=2}/I_{n=1}$ and small V_0 , < 50 mV rms. This is the case when alternating variation \bar{c} in the reactant concentration in the Taylor expansion of the Butler-Volmer equation is proportional to the perturbation voltage, *i.e.*, the expansion shows that if $\bar{c} \propto V_0$, then $I_{n=1} \propto V_0$ and $I_{n=2} \propto V_0^2$, so $I_{n=2}/I_{n=1}$ must be proportional to V_0 . In Fig. 3, there is a linear relation between $I_{n=1}$ and V_0 and also between $I_{n=2}^{1/2}$ and V_0 at small V_0 . But these three plots deviate from linear lines at similar V_0 . The deviation at large V_0 , > 50 mV rms, may possibly arise from a complicated diffusion process.

A perturbation voltage of 30 mV rms was selected, though this value has no special meaning. At least the second harmonic is large enough to be measured easily at this voltage and the total current is small enough to flow using a common potentiostat. In the following sections, the application of this parameter to the state-of-charge indicator is discussed based on the amplitude, 30 mV rms, and a small number of frequencies.

Relation between second-order harmonic and state-of-charge.—In the previous section, some general features of second-order harmonic in current response were discussed for a lead-acid battery. In this section, the behavior of the second harmonic as a function of state-of-charge is discussed.

The battery was discharged at a constant current, 10 HR, for a certain period. After a 20 min rest, a sinusoidal perturbation voltage, 1 Hz and 30 mV rms, were superimposed on the inherent terminal voltage. Figure 4 shows

Fig. 2. Ratio of second harmonic to fundamental tone in current response for a fully charged lead-acid battery as a function of amplitude (open circle) or frequency (closed circle) of input.

Fig. 3. Amplitude of fundamental tone (open circle) and the square root of the second harmonic (closed circle) in current response as a function of the input voltage for a fully charged lead-acid battery.

the second harmonic in current response, where the abscissa is the residual charge. From the figure, a linear correlation is evident. The residual charge may thus be easily obtained from the value of the second harmonic. Also, measurements of different cycles of the battery (represented by the different shapes at the data points) show good reproducibility of the parameter. Consequently, it may be said that the second harmonic can be applied to the state-of-charge indicator.

However, it should be pointed out that, considering the practical usage of the battery, a rapid and precise measurement is required under various conditions of practical use. But there are many questions in regard to the influence of the discharge rest time, the degree of the parameter change when measured in the presence of a load, and the effect of the magnitude of a load on the value. In other words, only a parameter not influenced by the conditions of measurement or state of the battery except for its charge must be used.

The next section covers these problems, and a comparison is made with classical parameters such as terminal voltage and impedance of the fundamental tone.

Application to the state-of-charge indicator.—The linearity of the relation between the second harmonic in current response and state-of-charge was shown in the previous section. However, it may be influenced by the history of the battery, its environment, and its state, as well as the charge.

We first consider the load. When present, there is a certain concentration gradient in the solution near the electrode. After a sufficient off-load time, there is no concentration gradient, indicating an equilibrium state. Of course, in the former case, there is a deviation of the electrode potential owing to the concentration and reaction overpotential generated by the direct current. These phenomena should be considered in relation to the change in amplitude of the second harmonic as well as fundamental tone. They are influenced by the magnitude of the discharge current itself.

Second, fundamental tone impedance has been reported to depend on the rest time of the battery (6). After load is switched off, concentration gradient decreases and the electrode surface changes slowly, though it is difficult to interpret quantitatively because of its complexity. It is quite probable that the second harmonic is also influenced by the rest time.

The parameters may depend on such factors as ambient temperature, bulk concentration of sulfuric acid, and cycle history, and their effects on the parameters should be clarified. But, at this point, it should be sufficient to say

Fig. 4. Second harmonic in current response to perturbation voltage, 1 Hz and 30 mV rms, measured after a 20 min rest in 10 HR discharge for a lead-acid battery as a function of state-of-charge, Q .

that in the course of the work the battery was immersed in thermostat controlled at $25^\circ \pm 1^\circ\text{C}$, the bulk concentration was not strictly controlled, and the charge-discharge cycle of the battery was from about 10 to 60, the discharge or measurement modes being taken arbitrarily.

Measurement was carried out at various frequencies of input. There must be a frequency that is most ideal for application to the indicator. Here the results are shown for three frequencies, 1, 10, and 100 Hz, representative of the diffusion-controlled, both the diffusion- and reaction-controlled, and reaction-controlled regions, respectively. The amplitude of the input was 30 mV rms for all measurements.

In order to determine the differences in parameter behavior arising from the state and conditions of the battery, the second harmonic, fundamental tone in the output wave, and terminal voltage were measured in the presence of a load, 10 HR, and in its absence after 20 and 120 min rests. This measurement was also carried out in the presence of two other loads, 8 and 5 HR.

The apparent total charge or capacity of the battery may vary between continuous discharge and intermittent discharge, but the resulting difference in the capacity is negligibly small. Therefore, no correction was made for the measured capacity.

Measurements for terminal voltage are given in Fig. 5. As expected, the lines are separated into two classes, one for the presence and the other for the absence of a load. The difference is so large that direct application of this parameter to an indicator would not be possible.

The second harmonic and fundamental tone are shown in Fig. 6-8 as a function of state-of-charge for three frequencies, 1, 10, and 100 Hz. In each figure, there are six kinds of plots corresponding to different discharge and measurement modes. The dispersion of the lines or curves in the figure must be a measure of the stability of the parameter toward the state or condition of the battery.

In Fig. 6, larger currents are found in the case without rest of the load than that with it, both for the second harmonic and fundamental tone. This means that $|z|$ probably increases by the rest or load-off and is in good agreement with other observations for similar frequency regions (6). In regard to the fundamental tone, Fig. 6b, the curves spread out like a fan. The dispersion of the plots exceeds about 60% of total battery charge. This means that when this parameter is used as a state-of-charge indicator, it contains an error larger than 60%. Thus, it is im-

Fig. 5. Terminal voltage of a lead-acid battery for various discharge and measurement modes as a function of the state-of-charge, Q . Open circles: 10 HR and 20 min rest. Open triangles: 10 HR and 120 min rest. Open squares: 5 HR and 15 min rest. Darkened circles: 10 HR without rest. Darkened triangles: 8 HR without rest. Darkened squares: 5 HR without rest.

possible to apply this parameter to a state-of-charge indicator. As for the second harmonic (Fig 6a), however, the line dispersion is remarkably small compared to that of the terminal voltage and fundamental tone at this frequency. It is less than 10% at the first stage of discharge, and increases somewhat at the final, but does not exceed 15%. This satisfies the requirement for accuracy of the indicator as a fuel meter for electric vehicles, *i.e.*, <15%. Thus, the second harmonic is excellent as a parameter for the state-of-charge indicator.

The behavior of the second harmonic is even better at 10 Hz, as shown in Fig. 7a. Although it has a large deviation after a long load-off time, other lines only have errors of less than 10% and are little influenced by the magnitude of the direct current in the case of continuous discharge. Thus, after a small load, at just the initial starting, remarkably accurate information for residual charge of the battery can be obtained and is scarcely influenced by a subsequent short time rest. From Fig. 7b, it is impossible to apply fundamental tone impedance to the indicator, since its dispersion is too large.

The results for fundamental tone measurement are shown in Fig. 8 at 100 Hz. The fraction of the second-order harmonic is within only 0.1% of the total wave at this frequency. It would be difficult to detect such small signals correctly at low cost. The curve of the second harmonic has a minimum in the intermediate region. Consequently, it cannot be applied to an indicator and therefore is not shown here.

The plots for fundamental tone impedance show two separated groups of curves, one with rest time and another without it. The curves within each group are quite similar. The dispersion was about 15% for the former and only a few percent for the latter. However, the groups are somewhat separated and the error exceeds 20%, particularly in the initial region of discharge where the slope of the curves are low. Consequently, it is necessary to construct a device capable of covering this separation.

Concluding Remarks

General pictures have been given for the behavior of the second harmonic, fundamental tone in current response, and terminal voltage as functions of state-of-charge for a lead-acid battery. The frequencies of the input sinusoidal voltage were 1, 10, and 100 Hz, which are representative of the regions where diffusion, both diffu-

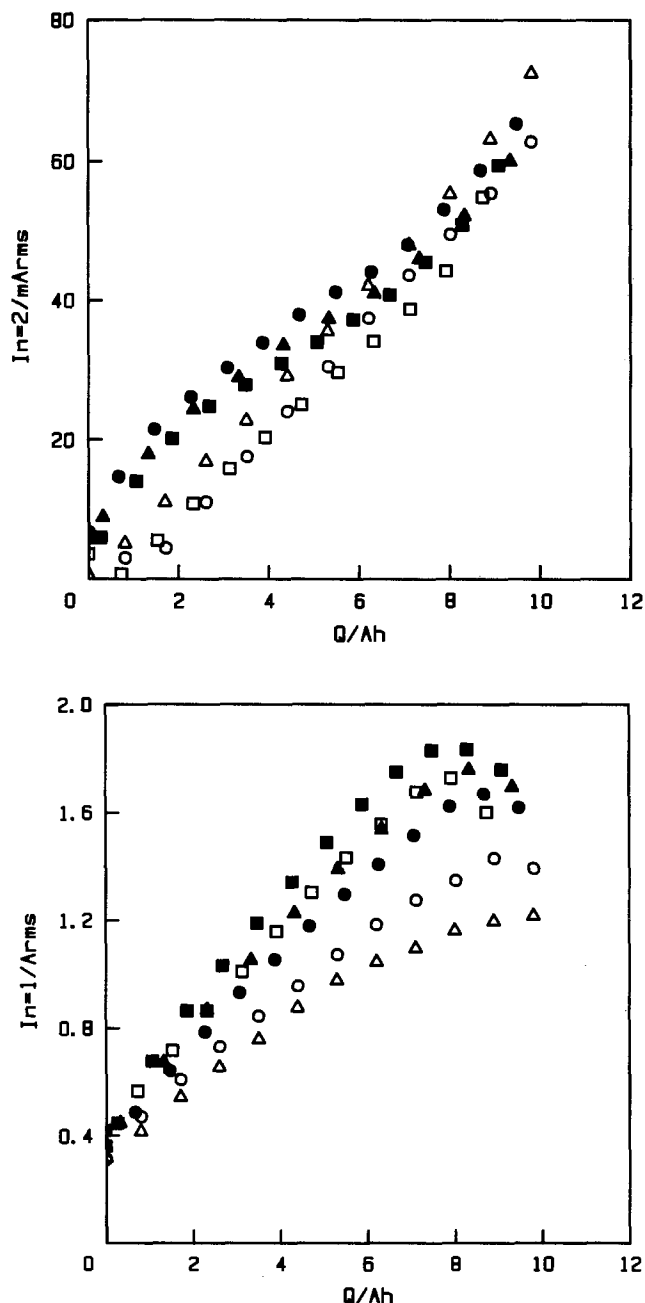

Fig. 6. Second harmonic (a, top) and fundamental tone (b, bottom) in current response to the perturbation voltage, 1 Hz and 30 mV rms, for lead-acid battery for various discharge and measurement modes as a function of the state-of-charge, Q . Symbols are the same as in Fig. 5.

sion and reaction, and reaction play important roles in output, respectively. The second harmonic was found superior to fundamental tone and terminal voltage and to be less influenced by measurement conditions and state of the battery, other than its charge. It satisfies the requirements for electric vehicular use and should find practical application.

In this work, the second harmonic was evaluated by a Fourier transform of the primary wave so as to obtain precise ones. The apparatus is very expensive for state-of-charge indicators. But an ordinary high pass filter is sufficient for the second harmonic, in principle. It is possible to use the electromotive force of the battery itself instead of an external power supply such as a potentiostat. That is, a lower voltage must be used in place of the terminal voltage, and from this direct voltage level, the voltage is perturbed sinusoidally. The final problem is display. This is a rather simple problem. It may be possible to produce the indicator at low cost. Many problems still prevent development of the indicator for practical

Fig. 7. Second harmonic (a, top) and fundamental tone (b, bottom) in current response to the perturbation voltage, 10 Hz and 30 mV rms, for a lead-acid battery for various discharge and measurement modes as a function of the state-of-charge, Q . Symbols are the same as in Fig. 5.

use, such as comparison with galvanostatic method, determination of the best frequency and amplitude, influence of ambient temperature, charge-discharge cycle history, and battery differences.

It should be mentioned that the parameters discussed here have application only when a battery is discharged. They are not applicable to the case of charging and thus

Fig. 8. Fundamental tone in current response to the perturbation voltage, 100 Hz and 30 mV rms, for lead-acid battery for various discharge and measurement modes as a function of the state-of-charge, Q . Symbols are the same as in Fig. 5.

have limited use for SLI batteries. Such an application of these parameters by a technique such as forcing a small discharge current to flow for a short time before measurement may be possible.

AC Impedance Analysis of Polycrystalline Insertion Electrodes: Application to $\text{Li}_{1-x}\text{CoO}_2$

M. G. S. R. Thomas, P. G. Bruce, and J. B. Goodenough

Inorganic Chemistry Laboratory, Oxford University, Oxford OX1 3QR, England

ABSTRACT

It is argued that a porous insertion electrode can be modeled, for purposes of ac impedance analysis, by a modified Randles equivalent circuit containing a generalized constant-phase-angle impedance in series with the double-layer capacitance. The impedance spectrum of the disintercalation system $\text{Li}_{1-x}\text{CoO}_2$ showed two time-dependent semicircles, indicating the need for a further modification of the equivalent circuit by a physical process that could be represented by a resistor/capacitor combination. An adsorption process and a Li^+ -ion-electrolyte surface layer are each shown to refine to identically low R factors and to be represented by equivalent circuits that transform one into the other, each having circuit values with reasonable values for the physical processes represented. Time-dependent experiments could eliminate the adsorption models, and electron microscopy gave direct evidence for the surface-layer model; further indirect evidence came from constant-voltage experiments and the preparation of electrodes with greater electrode/electrolyte interface area. Although propylene carbonate appears to be kinetically stable in contact with $\text{Li}_{1-x}\text{CoO}_2$ at potentials of up to 4.5V vs. lithium, mixtures of propylene carbonate with oxide particles having $x = 0.34$ produce thick polymer films.

Many successful battery systems, primary as well as secondary, are based on electrodes that utilize insertion compounds. An insertion compound is a mixed electronic/ionic conductor into which atoms may be topotactically inserted over a wide range of solid solution. The mobile species generally enters the host as a cation, donating an electron(s) to the conduction band of the host matrix; it may also enter as an anion, taking an electron(s) from the conduction band of the host matrix. The most successful insertion-compound electrodes now in use are based on mobile H^+ or Li^+ ions in the host matrix, and the search for alternate insertion compounds represents an active area of research.

Although the reversible insertion/removal of mobile Li ions has been extensively studied in layered structures such as Li_xTiS_2 ($0 \leq x \leq 1$) (1) and $\text{Li}_x\text{V}_6\text{O}_{13}$ ($0 \leq x < 7$) (2), fundamental electrochemical investigations have been mostly limited to studies of the ionic diffusion within the insertion compounds, as this has been assumed to be the rate-limiting process. However, other processes, such as charge transfer and adsorption at the surface, are important and could prove rate limiting, especially if new materials provide a high alkali-ion mobility within the host. In this paper, we report an electrochemical investigation of the system $\text{Li}_{1-x}\text{CoO}_2$ ($0 < x < 1$), a system first explored by Mizushima *et al.* (3), in which the interfacial processes prove to be increasingly important as x increases.

The kinetics of insertion-electrode reactions have been most commonly studied by potentiostatic or galvanostatic pulse measurements. However, ac measurements are also applicable; in fact, they have been utilized extensively in classical electrochemistry (4). Whereas, in principle, pulse and ac measurements contain the same information, in practice, ac measurements offer several important advantages over pulse techniques. These advantages are as follows.

