190°C for reaction times of 18, 40, 70, and 140h. Water (500 ml) was then added to the suspension, and the solution was filtered. The product was then washed with water until the filtrate became colorless. Finally, the product was washed with acetone. (iii) The gas-phase method, where ferrocene, TCB, and the carbon supports (14:7:24 weight ratio) were mixed and heated at 250°C for 20h in an evacuated sealed tube (3). The product was washed with pyridine and methanol as in method (i).

The second way was by impregnation, where 8g of the carbon supports were added to 200 ml of 96% H₂SO₄ containing 0.3g of poly-FePc. The poly-FePc was then precipitated onto the supports by pouring the mixture into 2 liter of ice water. After filtering, the carbon supports impregnated catalyst were washed with water until the pH of the filtrate reached 7.

Poly-FePc was synthesized from TCB, FeCl₃, and urea. The starting materials for poly-FePc synthesis were mixed and heated at 300°C for 18h in an N₂ atmosphere. The temperature was then raised to 350°C and heated for an additional 2h. The product was purified according to the method reported by Epstein *et al.* (10).

Electrode preparation.—Carbon powder (C, Nippon Carbon Company), acetylene black (AB, Denki Kagaku Kogyo Company), and Ketjen black EC (EC, Akzo Chemie Company) were used as carbon supports for the air electrodes in a 1:3:4 weight ratio (12). The catalysts were prepared on the carbon supports by the methods described above. The catalyst-prepared carbon supports were then mixed in a ratio of 9:5 with polytetrafluoroethylene (PTFE) emulsion (60 weight percent [w/o] solution, Mitsui Florochemicals Company) and kneaded with ethanol and water. The mixture was rolled into a sheet and a Ni screen (Exmet Company, 3Ni7-3/0) together with a porous PTFE sheet (Nitto Denko Company, NTF5205) was applied to one side and pressed at 82.5 kg/cm²/250°C for 30 min.

Electrochemical measurements.—**Polarization.**—The air electrode (2 cm²) was placed into a polytetrafluoroethylene (PTFE) cell with a Pt foil counterelectrode, 1N KOH (Kanto Chemical Company, $f = 1.002$) electrolyte, and a saturated calomel reference electrode (SCE). One side of the electrode was contacted with electrolyte, and another side was contacted with atmospheric air. Polarization measurements were carried out in atmospheric air at room temperature (20°-25°C). Polarization curves were recorded galvanostatically with a stepwise increasing current density up to 100 mA/cm², followed by a stepwise decrease back to zero.

Rotating ring-disk electrode measurements.—The carbon supports with poly-FePc were mixed with a spectroscopically pure paraffin wax (Uvasol, Aldrich Company) in a

*Electrochemical Society Active Member.

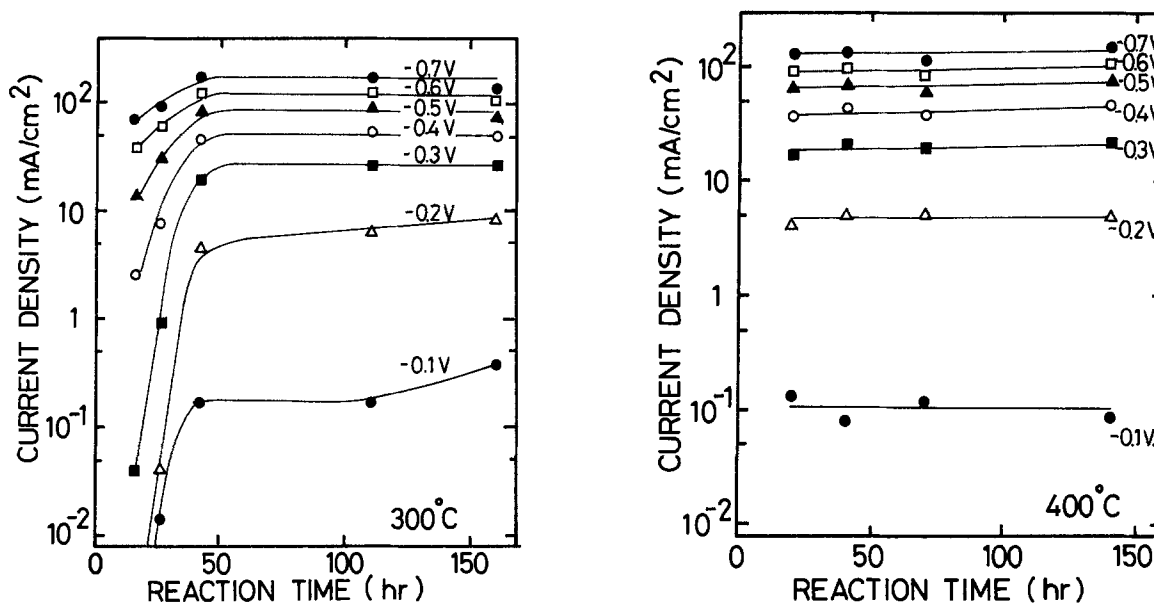

Fig. 1. Reaction time dependence on polarization characteristics of melt synthesis electrodes. Reaction temperature is 300°C (a, left) and 400°C (b, right).

2:1 weight ratio. The mixture was introduced into the disk cavity (8.00 mm diam) and was smoothed with a razor blade (13). The ring electrode consisted of gold (8.00 mm id and 12.16 mm od). A platinum sheet counterelectrode, the SCE, and a 0.1N KOH (Kanto Chemical Company, $f = 1.001$) electrolyte were used. The calculated collection efficiency of the RRDE was 0.366. Before measurements, N_2 gas was bubbled into the electrolyte to purge the O_2 in the electrolyte, and very small or no residual current for ring and disk electrodes was checked. The measurements were carried out bubbling O_2 gas into the electrolyte (O_2 concentration was 1.21×10^{-3} mol/liter). The potential of ring electrode (E_R) was maintained at +0.20V vs. SCE, where the diffusion limiting current for the oxidation of peroxide was observed (14).

All potential values for polarization and RRDE measurements were expressed in those vs. SCE.

Results and Discussion

Synthesis conditions for poly-FePc by the melt and liquid phase methods.—Direct synthesis of poly-FePc onto the carbon supports by the melt method has been examined (8). However, the poly-FePc could not be synthesized under the same conditions as those for poly-FePc synthesis alone, suggesting that the carbon supports acted as synthesis inhibitors. Therefore, the synthesizing conditions for the melt method and the liquid phase method were examined. Poly-FePc was synthesized directly onto the carbon supports using different reaction time and temperature conditions. The synthesis condition of poly-FePc was decided as a result of the cathodic polarization of the various electrodes.

Melt synthesis method.—The relationship between the reaction time and the current density at a constant potential is shown in Fig. 1. For the samples synthesized at 300°C, the current densities at constant potential increased with increasing a reaction time up to 50h (Fig. 1a). In the range 300°C/> 50h, current densities were independent of reaction time. However, when poly-FePc was synthesized at temperatures higher than 350°C, no significant difference in the activity in respect to reaction time and temperature was observed. The result at 400°C, as a typical case, is shown in Fig. 1b. Consequently, we suggest that poly-FePc should be synthesized on carbon supports by the melt method under 300°C/> 50h or 350°-500°C/> 20h conditions.

Liquid phase synthesis method.—Polarization characteristics were the same at -0.4 and -0.5V for different samples (Fig. 2). Current densities at -0.2 and -0.3V in-

creased with increasing reaction time. The current densities in the range of < 100h were larger than those at -0.2 and -0.3V in the range of < 40h in Fig. 1a. We judged this tendency was due to an increase in amount of poly-FePc synthesized onto carbon supports. The difference of current densities in the range of -0.5 to -0.7V may be due to the difference in electrode structure, for example, pore size and number of pores. In this method, it is suggested that poly-FePc should be synthesized on the carbon supports under 190°C/> 20h conditions.

Thermogravimetric measurements were carried out for the carbon supports on which the poly-FePc was synthesized by all three methods. The results are shown in Table I. The temperature where sample weight decreased rapidly was in the range of 372°-378°C, which was slightly higher than, or equal to, the decomposition temperature of the poly-FePc synthesized by the corresponding method. However, the temperature was higher than that for the monomeric FePc (335°C) and was far higher than the decomposition temperature of TCB (248°C). The results indicated that poly-FePc was the material supported on the carbon surface.

Fig. 2. Reaction time dependence on polarization characteristics of liquid phase synthesis electrodes. Reaction temperature is 190°C.

Table I. Decomposition temperature of poly-FePc

Synthesis method	Sample	
	Poly-FePc (°C)	Carbon supports containing poly-FePc (°C)
Melt	370	372
Liquid phase	372	380
Gas phase	372	378

Table II. Poly-FePc electrodes

Synthesis method	Synthesis conditions		Poly-FePc weight on carbon supports (g/m ²)
	Temperature (°C)	Time (h)	
Melt	(500 550)	(40 2)	7.88×10^{-4}
Liquid phase	190	140	1.28×10^{-3}
Gas phase	250	20	$> 4.00 \times 10^{-4}$

Electrochemical characteristics of direct synthesis electrodes.—As a result of the experiments conducted above, the electrode preparation conditions used were selected as listed in Table II. For the gas phase synthesis electrode (electrode 3), the correct amount of poly-FePc could not be evaluated because of the loss of carbon supports during the evacuation procedure. Judging from results of the dependence of amount of FePc on activity (15), the poly-FePc almost entirely covered the carbon supports.

Polarization curves are shown in Fig. 3. The poly-FePc electrode prepared by the melt method (electrode 1) exhibited the most positive potential. No polarization hysteresis of electrode 1 was observed. The hysteresis of electrode 2 was in the opposite direction. (That of curve 3 in Fig. 7 was also in the same direction.) The behavior may be rest of solvent (ethylene glycol) in micropores of carbon supports (or less wettability of bare carbon surface), although we cannot surely show that. We are now engaged in experiments about the behavior.

The potential-time curves at 10 mA/cm² discharge are shown in Fig. 4. Electrode 1 retained the most positive potential for 300h. The potential drop after a 300h discharge was as follows: for electrode 1 it was 0.01V; for the liquid phase method electrode (electrode 2) 0.08V, and for the gas phase method electrode (electrode 3) 0.067V.

As seen from the results, poly-FePc directly synthesized on the carbon supports by the melt method showed the most active catalytic effect, low polarization, and an excellent stability of activity.

Fig. 3. Polarization curves for poly-FePc electrodes. Curve 1: melt synthesis. Curve 2: liquid-phase synthesis. Curve 3: gas phase synthesis.

Fig. 4. Dependence of potential drop at 10 mA/cm² on time. Curve 1: melt synthesis. Curve 2: liquid phase synthesis. Curve 3: gas phase synthesis.

Elemental analysis was carried out for poly-FePc and the carbon supports deposited poly-FePc by three synthesis methods. The results are given in Tables III and IV. The N/Fe ratio of the carbon supports containing poly-FePc by melt synthesis method was 8.8. The value was close to that of poly-FePc in Table III. This suggests that the poly-FePc on the carbon supports consisted of almost all ligand units with a central Fe metal. In another study (8), a poly-FePc with few ligand units containing no Fe atoms was synthesized directly onto carbon supports using a larger amount of FeCl₃ than for the stoichiometric ratio of FeCl₃/PA. In the present work, however, poly-FePc with few Fe defect units was synthesized directly on supports by increasing reaction time and temperature with TCB and FeCl₃ in a stoichiometric ratio. Nevertheless, liquid and gas phase synthesis resulted in carbon supports containing poly-FePc with many ligands lacking Fe atoms, while the corresponding poly-FePc in Table III had a few ligands with no Fe atoms. Though the catalyst activity has correlation with conductivity (16), we believe that the excellent activity observed in the melt method mainly results from the synthesis of poly-FePc containing fewer units with no Fe metal.

The quantity of Fe atoms in poly-FePc was evaluated by atomic absorption analysis. In one treatment, the carbon supports with poly-FePc were pyrolyzed at 500°C for 2h and then placed in conc. HCl and filtered. In another treatment, they were placed in conc. H₂SO₄ for 5h, and then were filtered. The amounts of poly-FePc dissolved in conc. H₂SO₄ were evaluated from the ratio of Fe content obtained by the latter treatment to that by the former treatment. Those were 59.2 w/o for the melt method, 81.3 w/o for the liquid phase method, and 43.9 w/o for the gas phase method. This suggests that large potential drop after 300h for electrode 2 may be correlated with the solubility of liquid phase poly-FePc.

Table III. Elemental analysis of poly-FePc

Sample ^a	C (%)	H (%)	N (%)	Fe (%)	C/N	N/Fe
Melt	61.3	2.5	24.5	11.7	2.92	8.4

Fig. 5. Dependence of potential at constant current density on poly-FePc coverage (g/m^2) for melt synthesis electrodes.

Effect of poly-FePc amount on activity.—The dependence of the amount of poly-FePc on electrode activity for the melt synthesis method was examined. This amount was controlled by changing the ratio of the starting materials to the carbon supports. The reaction temperature was maintained at 500°C for 40h, followed by 550°C for an additional 2h. Electrode potentials at constant current density for electrodes with various amounts of poly-FePc are shown in Fig. 5. The potential became more positive with increasing coverage of poly-FePc in the range of 0.89×10^{-4} to $6 \times 10^{-4} \text{ g/m}^2$. Above this range (6×10^{-4} to $9.3 \times 10^{-4} \text{ g/m}^2$), the potentials changed little with the amount of poly-FePc present. It appears that the carbon supports were completely covered with poly-FePc molecules when more than $6 \times 10^{-4} \text{ g/m}^2$ of poly-FePc was supported. The optimum poly-FePc coverage for melt synthesis electrodes was $7.9 \times 10^{-4} \text{ g/m}^2$. Poly-FePc was supported on the carbon supports in a monolayer, based on the calculated value of $6.6 \times 10^{-4} \text{ g/m}^2$. As can be seen, the experimental optimum is close to the calculated value.

Voltammetry curves at 1000 rpm for samples with different loadings of poly-FePc are illustrated in Fig. 6. The O_2 reduction occurred in the range of $< -0.1 \text{ V vs. SCE}$ on the disk electrode with poly-FePc, while without catalyst O_2 reduction occurred in the potential range of $< -0.25 \text{ V vs. SCE}$. A ring current, I_R , was observed in the potential range of $< -0.25 \text{ V vs. SCE}$. I_R decreased with an increase in the amount of poly-FePc on the carbon supports. The

Fig. 6. Rotating ring-disk (RRDE) data for O_2 reduction on carbon supports with various amounts of poly-FePc in 1 N KOH . Scan rate: 20 mV/s . Ring potential: $+0.20 \text{ V vs. SCE}$. Rotation speed: 1000 rpm . Calculated RRDE collection efficiency: $N = 0.366$. O_2 concentration: $1.21 \times 10^{-3} \text{ mol/liter}$.

ratio of I_R to the disk current, I_D , was the smallest at a poly-FePc loading of $9.32 \times 10^{-4} \text{ g/m}^2$.

Comparison of the direct synthesis method with impregnation method on the catalytic effects of poly-FePc.—When the impregnation method was used, poly-FePc was supported on the carbon surface less uniformly because of its low solubility. Furthermore, by analogy with results for monomeric FePc (15), it is possible that the activity of poly-FePc supported by the impregnation method decreases with time. Consequently, poly-FePc supported on the carbon by the method of Kreja *et al.* showed insufficient electrochemical activity.

Polarization characteristics for O_2 reduction for poly-FePc electrodes made by the impregnation and direct synthesis (melt) methods are shown in Fig. 7. The electrode prepared by the latter method showed more negative open-circuit potential than the former electrode, although it showed more positive potential at current densities higher than 2 mA/cm^2 . In addition, the polarization hysteresis was smaller in the latter than in the former.

Discharge measurements as a function of time were carried out at 10 mA/cm^2 . Results are shown in Fig. 8. The electrode prepared by direct synthesis maintained more positive potential than that prepared by impregnation. The potential drop after discharge over 200h was -0.140 V for the latter electrode, whereas the former electrode showed no potential drop over the same period. Poly-FePc synthesized on the carbon supports therefore showed excellent stability in its electrocatalytic activity for O_2 reduction in KOH solution.

Conclusion

Poly-FePc was synthesized on carbon supports by three methods (melt, liquid phase, and gas phase) to examine

Fig. 7. Polarization curves for air electrodes. Curve 1: with poly-FePc prepared by direct synthesis. Curve 2: with poly-FePc prepared by impregnation. Curve 3: support without catalyst.

Fig. 8. Time dependence of electrode potential at 10 mA/cm^2 . Curve 1: direct synthesis poly-FePc. Curve 2: impregnation poly-FePc.

the catalytic effects on oxygen reduction in KOH solution.

Poly-FePc was successfully synthesized on the carbon supports under 300°C/> 50h or 350°-500°C/> 20h conditions for the melt method and 190°C/> 20h for the liquid phase method. From elemental analysis, the N/Fe ratio of poly-FePc supported on the carbon by the melt method was 8.8. The poly-FePc, therefore, consisted almost entirely of ligands with a central Fe metal.

The melt synthesis electrode showed the lowest polarization and maintained the most positive potential for a period of at least 300h at a 10 mA/cm² discharge. The activity of the poly-FePc was in the order of melt > liquid phase > gas phase synthesis. It is suggested that the highest activity of poly-FePc made by the melt method is due to the presence of a few monomer units with no central Fe metal. From the dependence of the poly-FePc amount on polarization, poly-FePc synthesized by the melt method entirely covered the carbon supports in the range of > 6 × 10⁻⁴ g/m². The optimum poly-FePc coverage for the activity of melt synthesis electrodes was 7.9 × 10⁻⁴ g/m², which was nearly equal to the calculated value (6.6 × 10⁻⁴ g/m²) of a poly-FePc monolayer. The RRDE results suggest that the excellent polarization characteristics obtained with this poly-FePc coverage are due to the predominant occurrence of the four-electron O₂ reduction process on poly-FePc electrodes.

The melt synthesis electrode with poly-FePc showed lower polarization in the range of 2-100 mA/cm² and a smaller potential drop over 200h during 10 mA/cm² discharge tests than that for the electrode made by impregnation. It is concluded that the poly-FePc melt synthesis electrode showed the higher electrochemical activity and stability for O₂ reduction in KOH solution.

Preparation and Properties of Electrodes Modified by Polymeric Films with Pendant Anthraquinone Groups

P. M. Hoang, Steven Holdcroft, and B. Lionel Funt*

Department of Chemistry, Simon Fraser University, Burnaby, Vancouver, British Columbia, Canada V5A 1S6

ABSTRACT

Polymeric films of poly-[p-(9,10-anthraquinone-2-carbonyl)styrene]-co-styrene were deposited on Pt by evaporation of solvent from toluene solutions. The films were insolubilized and stabilized by cross-linking reactions initiated by UV irradiation. The voltammetric reduction to the radical anion is reversible in dimethylsulfoxide solution containing tetraethylammonium perchlorate. The redox peaks occur at identical potentials and show the linear current dependence on scan rate characteristic of adsorbed systems. Spectroelectrochemistry of successive reduction cycles confirmed the reversible formation of the radical anion and dianion. The electrocatalytic reduction of O₂ was conducted with these modified electrodes.

Electrodes modified with quinoid compounds have been utilized for electrocatalytic purposes. The oxidation of NADH and of ascorbic acid mediated by catechols have been described (1-4). The covalent attachment of naphthoquinone to semiconductors was utilized by Wrighton and co-workers in photoelectrochemical reductions (5, 6). Degrand employed an adsorbed film of an anthraquinone polymer with an amine backbone for electrocatalytic reduction of O₂ (7).

We previously reported the preparation of a series of polymers with pendant electroactive anthraquinone groups and investigated the electrochemical response of these polymers in solution (8). The electroactive units responded independently, and the spacing of electroactive units on the chain could be changed without affecting

*Electrochemical Society Active Member.

their electrochemical behavior. Previous work indicated that such systems could conform to theoretical expectations as polymeric films (9).

In this report, we describe the preparation of these films and their stabilization and insolubilization by cross-linking reactions produced by irradiation of the film. The reversibility and stability of the modified electrodes is explored by electrochemical and spectroelectrochemical techniques, and the effects of spacing of electroactive units on the backbone chain and of overall film thickness are examined. These modified electrodes are utilized for the mediated reduction of O₂ in a nonaqueous medium.

Experimental

The synthesis of a model compound 2-(p-ethyl-benzoyl)-9,10-anthraquinone (EBAQ) and of the polymer

poly-[p-(9,10-anthraquinone-2-carbonyl)styrene]-co-styrene (PAQ) was described previously (8)

Dimethyl sulfoxide (DMSO) was fractionally distilled and stored over molecular sieve 4Å, which had been activated by heating for several days at 300°C in vacuum. Tetraethylammonium perchlorate (TEAP) was recrystallized twice from distilled water and dried in vacuum.

Film preparation.—A measured volume of toluene solution of the polymer was placed on the surface of the working electrode and the solvent was allowed to evaporate slowly. The electrode was subsequently dried *in vacuo* for 5 min. The film thickness was estimated from the quantity of polymer initially present in the solution.

The films were cross-linked by irradiating the coated electrode, which was immersed in isopropanol, with light from a 100W Hg lamp (Engelhard Hanovia). The electrode was subsequently dried *in vacuo* for 10 min.

Electrochemistry.—A three-compartment cell was used which had a 5 mm ϕ Pt working electrode (Beckmann), a Pt wire counterelectrode, and a SCE reference. The working electrode was polished successively with SiC 600, 3 μm diamond paste and 2, 0.1, and 0.05 μm alumina and then sonicated in distilled water for 10 min. The reference electrode was provided with a salt bridge of 0.1M TEAP/DMSO in the Luggin capillary. The stability of the background current indicated that insignificant contamination by water occurred within the time scale of the experiments. Before each set of runs, polymer from the previous experiment was removed with tissue paper and the electrode was then cleaned chemically and electrochemically as described in the literature (10).

The solutions were flushed with Ar and an Ar atmosphere was maintained throughout the voltammetric measurements. A PAR 170 electrochemical system with IR compensation was used for stationary voltammetry, and a Pine Instrument rotating ring-disk electrode and ancillary potentiostat and controller were used for the dynamic studies. An Apple II microcomputer-based data acquisition system was employed for step function Cottrell experiments.

Fig. 1. Spectroelectrochemical cell

Spectroelectrochemistry.—A $1 \times 1 \times 4$ cm square cross-sectional optical cuvette, with a quartz-to-glass seal to a $1.2 \phi \times 5$ cm tube, was fitted with a Teflon cap with ports for a SCE, miniature counterelectrode, and Ar inlets, as shown in Fig. 1. The working electrode was a sheet of tin oxide-coated glass (VWR Scientific) on which the polymer sample was deposited. Electrical connections were made using silver dag, which was subsequently covered with epoxy resin. Visible spectra were recorded on a Unicam SP 8000 spectrophotometer.

Fig. 2. Cyclic voltammograms of 3.47 mM EBAQ (a), unirradiated PAQ-coated electrode (b), and irradiated PAQ-coated electrode (1000Å thick) (c). Scan rate 50 $\text{mV}\cdot\text{s}^{-1}$; 0.1M TEAP in DMSO.

Results

The voltammetry of the polymer films and of the model compound, EBAQ, is shown in Fig. 2. A cyclic voltammogram of the model compound at a bare Pt electrode shows two well-defined nernstian peaks. An electrode coated with PAQ, which had not been cross-linked, produced successive peaks which decreased in magnitude due to desorption of the polymer, and deviations from nernstian response were also evident.

The electrode could be stabilized by cross-linking the polymer chains through exposure to UV radiation. Figure 2c shows the effect of 10 min irradiation. Only a minor decrease in peak current or in integrated charge is found after 50 cycles. The electrochemical activity was maintained for a period of many days. Moreover, the first and second reduction potentials of the AQ groups in the polymer film were essentially identical with those of the model compound, EBAQ, in solution. In contrast to our experiments with poly(vinylbenzophenone) films, where cycling above the second reduction potential leads to a loss of electroactivity, the PAQ films remain physically and chemically stable on repeat cycles to the doubly charged anion.

The effect of varying the period of UV irradiation was investigated in order to optimize film preparation. Obviously, too much irradiation will lead to destruction of electroactive centers and excessive cross-linking of chains, whereas insufficient irradiation will result in desorption from the electrode. The data in Fig. 3 show that maximum peak currents were obtained after 10 min exposure. This condition was chosen for all film preparations reported here.

Spectroelectrochemistry.—The $\text{PAQ}^{\cdot-}$ radical anion is green, and the doubly charged PAQ^{2-} is blue. The spectroelectrochemistry of successive reduction cycles was examined in order to characterize the films and to probe their stability and reversibility. Polymeric films were deposited on conducting glass in the apparatus shown in Fig. 1. The films were potentiostated at a chosen potential until maximum optical absorption was exhibited. The results are presented in Fig. 4. Below -0.7V , no effect is obtained. Between -0.7 and -1.2V , a strong absorption develops at 690 nm , which corresponds to the formation of $\text{PAQ}^{\cdot-}$ radical anions. Further increase to -1.3V and more cathodic values produces a new peak at 595 nm , (PAQ^{2-}) and a decrease in the $690, 415,$ and 392 nm peaks. The process is reversible and reproducible, and similar intensities were obtained on successive cycles.

Charge transport.—The influence of film thickness on the electrochemical performance was determined (Table I). For a 100 \AA film, the voltammogram shown in Fig. 5 was obtained. The positions of the anodic to cathodic peaks almost coincide, as expected theoretically for a

Fig. 3. Effect of time of UV irradiation on the cathodic peak current of PAQ 200(2)-coated electrodes, film thickness 1000 \AA . Scan rate $50\text{ mV}\cdot\text{s}^{-1}$; 0.1M TEAP in DMSO.

Fig. 5. Cyclic voltammogram of 100 \AA thick PAQ 200(2)-coated electrode. Scan rate $50\text{ mV}\cdot\text{s}^{-1}$; 0.1M TEAP in DMSO.

highly adsorbed substrate. The peak width at half-height is 98 mV , which is in good agreement with the theoretical value of 90.6 mV (11).

Even a 100-fold increase in film thickness to $10,000\text{ \AA}$ did not lead to major deviations. The peak separation became 16 mV and the width at half-height 112 mV for these thick films.

The dependence of peak current on thickness for the various films is shown in Fig. 6.

0.1M TEAP/DMSO ; $50\text{ mV}\cdot\text{s}^{-1}$; UV irradiation time 10 min.

Fig. 6. Effect of scan rate for films of PAQ 200(2) of various thicknesses. Film thickness for curves from top to bottom: 3×10^4 , 2×10^4 , 1×10^4 , 5×10^3 , 1×10^3 , 5×10^2 , and $1 \times 10^2 \text{ \AA}$; 0.1M TEAP in DMSO.

The concentration of electroactive units in a unit volume is determined by the spacing of AQ groups on the backbone chain. All the PAQ polymers were prepared from a parent styrene polymer of 200 unit average chain length. The concentrations of AQ groups ranged from 19.5 to 47.4% AQ. The voltammetric characteristics obtained at a sweep rate of $50 \text{ mV}\cdot\text{s}^{-1}$ are summarized in Table I. No substantive changes in reversibility or peak shape are apparent. The ratio $\Gamma_{\text{obs}}/\Gamma_{\text{cal}}$ is the ratio of electroactive centers which undergo redox processes to that expected for the amount of polymer deposited on the electrode. This ratio remained insensitive to AQ content in the 1000 \AA film.

The process of charge transport in the film was investigated by chronoamperometry. The potential was stepped from -0.2 to -0.9 V to produce the reduction to the radical anion. A Cottrell plot (12) of the data is shown in Fig. 7. It yielded a diffusion coefficient $D_{\text{CT}} = 5.1 \times 10^{-11} \text{ cm}^2\cdot\text{s}^{-1}$ from the linear portion of the curve. Precise comparisons are not possible because of the curvature exhibited in these plots. However, similar values were obtained with cations of differing size, *i.e.*, K^+ and $(\text{C}_2\text{H}_5)_4\text{N}^+$. Closer spacing of AQ groups along the chain did not produce any detectable shift in D_{CT} . The value of this diffusion coefficient is comparable to that obtained by Murray and co-workers for cobalt porphyrin-modified electrodes (13). Table II summarizes the data obtained.

Electrocatalysis.—The catalytic reduction of O_2 to O_2^- was attempted at a PAQ-coated electrode immersed in 0.1 M tetraethylammonium perchlorate solution in DMSO. Figure 8 shows the reduction of an O_2 saturated solution (2.1 mM) at both a bare and a coated electrode. At a bare Pt electrode, a quasi-reversible curve is obtained with $E_{\text{pc}} = -0.88 \text{ V}$ and $E_{\text{pa}} = -0.66 \text{ V}$ vs. SCE. The large peak separation potential, $\Delta E = 222 \text{ mV}$, indicates that the electron transfer is not fast, and the results are consistent with those reported by Sawyer and Roberts (14).

Fig. 7. Cottrell plot for PAQ 200 (2) film; 0.1M TEAP in DMSO

At the PAQ-coated electrode, the smaller peak separation ($\Delta E = 68 \text{ mV}$ and $E_{\text{pc}} = -0.78 \text{ V}$ and $E_{\text{pa}} = -0.71 \text{ V}$) indicates improved reversibility. Of greater interest is the 98 mV positive shift of the cathodic peak. This indicates the catalytic reduction of O_2 by PAQ and shows that the electron transfer from Pt to O_2 in solution via the PAQ film is faster than direct electron transfer from the electrode. The absence of a peak at -0.88 V in Fig. 8d shows that there is little O_2 present at the electrode surface at this potential and indicates that it has all been reduced by the PAQ film.

The presence of a single wave is consistent with a rapid electrocatalytic reduction, as found with homogeneous catalytic systems (15). A slow process should exhibit two peaks associated with the catalytic and direct reduction steps, respectively. Conversely, a very fast reduction should exhibit a precatalytic wave due to the electrocatalysis of O_2 and a second peak associated with the reduction of the polymer film.

Dynamic measurements were performed with a polymer-coated, rotating disk electrode. A shift of 60 mV in half-wave potential was observed. This compares with a shift of 98 mV in peak potential obtained with stationary cyclic voltammetry.

Discussion

Despite the similarity of the PAQ polymer and the anthraquinone polymer utilized by Degrand and Miller (16), significant differences exist. Their polymer was based on a structure

The presence of amino groups in the main chain conferred hydrophilic properties to the polymer which per-

mitted its utilization in aqueous media. In contrast, the PAQ polymer is inactive in water. More surprisingly, the layer-to-layer conductivity is higher, as demonstrated in the behavior of thick films of PAQ. The difference in conductivity may result from the single-electron transfer process found in this work, in contrast to the two-electron, two-proton transfer found in Miller's more complex reaction (15). Furthermore, peak broadening is not found at higher anthraquinone loadings with PAQ, but was obtained with the amino-linked polymer. These results reflect the influence of the conformation and structure of the backbone chain on ion migration and electron hopping processes.

The voltammetric results with PAQ polymers show that the 100\AA films are in accord with theoretical expectations for highly adsorbed material. The symmetry, scan rate dependence, and coulometry reflect essentially ideal behavior. For films of increased AQ content, there is little indication of deviation due to interference between neighboring groups. However, an increase in overall conductivity could be expected as electron hopping between neighboring sites is facilitated. This, as Murray has recently stated (17), is an oversimplification. To be exact, each site removed in a dilution process, or replaced in a loading process, should be comparable in size, polarity, morphology, etc., in order to ensure that distance between groups rather than chain conformation is the dominant factor. The dependence of D_{CT} on concentration has been expressed analytically (18) for Os and Ru contained in copolymer compositions. However, Buttry and Anson (19), Facci (20, 21), and Kuo (22) found D_{CT} to be independent of concentration or to decrease at high concentrations (17).

In our work, the interpretation is further complicated by an extraneous factor. The UV irradiation of the films may lead to increased cross-linking at higher AQ loadings with identical irradiation conditions. With this proviso in

mind, the failure to observe an increase in $\Gamma_{obs}/\Gamma_{calc}$ ratio in Table I may indicate that competing effects balance out the expected increase in electron transport due to smaller distances between electroactive groups.

A similar analysis applies to the effect of increase in film thickness. The change in peak current is not proportional to the total AQ content of the films. The percentage of AQ groups reduced electrochemically drops from 79 to 5.0% for a 300-fold increase in film thickness from 100 to $30,000\text{\AA}$. If reduction occurred by slow progression through successive layers, then, presumably, a limiting thickness would be encountered at which further reaction would not occur. Such a model should not show the increase of current with thickness shown in Fig. 6.

We suggest that the orientation of the polymer chains in the film leads to preferred pathways or channels for electrical conductivity. It is recognized that long chain molecules can be oriented by stretching and that such orientation results in higher crystallinity and regularity in the polymer. Thus, for films thicker than 100\AA , some regions may be completely reduced in channels from the electrode to the solution interface, while other regions may only be reduced in the first 100\AA or so layer. Such a model is consistent with the finding that films of greater thickness yield currents whose increase is not proportional to the total AQ content.

ABSTRACT

A series of trivalent and tetravalent metal phthalocyanines (Pc) has been examined in thin film form on metal substrates by electron microscopy, UV-visible spectrophotometry, and electrochemical and photoelectrochemical techniques. These Pc's are compared with other divalent metal and demetallated phthalocyanines. The tri- and tetravalent phthalocyanines show enhanced photoresponses *vs.* the divalent metal and demetallated systems. This enhanced activity correlates with their broadened and red-shifted visible spectra and their tendency to grow as block-like or platelet-like microcrystals in the thin film. The divalent and demetallated Pc's grow as smaller, needle-like deposits with poor photoresponses. The trivalent and tetravalent Pc's have been grown in this study as thin films that act as highly doped p-type photoelectrodes or as nearly intrinsic photoconductors, exhibiting both positive and negative photopotentials, depending upon the E° of the redox couple.

There continues to be interest in the use of thin film organic materials for photovoltaic (PV) and photoelectrolytic (PE) applications (1-15). PV applications include dry cell materials, where the chromophore is sandwiched by itself or in a polymer matrix between two conductive substrates of dissimilar work functions (1-3, 16, 17). Wet cell PV and PE applications include the use of an electrolyte solution in contact with the photoactive organic material and a counterelectrode to complete the cell. Phthalocyanines (Pc) have been used in many instances as the light-sensitive, charge separating medium for these applications (5-15, 26-33). They also continue to be of interest as the primary photoreceptors in electrophotography and information processing applications, along with several other chromophores of the merocyanine, cyanine, and squarane families (34-39).

Thin film inorganic solar cells (*e.g.*, a-SiH_x) have been proposed by several researchers, which all take the same general form (Fig. 1) (16, 17, 40, 41). To the extent that organic thin film materials can be described by an energy-band model, this will apply as well to their application. Two contacting phases (labeled 1 and 3 in the figure) of dissimilar work function (or differing electrochemical potential) are sandwiched around a photoconductive material (labeled as 2 in the figure) of thickness d . This material is nearly intrinsic, but is doped to a density that must be able to support the development of a space-charge or depletion layer (of thickness δ) at both interfaces (hole blocking contacts, Fig. 1a, interface between 1 and 2; and electron blocking contacts, Fig. 1a, interface between 2 and 3). The direction of the electric field gradient within the photoconductive film depends upon the dopant density in the photoconductor (initial position of the Fermi level before contact), the thickness of the Pc film, and the relative electron affinities of the photoconductor and the two contacting phases (29-32). Two of several possible limiting cases are shown in Fig. 1a and b, both of which produce a net potential gradient which affect the photoresponse within the film and drive photogenerated holes to the interface between phases 2 and 3. These diagrams are discussed further below. Aqueous and nonaqueous electrolyte solutions are recognized to be good candidates as one of the contacting media in these cells (20-25). By changing the thermodynamic formal po-

tential, E° , of the redox couple in solution, it is possible to change the effective work function of a contacting phase (*e.g.*, phase 3) and systematically vary the sign and magnitude of the potential gradient in phase 2, and thus vary the photopotential.

Several limitations arise with the use of organic photoelectrode materials such as phthalocyanines. Rose has set forth some of the objectives for the use of any thin film photoconductor material sandwiched between two phases of dissimilar work function (16, 17); (i) the films

Fig. 1. Energy level schematic of an intrinsic photoconductor (phase 2) sandwiched between two contacting phases (phase 1 and phase 3). Left Side: Before contact, flatband condition. Right Side: After contact, equilibrium condition. A: Fermi levels of phases 1, 2, and 3 arranged in descending order (electron affinities increase from 1 through 3). B: Fermi level of phase 2 above either phase 1 or phase 3. Energy *vs.* electron in vacuum increases negatively in downward direction, electrochemical formal potentials increase in downward direction. V_{oc} is the maximum obtainable photopotential at open circuit.

must possess strong light absorptivity over a large wavelength range (centered in the red), so that a thin film can capture most of the available visible wavelength light—this is generally attainable with Pc thin films; (ii) defect densities must be low enough to permit efficient transport of charge across the entire thin film in less time, τ_d , than the lifetime before recombination, τ_r —Pc films have traditionally shown excessive defect densities and inefficient charge transport; and (iii) nearly ohmic contact of the photoconductor with phases 1 and 3 (Fig. 1). This last point requires some additional modification since one of the contacts must be blocking for electrons and the other contact blocking for holes and the two contacts must have sufficiently dissimilar work functions to provide the driving force for charge separation.

Our studies of phthalocyanines have concentrated recently on chlorogallium phthalocyanine (GaPc-Cl), which exhibits unusual optical and electronic properties relative to many Pc's that have been studied previously (27-33). Films of GaPc-Cl (ca. 1 μm thick) grown very slowly on Au, and in contact with a variety of electrolyte solutions, can behave as expected for a nearly intrinsic semiconductor. The Fermi level (of several of the films studied to date) is at least 0.7 eV above the valence bandedge (29, 30). Both positive and negative photopotentials have been observed for these slowly grown films, with absorbed light photoelectrochemical quantum efficiencies of ca. 2-10%. Much thinner films of GaPc-Cl grown more rapidly on Au. (ca. 200-500 nm thickness) have shown much smaller photopotentials, but showed the same high photoconductivity and high contrast between light and dark electrochemical response (27). These films also showed an unusually red-shifted and broadened absorbance spectrum. Preliminary electron micrographs showed a high degree of long-range ordering in the microcrystalline deposits comprising each thin film. We have recently extended these studies to include several other trivalent and tetravalent metal phthalocyanines which also exhibit strong red shifting of their solution absorption spectra over most of the visible and near-IR regions. Some of these same phthalocyanines, embedded in polymer matrices, have been recently used in solid-state thin film photovoltaic cells (6-8, 42).