1. A cell suffers a significantly smaller perturbation in an ac measurement (< 10 mV) than in a pulse measurement (> 100 mV); therefore, the cell is not displaced so far from equilibrium during the measurement. The severe polarizations induced by a current or voltage pulse may introduce concentration gradients of such a magnitude that the diffusion coefficient can no longer be assumed to be invariant with distance along the diffusion path, making invalid the simple diffusion equation on which analysis of the pulse data is generally based.

2. The cyclic nature of an ac perturbation produces a pseudo steady state within the cell, so no net electrolysis occurs.

3. In an ac experiment, it is possible to obtain a clear separation of the kinetics of the several different electrochemical processes involved by determining the ac re-

sponse as a function of applied frequency; with pulse techniques, the kinetics of the different processes are generally not well resolved.

4. The ac data may be interpreted directly, whereas pulse data must generally be Fourier transformed into the frequency domain before analysis.

The use of ac techniques for classical electrochemical measurements have been reviewed by Sluyters (4), Grahame (5), and Armstrong (6). Ho *et al.* (7) have discussed application of the method to single-crystal and thin film WO_3 insertion electrodes; they focused attention on solution of the diffusion equation in the frequency domain, but they avoided the problem of surface roughness and porosity encountered in pressed-powder insertion electrodes. The latter problem is important because the insertion-compound electrodes used in commercial cells, and many that are tested in the laboratory, consist of finely divided powders pressed so as to ensure electronic conduction between particles, but not so as to eliminate a continuously connected porous space between the particles. The interparticle space allows the electrolyte access to a large surface area. In this paper, we present an equivalent-circuit model for interpreting the ac impedance of a pressed-powder insertion-compound electrode in contact with a liquid electrolyte that penetrates the pores.

The ac results presented below demonstrate that the electrode material $\text{Li}_{1-x}\text{CoO}_2$ in propylene carbonate cannot be characterized in terms of a simple intracomponent Li^+ ion diffusion; more complex electrochemical processes, including the formation of a surface layer on the electrode due to oxidation of the electrolyte, must be considered. A model for the ac impedance of these complex electrochemical reactions, including adsorption and surface-layer formation, is presented and rationalized.

Experimental

Samples of LiCoO_2 were prepared by heating an intimately ground, stoichiometric mixture of Li_2CO_3 (BDH Chemicals Limited, ANALAR purity) and cobalt metal (Koch-Light Laboratories, 1 μm , 99.5% purity) in air initially at 600°C for 12h with subsequent heating at 900°C for 24h. The product was repeatedly ground and reheated at 900°C until x-ray diffraction indicated it was single phase. Atomic absorption analysis confirmed production of a Li:Co ratio of 1:1, and the semiconducting character of the blue-black product indicated an essentially stoichiometric oxide-ion concentration. Lithium-deficient electrodes $\text{Li}_{1-x}\text{CoO}_2$ were prepared by galvanostatic titration of a two-terminal cell constructed as the three-terminal cell described below.

Because the materials used in these studies are air sensitive, the cells were constructed in an argon-filled Vac-

uum Atmospheres glove box in which the dioxygen level was maintained in the region of 3 ppm and the H₂O level in the region of 7 ppm.

A three-terminal cell suitable for kinetic measurements on pressed-powder electrodes is shown in Fig. 1. The working electrode consisted of a 200-mesh stainless steel gauze (N. Greening and Company) current collector shaped as a 13 mm diam disk onto which was pressed (5 ton) about 20 mg of the powdered Li_{1-x}CoO₂ that, in some cases, was premixed with one or two drops of the liquid electrolyte, a 1M solution of LiBF₄ (Ventron GMBH) in propylene carbonate (Aldrich). Nickel gauze was found to be unstable in contact with an oxide containing cobalt in the highly oxidizing Co^{4+/3+} mixed-valence state. Similarly, propylene carbonate was selected for the electrolyte because it appears kinetically stable in contact with Li_{1-x}CoO₂ at potentials of up to 4.5V vs. lithium. The propylene carbonate was distilled under reduced pressure at 80°C and dried over Li chips before preparation of the electrolyte. The pressed-powder compact was placed against one of the two stainless steel spigots, Fig. 1; a freshly cut disk of lithium metal was placed against the other spigot to act as the counterelectrode. The working and counterelectrodes were separated by Whatman glass-fiber pads that had been saturated with electrolyte; one low porosity pad (type GF/F) was placed next to the working electrode and two type GF/D pads next to the counterelectrode. A lithium annulus placed between the two GF/D pads acted as a voltage-reference electrode. The whole cell assembly was compressed by screwing together the stainless steel spigots; pressure on the cell components was increased until a stable and identical voltage was obtained between the working electrode and both counter and reference electrodes.

Impedance measurements were carried out by connecting the cell to a Solartron 1186 Electrochemical Interface that was, in turn, connected to a Solartron 1174 Frequency Response Analyser. The combined system potentiostatically controls the cell voltage and supplies a 10 mV-rms ac perturbation sweeping the frequency range 10⁰-10⁻⁴ Hz. The Model 1186 is a four-terminal device; the two reference leads are provided with driven shielding, which minimizes the stray lead capacitances and inductances, a potential problem with ac measurements. The cell-Solartron system was under the control of an Intertec Superbrain microcomputer; the Superbrain was also used to apply a dc bias to the cell via a digital-to-analog converter and to provide a graphical presentation of the data. The results reported here are presented exclusively in the complex-impedance plane.

The data were analyzed with a complex-nonlinear-least-squares refinement program developed for microcomputers (8). The program allows interactive specification of equivalent-circuit models and their component values. (We are grateful to Dr. B. A. Boukamp for recommending the use of an interactive approach.) The program generates as output the refined component values, the observed and calculated impedance responses and their percentage difference, and a reliability factor *R* calculated as

$$R = \frac{\sum_i [O(\omega_i) - E(\omega_i)]^2}{\sum_i O(\omega_i)^2}$$

where *O*(ω_i) and *E*(ω_i) are the observed and estimated re-

Fig. 1. Electrochemical cell

sponses at the frequencies ω_i . With this program, the optimized component values for a wide variety of different equivalent-circuit models could be rapidly evaluated. This procedure allows comparison of alternative models and an evaluation of the physical interpretation of the components used in any given model.

AC Impedance of a Model Pressed-Powder Electrode

The ac impedance of an electrochemical cell containing a pressed-powder electrode can be described by an equivalent circuit such as that shown in Fig. 2a; a model of the electrode/electrolyte interface is shown in Fig. 2b. The model of Fig. 2a is based on the assumption that the electronic conductivity of the insertion compound is high and that the powder is compacted sufficiently to ensure that each particle is in contact with the aggregate across a solid-solid interface making an ohmic contact of low resistance to electron flow. Under these conditions, the insertion-compound aggregate forms a rough, but continuously interconnected, porous solid of low bulk resistance $R_b \ll R_e$, where R_e is the bulk electrolyte resistance.

The model divides the problem into three segments: the bulk electrolyte, the interface region, and the bulk electrode. The bulk electrode resistance consists of a very low electronic resistance in parallel with a higher insertion-ion resistance. The interface region includes three segments: the interface itself across which insertion-ion transfer and double-layer charging occur, and regions on either side of the interface where these processes introduce insertion-ion concentration gradients in the electrolyte and/or the electrode. In a porous electrode, electronic currents in the solid induce ionic countercurrents in the electrolyte to produce a circuit element analogous to that of a nonuniform RC-transmission line (see Fig. 3). Two

Fig. 2. Modified Randles circuit (a, top) and electrode/electrolyte interface (b, bottom).

Fig. 3. Transmission-line equivalent circuit

types of currents through the interface must, therefore, be distinguished: that due to insertion-ion and electron migration (faradaic process), and the displacement current due to charge polarization (nonfaradaic process). These two currents flow in parallel branches. We now argue that the faradaic-current branch may be represented by a charge transfer resistance R_{ct} and by a Warburg impedance Z_w , the nonfaradaic-current branch by a generalized Warburg impedance Z'_w and a double-layer capacitance C_{dl} .

Representation of the insertion-ion migration across the interface by a charge transfer resistance R_{ct} is more generally valid, but it may be conveniently derived from the Butler-Volmer equation used in classical electrochemical systems for charge transfer current across an interface of effective area A

$$I = AnFk [a_o \exp(-\alpha\phi) - a_r \exp(\beta\phi)] \quad [1]$$

where reduction currents are defined as positive quantities. In Eq. [1], k is the charge transfer rate constant, $\phi = nF\eta/RT$ (with $n = 1$ for alkali-ion transfer) is proportional to the overpotential η and the Faraday constant F , and the transfer coefficients obey the relation $\alpha + \beta = 1$. The coefficients a_o and a_r represent the insertion-ion activities at the interface in the electrolyte and electrode, respectively. At low overpotentials, linearization of Eq. [1] allows the faradaic current flowing across the interface to be represented by η/R_{ct} , where

$$R_{ct} \equiv RT/nFI_o; \quad I_o \equiv AnFka_o^\beta a_r^\alpha \quad [2]$$

is the charge transfer resistance and I_o is the exchange current. In the case of a layered compound supporting only two-dimensional conductivity, the effective area A across which ions are inserted into or withdrawn from the solid is only a small fraction of the total surface area; this reduction is exaggerated by the tendency of layered-compound particles to form as platelets supporting ion transfer only across an edge interface.

Diffusion-controlled migration, whether in the electrolyte or the solid, may be described by the Warburg impedance (7)

$$Z_w = A_w (1 - j)\omega^{-1/2}; \quad A_w = \frac{V_m}{AnF(2D)^{1/2}} \frac{\partial V_{oc}}{\partial c} \quad [3]$$

provided the applied frequencies are high enough to satisfy the relation $\omega > D/l^2$, where D is the chemical diffusion coefficient and l is the width of the layer supporting a mobile-ion concentration gradient. At lower applied frequencies $\omega < D/l^2$, the impedance may be represented by a resistance and a capacitance in series (7)

$$Z_L = R_L - j(\omega C_L)^{-1} \quad [4]$$

In Eq. [3], V_m is the molar volume of the solid and $\partial V_{oc}/\partial c$ is the slope of the open-circuit voltage V_{oc} vs. mobile-ion concentration c . In the absence of any supporting electrolyte, ionic transport in the electrolyte is not diffusion controlled, and the Warburg impedance in the faradaic branch is related only to the chemical diffusion coefficient D_b of the bulk via Eq. [3]. For an ion blocking electrode, there is no ionic transport in the bulk of the electrode ($l = l_b \rightarrow 0$), and any Warburg impedance in the faradaic branch is related only to diffusion-controlled processes in the electrolyte; this situation has been discussed by Randles (9) for a diffusion-controlled reaction between soluble species at an ion blocking electrode. In the general case, the Warburg impedance in the faradaic branch must be related to the diffusion coefficients of the insertion ion in both the electrolyte and the electrode.

If the concentration of the insertion ion in the electrolyte is low, it may be necessary to introduce a concentration overpotential where there is no supporting electrolyte. In our experiments, a 1M solution of LiBF_4 in propylene carbonate gives a high enough Li^+ ion concentration that any concentration overpotentials may be ignored. However, for a pressed-powder electrode containing a layered insertion compound having only two-dimensional ionic conduction, ion transport between particles is generally difficult; the interfaces are only good electronic conductors. In this case, the width l_b of the mobile-ion concentration gradient in the solid is essentially limited to the radius of the particle in the conducting plane, so we may expect to encounter, at lower applied frequencies, the condition $\omega < D/l_b^2$ where Eq. [3] transforms to Eq. [4]. Although this transformation introduces an effective capacitance into the faradaic branch, it must be appreciated that, as dc conditions are approached, the circuit component transforms further to a simple resistance.

For a smooth electrode or at lower frequencies, uniform charging of the entire electrode surface gives rise to a capacitance C_{dl} , the classical double-layer capacitance, in the nonfaradaic branch. This was the situation in the cell investigated by Randles (9); the Randles circuit has also been used to model the ac response of electrochromic WO_3 films (7). However, in the former case, the Warburg component in the faradaic branch represented diffusion-controlled processes in only the electrolyte; in the latter, the Warburg impedance includes diffusion-controlled processes in the solid.

On the other hand, at higher frequencies with a rough or porous electrode in which the ac signal penetration depth is comparable to the depth of the pores, an in-pore ionic current counter to the in-solid electronic current produces a situation analogous to an RC-transmission-line network (Fig. 3) (10). Current flow in a semi-infinite, uniform transmission line is described by the telegrapher's equation, which has the same form as the diffusion equation since the process taking place in an RC line may be regarded as electronic diffusion into a semi-infinite medium (11). The RC line may therefore be represented by a Warburg impedance. For a porous electrode, the RC-transmission line is nonuniform, and a more general constant-phase-angle impedance is required to represent it (12)

$$Z'_w = A'_w (j\omega)^{-m} = A'_w \omega^{-m} \left[\cos\left(\frac{m\pi}{2}\right) - j \sin\left(\frac{m\pi}{2}\right) \right]; \quad 0 < m < 1 \quad [5]$$

If the nonfaradaic branch of the equivalent circuit of Fig. 2a includes the two components Z'_w and C_{dl} in series, then at low frequencies C_{dl} dominates and at high frequencies Z'_w dominates.

The ac response of the equivalent circuit of Fig. 2a is shown in Fig. 4. This is similar to that for the circuit proposed by Randles (9) except for its modification by Z'_w to include the effect of electrode porosity at higher applied frequencies ω . Inclusion of Z'_w results in the charge transfer semicircle being replaced by a semicircle with a high frequency linear tail.

Fig. 4. Simulated ac impedance response for modified Randles circuit: $R_e = 50\Omega$; $R_{ct} = 200\Omega$; $C_{dl} = 10\mu\text{F}$; $A_w = 4\Omega$; $A'_w = 10^5\Omega/\text{s}^{-1/2}$; $m = 0.5$.

Application to $\text{Li}_{1-x}\text{CoO}_2$

A four-probe dc-conductivity measurement was carried out on a $\text{Li}_{0.6}\text{CoO}_2$ pellet fabricated with a pressure (ca. 5 ton) similar to that used to make electrodes. An electronic conductivity (stainless steel electrodes) of $0.2 \Omega^{-1}\text{cm}^{-1}$ confirms that this pressure is sufficient to establish a porous electrode in which the individual particles are making electrical contact. Therefore, the physical model described in the last section should be applicable to our electrodes of $\text{Li}_{1-x}\text{CoO}_2$. However, the observed ac response (see Fig. 5) differs markedly from the response predicted for a modified Randles circuit (Fig. 4); two semicircles are clearly observed. Since each semicircle requires the inclusion of a resistor/capacitor combination in the equivalent-circuit model, the modified Randles circuit is clearly an inadequate model of the electrode reaction.

The appearance of two semicircles proved highly reproducible; of more than 200 impedance-response spectra collected from many different samples of different stoichiometries of $\text{Li}_{1-x}\text{CoO}_2$, every one showed this feature. However, the relative sizes of the semicircles were found to depend on the previous history of the cell; both semicircles were generally found to increase in size with time. The spectrum in Fig. 5 was obtained within one day of construction of the cell; other cells of similar age had impedance spectra of a similar form. Visual inspection of Fig. 5 clearly reveals that at least six circuit components—three resistors, two capacitors, and a Warburg component—are required to produce the basic form of the response.

Two different physical processes may be invoked to account for the addition of a resistor/capacitor pair to the Randles equivalent circuit: (i) adsorption of Li^+ ions or propylene carbonate onto the surface of the electrode without charge transfer and (ii) formation of an ionically conducting but electronically insulating surface layer at the electrode surface. In order to distinguish between these two possibilities, it is necessary first to construct the corresponding equivalent circuits, which are illustrated in Fig. 6.

Adsorption represents a nonfaradaic process that occurs in parallel with the nonfaradaic processes already discussed for the modified Randles circuit of Fig. 4. The adsorption branch of the circuit has two components, one representing the kinetics of formation of the adsorbed species and the other the energy stored by subsequent bond formation (see Fig. 7). The kinetic component may be represented by a resistance (Fig. 6a) or, if diffusion controlled, by a Warburg impedance in series with a resistance (Fig. 6b); the energy-storage component by a capacitance. These two steps occur in series, so they form a single adsorption branch in parallel with the interfacial-region branches of the modified Randles circuit.

A surface-layer electrolyte having a smaller insertion-ion conductivity than the liquid electrolyte is illustrated in Fig. 8. Across the surface layer, the ion transport may be represented by the insertion-ion resistance R_{sl} , and polarization of the surface-layer electrolyte by a capacitance C_{sl} in parallel. The existence of a surface-layer electrolyte modifies the double-layer capacitance, which is associated with the mobile species in the surface layer. Since the double layer is confined to a small fraction of the sur-

Fig. 5. Measured ac impedance response for $\text{Li}_{0.65}\text{CoO}_2$

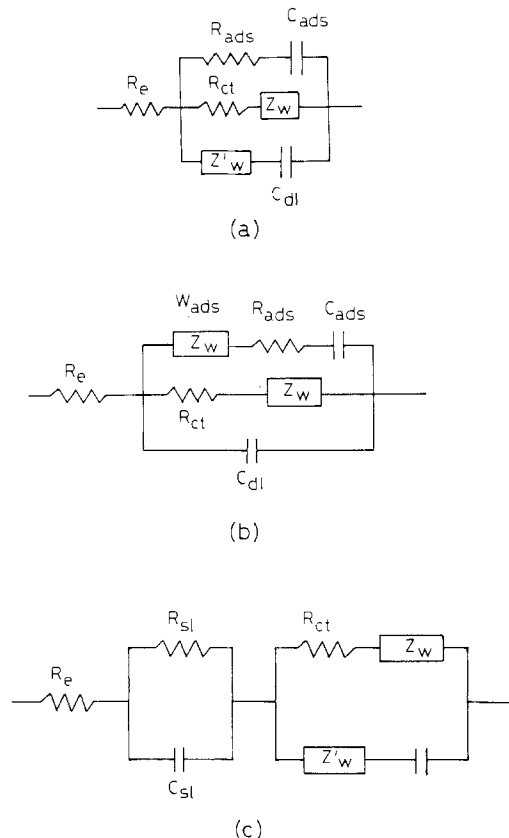

Fig. 6. Equivalent circuits for three models: adsorption (a), diffusion-controlled adsorption (b), and surface layer (c).

face layer, the relation $C_{dl} \gg C_{sl}$ can be anticipated, so we are justified in putting the surface-layer segment in series with the interfacial-region segment as shown in Fig. 6c.

Although the two equivalent circuits given in Fig. 6a and 6c were developed to represent different physical processes, they may be formally transformed one into the other (13), and simulation of the impedance responses for all three circuits of Fig. 6 are indistinguishable from one another with realistic resistor and capacitor values for either the adsorption or surface-layer model. It is therefore not possible to determine which physical model is most applicable to the $\text{Li}_{1-x}\text{CoO}_2$ system simply by least squares refinement of the impedance data. This example demonstrates the danger inherent in any justification for selection of a physical model purely on the grounds of "goodness of fit" between a simulated and an observed

Fig. 7. Modeling of the adsorption process

Fig. 8. Surface layer of thickness L

impedance spectrum; the choice of either the circuit or the physical process it represents need not be unique. The equivalence of at least two superficially different equivalent circuits used to model two distinguishable physical processes demands the establishment of more rigorous criteria upon which to base acceptance of a physical model. The following criteria can be identified.

1. Viable model circuits must contain components that are connected together in the same order as the physical processes they represent.

2. Convergent fits of simulated and observed impedance spectra must be obtained through least squares refinement.

Nonconvergence arises either if the component values are significantly different from those needed for an optimum fit or if two or more of the component values are highly correlated, which indicates that one of them may have no basis in reality. Without a convergent fit, the values of the components in the equivalent circuit may not be determined, in which case the following criteria cannot be met.

3. A low R factor as well as visual inspection of the graphical output produced by the fitting program must verify good agreement between calculated and observed impedance spectra.

4. The optimized values of the individual circuit components produced by the fitting program must correspond to reasonable values for the physical processes they represent. The magnitude of any component value must be significantly greater than the calculated estimated standard deviation.

5. The individual circuit-component values should vary in an explicable and self-consistent manner as the conditions of an experiment are varied.

6. Independent evidence, not based on ac-impedance studies or circuit fitting, should be sought to verify specific conclusions of the fitting procedure.

All three of the equivalent-circuit models shown in Fig. 6 are found to satisfy generally the first four of the above criteria, as can be seen from Fig. 9. However, criterion 3 could not be met for Fig. 9a and 9c without use of the constant-phase element (modified Randles circuit) to parametrize the electrode porosity. It should be noted that the values for the charge transfer resistance and the Warburg prefactor A_w for the intraelectrode diffusion are generally independent of the model used for fitting. This proved reproducibly true for all of the data that were fitted for these three equivalent circuits. In contrast, the values of the double-layer capacitance C_{dl} vary widely with the choice of model.

In order to differentiate between the models, the conditions of the cells were varied systematically. The aim of these experiments was to identify correlations between the variations in the external conditions and the variations in the fitted values of the individual circuit components. Three separate types of experiment were carried out to determine: (i) the time dependence of the ac-impedance response, (ii) the influence of premixing of the electrolyte with the cathode material, and (iii) the variation of the circuit parameters with applied voltage.

As discussed above, the relative sizes of the semicircles characteristic of our $\text{Li}_{1-x}\text{CoO}_2$ electrodes increased with the age of the cell. Impedance-response spectra were recorded at increasing time intervals over a period of seven

Fig. 9. Fitted ac-impedance response for $\text{Li}_{0.65}\text{CoO}_2$. (c) Surface layer: $R_e = 53.1(2)\Omega$, $R_{sl} = 12.4(5)\Omega$, $C_{sl} = 10.1(6)\mu\text{F}$, $R_{ct} = 1097(7)\Omega$, $A_w = 2.8(1)\Omega\text{-s}^{-1/2}$, $C_{dl} = 1.13(4)\mu\text{F}$, $A'_w = 682(28)\Omega\text{-s}^{-0.442}$, $m = 0.442(7)$.

days; the time-dependent behaviors of the optimized equivalent-circuit parameters for each of the three models of Fig. 6 are shown in Fig. 10-18.

Premixing the electrolyte and electrode material together was done to increase the electrode/electrolyte interface area; the results of this experiment are given in Table I.

To investigate the variation in circuit parameters with applied voltage, the high frequency (> 1 Hz) impedance response was monitored during short potentiostatic

Table I. Dependence of resistances and capacitances upon preparation method for two equivalent-circuit models

Parameter	Dry-pressed electrode	Premixed electrode

pulses. The voltage dependence of the electrochemical parameters are shown in Fig. 19 for the diffusion-limited adsorption model and the surface-layer model.

It is immediately apparent from Fig. 10 that the Warburg prefactor A_w is essentially independent of both time and the choice of model, as required for bulk diffusion. A slight decrease with time is observed; it is attributable to an electrolyte penetration that increases the effective electrode/electrolyte surface area A .

Adsorption models.—The simple adsorption model of Fig. 7 may be eliminated by inspection of Fig. 11 and 12; inexplicable changes in the adsorption resistance and capacitance over a 24h period are required by this model.

Fig. 11. Time dependence of resistances (adsorption model)

Fig. 12. Time dependence of capacitances (adsorption model)

Fig. 13. Time dependence of C_{ads} (diffusion-controlled adsorption)Fig. 14. Time dependence of C_{dl} (diffusion-controlled adsorption)

Initially, a $C_{dl} > C_{ads}$ is found; this is a physically unreasonable situation. Moreover, it is most improbable that adsorption should cause C_{dl} to decrease with time; rather, increasing electrolyte penetration with time should increase C_{dl} . Therefore, this model was not considered further.

Similarly, the diffusion-controlled adsorption model, Fig. 6b, could be discarded. The irregular increase in C_{ads} with time is peculiar; see Fig. 13. This model gives a C_{dl} , see Fig. 14, that is two to three times smaller than the C_{dl} measured by Bruce (14) for a Li_xTiS_2 electrode in 1M $LiBF_4$ in propylene carbonate. The Li_xTiS_2 system shows only one semicircle; it can be expected to have a similar surface roughness and, hence, a similar C_{dl} value. Moreover, the small decrease in C_{dl} with time, as in the simple-adsorption model, is inconsistent with the rationalization of the decrease in A_w with time as a manifestation of increased electrolyte penetration. To check this rationalization further, the contact surface area was deliberately increased by premixing the cathode material with the electrolyte before pressing the electrode. The resulting decrease in the Warburg prefactor A_w (Table I), which is consistent with a larger effective contact area A , is clearly inconsistent with the tenfold reduction in C_{dl} obtained with the diffusion-controlled adsorption model. Finally, the physical basis for a diffusion-controlled adsorption model does not exist, as all of the experiments were carried out in the absence of any supporting electrolyte. Under our conditions, Li^+ ion transport in the electrolyte is controlled by field migration. Propylene carbonate is the only other species that could be adsorbed on the electrode; it is present in such high concentrations that its movement could not possibly be diffusion controlled.

Surface-layer model.—Having eliminated adsorption as a plausible explanation for the appearance of two semicircles in the impedance plane, we now argue that the

Fig. 15. Time dependence of resistances (diffusion-controlled adsorption).

Fig. 16. Time dependence of resistances (surface-layer model)

Fig. 17. Time dependence of C_{sl} (surface-layer model)

surface-layer model provides a consistent and physically reasonable interpretation of our experimental data.

According to the model of a Li⁺ ion electrolyte surface layer having a fixed resistivity ρ and permittivity ϵ with thickness L , the resistance $R_{sl} = \rho(L/A)$ should increase with the layer thickness L , and hence with time; the surface-layer capacitance $C_{sl} = \epsilon(A/L)$ should decrease with time. From Fig. 16 and 17, this is just the behavior that is observed. The monotonic increase in R_{sl} and decrease in C_{sl} with time was maintained over a period of at least seven days. The data also imply that the rate of growth of the surface layer is rapid over the first 6h after construction of the cell and thereafter slows continuously with increasing thickness.

According to Fig. 18, the C_{dl} of the surface-layer model increases from 113 to 200 μF over the duration of the experiment. This increase is consistent with an increase in

the total surface area as a result of greater electrolyte penetration even though the relative invariance of the Warburg prefactor A_w indicates that the effective surface area (the particle edges) does not increase significantly over the time scale of the experiment. Since the particles are platelike, this discrepancy can be rationalized.

From Fig. 16, the charge transfer resistance increases by about 30% over the time scale of the experiment. Comparison with Fig. 11 and 15 shows that this variation is model independent. From Eq. [2], the exchange current $I_0 \approx AFka_0^p a_r^q$ decreases with time, *i.e.*, with surface-layer thickness L . Surface-layer formation would tend to trap Li⁺ and BF₄⁻ ions in the same concentration as that in the liquid electrolyte. If the equilibrium concentration of Li⁺ and BF₄⁻ ions in the surface layer is smaller than that in the liquid electrolyte, then a_0 would decrease with time. Thus, the observed increase in R_{ct} with time is understandable with the surface-layer model.

Table I indicates that premixing of the electrode powder with the electrolyte, which must increase the effective surface area A , significantly decreases R_{ct} and A_w while increasing C_{dl} for the surface-layer model. From Eq. [2] and [3], an increase in A is expected to decrease R_{ct} and A_w . The increase in C_{dl} also follows directly from an increase in A . Table I also shows that premixing increases R_{sl} and decreases C_{sl} , indicating an increase in the surface-layer thickness and, hence, initiation of the surface-layer growth in the premixing.

The fitted values derived from the voltage stepping experiments, see Fig. 19 and 20, provide the final evidence for acceptance of the surface-layer model. These data show that R_{sl} and C_{sl} are, as expected, independent of the applied voltage, whereas R_{ads} and C_{ads} vary irregularly.

In conclusion, the surface-layer model—and only the surface layer model—contains equivalent-circuit parameters that vary in a self-consistent manner with the electro-

Fig. 18. Time dependence of C_{dl} (surface-layer model)

chemical processes they represent as the cell conditions are varied.

Independent support for the surface-layer model is provided by the electron micrograph picture in Fig. 21, which clearly shows an amorphous layer surrounding the crystalline area where lattice-image fringes occur. The sharp boundary between the two regions makes it unlikely that the amorphous region was created by electron-beam reduction in the electron microscope. Electron-beam reduction is generally much more catastrophic,

Fig. 21. Lattice image of a $\text{Li}_{0.1}\text{CoO}_2$ crystal showing lattice deformation in the layer planes.

affecting the entire crystalline region rather than the edges alone. With the separation of the (003) lattice fringes as a guide, the surface-layer thickness is estimated to be 30Å , which is in good agreement with values estimated from the surface-layer capacitance.

Studies of the impedance response as a function of composition over the range $0 < x < 0.5$ in the system $\text{Li}_{1-x}\text{CoO}_2$ gave the same form of response as the spectrum of Fig. 5, which indicates that the surface Li^+ ion electrolyte layer forms on the particles of $\text{Li}_{1-x}\text{CoO}_2$ for all values of x . The different stoichiometries were prepared *in situ* by application of a constant-voltage step to the cell. The impedance response of the cell was measured once the cell current had decayed to less than $1\ \mu\text{A}$; the voltage was subsequently stepped to a new value. The compositional ranges studied by this procedure were $0 < x < 0.3$ and $0.2 < x < 0.5$. A steady change from a regime totally dominated by the Warburg component representing bulk diffusion occurred between 3.3 and 3.9V ($0 < x < 0.05$); above 3.9V, the response had the form of that in Fig. 5.

A mixture of propylene carbonate with $\text{Li}_{1-x}\text{CoO}_2$ ($x \approx 0.35$) produces immediately a polymer, which is consistent with the strong oxidizing power of a Co^{4+} cation on the surface of an $\text{Li}_{1-x}\text{CoO}_2$ particle. For $x < 0.35$, polymerization is probably still present, though less extensive. Although we have no direct information on the composition of the surface layer formed on our electrodes, these results are consistent with the formation of a polymeric film on the electrode surface that traps within it Li^+ and BF_4^- ions. Also consistent with such a model are the time dependence of surface-layer formation and growth, the apparent lack of a comparable surface layer on the less oxidizing Li_xTiS_2 particles, and a lowering of the surface-layer time constant $R_{sl}C_{sl} = \rho\epsilon$ for the premixed electrodes; a better LiBF_4 distribution is made possible during premixing.

Allied Corporation, Corporate Technology, Morristown, New Jersey 07960

ABSTRACT

The conjugated polymers polyacetylene (PA) and poly(p-phenylene) (PPP) have been examined for their possible use as negative electrode materials in nonaqueous secondary batteries. Cathodically stable electrolytes have been identified which allow high reduction levels for these polymers, and charge-storage capacities of 0.34 Ah/g for PA and 0.15 Ah/g for PPP have been demonstrated. Structural evolution of these polymers during cation insertion and extraction has been shown to have a significant influence on their electrochemical behavior. Several new stoichiometric phases have been identified.

Polyacetylene (PA) (1) and poly(p-phenylene) (PPP) (2, 3) are crystalline conjugated polymers which can be either partially oxidized or reduced electrochemically. This process results in the formation of a highly conducting complex between the reduced or oxidized polymer and the appropriate counterion from the electrolyte. The electrochemical reaction which occurs in a cell containing PA or PPP electrodes involves the removal or addition of electrons through the external circuit and the insertion of ions from the electrolyte into the polymer lattice.