In this publication, we compare these tri- and tetravalent metal phthalocyanines with demetallated and divalent metal Pc's (the focus of the most previous photoelectrochemical studies) using (i) scanning electron microscopy (SEM) of both the bulk and thin film materials, (ii) UV-visible absorption spectroscopy of thin films, and (iii) electrochemical and photoelectrochemical activity of both thin (0.3-0.5 μm) and thick ($\geq 0.7 \mu\text{m}$) Pc films grown at different rates on metallized polymer substrates. Many of the tri- and tetravalent metal phthalocyanines (in comparison to phthalocyanines of divalent metals) show a superior photoresponse. We believe this is in part due to structural differences in the cofacial stacking of the Pc rings, and in part to the enhanced electrical contact with the conductive substrate.

Advantages are also observed in the use of an electrolyte solution as the third contacting phase, instead of a metal or semiconductor. Many of the defect and pore sites (short-circuit sites) of the Pc film are effectively ignored by an electrolyte with a low charge density, relative to the situation that would prevail with a contacting metal phase.

Experimental

The phthalocyanines (Pc) used, except for GaPc-Cl, were purchased commercially and purified by sublimation. Generally, two to three sublimations were required to purify the Pc to an acceptable level (with no detectable impurities found using UV-visible or infrared spectrophotometry).

Our synthesis method for GaPc-Cl has been described in detail elsewhere (43). In summary, GaCl_3 was dissolved in dry benzene while in a dry glove box. This was added dropwise to a solution of phthalonitrile dissolved in nitro-

benzene with the temperature kept at the boiling point of nitrobenzene (210°C). A bluish-black mass resulted, which was Soxhlet extracted with benzene followed by ethanol. The final product required three sublimations to obtain a very pure sample of GaPc-Cl. The absorbance spectrum in pyridine was identical to previously prepared samples and to published spectra.

The following reagents were used in this work. Electroactive species were the following: benzoquinone (BQ) (Eastman Kodak) sublimed twice at atmospheric pressure; hydroquinone (H_2Q) (Eastman Kodak) recrystallized twice from H_2O ; potassium ferricyanide $\text{K}_3\text{Fe}(\text{CN})_6$ (MCB, reagent ACS) used as obtained; potassium ferrocyanide $\text{K}_4\text{Fe}(\text{CN})_6 \cdot 3\text{H}_2\text{O}$ (Mallinckrodt, analytical reagent) used as obtained. Buffers and electrolytes were the following: potassium hydrogen phthalate (KHP) (MCB, reagent ACS) used as obtained; nitrogen N_2 (local supplier, electrochemical grade) passed through a molecular sieve and catalyst (Chemalog R3-11) to remove residual O_2 ; pyridine (Py) (Fischer, certified ACS) used as obtained; and water H_2O (TDW) triply distilled with second distillation from permanganate.

Most solutions were a pH = 4 buffer of 0.2M KHP. Redox couples were generally 1 mM in concentration. Special solutions were occasionally required for electrode surface modification. Solutions of 0.1M phenol, or a 0.1M β -naphthol, and 0.3M NaOH in methanol were used for electrochemical polymerization to give an insulating layer of polyphenol or polynaphthol. *m*-Aminophenols were electropolymerized from the normal pH = 4 aqueous electrolyte.

Oxygen was removed from the solutions before use. For stationary electrode cells, a vacuum degassing bulb was used and electrochemical-grade nitrogen used to overpressure the solutions into the cell.

Electrode preparation.—Metallized plastic optically transparent electrodes (MPOTE), gold substrates, were obtained from Sierracin Corporation. They consisted of a vapor deposited, thin (300Å), gold film on a transparent polyester sheet (Au-MPOTE) (44, 45). The platinum counterpart to this (Pt-MPOTE) was produced by a sputtering process on similar polyester sheets by Len Raymond at the Microelectronics Laboratory at the University of Arizona. The substrate electrodes were rinsed briefly in absolute ethanol, then in water, and allowed to air dry. Deposition of the Pc films occurred in a 75 mm diam glass cylinder, with several milligrams of Pc spread evenly across the bottom. The electrodes were suspended 1.75 in. above the bottom, by an aluminum (or Teflon) masking plate, held in place by indentations in the wall of the vessel. The masking plate was a 1/16 in. thick aluminum disk with seven 3/8 in. diam holes. The vessel was placed in a 500 ml heating mantle (Glas-Col), and glass wool was packed around the vessel, filling the volume of the mantle. The temperature was measured by a thermometer inserted through the glass wool to as near the base of the vessel as possible. The vessel was evacuated to ca. 10^{-7} - 10^{-6} torr and the temperature increased, at typically 10°C/min, until a steady state of about 275°C was obtained. Rapid heat-transfer to the dye at the bottom of the vessel was necessary with adequate cooling of the glass near the template to prevent excessive heating of the substrates. Sublimation took place over a period of 2-8h (Type A films, see below) or 24-100h (Type B and C films, see below). Sublimation rates of 0.3-0.5 equivalent monolayers per minute (EQM/min) resulted for the Type B and C films and rates of 1-10 EQM/min for the Type A films. The vessel was allowed to cool before opening, and the electrodes were stored covered in ambient atmosphere.

The surface coverage was obtained by dissolving the dye from the substrate with a measured volume of pyridine and comparing the peak absorbance at 670 nm to standards prepared from a fresh GaPc-Cl/Py stock solution. Film thickness is defined, in these studies, as the number of equivalent closest packed monolayers (EQM).

If each GaPc-Cl molecule is assumed to occupy a 160 \AA^2 surface when lying flat, then one EQM corresponds to $1.11 \times 10^{-10} \text{ mol/cm}^2$.

Various light sources were used, including a 450W xenon arc lamp (Oriell) powered by an Electro-Powerpacs power supply or an Oriell power supply. The output of the lamp was focused through a 4 in. IR water filter, and a long pass 470 nm filter (LP47) for polychromatic illumination (470-900 nm) in the visible region. The output of the lamp, at the point of electrode illumination, was about $100\text{-}150 \text{ mW/cm}^2$, with about half of this being heat not effectively blocked by the IR filter. Lamp output power was measured with a Coherent 210 powermeter.

Electrochemistry.—Open-circuit photopotentials were measured by two methods: (i) the potential difference (measured from the voltammograms) between the equilibrium potential of a redox couple measured at the photoelectrode and the same redox couple measured at a bare Pt or Au electrode, and (ii) the open-circuit potential was measured using a high input impedance voltmeter between the illuminated photoelectrode and bare Pt or Au electrodes in contact with the redox couple. In general, the two measurements agreed to within a few millivolts.

Electron microscopy.—Scanning electron micrographs were taken with an ISI DS-130 electron microscope, using Polaroid Type 55 positive/negative 4×5 Land film. Electrodes were mounted via double-stick tape onto the regular SEM stub and were grounded at the edge with a car-

bon cement. The electrode samples were then sputter coated with a 300\AA film of a Au-Pd alloy. This overlayer was necessary to prevent charging of the sample, which otherwise distorts the image and causes contrast problems. The Au-Pd film was sufficiently thin that it did not alter the appearance of any structure observed at the magnifications used ($10,000\text{-}34,000\times$).

Results and Discussion

Scanning electron microscopy of bulk and thin film deposits.—Table I lists all of the Pc's that have been examined for this report, and Fig. 2a-d show selected SEM's of several of the Pc's explored. Figure 2a was obtained from bulk, purified FePc, simply coated onto the SEM sample stub. Needle-like phases were formed most readily for FePc as well as for H_2Pc , CoPc, CuPc, CrPc, ZnPc, MgPc, NiPc, PdPc, and PtPc (Class II Pc's). The needles (probably representative of the α -phase form) that are obtained after a simple sublimation purification at high sublimation rates are generally long (up to $50 \mu\text{m}$) and narrow (generally $< 0.5 \mu\text{m}$). In contrast, the structures formed by bulk, tri- and tetravalent Pc's (Class I) during the purification process show a clear tendency to spontaneously form block-like or platelet-like structures. The structure of VOPc crystallites generally gives large structures with an assembly of stacked platelets. The bulk phase InPc-Cl tends to form in very large platelets whose dimensions can exceed $50 \mu\text{m}$, with several additional platelets stacked at angles and with smaller dimensions.

^a Type A films examined (see text).

^b Type B films examined.

^c Type C films examined.

^d Previous x-ray data predicts a structure and behavior like that of AlPc-F, Class II (57). Our studies place it in this Class I.

^e Monomer, dimer, trimer, and polymers of cofacially stacked molecules studied as thin films (60).

^f Studied by SEM only.

The GaPc-Cl and AlPc-Cl systems tend to favor a large block-like or rhombohedral structure in the bulk phase.

Many of the above Pc's were sublimed as thin films on MPOTE substrates, as well as several other substrates, with conditions known to favor formation of films designated Type A (deposition rates of ≤ 10 Å/min, 2-8h) or films designated Type C (deposition rates of ≤ 1 Å/min, 1-5 days) which are distinguished below. As discussed later, this distinction between Types A and C films can be somewhat arbitrary depending upon other vacuum deposition factors. Nevertheless, we use this notation here to designate differences in crystallite size that occur with different deposition conditions. Representative SEM's of films are shown in Fig. 2b, 2c, and 2d for the InPc-Cl and GaPc-Cl films. Other SEM examples of the Type A and Type C GaPc-Cl films have been reported previously (29, 30). The tri- and tetravalent Pc films that are formed on the MPOTE substrates consist again of block-like or platelet-like crystallites with average dimensions of 0.3-0.5 μm (Type A films, Fig. 2c) and 0.8-1.0 μm (Type C films, Fig. 2b and 2d), and appear to be tightly packed over the substrate surface. There is still occasionally a tendency to grow more than one layer of crystallites if the deposition rates are too fast (as discussed in the photoelectrochemistry section). Many of the crystallites also appear to be composed of layers of smaller units which have coalesced in the growth process. One of the targets in the growth of these films for any energy conversion application is the formation of a single layer of well-ordered crystallites.

While producing Type C films at shorter deposition times, it is possible to observe isolated crystallites on the MPOTE surface which leave exposed metal substrate between them (Type B films) (30). The problems associated with the photoelectrochemical properties of such porous films are discussed below.

Thin films of (FePc, CoPc, H₂Pc, etc.) under the growth conditions used for the tri- and tetravalent films shown above showed a much more polycrystalline thin film deposit. The individual crystallites were very difficult to observe with the SEM, having dimensions less than 500-1000Å. Where they could be observed, it was clear that the needle-like morphology had been retained. The deposits were not tightly packed crystallites, and attempts to vary the deposition conditions so as to form tightly packed deposits have been unsuccessful. There is a tendency in the tri- and tetravalent Pc systems to form a low surface to volume ratio film, with more intimate contact between the substrate and the Pc (and with fewer "short-circuit" sites).

Of particular note is that the Type C films of the quality shown above have only been grown on metallized polymer substrates (MPOTE). During the course of these studies, SEM structures of the type shown above for the Class I Pc's were obtained on both commercially available and in-house-produced MPOTE's (Au, Pt, Ag) and on indium-tin oxide (ITO) ranging in thickness from 300Å to 1 μm . Substrates such as polished glass, various metal foils and polished bulk metals, and metal oxides such as SnO₂ and ITO on glass substrates, were all unsuccessful in producing the optimum Type A or C film structure. In most cases, even with the Class I Pc's, a very polycrystalline deposit was formed on these substrates, with crystallite dimensions of <0.2 μm . In some cases, it was observed that large crystallites were formed on the substrate, but were surrounded by deposits of much smaller crystallites (43). These all led to uniformly poor photoactivity.

Previous work in this laboratory has shown that the surface composition of these metallized polymer films is not pure metal (44, 45). During the formation of the metallization layer, there is some admixture of polymer constituents with the metal film. The resultant surface has monolayer concentrations of carbon-oxygen molecules, some of which can be activated by ion-beam etching to form electrochemically active groups. Studies are currently underway to ascertain if these surface functionalities provide the initial nucleation sites for deposition of the aggregate Pc layers. The morphology of the MPOTE surface is smooth down to the level of 250-500Å. SEM studies were not able to resolve the surface roughness on this scale, in contrast to all other substrates. The degree of polycrystallinity of these Pc films is presumed to be due to the number of Pc nuclei that form per unit surface area and the growth rate of these nuclei (46, 47). There seems to be an inverse correlation between growth rates and final crystallite sizes and densities in the finished films. Nucleation theory indicates that low rates of deposition are essential for these large molecules (46, 47). Low rates of encounter between depositing Pc molecules, with high substrate temperatures, seems to insure a minimal number of nuclei will form on the smooth surface. These nuclei can grow into relatively sizable crystallites as long as they do not intersect in the process. The average maximum size we have attained thus far have length, width, and depth of 0.7-1.0 μm before they intersect.

UV-visible spectrophotometric assay of Pc thin films.—Figures 3a-3f show the visible wavelength solution and solid film spectra of several of the Pc films. The phthalocyanine chromophore has two distinct electronic transitions in the UV-visible region, the Soret band at 300-350 nm, and the Q-band region at ca. 600-700 nm. The Soret transition arises from a $\pi \rightarrow \pi^*$ excitation which is strongly localized on the Pc ring and shows little dependence on the changing environment of the molecule (48-52). The Q-band transition is a $\pi \rightarrow \pi^*$ transition of lower energy. In many instances, with the appropriate metal center, metal-to-ligand or ligand-to-metal charge transfer transitions can also be involved (57). The major band in solution is generally accompanied by one or more weaker transitions shifted to slightly higher energies corresponding to higher vibronic modes of the ground state participating in the $\pi \rightarrow \pi^*$ excitation (52). In many cases, it has been found that this Q-band region is very sensitive to the environment of the molecule, and is also more sensitive to changes in number and orientation of nearest neighbor Pc's in the solid state.

Figures 3a and 3b are representative of the visible absorbance spectra of the divalent metal phthalocyanines when prepared as thin films of thickness <0.5 μm (Type A conditions). The optical density of the Pc layer/metallized polymer substrate is <1.0 , making transmission spectra possible. Comparing these thin film spectra with the spectra in pyridine or chloronaphthalene solutions shows that the Q-band region is broadened and the maximum absorbance blue shifted. The solution spectrum of

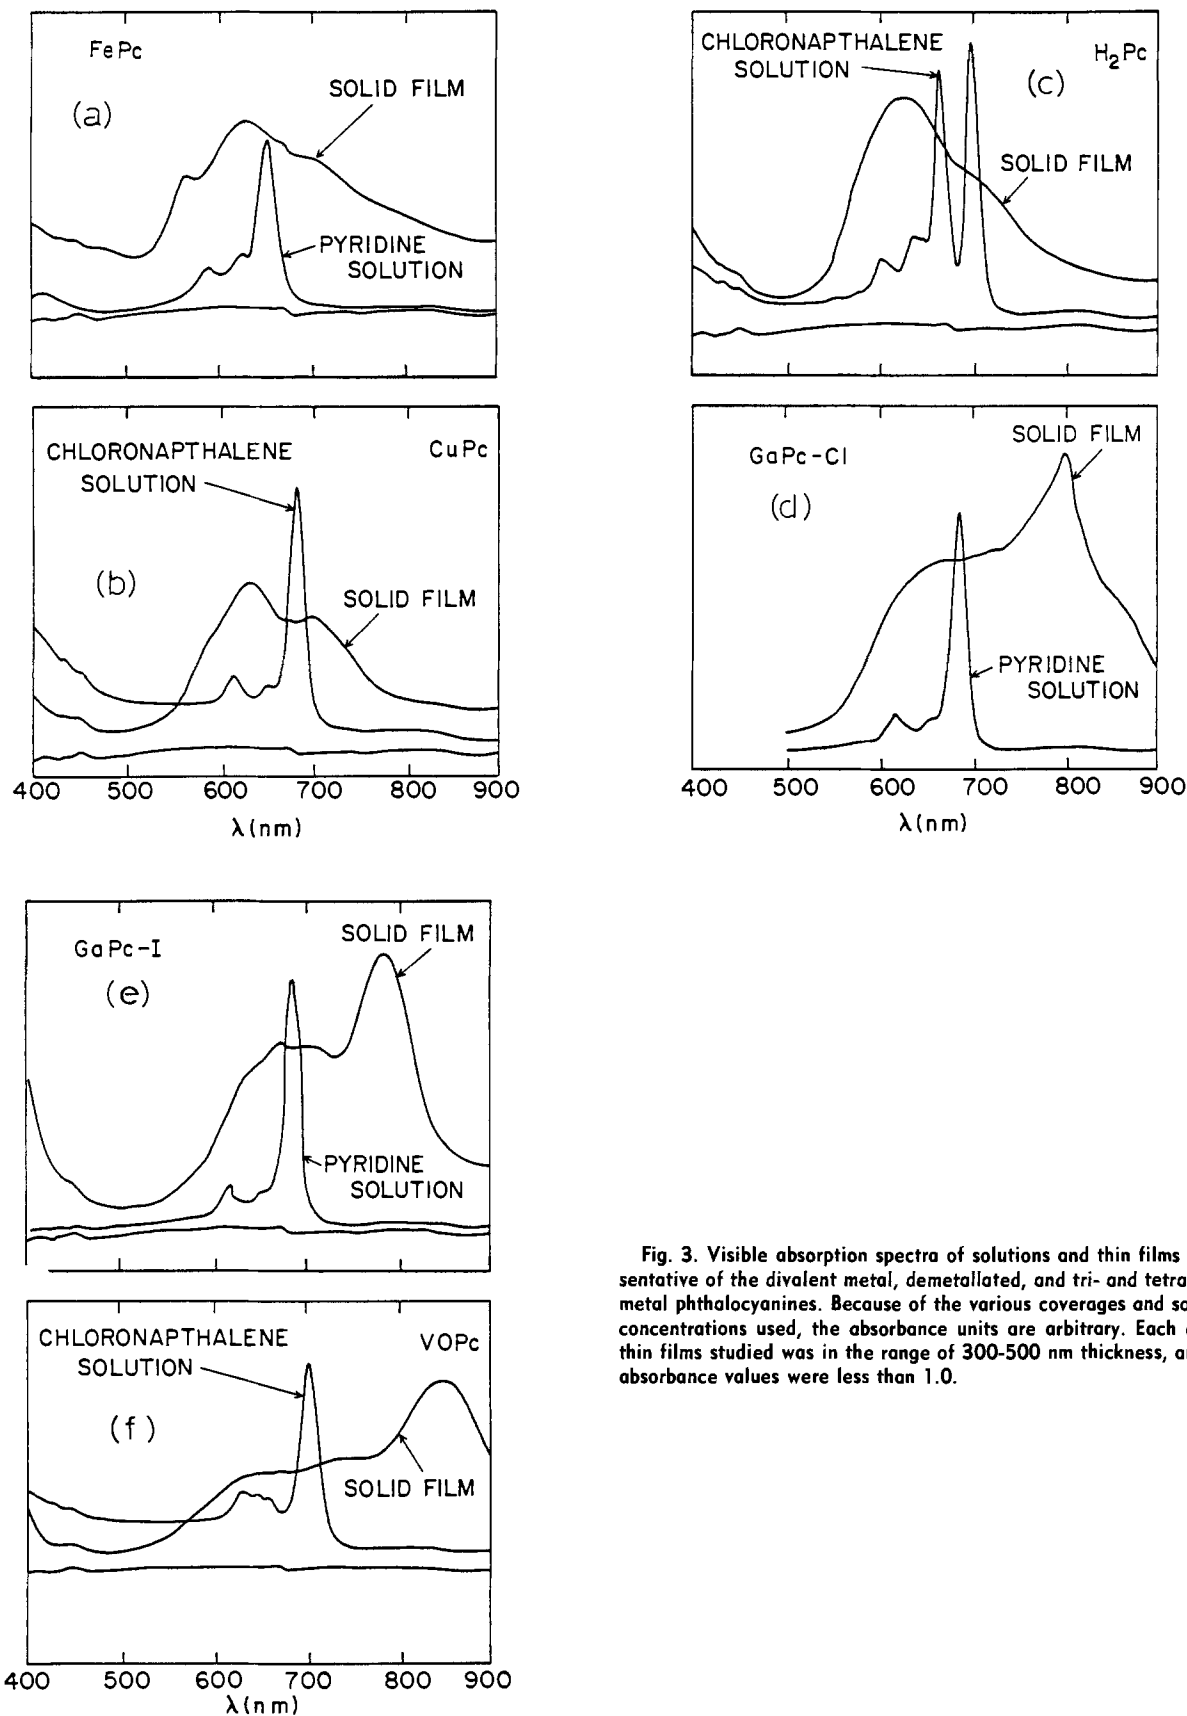

Fig. 3. Visible absorption spectra of solutions and thin films representative of the divalent metal, demetallated, and tri- and tetravalent metal phthalocyanines. Because of the various coverages and solution concentrations used, the absorbance units are arbitrary. Each of the thin films studied was in the range of 300-500 nm thickness, and the absorbance values were less than 1.0.

H₂Pc (Fig. 3c) is split in the Q-band region because of the reduction of symmetry in this molecule from D_{4h} to D_{2h} by removal of the metal center (48-52). In the thin film (Fig. 3c), the Q-band region is again broadened and the maximum absorbance blue shifted (away from the region of maximum solar flux). Recent IR studies of H₂Pc thin films in this laboratory indicate that the "α-phase" is predominantly formed under these growth conditions (53).

Figures 3d and 3e are representative of the solution and thin film spectra of the trivalent Pc's, and Fig. 3f shows the solution and thin film spectra for the tetravalent vanadyl phthalocyanine. In contrast to all of the Class II Pc's studied, these Pc systems in the solid state show strongly red shifted and broadened visible spectra. In the case of the VOPc (33) and InPc-Cl, this absorbance is shifted well into the near-IR, with high absorptivities.

Crystallographic structures have now been solved for several phthalocyanines (39, 54-59) including GaPc-Cl, VOPc, AlPc-F, AlPc-Cl, and several other Pc's in the Class II category as well as different polymorphs of H₂Pc (39, 57, 58). Several forms of silicon and germanium phthalocyanine cofacially stacked polymers have also been characterized (54-56). The polymeric SiPc and GePc species are constrained to stack in an aligned, cofacial orientation by virtue of the bond between the central silicon and the axial oxygens of each molecule. When the stacking of these adjacent Pc's is confirmed to be in this orientation, with only rotation about the central molecular axis allowed, the Q-band region of the visible spectrum appears to be blue shifted and the entire absorbance spectrum broadened. In such systems (as sublimed thin films), we have seen uniformly low photoelectrochemical activity (60).

A slip-stack orientation of adjacent Pc's has been found for several Pc's, starting first with H₂Pc and CuPc (61, 62). Other similar polymorphs were found and characterized in the VOPc system by Griffiths and co-workers (39). X-ray structures have shown that the central metal atom is displaced out of the plane of the Pc ring and that the axial oxygen counterion prevents a perfect cofacial stacking of the adjacent Pc rings. Two types of structure appear possible; those either with the oxygen double bonds oriented toward the adjacent ring, or with those bonds oriented away from the adjacent rings. Their reported visible spectra of VOPc thin films, which probably contain both of these polymorphs, agree well with the spectrum shown in Fig. 3f (33). There is little question that the typical VOPc thin films are not solely of one phase (more than one slip-stack orientation may be possible). Annealing the films at high temperature after growth causes a further red shifting of the Q-band due to phase changes in the film (39).

A crystallographic study of one of the stable configurations of the GaPc-Cl system has been recently solved by Wynne (58). As with the VOPc system, the Ga atom sits 0.439Å out of the plane of the Pc ring and the Cl counterion is not involved in cofacial stacking of the adjacent rings. The unit cell that was solved shows the adjacent Pc rings slipped so as to force overlap of the outer phenyl portions of each Pc ring. The AlPc-Cl system was also examined and appeared to align similarly (58). It is interesting to note that previous crystallographic studies of the AlPc-F and GaPc-F systems had shown them to be aligned in a cofacial fashion with the M-F bonds possessing a strong enough dipole to favor an electrostatic interaction of the type (M⁺-F⁻ . . . M⁺-F⁻ . . . M⁺-F⁻ . . .) (57). This resulted in a geometry similar to the silicon and germanium phthalocyanine polymers (54-56). For AlPc-F thin films, we have previously reported that the Q-band region was indeed broadened and slightly blue shifted from the solution spectrum, and that the photoresponse was poor (63). The GaPc-F system seemed to behave like the GaPc-Cl system, with a red-shifted visible absorbance and photoresponse comparable to that of the GaPc-Cl thin films (63).

There have been several studies on cyanine, merocyanine, and squarane-type dyes (all planar aromatic systems) that show the tendency for these systems to aggregate in slipped-stack configuration in the solid state (2, 59). Calculations have shown that the extent of overlap and the relative placement of the adjacent aromatic centers controls the direction and extent of spectral shifting observed in their absorbance spectra in the 600-850 nm region. Extensively "slipped stacks" of these planar molecules result in a "J aggregate" with a strongly red-shifted and narrowed absorbance spectrum (2, 59). By inference, we assume that the Class II Pc's belong to a similar category as the J aggregates, but are more disordered.

Photoelectrochemical studies.—The cyclic voltammetric response of the Pc thin films in contact with an electrolyte have been studied in a number of ways. The studies have been generally divided between techniques which

involve stirred solutions and rotated electrodes, or quiet solutions and stationary electrodes (29). The last technique is the most common approach and was used in the studies reported here.

Figure 4a shows the current-voltage response for the electrolysis of the hydroquinone/benzoquinone (H₂Q/BQ) redox couple (a two-electron, two-proton, chemically reversible redox process). On the bare Au electrode, there is no photoactivity and the current-voltage response is drawn out, well away from the E° for both the oxidation of H₂Q and the reduction of BQ. The E° lies roughly midway between the potentials of oxidative and reductive peak currents and is an approximate measure of the thermodynamic reactivity of the probe molecules to holes or electrons which might be produced at a photoactive surface. Figure 4a also shows the light and dark response for the same redox couple in contact with a Au/GaPc-Cl (Type A) electrode. Figure 4b shows the same responses for a Au/GaPc-I electrode (Type A). These responses are typical of our earliest Type A, Class I, Pc films (27). The dark current response in the vicinity of the E° is negligible at the current sensitivities shown, and the contrast between light and dark photoresponse is greater than 100:1.

Illumination of the Type A film with polychromatic light (470-900 nm) of ca. 100 mW/cm² produces a current response in the vicinity of the E° which is a factor of 20-50 higher than on the bare Au substrate. Surface deactivation of the bare Au (which does not occur at the Pc film) seems to be primarily responsible for the loss of electrochemical activity on Au for redox reactions of organic systems such as the quinones (43). For redox systems such as ferri/ferrocyanide, there are only small differences in maximal response, so that surface differences cannot be the cause of the above behavior for quinone systems.

Of particular note is the fact that for these Type A GaPc-Cl films under illumination only small shifts in the zero current potential (apparent E°) away from the value observed on the bare metal substrate were observed. The photocurrent response was directly dependent upon the flux of photons to the surface, only small photopotentials for the H₂Q/BQ and ferri/ferrocyanide redox couples were observed, even at the highest illumination intensities.

Figure 4c is representative of the Type A VOPc film on the same Au substrate (33). Nonporous films of VOPc show a dark oxidation of H₂O, but the reduction of BQ is suppressed. Upon illumination, the reduction of BQ is activated and the redox process appears reversible. Redox couples with the negative of E° for H₂Q/BQ are inactive in the dark. Upon illumination, the potential for photocurrent onset is shifted positively to a value very near that shown for the reduction of BQ. Redox couples positive of the E° for H₂Q/BQ show uniformly uninhibited oxidation/reduction reactions in the dark and little photoactivation (33). The Type A VOPc film is behaving like it is a highly doped p-type semiconductor electrode with a flatband potential near +0.3V vs. Ag/AgCl. Similar conclusions regarding electrochemical properties have been reported previously for other Pc films (10-14). The acceptor density in these VOPc films has been measured from Mott-Schottky capacitance plots to be ca. 6×10^{18} cm⁻³. This density is appreciably higher than our estimates for the acceptor densities in the typical Type C trivalent metal Pc films (<10¹⁷ cm⁻³; see discussion below).

Figure 4d shows the current-voltage response of a Type A H₂Pc film in contact with the same redox electrolyte. The dark current was unchanged from that of the bare gold substrate (see Fig. 4a). When the Pc films are porous, the probe molecule diffuses to the exposed metal substrates such that the peak currents and peak potentials at low scan rates are those due to the bare metal substrate (30, 64). Upon illumination, the oxidation of H₂Q remains virtually unaffected. The reduction of BQ, however, is enhanced in the region of the E° (as for the above Pc's), but the original dark current process is still observed. As the illumination intensity was changed the ratio of photocurrent current (l) to dark current (d) was also

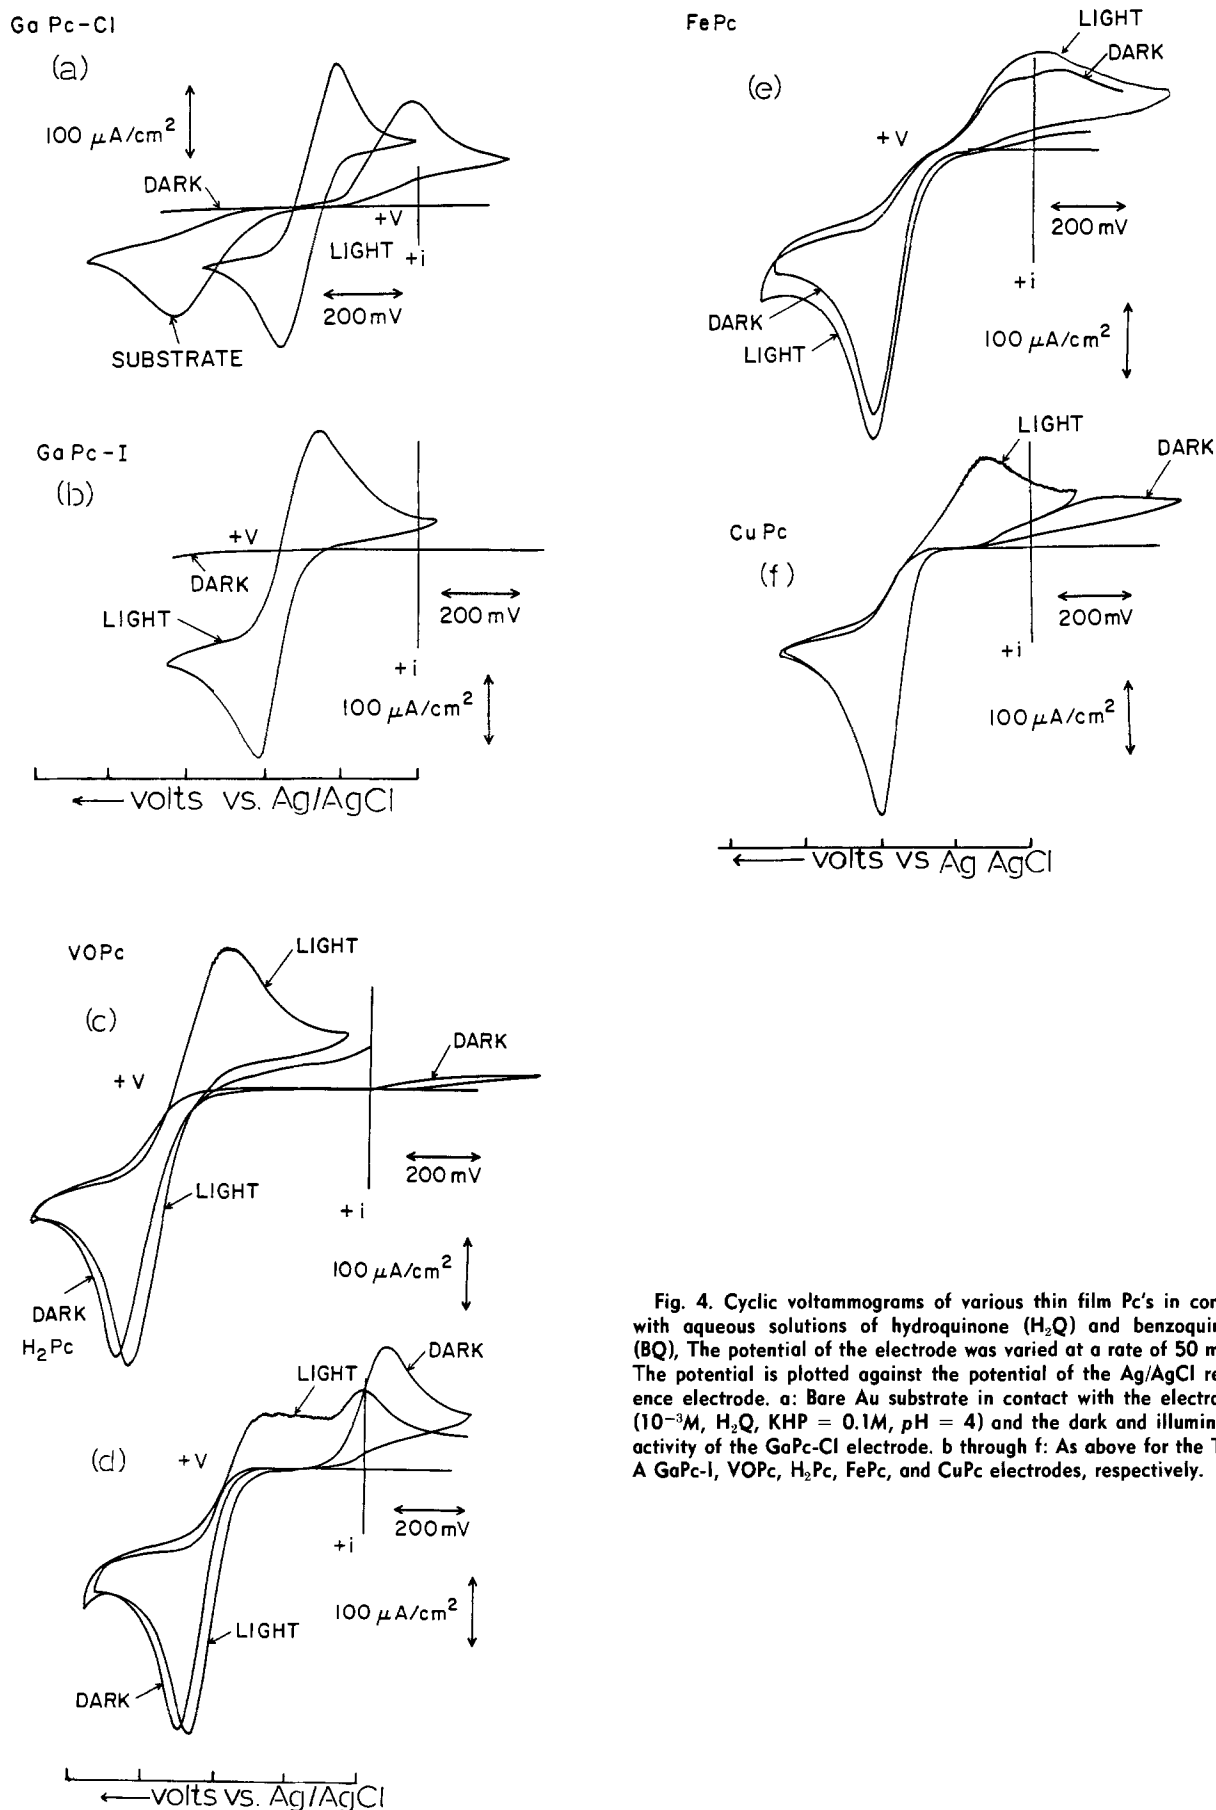

Fig. 4. Cyclic voltammograms of various thin film Pc's in contact with aqueous solutions of hydroquinone (H_2Q) and benzoquinone (BQ). The potential of the electrode was varied at a rate of 50 mV/s . The potential is plotted against the potential of the Ag/AgCl reference electrode. a: Bare Au substrate in contact with the electrolyte (10^{-3}M , H_2Q , $\text{KHP} = 0.1\text{M}$, $\text{pH} = 4$) and the dark and illuminated activity of the GaPc-Cl electrode. b through f: As above for the Type A GaPc-I, VOPc, H_2Pc , FePc, and CuPc electrodes, respectively.

proportionally changed. There is direct competition between the light-active H_2Pc sites and the exposed Au sites for the BQ molecule. When the light intensity was high

enough, it could be seen that the H_2Pc thin-film is acting as a p-type semiconductor, as seen in previous studies (5, 10). Under our conditions of Type A film formation, we

were never able to produce a truly nonporous film of H_2Pc . Because of its poor absorptivity above 650 nm, we have not pursued its use as a photoelectrode.

Figures 4c and 4f show the current voltage behavior of FePc and CuPc Type A films, typical of the remainder of the Class II Pc's. In the dark, the current voltage activity was virtually unchanged from that of the Au and showed little activation upon illumination. Films of FePc, CoPc, CuPc, etc., were quite porous and gave low photoreponses. Of the three Pc's mentioned, CuPc resembled most closely the response observed for H_2Pc when it was possible to produce a film with only partial porosity. In those cases, the voltammetric response was consistent with the notion that the CuPc film was also acting as a p-type semiconductor.

Figure 5 shows the voltammetric activity for the reduction of AQ on a recently developed Type A, nonporous InPc-Cl film (ca. 0.3 μm thick), similar in structure to that shown in the SEM of Fig. 2g. On bare gold, this redox couple has an E° of ca. -0.5V vs. Ag/AgCl . The dark current activity of the Au/InPc-Cl electrode is quite small and featureless. Upon illumination of the Pc/electrolyte interface, a sizable shift in the current-voltage curve (the apparent flatband potential for this system) is seen at $+0.2\text{V}$. In a photovoltaic device, an open-circuit photopotential (V_{oc}) of $+0.7\text{V vs. a bare Au or Pt}$ counterelectrode was observed. The electrochemical behavior of an InPc-Cl film grown under these conditions again points to p-type semiconducting properties. In the case of the InPc-Cl and VOPc films grown in this manner, we have also observed a strong directionality of the photoeffect—one dependent upon which of the interfaces is illuminated first. If the Au/Pc interface is illuminated first (back side), then the photoeffect is diminished, with a 100 mV drop in the open-circuit photovoltage (V'_{oc} vs. V_{oc}). This kind of directionality is even more evident in the VOPc films when the photocurrent is monitored as a function of wavelength (33). The reasons for this have been postulated first by Bard and co-workers (11) and appear to arise from the formation of a multiple-phase crystallite layer on the substrate, giving rise to at least two Pc layers of different photoactivity. In the InPc-Cl and VOPc films, made under these Type A conditions, the layer adjacent to the Au interface appears to be less photoactive (for transport of the photogenerated electrons). This layer absorbs some of the light that needs to reach and excite

Fig. 5. Dark and illuminated current voltage activity for the Au/InPc-Cl system, in contact with 10^{-3}M aqueous, $\text{pH} = 7$ anthraquinone sulfonate (AQ) solution. The activity for the bare Au substrate is shown and forms the reference point for computation of open-circuit photopotentials. Potentials were varied at a rate of 50 mV/s. V_{oc} represents the approximate open-circuit photovoltage expected [using front side illumination (FS)] vs. a bare Au counterelectrode. V'_{oc} represents the same photopotential with illumination of the Au/InPc-Cl interface (BS) first.

the molecules at the Pc/solution interface. The metal/polymer substrate is sufficiently transparent that reflection of light from the back interface cannot be the cause of the difference in photoactivity. Recent experiments show that, if both interfaces can be illuminated simultaneously, this effect can be partially overcome and the photocurrents and photopotentials increased (65). The origin of the different layers in these films and the nature of the deposition parameters which leads to this p-type behavior is currently under exploration.

Figure 6 shows the electrochemical response typical of the Type C, GaPc-Cl films compared to a bare Au substrate. Figure 6a shows the dark current-voltage response of $\text{Fe}(\text{CN})_6^{-3}/\text{Fe}(\text{CN})_6^{-4}$ on bare Au or Pt. Figure 6a also shows the dark (d) and illuminated current-voltage responses for the Au/GaPc-Cl, Type C film. In the dark, little current is seen, indicative of the nonporous nature of the film. Upon illumination, the current-voltage response is greatly enhanced, having the same general appearance as on the Au substrate. The slope of the current-voltage response near the zero-current intercept is less steep than on bare Au and directly dependent upon the illumination intensity. The current at any potential is lower because of the lower photoconductivity of the Pc film. The entire current-voltage curve however, has been shifted negatively to ca. $+0.075\text{V}$. We have previously demonstrated that this potential shift will occur to a limit which is the approximate flatband potential of each Au/GaPc-Cl system and that this effect can be due in part to the work function of the substrate (phase 1, Fig. 1) with respect to the reference electrode potential (29, 16, 41). In a PV cell, with a Au/GaPc-Cl anode and a bare Au cathode, an open-circuit photopotential [$V_{oc}(\text{Au}) = \text{ca. } 0.3\text{V}$] is measured. The magnitude and direction of the photopotential is also varied by simply changing the redox couple and its E° (i.e., changing the work function of the contacting phase 3, Fig. 1) (29). In those cases, the Type C GaPc-Cl films behave as nearly intrinsic photoconductors. The Fermi level is apparently close enough to the middle of the bandgap to permit both positive and negative photopotential excursions.

Figures 6b and 6c show the current-voltage response of the Pt/GaPc-Cl Type C film in contact with the same electrolyte. The dark current process in Fig. 6b is en-

Fig. 6. Dark (d) and illuminated voltammograms for Type C GaPc-Cl electrodes on Au and Pt substrates in contact with 10^{-3}M solutions of ferricyanide and ferrocyanide, $\text{pH} = 4$ electrolyte. a: Voltammetric activity of the bare Au or Pt substrate and the dark and light activity of the Au/GaPc-Cl Type C thin film. b: Dark and light activity of the Pt/GaPc-Cl Type C thin film. c: Dark and light activity of another Pt/GaPc-Cl electrode with diminished porosity and lower dark current.

hanced over that seen on the Au/GaPc-Cl electrode (Fig. 6a). The dark current process in Fig. 6c has been diminished but at some sacrifice to the photocurrent activity. Our efforts thus far have not yielded a totally nonporous film on the Pt-MPOTE substrates. The pore sizes are small enough that the dark current activity is greatly suppressed as compared to that of the bare substrate. We estimate that the surface is greater than 90% covered with the Pc film (64).

Of particular note is that, for the same redox couple, the entire current-voltage response on the Pt/GaPc-Cl electrode is now shifted positively from the E° on the bare metal. This is consistent with the fact that the Pt substrate has a higher work function than both Au and the electrochemical potential of the electrolyte. It is understood that the Pt work function is high enough to position the Fermi level of the Pt in the valence band region for the Pc film. This may not produce a hole blocking contact that would be required to produce the current-voltage response seen (16, 17, 29, 66). The effective work function of Pt is easily changed (lowered), however, by the presence of surface impurities (67). We feel that the zero-current potential noted for the illuminated Pt/GaPc-Cl systems represents that effective work function value.

These results demonstrate the possibility of a PV cell formed by two electrodes consisting of the same photoconductor on metal substrates of different work function, immersed in an electrolyte ($M_1/Pc/Ox$, red/ Pc/M_2) (16). Under simultaneous polychromatic illumination (ca. 75-100 mW/cm²) of both electrodes with illumination of the solution interface first for the Au/GaPc-Cl electrode, and illumination of the metal/Pc interface first for the Pt/GaPc-Cl electrode, open-circuit photopotentials of ca. 0.55-0.65V were obtained. Short-circuit photocurrents of ca. 0.1-0.2 mA/cm² were observed with fill factors near 0.5, such that power conversion efficiencies of ca. 0.05% were obtained (68). The short-circuit currents, or currents at any load resistance, were limited by the photon flux, i.e., Pc-film resistance.

In the case where the projected area of the Pc microcrystals does not totally block the surface of the metal substrate to solution contact, the photoelectrochemical process, e.g., the oxidation of R to Ox at the Pc sites, is offset by the opposite reaction, Ox \rightarrow R, at the exposed metallic sites. On a Au/GaPc-Cl film, the illuminated M/Pc/solution sites are typically poised at potentials negative of the E° for the redox couple, so that if bare metal sites are nearby, the product (Ox) can move to this region and undergo back reaction. The opposite case pertains to photoassisted reduction processes. The result of this is to lower the net photocurrent at any potential and also to reduce the magnitude of the photopotential at even low current loads (30). This situation is even more of a problem when the contacting phase (phase 3 in Fig. 1) is a metal rather than an electrolyte solution. The charge density of a metal overlayer is significantly higher than the most concentrated electrolyte solutions. "Short-circuit" sites in intimate contact with a metal overlayer may prevent the formation of any photopotential under even intense illumination. We have thus far been unable to avoid serious short circuiting of metal/Pc/metal' composites (made by evaporation of another metal layer over the Au/Pc film), presumably because of the short circuiting of the two highly conductive metal phases. This is apparently due to the creation of pore sites within the Pc layer during the deposition of the second metal phase, and therefore may be ultimately remedied by modification of this step.

In electrolyte solutions, as long as the exposed substrate area is below 10% of the geometric area of the surface (estimated from voltammetric currents), the shorting reactions cannot keep up with the photoelectrochemical process, and a photopotential can be generated. Referring back to Fig. 6b and c, to the dark and illuminated current-voltage curves on Pt/GaPc-Cl electrodes of differing porosities, it can be seen that as the dark current on the exposed metal sites decreases, the illuminated i/V curves

are shifted more positively and the open-circuit photopotentials are increased [$V_{oc}(Pt)^2$ vs. $V_{oc}(Pt)^1$ in Fig. 6].

Electrochemical polymerization of easily oxidized or reduced molecules to form nonconductive surface films have been explored for some time and offer a potential solution to the problem of short circuiting (69). We have used phenol, β -naphthol, and m-aminophenol at 0.1M concentrations, electrochemically oxidized in the dark, to form insulating polymers (layers 20-40 nm thick). These polyphenoxide films have been used to seal off exposed metal sites on porous GaPc-Cl and VOPc films (30, 70). Porous Pc films treated in this fashion show significantly decreased porosity to solution components (lower dark currents), but also show a current/voltage response indicative of a more resistive film (similar to that shown in Fig. 6c). The contrast between light and dark activity is increased over the untreated films, but the overall photoactivity may be lowered. During the electropolymerization process, there is apparently some etching and/or deterioration of the Pc/metal interface which leads to this more resistive film and hence a poorer photoresponse. Postmortem visible spectroscopy of these films does not indicate loss of phthalocyanine. Electron micrographs show some smoothing of the polycrystalline material, indicating that etching of the surface layers occurred which may be paralleled by attack of the Pc/metal interfaces. It is clearly more desirable to attempt to achieve a nonporous film from the initial vacuum growth stage, such as with our best Type C GaPc-Cl films.

Conclusion

The trivalent and tetravalent phthalocyanines should give a superior photoresponse when compared to the divalent and demetallated phthalocyanines prepared under the same conditions. These new systems are distinguished by crystallites in the thin films that are larger and generally have a lower aspect ratio (ratio of length to width) than the Class II Pc's. Their spectral responses are all uniformly broadened and red shifted, which we feel correlates with their tendency to stack cofacially in orientations that cause overlap in a staggered fashion (37-39, 58, 59, 61, 62). This slip-stack configuration is apparently assisted by the presence of the central metal-counterion which does not favor direct cofacial stack of the adjacent Pc centers (39, 58). There is a clear need for the study of the electrical and photoconductivity properties of single crystals of these materials.

Within the tri- and tetravalent metal Pc series, we have observed two basic types of photoelectrochemical response. Certain film growth conditions lead to photoelectrochemistry similar to that of a p-type semiconductor, with only positive photopotentials observed in films thinner than 0.5 μ m. Other slower growth rates lead to Pc films that behave more as intrinsic semiconductors (as in Fig. 1), with both positive and negative photopotentials possible.

Under the appropriate growth conditions, the VOPc, TiOPc, InPc-Cl Type A films can behave as p-type materials with high acceptor concentrations. Recent surface analysis studies have indicated that the source of the higher acceptor concentration in VOPc films may be the presence of oxygen entrained in the Pc film for which VOPc films have a high affinity (33). The thinner versions of the GaPc-Cl and GaPc-I films, as grown under the conditions described here, are apparently nearly intrinsic and show only small photopotentials for molecules with E° values near H₂Q/BQ and ferri/ferrocyanide. For thin Pc films such as the VOPc or InPc-Cl Type A variety, the acceptor density may be high enough that a space-charge layer can form in less than the thickness of the film (30-32). However, this precludes the observation of both positive and negative photopotentials, since the material becomes strongly p-type. Work currently in progress in our laboratory indicates that the electrochemical properties of GaPc-Cl and InPc-Cl films can be further varied between the extremes of behavior shown in Fig. 5 and 6 through variation of the growth rate, sub-

strate temperature, and O₂ treatments of each film. Photoelectrochemical efficiencies have improved considerably through the use of these tri- and tetravalent Pc's. There is still an incomplete understanding, however, of the manner in which substrate chemistry, entrained dopants, and the deposition of the first layers of Pc affect the electrical properties of the entire film.

We have recently demonstrated that for the GaPc-Cl, Type C thin films, the photocurrents are limited by trapping and recombination sites, which form at the interface between the Pc and metal substrate, the bulk of the Pc crystallites, and also at the surface and intersection of the individual microcrystallites (28, 31, 32). Figure 1b shows the consequence of the deposition of an intrinsic photoconductor film on a metal surface such as Au, where the Fermi energies before contact are not arranged in descending order, as shown in Fig. 1a. Provided that sufficient charge exchange pathways exist within the film so that equilibrium can be reached, this mismatch of Au and Pc work functions leads to a potential inversion at the interface which can act as trap for photogenerated charge, accelerating the recombination rate of electron-hole pairs in that region. It must also be assumed that the surface of the Pc microcrystals are chemically distinct from the bulk (e.g., adsorbed O₂ would raise the electron affinity of the surface Pc's). It is expected that the intersection points of the Pc microcrystals will also lead to these potential inversions and regions of trapped charge.

Rose has demonstrated that the tolerable defect site density in polycrystalline thin films of this type is ca. 10¹⁷/cm³ or about 3-4 orders of magnitude above those tolerated in single-crystal materials (16, 17). Examining the average SEM of a Type C, Class I Pc film and estimating the projected surface area of the average crystal, and the number of surface Pc's per crystallite (ca. 160 Å²/molecule), we calculate that the defect site density due to chemically distinct Pc's is ca. 10¹⁹/cm³. Compared to the average Class II Pc film, this is an improvement of 2-3 orders of magnitude, consistent with the improvements noted in the photoelectrochemical responses and the decrease in surface-to-volume ratio of these films. This analysis does not account for the defects from disorder within the bulk of each of the Pc microcrystals and at the metal substrates. A decrease of at least one more order of magnitude in defect densities in these films is needed to lead to PV cells with power conversion efficiencies of 1% or higher.

ABSTRACT

The electrochemical properties of solid films of Mt-2,3,9,10,16,17,23,24-octacyanophthalocyanine **2** [Mt = 2H, Zn(II), Cu(II)] were studied by cyclic voltammetry in aqueous electrolytes. The thin (10-100 nm) film electrodes show remarkably stable electrochromic redox behavior, and the charge exchanged in the cathodic and anodic waves, respectively, was found to be between 2 and 3 F/mol for scan rates up to 400 mV/s. For charge compensation, the intercalation of cations is required. At low pH values (intercalation of protons), nernstian behavior was observed, while in alkaline solutions the intercalation of the cations Li⁺, Na⁺, or K⁺ into the solid film was found to be the rate-determining step. From the half-width of the current waves, the number of electrons involved in the overall reaction was inferred and found to be different in acid and alkaline solutions. Compared to unsubstituted phthalocyanines **1**, the characteristic qualities of the electrodes are associated with the high electric conductivity of **2** and the electron accepting properties of the substituents of the ligand.

Monomeric phthalocyanines **1** and their polymeric analogues (**1**, **2**) exhibit a variety of interesting physicochemical properties. A great deal of work has been published on their semiconducting properties, and even metallic conductivity has been observed following the doping with acceptors (3-9). The properties of phthalocyanines as catalysts for the dioxygen reduction in fuel cells have been investigated intensively [(10-16), *cf.* Ref. (2)]. Titanium electrodes covered with thin layers of polymeric phthalocyanines were found to exhibit faradaic activity comparable with platinum in redox electrolytes like [Fe(CN)₆]⁴⁻/[Fe(CN)₆]³⁻ (17, 18). The effect of spectral sensitization of inorganic semiconductors by phthalocyanines on their photoelectrochemical and photovoltaic properties has been studied extensively (19-25).

Detailed investigations of the redox behavior of dissolved **1** have been reported (15, 16, 22, 26-28). As many as four reversible ligand reductions and two ligand oxidations were determined by electrochemical methods. Corresponding to the redox behavior in solution a reduction or oxidation of solid semiconducting layers of **1** can be expected. Such processes are of interest for the study of reversible charge storage and electrochromism (29-32). Cyclic voltammetric measurements of thin films of **1** (Mt = metal ion) on gold electrodes in contact with an aqueous

electrolyte resulted in the oxidation and the subsequent reduction of the films with one to two electrons per molecule under intercalation of anions (29). The charge storing capability dropped rapidly with the number of cycles. The electrode processes are impeded by the low electronic conductivity of the layers.

2,3,9,10,16,17,23,24-Octacyanophthalocyanine **2** (33) shows a high conductivity and a more positive redox potential than **1**. Depending on the central ion, *e.g.*, Mt = 2H, Zn, Cu, conductivities for the polycrystalline materials range from 10⁻¹ to 10⁻⁸ Ω⁻¹·cm⁻¹ for **2** (2) and from 10⁻⁹ to 10⁻¹⁴ Ω⁻¹·cm⁻¹ for **1** (3). In the solvent system DMF/0.1M TBAP, the first standard redox potential was found to be E° = 0.09V vs. NHE for the couple [2]/[2]⁻ (Mt = Zn) and E° = -0.62V vs. NHE for the couple [1]/[1]⁻ (Mt = Zn) in Ref. 34. In the case of **1** with other central metal ions, E° values between -0.42 and -0.65V vs. NHE have been reported (27). **2** therefore appeared to be suitable for a study of the reduction and reoxidation of solid films in contact with an aqueous electrolyte. The aim of the present work was to develop stable thin film electrodes, which could undergo reduction and reoxidation cycles not limited by diffusion processes, up to relatively fast voltage scans. The intensely studied properties of electrodes coated with redox active organic layers (35-39) are less satisfactory in these respects.

* Electrochemical Society Active Member.

Experimental

Metal free, copper(II) and zinc(II)octacyanophthalocyanine **2** were synthesized following Wöhrle *et al.* (33). All chemicals were analytical grade (Merck). All aqueous solutions were prepared from doubly distilled water. The solvent, N-methylpyrrolidone, was purified by distillation under nitrogen and reduced pressure.

The working electrodes were prepared from 0.8 cm diam gold disks (99.99%, Degussa). They were ground and polished (1200 mesh emery paper, 1 μm , 0.3 μm alumina), cleaned in chrome sulfuric acid (10 min), and then rinsed in distilled water in an ultrasonic bath. Prior to the deposition of **2**, the gold substrate was etched in aqua regia for 2s, then rinsed in distilled water and dried in air. For the film deposition, 10^{-6} mol of **2** were dissolved in 1 ml N-methylpyrrolidone. 1 to 10 μl iter containing 10^{-9} – 10^{-8} mol of **2** were spread onto the electrode surface. Upon evaporation of the solvent under vacuum (0.1 Pa), the deposited green film was tempered for 1h at 473 K within the same vessel. The electrodes were stored in vacuum until use. From the specific gravity of the bulk material (1.49 g/cm³), the film thickness was calculated to be between 10 and 100 nm. Transmission electron micrographs confirmed the formation of homogeneous films and, in contrast to evaporated layers of **1**, no microcrystallites could be observed within the resolution of the microscope (< 5 nm).

The electrodes were mounted in the window of a PTFE holder, exposing an area of 0.5 cm² to the electrolyte. Electrical contact was established by a gold wire pressed onto the back of the electrode.

Cyclic voltammetry was carried out using a Model 1003 T-NC Jaisle potentiostat and a Wenking VSG 72 voltage scan generator. The data were recorded on a HP 7004B X-Y recorder, and for fast scans on a 7623 A Tektronix storage oscilloscope. The experiments were carried out in deoxygenated solutions under nitrogen at 298 K in a two-compartment PTFE cell (80 ml), equipped with a Ag/AgCl reference electrode (205 mV *vs.* NHE), the appropriate working electrode, and a Pt counterelectrode. The reference electrode was kept at a distance less than 0.1 mm from the dye film by means of a Haber-Luggin capillary.

The color change of the film undergoing redox cycles was characterized by UV/VIS transmission spectroscopy. For this purpose, 100 nm thick films of **2** (Mt = 2H) deposited on quartz plates were chemically reduced by Sn²⁺ ions (50 mmol SnCl₂ in 1M HCl).

Results

Measurements in acid electrolyte.—A typical cyclic voltammogram for the second cycle is depicted in Fig. 1a for a 100 nm metal-free film of **2** (total amount of **2** was 10^{-8} mol) in 1M HCl. The redox cycles run between 495 and -235 mV *vs.* Ag/AgCl. Between 195 and -105 mV, the entire film is reduced, requiring the intercalation of charge compensating cations, and two peak currents can be observed at +81 and +20 mV (*vs.* Ag/AgCl) for the second cycle (Table I). Again, two peak currents appear during the reoxidation of the film at 100 and 33 mV. A broadening of the curve and the appearance of more pronounced anodic peaks can be observed following the first cycle. Up to the measured 600 cycles, no further change or loss of electrochemical activity occurs, demonstrating the high electrochemical stability of the system. The separation of the corresponding cathodic and anodic current maxima is less than 30 mV, indicating the reversi-

Fig. 1. Cyclic voltammograms (second cycle) of different films of octacyanophthalocyanine **2** (10^{-8} mol on 0.5 cm² gold electrodes) in acid electrolyte (1M HCl). a: **2** (Mt = 2H). b: **2** (Mt = Zn). c: **2** (Mt = Cu). Scan rate: 40 mV/s.

bility of the solid-state electrochromic redox process (Table I).

The color changes between green and dark brown during the redox cycle can also be established by chemical reduction with Sn(II) in 1M HCl. The corresponding transmission spectra are depicted in Fig. 2. The λ_{max} value of the Q band shifts from 650 to 580 nm.

The charge under the curve corresponds to 2.8 electron/molecule or to 2.8 F/mol for the cathodic as well as for the anodic branch of the second cycle, after correction for the double layer capacitance of the thin film electrode. This value was roughly estimated from the linear dependence of the constant residual current on the scan rate in the anodic region of the scan where no faradaic activity is observed. Figure 3 depicts the dependence of the stored charge on the thickness of the film of **2** (Mt = 2H). The exchanged charge of about 3 F/mol does not depend on the film thickness between 10 and 100 nm ($0.2\text{--}2 \times 10^{-8}$ mol/cm²).

Figure 4 depicts the dependence of the cathodic peak current on the scan rate v for a 100 nm film. No marked

	0.1M NaOH/1M NaCl ^a	-328	-235	-640	-575	3.0

^a $E_{red}^{III} = -905$, $E_{ox}^{III} = -845$ mV vs. Ag/AgCl.

deviation from linearity can be observed in the range from 20 to 400 mV/s. The same relationship holds for the anodic peak current. The time constant of the film reduction was estimated to be below 5 ms from potential step measurements. The charge exchanged during the cycle does not depend on the scan rate in this range. The observed separation between the cathodic and the corresponding anodic peak current remained within the IR drop between the Luggin capillary and the electrode surface for all experiments depicted in Fig. 3 and 4 and listed in Table I.

Compared to 2 (Mt = 2H), a similar voltammogram, however, with a more pronounced double peak profile, was observed for films of the Zn chelate of 2 (Fig. 1b). The reduction and reoxidation potentials are shifted into the negative direction by about 30-45 mV (Table I). The charge under the cathodic and the anodic branch was found to be 2.7 F/mol after correction for the double layer

Fig. 2. Transmission spectrum of 50 μg 2 (Mt = 2H) deposited on a 3 cm^2 quartz plate (a) and following chemical reduction (5×10^{-2} M SnCl_2 in 1M HCl) (b).

Fig. 3. Charge exchanged per mol of 2 (Mt = 2H) in either branch of the cyclic voltammogram in dependence on the amount of 2. Scan rate: 40 mV/s; acid electrolyte (1M HCl).

capacitance and irrespective of the scan rate up to $v = 400$ mV/s. Compound 2 (Mt = Zn) exhibits distinct electrochromic behavior during the redox cycle. The green color of the layer changes to intense blue (reduction peak I), and then to brown (reduction peak II).

In the case of the copper chelate of 2, no double peak can be observed in the voltammogram (Fig. 1c). The reduction peak current is shifted to a more negative potential (-63 mV vs. Ag/AgCl). Again, the stored charge during the redox cycle was found to be 2.7 F/mol and did not depend on the scan rate up to 400 mV/s.

In the range of low pH values up to $\text{pH} = 2.5$, the potential of the respective peak currents in the voltammogram shows a linear dependence on pH of about 60 mV/pH.

Measurements in alkaline electrolytes.—In order to study the dependence of the redox behavior of layers of 2 on the nature of the cation, which has to be intercalated for charge compensation, the following alkaline electrolytes were used: 0.1M LiOH/1M LiCl, 0.1M NaOH/1M NaCl, and 0.1M KOH/1M KCl. The results are depicted in Fig. 5 and 6.

In comparison to the acid electrolyte, the potentials of the cathodic and anodic peak currents are shifted negatively (Table I). In the case of metal-free films of 2, the current peaks in the cyclic voltammograms are considerably broadened (Fig. 5a and 6b). As found with acid electrolytes, the charge exchanged during the electrochromic redox process was found to be 2.7 F/mol for either branch of the cycle. The peak currents, however, do not depend linearly on the scan rate, even in the range of slow scans ($v = 40$ -160 mV/s), which indicates some hindrance of the intercalation mechanism.

Figures 5c and 6c depict representative cyclic voltammograms obtained for thin film electrodes of 2 (Mt

Fig. 4. Linear dependence of cathodic peak current I_p on the scan rate for a 100 nm film of 2 (Mt = 2H) $\approx 10^{-8}$ mol in acid electrolyte (1M HCl).

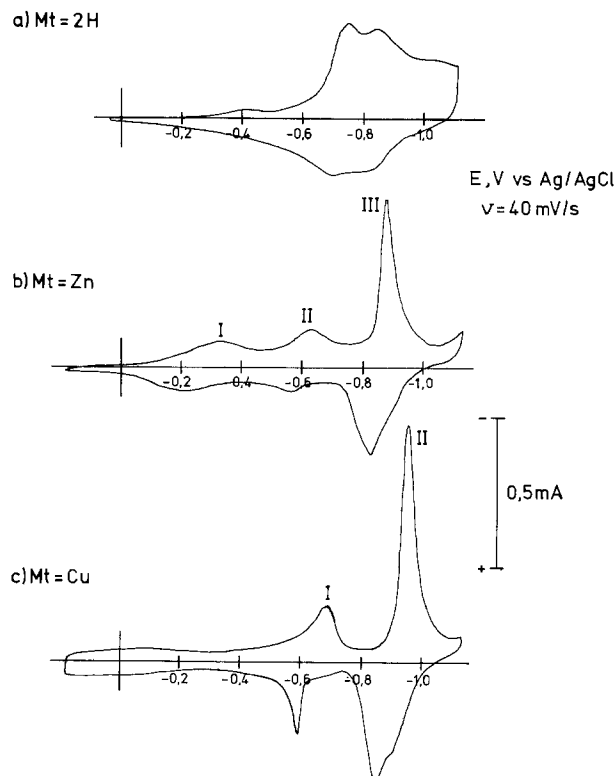

Fig. 5. Cyclic voltammograms (second cycle) of different films of octacyanophthalocyanine **2** (10^{-8} mol on 0.5 cm^2 gold electrodes) in alkaline electrolyte (0.1M NaOH/1M NaCl). a: **2** (Mt = 2H). b: **2** (Mt = Zn). c: **2** (Mt = Cu).

= Cu) in alkaline electrolytes. Compared to **2** (Mt = 2H), a tenfold increase in double layer capacitance points towards a larger real surface area of the film. In contrast to acid electrolytes, two clearly separated redox peaks, I and II, can be observed. The heights of the first cathodic (I) and of the corresponding anodic peak current are still linearly dependent on the scan rate regardless of the electrolyte. For the second cathodic (II) and corresponding anodic peak, and in the case of Li^+ the peak current is found to depend on $\nu^{1/2}$, which is indicative of a diffusion-controlled process (Fig. 6d). A deviation from linearity is also observed in alkaline electrolytes containing Na^+ or K^+ . A peak current- $\nu^{1/2}$ relationship, however, could not be established in the range of scan rates of $2.5\text{--}640 \text{ mV}\cdot\text{s}^{-1}$ in these cases. The experimental results obtained in alkaline Li^+ or K^+ containing electrolytes are summarized in Table II. For successive experiments, the scan rate was always doubled. The ratio of the corresponding peak currents $I_{p,n+1}/I_{p,n}$ was calculated and also listed in the table. The deviation from linearity is even less pronounced for the anodic wave.

The position of the first redox peak E_{red}^1 depends on the nature of the cation. A pronounced shift can be observed changing from Li^+ to Na^+ containing electrolytes (Table I). The position of the second redox peak $E_{\text{red}}^{\text{II}}$ is less affected by the choice of the cation.

After correction for the double-layer capacitance, the charge under either branch of the cyclic voltammogram is found to be less than 2 F/mol (Table I) with about 25% of the charge located under peak I and about 75% under peak II (Fig. 5c and 6c). A remarkable feature of the voltammograms obtained in Na^+ and K^+ containing electrolytes is the small half-width of the second peak, $\Delta E_{1/2} = 55 \text{ mV}$ and $\Delta E_{1/2} = 40 \text{ mV}$, respectively.

Three redox peaks, I, II, and III, can be observed in the cyclic voltammogram obtained for electrodes of **2** containing Zn as the central atom (Table I, Fig. 5b). Also in this case, the peak positions do not depend on the scan rate in the range of $40\text{--}160 \text{ mV/s}$. A total of 3 F/mol is exchanged in the electrochromic redox process in either

Fig. 6. Cyclic voltammograms of different films of octacyanophthalocyanine **2** (10^{-8} mol on 0.5 cm^2 gold electrodes) in alkaline electrolyte (0.1M LiOH/1M LiCl). a: Gold support. b: **2** (Mt = 2H) first and second cycle, 40 mV/s . c: **2** (Mt = Cu) first and second cycle, 40 mV/s . d: Electrode c, Different scan rates (80 and 160 mV/s).

branch of the voltammogram, with most of the charge located in peak III, which, in analogy to results obtained for **2** (Mt = Cu), shows a remarkably small half-width of $\Delta E_{1/2} \approx 50 \text{ mV}$ in a sodium hydroxide electrolyte.

There is a loss of charge of up to 10% from the first to the second cycle for all electrodes (Fig. 6b and 6c). Thereafter, the charge involved in the cathodic and the anodic waves, as well as the position of the peaks, remains unchanged and shows little dependence on the scan rate beyond the IR drop up to 160 mV/s (Fig. 6d) and on the nature of the cation involved, with the exception of Li^+ (Table I).

Discussion

The relatively good solubility of octacyanophthalocyanines **2** in organic solvents as compared to that of the unsubstituted compounds **1** allows the preparation of films from corresponding solutions by evaporation of the solvent. This is the only way for the preparation of solid-state films of **2** since sublimation would lead to partial thermal decomposition of the material. The influence of substituents on the solid-state properties of porphyrins is well known and leads to excellent electrochemical behavior in the case of films of **2**. They were found to be electrochemically and mechanically stable within the

Table II. Dependence of the second cathodic peak current I_p (Fig. 6d) on the scan rate v for films of **2 (Mt = Cu; film thickness ≈ 100 nm; electrode area 0.5 cm²) in alkaline electrolytes**

Electrolyte	n	Scan rate (mV/s)	I_p (μ A)	Ratio of peak currents $I_{p,n+1}/I_{p,n}$

range of potentials investigated. Up to scan rates of 2×10^5 mV/s, films of **2** exhibit electrochromic reduction and reoxidation processes in acid as well as in alkaline electrolytes. Up to the scan rates of 400 mV/s and 600 cycles investigated, the exchanged charge was found to be stable in most cases for either branch of the cyclic voltammogram.

Two processes characterize the reversible reduction and reoxidation of films of **2**: injection of electrons at the Au/**2** interface, followed by the transport of the charge through the film and intercalation of charge compensating cations or their ejection during the redox cycle. The high intrinsic conductivity of **2** provides for a reversible charge transfer in acid electrolytes (intercalation of protons) up to moderate scan rates. The electron attracting nitrile groups in **2** may be responsible for reduction easier than that of **1**, which could not be reduced under the same experimental conditions.

In solution the reduction of **2** (Mt = Zn) proceeds in distinct steps at -0.15 , -0.50 , -1.10 , and -1.35 mV vs. SCE (34). In the solid state, the potentials merge. For an ideal nernstian one-electron reaction of a solid thin film on an electrode surface, the model of Anson and Brown (40) predicts a half-width of the current peak of $\Delta E_{1/2} = 90.6$ mV. $\Delta E_{1/2}$ values around 190 mV were measured for the films of **2** in acid electrolytes and might be explained by the close proximity of up to three one-electron steps. In the case of **2** (Mt = Zn), two neighboring peaks can even be distinguished (Fig. 1b). The narrow half-widths observed for the most cathodic wave for films of **2** (Mt = Zn, Cu) in alkaline Na⁺ and K⁺ containing electrolytes can be accounted for by the exchange of 1.5 F/mol in one step (Fig. 5b, peak III and Fig. 5c, peak II, respectively). The observed asymmetry of these peaks in comparison with the corresponding anodic waves could be due to the interactions between the phthalocyanine molecules combined with the observed diffusion control in the behavior of the redox system in alkaline solutions. This interpretation follows a model put forward by Laviron and Roullier (41). The shape of the wave observed for the metal-free **2** (Mt = 2H) in the same electrolytes again appears to be due to the close proximity of one-electron steps. This could be explained by the existence of distinguishable energy levels for the successive intercalation of the charge compensating cations.

At low pH values, a total charge of about 3 F/mol is consumed in the reduction and in the reoxidation of the phthalocyanine. It is well known that the nitrogen atoms in positions 6, 13, 20, 27 of the phthalocyanine can be protonated (42, 43). An acid base reaction might be the cause for the rapid intercalation of protons leading to the observed nernstian behavior of the electrodes. Up to pH

2.5 the potential of the peak current shifts 60 mV/pH (298 K) for any distinguishable peak. This pH-sensitive behavior can be expected for the exchange of protons according to the overall reaction

At high pH values, the transport of charge compensating cations other than protons may become the rate-determining step in the redox process. As a common feature of the cyclic voltammogram of **2** (Mt = Cu) in alkaline solutions, two peaks (I, II) have been established by the experiments (Fig. 6c and 6d). A dependence of the height of the cathodic peak II and the corresponding anodic peak on the square root of the scan rate is indicative of a diffusion-limited intercalation of the cation (40).

In the observed range of scan rates the $v^{1/2}$ dependence is established clearly in case of Li⁺ (ratio of successive peak currents $I_{p,n+1}/I_{p,n} \approx \sqrt{2}$). A trend towards the linear dependence of the peak current on the scan rate v can be observed in the case of electrolytes containing the larger cations Na⁺ and K⁺ at least for the low range of scan rates ($I_{p,n+1}/I_{p,n} \approx 2$). This seems to reflect decreasing electrostatic interaction with increasing size of the cation during migration through the phthalocyanine bulk.

The properties and the shape of the first cathodic (I) and the corresponding anodic wave (Fig. 5c and 6c) could be due to the reduction of a surface layer, i.e., the creation of surface states for the adsorption of the cation. The dependence of the position of the peak on the nature of the cation is therefore no surprise, even though the trend cannot be explained at the present time. From the reproducibility of the cycles with respect to the charge, and to the position of the peak currents as well as the close proximity of the anodic and the cathodic peak currents on the potential scale, nernstian behavior of the thin film electrodes without diffusion control can be inferred in the case of acid electrolytes. The pH dependence of the potential of the peak current lends additional support to this assertion. In the case of alkaline electrolytes, nernstian behavior with some diffusion limitation of the intercalation of the charge compensating cations cannot be distinguished from irreversible steps in the redox process, based on the available data.

Conclusions

Thin film electrodes of octacyanophthalocyanine **2** were found to function as reversible solid-state redox systems. The outstanding electrochemical properties appear to be due to a combination of the high intrinsic conductivity and the electron accepting properties of the substituents of **2**. The choice of the cation in the ligand of **2**, of the cation in the electrolyte, and eventually of the substituents determines the potential range for the solid-state redox processes. Applications in batteries, in redox active membranes, and in memory devices can be envisaged.

Indirect Electrochemical Processes at a Rotating Disk Electrode

Oxidation of Sulfite Catalyzed by Iodide

Shi-Chern Yen and Thomas W. Chapman

Department of Chemical Engineering, University of Wisconsin-Madison, Madison, Wisconsin 53706

ABSTRACT

The anodic oxidation of sulfite in sulfuric acid solution is catalyzed by small amounts of iodide ion. The mechanism of this process is viewed as the electrochemical oxidation of iodide followed by the homogeneous oxidation of sulfite by iodine. The homogeneous reaction is too fast for its rate to be measured conveniently by cyclic voltammetry so the enhancement by sulfite of the iodide limiting current to a rotating disk electrode is used to determine the second-order rate constant ($7.5 \times 10^8 \text{ cm}^3/\text{mol}\cdot\text{s}$ at 22°C). A collocation technique is used to simulate the electrochemical-chemical process. The electrode kinetics parameters of iodide oxidation on pyrolytic graphite are also determined. The collocation model is successful in predicting anodic polarization curves in the sulfite-iodide system. The sulfite anode is depolarized by as much as 400 mV by the iodide catalyst.

The oxidation of sulfur dioxide has been investigated extensively in recent years. Most studies have been directed at direct electrochemical oxidation of SO_2 on platinum, gold, alloy, carbon, or graphite electrodes (1-17). A few investigations (18-24) were performed by using a chemical depolarizer, such as a halide ion, to facilitate the anodic oxidation of sulfur dioxide. This paper considers the anodic oxidation of SO_2 , its depolarization by iodide, and the rate of the homogeneous reaction between SO_2 and iodine.

The oxidation of SO_2 has both theoretical interest and practical applications. Besides its electroanalytical use, it offers the following potential applications: (i) anode depolarization in electrowinning of copper and other metals (25, 26), (ii) hydrogen production with SO_2 as an interme-

diating in an electrochemical-thermochemical water-splitting cycle (27-29), (iii) production of sodium hydroxide and sulfuric acid (14, 15), and (iv) electrochemical treatment for SO_2 removal from flue gas (29).

The anodic oxidation of SO_2 on platinum and many other materials in sulfuric acid solution is inhibited by the formation of a surface oxide layer or by reaction-product adsorption (9). Therefore, the electrochemical oxidation rate of SO_2 decreases with time, and at steady state the reaction is quite irreversible. If a suitable depolarizer can be added to the system, one may hope to accelerate the steady-state reaction rate. Here, we employ iodide ion because its electrode potential is close to the SO_2 oxidation potential, its electrode kinetics are nearly reversible, and its reaction product, iodine, reacts very rap-

idly with SO_2 to regenerate iodide and produce sulfuric acid.