Polyacetylene (1), polyphenylene (2, 3), and other conjugated polymers have been considered for application to nonaqueous-electrolyte secondary batteries, where they may function as either anode or cathode. Recently, the prospects for a particular cell employing polyacetylene as a cathode have been reviewed (4). In this paper, we will discuss the characteristics of polyacetylene and polyphenylene as they relate to the potential use of these polymers as anodes. In this case, we will only be concerned with partially reduced polymers for which the ion-insertion reaction may be represented by

where P denotes the polymer compositional repeat unit, C⁺ the inserted cation, y the fractional charge per repeat unit (frequently called the doping level), and x the degree of polymerization. In this paper, P denotes —CH— for PA and —C₆H₄— for PPP.

Two of the most important considerations relating to use in batteries concern the charge storage capacity (maximum value of y) and the operating voltage of the polymer. To date, there has been a discrepancy in the reported values of y obtainable with Li⁺ for polyacetylene by chemical means (5) (y = 0.3) and by electrochemical means (6) (y = 0.08). We have been able to resolve this discrepancy by performing electrochemical reductions in more cathodically stable electrolytes.

Having found a stable electrochemical system, we have been able to study the intrinsic properties of polyacetylene and polyphenylene at varying degrees of reduction.

Experimental

As we will detail in the following sections, we have found that a variety of organoborate salts offer superior stability to the reduced polymers. Some of these salts, lithium tetraphenyl borate (LiBPh₄), lithium tetrabutyl borate (LiBBu₄), and sodium tetraethyl borate (NaBEt₄), were purchased from Alfa Products. Others, which included lithium tetramethyl borate (LiBMe₄) and potassium tributyl(N-pyrrolyl)borate (KBBu₃Py), were synthesized by methods analogous to those of Ref. (7) and (8), respectively. The LiBMe₄ was prepared by reacting methyl lithium and trimethylborane, (CH₃)₃B, in diethyl ether. The KBBu₃Py was prepared by first reacting po-

tassium hydride and pyrrole in tetrahydrofuran to form KC₄H₉N. A stoichiometric amount of tributylborane, (C₃H₇)₃B, was then added to form the desired salt. Lithium perchlorate was obtained pelletized and sealed under vacuum from Anderson Physics. Lithium tetrafluoroborate and lithium hexafluorophosphate were obtained from Alpha Products, lithium trifluoromethane sulfonate from 3M, and lithium hexafluoroarsenate from U.S. Steel. The solvents used in this study, tetrahydrofuran (THF), 2-methyltetrahydrofuran (2-MTHF), methyl tetrahydrofurfuryl ether (MTFE), and diethyl ether (DEE), were all purified by distillation and storage over sodium benzophenone ketyl.

Since reduced PA and PPP are powerful and even catalytic reducing agents, extreme care was taken in purifying both electrolytes and solvents. The borate salts were typically dissolved in either THF or diethyl ether and crystallized by solvent removal. The salts were then washed with pure pentane and vacuum dried as a final step. After dissolving the salt in the chosen solvent, the electrolytic solution was stirred over a mercury amalgam of the corresponding alkali metal for at least 16h to remove any remaining reductively unstable impurities.

The Lewis acid salts were purified by heating at ca. 100°C under vacuum for 16h, followed by stirring as a solution over Li/Hg amalgam. Where necessary, solutions were centrifuged and recrystallized a final time.

Measurements of potential vs. composition were taken with a computer-controlled incremental-voltage-step (IVS) technique (9). The potential of the polymer electrode vs. an M/M⁺ reference was stepped in 10, 25, 50, or 100 mV increments or decrements between preset voltage limits. The current after each voltage step was allowed to decay to a preset minimum, typically corresponding to 25 μA/cm². Once the minimum current was reached, the circuit was opened for 1 min, and the potential of the polymer was recorded after this wait. A typical insertion and extraction cycle required 30h to complete with the longest high resolution cycles requiring up to 10 days.

Test cells were assembled in glass containers in an argon-filled dry box, degassed under vacuum, and sealed. Each cell contained an alkali metal reference/counter electrode along with the polymer working electrode. The cells contained about 1 ml of electrolyte solution and 8-30 mg of polymer. Polymer electrodes were contacted by expanded nickel screen which was wrapped around the outside surface of the electrode. Polyacetylene was in the form of a film grown by the technique of Shirakawa *et al.* (10). Such PA films were typically 0.01 cm thick, had a density of ca. 0.4 g/cm³, and were composed of 500Å diam fibrils. After synthesis the polyacetylene was stored at -40°C within the dry box. This procedure allowed the film to maintain a high *cis* isomer content (*cis:trans* > 80%). Isomerization to the all *trans* polymer was accomplished during the first cycle to a reduction level greater than 6% (*i.e.*, y > 0.06). This method of isomerization has been shown to produce

* Electrochemical Society Active Member.

longer conjugation lengths (fewer defects) than are produced by thermal isomerization (11).

Poly(p-phenylene) electrodes were fabricated from powdered polyphenylene synthesized from benzene with an $\text{AlCl}_3/\text{CuCl}_2$ catalyst in accordance with the method of Kovacic (12). These electrodes were composed of 80 weight percent (w/o) PPP, 10 w/o carbon black (Shawinigan Black®), and 10 w/o poly(ethylene-chlorotrifluoroethylene) (Halar®). They were compressed and cured at 175°C. Such PPP electrodes were typically 0.025 cm thick and had a density of ca. 0.9 g/cm³.

Results

Compatibility of electrolyte with highly reduced polymer.—The problem with the electrolytes used previously (5) is illustrated in Fig. 1, which shows the reduction (Li^+ insertion) of polyacetylene in an electrolyte solution composed of 1M LiClO_4 in THF. The discharge curve shows a reversible portion for a reduction level of ca. 8% ($y = 0.08$), followed by a large irreversible decomposition of the electrolyte (presumably ClO_4^-) between 0.6 and 0.5V vs. Li/Li^+ on the 8% reduced polyacetylene substrate. The flat (irreversible) portion of the curve was terminated after a fixed amount of charge had passed. The system would not reach an equilibrium at 0.5V vs. Li/Li^+ . The charging of the cell (Li^+ extraction) reoxidized the original 8% reduced polymer. This cycle, as depicted in Fig. 1, was repeated several more times. It exhibited identical behavior each time. Therefore, no significant part of the irreversible portion of the reduction curve involved a degradation of the polyacetylene itself. Any such degradation would have increased the cell resistance and/or decreased the capacity with cycling. The 8% reduced polyacetylene, $[(\text{CH})^{-0.08}\text{Li}_{0.08}]_x$, evidently serves as a catalytic substrate for the reduction of ClO_4^- dissolved in THF. As long as the voltage is maintained above 0.6V, the coulombic efficiency of the reduction and reoxidation process is essentially 100% (3).

At this point, the failure of previous attempts to obtain high reduction levels electrochemically can be associated with the failure of the electrolyte used, LiClO_4 in THF. Other Lewis acid salts were also investigated. Results are summarized in the upper portion of Table I. In this table, "minimum stable voltage" refers to the lowest voltage with respect to an M/M^+ reference where an equilibrium could be obtained. A typical cycle from neutral polyacetylene (at ca. 2.0V vs. M/M^+) to the minimum potential and back over a 10-30h period could be accomplished in each case with at least 95% coulombic efficiency. These criteria determine the definition of the term stability as employed in Table I. As an added caution, the reader should note that less or more rigorous purification procedures may influence the results of Table I. There can also be a solvent dependence to the stability ranges given. For all cases presented in the table, there was no evidence for the

Fig. 1. Reduction of a polyacetylene film in an electrolyte of 1M LiClO_4 in THF. Irreversible reduction of the electrolyte occurs on the partially reduced polyacetylene, $[(\text{CHLi})_y]_x$, when $y > 0.08$.

Table I. Cathodic stability of electrolytes against reduced polyacetylene

Salt, solvent	Minimum stable voltage vs. M/M^+	Maximum reversible y value in CHM _x
LiClO_4 , THF	0.6	0.08

formation of any protective (passivating) film on the polyacetylene. We have observed, however, that some solvents can react with the surface of reduced polyacetylene to produce a protective interface which limits further decomposition of either salt or solvent (13). Of all the Lewis acid salts studied here, LiPF_6 exhibits the best performance and LiAsF_6 the worst. Interestingly, this order of performance is the reverse of that observed for the plating and stripping of lithium metal from ether solutions of LiPF_6 (14) and LiAsF_6 (15). The difference between polyacetylene and lithium metal lies with the importance of the formation of a passivating film (or solid electrolyte interface) in the latter case.

In addition to lithium hexafluorophosphate, we have found that various organoborate salts possess even greater cathodic stability against reduced polyacetylene and polyphenylene. As can be seen in Table I and Fig. 2, we have been able to approximately double the previously reported (5) reversible doping levels by going to a more cathodic potential (*i.e.*, to 0.15V vs. Li/Li^+ in Fig. 2) in an electrolyte solution of 1.5M LiBMe_4 in THF. Maximum reduction levels obtained with other alkali-metal counterions (Na^+ and K^+) are comparable as can be seen in Fig. 3 and 4. The maximum electrochemically reversible reduction level for polyacetylene is obtained with lithium counterions in THF and is approximately $y = 0.18 \pm 0.01$. This value is supported by our electrochemical data and by elemental analysis of samples chemically doped with lithium. The remaining discrepancy with the literature (5) probably results from solvent coinsertion, which will raise the apparent lithium content as determined by weight increase. The maximum charge storage capacity of reduced polyacetylene is then 0.34 Ah/g (including the weight of Li^+ but not the weight of coinserted solvent).

Fig. 2. Lithium ion insertion and extraction in polyacetylene, $[(\text{CHLi})_y]_x$, with an electrolyte of lithium tetramethylborate in THF. The curve shown represents the open-circuit potential after a 1 min wait during the third cycle by the incremental-voltage-step (IVS) method.

Fig. 3. Sodium ion insertion and extraction in polyacetylene, $[\text{CHNa}_y]_x$, with an electrolyte of sodium tetraethylborate in 2-MTHF. Curve represents the open-circuit potential taken by the IVS method (10 mV steps at a minimum current of $25 \mu\text{A}/\text{cm}^2$).

Fig. 4. Potassium ion insertion and extraction in polyacetylene, $[\text{CHK}_y]_x$, with an electrolyte of potassium tributyl (N-pyrrolyl)borate in 2-MTHF. Curves represent open-circuit potential after a 1 min wait during the third cycle with the IVS method (25 mV steps at a minimum current of $25 \mu\text{A}/\text{cm}^2$).

Solvent coinserction.—The weak van der Waals forces which bind polymer chains together also readily allow the coinserction of solvent. Clearly, the charged polymer itself will act to some degree in “solvating” the inserted cation; however, the structural constraints imposed on the polymer may prevent it from achieving a coordination with the cation which has minimum energy. In this latter case, solvation of the inserted cation may be partially accomplished by coinsercted solvent. One expects that solvent coinserction will be the most pronounced for small cations which are the most strongly solvated. The solvating power of the solvent is also important. In this regard, Gutmann (16) has developed the concept of donor number (DN), which may be measured for a given solvent. For our purposes, the magnitude of DN gives an empirical measure of the tendency of the solvent to donate electrons (Lewis base) and hence a qualitative measure for the solvation energy of cations in that solvent. Solvents with high donor numbers will tend to be more readily coinsercted into our polymers. The size and structure of the solvent is also important. For example, tetrahydrofuran (THF) and glyme (DME) have the same relatively high donor number (DN = 20) (16), but the size and bidentate nature of DME allow it to more strongly solvate larger cations such as Na^+ and K^+ .

We have observed that the coinserction of solvent is accompanied by significant changes in the shape of the voltage vs. reduction level curves. Note the marked differ-

Fig. 5. Comparison of the behavior of polyacetylene during lithium ion insertion and extraction performed in three different solvents: (a) 1M LiBMe_4 in THF, (b) LiBBu_4 in 2-MTHF, and (c) LiBBu_4 in MTFE. Curves were taken with the IVS technique.

ences in the curves presented in Fig. 5 for the solvents tetrahydrofuran (THF), 2-methyltetrahydrofuran (2-MTHF), and methyl tetrahydrofurfuryl ether (MTFE). The potential variation in each solvent is characterized by three plateaus; however, the voltage and extent of each plateau is markedly different. These differences are presumably brought about by the different size and solvating power of each solvent molecule. Other workers (17) have previously shown that THF is reversibly incorporated into lithium-doped polyacetylene by alternate exposure to THF vapor and vacuum.

In this work, we attempted to make a rough quantitative estimate of the solvent coinserction effect during Li^+ ion insertion in polyacetylene by performing a chemical doping experiment in 2-MTHF. We employed lithium biphenyl as the doping agent in order to obtain a very high reduction level of the PA.

Table II gives the history of one sample that was doped, evacuated for 2h at 25°C , and then evacuated for 16h at 60°C .

Electrochemical undoping of half of the PA after the final annealing under vacuum at 60°C determined the doping level to be $y = 0.168$. Elemental analysis of the

Table II. Solvent coinserction in $(\text{CHLi}_y)_x$.

Procedure	Conductivity (S/cm)	Molecules of 2-MTHF/ Li^+
Dynamic vacuum 2h, 25°C	51	0.23
Dynamic vacuum 16h, 60°C	59	0

other half of the sample after this final anneal gave a doping level of $y = 0.177$ and no evidence for incorporated solvent. Solvent content after 2h evacuation at room temperature was calculated from the weight difference between the two entries in the table. This evacuation at 25°C was performed to remove any solvent which might have been simply adsorbed on the surface of the PA or trapped in its pores. Since this procedure might also have removed some of the coinserted solvent as well, the value of 0.23 molecules of 2-MTHF per Li^+ should be considered a lower limit. Similar experiments which were performed with K^+ insertion in 2-MTHF indicated minimal solvent coinsertion with this larger counterion.

The role of structure.—Solvent coinsertion in these polymers is controlled by a complex interplay of electrochemical and structural effects. At this point, we need to enlarge our discussion by considering in more detail certain structural aspects of PA and PPP. In all cases in Fig. 2, 3, and 4, one or more plateaus are evident in the voltage vs. percent reduction curves. The first major plateau (highest voltage) ends in the range 4-6% reduction for all cations, and the second major plateau ends in the range 12-16%. These features may reflect a maximum in the electronic density of states of the polymer, but are more likely to have a structural origin. Sharp plateaus in voltage vs. composition curves are normally indicative of multiphase structural effects as seen in the electrochemical intercalation of graphite (18, 19), TiS_2 (20), and WO_2 (21). For instance, in the electrochemical intercalation of graphite with Me_4N^+ ions (19), a series of plateaus is observed, corresponding to various discrete stoichiometric phases [in particular, $\text{C}_{48}(\text{Me}_4\text{N})$ and $\text{C}_{24}(\text{Me}_4\text{N})$].

Structural modification in crystalline polymers upon ion insertion is expected to be a complex function of ion size and shape. Both polyacetylene and polyphenylene are crystalline polymers which possess similar packing arrangements when in their neutral (undoped) state (22). When inserted with certain cations or anions, these polymers again form crystalline complexes. Since the polymer chains are only weakly bonded to each other, the polymer chains readily reorganize to accommodate the inserted counterion. In general, different crystalline structures appear for different counterions. The particular new structures arising from charge-transfer complex formation are known in some detail only for alkali-metal-doped polyacetylene (23), although staged structures have been found for iodine-doped polyacetylene (24). In the case of polyacetylene heavily doped with an alkali-metal, a channel-like structure is formed in which alkali-metal atoms are inserted into channels formed by four polyacetylene chains (left side of Fig. 6). This tetragonal structure has been identified for polyacetylene chemically doped to saturation with the alkali metals: Na, K, Rb, and Cs (23). The structure is flexible in that the interchain distance expands to accommodate the larger ions, Rb^+ and Cs^+ . The plateaus observed at low levels of reduction

Fig. 6. Proposed first-stage structure, where a' (calc) = 6.04 Å and a' (obs) = 5.98 Å, and second-stage structure, where $b'/2$ (calc) = 8.18 Å and $b'/2$ (obs) = 8.20 Å. View is along the chain direction. K^+ ions (black circles) are arranged in columns.