Figure 1 shows anodic polarization curves for a vertical graphite electrode, which were obtained in a study of anode depolarization in electrowinning cells (30). Curve 1 is the potential obtained for oxygen evolution at 50°C in $0.2M$ sulfuric acid. Curve 2 is the anode potential when 0.1 sodium sulfite is added to the solution. Curve 3 is the anode polarization curve when 1.0 g/liter sodium iodide is added to the sulfite solution. It is seen that the iodide catalyzes, or depolarizes, the sulfite anode and reduces the anode potential by almost 300 mV at high current densities. Furthermore, this potential is almost 900 mV less anodic than that of the oxygen electrode. Thus, the iodide-catalyzed sulfite anode offers interesting energy saving possibilities in the applications listed above. The purpose of this paper is to examine the behavior of the sulfite-iodide electrode. A specific objective is to present methods for modeling and measuring the kinetics of a fast homogeneous reaction that is coupled with an electrode reaction.

The electrochemical oxidation of iodide has been studied by many investigators (31-43), but its mechanism has not been definitely established. Vetter (44) proposed a mechanism for the iodide-iodine redox reaction on platinum with electron transfer as the rate-determining step. This was confirmed by Newson and Riddiford (39). The anodic transfer coefficient reported by Vetter was 0.78 , but Newson and Riddiford found that the transfer coefficient depended on the concentrations of iodine and iodide and on the rotation speed of the rotating disk electrode, which they attributed to surface nonuniformity.

Swathirajan and Bruckenstein (45, 46) have recently investigated the behavior of the iodide electrode under conditions where iodine films form on a platinum anode. This phenomenon occurs when the iodide concentration exceeds 5 mM. The iodide concentrations used in this study were all $0.001M$ or lower.

In this paper, we report studies on the anodic oxidation rates of sulfite and iodide on rotating platinum and pyrolytic graphite disk electrodes. The depolarization of the sulfite anode by small concentrations of iodide is modeled as the electrochemical discharge of iodide coupled with a second-order homogeneous reaction between iodine and sulfite. The kinetics of the iodide electrode on pyrolytic graphite and of the homogeneous reaction are determined quantitatively.

Fig. 1. Anodic polarization curves on a vertical graphite electrode in $0.2M$ sulfuric acid at 50°C . Curve 1 is oxygen evolution. Curve 2 is sulfite oxidation when sodium sulfite is present at $0.1M$. Curve 3 is obtained when 1.0 g/liter sodium iodide is added to the sulfite solution.

Experimental Methods

All chemicals were of analytical grade, and solutions were prepared with double-distilled water. Sodium sulfite was used as a source of SO_2 in solution. A saturated calomel electrode was employed as the reference electrode, and a platinum counterelectrode was used. Potentiostatic and potentiodynamic measurements were taken by using a PAR Model 170 electrochemical instrument and a PIR disk electrode rotator from Pine Instrument Company. A diagram of the apparatus is shown in Fig. 2.

Pyrolytic graphite and smooth platinum electrodes (Pine Instrument) served as working electrodes, each with an area of 0.485 cm^2 . Prior to polarization experiments, the working electrodes were prepared by the following procedure: (i) immersion in chromic acid cleaning solution for 5 min and rinsing with redistilled water, (ii) immersion in $6M$ H_2SO_4 solution for 5 min and then rinsing with redistilled water, (iii) placement of the electrode in the test solution ($1M$ H_2SO_4) and passage of nitrogen through the solution, (iv) application of potential at $-0.2V$ (SCE) for 1 min and then three cyclic scans at 10 mV/s from -0.2 to $1.2V$ (SCE), and (v) changing the potential from $-0.2V$ (SCE) to slightly anodic, $+0.4V$ (SCE), to reoxidize any absorbed hydrogen on surface, then performance of the measurements.

The temperature was approximately 22°C (room temperature), and IR compensation was applied to the rotating disk electrode measurements.

Characterization of the Iodide Electrode

Slow potentiodynamic scans were made on the rotating platinum and graphite electrodes with solutions of sodium iodide in $1.0M$ sulfuric acid. Typical results are shown in Fig. 3 and 4. Although some hysteresis was observed when the potential was scanned in the negative direction after anodic polarization because of iodine formation and possible surface oxidation, it is clear that the iodide reaction is quite reversible on both platinum and pyrolytic graphite.

Steady-state limiting currents were observed for iodide oxidation on the rotating graphite electrode at $0.6V$ (SCE) in $1.0M$ sulfuric acid solutions over a range of rotation speeds and iodide concentrations. The results shown in Fig. 5 verify that the limiting current is proportional to reactant concentration. Although iodide may be oxidized by sulfuric acid on standing, the linearity of the limiting current data seen in Fig. 5 indicates that there was negligible loss of iodide during the course of the experiments. Application of the Levich equation to the limiting currents yields an iodide diffusivity value of 1.46×10^{-5} cm^2/s . Cathodic limiting currents were also observed with

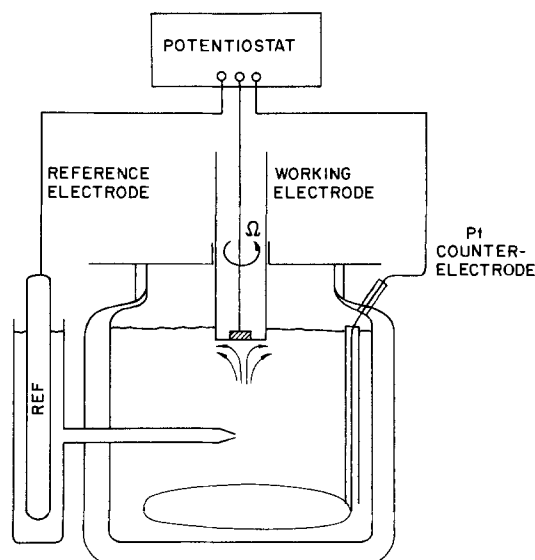

Fig. 2. The rotating disk electrode apparatus

Fig. 3. Anodic polarization curves on a platinum disk electrode rotating at 1600 rpm. Area was 0.4845 cm^2 , and scan rate was 1.0 mV/s . Curve 1: $1.0M$ sulfuric acid. Curve 2: $2 \times 10^{-5}M$ sodium iodide in $1.0M$ sulfuric acid.

Fig. 4. Anodic polarization curves on a pyrolytic graphite disk electrode rotating at 1600 rpm. Scan rate was 1.0 mV/s , and electrode area was 0.4845 cm^2 . Curve 1: 1.0 mM sodium iodide in $1.0M$ sulfuric acid. Curve 2: 1.0 mM sodium iodide and 19 mM sodium sulfite in $1.0M$ sulfuric acid.

iodine solutions from which the iodine diffusivity was determined to be $0.93 \times 10^{-5} \text{ cm}^2/\text{s}$. These values are based on a kinematic viscosity value of $0.96 \text{ cm}^2/\text{s}$ for $1.0M$ sulfuric acid.

The kinetics of the iodide electrode on pyrolytic graphite in $1.0M$ sulfuric acid were determined quantitatively by observing the polarization curve potentiostatically at various potential values. The bulk solution contained $0.001M$ sodium iodide and $0.001M$ iodine in the sulfuric acid. For data-fitting purposes, it was assumed that the redox electrode kinetics followed a simple Butler-Volmer form, which may be written as

$$i_n = Fk_a r \left[C_{1,\infty} e^{\frac{\alpha F(E - E_0)}{RT}} - \frac{C_{1,\infty} C_{2,0}^{1/2}}{C_{2,\infty}^{1/2}} e^{\frac{-(1-\alpha)F(E - E_0)}{RT}} \right] \quad [1]$$

where E_0 is the equilibrium electrode potential for $C_{1,\infty} = C_{2,\infty} = 0.001M$ [$E_0 = 0.4535V$ (SCE)], α is the anodic transfer coefficient, and k_a^r is a specific anodic rate constant referred to the equilibrium potential E_0 .

The evaluation of the kinetic parameters was done by following the procedures outlined by Gileadi (47). The surface concentrations of iodide and iodine are expressed

Fig. 5. Limiting anodic current density on a rotating pyrolytic-graphite disk electrode as a function of rotation speed and iodide concentration in $1.0M$ sulfuric acid.

in terms of their respective bulk values and limiting currents. For example

$$C_{1,\infty} = C_{1,\infty} \left(1 - \frac{i_n}{i_{L,a}} \right) \quad [2]$$

where $C_{1,\infty}$ is the bulk iodide concentration and $i_{L,a}$ is the anodic limiting current density for iodide oxidation. Substituting for the interfacial concentrations in this form, one may rewrite Eq. [1] as

$$\ln \left\{ F C_{1,\infty} \left[\left(\frac{1}{i_n} - \frac{1}{i_{L,a}} \right) - \frac{1}{i_n} \left(1 - \frac{i_n}{i_{L,c}} \right)^{1/2} \exp \frac{-F(E - E_0)}{RT} \right] \right\} \equiv \ln(k_a) \\ = -\frac{\alpha F}{RT} (E - E_0) - \ln(k_a^r) \quad [3]$$

where E is the electrode potential at which the current density i_n is measured.

Figure 6 is a plot vs. overpotential, $E - E_0$, of the left-hand side of Eq. [3], calculated for several levels of anodic polarization and abbreviated k_a . In agreement with Eq. [3], the data fall on a straight line. The intercept and slope indicate the values of k_a^r and α to be $6.18 \times 10^{-3} \text{ cm/s}$ and 0.80 , respectively. This rate constant value corresponds to an exchange current density of 0.6 mA/cm^2 for the iodide electrode at these bulk concentrations.

Fig. 6. Plot of anodic polarization data for iodide oxidation on pyrolytic graphite according to the form of Eq. [3].

Mathematical Model of Steady Current to a Rotating Disk Electrode with a Catalytic Chemical Reaction

The anodic oxidation of sulfur dioxide catalyzed by iodide is called an indirect electrochemical process, an electrochemical reaction coupled with a catalytic chemical reaction, and it is represented by the following reaction scheme

on electrode surface and

in solution, where R is a reduced species, such as iodide, O is an oxidized species, such as iodine, S is an electrochemically inactive reactant, such as SO₂, k is a second-order reaction rate constant, and a, b, and n are stoichiometric coefficients. The reduced species R is regenerated in solution and then transported to the electrode surface to be oxidized. The oxidized species O is transported out to react with the reactant S in solution to achieve the overall reaction

For SO₂ + 2H₂O → H₂SO₄ + 2H⁺ + 2e⁻, the stoichiometric coefficients are a = b = 1/2 and n = 1.

In order to formulate a model of this electrochemical-chemical reaction system on a rotating disk electrode, we adopt the following assumptions: (i) the electrochemical reaction rate contributed by the direct SO₂ electrode reaction is negligible; (ii) the effect of electrical migration is negligible because of the high acid concentration; (iii) the diffusivities of all species are constant; and (iv) the homogeneous chemical reaction is of second order and irreversible. The first case to be treated is that where the applied potential is high enough to force limiting current.

The analysis of a steady-state electrochemical reaction coupled with a homogeneous catalytic chemical reaction on a rotating disk electrode has been conducted by several investigators (48-50). Levich treated first-order catalytic electrochemical processes analytically. Ulstrup (51) and Holub (52) investigated an electrochemical process with a catalytic reaction in which the electroactive reactant is regenerated by disproportionation. Pospisil (53) determined the rate constant of the reaction between the ferrous ion and hydrogen peroxide by the polarographic method. Generally, an electrochemical process coupled with a second-order catalytic reaction must be analyzed numerically.

The governing equations of the above electrochemical system at steady state are expressed as follows (48, 54)

$$v_z \frac{dC_O}{dz} = D_O \frac{d^2 C_O}{dz^2} - a k C_S C_O \quad [4]$$

$$v_z \frac{dC_R}{dz} = D_R \frac{d^2 C_R}{dz^2} + k C_S C_O \quad [5]$$

$$v_z \frac{dC_S}{dz} = D_S \frac{d^2 C_S}{dz^2} - b k C_S C_O \quad [6]$$

where $v_z = -a'\Omega(\sqrt{[\Omega/\nu]z})^2$, $a' = 0.51023$, Ω is the rotating speed, ν is the kinematic viscosity, z is the normal distance from the rotating disk electrode, C_i and D_i stand for concentrations and diffusivities of the species.

We may first consider a special case, the instantaneous homogeneous reaction.

For the case of an infinite rate constant, the reduction occurs at a plane, and an analytical solution may be obtained by modifying Eq. [4]-[6] and making them dimensionless

$$\frac{d^2 \theta_O}{dx^2} + 3x^2 \frac{d\theta_O}{dx} = 0, \text{ for } 0 \leq x \leq x_R \quad [7]$$

$$\frac{d^2 \theta_O}{dx^2} + 3\alpha_0 x^2 \frac{d\theta_O}{dx} = 0, \text{ for } 0 \leq x \leq x_R \quad [8]$$

$$\frac{d^2 \theta_S}{dx^2} + 3\alpha_s x^2 \frac{d\theta_S}{dx} = 0, \text{ for } x_R \leq x \leq \infty \quad [9]$$

where $\theta_O = (C_O/C_{R,x})$, $\theta_R = (C_R/C_{R,x})$, and $\theta_S = (C_S/C_{R,x})$ are the dimensionless concentrations, $\alpha_0 = (D_R/D_O)$ and $\alpha_s = (D_R/D_S)$ are dimensionless diffusivity ratios, $x = z/\delta$, $C_{R,x}$ is the bulk concentration of species R, x_R is the dimensionless position of the reaction plane, and δ is the thickness of the diffusion layer adjacent to the rotating electrode, which is

$$\delta = \left(\frac{3D_R}{a'\nu} \right)^{1/3} \left(\frac{\nu}{\Omega} \right)^{1/2} \quad [10]$$

The boundary conditions are

$$\text{at } x = 0, \theta_R = 0; \frac{d\theta_O}{dx} + a\alpha_0 \frac{d\theta_R}{dx} = 0 \quad [11]$$

$$\text{at } x = \infty, \theta_S = \theta_{S\infty}; \theta_{R\infty} = 1 \quad [12]$$

$$\text{at } x = x_R, \theta_S(x_R) = 0; \theta_O(x_R) = 0 \quad [13]$$

$$\left. \frac{d\theta_S}{dx} \right|_{x_R} = -\lambda \left. \frac{d\theta_O}{dx} \right|_{x_R}; \lambda = \frac{b}{a} \frac{D_O}{D_S} \quad [14]$$

Equations [7]-[9] with their boundary conditions, Eq. [10]-[14], may be solved to yield the concentration profiles for each species as

$$\theta_R = \int_0^x e^{-x^3} dx / \int_0^{x_R} e^{-x^3} dx, \text{ for } 0 \leq x \leq x_R \quad [15]$$

$$\theta_R = 1, \text{ for } x \geq x_R \quad [16]$$

$$\theta_O = a\alpha_0 \int_x^{x_R} e^{-\alpha_0 x^3} dx / \int_0^{x_R} e^{-x^3} dx, \text{ for } 0 \leq x \leq x_R \quad [17]$$

$$\theta_O = 0, \text{ for } x \geq x_R \quad [18]$$

$$\theta_S = \theta_{S\infty} \int_{x_R}^x e^{-\alpha_s x^3} dx / \int_{x_R}^{\infty} e^{-\alpha_s x^3} dx, \text{ for } x \geq x_R \quad [19]$$

$$\theta_S = 0, \text{ for } 0 \leq x \leq x_R \quad [20]$$

The position of the reaction plane, x_R , can be found by solving the following equation

$$\frac{\theta_{S\infty}(\alpha_s)^{1/3}}{a\alpha_0\lambda} = e^{(\alpha_s - \alpha_0)x_R^3} \frac{\int_{\alpha_s x_R^3}^{\infty} t^{-2/3} e^{-t} dt}{\int_0^{x_R^3} e^{-t} t^{-2/3} dt} \quad [21]$$

which is obtained from Eq. [14].

From the concentration profile of species R near the electrode, one can calculate the limiting current and show that it exceeds that expected for species R in the absence of species S. The extent of the limiting current enhancement may be expressed by defining a mass transfer enhancement factor (MTEF) as

$$\text{MTEF} = \frac{i_L(\text{with chemical reaction})}{i_L(\text{without chemical reaction})} \quad [22]$$

where the limiting current without reaction refers to that of species R alone.

The MTEF for the case of instantaneous chemical reaction can be expressed as a function of the position of the reaction plan as

$$\text{MTEF} = \frac{\Gamma(4/3)}{\int_0^{x_R} e^{-x^3} dx} = \frac{\Gamma(1/3)}{\Gamma(1/3, x_R^3)} \quad [23]$$

where $\Gamma(1/3)$ is the gamma function of $1/3$, and $\Gamma(1/3, x_R^3)$ is an incomplete gamma function. If all diffusivities are equal (i.e., $\alpha_0 = \alpha_s = 1$), then

$$\Gamma(1/3, x_R^3) = \Gamma(1/3) \left(\frac{\theta_s}{\alpha\lambda} + 1 \right) \quad [24]$$

Combining Eq. [23] and [24] gives

$$\text{MTEF} = 1.0 + \theta_{s\infty}/b \quad [25]$$

This result means that the enhanced limiting current is equivalent to that for the direct electrode reaction of species S, if it were possible, plus that of the independent limiting current of the depolarizer R itself. This special limiting case for an instantaneous chemical reaction indicates the maximum possible mass transfer enhancement provided by a homogeneous reaction.

For a finite rate of the second-order homogeneous reaction, one may make Eq. [4]-[6] dimensionless as follows

$$\frac{d^2\theta_R}{dx^2} + 3x^2 \frac{d\theta_R}{dx} + \psi\theta_s\theta_0 = 0 \quad [26]$$

$$\frac{d^2\theta_0}{dx^2} + 3\alpha_0x^2 \frac{d\theta_0}{dx} - \alpha\alpha_0\psi\theta_s\theta_0 = 0 \quad [27]$$

$$\frac{d^2\theta_s}{dx^2} + 3\alpha_sx^2 \frac{d\theta_s}{dx} - b\alpha_s\psi\theta_s\theta_0 = 0 \quad [28]$$

where ψ is a dimensionless rate constant defined as

$$\psi = \frac{kC_{R,\infty}}{D_R} \delta^2 \quad [29]$$

The boundary conditions are

$$\text{at } x = 0, \theta_R = 0 \quad [30]$$

$$\frac{d\theta_R}{dx} = 0 \quad [31]$$

and

$$\frac{d\theta_0}{dx} + \alpha\alpha_0 \frac{d\theta_R}{dx} = 0 \quad [32]$$

and

$$\text{at } x = \infty, \theta_0 = 0, \theta_R = 1, \theta_s = \theta_{s\infty} \quad [33]$$

This set of simultaneous differential equations can be solved numerically by the orthogonal collocation method (55). The first- and second-order derivatives of Eq. [26]-[32] can be represented by means of the associated $\underline{\underline{A}}$ and $\underline{\underline{B}}$ matrices, and the equations can be transformed into a set of algebraic equations

$$\sum_{j=0}^{n+1} (3x_i^2 A_{ij} + B_{ij})\theta_{R,j} + \psi\theta_{s,i}\theta_{0,i} = 0; \quad i = 1, \dots, n \quad [34]$$

$$\sum_{j=0}^{n+1} (3\alpha_0x_i^2 A_{ij} + B_{ij})\theta_{0,j} - \alpha\alpha_0\psi\theta_{s,i}\theta_{0,i} = 0; \quad i = 1, \dots, n \quad [35]$$

$$\sum_{j=0}^{n+1} (3\alpha_sx_i^2 A_{ij} + B_{ij})\theta_{s,j} - b\alpha_s\psi\theta_{s,i}\theta_{0,i} = 0; \quad i = 1, \dots, n \quad [36]$$

including the boundary conditions

$$\text{at } i = 0 \text{ (i.e., } x = 0), \theta_{R,0} = 0 \quad [37]$$

$$\sum_{j=0}^{n+1} (\theta_{0,j} + \alpha\alpha_0\theta_{R,j})A_{0,j} = 0 \quad [38]$$

and

$$\sum_{j=0}^{n+1} A_{0,j}\theta_{R,j} = 0 \quad [39]$$

and

$$\text{at } i = n + 1 \text{ (i.e., } x = \infty), \theta_{R,n+1} = 1, \theta_{0,n+1} = 0, \theta_{s,n+1} = \theta_{s\infty} \quad [40]$$

Equations [34]-[40] constitute $3n + 6$ simultaneous algebraic equations with $3n + 6$ unknowns so they can be solved numerically by standard numerical methods. The result represents an approximate solution to the original differential equations.

The mass transfer enhancement factor (MTEF), which now depends on the dimensionless rate constant ψ as well as the bulk concentration ratio $\theta_{s\infty}$, is calculated from

$$\begin{aligned} \text{MTEF} &= \frac{\left(\frac{d\theta_R}{dx} \right)_{x=0} \text{ (with reaction)}}{\left(\frac{d\theta_R}{dx} \right)_{x=0} \text{ (without reaction)}} \quad [41] \\ &= \frac{\sum_{j=0}^{n+1} A_{0,j}\theta_{R,j}}{1.1198465} \end{aligned}$$

The MTEF can be found if k (i.e., ψ) is known, and vice versa. Computed results are given in Fig. 7 for $\alpha_0 = 1.6$, $\alpha_R = 0.8$, and $a = b = 1/2$, which correspond to the properties of the iodide-iodine-sulfurous acid system. Note that the limits for large ψ correspond to the result given in Eq. [23] for an instantaneous reaction. The large ψ asymptotes in Fig. 7 do not agree exactly with Eq. [25] because the latter is obtained only for $\alpha_0 = \alpha_s = 1$.

The above case was taken to be at the limiting current where $\theta_R(0) = 0$. Below the limiting current, the zero-concentration boundary condition at the electrode surface must be replaced by the electrode kinetics of the electroactive species R. The electrode kinetics of the iodide-iodine redox reaction, as given in Eq. [1], provide the appropriate boundary condition to relate current density to electrode potential. It is assumed in this analysis that any sulfite (species S) reaching the electrode surface is not electroactive in the potential range of interest. Thus, at the electrode surface, instead of $\theta_R = 0$, the boundary condition in Eq. [30] and [37] is changed to

$$\begin{aligned} \frac{d\theta_R}{dx} \Big|_{x=0} &= \frac{k_a r \delta}{D_R} \theta_{R,0} e^{\frac{\alpha F}{RT}(E - E_0)} \\ &- \frac{\theta_{0,0}^{1/2} e^{-\frac{(1-\alpha)F}{RT}(E - E_0)}}{\theta_{0,\infty}^{1/2}} = \sum_{j=0}^{n+1} A_{0,j}\theta_{R,j} \quad [42] \end{aligned}$$

Then, in a manner similar to that used in the limiting current case, the set of differential equations can be

Fig. 7. Plot of the mass transfer enhancement factor (MTEF), defined by Eq. [22], for an anodic limiting current computed for the case when a second-order homogeneous reaction regenerates the reduced form of the electroactive species. Computed for $\alpha_a = 1.6$, $\alpha_R = 0.8$, and $a = b = 1/2$.

solved approximately for specified values of the chemical rate constant, the electrode rate constant, and the disk rotation speed. The current density at each applied potential can then be calculated, and the entire polarization curve may be simulated.

Determination of the Homogeneous Reaction Rate

The second-order rate constant k for the homogeneous reaction between sulfur dioxide and iodine in 1.0M sulfuric acid was determined by measuring anodic limiting currents on the rotating disk in solutions containing iodide and sulfite. Forty-five limiting current values were measured on the pyrolytic graphite electrode over a range of rotation speeds from 400 to 4900 rpm and at various concentrations of iodide (2×10^{-5} to $2 \times 10^{-4}M$) and sulfite (10^{-4} to $5 \times 10^{-4}M$). In all experiments with sulfite, a closed cell was used to prevent loss of sulfur dioxide.

For each limiting current measurement the MTEF was calculated by comparison with the limiting current of iodide in the absence of sulfite. Figure 7 was then used to determine the corresponding value of k . Some of the results are shown in Fig. 8, where the calculated value of k for various determinations is plotted vs. the disk rotation speed. It is seen that the value of the rate constant is independent of rotation speed. This indicates that the assumptions of second-order kinetics and negligible electrochemical oxidation of sulfite yield an adequate description of the electrode processes on graphite. The average value of the rate constant determinations is $7.5 \times 10^9 \text{ cm}^3/\text{mol/s}$.

Similar measurements were made on the platinum electrode. The results are shown in Fig. 9. It is seen that on platinum the apparent homogeneous rate constant falls in the same magnitude range but exhibits a dependence on rotation speed. In this case, it is likely that the sulfite does react on the electrode to some extent, enhancing the current at high rotation speed and possibly blocking the surface at lower rotation speeds.

Depolarization of the Sulfite Anode

Figure 10 shows several anodic polarization curves obtained on the rotating pyrolytic graphite electrode at 22°C and a scan rate of 1.0 mV/s. Curve 1 is that observed with only sulfuric acid in the cell. At potentials up to 1.2V (SCE), no significant current is observed because of the slow kinetics of the oxygen electrode. Curve 2 is that obtained with $19 \times 10^{-3}M$ sodium sulfite present in the solution. Significant current passes only at potentials in excess of 1.0V, although the reversible sulfite potential should be near 0.0V (SCE). These results may be compared with the higher temperature data shown in Fig. 1.

Fig. 8. The second-order rate constant for reaction of iodine with sulfite as determined from the enhancement of the anodic iodide limiting current to the rotating pyrolytic graphite disk electrode at various operating conditions.

Fig. 9. The second-order rate constant for reaction of iodine with sulfite as determined from the enhancement of the anodic iodide limiting current to the rotating platinum disk electrode at various operating conditions.

Curve 3 in Fig. 10 is that obtained when $0.2 \times 10^{-3}M$ sodium iodide is added to the sulfite solution, and curve 4 is that with $10^{-3}M$ iodide. It is seen that the iodide is quite effective in catalyzing the sulfite oxidation. That sulfite is reacting is indicated by the fact that only a small fraction of the limiting current observed on curve 4 can be provided by the low concentration of iodide in the solution.

With the transport-reaction model presented in Eq. [26]-[32] and the values of relevant system parameters, one can compute the anodic polarization curve expected on the rotating disk electrode. Curve 5 shows the result of this calculation when Eq. [42], for iodide oxidation kinetics, was used as the boundary conditions on the electrode surface. This calculation used the kinetics and transport

Fig. 10. Experimental and computed anodic polarization curves for the rotating pyrolytic-graphite disk electrode, area = 0.485 cm^2 . Experimental scan rate = 1.0 mV/s. Dashed curves are computed for steady-state polarization.

properties of the system as obtained in the experiments described in earlier sections. The diffusivity of sulfite was taken to be 1.8×10^{-5} cm²/s (56). It is seen that excellent agreement is obtained between the computed and experimental polarization curves.

Curve 6 shows the computed polarization curve corresponding to curve 4 obtained when an iodide-iodine equilibrium (Nernst equation) was used as a boundary condition on the electrode instead of the electrode kinetics expression. Although the iodide electrode reaction exhibits fast kinetics, they are finite and do affect the sulfite-iodide polarization at these concentrations and temperature.

In the analysis of this system, we have treated iodide, iodine, and sulfite each as single species. At the low concentrations considered, formation of triiodide should not be extensive so it has been neglected. The "sulfite," or dissolved sulfur dioxide, should be primarily in the form of undissociated sulfurous acid in these strong acid solutions. Therefore, the effective second-order rate constant that we report refers to the reaction of that species with iodine.

Conclusions

The work reported here has verified that iodide is effective in catalyzing the sulfite anode on pyrolytic graphite. Figure 10, for example, shows that a small amount of iodide reduces the sulfite anode potential by as much as 400 mV or more. The model, and its associated parameters, make possible a quantitative prediction of the effects of species concentrations and mass transfer conditions on the anode polarization. Although the parameter determinations were done at room temperature (22°C), the transport model permits extrapolation to higher temperatures. At higher temperature, the kinetics of both the electrode and the homogeneous reactions should become faster. In that case, the polarization curve should approach the potential behavior of the reversible iodide-iodine electrode and a limiting current given by Eq. [25].

The more general result of this work is the development of the collocation model for mass transfer to a rotating disk electrode accompanied by a homogeneous reaction. The model may be modified to treat various reaction stoichiometries and kinetics laws. The resulting prediction of a limiting current mass transfer enhancement factor, such as that given in Fig. 7, may be used to determine the kinetics of reactions that are too fast to measure by more conventional techniques. Use of this method requires that experimental observation of limiting currents must be possible, but if it is the method is otherwise independent of electrode kinetics behavior.

Manuscript submitted Dec. 6, 1984; revised manuscript received May 1, 1985.

LIST OF SYMBOLS

A_{ij}	collocation coefficients for first derivatives of the first-order derivatives
a, b	stoichiometric coefficient
a'	velocity profile constant ($a' = 0.51023$)
B_{ij}	collocation coefficients for second-order derivatives
C_i	concentration of species i (mol/cm ³)
D_i	diffusion coefficient of species i (cm ² /s)
E	electrode potential (V)
E_0	equilibrium electrode potential (V)
F	Faraday's constant (96,487 C/eq)
i_n	current density on electrode (anodic current is positive) (A/cm ²)
k	second-order homogeneous reaction rate constant (cm ³ /mol/s)
k_a	argument of ln on left-hand side of Eq. [3] (cm/s)
k_a^r	anodic rate constant referred to the equilibrium potential (cm/s)
MTEF	mass transfer enhancement factor
n	stoichiometric number of electrons
O	oxidized species
R	reduced species
T	temperature (K)
v_z	velocity in z direction (cm/s)

x	dimensionless distance from electrode
x_R	position of reaction plane, dimensionless
z	distance from electrode surface (cm)

Greek Symbols

α_o, α_s	ratios of diffusion coefficients
α	anodic transfer coefficient
δ	thickness of diffusion layer (cm) (see Eq. [10])
θ_i	dimensionless concentration of species i
λ	flux ratio defined in Eq. [14]
ν	kinematic viscosity (cm ² /s)
ψ	dimensionless second-order rate constant (see Eq. [29])
Ω	rotation speed (rad/s)

Subscripts

O	at electrode surface
∞	in bulk solution
L	limiting current
a	anodic
c	cathodic

ABSTRACT

Transport numbers were measured for the Lewis basic aluminum chloride-1-methyl-3-ethylimidazolium chloride ionic liquid over the range of AlCl_3 mole fractions, $0.50 > x_{\text{Al}} > 0.30$. The 1-methyl-3-ethylimidazolium cation external and internal (relative to chloride) transport numbers were found to be independent of melt composition; average values for these parameters were 0.71 ± 0.02 and 0.99 ± 0.02 , respectively, at the 95% confidence level. Numerical models derived for the anionic constituents of these melts suggest that the AlCl_4^- and Cl^- ionic mobilities are approximately equal. Factors that may lead to these results are discussed.

Chloroaluminate molten salts which are liquid at room temperature have become popular solvents for electrochemical and spectroscopic studies (1, 2). The relatively high intrinsic conductivity and the variable Lewis acid-base properties of these melts have contributed significantly to their popularity. Familiar examples of these ionic liquids are mixtures of aluminum chloride with 1-n-butylpyridinium chloride (BPC) or 1-methyl-3-ethylimidazolium chloride (MEIC). Both systems have been studied with ^{27}Al NMR spectroscopy (3-5), while the former liquid was also investigated by using Raman spectroscopy (6). It was concluded from these studies that AlCl_4^- and Al_2Cl_7^- are the principal anionic components of acidic melts in the range of aluminum chloride mole fractions, $0.50 < x_{\text{Al}} < 0.67$, while AlCl_4^- and Cl^- are the extant anions in basic melt ($0 < x_{\text{Al}} < 0.50$).

Although the ionic speciation in these melts has been probed, very little is known about charge transport by the ions in these systems. In a previous paper (7), we reported the external and internal transport numbers of the organic cation in the acidic composition range of the AlCl_3 -MEIC melt and presented models for the external transport numbers of AlCl_4^- and Al_2Cl_7^- . The external transport number of the organic cation was determined to be 0.71 ± 0.03 , while the internal transport number of the cation relative to chlorine was found to be 1.01 ± 0.04 . The ionic mobilities of AlCl_4^- and Al_2Cl_7^- appeared to be

approximately equal. The present study extends the study of transport numbers in the AlCl_3 -MEIC ionic liquid to the basic composition region.

Experimental

The procedures followed for purification of chemicals, the method used to determine melt composition, and the experimental methodology employed during this study are essentially the same as those described in a previous publication (7). The transference cell used over the range of melt compositions $0.40 < x_{\text{Al}} < 0.50$ was identical to that used in acidic melts. The transference cell used with very basic melts, $x_{\text{Al}} < 0.40$, was similar to this cell except that the porous areas of the fine porosity (4-8 μm) fritted glass disk separators were slightly larger. This modification was necessary in view of the high viscosity and diminished conductivity of melts with $x_{\text{Al}} < 0.40$. The hydrostatic resistances of these separators were tested with the appropriate melt, and no correction for hydraulic flow was found necessary in the time interval which encompasses a typical experiment. As an additional precaution, the center compartment of the cell [cf. Ref. (7)] was analyzed after each experiment. The experimental results were discarded if the composition of melt in the center compartment differed from the initial melt composition by more than twice the precision of the analysis. Transference experiments were run at $25^\circ \pm 3^\circ\text{C}$. The electrolysis current density varied between 0.04 and 0.12 mA/cm^2 , depending on the melt composition.

*Electrochemical Society Active Member.

Results and Discussion

The electrochemical reaction that occurred in the cathode compartment of the transference cell imparted an orange coloration to the melt and did not result in the deposition of aluminum metal at the cathode. Since the nature of this reaction was unknown, no attempt was made to obtain information about transference from the concentration changes that took place in this cell compartment. Aluminum metal could be anodized to aluminum chloride in basic melt with no obvious side reactions. However, the aluminum anode weight loss was approximately 5% larger than predicted based on the charge passed. Similar effects were noticed in acidic melt and were attributed to corrosion of the aluminum electrode by oxidizing impurities in the melt, possibly hydrogen ion (7). This phenomenon has been observed in this melt by other workers as well (8). Also, it should be noted that the oxidation of aluminum metal by the 1-methyl-3-ethylimidazolium cation appears to be thermodynamically favorable in basic melt (9). However, trial calculations indicated that errors in the melt composition and weight that may arise from this corrosion process were negligible compared to the estimated total error associated with a transference experiment. Therefore, the effects of this corrosion process were ignored.

Experimental transference data are collected in Table I. The precision with which the aluminum chloride mole fraction, x_{Al} , could be determined is listed for each melt and expressed as the relative average deviation from the mean for triplicate samples. The superscript o denotes the conditions in the anode compartment before charge was passed, while a denotes the conditions in the same compartment after electrolysis; w and Q represent the melt weights and the charge passed, respectively.

External transport numbers.—The formal external transport numbers for the organic component, t_R , and aluminum, t_{Al} , were calculated from the data listed in Table I by using Eq. [1] and [2] (7)

$$t_R = \frac{F}{Q} \left[\frac{(1 - x_{Al}^o)w^o}{x_{Al}^o M_{AlCl_3} + (1 - x_{Al}^o)M_{RCl}} - \frac{(1 - x_{Al}^a)w^a}{x_{Al}^a M_{AlCl_3} + (1 - x_{Al}^a)M_{RCl}} \right] \quad [1]$$

$$t_{Al} = \frac{3F}{Q} \left[\frac{x_{Al}^o w^o}{x_{Al}^o M_{AlCl_3} + (1 - x_{Al}^o)M_{RCl}} - \frac{x_{Al}^a w^a}{x_{Al}^a M_{AlCl_3} + (1 - x_{Al}^a)M_{RCl}} \right] + 1 \quad [2]$$

The formal external transport number for chloride, t_{Cl} , was calculated from t_R and t_{Al} with Eq. [3]

$$t_{Cl} = 1 - t_R - t_{Al} \quad [3]$$

The results of these calculations are recorded in Table II.

The transport numbers for the actual anionic species in the basic $AlCl_3$ -MEIC melt, i.e., $AlCl_4^-$ and Cl^- , are related to t_{Al} through the following equations

$$t_{AlCl_4^-} = -1/3 t_{Al} \quad [4]$$

$$t_{Cl^-} = 1/3(3t_{Cl} + 4t_{Al}) \quad [5]$$

The transport number for the organic cation, t_{R^+} , is synonymous with t_R , and therefore

$$t_{R^+} + t_{AlCl_4^-} + t_{Cl^-} = 1 \quad [6]$$

Figure 1 shows plots of t_{R^+} , $t_{AlCl_4^-}$, and t_{Cl^-} as a function of x_{Al}^o . From this plot, it appears that t_{R^+} is essentially independent of melt composition, while $t_{AlCl_4^-}$ and t_{Cl^-} increase and decrease, respectively, with increasing x_{Al}^o . Least squares analysis of t_{R^+} vs. x_{Al}^o yielded a slope of 0.056 ± 0.068 at the 95% confidence level. This confirms that t_{R^+} is essentially independent of melt composition with an average value of 0.71 ± 0.02 at the 95% confidence level. Similar constancy was found for t_{R^+} in acidic melt with an average value of 0.71 ± 0.03 (7). The average values of t_{R^+} measured in acidic and basic melt do not appear to be significantly different at the confidence level employed.

The large external transport numbers obtained for the organic cation over the range of compositions $0.30 < x_{Al} < 0.667$ are unexpected in view of the large ionic radius of this species compared to the radii of the extant anions. The organic cation may function as the majority charge carrier because the smaller anions are structurally constrained in the charge transport process.

Internal transport numbers.—The transport numbers for the organic component relative to chloride as the reference, t'_R , were calculated from the data listed in Table I with Eq. [7] (7)

$$t'_R = \frac{3F w^a (x_{Al}^a - x_{Al}^o)}{Q [x_{Al}^a M_{AlCl_3} + (1 - x_{Al}^a)M_{RCl}] (2x_{Al}^o + 1)} \quad [7]$$

The results of this calculation are collected in Table II. A plot of t'_R vs. x_{Al}^o is shown in Fig. 1. Least squares analysis of this plot produced a slope of 0.037 ± 0.072 at the 95% confidence level. This suggests that t'_R is independent of melt composition within the precision of the experimental data. The average value of t'_R , 0.99 ± 0.02 at the 95% confidence level, suggests that $t'_R \approx 1.00$. Therefore, the internal transport number for aluminum relative to chloride, t'_{Al} , must be essentially zero since

$$t'_R + t'_{Al} = 1 \quad [8]$$

Fig. 1. Plots of t_{R^+} (filled circles), t_{R^+} (open circles), $t_{AlCl_4^-}$ (squares), and t_{Cl^-} (open triangles) as a function of x_{Al}^0 . The solid lines were calculated from Model [IIa] and $t_{R^+} = 1.00$.

and t_{Cl^-} is defined as zero. These results indicate that transport by the anions in basic melt is prescribed by the melt stoichiometry. Similar results were obtained in acid melt (7).