($y \sim 0.05$) in Fig 2, 3, 4 are indicative of different "higher-stage" structures for these more dilute compositions. A more detailed description of the structure of these different phases based on electrochemical and x-ray diffraction data has been presented elsewhere (25, 26). This study was primarily devoted to the structure of potassium-doped polyacetylene and poly(p-phenylene), since these complexes are the most crystalline and since solvent coinsertion does not occur when either THF or 2-MTHF are used. Polyacetylene film was electrochemically reduced in an electrolyte of $\text{KBBu}_3\text{Py}/\text{THF}$ and samples were removed for x-ray analysis at compositions near $y = 0.06, 0.12,$ and 0.16 . (Electrical conductivities were 170, 220, and 260 S/cm, respectively.) The x-ray data suggest that the organization of K^+ ions in columns is preserved in the more dilute compositions. However, the spacing of ions within columns and the number of chains per column are variable.

At the highest doping levels obtained, the "first-stage" structure of Ref. (23) is observed where the ratio of PA chains to columns of K^+ ions is 2 (Fig. 6). Meridional x-ray data suggest a separation around 3.7 Å between K^+ ions in a given column. Such a spacing leads to a commensurate arrangement of ions along a given polymer chain, as shown in Fig. 7. Since there are three CH units per ion and two chains per ion column in this phase, we denote this composition by $(\text{C}_3\text{H}_3)_2\text{K}$, i.e., $y = 0.167$. Various possible phases are plotted in Fig. 8 according to their particular composition. X-ray data from samples taken at the end of the first plateau ($y = 0.06$) exhibit a long spacing of ca. 8.2 Å, which supports the "second-stage" structure of Fig. 6 where there are three polymer chains per ion column. Other higher-stage compounds are likely to be identified by further study since preliminary evidence suggests a longer spacing (11.7 Å) for samples taken near 5% reduction. Samples taken at $y = 0.12, 0.15,$ or 0.16 all exhibit a long spacing of 6.0 Å and other shorter spacings characteristic of the first-stage structure of Fig. 6. The samples near 16% reduction also exhibit a meridional line corresponding to a 3.72 Å spacing between K^+ ions. As mentioned above, this spacing leads to a theoretical composition of 16.7% for the crystalline regions observable by x-ray diffraction. Amorphous regions of the sample may be doped to a lesser degree.

Electrochemical reversibility.—Another general feature of the electrochemical behavior of polyacetylene which suggests structural transformations over the plateau re-

Fig. 7. Possible commensurate phases of reduced polyacetylene. Black dots show the positions of K^+ ions in a given ion column in relation to one of four neighboring PA chains. The spacing of 3.72 Å has been observed for heavily reduced PA.

Fig. 8. Immediate open-circuit voltage (solid curve) and its derivative (broken curve) are plotted for K⁺ insertion (a, left) and extraction (b, right). Maxima in $-dE/dy$ indicate probable transition points between the growing of one phase and the next. Possible stoichiometric compositions are also plotted according to their predicted y value.

gions is the appearance of hysteresis in the discharge (ion-insertion) and charge (ion-extraction) curves (Fig. 2, 3, and 4). The disproportionation into two or more separate phases involves first-order phase transformations which proceed with appreciable kinetics only when the reaction takes place some distance from the critical point. Thus, some degree of hysteresis is expected for all systems involving multiple structurally different phases. Hysteresis is best seen with voltammetry measurements. Such measurements are difficult to perform by conventional means on thick nonswollen electrodes. Fortunately, Thompson (9) has developed a stepped-potential technique, called electrochemical potential spectroscopy (ECPS), which is equivalent to linear sweep voltammetry (LSV) at nearly infinitesimal effective sweep rate. Exam-

ples of such scans presented in Fig. 9 and 10 were obtained for Na⁺ and K⁺ insertion (cathodic sweep) and extraction (anodic sweep). Peaks in these voltammograms correspond to the voltages at which plateaus appear in Fig. 3 and 4. In order to have a one-to-one correspondence with LSV, each voltage step should be made at equal time intervals. Then dV/dt is constant for each step and dQ/dV will then be directly proportional to average current per step. In the present case, however, the current was allowed to decay to a fixed low value ($25 \mu A/cm^2$) followed by an open-circuit stand of 1 min; hence, the system was allowed to nearly approach equilibrium at the end of each step rather than being continually perturbed from equilibrium by the imposition of a constant sweep rate. However, very similar curves are in fact obtainable by traditional LSV provided relatively thin films ($< 75 \mu m$) and slow scan rates (0.1 mV/s) are employed (27).

Fig. 9. ECPS data for $[CHNa_y]_x$ in an electrolyte of 1M NaBEt₄ in 2-MTHF. The cathodic sweep corresponds to Na⁺ insertion, the anodic sweep to Na⁺ extraction.

Fig. 10. ECPS data for $[CHK_y]_x$ in an electrolyte of 1M KBBu₃Py in 2-MTHF.

The curves of Fig. 9 and 10 show that ion insertion in PA is not a simple reversible process. Particularly with K^+ ion insertion and extraction, the cathodic and anodic peaks are not well matched. By scanning only in the range 1-1.8V vs. K/K^+ , it can be shown that the reduction at 1.32V is reoxidized at 1.49V. The other two reduction peaks at 1.12 and 0.95V are associated with the reoxidation at 1.24V. Thus, there is not only considerable inherent hysteresis, but also clear evidence for a different sequence of reactions upon ion insertion than appears on ion extraction. This difference is not likely to be the result of solvent coinsertion, since we have observed no tendency for 2-MTHF to be coinserted with K^+ . The explanation lies at least partly with the structural evolution of the polymer during ion insertion and extraction. Figure 8 suggests that the sequence of phases obtained during insertion may be different from that during extraction. This different sequence may be caused by kinetic limitations on transformation from one phase to another. Even though the scan rate is effectively very low, the structural evolution of the sample will tend to proceed along a kinetically favored path. In particular, long spacings between K^+ ions in a given channel [e.g., with $(C_6H_5)_2K$] are most likely to be observed during ion extraction from already established channels. Likewise, one expects that compression into established channels will be kinetically favored over the creation of new channels during ion insertion. Such different pathways on insertion and extraction will cause a large part of the differences observed between cathodic and anodic waves in Fig. 9 and 10. Note that in Fig. 4 there is very little hysteresis in the region above 12% reduction, where x-ray studies indicate that a single structure ("first stage" in Fig. 6) persists over the entire composition range from 12 to 17%. The voltage over this range is rapidly varying because changes in y result in continuous changes in the actual degree of reduction of each chain rather than the growth of a new phase at the expense of an old. The latter process (nucleation and growth) results in a discontinuous change in y and an abrupt change in voltage to a new level, which remains nearly constant while the new phase grows. Other possible influences on hysteresis and reversibility include (i) geometrical relaxation of polymer chains subsequent to insertion (e.g., approach to equalization of bond lengths), (ii) initial insertion of anions rather than removal of cations during reoxidation [the reverse process having been observed for oxidized polypyrrole by microgravimetric measurements (28), and (iii) solvent coinsertion (largely discounted for Na^+ and larger cation insertion with the use of 2-MTHF, but of significant importance with Li^+ or with strongly solvating solvents such as diglyme and DMSO).

Poly(p-phenylene) structure and electrochemistry.—Reduced poly(p-phenylene) also displays many of the characteristics observed with polyacetylene, although reduction takes place at generally lower potentials ($\leq 1V$ vs. Li/Li^+). Reduction of PPP with Li^+ counterions (and with K^+ , not shown) exhibits a series of weak plateaus which are indicative of multiple phases as with PA (Fig. 11). With PPP, both chemical and electrochemical doping techniques give rise to the same approximate limiting reduction level: $y = 0.50$ in Eq. [1] where P is $-C_6H_4-$. The maximum reduction level achieved electrochemically with the use of alkali-metal organoborate salts in an ether is approximately 0.45 for Li^+ , K^+ , and Na^+ (Fig. 12). Thus, the maximum charge storage capacity with Li^+ is 0.15 Ah/g (including weight of Li^+).

As mentioned above, the packing arrangement of pristine polyphenylene is very similar to that of polyacetylene. Likewise, PPP also forms crystalline complexes when inserted by alkali-metal counterions. X-ray diffraction studies on heavily reduced PPP suggest the structure illustrated in Fig. 13, where again alkali-metal atoms are arranged in columns with each column being associated with two polyphenylene chains. If one assumes a commensurate arrangement of ions along each chain (a spacing of K^+ ions in each column matching that of

Fig. 11. Li^+ insertion and extraction in poly(p-phenylene), $[C_6H_4Li_y]_{r,r}$, using an electrolyte of lithium tetraphenylborate in THF.

phenyl rings, 4.35Å), then a series of phases may be postulated as described in Table III, where the observed number of chains per column varies from two to four. As this ratio increases, planes containing K^+ columns are presu-

Fig. 13. Proposed structure for PPP inserted by K^+ ions (black circles) to the maximum composition, $y = 0.50$. View is along chain direction. Spacing of ions within each column is assumed to be 4.35Å.

Table III. Possible commensurate phases for alkali-metal-doped poly(p-phenylene)

	Value of y from theory	Value of y from Li ⁺ insertion	Value of y from Li extraction	Value of y from K ⁺ insertion
(C ₆ H ₄) ₁ M	(1.00)		Not observed	
(C ₆ H ₄) ₂ M	0.50	0.48	0.48	0.50
(C ₆ H ₄) ₃ M	0.33	0.35	0.34	0.37
(C ₆ H ₄) ₄ M	0.25	0.25	0.20	0.25

(C₆H₄)_mM denotes m polymer chains per alkali-metal column.

ably separated by increasing numbers of planes containing only PPP chains. Table III illustrates the excellent agreement between the compositions predicted by this model and the inflection points observed for Li⁺ and K⁺ insertion in PPP (25, 26).

Thus as with PA, structural changes during reduction influence electrochemical behavior. PPP, however, does not exhibit plateaus so pronounced as those observed for PA. Hysteresis between insertion and extraction is also significantly less. In addition, although we have not studied it directly, solvent coininsertion does not appear to play as much of a role with PPP, since all three counterions (Li⁺, Na⁺, K⁺) give nearly identical behavior. As we have seen, the behavior of PA with Li⁺ is generally different from its behavior with Na⁺ and K⁺ and is strongly solvent dependent (Fig. 5).

Conclusions

Polyacetylene and polyphenylene have been shown to have competitively high gravimetric charge storage capacity (0.34 Ah/g for PA, 0.15 Ah/g for PPP) when compared with other ion insertion anode materials (e.g., 0.12 Ah/g for Li_xWO₃, 0 < x < 1). Less competitive volumetric charge storage capacities, however, still pose challenges for the practical realization of nonaqueous batteries with electroactive polymeric anodes.

Our electrochemical and x-ray diffraction data demonstrate that alkali-metal insertion in PA and PPP proceeds at least in part via a sequence of stoichiometric phases. The discontinuous transformation from one phase to the next causes the appearance of plateaus in potential vs. composition curves obtained during ion insertion or extraction. Such a process will lead to the nucleation and growth of particular stoichiometric phases and not to a homogeneous distribution of dopant. In other regimes, where plateaus are not evident, continuous evolution of nonstoichiometric phases is suggested.

Since transformations between phases dominate the electrochemistry of reduced polyacetylene and poly(p-phenylene), reduction of these polymers does not proceed by a simple reversible process, although the coulombic efficiency of reduction and reoxidation cycles approaches 100%.

Optimization of Carbon Cathodes for Li/SO₂Cl₂ Cells

Charles W. Walker, Jr., Michael Binder,* William L. Wade, Jr., and Sol Gilman*

US Army ERADCOM, Power Sources Division, Fort Monmouth, New Jersey 07703-5302

ABSTRACT

Five carbon blacks were evaluated for use as cathode materials in lithium-sulfuryl chloride half-cells. The best overall performance at high discharge rates was obtained with Cabot's CSX-179B. Cathode load voltage and capacity were dramatically increased at 40 mA/cm² current density without resorting to catalysts or additives by chemically treating either Shawinigan acetylene black or CSX-179B powder with acetone prior to cathode fabrication.

The lithium sulfuryl chloride (Li/SO₂Cl₂) primary system employing LiAlCl₄ as conductive electrolyte salt and porous carbon black cathodes has recently evoked considerable interest (1-3) because of its high open-circuit voltage (3.91V). During cell discharge, the lithium anode is oxidized and liquid sulfuryl chloride is reduced at the carbon black cathode. The major conclusions from various studies indicated that the capacity (*i.e.*, life) of the oxyhalide cathodes is determined by the ability of the cathode to accommodate solid LiCl product formed during cell discharge. This is especially prevalent during discharge at high current rates and/or low temperature, where cathode surfaces facing the anode are blocked by deposited LiCl leading to inefficient cathode use. The search for new or improved high performance cathode materials is a major goal in most laboratories.

Although physical and chemical characterizations of carbon blacks, graphites, and activated carbons are known, many aspects of electrochemical interactions of surfaces are not sufficiently understood. Improvements in cathode performance such as increased cathode output voltage and specific cathode capacity are still results of trial and error techniques in cathode fabrication and preparation. Our aim was to increase rate capability and specific room temperature cathode capacity of high rate Li/SO₂Cl₂ cells.

Improved cathode performance is also important from a safety point of view, since, in cathode-limited cells, more efficient cathodes allow less unreacted lithium anode at end of discharge. This implication for greater safety is an important concern for a dense energy package; the energy density of lithium sulfuryl chloride cells (600 Wh/kg) approaches that of dynamite (920 Wh/kg). Although cathodes for lithium thionyl chloride cells formulated with Shawinigan acetylene carbon black (a relatively low surface area carbon black of 60 m²/g) achieve satisfactory performance (4), similarly constructed cathodes in lithium sulfuryl chloride cells produce reduced operating voltages and capacities (1). The explanation for this depends on the nature of sulfuryl chloride itself. Active carbon blacks catalytically induce a decomposition of sulfuryl chloride, SO₂Cl₂, to yield SO₂ and Cl₂, both of which are soluble in SO₂Cl₂. Molecular Cl₂ reduces at higher potentials than does SO₂Cl₂, thereby contributing to increased operating voltages. Gilman and Wade (1) evaluated a number of carbon blacks for use as cathodes in sulfuryl chloride cells and postulated that high surface area carbons increase the SO₂Cl₂ decomposition rate by providing absorption or reaction sites where parent SO₂Cl₂ molecules can absorb and subsequently decompose formation of an adequate supply of chlorine is necessary to maintain high cathode operating voltages.

Gilman and Wade (1) found that highest cathode capacity and operating voltages in lithium sulfuryl chloride cells discharged at medium current densities were obtained using United XC-6310, an experimental, high surface area (1000 m²/g) carbon black. However, the mixability and wettability of this high area carbon black with water are not particularly good; resulting porous cathodes tend to crack and crumble rather easily. Because of these problems, and the fact that United XC-6310

is no longer commercially available, state-of-the-art cathodes for sulfuryl chloride cells have continued to be constructed using lower surface area carbon blacks such as Shawinigan acetylene black.