The result that $t_{R^+} \approx 1.00$ is also significant in that it permits the use of simplified formulas to represent the relationships between the potential of a chloroaluminate concentration cell and the chemical potential of aluminum chloride in the cell when it contains melt with a composition that is within the range spanned by this and the previous study (7). A detailed discussion of the advantage afforded by this result appears in a previous paper (7).

Numerical models for the external transport numbers.—The internal and external transport numbers for aluminum and the organic cation are related to one another through the following equations (7)

$$t_{Al} = t_{Al} + \frac{3x_{Al}^0}{2x_{Al}^0 + 1} t_{Cl} \quad [9]$$

$$t_{R^+} = t_{R^+} + \frac{1 - x_{Al}^0}{2x_{Al}^0 + 1} t_{Cl} \quad [10]$$

The results that $t_{R^+} = 0.71$, $t_{R^+} \approx 1.00$, and $t_{Al} \approx 0$ can be used with Eq. [9] and [10] to give the following models for the formal external transport numbers of the organic component, aluminum, and chloride

$$t_{R^+} = 0.71; t_{Al} = -0.29 \frac{3x_{Al}^0}{1 - x_{Al}^0}; t_{Cl} = 0.29 \frac{2x_{Al}^0 + 1}{1 - x_{Al}^0} \quad [I]$$

Models for the transport numbers of the actual component ions in basic $AlCl_3$ -MEIC melt ($0.30 < x_{Al}^0 < 0.50$) can be obtained from the models shown above by the appropriate application of Eq. [4] and [5]

$$t_{R^+} = 0.71; t_{AlCl_4^-} = 0.29 \frac{x_{Al}^0}{1 - x_{Al}^0}; t_{Cl^-} = 0.29 \frac{1 - 2x_{Al}^0}{1 - x_{Al}^0} \quad [IIa]$$

The solid lines shown in Fig. 1 were calculated from Model [IIa] and $t_{R^+} = 1.00$. It can be seen that this model provides a reasonable representation of the experimental data. Model [IIa] can be further reduced when it is considered that the anion fractions of $AlCl_4^-$ and Cl^- in basic melt are given by

$$x_{AlCl_4^-} = \frac{x_{Al}^0}{1 - x_{Al}^0} \quad [11]$$

$$x_{Cl^-} = \frac{1 - 2x_{Al}^0}{1 - x_{Al}^0} \quad [12]$$

This results in

$$t_{R^+} = 0.71; t_{AlCl_4^-} = 0.29x_{AlCl_4^-}; t_{Cl^-} = 0.29x_{Cl^-} \quad [IIb]$$

These results indicate that the mobilities of $AlCl_4^-$ and Cl^- are identical in basic melt within the precision of the experimental data. It should be noted that equal mobilities were also found for $AlCl_4^-$ and $Al_2Cl_7^-$ in acid melts (7). The equal mobilities of Cl^- , $AlCl_4^-$, and $Al_2Cl_7^-$ in the 1-methyl-3-ethylimidazolium chloroaluminate melt is surprising and of fundamental significance. This finding rules out a simple independent hopping mechanism which is dependent on the size of the anions, because a mechanism of this type would be expected to lead to mobilities in the following order $Cl^- > AlCl_4^- > Al_2Cl_7^-$.

A possible cause of the equal mobility phenomenon is ion-pair interactions. For example, strong ion-pair interactions between the organic cation and the more polarizing Cl^- ion in the basic melts may counteract the size advantage of this ion while the comparatively weaker ion-pair interactions between the cation and $AlCl_4^-$ may result in greater relative mobility for the latter. Ion-pair formation has also been proposed from proton NMR studies of cation-anion interactions in the $AlCl_3$ -MEIC melt (10, 11) and the related $AlCl_3$ -BPC system (12).

Another explanation for these results is strong coupling of the ion movements, i.e., a displacement of the cation is accompanied by a structural rearrangement of the anions in the other direction proportional to their concentrations. The movement of the anion may hence be considered a quasi-lattice movement accomplished by bridge and apical Cl^- exchange.

Film Formation and Current Oscillations in the Electrodeposition of Copper in Acidic Chloride Media

II. Mathematical Model

ABSTRACT

A mathematical model of the current oscillations observed in the potentiostatic electrodeposition of a Cu rotating disk electrode is described and analyzed. The model predicts the conditions under which a CuCl film of constant thickness exists on the Cu surface, along with the conditions under which the film thickness and current density will be oscillatory (in some cases periodic) functions of time. The theoretical predictions are in excellent qualitative agreement with experimental results.

The electrodeposition of copper, iron, and other metals in acidic media is known to give rise to anodic film formation and oscillatory behavior during polarization [(1-7) and references cited by Hedges (8, 9) and Wojtowicz (10)]. Our recent potentiostatic experiments with a Cu rotating disk electrode in aqueous HCl/NaCl electrolyte show that these current oscillations can be obtained over a wide range of potential, rotation rate, and chloride ion concentration (11).

Previous efforts to model oscillatory behavior in electrochemical systems under nominally steady (*e.g.*, potentiostatic or galvanostatic) conditions include Ref. (1, 2, 4, 5, 12, 13). These and other works have been reviewed by Cooper *et al.* (2) and Wojtowicz (10). As previously discussed [Ref. (10), pp. 65-66], most models have taken as given that oscillations occur, and have then presented differential equation models that exhibit oscillatory behavior. These mathematical models tend to be ordinary differential equations that are either linear and forced, or nonlinear. The forced linear systems are completely inadequate to the task of explaining why oscillations occur under galvanostatic or potentiostatic conditions, and the nonlinear systems have had little capability to distinguish between conditions for which oscillations do or do not occur.

We propose here a detailed mechanism for the formation and dissolution of a CuCl film at the Cu electrode surface, and construct a simple mathematical model in the form of a moving boundary problem, the solution of which predicts the steady film thickness and dissolution rate under potentiostatic conditions. The model includes the kinetic scheme considered in the previous paper (11), and accounts for the diffusion of Cl⁻ through the film to the electrode. A linear stability analysis shows that the unique steady solution of the nonlinear partial differential equation system is sometimes unstable, and that a time-dependent (and, under some conditions, periodic) solution of the moving boundary problem must also exist for certain values of the parameters. The portions of the parameter space in which the steady solution is unstable are compared to the portions in which current oscillations are observed experimentally.

Mechanism and Description of Model

We consider the one-electron process

*Electrochemical Society Active Members.

at the electrode followed by the elementary processes

and

If the reaction product is not removed fast enough, a porous film of CuCl forms at the electrode surface (1). If further reaction of the Cu electrode via reaction [1] is to occur, chloride ions (in the electrolyte) will have to diffuse through the CuCl film to the Cu-film interface. Reaction [2a] is much faster than the desorption step [2b], and [2a] and [2b] together constitute a mass transfer-limited nonelectrochemical process, while [3] is a kinetically limited electrochemical reaction that is important only at relatively high applied potentials, as shown by rotating ring-disk electrode experiments (14).

Mathematical Model

Our one-dimensional model focuses on the diffusion of Cl⁻ through the porous film from the aqueous electrolyte phase to the Cu electrode, as shown in Fig. 1. This process is governed by the diffusion equation

$$\frac{\partial C}{\partial t} = D_1 \frac{\partial^2 C}{\partial z^2}, \quad g(t) < z < h(t) \quad [4]$$

Fig. 1. One-dimensional idealization of the Cu rotating disk electrode and CuCl film.

where C is the Cl^- concentration in the film region bounded by $g(t)$ and $h(t)$. Here, D_f is the effective diffusivity of chloride ions in the porous CuCl film.

This simple model neglects all non-Fickian transport effects, assumes that the porosity, pore size distribution, and other properties of the film are uniform across its thickness, neglects the dependence of Cl^- diffusivity on porosity, neglects variations in the radial and azimuthal directions, assumes that both interfaces are planar and perpendicular to the axis of rotation, and assumes that reactions [1]-[3] occur only at the indicated interfaces and not within the film itself.

Equation [4] will be solved in the domain shown in Fig. 1; the moving locations of the Cu-film and film-electrolyte interfaces are indicated by $z = g(t)$ and $z = h(t)$, respectively. Film is produced by $z = g(t)$ by reaction [1] and is destroyed at $z = h(t)$ by reactions [2a, b] and [3]. These reactions are incorporated into the model as auxiliary conditions appended to [4].

As [4] is second order in the spatial coordinate z , two boundary conditions involving the Cl^- concentration and/or flux are needed: one at the Cu-film interface and the other at the film-electrolyte interface.

At the Cu-film interface, the Cl^- flux is related to the electrochemical reaction rate by the first boundary condition

$$D_f \frac{\partial C[g(t),t]}{\partial z} = k_1 C[g(t),t] \quad [5a]$$

where the electrochemical rate constant k_1 is that for the reaction [1] per unit area of exposed electrode.

At the film-electrolyte interface, the chloride ion concentration in the film at this boundary is assumed to be in equilibrium with its concentration C_∞ in the bulk electrolyte. This gives the second boundary condition

$$C[h(t),t] = k_H C_\infty \quad [5b]$$

where k_H is the solute distribution coefficient.

Since the two interfaces move as the Cu electrode and film dissolution processes proceed, the locations of the two interfaces, where [5a, b] are to be applied, are not known in advance but must be determined as part of the solution procedure. These two additional unknowns require two additional equations, which are obtained by performing Cu balances across the Cu-film interface

$$-\frac{\rho_{\text{Cu}}}{M_{\text{Cu}}} \frac{dg(t)}{dt} = k_1 C[g(t),t] \quad [5c]$$

and across the film itself

$$\begin{aligned} \frac{\rho_{\text{CuCl}}}{M_{\text{CuCl}}} (1 - \epsilon) \frac{d[h(t) - g(t)]}{dt} \\ = -\frac{\rho_{\text{Cu}}}{M_{\text{Cu}}} \frac{dg(t)}{dt} - [\alpha(\omega)C_\infty + k_3] \end{aligned} \quad [5d]$$

where ϵ is the void fraction of the porous film, ρ_{Cu} is the density of the Cu electrode, ρ_{CuCl} is the density of crystalline CuCl , M_{Cu} and M_{CuCl} are the molecular weights of Cu and CuCl , respectively, $\alpha(\omega)$ is the rate (depending on rotation rate ω) of the mass transfer-limited reaction [2a, b], and k_3 is the electrochemical rate constant for the film dissolution reaction [3], per unit area of film exposed to the external electrolyte phase.

The fact that the boundaries of the domain in which [4] is to be solved are moving is the reason partial differential equations of this type are known as moving boundary problems. The fact that the boundary conditions [5a, b] are to be applied at unknown locations which must be determined as part of the solution procedure, and that the rate at which the boundaries move is dependent on the solution of [4], as displayed in [5c, d], is what makes the problem [4]-[5a-d] nonlinear, and is the mathematical source of the steady solution's instability.

The functional forms of α , k_1 , and k_3 are given by

$$\alpha(\omega) \propto \omega^{1/2} \quad [6a]$$

and

$$k_i = k_{i0} \exp \left[\frac{n_i F E}{RT} \right] \quad i = 1, 3 \quad [6b]$$

where n_1 and n_3 are the numbers of electrons in [1] and [3].

Steady Film Solution

The solution of [4]-[5a-d] that corresponds to the existence of a "steady state" is steady only in the sense that the film thickness and reaction rate (and hence the current) do not vary with time. Such a steady solution corresponds to a film of constant thickness $\Delta_0 = h(t) - g(t)$ (see Fig. 1) as time increases. If u_0 denotes the constant speed at which the film moves toward the bulk Cu, then the galilean transformation (15)

$$\begin{aligned} t' &= t \\ z' &= z - u_0 t \end{aligned}$$

gives

$$\frac{\partial C}{\partial t} = \frac{\partial C}{\partial t'} \frac{dt'}{dt} + \frac{\partial C}{\partial z'} \frac{dz'}{dt} = \frac{\partial C}{\partial t'} - u_0 \frac{\partial C}{\partial z'}$$

and

$$\frac{\partial C}{\partial z} = \frac{\partial C}{\partial t'} \frac{dt'}{dz} + \frac{\partial C}{\partial z'} \frac{dz'}{dz} = \frac{\partial C}{\partial z'}$$

Under this transformation, [4]-[5a-d] become

$$\frac{\partial C}{\partial t'} - u_0 \frac{\partial C}{\partial z'} = D_f \frac{\partial^2 C}{\partial z'^2} \quad \theta'(t') < z < \Delta_0 + \Delta'(t') \quad [7]$$

$$D_f \frac{\partial C[\theta'(t'),t']}{\partial z'} = k_1 C[\theta'(t'),t'] \quad [8a]$$

$$-\gamma_{\text{Cu}} \left[\frac{d\theta'(t')}{dt'} - u_0 \right] = k_1 C[\theta'(t'),t'] \quad [8b]$$

$$\gamma_{\text{CuCl}}(1 - \epsilon) \frac{d\Delta'(t')}{dt'} = -\gamma_{\text{Cu}} \left[\frac{d\theta'(t')}{dt'} - u_0 \right] - [\alpha C_\infty + k_3] \quad [8c]$$

$$C[\Delta_0 + \Delta'(t'),t'] = C_\infty k_H \quad [8d]$$

where $\gamma_i = \rho_i/M_i$, and θ' and Δ' denote possible deviations from the steady values of the Cu-film and film-electrolyte interface locations, respectively.

For a solution that is steady in this frame, $\theta'(t') = \Delta'(t') = 0$, and the steady concentration profile $\bar{C}(z')$, film thickness Δ_0 , and dissolution rate u_0 satisfy

$$-u_0 \frac{d\bar{C}}{dz'} = D_f \frac{d^2 \bar{C}}{dz'^2} \quad 0 < z' < \Delta_0 \quad [9]$$

$$D_f \frac{d\bar{C}(0)}{dz'} = k_1 \bar{C}(0) \quad [9a]$$

$$\gamma_{\text{Cu}} u_0 = k_1 \bar{C}(0) \quad [9b]$$

$$0 = \gamma_{\text{Cu}} u_0 - [\alpha C_\infty + k_3] \quad [9c]$$

$$\bar{C}(\Delta_0) = C_\infty k_H \quad [9d]$$

Therefore, from [9]

$$\bar{C}(z') = a + b \exp(-u_0 z'/D_f) \quad [10]$$

Application of boundary condition [9c] yields the dissolution rate

$$u_0 = \frac{\alpha C_\infty + k_3}{\gamma_{\text{Cu}}} \quad [11]$$

Substitution of [10] into [9a, b, d] gives

$$a = \gamma_{\text{Cu}} + \frac{\alpha C_{\infty} + k_3}{k_1} \text{ and } b = -\gamma_{\text{Cu}}$$

and

$$\Delta_0 = \frac{D_f \gamma_{\text{Cu}}}{\alpha C_{\infty} + k_3} \ln \frac{\gamma_{\text{Cu}} k_1}{C_{\infty}(\alpha - k_1 k_{\text{H}}) + k_1 \gamma_{\text{Cu}} + k_3} \quad [12]$$

From this, it follows that there is no film if

$$\alpha(\omega) \cong (k_1 k_{\text{H}} - k_3 / C_{\infty})$$

so that for any combination of potential and $[\text{Cl}^-]$, the model predicts that the film can be eliminated by making the rotation rate ω , and hence the mass transfer coefficient α , sufficiently large.

Finally, since the coefficients a and b in [10] are uniquely determined, there is only one one-dimensional solution for which the film thickness Δ_0 , dissolution rate u_0 , and concentration distribution $\bar{C}(z')$ are steady in time.

Linear Stability Analysis of the Steady Film Solution

The stability of the steady solution [9]-[9a-9d] with respect to small disturbances to the concentration distribution, interface locations, and film thickness depends on whether small disturbances grow or decay in time. If every sufficiently small disturbance decays, then the steady solution is said to be linearly stable, whereas if some small disturbances grow, the steady solution is definitely unstable. Because of the restriction to small disturbances, these criteria are necessary for stability and sufficient for instability. The stability of the solution with respect to larger disturbances can be decided only by nonlinear methods.

Equations [7]-[8a-d] are recast in nondimensional form, taking the nominally steady film thickness Δ_0 as the length scale and defining the dimensionless variables

$$S = \frac{C}{C_{\infty}} \quad y = \frac{z'}{\Delta_0} \quad \tau = \frac{t' D_f}{\Delta_0^2}$$

$$\delta = \frac{\Delta'}{\Delta_0} \quad \chi = \frac{\theta'}{\Delta_0}$$

and dimensionless parameters

$$\beta = \frac{\alpha C_{\infty} + k_3}{k_1 C_{\infty}} \quad \Gamma = \frac{C_{\infty}}{\gamma_{\text{Cu}}} \quad \phi = \frac{\gamma_{\text{CuCl}}(1 - \epsilon)}{\gamma_{\text{Cu}}}$$

where β is a measure of the ratio of the film dissolution rate to the film formation rate, Γ is a dimensionless chloride ion concentration, and ϕ is the ratio of the film density to the density of Cu. This choice of dimensionless parameters is not unique, but has several important advantages. One of the dimensionless parameters (ϕ) depends on none of the operating variables (ω , E , C_{∞}), another (Γ) depends only on C_{∞} , and two of the operating variables (ω and E) appear only in one dimensionless parameter (β). Finally, as shown later, this nondimensionalization, which does not involve k_{H} , enables one to compute all of the results (for arbitrary k_{H}) by using $k_{\text{H}} = 1$, followed by a simple transformation. Substitution into [7]-[8a-d] yields

$$\frac{\partial S}{\partial \tau} - p\beta\Gamma \frac{\partial S}{\partial y} = \frac{\partial^2 S}{\partial y^2} \quad \chi(\tau) < y < 1 + \delta(\tau) \quad [13]$$

$$\frac{\partial S[\chi(\tau), \tau]}{\partial y} = pS[\chi(\tau), \tau] \quad [14a]$$

$$\frac{d\chi(\tau)}{d\tau} - p\beta\Gamma = -p\Gamma S[\chi(\tau), \tau] \quad [14b]$$

$$\phi \frac{d\delta(\tau)}{d\tau} = -\frac{d\chi(\tau)}{d\tau} \quad [14c]$$

$$S[1 + \delta(\tau), \tau] = k_{\text{H}} \quad [14d]$$

where the dimensionless film thickness is

$$p = \frac{\Delta_0 k_1}{D_f} \quad [15a]$$

and

$$\Delta_0 = \frac{D_f}{k_1 \beta \Gamma} \ln \frac{1}{\Gamma(\beta - k_{\text{H}}) + 1} \quad [15b]$$

A steady film solution can exist only if

$$0 < \Gamma(\beta - k_{\text{H}}) + 1 < 1 \quad [16]$$

The steady dissolution rate can be written as $u_0 = k_1 \beta \Gamma$.

By superimposing disturbances (primed quantities) on the nominally steady solution

$$S(y, \tau) = \bar{S}(y) + S'(y, \tau)$$

$$\chi(\tau) = 0 + \chi'(\tau)$$

$$\delta(\tau) = 0 + \delta'(\tau)$$

Substituting these representations into [13]-[14a-14d] and retaining only terms that are linear in the disturbance quantities gives the linear perturbation equations

$$\frac{\partial S'}{\partial \tau} - p\beta\Gamma \frac{\partial S'}{\partial y} = \frac{\partial^2 S'}{\partial y^2} \quad 0 < y < 1 \quad [17]$$

$$\frac{\partial S'(0, \tau)}{\partial y} + \chi'(\tau) \frac{d^2 \bar{S}(0)}{dy^2} = p \left[S'(0, \tau) + \chi'(\tau) \frac{d\bar{S}(0)}{dy} \right] \quad [18a]$$

$$\frac{d\chi'(\tau)}{d\tau} = -p\Gamma \left[S'(0, \tau) + \chi'(\tau) \frac{d\bar{S}(0)}{dy} \right] \quad [18b]$$

$$\phi \frac{d\delta'(\tau)}{d\tau} = -\frac{d\chi'(\tau)}{d\tau} \quad [18c]$$

$$S'(1, \tau) + \delta'(\tau) \frac{d\bar{S}(1)}{dy} = 0 \quad [18d]$$

where the nondimensional steady solution is

$$\bar{S}(y) = \frac{\bar{C}(z)}{C_{\infty}} = \beta + [1 - \exp(-p\beta\Gamma y)]/\Gamma$$

In the boundary conditions [18a, b, d], linearization results in the concentration and flux being evaluated at the nominal interface locations $y = 0, 1$.

Substitution of the expression for $\bar{S}(y)$ into [17]-[18a-d] yields a second set of linear perturbation equations

$$\frac{\partial S'}{\partial \tau} - p\beta\Gamma \frac{\partial S'}{\partial y} = \frac{\partial^2 S'}{\partial y^2} \quad 0 < y < 1 \quad [19]$$

$$\frac{\partial S'(0, \tau)}{\partial y} - p^2 \beta^2 \Gamma \chi'(\tau) = p[S'(0, \tau) + p\beta\chi'(\tau)] \quad [20a]$$

$$\frac{d\chi'(\tau)}{d\tau} = -p\Gamma[S'(0, \tau) + p\beta\chi'(\tau)] \quad [20b]$$

$$\phi \frac{d\delta'(\tau)}{d\tau} = -\frac{d\chi'(\tau)}{d\tau} \quad [20c]$$

$$S'(1, \tau) + \delta'(\tau) p\beta \exp(-p\beta\Gamma) = 0 \quad [20d]$$

involving only the previously defined dimensionless parameters. The distribution coefficient k_{H} appears in these equations (only) through p , as defined in [15a, b].

The steady solution $(S, \chi, \delta) = (\bar{S}, 0, 0)$ of [13]-[14a-d] will be linearly stable if every solution (S', χ', δ')

$$S'(y, \tau) = e^{\lambda \tau} [A_1 e^{\sigma_+ y} + A_2 e^{\sigma_- y}] \quad [21a]$$

$$\chi'(\tau) = A_3 e^{\lambda \tau} \quad [21b]$$

$$\delta'(\tau) = A_4 e^{\lambda \tau} \quad [21c]$$

of [19]-[20a-d] decays in time. That is, every temporal eigenvalue λ must lie in the left half plane. Here, σ_+ and σ_- are the two solutions

$$\sigma_{\pm} = \frac{-p\beta\Gamma \pm [p^2\beta^2\Gamma^2 + 4\lambda]^{1/2}}{2}$$

or

$$\sigma^2 + p\beta\Gamma\sigma - \lambda = 0$$

Substitution of [21a-c] into [19]-[20a-d] yields four linear equations in the unknowns $A_1, A_2, A_3,$ and A_4 . In order for the system of linear equations to have a solution, it is necessary for the determinant of the coefficient matrix to vanish, from which it follows that

$$e^{-s(1+4\eta)^{1/2}} = \phi \{ \xi \eta (r_- e^{s\tau_+} - r_+ e^{s\tau_-}) + e^{s\tau_+}(1 - \eta + r_-) - e^{s\tau_-}(1 - \eta + r_+) \} \quad [22]$$

where

$$\xi = \beta\Gamma \quad \eta = \frac{\lambda}{p^2\xi^2} \quad s = p\xi$$

and

$$r_{\pm} = \frac{-1 \pm (1 + 4\eta)^{1/2}}{2}$$

For a stable situation, all of the temporal eigenvalues must lie in the left half plane. For an unstable situation, one or more temporal eigenvalues lie in the right half plane. Thus, marginal stability corresponds to the situation where one or more eigenvalues lie on the imaginary axis, and all others are in the left half plane.

Rather than computing the denumerable infinity of solutions of [22] and deciding whether or not any of them lie in the right half plane, the D-decomposition method of Neimark (16) will be used to directly compute points on the stability boundary. The stability boundary is the locus of points that separates regions in which the steady solution [10]-[12] is stable from regions in which the steady solution is unstable. The technique actually employed is a variation of Neimark's method that has been developed to deal with problems in which the parameterized variables appear nonlinearly and implicitly, rather than in the linear fashion discussed by Neimark.

By setting $\eta = 0, r_+ = 0, r_- = 1,$ and from [22], $e^{-s} = -\phi e^{-s}$. From this, it follows that $\phi = -1$, which is not meaningful, so $\eta = 0$ is not possible and instability does not arise as a result of a temporal eigenvalue crossing into the right half plane along the real axis (as shown in Fig. 2a).

Fig. 2.(a) Instability arising as a single real eigenvalue crosses into the right half plane. (b) Instability arising as a pair of complex eigenvalues cross into the right half plane (Hopf bifurcation).

The remaining possibility is that one or more complex conjugate pairs of temporal eigenvalues cross the imaginary axis as shown in Fig. 2b [a Hopf bifurcation (17)], in which case it can be shown that the steady states lying on the unstable side of and close to the stability boundary are unstable with respect to time-periodic disturbances.

Equation [22] is rewritten as

$$f_1(s, \eta) = \phi [f_2(s, \eta)\xi + f_3(s, \eta)] \quad [23]$$

where

$$f_1(s, \eta) = e^{-s(1+4\eta)^{1/2}}$$

$$f_2(s, \eta) = \eta(r_- e^{s\tau_+} - r_+ e^{s\tau_-})$$

and

$$f_3(s, \eta) = e^{s\tau_+}(1 - \eta + r_-) - e^{s\tau_-}(1 - \eta + r_+)$$

are functions of the real variable s and the complex variable $\eta = i\Omega_0$.

Separating $f_1, f_2,$ and f_3 into real and imaginary parts, [23] can be written as two real equations

$$f_{1r} = \phi(f_{2r}\xi + f_{3r}) \quad [24a]$$

and

$$f_{1i} = \phi(f_{2i}\xi + f_{3i}) \quad [24b]$$

in the two real variables s and Ω_0 .

Therefore

$$\xi = \frac{f_{1i}f_{3r} - f_{1r}f_{3i}}{f_{2i}f_{1r} - f_{1i}f_{2r}} \quad [25]$$

and

$$\phi = \frac{f_{1r}}{f_{2r}\xi + f_{3r}} \quad [26]$$

Equations [25] and [26] can be used to find the stability boundary, for fixed ϕ , in the following manner.

After fixing ϕ , a value of Ω_0 is chosen. An initial guess is made of s , and ξ and ϕ are computed from [25] and [26]. Then s is iteratively adjusted until the desired value of ϕ is obtained.

Equations [15a] and [15b] the definitions of ξ and β give the relations

$$\Gamma = \frac{1 + \xi - e^{-s}}{k_H}$$

and

$$\beta = \xi/\Gamma$$

Therefore, once a value of s that gives the desired ϕ is obtained, Γ and β can be computed directly.

By a suitable change of variables, [19]-[20a-d] can be transformed into a form that depends only on p and the product $\beta\Gamma$. Since k_H appears only through p , it is possible to compute points on the stability boundary (for fixed ϕ) by first setting $k_H = 1$ and then expressing the results in the form shown in Fig. 3(a)-(g), where k_H appears only in the definition of the horizontal and vertical axes. Both p and $\beta\Gamma$ are invariant under the change of variables (β, Γ, k_H) \rightarrow ($\beta/k_H, \Gamma k_H, 1$).

Each point ($\beta/k_H, \Gamma k_H$) computed this way is a point on the stability boundary, and if the above process is repeated for different Ω_0 , the stability boundaries shown in Fig. 3(a)-(g) are obtained.

Results and Discussion

The results presented in Fig. 3(a)-(g) are described below and related to our experimental work (11), as well as to the instability mechanism proposed therein.

When a steady solution $(\bar{S}(y), 0, 0)$ of [13]-[14a-d] exists, it is unique, as shown in the section on steady film solution. It is well known that when a system such as [13]-

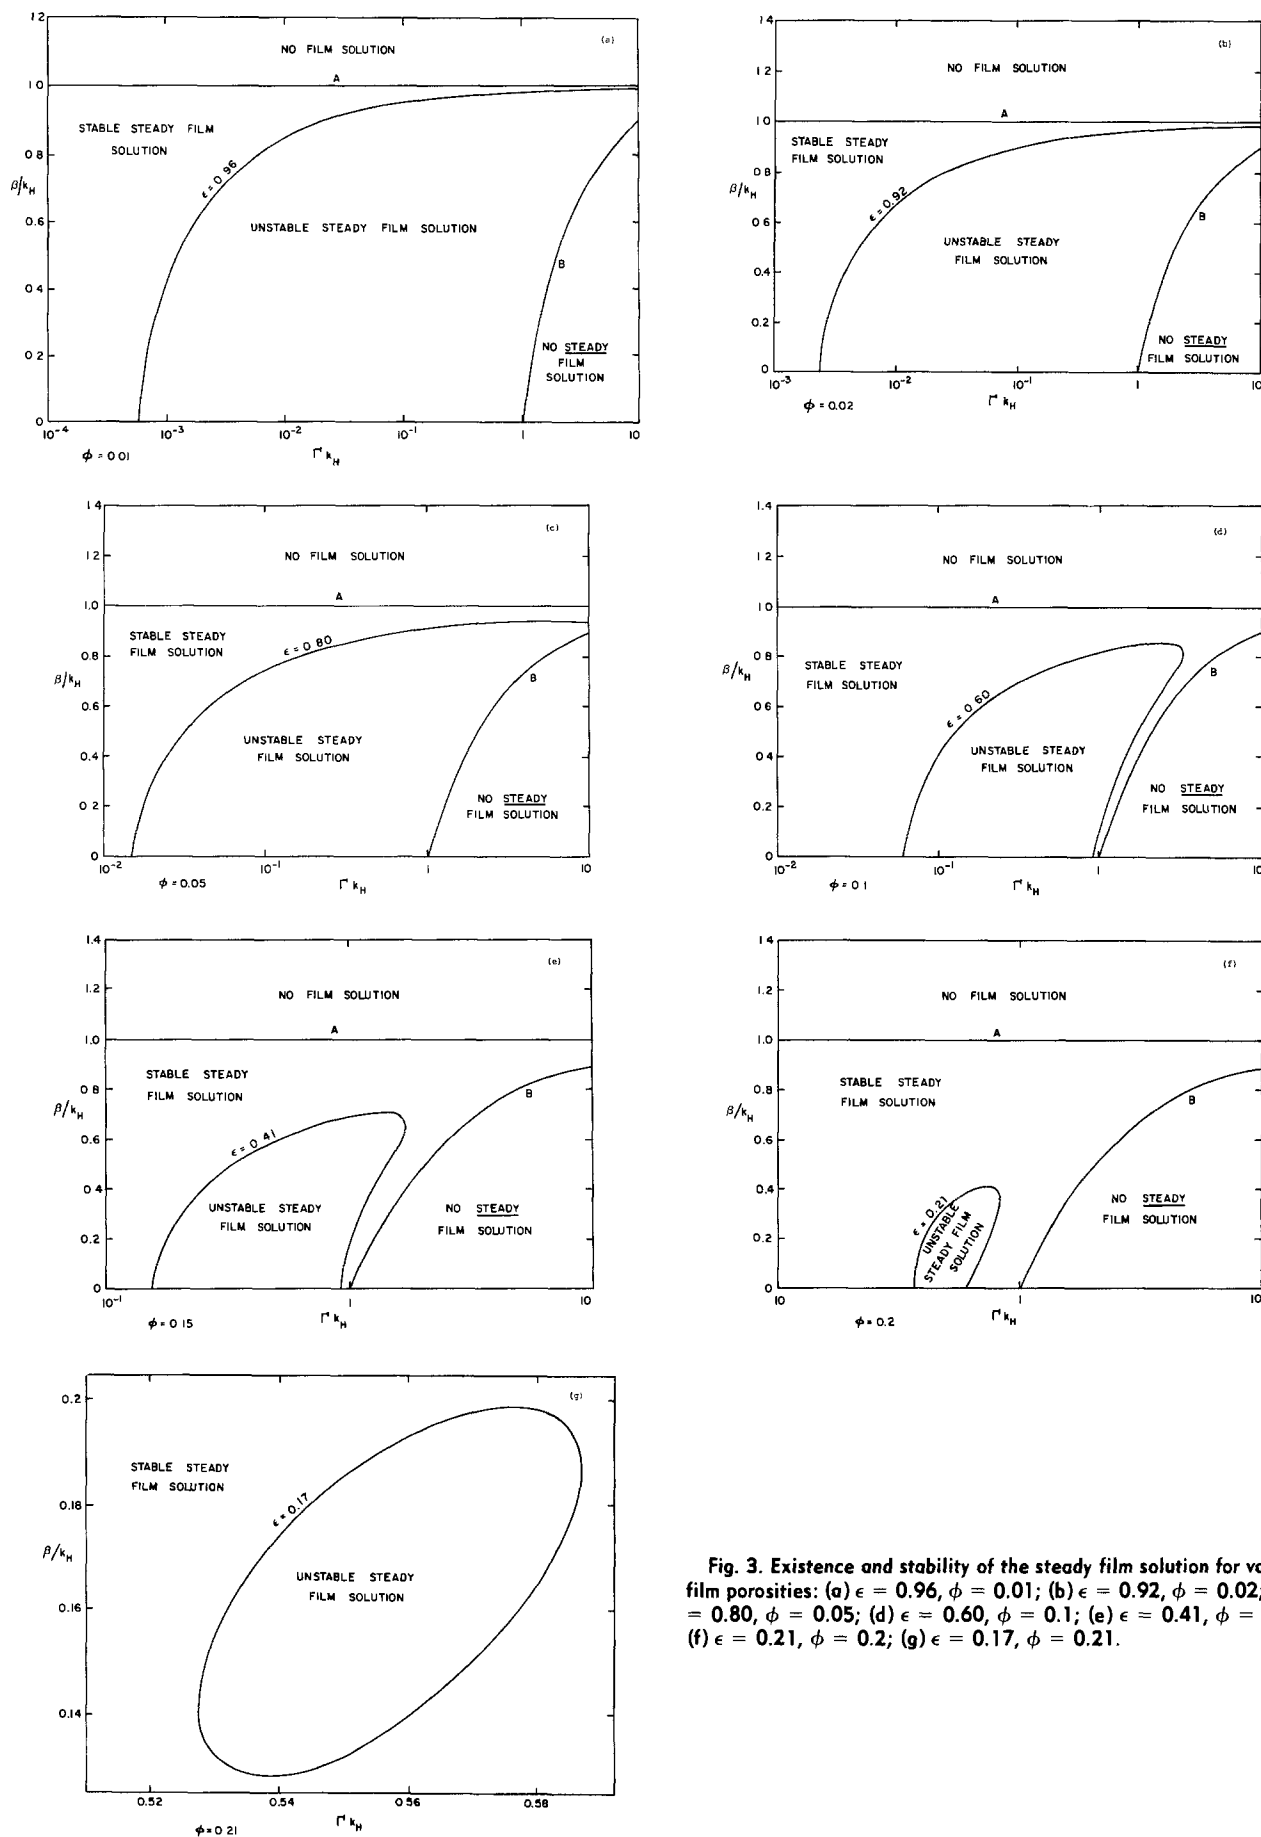

Fig. 3. Existence and stability of the steady film solution for various film porosities: (a) $\epsilon = 0.96$, $\phi = 0.01$; (b) $\epsilon = 0.92$, $\phi = 0.02$; (c) $\epsilon = 0.80$, $\phi = 0.05$; (d) $\epsilon = 0.60$, $\phi = 0.1$; (e) $\epsilon = 0.41$, $\phi = 0.15$; (f) $\epsilon = 0.21$, $\phi = 0.2$; (g) $\epsilon = 0.17$, $\phi = 0.21$.

[14a-d] has a unique steady solution that is also unstable, the full nonlinear equations must also admit at least one time-dependent solution. [For a discussion, see pp. 82-84 of Ref. (18)]. On the basis of Hopf's theorem (17), it is

known that if $(\Gamma k_H, \beta/k_H)$ is sufficiently close to the stability boundary, then the time-dependent solution is periodic for points $(\Gamma k_H, \beta/k_H)$ in the unstable region, and that the frequency and small amplitude approach Ω_0 and zero,

respectively, as $(\Gamma k_H, \beta/k_H)$ approaches the stability boundary. (Here Ω_0 is the magnitude of the imaginary parts of the two temporal eigenvalues that cross the imaginary axis in Fig. 2b as the stability boundary is traversed.)

Based on what is known about the dynamical behavior of systems like [13]-[14a-d], it is likely that as one moves farther into the unstable region the small amplitude time-periodic solution will eventually become unstable itself and will be replaced by a temporally more complicated solution. Whether the new solution will also be periodic (typically with a longer period), or whether it will be almost periodic or temporally chaotic, is a question that cannot be answered by our linear stability analysis. It is likely, however, that in the unstable region the only bounded solutions are in some sense oscillatory. "Oscillations" and "oscillatory" behavior in the unstable region are discussed below without any intent to further categorize the temporal behavior.

Above the horizontal line labeled A at $\beta = k_H$, no steady solution exists, as seen by inspection of [15]. Therefore, the steady film solution cannot be unstable, and no oscillations are predicted by our model. In fact, our model predicts that a "clean" electrode surface with no film will occur for $\beta > k_H$. Similarly, it can be seen from [16] that a solution with constant positive film thickness does not exist for $\Gamma > 1/(k_H - \beta)$ and, hence, to the right of and below the curve labeled B, our model predicts that there is no steady film solution. In this second region, the film forms faster than it can be dissolved, and no steady balance is possible. This is confirmed by Fig. 4, which shows contours of constant dimensionless film thickness p in the $(\Gamma k_H - \beta/k_H)$ plane. As curve B is approached, the steady (time-independent) film thickness increases without bound, as does the time $\tau_{0.99}$ required to achieve, say, 99% of the ultimate dimensionless steady film thickness p . As curve B is crossed, a steady film thickness is not approached asymptotically in time, and the film thickness apparently grows temporally without limit.

For each ϕ shown, the steady film solution exists and is linearly stable for values of Γk_H and β/k_H above and to the left of the indicated stability boundary but lying below the horizontal line $\beta = k_H$. In the region lying below and to the right of each stability boundary (and to the left of and above curve B), the steady film solution exists but is unstable, and oscillatory behavior is predicted.

For each ϕ shown, the appropriate value of the void fraction ϵ , based on $\rho_{Cu} = 8.96 \text{ g-cm}^{-3}$ and $\rho_{CuCl} = 3.53 \text{ g-cm}^{-3}$, is indicated. Since our experiments (11) do not provide any direct information as to the values of ϵ and k_H encountered experimentally, numerical results are presented for a range of ϵ , as shown in Fig. 3(a)-(g). Results for any value of k_H are included in each of Fig. 3(a)-(g).

Before considering the physical interpretation of these results in terms of the operating parameters (rotation rate ω , chloride ion concentration C_∞ , and potential E), it should be noted that the rate of the electrochemical film

dissolution reaction [3] depends more strongly on potential than does the rate of the electrochemical film formation reaction [1].

Thus, β/k_H is a monotonically increasing function of the rotation rate ω , and Γk_H is independent of ω , so that increasing (decreasing) ω will result simply in moving up (down) in the $\Gamma k_H - \beta/k_H$ plane. On the other hand, β/k_H is a monotonically decreasing function of C_∞ , while Γk_H increases monotonically with increasing C_∞ . Thus, increasing C_∞ results in moving down and to the right in the $\Gamma k_H - \beta/k_H$ plane, whereas an increase in C_∞ corresponds to a movement up and to the left in the $\Gamma k_H - \beta/k_H$ plane.

The dimensionless chloride ion concentration Γ is independent of potential, whereas β varies nonmonotonically with E . At low E , the nonelectrochemical film dissolution reaction [2a, b] proceeds at its potential-independent rate, whereas the rates of the Cu electrode reaction [1] and electrochemical film dissolution reaction [3] are very slow. Therefore, at low E , β is very large. At very high potentials, the electrochemical film dissolution (forming Cu^{2+}) is the fastest, and β is also very large for high E . At some intermediate potential, β reaches a minimum. Therefore, increasing E may result in going up or down in the $(\Gamma k_H - \beta/k_H)$ plane depending on the actual potential.

Beginning in the unstable region of the $\beta/k_H - \Gamma k_H$ plane (*i.e.*, the region in which the steady film solution exists and is unstable) for a given ϕ , large enough increases in the rotation rate result in vertical upward movement into the stable film region [*i.e.*, the region in which the steady film solution exists and is (linearly) stable]. Further increases in ω will eventually result in moving across the $\beta = k_H$ line and into the region in which no film exists (the filmless region). This behavior is exactly that which is shown in Fig. 2 and 4 of Ref. (11).

Decreasing the chloride ion concentration results in a move up and to the left in Fig. 3. Lowering the chloride ion concentration sufficiently (*i.e.*, reducing Γk_H to a small enough value) will result in movement far to the left of and outside of the unstable film region, into either the stable film region or the filmless region lying above curve A. In either case, the model predicts that there will be no current oscillations at sufficiently low chloride ion concentrations.

As inferred from Fig. 3(f) and (g), the present model predicts that the steady film solution (when it exists) is stable for all values of β/k_H and Γk_H if ϕ exceeds approximately 0.21, corresponding to a film void fraction of about 0.17. The existence of this "cutoff void fraction" has an explanation which is consistent with both the mathematical model of the present paper as well as with the instability mechanism proposed previously (11).

Neither the steady solution of [13]-[14a-d] nor the values of β/k_H and Γk_H for which the steady solution exists depend on ϕ , as shown in Fig. 4. The parameter ϕ (and hence the void fraction ϵ) do appear in the dynamic equations [13]-[14a-d], and hence in the linear stability analysis. In the full nonlinear equations, ϕ appears only in the boundary condition [14c], where it is the constant of proportionality that relates changes in the rate of Cu electrode dissolution to the rate of change in film thickness. In other words, if the rate of movement of the Cu-film interface ($d\chi/d\tau$) is increased by one dimensionless unit, then $1/\phi$ is the "amplification" factor that determines the magnitude of the increase in the actual film thickness ($1 + \delta - \chi$). Clearly, when the film is very porous and ϕ is very small, the dissolution of one unit of Cu electrode will be translated (by $1/\phi$) into a very large change in $(1 + \delta - \chi)$, according to [18c]. This in turn will result in a major increase in the time required for diffusional communication of information concerning the altered conditions (increased Cu electrode dissolution rate) at the Cu-film interface out to the film-electrolyte interface. According to the instability mechanism proposed previously (11), this increase in the time lag associated with diffusional communication across the suddenly thicker film will give rise to an "overshoot" type of instability. When ϵ is too small (and hence ϕ is large), $1/\phi$ will be too small, and

Fig. 4. Existence of the steady film solution and dimensionless thickness (p) of the steady film.

hence even relatively large disturbances to the Cu electrode dissolution rate will not be amplified by [18c] into large changes in the film thickness. Thus, large changes in the film thickness ($1 + \delta - \chi$) are not possible, major changes in the time lag associated with diffusional communication of concentration information across the film do not occur, and the overshooting instability ("overstability") proposed previously (11) is not predicted for large enough values of ϕ .

Thus, the progressive diminution, with increasing ϕ , of the unstable film region in Fig. 3(a)-(g) [note the logarithmic nature of the abscissa in Fig. 3(a)-(f) and the linear abscissa in Fig. 3(g)] is in complete agreement with the instability mechanism advanced previously (11) and is rooted in the physicochemical model described in the section on mechanism and description of the model.

We are presently unable to provide an explanation for the detailed shapes of the stability boundaries in Fig. 3(d)-(g) ($0.1 < \phi < 0.21$), other than to say that the instability mechanism and physicochemical model both predict that the steady film solution will be stabilized by increasing ϕ , and that stabilization of the steady solution implies a reduction in the size of the unstable region, which is exactly what the results show. As for the correctness of the specific value of ϕ above which instability is impossible, or the detailed shape of the unstable region for smaller values of ϕ , little can be said. However, the general features of the stability boundaries are believed to be correct, as they are in excellent qualitative agreement with our experimental results (11), as discussed above.

As for possible improvements to the model, two are suggested. The first would be to construct a model for which the porosity is treated in a more sophisticated manner. Such a model could consist of a dual porosity film with a chloride ion diffusivity D_f that is dependent on the porosity. A second improvement would be to account for the fact that both of the film dissolution reactions occur not only at the film-electrolyte interface, but also within the pores of the film itself, and that the rates per unit volume will be proportional to the surface area per unit volume, which will in turn be related to the local porosity.

Conclusions

The general form of the model considered here may be useful in the analysis of the oscillations observed in other electrodisolution processes involving the formation of anodic films. The detailed kinetics of the film formation and dissolution will, of course, be different, but the formulation of the problem as a diffusion equation (or a system of diffusion equations) with moving boundaries, followed by the investigation of the existence and stability of the steady solution(s), seems to be a promising approach to the study of these oscillations.

LIST OF SYMBOLS

A_1, A_2, A_3, A_4 constants in Eq. [21a]-[21c]

a	$\gamma_{\text{Cu}} + \frac{\alpha C_{\infty} + k_3}{k_1}$
b	$-\gamma_{\text{Cu}}$
$\frac{C_{\infty}}{C(z')}$	chloride ion concentration in electrolyte steady concentration distribution in moving film reference frame
D_f	diffusion coefficient of Cl^- in film
f_1, f_2, f_3	$e^{-s(1+4\eta)^{1/2}} \eta (r_+ e^{sr_+} - r_- e^{sr_-}), e^{sr_+}(1-\eta+r_-) - e^{sr_-}(1-\eta+r_+)$
f_{1r}, f_{2r}, f_{3r}	real part of f_1, f_2, f_3
f_{1i}, f_{2i}, f_{3i}	imaginary part of f_1, f_2, f_3
$g(t)$	position of Cu-film interface

$h(t)$	position of film-electrolyte interface
k_H	solute distribution coefficient
k_1, k_3	electrochemical rate constants of reactions [1], [3]
$M_{\text{Cu}}, M_{\text{CuCl}}$	molecular weights of Cu, CuCl
p	dimensionless constant film thickness
τ_{\pm}	$[-1 \pm (1+4\eta)^{1/2}]/2$
s	$p\xi$
$\frac{S(y, \tau)}{\bar{S}(y)}$	dimensionless concentration variable dimensionless steady-state concentration in moving film reference frame
$S'(y, \tau)$	deviation of $S(y, \tau)$ from $\bar{S}(y)$
t	time variable
t'	time variable in moving film reference frame
u_0	steady speed of film movement
y	dimensionless position variable
z	position variable
z'	position variable in moving film reference frame

Greek Letters

$\alpha(\omega)$	rate of reaction [2a, b]
β	dimensionless constant ratio of film formation and dissolution rates
$\gamma_{\text{Cu}}, \gamma_{\text{CuCl}}$	$\rho_{\text{Cu}}/M_{\text{Cu}}$ and $\rho_{\text{CuCl}}/M_{\text{CuCl}}$
Γ	dimensionless constant chloride ion concentration
$\delta(\tau)$	dimensionless deviation of film thickness
$\delta'(\tau)$	deviation of $\delta(\tau)$ from zero
$\Delta'(t')$	deviation of film-electrolyte interface location, in moving film reference frame, from nominally steady value
Δ_0	steady film thickness
ϵ	void fraction of porous film
η	$\lambda p^{-2}\xi^{-2}$
$\theta'(t')$	deviation of Cu-film interface, in moving film reference frame, from nominally steady value
λ	temporal eigenvalue in stability analysis
ξ	$\beta\Gamma$
$\rho_{\text{Cu}}, \rho_{\text{CuCl}}$	densities of crystalline Cu, CuCl
σ_{\pm}	$\frac{-p\beta\Gamma \pm [p^2\beta^2\Gamma^2 + 4\lambda]^{1/2}}{2}$
τ	dimensionless time variable
ϕ	ratio of film and Cu densities
$\chi(\tau)$	dimensionless deviation of Cu-film interface location
$\chi'(\tau)$	deviation of $\chi(\tau)$ from zero
ω	rotation rate
Ω_0	$-i\eta$

Proton Conductivity in Mixed Solvents

Z. Stein and E. Gileadi*

Department of Chemistry, Tel Aviv University, Ramat Aviv, Israel

ABSTRACT

The equivalent conductivity at infinite dilution of an inorganic acid (HClO_4) and its salt (LiClO_4) were compared in mixtures of water with two aprotic solvents (acetonitrile and tetrahydrofuran). The variation of the ratio of equivalent conductivities with solvent composition reflects directly the anomalous conductivity of H_3O^+ , all other factors such as the changes in viscosity and dielectric friction being automatically compensated. The anomalous conductivity of the proton is not observed until the concentration of water exceeds ca. 10 volume percent which corresponds to a mole fraction of 0.24. When plotted as a function of the mole fraction of water, the ratio of equivalent conductivities at infinite dilution is almost the same for mixtures of water with AN and with THF, indicating that the aprotic solvent acts only as a diluent, increasing the distance between water molecules and destroying short-range order which may exist in water. When the same ratio is plotted as a function of the average distance between water molecules, it is found that hopping can no longer occur to a significant extent when the average distance is more than 2.2 times its value in pure water. A similar effect was observed recently in studies of the conductivity of Br^- in liquid bromine and its mixtures with nitrobenzene. The Walden product for the proton decreases significantly upon the addition of relatively small amounts of the aprotic solvent, and can decrease by a factor of two when the mole fraction of water decreases from unity to 2/3. Further studies in mixed solvents could shed light on the mechanism of proton conductivity in protic solvents and possibly on the structure of water.

The anomalous high conductivity of acids and bases has been observed over 150 years ago. According to Grotthuss, this is due to the hopping of protons from H_3O^+ ions to water molecules or from water molecules to OH^- ions. The field was reviewed by Conway (1) in 1964, by Erdey-Gruz and Lengyel (2) in 1977, and recently by Lengyel and Conway (3) in 1983. At 25°C, the equivalent conductivity at infinite dilution λ° is 349.8 for H_3O^+ and 198.1 for OH^- . This should be compared to values of 37.5, 50.1, and 73.6 for Li^+ , Na^+ , and K^+ , respectively, and to 76.4 and 68.1 for Cl^- and ClO_4^- , respectively, all in $\text{cm}^2\text{-}\Omega^{-1}\text{-eq}^{-1}$.

A smaller but still distinct effect is observed for D_3O^+ in D_2O (242.4 vs. 41.5 for Na^+ in D_2O) and in simple alcohols such as methanol and ethanol (4-6). The anomalous conductivity of H_3O^+ decreases with increasing temperature and with increasing concentration of a supporting electrolyte (7, 8). A decrease of the transference number for the positive ion with increasing concentration of HCl (which is tantamount to a decrease in the anomalous conductivity) was also observed (9). On the other hand, anomalously high conductivity was found in concentrated sulfuric (10) and phosphoric acids (11). This was associated with hopping of the proton from a protonated acid H_3SO_4^+ to a neutral acid molecule or from an acid molecule H_3PO_4 to a nearby ion H_2PO_4^- .

The anomalous conductivity was measured in mixed solvents, mostly in water and an alcohol or in water and dioxane (12-15). The product of viscosity and equivalent conductivity (the Walden product) should be independent of the composition of the solvent if simple movement of the ions through the viscous fluid is assumed. For acids, the Walden product is found to increase first with the addition of alcohols to water, then decrease below the value for pure water and increase again in pure or almost pure alcohol. The maximum observed can be associated with the maximum in viscosity of the mixture, as will be discussed below. The increase in the Walden product in pure or almost pure alcohol is due to hopping which can occur in this solvent.

The hopping of the proton has been associated in one way or another to the formation of hydrogen bonds in all the solvents discussed above. While this may be the case, it has been shown recently by Rubinstein *et al.* (16) that an anomalous conductivity occurs also in solutions of Br^- in pure bromine or in mixture of bromine and nitrobenzene.

In the present work, the anomalous conductivity of H_3O^+ in mixtures of acetonitrile and water was determined

by comparing the equivalent conductivities of LiClO_4 and HClO_4 at infinite dilution. Because acetonitrile is an aprotic solvent, its only effect should be to break up the regular structure of water and to increase the average distance between water molecules to the point that hopping can no longer occur. In pure water, the ratio of equivalent conductivities at infinite dilution is $417.9/105.6 = 3.96$, while in pure acetonitrile it is very close to unity. Thus, a moderate accuracy in the determination of the equivalent conductivities is sufficient to show the effect of solvent composition on the equivalent conductivities and particularly on their ratio.

Acetonitrile (AN) and water are completely miscible but do not form an ideal solution. This is shown by a nonzero volume of mixing and by the fact that the viscosity of mixtures of these two solvents is not a linear function of composition (17). For this reason, measurements were also taken in mixture of tetrahydrofuran (THF) and water for comparison. Although this solvent is less suitable because of its relatively low dielectric constant, the results were qualitatively the same as in AN/water mixtures, showing no major specific effect of the aprotic solvent.

Experimental

Solutions were made with deionized water which was distilled and had a conductivity of $1.0 \mu\text{mho}\text{-cm}^{-1}$ or less. Acetonitrile (Fluka AR) was distilled over molecular sieves (4Å), and the fraction boiling between 80.5° and 81.5°C was collected. Tetrahydrofuran (Merck AR) was treated with LiAlH_4 to remove peroxides and was distilled. The fraction boiling between 66.5° and 67.5°C was collected. Other chemicals, used as obtained, were LiClO_4 (Buchs SG, AR), HClO_4 70% (Merck AR), KCl (Merck AR), and LiAlH_4 (Fluka, pure). Note that the acid employed contains ca. 2.4 molecules of water per molecule of acid. Thus, even in pure AN or THF, there is always enough water to form H_3O^+ .

Conductivities were measured with a Radiometer CDM 2e conductometer which operates at 3000 Hz for conductivities above $500 \mu\text{mho}$ and at 70 Hz for lower conductivities. The accuracy of measurement was $\pm 1\%$. The cell has two flat Pt electrodes, situated about 0.3 cm apart. Temperatures were controlled to $\pm 0.1^\circ\text{C}$ above room temperature (Haake Type E52 thermostat) and to $\pm 0.2^\circ$ below room temperature (Neslab Type RTE-3 cooling thermostat). Since the conductivity changed with solvent composition by 50% for the salt and as much as 120% for the acid (*cf.* Fig. 1), this level of accuracy was considered

Fig. 1. The equivalent conductivities at infinite dilution (a) and their ratio (b) as a function of the v/o of water in AN. \circ : LiClO_4 , \blacksquare : HClO_4 . $C = 0.93 \text{ mM}$.

sufficient to bring out the significant features of the mixed solvents employed in this work.

Transference numbers were determined by the Hittorf method in a conventional, three-compartment cell, employing platinized Pt electrodes. The constant current was applied with an Elron Type CHG-1 galvanostat and measured with a four-digit multimeter (Data Precision). The change in acid concentration in the anode and cathode compartments was determined by following the changes in conductivity with two auxiliary electrodes in each compartment, following proper calibration. A typical experiment lasted 2-4h at a current of 1.5-3.0 mA. The data points shown in Fig. 7 are average values of four to eight experiments at each composition of the solvent.

The apparent energies of activation were determined by measuring the equivalent conductivities of 0.1 mM solutions of HClO_4 or LiClO_4 in different solvent mixtures at 5°C intervals between 5° and 50°C .

Results

The equivalent conductivity in AN/ H_2O mixtures.—The equivalent conductivity of solutions of LiClO_4 and HClO_4 in the range of concentrations of 1.0-5.0 mM was measured as a function of solvent composition in AN/water mixtures. In Fig. 1a, the values for the acid Λ°_A and for the salt Λ°_S , evaluated by plotting Λ vs. $c^{1/2}$ and extrapolating to zero, are shown as a function of the volume percent (v/o) of water in the solvent mixture. Λ°_S decreases initially from its value in pure AN as the amount of water is increased and remains constant above 60 v/o water. For HClO_4 , we find Λ°_A decreasing initially, but above ca. 10 v/o water it increases steadily to its maximum value in pure water. In Fig. 1b, the ratio $\Lambda^\circ_A/\Lambda^\circ_S$ is plotted in the same way. Note that up to about 10 v/o water (5.5M) the ratio is close to unity and independent of the amount of water present.

A plot of the viscosity η of the solvent mixture vs. composition is shown in Fig. 2 (17). For the salt, the product

Fig. 2. The viscosity of mixtures of AN/ H_2O and THF/ H_2O as a function of the v/o of water.

$\eta\Lambda^\circ_S$ (the Walden product) should be constant to the extent that the effective Stokes radius of hydration is constant. In Fig. 3, we note a moderate increase in the Walden product for the salt in passing from pure AN to pure water, implying a 35% decrease in effective Stokes radii of the ions. For the acid, the Walden product increases by a factor of six; this is associated with the hopping mechanism of the proton in pure water or in solvent mixtures rich in water.

The equivalent conductivity in THF/ H_2O mixtures.—Since it is evident that mixtures of water and

Fig. 3. The Walden product for LiClO_4 (\bullet) and for HClO_4 (\blacksquare) at infinite dilution as a function of composition in AN/water mixtures.

acetonitrile do not form ideal solutions, it is important to repeat the measurements presented above, replacing AN with another aprotic solvent which is completely miscible with water to identify features which may be due to specific interactions between water and acetonitrile. Tetrahydrofuran (THF) was chosen for this purpose. In the range of 10-100 v/o water, the equivalent conductivity was measured for concentrations of 1.0-6.0 mM and values at infinite dilution were obtained as before, by plotting Λ_A or Λ_S vs. $c^{1/2}$ and extrapolating back to zero. However, due to the relatively low value of the dielectric constant of THF (7.58), this procedure is inadequate when the concentration of water is below 10 v/o. For the range of 2-20 v/o water, the concentrations of salt and acid were 0.030-0.3 mM, respectively, and the equivalent conductivity at infinite dilution was determined employing the methods developed by Fuoss and Kraus (18, 19) for strong electrolytes in solvents of low polarity. The equivalent conductivities at infinite dilution in this range of solvent composition are shown in Fig. 4a, and the ratio Λ_A^0/Λ_S^0 is plotted in Fig. 4b. The ratio of equivalent conductivities is close to unity up to 10 v/o water as in AN/H₂O mixtures. The plots of equivalent conductivities at infinite dilution and their ratio over the full range of water composition are shown in Fig. 5.

The viscosity is plotted as a function of the composition of the solvent (20) in Fig. 2. The high maximum observed shows that this solvent mixture deviates significantly from ideality. The peak in the ratio of conductivities at infinite dilution shown in Fig. 5 is caused by the peak in viscosity, as will be discussed below. The Walden product at infinite dilution is plotted as a function of composition of the solvent in Fig. 6. For the salt, the Walden product increases by a factor of 2.5 as the water content changes from 4 to 100 v/o, while for the acid it increases by a factor of over nine in the same region.

Fig. 5. Same as Fig. 4 for the whole range of solvent composition.

Measurement of transference numbers.—The transference number of ClO₄⁻ in HClO₄ was determined in 0.01M HClO₄ as a function of the composition of the solvent, in mixtures of AN/H₂O, by the Hittorf method. The results are shown in Fig. 7. The transference number for ClO₄⁻ declines from 0.56 ± 0.03 in 10% water to 0.16 ± 0.005 in pure water. Since the transference number does not change significantly with concentration of the electrolyte below 0.01M, one can use the data in Fig. 7 to calculate the equivalent conductivities of the ions ($\lambda_{\text{H}_3\text{O}^+}^0$ and $\lambda_{\text{ClO}_4^-}^0$). From $\lambda_{\text{ClO}_4^-}^0$ and Λ_S^0 , the value for $\lambda_{\text{Li}^+}^0$ is derived. The equivalent conductivities at infinite dilution for the three ions used in the above measurements, in mix-

Fig. 7. Transference numbers for H_3O^+ and for ClO_4^- in 0.01M $HClO_4$ as a function of composition in AN/water mixtures.

tures of AN and water, are shown in Fig. 8. The corresponding Walden products ($\eta\lambda^\circ$) are shown in Fig. 9. Although measurements of Hittorf numbers were not conducted at concentrations of water below 10 v/o (because of the relatively high solution resistance), it is safe to assume, based on the data in Fig. 1, that the values of the Walden products shown in Fig. 9 are essentially constant from 0 to 10 v/o water.

The apparent energy of activation as a function of solvent composition.—The equivalent conductivity was measured as a function of temperature between 5° and 50°C at 5° intervals. All measurements were taken in 1.0 mM solutions of acid or salt in different mixtures of AN and water from 2 v/o to pure water. The apparent energies of activation were calculated from plots of $\log(\Lambda/T)$ vs. $(1/T)$. The change in molar concentration resulting from the change of volume of the solvent mixture with temperature was taken into account. The difference in energies of activa-

Fig. 9. The Walden product for the single ionic species at infinite dilution as a function of composition in AN/water mixtures.

tion of the salt and the acid was obtained by plotting $\log(\Lambda_A/\Lambda_S)$ vs. $(1/T)$. In this way, the effect of the change of viscosity with temperature is eliminated and the difference ($d\Delta H^\ddagger$) reflects the difference in the mechanism of conductivity of Li^+ and H_3O^+ ions, as a function of water content of the solvent. The results of these measurements are summarized in Fig. 10.

Discussion

The ratio of equivalent conductivities.—The anomalous conductivity of H_3O^+ can be represented by plotting the ratio of equivalent conductivities of an acid and its salt, or the difference between these quantities, as a function of the water content of the solvent. In the present work, the former representation was chosen. By considering the ratio of equivalent conductivities, changes of viscosity or any other factor affecting the hydrodynamic movement of ions through the solvent mixture are systematically can-

Fig. 10. The apparent heat of activation ΔH^\ddagger for conductance as a function of composition in AN/water mixtures. \circ : $LiClO_4$, \blacksquare : $HClO_4$, \triangle : Difference.

celed, and the departure of the ratio Λ_A^0/Λ_S^0 from a constant value (close to unity in an aprotic solvent) can be attributed in full to the Grotthuss-type hopping mechanism of conduction of the proton. Any artifact arising from incomplete dissociation of the electrolyte is eliminated by determining the equivalent conductivities at infinite dilution. In mixtures of H_2O/THF , the determination of equivalent conductivity at infinite dilution is less accurate at low concentrations of water due to the low dielectric constant of the medium. However, it turns out that in this region Λ_A is close to Λ_S and their ratio is quite independent of concentration below 1.0 mM at a constant composition of the solvent.

The most striking feature in Fig. 1 is that the ratio of equivalent conductivities is close to unity and is essentially independent of the concentration of water up to ca. 10 v/o, while Λ_A^0 and Λ_S^0 both vary significantly in the same region. It can be concluded that in this region the H_3O^+ ion behaves just like the Li^+ ion, moving through the solvent mixture in a simple hydrodynamic mode. This is rather surprising in view of the high molar concentration of water (at 10 v/o the mole fraction of water is ca. 0.24). If the anomalous proton conductivity is due to short-range order in liquid water, it could be argued that such structure is completely absent when water molecules constitute one out of four solvent molecules or less. Even when two out of three solvent molecules are water (40 v/o), the ratio of equivalent conductivities is only two (compared to four in pure water) showing that the anomalous conductivity is very sensitive to the structure of water.

The Walden product plotted in Fig. 3 as a function of solvent composition shows that even $LiClO_4$ does not follow the simple Walden rule and the product $\eta\Lambda_S^0$ increases from 60 to 92 $cm^2\text{-eq}^{-1}\text{-}\Omega^{-1}\text{-cP}$ from pure acetonitrile to pure water. This observation shows the advantage of considering the ratio of equivalent conductivities rather than their absolute value.

The effect of the aprotic solvent.—Replacing acetonitrile (AN) with another aprotic solvent, tetrahydrofuran (THF), should have no effect if this solvent acts only as a "spacer" diluting the water, increasing the average distance between water molecules and thus destroying the short-range order which exists in pure water. Comparing Fig. 3 to Fig. 6, we note that for the salt the Walden product is almost the same in the two solvent mixtures. For the acid, the difference is large. This difference is also evident when the ratios of equivalent conductivities in Fig. 1b and 5b are compared. Such comparison ignores, however, the differences of density and molecular weight between AN and THF. A better comparison between the effect of the two aprotic solvents is made when the ratios of equivalent conductivities are plotted as a function of the mole fraction of water, as shown in Fig. 11. Up to a mole frac-

Fig. 11. The ratio of equivalent conductivities at infinite dilution as a function of the mole fraction of water in AN (Δ) and in THF (\bullet).

tion of 0.85, the two aprotic solvents have the same effect, within experimental error.

An alternative way of presenting the same data is to plot the ratio Λ_A^0/Λ_S^0 as a function of the average distance between water molecules, based on the molar concentration of water in the solvent, ignoring the properties of the other component. This is shown in Fig. 12. It is of interest to note that when the average distance between water molecules exceeds about 2.2 times its value in pure water hopping of the proton no longer occurs. In an earlier study by Rubinstein *et al.* (16), the conductivity of Br^- in liquid bromine and its mixtures with nitrobenzene were determined. A very similar phenomenon was observed. A hopping mechanism of conductivity was found for the Br^- ion in bromine-rich solvent. This mechanism became inoperative when the concentration of bromine was below ca. 2M, which corresponds to an average distance 2.2 times that in pure bromine, as in the case of AN/ H_2O and THF/ H_2O mixture.

The effect of viscosity.—The maxima observed in THF/ H_2O mixtures (Fig. 5b, 6, 11, 12) is associated with the large maximum in viscosity of this mixture, shown in Fig. 2. For the salt, the conductivity is inversely proportional to the viscosity, hence the Walden product (*cf.* Fig. 6) is not significantly dependent on the viscosity. If proton hopping depends on the structure of water and does not require movement of ionic species through the viscous fluid, it should not decrease significantly with increasing viscosity. It is indeed seen that Λ_A^0 increases steadily with water content (Fig. 5a), with no significant change in its rate of increase around 60 v/o water, where the viscosity reaches its maximum. Thus, multiplying Λ_A^0 by η constitutes an "overcorrection" and the resulting maximum in the upper curve in Fig. 6 reflects mainly the maximum in viscosity. The same applies to the maxima in the plots of Λ_A^0/Λ_S^0 vs. solvent composition. In AN/ H_2O mixtures, the maximum in viscosity is rather small and its effect is obscured by the steady increase in Λ_A^0 with water content.

The above observations indicate that anomalous proton conductivity in THF/ H_2O mixtures occurs by a mechanism in which the rate-determining step is not dependent on the viscosity of the solvent. This would probably exclude rotation of a water molecule or of aggregates of water molecules as the rds.

Fig. 12. Same as Fig. 11, but plotted as a function of the average distance between water molecules (d), divided by the average distance (d_0) in pure water.

The equivalent conductivity of ions at infinite dilution in pure water as a function of temperature shows a similar effect. For Na^+ and K^+ , the Walden product increases by only a factor of 1.05 and 1.24, respectively, as the temperature is decreased from 100° to 0°C. For H_3O^+ the Walden product increases by a factor of 2.4 in the same temperature range. For the OH^- ion the increase is by a factor of 1.5. It was also observed that for Br^- in Br_2 (16) and for I^- in liquid iodine (21) the Walden product increases with decreasing temperature. It can be stated that a significant increase in the Walden product with increasing viscosity (be it as a result of a decrease in temperature in a pure solvent or as a result of a change in solvent composition in a mixture of solvents) is indicative of a non-stokesian mechanism of conductivity.

In a recent study of the conductivity of solution of Al_2Br_6 and KBr in aromatic hydrocarbons (22), the Walden product was found to increase with decreasing temperature in concentrated solutions, where a hopping mechanism of conductivity prevails (23, 24).

Transference numbers and the equivalent conductivities of single ions.—Employing the transference numbers found in HClO_4 (Fig. 7), we can proceed to calculate the equivalent conductivities of each of the ions at infinite dilution (Fig. 8) and the corresponding Walden products (Fig. 9). The tendency of the Walden product to level off for H_3O^+ at high concentrations of water is due to the maximum in the viscosity, as discussed above. For lithium, the Walden product increases from 24 $\text{cm}^2\text{-eq}^{-1}\text{-}\Omega^{-1}\text{-cP}$ in 10 v/o water to 30 $\text{cm}^2\text{-eq}^{-1}\text{-}\Omega^{-1}\text{-cP}$ in pure water, and for the perchlorate ion the change is from 36 to 58 $\text{cm}^2\text{-eq}^{-1}\text{-}\Omega^{-1}\text{-cP}$ in the same range of solvent composition. In pure AN, the Walden product for most inorganic ions is reported to be significantly lower than in pure water (25, 26). This can be attributed to a higher radius of solvation. The largest effect is observed for ions such as Cs^+ , Rb^+ , I^- , Br^- , ClO_4^- which have a solvation number close to zero in pure water. Due to the higher dipole moment of AN (3.97 vs. 1.84 for water), such ions may be expected to have a higher solvation number in AN than in water. The Walden products for ClO_4^- and for Li^+ observed here in 10 v/o water in AN are equal to those reported in pure AN (25, 26).

It should be noted that the above interpretation for the variation of the Walden products with composition, which is commonly used in the literature (25), is not entirely consistent with the results obtained in this work. Thus, comparison of Fig. 3 and 6 shows that the Walden product for the salt ($\eta\Lambda^0_s$) is essentially the same in AN/ H_2O and THF/ H_2O mixtures. This would seem to render any interpretation based on specific interactions of the ions with the aprotic solvent incomplete, in view of the significant differences between AN and THF.

The heat of activation for electrolytic conductivity.—The heats of activation for conductivity (at infinite dilution) are shown for the salt and for the acid in Fig. 10. At low water content the values for the acid and the salt are almost the same (the difference is about $0.5RT$ at room temperature). Since the energy of activation for the conductivity of the salt represents approximately that for the viscosity, it may be inferred from Fig. 10 that the Walden

product for the acid will increase with decreasing temperature in solvent mixtures as well as in pure water. The extent of this increase or the difference between the values of ΔH_s^\ddagger and ΔH_v^\ddagger is a good indication of the contribution of hopping to the mechanism of electrolytic conductivity of the acid in different solvent mixtures.

Application of a Modified Colloid Chemical Site Binding Model to Mott-Schottky Plots Determined at Oxidic Semiconductor/Electrolyte Systems

W. Smit

Laboratory of Electrochemistry, Group Colloid Chemistry, Eindhoven University of Technology, 5600 MB Eindhoven, The Netherlands

In their note on the interpretation of Mott-Schottky plots determined at semiconductor/electrolyte systems, De Gryse *et al.* (1) demonstrated theoretically that a linear relationship between C^{-2} and V can be found experimentally even when the inequalities

$$C_{sc} \ll C_H \quad [1]$$

$$|\phi_{sc}| \gg |\phi_H| \quad [2]$$

do not hold. Here, C represents the differential capacitance of the semiconductor/electrolyte system under circumstances where a depletion layer exists at the semiconductor surface and V represents the voltage applied to the semiconductor electrode and expressed with respect to a reference electrode. C_{sc} and C_H are the differential capacitances per square centimeter of the depletion layer of the semiconductor and of the Helmholtz layer at the semiconductor surface, respectively, ϕ_{sc} is the potential drop over the depletion layer, and ϕ_H the change in Helmholtz potential drop caused by the applied voltage.

The inequalities [1] and [2] will be satisfied when the doping level of the semiconductor is low. When this is the case, $C \approx C_{sc}$, then the Mott-Schottky relationship

$$C^{-2} = (2/\epsilon_0 \epsilon q N_D)(V - V_{FB} - kT/q) \quad [3]$$

can represent the C^{-2} vs. V data. Here V_{FB} is the flatband potential, and we consider an n-type semiconductor with donor density N_D .

In this note, we discuss, like De Gryse *et al.* (1), those cases where $N_D > 10^{19} \text{ cm}^{-3}$. We also assume absence of a redox system in the electrolyte solution. Such solutions are frequently indicated as "indifferent electrolyte" solutions. In their derivation of the equation for these conditions, De Gryse *et al.* assumed that ion adsorption on semiconductor electrodes like n-TiO₂ is absent, even at the high — from a colloid chemical point of view — electrolyte concentrations usually used [0.25M K₂SO₄ + buffer (2), 0.33M phosphate buffer (3, 4)].

We now direct our attention to some colloid chemical aspects of the oxide/electrolyte interface. For such systems, very large surface charge densities compared to the mercury or AgI surface are found accompanied by quite modest values of the electrokinetic potential (5). The very large surface charges, obtained from titration data, can be explained by the porous gel model (6) of the oxide-solution interface. This model, however, cannot be applied when such a gel layer is absent, as was proved for TiO₂ surfaces by Yates *et al.* (7) by tritium exchange studies. An alternative model for such cases is the site-dissociation site binding model (8-10) which involves a direct binding of counterions to the surface charges. This model compromises the notion of "indifferent electrolyte." Experimental evidence for the adsorption of sodium ions in the compact layer of vitreous silica and of α -Al₂O₃ single

crystals, in absence of a gel layer, was given by Smit *et al.* (11-13). The adsorption of anions in dependence on solution pH and adsorbate concentration was measured by the radiotracer method on TiO₂ electrode (14) and for Br⁻ ions on α -Al₂O₃ (12, 13).

In the site-dissociation site binding model, the following amphoteric ionization reactions of surface sites

are considered together, following Davis *et al.* (9), with the surface complex ionization reactions

Here, s refers to surface values, K⁺ is a cation, and A⁻ an anion. SO⁻-K⁺ is a neutralized SO⁻ site, and SOH₂⁺-A⁻ a neutralized SOH₂⁺ site. The surface charge density, as measured by titration, is given by

$$\sigma_o = F\{[\text{SOH}_2^+] + [\text{SOH}_2^+ \text{-A}^-] - [\text{SO}^-] - [\text{SO}^- \text{-K}^+]\} \quad [8]$$

The charge density of the adsorbed ions, which are located in the inner Helmholtz plane, is given by

$$\sigma_B = F\{[\text{SO}^- \text{-K}^+] - [\text{SOH}_2^+ \text{-A}^-]\} \quad [9]$$

In the original idealized planar surface model (9), the inner C_1 and outer C_2 capacitances of the compact layer and the diffuse layer capacitance are put in series. Values of around 20 $\mu\text{F}\cdot\text{cm}^{-2}$ for C_2 are generally found to be satisfactory for the site-dissociation site binding model. Since C_1 is much larger than C_2 , the apparent compact layer capacitance C_H will also be around 20 $\mu\text{F}\cdot\text{cm}^{-2}$. However, from capacity measurements on semiconductor electrodes an unexpectedly low value of the Helmholtz layer capacitance (3-6 $\mu\text{F}\cdot\text{cm}^{-2}$) was found as a common feature (15, 16). Dewald (16) questioned the use of a C_H value taken from work with the mercury electrode, for ZnO.

In our laboratory, we performed coulometric pulse relaxation experiments on oxidized Ti/electrolyte interfaces [see Van Leeuwen (17, 18) for a discussion of the method]. The potential transients can be transformed to complex impedance values $Z(j\omega)$. These impedance data are fitted to equivalent circuits containing frequency independent elements [aperiodic equivalent circuit (19, 20)] by analysis with complex nonlinear least squares (21, 22).

In the experiments on oxidized Ti, where more than 80% of the relaxation signal came from the electrolyte side of the interface, we found at least six relaxation times, among them a diffusional relaxation in the electrolyte. The equivalent circuits to be considered are rather complicated. We have not yet finished the evaluation of our data, but two facts have already been established.

First, the equivalent circuit on the electrolyte side is composed of at least two impedances in parallel. This is in agreement with circuits proposed by Gerischer (23) and Bousse and Bergveld (24), and with the aperiodic equivalent circuit for adsorption of electroinactive species with slow adsorption step and negligible charge transfer, as deduced theoretically by Pilla (20). Second, the value of the Helmholtz layer capacitance is much lower than $20 \mu\text{F}\cdot\text{cm}^{-2}$.

We proposed a modification of the site binding model (25) in order to reconcile this model with these experimental facts. When this model is applied with σ_0 and electrokinetic potential data obtained on $\alpha\text{-Al}_2\text{O}_3$ single crystals (13), lower (outer) compact layer capacitances are indeed required to fit the data.

We now return to the Mott-Schottky plots. In the following sections, we propose our modification of the treatment by De Gryse *et al.* (1). This modification is based on our modified site binding model.