The need to improve cathode performance in oxyhalide cells when using low surface area carbon blacks has led to a large number of innovative research efforts to consider whether incorporation of expensive additives, modification of TFE levels, or use of various added carbon blacks could improve cathode performance. Additives recently studied in sulfuryl chloride and thionyl chloride systems include Cl₂ (5), metal halides (6), copper metal (7), finely divided expensive precious metal catalysts such as platinum (8), addition of heterogenous and homogeneous macrocyclic electrocatalysts such as cobalt and iron phthalocyanines (9), and tetraazannulenes (10). Lithium anode stability and start-up is expected to be strongly affected by catalytic materials or additives dissolved within the oxyhalide electrolyte, and cathode improvements which do not rely upon external additives are favored.

We felt it was important to extend Gilman and Wade's comparison study to other carbon blacks in order to discover a reasonable substitute for United XC-6310 and also to understand how to improve performance of existing carbon blacks.

Experimental

The porous carbon cathodes were fabricated by slowly adding a 1:3 mixture of isopropyl alcohol:water to carbon black powder and mixing well until the carbon powder was adequately wetted. Typically, 100 cm³ of alcohol:water would wet 18g of carbon black. A 10% TFE-30:water emulsion (1:9 v/v) was slowly added (1 ml/g dry carbon) and mixed well until the resulting carbon paste took on a glossy shine. The resulting paste was spread into both sides of a nickel expanded metal screen and, while sandwiched between absorbing blotting paper, was rolled through a dough sheeter. The cathodes, sandwiched between two dry pieces of blotting paper, were then sandwiched between two flat steel plates, each weighing approximately 8 kg, and placed in a vacuum oven at 100°C for 1h. The cathodes were then removed and placed in an elevated drying oven at 280°C for 1h. Upon cooling, the cathodes were rolled to the desired thickness (1 mm) to give a relatively crack-free cathode surface. Cathodes were then cut to size, and nickel tabs were welded to the ends.

Final cathode dimensions were 0.5 cm on each side for a total geometric area (both sides) of 0.5 cm². Prepared cathode working electrodes were placed in glass half-cells with a large lithium counterelectrode and lithium reference and flooded with excess 1.5M LiAlCl₄-SO₂Cl₂ electrolyte. Our half-cells were clearly cathode limited. Individual cathodes were discharged at constant current and the voltage-time profile was monitored on a strip chart recorder.

Our pretreatment procedure for raw carbon blacks consisted of soaking the carbon black powder in an excess of acetone at room temperature, filtering, washing three times with deionized water, filtering again, and drying overnight at 140°C. We also attempted to oxidize the surface groups of Shawinigan acetylene black by following

* Electrochemical Society Active Member.

Fig. 1. $\text{Li}/\text{SO}_2\text{Cl}_2$ half-cell capacity curves at $40 \text{ mA}/\text{cm}^2$ constant current discharge for cathodes constructed with various carbon blacks.

an alkaline permanganate oxidation procedure. Approximately 2g of dry acetone treated carbon black was placed in 250 ml of 5% KMnO_4 solution containing 50 ml of 25% KOH solution and allowed to react at 50°C for approximately 1.5h. The carbon was filtered and rinsed with 5% oxalic acid solution and excess distilled water; the carbon was then dried overnight at 140°C . Cathodes were prepared from these carbon blacks in the same manner as cathodes prepared from untreated carbons. The pH's of the carbon blacks were measured at room temperature with a standard combination electrode immersed in enough water to make an aqueous slurry from the various carbon blacks and boiled deionized water.

Results and Discussion

Figure 1 shows typical discharge curves at $40 \text{ mA}/\text{cm}^2$ of geometric cathode area for cathodes constructed with four commercially available carbon blacks and assembled as working electrodes in $\text{Li}/\text{SO}_2\text{Cl}_2$ half-cells. Highest operating voltages and longest operating cathode life (to 1.5V) were obtained with cathodes constructed with CSX-179B. Similar data (within experimental error) were obtained with the commercial product Black Pearls 2000.

Figure 2 compares cathodes constructed with CSX-179B and cathodes constructed with United XC-6310, under both 40 and $80 \text{ mA}/\text{cm}^2$ constant current discharge conditions. Although United XC-6310 has been shown to be the optimum carbon black for $\text{Li}/\text{SO}_2\text{Cl}_2$ cells (1), cathodes constructed from CSX-179B also yield comparable load voltages and capacities. At current drains of $80 \text{ mA}/\text{cm}^2$, cathodes constructed with CSX-179B have even higher operating voltages and capacities than cathodes made from United XC-6310.

Since it was not experimentally possible to maintain constant carbon loadings for the various carbon types, constant current discharge cathode capacities from Fig. 1 and 2 were normalized to both geometric cathode volume and grams of carbon in the cathode (Table I). Untreated CSX-179B and United XC-6310 cathodes yield comparable ampere-hours per gram of carbon, which are about

Fig. 2. $\text{Li}/\text{SO}_2\text{Cl}_2$ half-cell capacity curves at 40 and $80 \text{ mA}/\text{cm}^2$ constant current discharge for cathodes constructed with CSX-179B and United XC-6310 carbon black.

twice that of Consel I and about three times that of the commonly used Shawinigan acetylene black. This is an important result; it shows that judicious selection of carbon blacks for cathode applications can yield dramatic improvements in cathode performance without one's resorting to added catalysts or alternate electrolytes. Cathode capacities normalized to cathode volume show that cathodes constructed with CSX-179B yield comparable capacities to cathodes constructed with United XC-6310 and more than three times the capacity of cathodes constructed with Shawinigan acetylene black.

Since Shawinigan acetylene black is one of the most widely used carbon blacks in fabricating cathodes, we first studied effects of solvent pretreatment of Shawinigan acetylene black. Figure 3 shows cathode discharge performance curves for $\text{Li}/\text{SO}_2\text{Cl}_2$ half-cells whose Shawinigan acetylene black cathodes were prepared with acetone-treated carbon black. The dramatic improvement in cathode load voltage and the approximate doubling of cathode capacity are remarkable. Since high surface area carbon blacks should be more susceptible to pretreatment due to larger percentage of exposed surface area, we also compared cathode performance in cathodes prepared from pretreated CSX-179B carbon blacks. Figure 4 clearly shows that acetone treatment of CSX-179B dramatically improves cathode operating voltages and capacities.

In order fully to understand the reasons for dramatic cathode improvements upon acetone treatment, the following experimental avenues were used to explore treated and untreated base line carbon blacks.

Chemical analysis.—There is no clear change in concentration of free radicals present in the carbon black, since ESR spectra of these carbon powders show no difference between treated and untreated samples. Acetone treatment may, however, remove soluble organic impurities. The acetone rinse solution from CSX-179B showed a weak UV fluorescence in the 3900-3500Å region and implies that fluorescing impurities are removed.

Table I. Physical characteristics and cathode capacity for various carbon blacks

Carbon type	Manufacturer	pH	Surface area (m^2/g)	Capacity at $40 \text{ mA}/\text{cm}^2$ (Ah/cm^3)	Capacity at $40 \text{ mA}/\text{cm}^2$ ($\text{Ah}/\text{g carbon}$)

Fig. 3. $\text{Li}/\text{SO}_2\text{Cl}_2$ half-cell capacity curves at $40 \text{ mA}/\text{cm}^2$ constant current discharge for cathodes constructed with treated and base line Shawinigan acetylene black.

From the combined acetone-water rinse solution from CSX-179B, a white fluffy solid was isolated and qualitatively identified by chemical microprobe analysis as containing calcium and sulfur. These impurities could have originated in feedstock or quench water during the carbon manufacturing process, since typical ash analysis by Cabot Corporation shows 2000 ppm of calcium ash present in CSX-179B. No such solid was isolated from the combined acetone-water rinse solutions of Shawinigan acetylene black. Perhaps CSX-179B, because of its higher surface area, absorbs more impurities than does the lower surface-area Shawinigan acetylene black. Acetylene black may also contain fewer impurities. Although calcium impurities are not likely to be soluble in acetone, the acetone rinse may change the water wettability of the carbon black and allow the subsequent water rinse to remove these calcium-based impurities. Soluble calcium ions in the form $\text{Ca}(\text{AlCl}_4)_2$ have been shown to severely reduce cathode capacity and operating voltage in $\text{Li}/\text{LiAlCl}_4/\text{SO}_2\text{Cl}_2$ cells (11). The reason for this decrease is believed to be preferential formation of glassy CaCl_2 at the cathode surface rather than the normally produced crystalline LiCl . Precipitated, glassy CaCl_2 tends to block cathode pores more efficiently than does LiCl , and the pore blockage leads to rapid cathode concentration polarization (12). Since the acetone treatment removes calcium ash from the carbon black starting material, the cathode capacity increases.

It is interesting that, although in lithium battery manufacturing processes extensive care is usually taken in anode and electrolyte preparation, typically no purification

Fig. 4. $\text{Li}/\text{SO}_2\text{Cl}_2$ half-cell capacity curves at $40 \text{ mA}/\text{cm}^2$ constant current discharge for cathodes constructed with treated and base-line CSX-179B carbon blacks.

procedure as such is carried out for carbon black powders. In the strong oxidizing agents such as SO_2Cl_2 , even traces of impurities from carbon black can be readily oxidized and react with the anode. Removal of this impurity from the carbon blacks prior to cathode and cell assembly should diminish anode start-up problems as well.

Treated carbon blacks are expected to show cathode performance improvements primarily at high ($30 \text{ mA}/\text{cm}^2$) cathode discharge rates where electrochemical kinetics considerations and restrictions overshadow mass-transport limitations. Applications would include pulsed power applications where high load voltage and current density are primary considerations and cathode capacity is only of secondary importance.

Cathode capacity improvement at $34 \text{ mA}/\text{cm}^2$, after acetone rinsing, have been recently demonstrated in Li/SO_2 laboratory cells by Reddy and Thurston (14), who found up to 56% improvement in cathode capacity upon treatment of various carbon blends.

We attempted to increase the amount of oxygen containing functional chemical groups on the Shawinigan black carbon surface by using alkaline KMnO_4 as a chemical treatment. Cathode operating voltage and specific cathode capacity of the resulting cathodes were severely decreased. This perhaps indicates that for the cathode reduction process in SO_2Cl_2 , the optimum carbon black would be one containing only a small number of surface oxide groups.

Physical analysis.—Acetone treatment does not change carbon lattice spacings; this is clear because powder x-ray diffraction patterns show that lattice parameters of carbon black powder remain unchanged after acetone treatment. Transmission electron micrographs of CSX-179B carbon black particles before and after acetone treatment also did not show discernable differences in average particle size aggregate morphology of particle shapes. However, a subtle but perhaps subjective change appeared. Particles of treated carbon black under $\sim 1.1 \times 10^6$ magnification appeared to be less dense (*i.e.*, transmitted more light) than the untreated base line carbons. This is fully consistent with our chemical microprobe data, which indicate that calcium and sulfur inorganics or organic species are chemically removed by acetone treatment. Removal of these impurities to give slight surface area enhancement improves interparticle contact and makes a more conductive cathode.

In order to quantify the effects of acetone treatment further, samples of treated and untreated Shawinigan acetylene carbon black were analyzed by Quantachrome, Incorporated (Syosset, New York) for surface area, average pore size, and mercury wetting characteristics. The results are summarized in Table II. This table lists various surface physical measurements using BET techniques on untreated and acetone-treated Shawinigan acetylene carbon black. As expected, the carbon black powder surface area is essentially unchanged after acetone treatment. However, the total pore volume, as well as the calculated average pore diameter (based on surface area and pore volume), more than doubles. This dramatic change is fully consistent with our hypothesis of impurity removal by acetone treatment. As the various impurities are removed, void volume is increased, and, in the finished cathode, more pores are available for deposition of the LiCl cell discharge product. The mercury contact angle is only slightly higher for the treated carbon black sample,

Table II. Comparison of various physical characteristics of acetone-treated and base line Shawinigan acetylene carbon black

	Shawinigan acetylene black	Shawinigan acetylene black (acetone treated)
Surface area (m^2/g)	53.6	54.0
Total pore volume (cm^3/g)	0.186	0.388
Average pore diameter (\AA)	139	287
Mercury contact angle	142.6°	148.5°

which implies less surface roughness. This is also consistent with impurity removal.

Conclusions

Results provided in this study show that substantial improvements in carbon cathode operating voltage and specific cathode capacity at high discharge current densities can be obtained in lithium sulfoxyl chloride cells by simple acetone treatment of the starting carbon black. This inexpensive and rapid treatment may provide a basis of extension to other battery systems which use carbon black in cathode fabrication.

Sodium Ion Conducting Glasses for the Sodium-Sulfur Battery

Andrew Herczog

Corning Glass Works, Research and Development Division, Corning, New York 14831

ABSTRACT

Composition and properties of sodium borate, aluminoborate, and aluminoborosilicate glasses are described. Electrolyte glass degradation by battery environment and chemicals and problems of thermal instability of some glasses are discussed and interpreted on the basis of glass chemistry and structure. A relationship between sodium ion conductivity and composition of the present glasses is established. Constraints on electrolyte glass composition based on its physical and electrical behavior and corrosion stability are tentatively defined, and options allowing various trade-offs between these properties are discussed.

Development of the sodium-sulfur storage battery has been based mostly on the use of β alumina as a solid electrolyte separating anodic and cathodic liquids in the battery operating at 300°C. An alternate approach of development is based on the use of a Na ion conducting glass instead of β alumina for solid electrolyte (1). Because the conductivity of glass is several orders of magnitude lower than β alumina, it has to be used as a large area thin membrane.¹ Glasses used under these conditions have to be stable against corrosion by battery chemicals and should not undergo phase transformation or structural changes; and these characteristics should be coupled with a sufficiently high ionic conductivity, of the order of 10^{-4} - 10^{-5} S, for satisfactory operation of the battery. The object of the present work is to define areas of glass composition best suited for these requirements. Mechanisms of glass corrosion by battery chemicals and structural changes in glasses in the 300°C range are discussed first based on data from the literature. Then, selected composition areas are described and their characteristics compared with the requirements.

Reactivity with metallic sodium.—Reaction between glasses and sodium metal at 300°-500°C has been studied

¹The best membrane configuration for mechanical strength is obtained by the use of capillaries or bundles of capillaries (2).

in the past for sodium vapor lamp applications (3). Two effects were observed: a discoloration of the glass due to absorption of sodium, and a surface reaction resulting in the formation of a thin layer of a sodium compound. Resistance to attack decreases in the order aluminates \rightarrow borates \rightarrow silicates \rightarrow phosphates (4). Silicate glasses show a great difference in behavior depending on composition. At high SiO₂ content over 70 mole percent (m/o), there is a strong attack and a black scale is formed, originated by the reaction

The free energy of this reaction at 25°C is -107.4 kcal; that is, the reaction is favored thermodynamically. This is not the case of the direct reduction step $4\text{Na} + \text{SiO}_2 \rightarrow 2\text{Na}_2\text{O} + \text{Si}$, having a low positive free-energy value. With increasing Na₂O content of Na₂O-SiO₂ glasses, scale formation is replaced by discoloration attributed to atomic diffusion of sodium in the glass. This process is at least partially reversible *e.g.* by heating in vacuum, but some residual reaction will take place modifying the transmission spectrum of the glass. At high Na₂O content (45 m/o Na₂O), absorption becomes too low to be detected by simple transmittance measurement. This lack of discoloration, however, does not mean immunity from attack on the surface of the glass by sodium. The explanation is

that diffusivity of neutral sodium atoms is low in the modifier ion-filled silicate glass, but on the glass surface a series of reactions can take place with the formation of silicate crystals in spots or as a thin layer. Later on, atomic diffusion will be replaced by ionic diffusion due to buildup of a large sodium ion concentration gradient. These reactions are

From the standpoint of the Na-S battery operation, both mechanisms, atomic diffusion and surface crystallization, are undesirable. According to Elyard and Rawson (4) discoloration of glass is an early indication of failure in sodium vapor lamps which eventually leads to mechanical embrittlement. Similar processes are likely in battery membrane glass. This assumption is supported by observation of discoloration in β alumina, which has been attributed to battery degradation (5). Structural changes in the glass caused by sodium diffusion can lead to losses of efficiency due to electronic conduction. Besides this bulk effect caused by sodium diffusion, the reaction products formed on the surface, by initiating faults on the glass, are a source of failure by fault propagation under stress. One can also see that, in view of the tendency to surface passivation, immersion tests are unreliable.