We consider a surface area of 1 cm^2 . The total surface charge density σ_0 is given by Eq. [8]. Two kinds of charged surface sites can be recognized: (i) sites SOH_2^+ and SO^- , which can influence the charge in the diffuse layer directly, and (ii) sites $\text{SOH}_2^+\text{-A}^-$ and $\text{SO}^-\text{-K}^+$, in which charges are shielded by the adsorbed ions. This also holds for the charges in the semiconductor.

For calculation purposes, we think the shielded sites moved to one part of the surface and the other sites, mainly SOH_2^+ , SO^- , and SOH , to the remaining part. In this way, we obtain two parallel capacitance branches. The fraction of the total surface occupied by incomplected sites is given by

$$f \approx ([\text{SOH}_2^+] + [\text{SOH}] + [\text{SO}^-])/N_s \quad [10]$$

where N_s = surface site density ($\text{mol}\cdot\text{cm}^{-2}$).

The capacitance between the surface area f of the uncomplexed sites and the outer Helmholtz plane is the real Helmholtz capacitance C_H ($\mu\text{F}/f\cdot\text{cm}^2$ of the 1 cm^2 considered).

We introduce the following assumptions: (i) the surface potential at the semiconductor surface is the same everywhere. Thus, the potential drop ϕ_{sc} over the depletion layer is also the same everywhere; (ii) the potential drop in the Gouy layer can be neglected; (iii) the variation of C_H as a function of the change of the potential drop ϕ_H over this capacitance is negligible. (Experimentally, we found some potential dependency, see Fig. 2); and (iv) the fraction f does not depend on the variation of the applied potential.

The last assumption is supported by the work of Kazarinov *et al.* (14), who found that the potential variation has virtually no effect on the amount of adsorbed anions.

The applied voltage (with respect to the flatband situation) can follow two pathways: over the complexed sites and over the uncomplexed sites. We follow the latter path

$$V - V_{FB} = \phi_{sc} + \phi_H \quad [11]$$

In the case considered, one has $V > V_{FB}$, $\phi_{sc} > 0$, and $\phi_H > 0$. In the Mott-Schottky approximation [$\exp(-q\phi_{sc}/kT) \ll 1$], the space charge q_{sc} in the semiconductor is given by

$$q_{sc} = (2\epsilon\epsilon_0 N_D)^{1/2} (\phi_{sc} - kT/q)^{1/2} \quad [12]$$

per square centimeter.

However, behind the surface area f , this charge is $f q_{sc}$. We take the charge in surface states $q_{ss,f}$ in the surface area f and the charge in the uncomplexed sites $\sigma_{o,f}$ together

$$Q_{ss} = q_{ss,f} + \sigma_{o,f} \quad [13]$$

Since we have now based the charges and the capacitance on the same surface area f , we can write

$$\phi_H = (f q_{sc} + Q_{ss})/C_H \quad [14]$$

From Eq. [13] and [14], the following relationship between ϕ_H and ϕ_{sc} follows

Fig. 1. Fit of Eq. [22] to C_{sc}^{-2} vs. applied potential data. Oxidized and activated Ti; $A = 4 \text{ cm}^2$; in 0.01M (crosses) and 0.25M (squares) KNO_3 at pH 3.0.

$$\phi_H = 2fa(\phi_{sc} - kT/q)^{1/2} + Q_{ss}/C_H \quad [15]$$

where

$$a = (\epsilon\epsilon_0 q N_D / 2C_H^2) \quad [16]$$

Inserting Eq. [15] into Eq. [11] and subtracting kT/q from both sides, the following quadratic equation in $(\phi_{sc} - kT/q)^{1/2}$ is obtained

$$V - V_{FB} - kT/q = \phi_{sc} - kT/q + 2fa(\phi_{sc} - kT/q)^{1/2} + Q_{ss}/C_H \quad [17]$$

Hence

$$(\phi_{sc} - kT/q)^{1/2} = -fa + [(fa)^2 + (V - V_{FB} - kT/q - Q_{ss}/C_H)]^{1/2} \quad [18]$$

Since ϕ_{sc} is assumed constant over the whole surface of the semiconductor, the ϕ_{sc} calculated with Eq. [18] can be inserted in the Mott-Schottky relationship

$$C_{sc}^{-2} = (2/\epsilon\epsilon_0 q N_D A^2) (\phi_{sc} - kT/q) \quad [19]$$

Fig. 2. Helmholtz capacitance vs. applied potential plots obtained by pulse relaxation experiments on oxidized and activated Ti. $A = 4 \text{ cm}^2$, in 0.01M (crosses) and 0.25M (squares; two runs) KNO_3 at pH 3.0.

Table I. Parameters and estimated uncertainties found by least squares fitting of Eq. [22] to C_{sc} data

^a Refers to fraction f of 1 cm^2 surface area.

where we introduced the surface area A of the electrode exposed to the solution.

Introduction of Eq. [18] in Eq. [19] yields

$$C_{sc}^{-2} = (2/\epsilon_0 \epsilon q N_D A^2) \{ (V - V_{FB} - kT/q - Q_{ss}^0/C_H + 2(af)^2 - 2af[(af)^2 + (V - V_{FB} - kT/q - Q_{ss}^0/C_H)]^{1/2} \} \quad [20]$$

Q_{sc} can be dependent on ϕ_{sc} . In order to keep the calculations manageable, we introduced a linear dependency of Q_{ss} on ϕ_{sc}

$$Q_{ss} = Q_{ss}^0 + P Q_{ss}^0 (\phi_{sc} - kT/q) \quad [21]$$

With this Q_{ss} introduced in Eq. [14], we arrive at

$$C_{sc}^{-2} = (2/\epsilon_0 \epsilon q N_D A^2 B^2) \{ B(V - V_{FB} - kT/q - Q_{ss}^0/C_H) + 2(af)^2 - 2af[(af)^2 + B(V - V_{FB} - kT/q - Q_{ss}^0/C_H)]^{1/2} \} \quad [22]$$

where

$$B = (C_H + P Q_{ss}^0)/C_H$$

For our experiments with the pulse relaxation method, it is not necessary to combine C_{sc} with a compact layer capacitance into a capacitance C , as done by De Gryse *et al.* (1). Two of the relaxations can be attributed to the semiconductor side. We turned the two RC circuits in series (Voigt circuit) into the Maxwell circuit as used by Tomkiewicz (3, 4). One of the two capacitances shows Mott-Schottky behavior and is C_{sc} ; the other capacitance is presumably C_{ss} . From our circuit analysis, we also find a value for C_H as used in the equations above.

However, we fitted Eq. [22] with V_{FB} , C_H , N_D , f , Q_{ss}^0 , and P as parameters to the experimental data by a nonlinear least squares computer program, using a Marquardt algorithm (26). Then we can compare the predicted C_H values with the experimental ones.

We shall now apply Eq. [22] to C_{sc} vs. $V(\text{SCE})$ data obtained on oxidized Ti [30 min in O_2 at 700°C , followed by activation at 600°C for 30 min in 1:7 $\text{H}_2\text{O}/\text{N}_2$ (27)] in KNO_3 solutions at pH 3. Figure 1 shows C_{sc}^{-2} vs. $V(\text{SCE})$ plots. The potential region accessible to measurement was limited by breakdown. The C_{sc} data are moderately accurate because less than 20% of the relaxation signal in these experiments originated from the semiconductor side of the interface. This is related to the low C_H capacitance and the high donor concentration in the semiconducting oxide layer. The values of C_H as found by analysis of the pulse relaxation data are shown in Fig. 2. Full details of these experiments will be presented elsewhere. In Fig. 1, fits of Eq. [22] to the experimental data are shown. The exposed surface area $A = 4 \text{ cm}^2$ and $\epsilon = 100$ was used in the calculations. The final values of the parameters found by the least squares fitting procedure, starting from two different sets of initial values, are shown in Table I, together with the uncertainty of these values. In the correlation matrix, the correlation coefficient between the V_{FB} and Q_{ss}^0 parameters is highest (> 0.6). With these parameters, ϕ_{sc} can be solved from Eq. [17] or Eq. [18]. In Fig. 3, the C_{sc}^{-2} data are plotted vs. these ϕ_{sc} values. The extrapolated linear least squares lines intersect the horizontal axis at $\phi_{sc} = kT/q$, conform Eq. [19]. The differences in slope are related to the uncertainties in N_D . According to these calculations, less than 10% of the

voltage applied to the electrode is found back as a change in ϕ_{sc} .

From Fig. 2, one can see that C_H varies from 1.17 to $1.03 \mu\text{F}\cdot\text{cm}^{-2}$ ($A = 4 \text{ cm}^2$) in the applied voltage interval. The mean value, $1.1 \mu\text{F}\cdot\text{cm}^{-2}$, is within the estimated uncertainties equal to the C_H values of Table I. Thus, the model is with respect to C_H consistent with the experimental facts. As the parameter f concerns, it is a support for the model to see that the values found by the curve-fitting are indeed fractions, although with the uncertainties unity can be exceeded. These uncertainties, unfortunately, make it impossible to draw conclusions about the extent of adsorption from these parameters. We attribute the shift of V_{FB} to more negative potentials on an increase of the KNO_3 concentration to a higher adsorption of NO_3^- ions. Approximately the same shift was found in KCl solutions at pH 3. This increase of adsorption of electrolyte ions with increasing bulk electrolyte concentration can also be derived from the circuit elements on the electrolyte side of the total equivalent circuit of the interface.

The Q_{ss} values calculated with Eq. [21] are negative, setting aside their uncertainties. From our zeta potential measurements on the same oxidized Ti plates, we found that pH 3 is below the isoelectric point (28). On isolator oxides like $\alpha\text{-Al}_2\text{O}_3$, $\sigma_{o,f}$ is equal to minus the charge in the diffuse layer and is of the order of $\mu\text{C}\cdot\text{cm}^{-2}$. Below the isoelectric point, $\sigma_{o,f}$ is positive for such oxides. If this remains true for the TiO_2 electrodes, then the negative Q_{ss} values would point to negatively charged surface states.

Conclusions

The model used is an extension of the treatment by De Gryse *et al.* (1). The model predicts from the C_{sc}^{-2} vs. applied voltage curves C_H values which are consistent with experimentally found C_H values. The model is based on a

Fig. 3. Mott-Schottky plots of the C_{sc}^{-2} data from Fig. 1 vs. ϕ_{sc} calculated with Eq. [17] and parameter values of Table I.

modified colloid chemical site-dissociation site binding model. This modification was introduced to reconcile the original model with experimental facts found at semiconductor/electrolyte electrodes: low values of the Helmholtz layer capacitance and at least two parallel impedance branches on the electrolyte side.

Economic Optimization of Electrolyzers by an Extension of Ibl's Formula

Thomas Z. Fahidy*

Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1

The well-known optimization formula of Ibl (1)

$$i^* = \left(\frac{a}{bR} \right)^{1/2} \quad [1]$$

is based on the assumptions that (i) a linear relationship between cell potential V and current density i exists

$$V = V_1 + Ri \quad [2]$$

(ii) the variable investment cost and time are linearly related

$$K = \alpha At \quad [3]$$

and (iii) the current efficiency (at the cathode) is independent of current density. In an electrorefining process where V_1 may be negligible, the sum of the investment cost and the cost of electricity may be written, in consequence, as

$$C_T \cong At(Rbi^2 + \alpha)$$

or, removing time as an explicit variable

$$C_T = \frac{zFm}{e_c M} \left[\frac{\alpha}{i} + Rbi \right] \quad [4]$$

If $e_c = \text{const.}$, Eq. [1] immediately follows by setting $dC_T/di = 0$.

The third condition, independence of current efficiency of current density, is obeyed only in a limited number of electrodeposition processes; in fact, e_c may be a distinct function of i , all other parameters being constant (e.g., in the electrowinning of zinc). Under such circumstances, Eq. [1] either underestimates or overestimates the true optimum, as illustrated in Fig. 1. The

optimum current density is found by differentiating Eq. [4] and setting it to zero

$$\frac{dC_T}{di} = \left(\frac{\partial C_T}{\partial i} \right)_{e_c} + \left(\frac{\partial C_T}{\partial e_c} \right)_i \frac{de_c}{di} = 0 \quad [5]$$

Upon rearrangement, the expression

$$\left(-\frac{\alpha}{i^2} + Rb \right) e_c = \left(\frac{\alpha}{i} + Rbi \right) \frac{de_c}{di}$$

is obtained; the final form of the optimization formula

$$\frac{d \log e_c}{d \log i} \equiv \mathbf{F}(i) = \frac{Rbi^2 - \alpha}{Rbi^2 + \alpha} \quad [6]$$

replaces Eq. [1]. As shown in Fig. 1, the intersection of the experimental $d \log e_c/d \log i$ curve with $\mathbf{F}(i)$ yields the optimal current density. The procedure is simpler if the current efficiency is a power function of the current density of the form $e_c = A/i^m$ or $e_c = Ai^m$ where A and m are empirical parameters. Then, $d \log e_c/d \log i$ equals $-m$ or $+m$, respectively, and defines a straight line parallel to the i -axis. In fact, the analytical solution

$$i^* = \left(\frac{1 \pm m}{1 \mp m} \right)^{1/2} \left(\frac{\alpha}{bR} \right)^{1/2} \quad [7]$$

in such cases obviates a graphical solution.

To illustrate the magnitude of error introduced by using Eq. [1] instead of Eq. [6] when the latter is warranted, consider a copper electrorefining process where the mild dependence

$$e_c = 95.94 - 6.25i\% \quad [8]$$

$$[i]: \text{kA/m}^2$$

*Electrochemical Society Active Member.

Fig. 1. Optimal current density via Ibl's formula (Eq. [1]) and its extension (Eq. [6]).

is assumed to be empirically known. Using Ibl's estimates (1) of $a = 6.29 \times 10^{-3} \text{ \$/m}^2\text{-h}$, $b = 1 \times 10^{-5} \text{ \$/Wh}$, and $R = 9 \times 10^{-4} \text{ \Omega-m}$, the expressions

$$d \log e_c / d \log i = -6.25i / (95.94 - 6.25i)$$

and

$$F(i) = (9i^2 - 6.29) / (9i^2 + 6.29)$$

are obtained. Then, a graphical construction yields $i^* \cong 792 \text{ A/m}^2$, which is 44 A/m^2 less than the estimate via Eq. [1]. If e_c is a sharper function of i , the error could be much larger. The extended Ibl formula is recommended for optimization problems where the $e_c(i)$ relationship cannot be ignored and the optimum is narrow, but more sophisticated optimization procedures (e.g., 2, 3) are not warranted.

Visible Absorption Spectra of Solid Thionine on an SnO_2 Substrate

T. I. Quickenden and I. R. Harrison

Department of Physical and Inorganic Chemistry, University of Western Australia, Nedlands, Western Australia 6009, Australia

J. M. Austin

Department of Chemistry, University of Canterbury, Christchurch, 1, New Zealand

Thionine-coated electrodes have received some attention (1-3) because of their possible use as converters of solar energy to electricity. Thionine has been electrochemically deposited on conducting electrodes held at static (1, 4) or cycled (2, 3) potentials. Unfortunately, little is known of the structure of the stable thionine layers deposited by these methods.

It has been suggested (2) that the layers consist of thionine molecules linked by carbon-nitrogen bonds; however, surprisingly little spectroscopic information is available to substantiate this suggestion. Albery *et al.* (1) have reported a broad absorption between 400 and 600 nm for layers deposited on SnO_2 at a fixed potential. This spectrum is largely unresolved, but it does indicate a general maximum between about 560 and 640 nm.

Thionine in aqueous solution absorbs with a relatively narrow peak centered at 600 nm with a shoulder absorption at 575 nm due to the presence of a labile dimer (5). It is clearly important to obtain more highly resolved absorption spectra for the electrochemically deposited thionine and to ascertain whether there are spectral differences between the layers deposited at static and cycled potentials. No absorption spectra have been previously reported for layers deposited by the latter method.

The purpose of the present paper was to obtain absorp-

tion spectra for both types of electrochemically deposited layers and to compare these with the spectra of solid thionine layers deposited by several different methods.

Materials and Methods

All reagents used in the present study were of analytical reagent grade, except for SbCl_5 , which was of reagent grade, ethanol, which was of spectroscopic quality (Ajax Chemicals, Spectrosil grade), and thionine, which was of biological grade (Gurr). The method of purification of the thionine and the purity checks carried out have been described previously (3). All solutions were prepared with water which had been redistilled once after distillation from alkaline permanganate. Argon gas was ICI Special Grade and contained less than 7 ppm of O_2 . Conducting SnO_2 electrodes were prepared by the method described previously (3).

Visible absorption spectra were determined with a Hewlett-Packard 8450A absorption spectrophotometer and fluorescence spectra were determined with a Perkin Elmer 650-40 fluorescence spectrophotometer. The cycled-potential deposition of thionine layers was carried out with the cyclic voltammetry equipment described previously (3), except that the working electrode comprised an $8 \times 5 \text{ cm}$ plate of conducting SnO_2 glass and the

counterelectrode was a polymethylmethacrylate plate of the same size coated with a thick layer of vacuum-deposited gold. The potential was cycled between 0.05 and 1.40V (NHE) during the deposition. A potential of 1.40V (NHE) was maintained for the static-potential depositions. Solutions for the electrochemical deposition of thionine contained $0.050 \text{ mol-dm}^{-3} \text{ H}_2\text{SO}_4$ and $6 \times 10^{-5} \text{ mol-dm}^{-3}$ thionine in water.

In order to enable the subtraction of the background absorbance of the uncoated SnO_2 plate, only half of the electrode was immersed in the deposition solution.

Absorption spectra were then measured at a minimum of five positions across the coated portion of the plate and at the same number of positions across the uncoated portion. The coated plates were washed in distilled water and dried in a vacuum desiccator before the spectra were measured.

Oxygen-free thionine depositions were carried out under an argon atmosphere inside a glove bag which was maintained under a positive pressure of argon during the deposition (ca. 12h). All solutions were thoroughly deoxygenated prior to use. Thionine was evaporated from aqueous solution in a polymethylmethacrylate "boat" constructed with an SnO_2 base. The evaporation process was carried out at 333 K inside the glove bag. Absorption measurements were also carried out in an argon atmosphere in these cases.

Results and Discussion

Figure 1 shows the progressive growth of the absorption spectrum of the SnO_2 electrode as thionine is deposited thereon by the cycled-potential method. Figure 2A shows the absorption spectra after 7h of deposition by the cycled-potential (curves 1-3 in Fig. 2A) and static-potential (curve 4 in Fig. 2A) methods. The differences between the spectra for the two modes of electrochemical deposition are not significant and are about the same order of magnitude as the reproducibility of the spectra.

The electrochemically deposited layers of thionine are compared with the layers of thionine deposited by evaporation of an aqueous thionine solution in Fig. 2C. The layers deposited by bulk evaporation did not differ significantly from layers obtained by spraying the electrode with an aqueous or ethanolic solution of thionine, and the spectra were not significantly different when the depositions were carried out in the absence of oxygen.

The electrochemically deposited layers in Fig. 2A mainly differ from the evaporated layers in the 490-500 nm region, where the electrochemical deposition has produced a prominent peak. Extensive leaching of the electrochemical layers with water, ethanol, dimethylene chloride, n-hexane, and toluene did not substantially reduce the peak at 495 nm, whereas the solid thionine peaks at longer wavelengths were largely removed after ethanol

Fig. 1. Absorption spectra showing the progressive growth of layers of solid thionine deposited on SnO_2 by the cycled-potential method. Deposition potential = 0.05-1.40V (NHE). Sweep rate = 100 mV-s^{-1} . Spectra were recorded after 20, 60, 120, 240, and 420 min of cycling (curves 1, 2, 3, 4, and 5 respectively). Each error bar represents the 50% confidence interval associated with the mean of five absorbances determined at different positions on the SnO_2 electrode.

Fig. 2. Region A: Absorption spectra of thionine electrochemically deposited on SnO_2 by the cycled-potential method (curves 1-3) and by the static-potential method (curve 4). Spectra were recorded after 420 min of deposition and have been normalized to the same absorbance at 495 nm. Region B: Absorption spectra of solid thionine deposited on SnO_2 by the cycled-potential method (420 min) after two types of extractive treatment. Curve 1: by solvent extraction in ethanol of the layer in Fig. 2A, curve 1. Curve 2: by voltage cycling of the layer in Fig. 2A, curve 2 in $0.050 \text{ mol-dm}^{-3} \text{ H}_2\text{SO}_4$ for 26h between 0.05 and 1.40V (NHE) at 100 mV-s^{-1} . Each error bar in regions A and B represents the 50% confidence interval associated with the mean of five absorbances determined at different positions on the SnO_2 electrode. Region C: Absorption spectrum of solid thionine deposited on SnO_2 by the evaporation of aqueous thionine in air at 333 K. The spectrum is the mean of the spectra of four different evaporated samples normalized to the same average absorbance, and the error bars represent 50% confidence intervals in the means.

leaching (Fig. 2B, curve 1). The eluent from the ethanol extraction had the same fluorescence excitation spectrum and fluorescence emission spectrum as thionine solution. The amount of fluorescent solute removed from the layer was in the vicinity of $4 \times 10^{-11} \text{ mol-cm}^{-2}$, which suggests that about 45% of the layer is soluble when one obtains an estimate of the layer thickness (45-50 monolayers) by cyclic voltammetry. Thionine deposited by evaporation from bulk solution or by spraying an SnO_2 glass surface was completely removed by ethanol.

Repeated voltage cycling (0.05 to 1.40V (NHE) at 100 mV-s^{-1}) of the electrochemically deposited layers in $0.050 \text{ mol-dm}^{-3} \text{ H}_2\text{SO}_4$ almost completely removed the solid thionine peaks in the 550-650 nm region, while the peak at around 495 nm was not substantially decreased, even after 26h of voltage cycling (Fig. 2B, curve 2).

The above observations indicate that the electrochemically deposited thionine layers contain a solvent extractable component which is probably occluded thionine and a strongly bonded component with a prominent absorption peak around 495 nm.

The variability of the solvent extractable thionine region (550-650 nm) in the layers in Fig. 2A suggests that electrochemical deposition causes the occlusion of varying amounts of loosely bonded thionine.

The strongly bonded material absorbing around 495 nm has an extinction coefficient of $(1.7 \pm 0.1) \times 10^3 \text{ m}^2\text{-mol}^{-1}$. This determination required the layer thickness, which was measured by cyclic voltammetry on the coated electrode in a background electrolyte comprising $0.050 \text{ mol-dm}^{-3} \text{ H}_2\text{SO}_4$. The layer thickness was obtained using the background-corrected charge enclosed by the cyclic voltammogram. It was assumed that the reduction and oxidation of the layer occurred by a process involving two electrons per monomer unit and that all the material in the layer was electrochemically active. If these assumptions do not hold, then the replication error shown for the

extinction coefficient may be an underestimate of the actual error.

The solvent-resistant material absorbing around 495 nm appears only in the electrochemically deposited layers and does not appear in the spectrum of evaporated thionine layers. This material is probably the thionine polymer, which Bauldrey and Archer (2) suggest is deposited by the electrochemical process.

Experimental Determination of the Collection Efficiency of a Metal/n-Type Semiconductor Rotating Ring-Disk Electrode

E. Verney, J. R. Martin, and P. Clechet*

Laboratoire de Physicochimie des Interfaces, Unité associée du CNRS no. 404, Ecole Centrale de Lyon, 69131 Ecully Cedex, France

The rotating ring-disk electrode (RRDE) is a very useful tool for studying chemical corrosion in the dark and light-stimulated corrosion of semiconductor materials immersed in liquid media (1-3). This method is most often used to evaluate the extent to which the capture of photogenerated minority carriers by soluble redox species competes with surface corrosion. The resolution of this problem is critical to the development of photoelectrochemical solar cells, especially for readily corrodable low bandgap n-type covalent materials (4-10). In this case, the efficiency of the protective reductant is measured by the stabilization factor, S , defined as the ratio of the current resulting from the oxidation of the reducing agent, i_{ox} , to the total photocurrent $i_{photo} = i_D$, obtained at the semiconductor disk electrode. The value of i_{ox} is calculated by dividing the ring current i_R by the collection efficiency N of the RRDE. Therefore, we must know the latter quantity accurately.

For a metal-metal RRDE, the evaluation of N is easily obtained from the geometric parameters of the electrode (11) or from the slope of the i_R vs. i_D curve. With a semiconductor disk, the problem is more complex. The first method is often inconvenient because of the low geometrical definition of round hand-machined semiconductor disks. The second method requires the use of a fully protective fast redox couple ($S = 1$) whose existence has to be proved beforehand, for example, by RRDE. There is therefore an obvious need for a method which does not imply the existence of such a couple. In this paper, we suggest a new method which consists in an *in situ* provisional metallization of the n-type semiconductor disk and the use of this Schottky diode, forward biased in the dark, to monitor the reduction of an oxidant. The value of N is then obtained by measuring the ring electrode current used in collection (oxidation) or shielding (reduction) of the oxidant being reduced at the metallized disk electrode. The thin metal layer deposited on the semiconductor protects its surface from possible chemical corrosion, by hole injection, from the dissolved acceptor species. Additionally, it can also protect it against reductive decomposition under the negative biases used here. Thus, the n-type semiconductor, being in the dark and cathodically polarized, is protected against any kind of corrosion.

To check this method, we have considered a corrodable n-type semiconductor material, n-GaAs, the photoprotection of which involved the use of strong air-sensitive reductants (8-12). The oxidizing agent was an aqueous solution of ferricyanide, and the deposited metal was gold. The ring electrode was also made from gold in order to avoid masking steps during plating.

The experimental data presented here lead to a collection factor which tallies well with that calculated on a carefully and geometrically well-defined electrode. As the deposited metal can be eliminated later by polishing and etching, the checked electrode can then be used for further experiments. This technique can evidently be adapted to other semiconductor materials.

Experimental

Our rotating ring-disk electrode consists of a demountable setup as first conceived by Menezes *et al.* (9). The semiconductor disk is cut from n-GaAs <100> single-crystal slices (MCP Electronic Materials Limited; thickness = 500 μm ; $N_D = 2 \times 10^{16} \text{ cm}^{-3}$).

Rear-side ohmic contacts are formed by melting a Sn and NH_4Cl mixture at 350°C under N_2 flow. The semiconductor is carefully centered in the system and threaded to planarity to the ring. The remaining gap between the disk and the ring is then filled with a cyanoacrylate (Loctite IS 430). Excess adhesive is removed with dimethylformamide (DMF), and the ring and disk made coplanar by polishing with 3 and 1 μm diamond pastes before each experiment. Samples are etched twice with $\text{H}_3\text{PO}_4\text{:H}_2\text{O}_2\text{:H}_2\text{O}$ (1:1:18 volume ratio, 15°C) solutions and then dipped for a few seconds in $\text{HCl:CH}_3\text{OH}$ (1:1 volume ratio) mixture. To dismount the disk, the adhesive is dissolved in an ultrasonically agitated bath containing DMF at 40°C.

Fig. 1. I-E curves at rotating disk electrodes in $\text{Fe}(\text{CN})_6^{3-}$, 10^{-3}M , pH 5 (acetate buffer), $\omega = 600 \text{ rpm}$. Curve a: n-GaAs/Au (photoassisted metallization). Curve b: n-GaAs/Au (electrolytic deposition). Curve c: gold electrode.

Electrolytic solutions are prepared from reagent-grade chemicals (Merck and Prolabo) and distilled water. The ferricyanide solution is $10^{-3}M$ at pH 5 (acetate buffer). We use a two-compartment cell containing 80 cm^3 of solution.

This cell is fitted with a saturated calomel electrode (SCE), a platinum counterelectrode, and an optical flat window at the bottom to allow the disk to be illuminated by light conducted by an optical fibre. The electrode is driven by an Oxford variable rotation speed motor. Current-voltage curves are obtained with a Tacussel bipotentiostat and an HP plotter monitored by an Apple IIe microcomputer.

Nominal dimensions are $(r_3/r_1) = 1,467$ and $(r_2/r_1) = 1,195$. The corresponding theoretical collection factor is $N = 0.328$.

Photoassisted deposition of gold is realized by illumination of the electrode immersed in a $3 \times 10^{-3}M$ $\text{AuCl}_3/0.1N$ HClO_4 solution for a few minutes. The surface is then rinsed with distilled water and blown dry. The thin film obtained does not seem to be uniform, and, following the statement of Frese *et al.*, the estimated gold thickness is around 200 \AA (14).

For electrolytic gold deposition, we use a 20 g-liter^{-1} KAu(CN)_2 , 100 g-liter^{-1} sodium citrate aqueous solution at pH 5 maintained at 70°C . The density of current is 10 mA-cm^{-2} , and the duration 15s. The electrode is then washed and dried as above. With a faradaic efficiency of 100%, the metal thickness should be close to 1500 \AA . The deposit is adherent and quite uniform.

Results and Discussion

The behavior of n-GaAs in ferricyanide solutions, at various pH values, has been studied in prior works (1, 2, 13-15). This redox system is pH independent above pH 4, and its Fermi level is located below the valence bandedge of GaAs at pH 14 and within its forbidden bandgap at pH 6 (1, 2). In an alkaline medium, hole injection is thus possible, and we do observe corrosion in such conditions in the dark. At pH 6, corrosion apparently stops. These results, as well as the general features of the current-voltage curves (not reported here), are in full accord with the experimental results of the above-cited works. After gold deposition, chemical corrosion is no longer observed. Such improvement in the stability of gold-covered GaAs has been previously noted by Frese *et al.* with other redox couples, even under illumination (14). These interfaces behave like Schottky diodes with a barrier height of several hundred millivolts (16) in series with the solution, as proved by Menezes *et al.* (15). The dark current-voltage curves obtained in $10^{-3}M$ Fe(CN)_6^{3-} at pH 5 with the gold-

Fig. 2. i_R - i_D curve in Fe(CN)_6^{3-} $10^{-3}M$, pH 5 (acetate buffer) at n-GaAs/Au electrode (photoassisted metallization). $E_D = -0.4V$ vs. SCE, $E_R = 0.6V$ vs. SCE, $\omega =$ from 0 to 1600 rpm collection efficiency, $N = 0.310$.

plated GaAs electrodes are compared with the curves obtained on a pure gold electrode in Fig. 1. With GaAs/Au electrodes, the curves normally shift toward negative voltages due to the solid-state Schottky barrier formed. The better barrier is clearly obtained with the electrolytic deposition of gold. As the shape of these curves has no influence on the precision of the S calculation, we do not try to optimize them.

Figure 2 shows the i_R vs. i_D plot obtained for the first type of metallization (photoassisted deposition). The slope yields a collection efficiency of 0.310, close to its estimated nominal value. The i_R vs. i_D curve obtained with the second method of metallization is represented in Fig. 3. The slope of this straight line gives a collection factor equal to 0.320, which seems very reliable.

After removing the protective thin gold layer by successive polishing and etching of the surface, the bare electrode can again be used for classical electro- or photoelectrochemical studies. The provisional gold deposition appears to have no remaining influence on the subsequent electrode behavior. This is proved by the i_D - E_D and i_R - E_D curves obtained with our electrode, in $7M$ NaI, $10^{-2}M$ HI under photon flux-limited conditions, (Fig. 4), as these curves are absolutely the same before and after gold treatment and subsequent cleaning. The highly concentrated iodide solution is used to suppress the semiconductor photocorrosion process by promoting hole transfer to the solution (17, 18). In the dark, the reverse disk

Fig. 3. i_R - i_D curve in Fe(CN)_6^{3-} $10^{-3}M$, pH 5 (acetate buffer) at n-GaAs/Au electrode (electrolytic metallization). $E_D = -0.4V$ vs. SCE, $E_R = 0.6V$ vs. SCE, $\omega =$ from 0 to 2400 rpm collection efficiency, $N = 0.320$.

Fig. 4. i_D - E_D and i_R - E_D curves at RRDE (recovered disk) in $7M$ NaI, $10^{-2}M$ HI under photon flux-limited conditions. $\omega = 600$ rpm. $E_R = -0.2V$ vs. SCE. The insert shows the corresponding i_R - i_D curve for this electrode, under illumination, in the same medium.

current is negligible (good Schottky barrier at the semiconductor/electrolyte interface). The residual ring current corresponds to the reduction of the iodine quickly formed in such highly concentrated iodide solution. The i_R vs. i_D plot in the insert of Fig. 4 is linear with slope $N = 0.317$, agreeing with the above. Inversely, this conformity proves that a good photo stabilization of GaAs is obtained in such media. These results will be discussed elsewhere.

Conclusion

The analysis of the reduction dark current generated at the metallized n-type semiconductor disk of a RRDE allows its collection efficiency to be determined reliably. The salient point is that this provisional gold metallization can be easily and completely removed when the measurement of the collection factor has been made. The recovered electrode can thus be successfully used for further photoelectrochemical quantitative experiments requiring knowledge of the collection efficiency.

Photoelectrochemical and Corrosion Study of n-Type SnS_xSe

B. Fotouhi, A. Katty, and O. Gorochov

Laboratoire de Physique des Solides, CNRS, 92195 Meudon Principal Cedex, France

ABSTRACT

Single crystals of n-type SnS_xSe_{2-x} ($x = 1.04$) obtained both by transport and Bridgman methods exhibit an energy gap of 1.53 eV. The flatband potential is pH dependent, and its values in acidic and alkaline solutions are, respectively, 0.06 and -0.6 V (SCE). In the dark, SnS_xSe is stable in acidic medium, but the stability decreases as pH increases. It is also unstable in acidic solutions containing the oxidizing form of a redox reagent with a sufficiently positive redox potential (ca. more positive than 0.8V/SCE). The presence of an oxidizing form of a redox couple in alkaline medium enhances the already existing corrosion reaction. The corrosion reaction is accompanied with an anodic current. The corrosion rate as well as the magnitude of the anodic current depends on pH and the concentration of the oxidizing state of the couple. Light-driven reactions in both acidic and alkaline media are corrosion reactions. However, decomposition may be avoided in acidic solution containing potassium iodide.

The solid solution SnS_xSe_{2-x} can be prepared over the entire composition range from SnS₂ to SnSe₂. Compounds obtained are layered semiconductor with CdI₂-type structure. Optical properties of the mixed series SnS_xSe_{2-x} (where $0 < x < 2$) have already been studied (1). Indirect energy gaps obtained vary linearly between SnSe₂ (1.09 eV) and SnS_{1.5}Se_{0.5} (1.75 eV). A deviation from linearity is observed between SnS_{1.5}Se_{0.5} and SnS₂ (2.22 eV). Photoelectrochemical properties of SnS₂ have already been studied (2), and it seems interesting to consider the ternary compound.

Although this ternary compound could present a particular interest in solar energy conversion because of its adjustable energy gap, it has not yet received attention in photoelectrochemistry. SnS_xSe, whose reported energy gap is 1.52 eV (1), which is an optimum value for solar spectrum, could be an interesting candidate for solar energy conversion into electrical or chemical energy.

Experimental

SnS_xSe_{2-x} single crystals were obtained both by transport and Bridgman methods. In both cases, stoichiometric amounts of purified tin sulfide and selenium were used. In the transport method, iodine and bromine were the transporting agents. The charge zone was at 630°C and the transport zone at 580°C. Single crystals of SnS_xSe_{2-x} ($3 \times 3 \times 0.1$ mm) were obtained within a week. In the Bridgman method, the transport zone was fixed at 780°C and the temperature gradient was 70°C. Ingots of 10 cm length with 1 cm diam were obtained. Microprobe analysis indicated that the composition of the samples prepared by transport was $x = 1.04$. For those prepared by Bridgman technique, the same composition was found for the higher part of the tube ($x = 1.05$). The composition for the lower and the central parts of the tube was approximately $x = 1.2$. Hall measurements gave a carrier concentration of 6×10^{17} cm⁻³ and a resistivity of 0.36 Ω-cm at room temperature for samples prepared by transport method, and a carrier concentration of 2×10^{16} cm⁻³ and a resistivity of 200 Ω-cm for those prepared by Bridgman method. Electrical contact was achieved using In-Ga eutectic and silver paste. Samples were mounted on a copper plate cleaved and insulated with Dow Corning glue. Only the van der Waals surface was exposed to the solution. Electrochemical experiments were performed using classical methods. Capacitance-voltage

measurements were performed using 5206 E.G.E. lock-in amplifier with an incorporated frequency generator. A 250W tungsten halogen lamp was used as light source. Samples were illuminated by monochromatic light ($\lambda = 600$ nm, $100 \mu\text{W}\cdot\text{cm}^{-2}$), using a JOBIN-YVON, monochromator. For the light-driven corrosion studies and photo-potential determination, white light was used ($200 \text{ mW}/\text{cm}^2$). Analytical-grade chemicals and deionized water were used for the preparation of the solutions. Results in this paper correspond to the crystal with a composition $x = 1.04$ grown by Bridgman technique designated as SnS_xSe in the text.

All potentials are referred to the saturated calomel electrode.

Results

Electrode reactions in the dark.—SnS_xSe has a diode-like blocking behavior in acidic solutions (the dark current being equal to 4×10^{-7} A-cm⁻² at anodic potentials); however, the dark current increases with increasing pH, and at pH = 14 a substantial increase in anodic current is observed. Figures 1 and 2 demonstrate the behavior of SnS_xSe in acidic and alkaline media. The variation of anodic current at 1.0V (SCE as a function of pH is shown in Fig. 3). A sharp increase in current is observed at pH values greater than 7. The anodic current is accompanied with the corrosion of the sample. The corrosion in alkaline solution is enhanced upon addition of the oxidized state of a redox reagent such as Fe(CN)₆³⁻. The corrosion, as well as the dark current, depends on the concentration of the oxidized form of the redox couple. The dark current and the corrosion intensity increase with increasing concentration of Fe(CN)₆³⁻. Figure 4 demonstrates the variation of anodic current as a function of Fe(CN)₆³⁻ concentration in KOH (pH = 14). In acidic medium, Fe(CN)₆³⁻ contributes very little to the increase of anodic current (8×10^{-7} A-cm⁻²) and corrosion of the electrode, whereas Ce⁴⁺ decomposes the electrode with a higher rate and an anodic current is established upon addition of Ce⁴⁺. The current is a function of the concentration of cerium ion (Fig. 5). The corrosion product in alkaline medium containing Fe(CN)₆³⁻ and acidic medium containing Ce⁴⁺ is a yellow-brown layer which deposits on the surface.

Cathodic polarization of SnS_xSe leads also to a decomposition reaction. Hydrogen evolution does not take place due to the energetic position of the conduction band. The

decomposition product which covers the electrode surface was proved to be the lower oxide of tin (SnO) by x-ray analysis.