Based on these earlier data (4, 5), one may conclude that high silica glasses are unsatisfactory, whereas borates and aluminoborates are stable, even with a minor percentage of silica in the network. This is important because control of viscosity-temperature characteristics and, therefore, practical usefulness of these glasses depend on their silica content. Below, a method is presented to define the usable silica content in more concrete terms based on kinetics of the reaction between sodium and silica in glass.

Storage of glass prior to use was observed to cause a more severe deterioration in corrosion resistance to sodium for silicate as well as for aluminoborate glasses (4). This question will be discussed later on in relation to corrosion by water vapor.

Reactivity with sulfur and sulfides.—No information has been found on corrosion of glasses by sulfur. There are several papers, however, dealing with the solubility of sulfur in glasses. It has been reported (6) that Na_2S can be substituted for Na_2O in all proportions in the $\text{Na}_2\text{O-SiO}_2$ binary at any $\text{Na}_2\text{O/SiO}_2$ ratio; that is, the network remains intact with S^{2-} replacing O^{2-} . Borate glasses behave differently; the amount of sulfur dissolved in the glass increases with the sodium content from zero at zero Na to a maximum for the $\text{Na}_2\text{O} \cdot 2\text{B}_2\text{O}_3$ composition, where up to 100% of the Na_2O can be replaced by Na_2S . The difference in behavior between silicates and borates is attributed to differences in basicity, a concept based on assumption of a Lewis acid-base equilibrium in the glass. Data on basicity have been reported in the literature (7). The main source of basicity is nonbridging oxygen in sites $-\text{O}^- -\text{Na}^+$. In silicate glasses, all the sodium is in such sites and all associated $-\text{O}^-$ ions can be replaced by $-\text{S}^-$ ions. In borate glasses, on the other hand, at first sodium will not break the network by association with nonbridging oxygen. It will, rather, enhance network connectivity by lending oxygen to boron atoms and changing them from three to fourfold coordination ($\text{B}^3 \rightarrow \text{B}^4$). With increasing concentration of B^4 , however, nonbridging oxygen sites will also be formed and the basicity increases. The maximum basicity is reached when the ratio B^4/B^3 reaches its maximum (≈ 1) together with the sulfur solubility. Al atoms in a glass of high Na content all have fourfold coordination and behave like the fourfold coordinated B atoms. In conclusion, sulfur solubility depends on the basicity of the glass, which increases in the order phosphates \rightarrow borates \rightarrow aluminates \rightarrow silicates.

Low concentrations of S in borate glasses give a blue color. These glasses become colorless when irradiated by

x-ray and are used for x-ray dosimetry (8). In silicate glasses of higher S content, the color is red due to polysulfide ions (9). The following mechanisms have been proposed

With high Na^+ activity (basicity) and availability of oxygen, the sulfur is dissolved as sulfate without sulfide formation

On the other hand, at very low Na^+ activity, the sulfur is oxidized to SO_2 and escapes from the melt. Water dissolved in the glass helps color formation by some synergistic mode.

All the discussion so far was related to the solubility of sulfur in glass melts. From the thermodynamic viewpoint, the processes described above are also allowed at lower temperatures such as 300°C ; because of kinetic limitations, however, the reaction may be limited to random spots or to a thin surface layer. In this respect, consideration has to be given to a reaction mechanism based on interdiffusion between Na_2O and Na_2S resulting in a $\text{O} \leftrightarrow \text{S}$ ion exchange. This process is thermodynamically allowed, and the bond energies Na-O and Na-S are -40 and -37 kcal, respectively. The question is whether the diffusion rates are sufficiently high to cause surface corrosion. The presence of traces of water vapor may be a factor accelerating corrosion by a mechanism to be discussed in the next section.

In conclusion, these considerations may provide some guidance for selecting compositions more resistant to attack by sulfur on sodium sulfides. Reactivity is lowered in glass compositions by the following conditions: high boron, or phosphorus, content; alumina content, particularly in association with boron; low soda content; low T/T_g , i.e., low network ion diffusivity; absence of surface water.

Effects of humidity exposure.—Problems from this source are originated from the fiber forming and assembly operations. The room temperature strength of silica fibers of high quality is rapidly degraded by heat-treatment at temperatures above 300°C . This degradation is the result of corrosion of the glass surface by water (10).

Some glasses of high B_2O_3 content are soluble in water. Exposed to humidity, they are gradually converted to crystalline hydrates. For glasses composed with a ratio of $\text{Na/B} : 1/2$, hydration can take place without a change in this ratio, by molecular diffusion of H_2O through the hydrated layer. A more common process applicable to practically all alkali containing glasses is based on the ion exchange mechanism proposed by Doremus (11)

surface: | bulk glass:

This process has been successively verified for soda-lime glass (12) and other glasses and was also used for dating antique glass objects (13). The first step is adsorption of H_2O . This will take place preferentially at defects present on the surface. Later on, an accumulation of NaOH takes place on the same spots forming small protrusions.

Silica glasses are more durable against water, and the durability of borate glasses is improved by silica addition. Durability increases with the SiO_2 content and is higher along the tie-line $\text{Na}_2\text{O} = \text{B}_2\text{O}_3$, near acid-base balance (14). A partial replacement of B_2O_3 by Al_2O_3 can slightly improve durability without changing the general trend.

Initial corrosion by water vapor can cause surface defects, leading to stress-induced fault propagation and mechanical failure. Stresses can be structural or of thermo-mechanical (10) origin. Corrosion by sodium metal is

accelerated by exposure to traces of moisture (4). The same has been reported in the case of sulfur corrosion (9). Such complexities make evaluation of corrosion resistance to sodium or to sulfur particularly difficult.

Stability of glass composition and structure.—Compositional homogeneity and structural stability of electrolyte glass throughout the thermal history of fiber forming, battery assembly, and operational cycling are other key requirements. Glasses known to phase separately should be avoided. An example of such instability is in the well-known Vycor range of sodium borosilicates and the middle range of the $\text{Na}_2\text{O}-\text{B}_2\text{O}_3$ glass system (15). Network former substitutions for boron may extend the range of instability to higher sodium content glasses of interest for electrolyte use. Another instability inherent to all boron containing glasses, in proportion to the boron content relative to other network formers, is the variability of boron coordination with respect to oxygen as a function of alkali content (16) of the glass, temperature, and time (17). Generally, a glass quenched from high temperature has a high B^4/B^3 ratio frozen in. Reheating to, say, 300°-400°C will cause a slow drift toward the low temperature value. This also means a drift in pertinent physical properties such as viscosity, density, electrical conductivity, etc. In aluminoborate glasses of high alkali content, Al is tetrahedrally coordinated, as $[\text{AlO}_4^-]$, while boron remains mostly trigonal (18), so that structural variability as a function of formation conditions and temperature cycling is greatly decreased (17). In sodium borosilicate glasses, on the other hand, the coordination state instability of boron is not affected substantially (17, 19) and these glasses show time dependence of properties.

Devitrification or crystallization of glass is another source of structural instability. Crystalline phases of high sodium content may have increased conductivity if present in concentration sufficient for forming an interconnected dispersion, so that current flow is not limited by the second, low conductivity phase. Grain boundaries, however, are a source of undesired conduction or corrosion processes. Aside from grain boundary effects, structural and corrosion stability is more difficult to obtain in two phases than in one. Crystallization may also be induced by surface reactions, as discussed in the earlier chapters, and proceed from there to the interior, causing current focusing leading to thermomechanical failure.

Other compositional instabilities are related to impurities present in the glass, in the sodium, sulfur, sealants, or electrodes. Most of these instabilities are caused by ion exchange or ion migration phenomena. Mobile ions introduced in the sodium conducting glass, like other alkali, calcium, hydronium, or protons from dissolved water (20), etc., can reduce conductivity due to the mixed alkali effect. Often impurity introduction in or removal from the glass is gradual, resulting in a steady drift in conductivity or other properties. Even anions such as Cl^- or F^- can cause problems. Movement of these ions is very slow compared to sodium, but their displacement can lead to inhomogeneity or accumulation layers at the surfaces. These inhomogeneities may cause resistivity drift, surface stresses, or corrosion.

Composition studies.—Excluded from this study were glasses containing modifiers other than sodium; glasses having network forming ions such as Ge, P, As, Te, easily reduced by sodium; and unstable glasses obtainable by fast cooling only.

Three groups of glasses were studied, all of high sodium content. Glasses of the first group were based on the composition $\text{Na}_2\text{O}-2\text{B}_2\text{O}_3$, and some variations. This work had the objective to improve understanding of the system. The second group included aluminoborate (NABAL) glasses to determine their relative merit compared to the first group. The third group was based on the Al-B-Si network former system. This was investigated systematically to explore any combination of properties of interest for battery use. All glasses were melted in Pt crucibles at 900°-1400°C and formed by pouring on a steel

plate. Afterward, they were annealed sufficiently to allow cutting and grinding necessary for making test samples.

Sodium borate glasses.—The base composition $\text{Na}_2\text{O}-2\text{B}_2\text{O}_3$ can be obtained by melting borax at temperatures sufficiently high for dehydration without significant volatilization. Dissolved water of 0.1% or less has been found to have little effect on electrical properties. The resistivity at 300°C is $6.10^4 \Omega\text{-cm}$ ($\log \rho = 4.8$). Depending on thermal history of the sample, variations of about $\pm 30\%$ in resistivity can be observed, together with variations in viscosity and other properties due to boron coordination changes as discussed earlier.

The composition used in batteries (1) is $\text{Na}_2\text{O}-2\text{B}_2\text{O}_3-0.16\text{NaCl}-0.2\text{SiO}_2$ (21). This has been selected to suit best the requirements for resistivity, formability, and cell performance. This glass has a resistivity of $2.5 \times 10^5 \Omega\text{-cm}$ at 300°C ($\log \rho = 4.4$), or about one-half of the value of the same composition without NaCl addition. Compositions were melted here with variations in the NaCl, SiO_2 , and Na_2O contents. The use of chlorides allows an increase in sodium content, hence the higher conductivity, without making the composition more basic, that is, more reactive with sulfur. The tendency to crystallization is not increased with NaCl addition as much as by the equivalent Na_2O addition. This seems to indicate that in Cl ion containing borate glasses, the equivalent Na^+ is not tied to nonbridging oxygen; it may form, instead, something like a $\text{Na}^+\text{-Cl}^-$ sublattice within the glass network. No such effect is seen in silicate glasses. This may be related to the relatively small ionic size of boron as compared to silicon and to availability of more space in the glass network. In conclusion, conductivity enhancement by chlorides is primarily related to an increase in the number of mobile, dissociable alkali ions and, second, in increased mobility. The use of NaCl addition also has some disadvantages, such as volatility, causing problems in fiber forming by deposition of crystallites by condensation on the fibers. Furthermore, anionic mobility, however slight, may lead to structural drift near the surfaces.

The use of SiO_2 at a low percentage has the purpose of improving glass workability and, very slightly, the humidity sensitivity. Glasses were prepared with combinations of SiO_2 and NaCl at levels up to three times those used in the original composition. At higher chloride levels, particularly if paired with an increase in silica content, crystallization and phase separation became a problem. Benefits were a two to threefold increase in conductivity and 20°-30°C increase in softening point.

Aluminoborate glasses.—Compositions as described before, sodium borate glasses with low SiO_2 content, with and without chlorides, were prepared with varying amounts of boron replaced by aluminum. The structure of aluminoborate (NABAL) glasses is well described in the literature (17, 18). The fraction of tetrahedral boron, $\text{B}^4/(\text{B}^4 + \text{B}^3)$, increases rapidly with the Na/B ratio with no Al in the glass, whereas the increase becomes much less at high Al content. In glasses of high Na content, on the other hand, Al is always tetrahedrally coordinated so that structural connectivity increases with the Al/B ratio. Because of the higher connectivity, higher Na contents are possible without devitrification, and slightly higher conductivities and softening point are obtained. This is well supported by the experimental data in Fig. 1. No advantage has been seen in the use of chlorides at high Al content. Selected compositions and properties are listed in Table I.

In glasses when the Al content is near to or higher than the Na content, there are not enough O ions to form Al-O_4 groups and some Al ions will assume higher coordination. This results in higher viscosities and lower conductivities.

From the standpoint of corrosion behavior, aluminoborate and borate glasses are similar. The stability of aluminoborates with respect to sodium corrosion is equal or better, while stability to sulfur attack is slightly lower be-

Fig. 1. Resistivity and softening point of sodium-aluminoborate or NABAL glasses. Composition keys: ●, aluminoborate only; ■, 3 ct.% Cl included; ○, 3 ct.% Si included; □, 3 ct.% each Cl and Si.

cause of the decrease in the more acidic trigonal boron content. With respect to sensitivity to water vapor, there is a little improvement with Al content. The use of these glasses for batteries has been proposed by Russian authors (22) and in a U.S. patent (23).

Alumino-borosilicate glasses.—Further search for electrolyte glasses was motivated mainly by the extreme humidity sensitivity of both borates and aluminoborates and by problems in sealing to these somewhat unstable low viscosity glasses. Having excluded phosphate containing systems because of sodium corrosion, the binary aluminosilicate system had to be discarded also because of sodium reactivity due to high silica content. Furthermore, glasses of high soda content, not containing boron, are also likely to fail by sulfur reactivity due to high basicity.

This leaves open for further consideration aluminoborosilicate and binary borosilicate glasses of lower silica content. The question to be addressed is what is the limit of SiO_2 admissible from standpoint of corrosion by sodium. Silica in the range of 3-10%, cation based, has been used without adverse reaction, whereas at more than 50% SiO_2 level reaction with sodium has been observed. In order to define better limits in the 10-50% range, a kinetic model is proposed to explain the reaction with sodium.

The corrosion process has been identified, as discussed earlier, by the reaction

For a polymolecular reaction to proceed at an appreciable rate in the solid state (at 300°-400°C), it is necessary to have the reactants localized in high concentration. For example, liquid sodium and SiO_2 in pure silica glass would satisfy this requirement. On the other hand, a glass network with lower percentage of SiO_2 , such as 10-50% of the network cations, may have the necessary accumulation of Si atoms only at some locations, owing to the randomness of the network. A few spots, however, may be too many if the crack propagation mechanism from point defects on the glass surface is considered. An approach to quantify the problem has been made based on statistical probability calculations.

In a network of tetrahedrally coordinated cations, each network cation shares oxygen with four others. Assuming one cation is silicon (Si) and the other something else (N), one can calculate the probability of finding two Si cations side by side for any given ratio Si/N. Designating

$$R = \text{Si}/N, A = N/(\text{Si} + N), B = \text{Si}/(\text{Si} + N), A + B = 1$$

the probability of finding two Si cations nearby is

$$P_2 = B(1 - A^4)$$

Table I. Selected sodium aluminoborate glasses

Composition	101	102	103	104	105

Similarly, the probabilities of finding 3, 4, or 5 silicons close by are respectively, $P_3 = P_2^2$, $P_4 = P_2^3$, and $P_5 = P_2^4$. Values of P_2 , P_3 , P_4 , and P_5 are plotted against R in Fig. 2. The graph shows the probability of finding five SiO_4 groups in proximity as needed for the corrosion reaction. One can see that the probability falls off rapidly at or below the ratio $\text{Si}/N : 1/2$, which has been adopted for the upper limit of silica content in the present compositions. In reality, the probabilities may be lower than indicated by the results obtained by random-distribution-based calculations because (i) there is a degree of ordering in glass melts favoring separation of identical groups, particularly (BO_4) , from each other (17); (ii) the proximity of sodium ions, many linked through nonbridging oxygen to silicon, has been disregarded; and (iii) a single reaction site according to the given equation may not provide a stable nucleus to start the corrosion process, as several events may have to interact locally for that purpose.

The criterion of stabilizing SiO_2 against sodium reduction by sharing oxygen with a cation of higher bond energy can be extended to glasses containing elements like Zr, Ta, lanthanides, etc., as network-formers or modifiers.

The compositions to be discussed are high soda glasses, close to the limit of glass stability in the Si-Al-B network-former ternary. The sodium content of these glasses (Na) is in the range of 36-42 cation-based percent (ct. %). As the effects of variations in sodium content are comparable—

Fig. 2. Probability of silicon clustering in a mixed cation network.

Fig. 3. Range of network forming components in sodium ion conducting glasses for Na-S batteries.

this will be shown below—the present discussion can be based on the network cation ternary system Al-B-Si, remembering that the total network cation content is

100-Na; and therefore, the individual network cation percentages in the compositions are $N(100-Na)/100$ where N is the percentage of Al, Si, or B read from the ternary diagram in Fig. 3. The Si cation content in the network ternary is 10% or more, up to about 33%, as explained above. Compositions below 10% were described earlier as aluminoborates. Al content is below 60% for meltability and above 5% for better structural stability. B content is below 70% to set a limit to humidity sensitivity. The composition and properties of the glasses based on the points shown in the diagram are listed in Table II. The sodium borate glass, no. 112, is included for comparison. All glasses were found to be sodium resistant in static corrosion tests, but glasses of high SiO_2 content were marginal with respect to sulfur corrosion at 350°C ; they were, on the other hand, the best for water durability. These observations are in agreement with the data and interpretations given as background earlier.

Effects related to sodium content.—Table III gives the composition of glasses of different sodium content, all based on point A of the diagram in Fig. 3 as the common network forming system. The change in properties with increasing sodium content illustrated in Fig. 4 is predictable and does not require comments. The main purpose of the series was to determine the maximum sodium content in a glass suitable for fiberdraw or similar forming techniques. The criterion used was devitrification at a

cooling rate of 2°C/min, a critical value based on past experience. By measuring the viscosity of the glass as a function of temperature at a constant rate of cooling by the rotating cylinder method, any trace of devitrification is readily observed; in the present case, this happened for composition no. 117.

If we assume a critical cooling rate as a constant factor, the associated sodium content, here called sodium threshold, becomes an important characteristic of the network forming system for sodium ion conductor applications. The sodium threshold increases with the coordination number of the network formers. Within the Al-B-Si ternary, it is the highest for silicates, aluminosilicate glasses being a close second, then decreases with increasing borate content. Figure 5 plots log resistivity against the measured or estimated sodium threshold of glasses prepared here or comparable glasses published in the literature. The numbered points of the curve give the resistivity of a particular glass at the sodium threshold. The compositions are identified in Table IV. This figure shows that sodium ion conductivity is determined mainly by the sodium content of these glasses and that differences in resistivity are due to differences in the capability of a network to accept more or less sodium without devitrification.

Ravaine and Souquet (26) demonstrated a linear relationship between sodium ion activity and conductivity in alkali silicate glasses. This is reflected approximately in Fig. 5. Activities are not too far off from the cation-based percentages of sodium ions used here to plot resistivities. Deviation from linearity results from changes in coordination and structure from fourfold coordinated silicates (6) and aluminosilicates (5) to aluminoborosilicates (4), aluminoborates (3), and borates (2, 1) which contain

Fig. 5. Resistivity vs. sodium threshold.

increasing amounts of threefold coordinated boron. A more detailed discussion of this relationship in terms of the weak electrolyte theory of glass will be prepared later.

Conclusions

Sodium ion conductivity in glasses based on the Al-B-Si network-former system is mainly determined by the amount of sodium in the glass. This should be maximized without causing devitrification at a preselected cooling rate compatible with the forming method used. This sodium threshold increases with the coordination number of the network forming cations in the glass.

Corrosion by metallic sodium does not affect aluminate and borate glasses. In silicates, because of kinetic limitations, only glasses having silicon in more than one-half of the network forming cation sites are significantly affected. Glasses containing ions more reducible than silicates should not be used. Sodium corrosion is mainly by surface reaction. Reaction below the surface is slight; it is preceded by atomic diffusion of sodium in the glass.

Corrosion by sulfur and sulfides is related to the basicity of the electrolyte glass. Basicity is enhanced by the sodium ion concentration, while it is reduced by the presence of boron and to a lesser extent of aluminum, which form Lewis acid sites in the glass. The mechanism of corrosion is likely to be $O^{2-} \leftrightarrow S^{2-}$ ion exchange. This is a diffusion-controlled process; therefore, the T/T_g ratio is important for the rate of corrosion.

Corrosion of bulk glass exposed to humidity is due to $H^+ \leftrightarrow Na^+$ ion exchange leading to high sodium ion concentration on the surface and a gradient of dissolved OH groups underneath. Sodium accumulation on the surface increases sulfur corrosion, whereas sodium depletion and OH groups under the surface enhance corrosion by sodium metal. Susceptibility to corrosion by humidity is enhanced by boron content and diminished by silicon content for high sodium content glasses.

Phase separation and structural instability is a problem affecting mainly borate and borosilicate glasses.

Summing up the question of glass composition *vs.* corrosion, the requirements for limiting sodium corrosion are less severe than those related to sulfur corrosion. Controlling the latter requires glasses of low sodium and high

boron content with a sacrifice with respect to conductivity, moisture resistance, and structural stability. Considering these factors, further work may be based on the following options.

1. There must be continued effort on sodium borate glass, avoiding exposure to humidity to preserve fiber strength, and using stress- and water-free sealing and assembly conditions.

2. There must be explorations of the use of compositions of the no. 115 type, barely adequate with respect to sulfur corrosion, good in other respects.

3. There must be use of compositions of the no. 108 type representing a compromise between the first and second options.

4. The perspective of electrolyte glass compositions could be broadened by concentrating on the sulfur corrosion problem and revising the battery system, particularly the anolyte. Reduced sulfur corrosion may be obtained by lowering T/T_g of the glass, for example, with the use of hard, high viscosity glasses. For such glasses, however, new forming techniques would have to be found. The same can be achieved by lowering the battery temperature from 300° to 200°C or below. This would require replacing the Na₂S_x anolyte with a lower melting system, preferably of lower basicity.

Acknowledgments

Summary information on corrosion measurements was obtained from Dr. Tsang and Dr. Gregory of Dow Chemical, D. E. Sempolinski and R. F. Bartholomew of Corning Glass Works. For all glass preparation and property measurements, the work done by the Melting Services and Technical Services group of Corning Glass Works is greatly appreciated.

Manuscript submitted Aug. 27, 1984; revised manuscript received Feb. 20, 1985.

Corning Glass Works assisted in meeting the publication costs of this article.

ABSTRACT

Linear stability and bifurcation analysis is applied to two passivation models from the literature. The necessary and sufficient conditions for multiple steady states are determined for one of the models. For the other model, the parameter values for oscillatory solutions of the two-dimensional system of equations are evaluated. The results of these analyses show the power of these mathematical techniques in determining the conditions for multiple steady states and periodic solutions of various nonlinear models

Over the past century, the formation of passive films on metals has been investigated experimentally and mechanisms for their formation have been hypothesized. There still remains much uncertainty about the specific electrochemical steps or the important elements necessary for passivity under particular environmental conditions. Efforts have been made to define the mechanism of passivation by developing models (1-4) to reflect the

special nature of the anodic polarization curves, which show that with increasing anodic potential the oxidation current reaches a maximum and then quickly decreases by several orders of magnitude to the passivation current at the Flade potential. Thus, the models developed have attempted to account for the multiple values of potential for a particular current in the active-passive transition region.

Current oscillations at constant potential or potential oscillations at constant current have often been observed

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

in the active-passive transition range for a variety of metal-electrolyte systems (5-8). These oscillations can take diverse forms, periodic or aperiodic, and of constant, changing, or even damped amplitude. Although most of the explanations of electrochemical oscillations are phenomenological, there have been some attempts to postulate mechanisms and to mathematically model these oscillations (9-11). However, the only endeavor prior to our own (12, 13) to model the oscillations found in the passivation process is that of Franck and Fitzhugh (10). Their work models iron polarized at a constant potential, focusing on the change of overpotential and of electrode surface coverage.

It may be possible to gain a better insight into the mechanisms of passivation by the investigation of the multiple values of potential characteristic of anodic polarization curves and the oscillatory behavior observed in the active-passive region. By utilizing linear stability and bifurcation analysis, the existence of and conditions for multiplicity of steady states and periodic solutions of the model equations may be determined. The purpose of this paper is to apply these mathematical tools to two models in the literature to show the usefulness of these techniques for evaluating the criteria for multiple steady states (MSS) in one case (4) and oscillations in another (10).

Linear Stability Analysis

Generally, differential equations which represent oscillatory behavior are nonlinear and seldom lend themselves to analytical solutions. There are many texts on the theory of analysis of nonlinear differential equations [for example, Ref. (14-16)], and only a brief discussion of certain fundamental concepts and results is needed here. Linear stability analysis allows qualitative information to be obtained about the solutions of differential equations by examining what a small change in the initial conditions does to the solution by linearizing the original nonlinear equations. Application of bifurcation theory results in information regarding the dynamic behavior of the system of equations as parameters change.

Suppose we have a system of nonlinear autonomous equations

$$\frac{dx}{dt} = F(x) \quad [1]$$

The steady-state solution is defined by

$$\frac{dx}{dt} = F(x_s) = 0 \quad [2]$$

If we expand $F(x)$ in a Taylor series about the steady-state solution, x_s , and truncate at the linear terms, we obtain

$$F(x) = F(x_s) + \frac{\delta F}{\delta x_s} (x - x_s) \quad [3]$$

By letting $u = x - x_s$ and substituting Eq. [3] into Eq. [1], and knowing by Eq. [2] that $F(x_s) = 0$, one obtains

$$\frac{du}{dt} = J u \quad [4]$$

where $J_{ij} = (\delta F_i / \delta x_j)_s$, the linearized Jacobian evaluated at the steady state. Since the solution of Eq. [4] is of the form $u = \exp(Jt)u_0$, the stability of the solution to infinitesimal perturbations depends on the eigenvalues of J . The character of the steady state is determined by the real parts of the eigenvalues (λ) of Eq. [4]: $\text{Re}(\lambda) < 0$ means stable, $\text{Re}(\lambda) > 0$ means unstable, and $\text{Re}(\lambda) = 0$, $\text{Im}(\lambda) \neq 0$ may indicate periodic solutions.

Usually, we are interested in the behavior of a system of equations such as Eq. [1] as parameters (p) vary, that is

$$\frac{dx}{dt} = F(x,p) \quad [5]$$

Bifurcation is the change of stability or changes in the qualitative structure of the solutions for certain values of

the parameters. A static bifurcation occurs when a single eigenvalue passes through the origin of the complex plane as a particular parameter changes, leading to MSS. Hopf bifurcation to periodic solutions occurs when a pair of complex conjugate eigenvalues crosses the imaginary axis of the complex plane. In other words, Hopf bifurcation requires two purely imaginary eigenvalues, with the remaining eigenvalues, if any, having negative real parts and $d \text{Re}(\lambda)/dp \neq 0$ at the imaginary axis.

For a two-dimensional system of differential equations, the eigenvalues are the roots of following equation

$$\lambda^2 - (\text{tr } J)\lambda + \det J = 0 \quad [6]$$

These roots are

$$\lambda_{\pm} = 1/2 \text{tr } J \pm 1/2 [(\text{tr } J)^2 - 4 \det J]^{1/2} \quad [7]$$

and they can be expressed in terms of the system parameters. The necessary and sufficient conditions for local asymptotic stability are that $\det J > 0$ and $\text{tr } J < 0$. If $\det J < 0$, the two eigenvalues are real and opposite in sign, and this specifies a saddle (an unstable steady state). If $\det J > 0$ and $\text{tr } J > 0$, an unstable steady state (node or focus) is signified. If, under certain parameter conditions, $\det J = 0$ with $\text{tr } J < 0$, then a static bifurcation to MSS would occur. If $\text{tr } J = 0$ with $\det J > 0$ and $d \text{Re}(\lambda)/dp \neq 0$, then Hopf bifurcation to oscillatory solutions would occur.

The results of stability analysis can be pictorially represented by phase-plane portraits where the solutions of Eq. [5] are traced as trajectories by plotting one variable *vs.* another. Trajectories can approach or leave the vicinity of a steady state depending on its stability. An isolated closed trajectory is called a limit cycle, such that any trajectory in the neighborhood either approaches it (a stable limit cycle) or leaves it (an unstable limit cycle). A limit cycle represents sustained oscillations independent of initial conditions. A stable limit cycle represents unchanging periodic oscillations, whereas an unstable limit cycle represents either damped or growing oscillations. Bifurcation diagrams trace the Hopf points or limit points (points of static bifurcation) as system parameters change.

Case I — Analysis of Griffin's Model

Griffin's simple phase-transition model (4) for metal passivation kinetics consists of only two rate processes: (i) the oxidation of surface metal atoms M to produce adsorbed cations M^{n+} , according to

and (ii) the subsequent dissolution of cations into the electrolyte, either from adsorbed atoms at low coverage on the electrode surface

or from a high coverage adsorbed layer, also called an oxide layer (4)

The rate constant for cation dissolution, whether according to Eq. [9] or [10], is written as

$$k_{\text{dis}} = k^{\circ}_{\text{dis}} \exp(-\beta\theta) \quad [11]$$

where k°_{dis} is the rate constant for the dissolution of an isolated adsorbed cation, θ is the surface coverage by adsorbed cations, and β is a Temkin-type adsorbate-adsorbate interaction parameter. The rate expression for the dissolution current for either Eq. [9] or [10] is given by

$$i_{\text{dis}} = k^{\circ}_{\text{dis}} \theta \exp(-\beta\theta) \quad [12]$$

and the rate of adsorbed cation formation (Eq. [8]) is expressed by the Tafel relation

$$i_{\text{ox}} = k^{\circ}_{\text{ox}} (1 - \theta) \exp(fE) \quad [13]$$

where $f = \alpha F/RT$, E is the potential, and k_{ox}° is the chemical rate constant. By equating Eq. [12] and [13], an expression relating the steady-state potential, E_s , and steady-state coverage, θ_s , is determined

$$E_s = (1/f)[- \beta \theta_s + \ln(k_{dis}^{\circ}/k_{ox}^{\circ}) + \ln(\theta_s/1 - \theta_s)] \quad [14]$$

The solution of Eq. [14] yields MSS for $\theta_s(E_s)$ for $\beta > 4$. Polarization curves for $\beta > 4$ calculated from Eq. [12]-[14] show the multiple-valued active-passive region. The critical value of 4 for the interaction parameter, β , represents the mean field approximation of a phase transition between isolated cations and the continuous oxide layer.

An alternate approach to determine the parameters necessary for multiplicity for Griffin's model is to apply bifurcation analysis. First, we must write a differential equation to express the change of surface coverage with time for the proposed mechanism, as follows

$$\begin{aligned} \Omega \equiv d\theta/dt &= k_{ox}(1 - \theta) - k_{dis}\theta \\ &= k_{ox}(1 - \theta) - k_{dis}^{\circ} \exp(-\beta\theta) \end{aligned} \quad [15]$$