Figures 6 and 7 demonstrate the Mott-Schottky plots for samples prepared by Bridgman and transport methods, respectively, flatband potential shifts to more negative value as pH increases. The slopes (assuming $\epsilon = 10$) gave a carrier concentration of 1.3×10^{16} and $4.6 \times 10^{17} \text{ cm}^{-3}$ for Bridgman and transport samples, respectively. These values are in agreement with those determined by Hall measurements.

Electrode reactions under illumination.— $I(V)$ curves are demonstrated in Fig. 1 and 2. A negative displacement of photocurrent onset in alkaline medium is observed. The flatband potential values are confirmed by a plot of square of photocurrent as a function of potential at 760

nm where the condition $\alpha\omega \ll 1$ and $\alpha L_p \ll 1$ is satisfied, Fig. 8.

The spectral dependence of the photocurrent at constant photon flux is shown in Fig. 9. A plot of $(I_{ph}/h\nu)^{1/2}$ as a function of $h\nu$ yields the value of 1.53 eV as the first indirect transition, which is in agreement with the value found in the literature (1). When electrodes were illuminated under white light ($200 \text{ mW}/\text{cm}^2$) at 0.5-1V polariza-

tion in either acidic or basic solution, a brown layer was formed after approximately 30 min. Therefore, the light-induced reactions in acidic and alkaline solutions are corrosion reactions. The same corrosion layer was found in the dark in the presence of the oxidized form of a redox couple. The stability of the electrode can be substantially improved in acidic solution containing 2M potassium iodide. The presence of I₃⁻ in acidic medium shifts the flatband potential and the photocurrent onset to more negative values as in the case of some other dichalcogenides. The negative shift depends on the concentration of I₃⁻. The shift has been considered to be due to I₃⁻ adsorption (2-5). Photopotentials (Table I) are small and do not vary with redox couples' potential as theoretically predicted.

The energy diagram of SnSSe and the position of different redox reagents with respect to energy bands is demonstrated in Fig. 10. It can be seen that the redox potentials of all couples used in this experiment are situated in the bandgap region.

Discussion

Corrosion reaction in the dark in the presence of redox reagents has already been reported in the case of CdS, CdSe, and SnS₂ (3, 6, 7). In the case of CdSe, the corrosion is independent of pH and redox couple concentration, and it depends primarily on the redox couple's potential, which should be sufficiently positive. The dark anodic current was not affected for CdSe or for CdS. Corrosion of SnS₂ is independent of pH in solutions not containing redox couples, but it depends on the concentration of redox reagents used and it is accompanied with an anodic

current. Corrosion of SnSSe, however, depends on the pH, and a substantial increase in the dark current is observed when pH is increased. At pH = 14, the analysis of the solution indicates that selenium, sulfur, and tin diffuse out into the solution. The corrosion product which stays back on the surface was also dissolved in KOH and the analysis indicated that it was constituted of a mixture of selenium, sulfur, and tin. It seems that in alkaline medium, hydroxide ions react with the semiconductor in such a way that selenium and sulfur are substituted by these ions in a reaction such as

From the fact that the corrosion reaction is accompanied with an anodic current, it is reasonable to assume that a part of S⁻ and Se⁻ formed according to reaction [1] whose energies are sufficiently high can inject electrons into the conduction band and a part diffuse out into the solution according to the following reactions

On the other hand, thermodynamic consideration indicates that Sn(OH)₄ dissolves partly to SnO₃²⁻ in alkaline medium (8)

The presence of sulfur, selenium, and tin, both in the solution and in the layer which deposits on the surface, and the fact that the total charge consumed during the electrolysis is six times smaller than the concentration of dissolved tin, would support this interpretation. The addition of Fe(CN)₆³⁻ to the alkaline solution increases the anodic current and the corrosion rate. The magnitude of the anodic current and the corrosion rate depend on the concentration of Fe(CN)₆³⁻. Corrosion leads to the formation of a yellow-brown layer on the surface, and in this case it primarily consists of sulfur and selenium.

The amount of tin found in the surface layer was very small, and the analysis of the solution indicated that it diffuses out into the solution. As in the preceding case, the total charge produced during the overall reaction was six times smaller than the concentration of SnO₃²⁻ found in the solution. The same phenomenon was observed in the case of SnS₂ (3), and it seems that the same mechanism for the corrosion reaction in the dark can be considered

According to reaction [4], (Ox) injects a hole in the surface states situated in the bandgap region (Fig. 11), breaking a chemical bond in a first step. In a second step, a part of the intermediate product formed injects an electron into the conduction band. 2(1-x)e⁻ would correspond to the anodic current observed. The corrosion product in this case is identical to that under illumination and tin is completely dissolved and passes into the solution, in contrast to corrosion in pure KOH. This may be due to the fact that (Ox) can inject a hole which is equivalent to a photo-induced hole.

In acidic solution, Fe(CN)₆³⁻ contributes very little to the increase of anodic current and to the corrosion reac-

Fig. 11. Redox potential of $\text{Ce}^{3+/4+}$ and $\text{Fe}(\text{CN})_6^{4-/3-}$ relative to the bandedges in H_2SO_4 0.5M and KOH 1M. The values of λ have been taken from Ref. (10).

tion. This may be due to the positive shift of the flatband potential so that a proper overlap does not exist between surface states and the energy level of the oxidized form of this couple for which $\lambda = 0.6$ eV (Fig. 11). However, the oxidized form of a couple with a more positive potential, such as Ce^{4+} , produces a corrosion reaction and increases substantially the anodic current in acidic solution. It can be seen from Fig. 11 that an overlap exists between surface states and the oxidized form of cerium for which $\lambda = 1.25$ eV. Note that only distribution functions of oxidized species ($\text{Fe}(\text{CN})_6^{3-}$ and Ce^{4+}) are plotted in Fig. 11.

As was mentioned, the electrode undergoes a cathodic decomposition reaction at cathodic potentials; the reaction product is the lower oxide of tin (SnO) which deposits on the electrode and has been identified by x-ray analysis. The following reaction can be considered for cathodic decomposition in acidic medium.

We shall now discuss the electrode reactions under illumination. These reactions are decomposition reactions in both acidic and alkaline media. In both cases, tin diffuses out into the solution and a mixture of sulfur and selenium stays on the surface according to the reactions

As previously mentioned, corrosion products are identical to those found during the electrode decomposition in the dark in the presence of redox reagents. Substantial improvement can be achieved in the stability in acidic solution containing potassium iodide. The anodic polarization (+1V) under white light ($200 \text{ mW}\cdot\text{cm}^{-2}$) for 4h in a 2M I^- , 0.05M I_2 , and 0.5M H_2SO_4 solution did not lead to corrosion. The analysis of the solution did not show any trace of tin, and current stayed stable at $7 \text{ mA}\cdot\text{cm}^{-2}$.

Shifts in photopotentials do not follow the redox couple's potential. This is due to the existence of dark cathodic current at potentials positive to the flatband position. Surface states should be at the origin of the dark current onset at potentials positive to V_{FB} . On the other hand, in the case of Ce^{4+} and Br_3^- , the anodic current, due to corrosion, limits the band bending; therefore, in the presence of $\text{Ce}^{3+/4+}$ and $\text{Br}^-/\text{Br}_3^-$, the band bending in the dark is much smaller than expected, leading to approximately the same photopotential as in the presence of $\text{Fe}^{2+/3+}$ and $\text{Fe}(\text{CN})_6^{4-/3-}$. The same phenomenon has been observed previously in the case of SnS_2 and ZrS_3 (1, 9). As the anodic and cathodic dark currents depend on the concentration of the redox species in the solution, it is worth mentioning that photopotential, particularly in the presence of $\text{Ce}^{3+/4+}$ and $\text{Br}^-/\text{Br}_3^-$, decreases with increasing concentration of the above reagents.

Conclusion

It has been shown that SnSSe , a layered-type semiconductor with an energy gap of 1.53 eV, has a diode-like behavior. Although light-driven reactions are corrosion reactions, the stability can be improved substantially in the presence of an acidic solution containing potassium iodide.

Reduction in Polysilicon Oxide Leakage Current by Annealing prior to Oxidation

K. Shinada, S. Mori, and Y. Mikata

Toshiba Corporation, Semiconductor Device Engineering Laboratory, Saiwai-ku, Kawasaki, Japan

ABSTRACT

The mechanism of leakage current reduction in phosphorus-doped polysilicon oxide by high temperature annealing prior to low temperature oxidation was investigated by bias polarity dependence of oxide leakage current, polysilicon grain size measurement, and polysilicon surface observation. Increased phosphorus concentration in polysilicon makes the grains larger and smoothens the surface roughness; consequently, the highest electric field is obtained at the phosphorus concentration of about $6 \times 10^{20} \text{ cm}^{-3}$. Even at the optimum concentration, leakage current due to field enhancement at the interface between polysilicon oxide and polysilicon is still high. Leakage current can be reduced remarkably by high temperature annealing prior to oxidation, especially at the optimum concentration. The annealing effect is explained by interface flatness improvement due to grain growth during annealing and increase of phosphorus atoms in grains. Phosphorus atom migration from the grain boundaries inside the grains is considered to enhance the grain growth.

Thermal oxide grown on heavily doped polysilicon is commonly used as the dielectric of MOS LSI's. Particularly, in a floating polysilicon gate EPROM's and EEPROM cells polysilicon oxide (poly-oxide) hardness to the electric field plays an important role in determining data retention characteristics. However, poly-oxide is well known to be more conductive than bulk silicon oxide, which has been attributed mainly to surface roughness at the poly-oxide/polysilicon interface.

A smoother interface is obtained by oxidizing polysilicon at higher temperatures (1), where the viscous flow of the oxide and the small dependence of oxidation rate on polysilicon orientation can moderate the surface roughness generated by oxidation. A similar improvement in the surface roughness is attained by using polysilicon with amorphous structure (2). Also, high temperature annealing just after polysilicon oxidation improves the breakdown field (3). This improvement is explained by the release of stress in the structure, which prevents further flawing induced after the oxidation and thermal cycling.

In this paper, the role and mechanism of high temperature annealing prior to oxidation of phosphorus-doped polysilicon is investigated as an effective means of improving the reliability of low temperature oxidized poly-oxide. The bias polarity dependence of Fowler-Nordheim tunneling current through poly-oxide, measurement of the polysilicon grain size, and observation of the oxidized polysilicon surface using TEM and replica techniques are reported.

Experimental

Polysilicon films with thickness of $0.40 \mu\text{m}$ were deposited by low pressure chemical vapor deposition (LPCVD) at 620°C onto thermally oxidized Si substrates and were doped with phosphorus by diffusion at 900°C from a POCl_3 source. Prior to oxidation, $0.30 \mu\text{m}$ thick CVD oxide films were deposited onto the doped polysilicon films, and annealing was performed at 950° and 1100°C for 10 min in N_2 atmosphere. Some of the Si substrates remained unannealed, as shown in the experimental procedure of Fig. 1. High temperature annealing without CVD film in inert gas atmosphere causes the outdiffusion of phosphorus and sometimes results in grain growth in the vertical direction, which enhances the surface roughness. After annealing, CVD oxide film was removed and $400\text{-}500\text{\AA}$ thick poly-oxide was formed at 950° and 1000°C in dry O_2 atmosphere. The upper doped polysilicon electrodes were formed to fabricate polysilicon/poly-oxide/polysilicon capacitors. The capacitor area was $250 \times 400 \mu\text{m}^2$.

The Fowler-Nordheim current through poly-oxide was measured by applying positive and negative bias voltage to the upper polysilicon electrodes, and effective barrier

height ($\phi_{B, \text{eff}}$) for the poly-oxide was calculated from Fowler-Nordheim plots, using the well-known equation [1] (4)

$$J/E^2 \propto \exp\left(-\frac{4(2m)^{1/2}(\phi_{B, \text{eff}})^{3/2}}{3e\hbar} \cdot \frac{1}{E}\right); m = 0.4m_0 \quad [1]$$

It is said, based on photocurrent measurements, that the barrier height for poly-oxide is comparable to that for oxide grown on single Si substrate (5), but it is speculated that the electrical barrier height is lowered by field enhancement at the poly-oxide/polysilicon interface.

The critical electric field for the poly-oxide was estimated from the applied positive voltage to provide 10^{-9} A/mm^2 low level leakage current. Grain size and surface roughness of the oxidized polysilicon were investigated

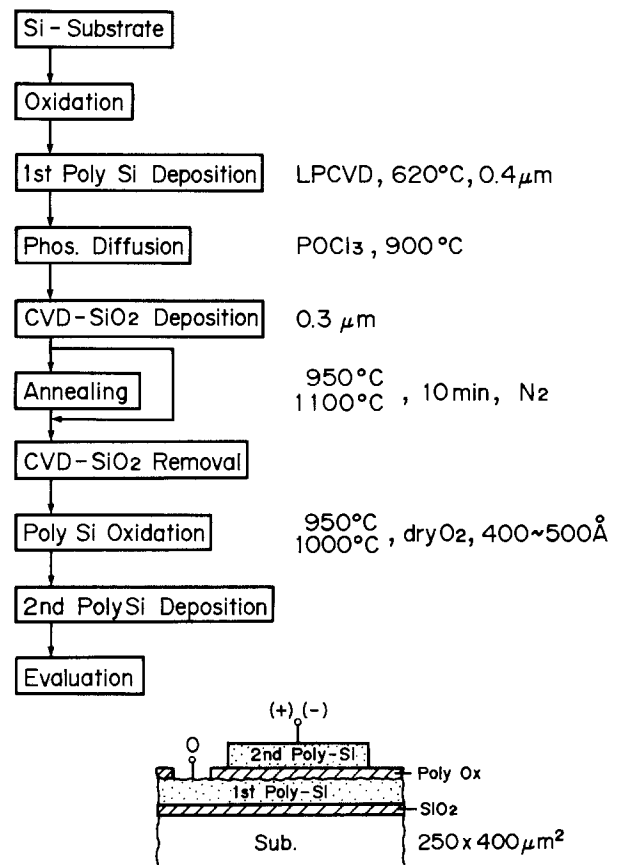

Fig. 1. Experimental procedures and capacitor structure

Fig. 2. Relation between critical field and phosphorus concentration in polysilicon. Critical field is defined as applied positive voltage, which provides 10^{-9} A/mm², divided by poly-oxide thickness.

by means of TEM and replica observations. The poly-oxide thickness was obtained by capacitance measurement. The phosphorus concentration in polysilicon was analyzed by AES. In these experimental conditions, the concentration profiles are nearly uniform in the polysilicon films even after phosphorus diffusion from a POCl_3 source, because of the high diffusivity along grain boundaries.

Results and Discussion

A critical electric field depends upon phosphorus concentration in the polysilicon. An optimum concentration exists at about 6×10^{20} cm⁻³, and the critical field decreases in regions of both lower and higher concentration, as shown in Fig. 2. This result agrees with the data of previous reports (6, 7). Oxidation was performed at 950°C.

Fowler-Nordheim plots for the poly-oxide leakage current at 2.5×10^{20} cm⁻³ and a photograph of the oxidized polysilicon surface obtained by replica technique are shown in Fig. 3. Poly-oxide is first removed in NH_4F in order to observe the interface between poly-oxide and polysilicon by this technique. When a positive bias is applied to the upper polysilicon electrode, the poly-oxide is more conductive, owing to electron emission from the lower polysilicon. This phenomenon can be explained by surface roughness at the poly-oxide/polysilicon interface, as indicated by the polysilicon surface photograph. Thus, the Fowler-Nordheim current is determined by low effective barrier height induced by local field enhancement at the asperity.

The grain size is larger and the surface roughness becomes smoother with increasing phosphorus concentra-

Fig. 3. Fowler-Nordheim plots for poly-oxide leakage current and photograph of oxidized polysilicon surface. Oxidation at 950°C. Phosphorus concentration: 2.5×10^{20} cm⁻³.

tion in polysilicon, as clearly shown in Fig. 4. The grain and grain boundary are clearly distinguished in the polysilicon surface photograph. This surface flatness improvement is based on grain growth due to incorporation of more phosphorus atoms into the grains during the period of phosphorus diffusion from POCl_3 . As a result, the critical electric field increases and the maximum value of 3.5 MV/cm is obtained at the optimum concentration of about 6×10^{20} cm⁻³. However, electron emission from the lower polysilicon is still higher than that from the upper polysilicon, even at the optimum concentration. On the other hand, in the case of oxidation at 1000°C, effective barrier heights at (+) and (-) bias are 1.14 and 1.63 eV, respectively, and the bias polarity dependence of Fowler-Nordheim current is small compared to that at 950°C oxidation, because high temperature oxidation improves the surface flatness.

At concentrations higher than about 6×10^{20} cm⁻³, the critical electric field decreases with phosphorus concentration, in spite of better surface flatness. There is no bias polarity dependence of leakage current through poly-oxide, as shown in Fig. 5. This means that the critical electric field is not necessarily determined by the surface roughness. A possible interpretation of the phenomenon is poly-oxide degradation, caused by phosphorus and/or others clusters in the poly-oxide. Precipitation of a large number of phosphorus atoms at the grain boundary, which exceeds the solid solubility of about 6×10^{20} cm⁻³ at 950°C (8), must play an important role in forming such clusters.

The critical electric field becomes higher when the sample is annealed at temperatures higher than the phosphorus doping temperature prior to oxidation, as shown in Fig. 6. Phosphorus concentration is 5.7×10^{20} cm⁻³. Figure 7 shows the relation between the critical electric field and phosphorus concentration, for 1100°C annealing and no annealing. Solid and dashed lines represent the relations with and without annealing, respectively. Im-

Fig. 5. Fowler-Nordheim plots for poly-oxide leakage current and photograph of oxidized polysilicon surface. Oxidation at 950°C. Phosphorus concentration 8.6×10^{20} cm⁻³.

Fig. 6. Relation between critical field and annealing temperature

provement in the critical electric field is attained independent of the phosphorus concentration. In particular, poly-oxide leakage current drastically decreases at the optimum concentration and the critical field of 4.6 MV/cm is obtained, which approaches the critical field of ~7 MV/cm for oxide grown on single-crystal silicon.

Fowler-Nordheim plots for poly-oxide leakage current at the optimum concentration for 1100°C annealing and no annealing are shown in Fig. 8. The leakage current of the annealed sample is almost independent of the polarity of the applied bias voltage. By this annealing, the effective barrier height increases from 0.83 to 1.21 eV. This phenomenon can be understood by more reduction of surface roughness of the grain due to grain growth during high temperature annealing, as clearly indicated in polysilicon surface photographs of Fig. 4 and 8. The relation between the critical electric field and average grain size of samples with and without 1100°C annealing is shown in Fig. 9. It is clearly seen that the critical electric field correlates with the grain size in the phosphorus con-

Fig. 7. Relation between critical field and phosphorus concentration in polysilicon. Solid line is for 1100°C annealing, and dashed line is for no annealing.

centration region below about $6 \times 10^{20} \text{ cm}^{-3}$ and high temperature annealing plays an important role in increasing the grain size. The ratio of phosphorus atoms in the grains to the total phosphorus atoms in polysilicon, N_G/N is represented by solid and open circles for 1100°C annealing and no annealing in Fig. 10. N_G is defined as the number of carriers estimated from the polysilicon sheet resistivity and Hall mobility, and N is the number of phosphorus atoms obtained from AES analysis. Values of N_G/N for the samples with and without 1100°C annealing are 0.87 and 0.74, respectively, at a phosphorus concentration of $5.7 \times 10^{20} \text{ cm}^{-3}$. In the case of $2.5 \times 10^{20} \text{ cm}^{-3}$, values of N_G/N are 0.80 and 0.41 for the samples with and without 1100°C annealing, respectively. These values are in good agreement with calculated values as a function of annealing temperature for experimental grain size, using Mandurah's segregation model (9). The calculated values are represented by solid and dashed lines in Fig. 10. Entropy factor of 1.5 and heat of segregation of 10 kcal/mol are used in this calculation. From these results, phosphorus atom migration from the grain boundaries inside the grains is considered to enhance the grain growth during high temperature annealing. It is concluded that high temperature annealing prior to oxidation can make phosphorus atoms doped into the polysilicon efficiently contribute to the surface flatness improvement.

Figure 11 shows critical electric field histograms for the samples oxidized at 950° and 1000°C. In the case of 950°C oxidation, the distribution peak for the annealed samples clearly moves toward higher electric field and the critical electric field for this annealed sample is higher than that for unannealed samples oxidized at 1000°C.

Fig. 10. N_c/N as a function of annealing temperature. Solid and open circles represent experimental values of N_c/N for annealed and unannealed samples, respectively. Solid and dashed lines represent calculated results for $N = 5.7$ and $2.5 \times 10^{20} \text{ cm}^{-3}$, respectively.

Conclusion

Leakage current characteristics of the phosphorus-doped polysilicon oxide formed at low temperature are studied by bias polarity dependence of leakage current, polysilicon grain size measurement, and polysilicon surface observation.

Increased phosphorus concentration in polysilicon makes the grains larger and smoothens the surface roughness. Simultaneously, the leakage current decreases in the concentration region below about $6 \times 10^{20} \text{ cm}^{-3}$. The highest electric field is obtained at about $6 \times 10^{20} \text{ cm}^{-3}$. However, leakage current due to field enhancement at the interface between poly-oxide and polysilicon is still high. At concentrations of greater than about $6 \times 10^{20} \text{ cm}^{-3}$, leakage current is not determined by the surface roughness but presumably is due to poly-oxide degradation. Leakage current can be reduced remarkably by high

Fig. 11. Critical field histograms for samples oxidized at 950° and 1000°C.

temperature annealing prior to oxidation, especially at about $6 \times 10^{20} \text{ cm}^{-3}$. This annealing effect is explained by surface flatness improvement due to grain growth during annealing and increase of phosphorus atoms in grains. Phosphorus atom migration from the grain boundaries inside the grains is considered to enhance this grain growth.

Compositional Studies of Thermally Nitrided Silicon Dioxide (Nitroxide)

M. M. Moslehi, C. J. Han, K. C. Saraswat,* C. R. Helms,* and S. Shatas¹

Integrated Circuits and Solid State Laboratories, Department of Electrical Engineering, Stanford University, Stanford, California 94305

ABSTRACT

The kinetics of thermal nitridation of silicon dioxide in ammonia ambient has been studied. SiO₂ films of 100-1000Å thick were thermally nitrided at 950°-1100°C for times from 15s to 2h. Our experimental results based on etch rate and Auger electron spectroscopy measurements clearly indicate the multilayer structure of nitrided-oxide films. Nitrogen-rich layers are formed at the surface and interface regions at a very early stage of the nitridation process. After a few minutes, the nitridation reaction mainly goes on in the bulk region, with the surface and interface nitrogen content remaining fairly constant. The Auger depth profiles show that the interface moves away from the nitrogen-rich layer as the nitridation proceeds. In addition, our results indicate the formation of an oxygen-rich layer underneath the nitrogen-rich layer whose thickness increases with nitridation time. The formation of this oxide-like layer can be attributed to a slow oxidation of the silicon substrate at the nitroxide/silicon interface by the oxygen which is a by-product of the bulk exchange reaction between NH₃ (or nitrogen containing species) and SiO₂. The results of this work can be qualitatively used to explain effects such as enhanced boron and phosphorus diffusion and growth of stacking faults in the silicon substrate during nitridation of oxide.

Thermally grown silicon dioxide films have many obvious applications in silicon devices and technology including gate insulators of IGFET's and tunnel insulators for nonvolatile memories such as E²PROM. In VLSI, the trend towards smaller device dimensions and higher integration density implies that very thin ($\leq 100\text{\AA}$) gate and tunnel insulators will be required in future devices. For instance, megabit DRAM and high density FLOTOX E²PROM devices will need gate or tunnel insulators in the subhundred angstrom region. There are, however, several technological and reliability problems with silicon dioxide in the very thin regime. The fact that very thin layers of thermal SiO₂ are poor masks against impurity diffusion places additional constraints on processing steps following the growth of gate or tunnel oxides. Moreover, the growth of high quality very thin layers of SiO₂ is rather difficult due to defect density, integrity, and yield problems. It is also known that high energy radiation can generate a high density of interface states in the oxide, resulting in degradation of device performance.

Thermal nitridation of silicon and silicon dioxide is an alternative approach for growing very thin gate and tunnel insulators. It has been observed that thermal nitridation of silicon dioxide films results in the formation of a nitrided-oxide or nitroxide layer with a composition profile that varies with depth. It has also been reported that both thickness and refractive index of thin oxide films are increased after high temperature nitridation in ammonia (1, 2). The changes in composition of the initial oxide film after nitridation in ammonia have been studied using several techniques such as Auger electron spectroscopy (AES), etch rate, Rutherford backscattering spectroscopy, infrared transmittance spectroscopy, and oxidation resistance measurements (1, 3-6, 11, 13-16). Ito *et al.* observed that, after nitridation of a 500Å oxide at 1200°C, a nitrogen-rich layer is formed at the surface and nitrogen gradually decreases moving farther from the surface of the film (3). However, their AES data did not show the presence of significant amounts of nitrogen near the silicon interface. Therefore, Ito *et al.* concluded that direct nitridation occurs predominantly at the surface of SiO₂ rather than at Si/SiO₂ interface.

Their conclusion that there is no pile-up of nitrogen close to the silicon interface is surprising, since we have evidence for the presence of nitrogen-rich layers both at the surface and interface regions for films nitrided under a wide range of nitridation conditions, consistent with the findings of several other investigators. Since their AES data were for 500Å thick oxides nitrided at 1200°C for 1h, a

possible reason for their conclusion was the relatively high temperature used for nitridation. At 1200°C for 1h, the amount of nitrogen incorporated into the bulk is quite significant, and therefore the level of the bulk signal and Auger broadening effects associated with the interface could easily mask the interface nitrogen.

Wong *et al.* performed nitridation of 100Å oxides at relatively low temperatures (925°C) and low pressures in ammonia and an ammonia plasma ambient (4). Their AES data for 100Å SiO₂ nitrided at 925°C show nitrogen peaks at the surface and the interface regions, with negligible nitrogen in the bulk. Their data also indicated that more nitrogen was present at the interface than at the surface and that the interface nitrogen belongs to a more stoichiometric Si₃N₄ layer as opposed to the surface layer. The fact that after nitridation of oxide there is a relatively high concentration of nitrogen at the outer surface and interface regions with a smaller concentration in the bulk of the film now is well established and confirmed (5, 6). Aucoin *et al.* attributed the enhanced nitridation of oxide at the surface to reconstruction of the SiO₂ surface by ammonia (7). Their work indicates that the equivalent nitride thickness at the surface is fairly independent of nitridation time and is saturated after a short time. This is also confirmed by the results of this work.

It has also been observed that the ammonia partial pressure has a significant effect on composition of nitrided-oxide films (1). Higher ammonia partial pressure results in an increase in the nitrogen content of the films, as shown by the etch rate and oxidation resistance data of Hayafuji and Kajiwara (1). Their AES data for 100Å oxide nitrided at 1000°C for 5h did not show however any peak nitrogen concentration at the surface. This nitrogen peak at the interface was not observed, possibly because of the high level of bulk nitrogen and broadening effects.

The influence of nitridation of SiO₂ on impurity diffusion and stacking fault growth in the silicon substrate have also been studied, and it has been observed that the length of preexisting stacking faults increased during nitridation of oxidized silicon (2). The growth was observed to be linear with nitridation time even after 10h of nitridation. Moreover, for a given set of nitridation conditions, an increase in the thickness of the initial oxide increased the growth rate of the stacking faults.

Consistent with stacking fault data, nitridation of SiO₂ films thermally grown on Si substrate enhances diffusion of P and B and retards the diffusion of Sb dopant profiles located in the Si substrate underneath the nitroxide film (8, 9). These phenomena are similar to those observed during oxidation processes (oxidation-enhanced diffusion or OED) and have been attributed to injection of silicon interstitials into the Si substrate during nitridation

¹Present address: AG Associates, Palo Alto, California 94303.

*Electrochemical Society Active Member.

of oxide (8, 9). However, the actual physical mechanism responsible for these phenomena has not yet been firmly established. The results of this work indicate that the most possible physical mechanism responsible for these phenomena is the liberation of oxygen species in the bulk of the oxide, which reoxidizes the interface to the silicon similar to what occurs during oxidation of silicon.

Vasquez *et al.* (10) used x-ray photoelectron spectroscopy (XPS or ESCA) to study the composition of 100Å thermal SiO₂ nitrided in pure ammonia at atmospheric pressure at 1000°C for 4h. In order to preserve the original chemical composition, they used depth profiling by chemical etching instead of ion sputtering. Back-side etch of the Si bulk by XeF₂ was used to verify the structure of the film at the interface. It was observed that nitrogen was distributed throughout the film with a higher concentration at the surface and interface regions. XPS results show that the peak nitrogen concentration close to the interface was about 25Å away from the silicon/film interface. The results indicated the presence of a relatively oxygen-rich layer within 15Å of the interface. However, they found that, while the interface is oxygen-rich relative to the rest of the film, a significant amount of nitrogen is incorporated in this interfacial layer. They suggested that the strained interfacial SiO₂ is more reactive to ammonia than the bulk oxide, resulting in the formation of a nitrogen-rich layer. They also suggested that the formation of the relatively oxygen-rich layer at the interface is due either to the reaction of a nitrogen species with the top layer of the strained region or to reaction of the nitridation by-products with the silicon substrate. The results of our kinetics studies are in favor of the latter and rule out the reaction with top strained region as the only cause of the presence of an oxygen-rich interfacial layer.

Yoriume has also studied the distribution of nitrogen in thermally nitrided SiO₂, using AES and other techniques (11). For 100Å oxide nitrided at 1100°C for 2h, the nitrogen-to-oxygen concentration ratio at the surface was estimated to be about 1. The data showed that the maximum nitrogen Auger signal strength at the interface was relatively temperature independent and that a highly nitrided layer was formed at the interface. The surface nitrogen concentration decreases slightly with the film thickness, and the temperature dependence was observed to be rather small. For nitridation at 900°C, the bulk nitrogen concentration was negligible even after 2h of nitridation. The results also indicated that the surface nitrogen pile-up occurs in the early stages of nitridation (≤ 30 min) and nitrogen permeates through the oxide films even as thick as 1000Å at 900°-1100°C. However, his calculation of the diffusion coefficient of the nitrogen species from the profile near the surface assuming a complementary error function distribution may be erroneous since the effect of AES broadening on the nitrogen profile was not taken into account.

This paper follows our earlier published letter on time-dependent compositional variation in SiO₂ films nitrided in ammonia (12). Two of the major new results reported in that letter were the quantitative observation of oxygen depletion in the nitroxide "bulk" region and the reoxidation of the interface by oxygen presumably liberated by the bulk exchange reaction. In this study, we have investigated the time evolution of the nitridation process of SiO₂ in atmospheric ammonia at temperatures from 950° to 1200°C. The SiO₂ thickness varied from 100 to 1000Å. Special attention has been given to the interfacial oxygen-rich layer observed by Vasquez *et al.* A model for the nitridation process will be given based on the findings.

Experimental

The oxide films used in this work were thermally grown in dry O₂ at 900°C to a thickness of 95Å and at 1000°C to thicknesses of 270, 405, and 1021Å, on 5-10 Ω -cm (100) silicon wafers. The thermal nitridation experiments were performed for times from 15s to 2h at 950° and 1100°C in pure ammonia at atmospheric pressure. All the short-time nitridations (15s-4 min) were performed in a

lamp-heated rapid thermal annealing (Heatpulse 210) system manufactured by AG Associates (Palo Alto, California). In each of the rapid thermal nitridation (RTN) experiments, the system was thermal, first in pure argon and then in pure ammonia after loading the wafer. After establishing a pure flowing ammonia ambient in the quartz chamber, the temperature was ramped up to the desired process temperature in pure ammonia. At the end of all rapid thermal nitridation experiments, the temperature was ramped down while ammonia was still flowing. Finally, the wafer was unloaded after purging the system in argon flow. The ramp-up and ramp-down times at the beginning and at the end of each rapid thermal nitridation cycle were usually very fast (≤ 10 s) and much shorter than the actual nitridation time. As a result, the effects of ramp-up and ramp-down times on rapid nitridation kinetics were expected to be insignificant. The longer nitridation experiments were carried out in a cold-wall RF-heated reactor which has been described elsewhere (5). After loading the wafers, the system was purged first in pure nitrogen and then in pure ammonia. Temperature was then ramped up to the nitridation temperature while ammonia was flowing, and at the end of the nitridation, the temperature was ramped down while ammonia was still flowing. The wafers were unloaded after purging the system in nitrogen. The ramp-up and ramp-down times for nitridation experiments performed in the RF-heated reactor were relatively fast (≤ 2 min) and usually much shorter than the minimum nitridation time (the shortest nitridation time in the RF-heated reactor was 15 min) for the experiments in the reactor. Therefore, the effects of ramp-up and ramp-down times on the kinetics data including those for 15 min nitridation were expected to be negligible, similar to the rapid thermal nitridation experiments.

The nitrided oxide films were investigated using step-by-step etch rate measurements and Auger electron spectroscopy. In the etch-rate measurements, the thickness of the remaining film was measured using single-wavelength ellipsometry after step-by-step etching in 50:1 DI H₂O:HF. The wavelength of the laser was 6328Å incident at 70° from the normal to the surface of the film. In all the ellipsometry measurements the refractive index used for the single-crystal Si substrate was 3.85-0.02i.

The system for the Auger sputter profiling analyses was a Varian 2730 spectrometer, which uses an integral electron source located coaxially with a single-pass cylindrical mirror analyzer (CMA). The electron gun was operated at 4.5 keV and at 3 μ A rastered over a 900 \times 900 μ m area. These conditions were chosen to reduce any electron-beam damage, stimulated desorption, and electron-beam-induced diffusion to the surface. The samples to be analyzed were located at the focus of the CMA and tilted 30° from the normal surface of the electron beam. The resolution of the CMA was set to 1.2% for these studies and a 2V peak-to-peak modulation voltage with lock-in detection was used. The concentrations of elements were obtained by comparing the peak-to-peak heights of the derivative Auger spectra with those of a standard sample. This standard calibration sample consisted of 500Å of LPCVD stoichiometric silicon nitride deposited on oxidized silicon with 100 and 1000Å initial thermal oxides. Depth profiles of the samples were obtained by sputter etching with Ne⁺ ions during the Auger analyses. The ion beam was operated at 1 keV, 49° incidence, and rastered over a 0.5 \times 0.5 cm² area. The effective current density of the ion beam was 36 μ A/cm², which provided a sputtering rate of nearly 20 Å/min for SiO₂. In addition to the standard and samples investigated using these two techniques, selected nitroxide samples were studied using a hybrid wet etch/sputter etch technique to assess the effects of sputter-induced artifacts in the profiles.

Results and Interpretation

Auger electron spectroscopy.—To calibrate the relative sensitivity factors, a Si₃N₄/SiO₂ standard was used. It was a 500Å thick CVD Si₃N₄ film on a layer of 1000Å thick

Fig. 1. The AES depth profile for a 500Å CVD Si_3N_4 on 1000Å SiO_2 on Si. This was used as a standard to calibrate the relative sensitivity factors for oxygen and nitrogen.

SiO_2 thermally grown on Si. The profile we obtained for this sample is shown in Fig. 1. Since both the nitride and the oxide are of known stoichiometry and hence of known oxygen and nitrogen concentrations, we were able to calibrate the concentrations of elements in the nitride samples using this result. The horizontal axis of the profile is the sputtering time of the analysis. Assuming a uniform sputtering rate in each region of the sample, this axis can easily be converted to the depth from the surface. The sputtering rate for each material was calculated by specifying the location of interfaces from the 50% transition positions in the Auger depth profiles (and the corresponding sputtering times) and the nitride and oxide thicknesses measured by ellipsometry. For our conditions, the sputtering rate in the SiO_2 (depth/time) is about 30% faster than the rate in Si_3N_4 . The sputtering rate is proportional to the ion flux of the incident ions; hence, various factors such as the Ne pressure inside the chamber, the contamination on the surface of the ion gun filament, and the warmup time of the ion gun may affect the current density of the ion beam. Our experience has shown that this sputtering rate may vary by 10% over a typical run. Similarly, the vertical scale may fluctuate by as much as 15% because of varying electron-beam intensities and sample charging which may affect the energy analyzer collection efficiency. In the presentation of the data below, all of our profiles were normalized such that the samples with the same insulator film thickness have the Si_{LVV} (92 eV) transition 50% point located at the same point. Also, the peak intensities of the Si_{LVV} (92 eV) transition are normalized to the same value.

Figure 2 shows the results from three nitroxide samples with different starting SiO_2 thicknesses all nitrided in NH_3 for 15 min. We identify three obviously distinct regions in the profiles of 405 and 270Å samples. (These are the initial oxide thicknesses, not necessarily the total thickness.) Two of these regions originate from rapid thermal nitridation at the SiO_2 surface and at the Si/ SiO_2 interface. Similar results have been observed by other investigators (10). In addition, nitridation at a much slower rate is observed in the bulk of the SiO_2 . This nitrogen concentration remains approximately constant with depth in the bulk. The 95Å sample, however, shows a merging of the surface and the interface peak, and the bulk region is not clearly observed. The apparent loss of this bulk region is probably an artifact of instrumental broadening rather than a real physical effect, as will be shown below. In principle, by measuring the sputtering time to the interface the film thickness can be determined. However, the difference in sputtering rate between Si_3N_4 and SiO_2 (30%) and the normal experimental uncertainty in the ion flux (5%) makes this determination difficult. Within these limits, the film thickness does not appear to change significantly after nitridation; however, other experimental evidences (5, 1, 2) from ellipsometry measurements (with single wavelength 6328Å laser) and etch rates suggest some increase in the thickness and effective refractive index, specially for the thinner initial oxides, which

Fig. 2. The AES data for different SiO_2 thicknesses (95, 270, and 405Å) all nitrided at 1100°C for 15 min.

would be within the limits of the sputter time measurements. Considering the fact that nitroxide has an inhomogeneous structure, ellipsometry measurements yield values for effective refractive index and thickness calculated from measured values of ellipsometry parameters ψ and Δ . In single-wavelength ellipsometry, the mapping from ψ - Δ plane to thickness-refractive index plane is done based on the assumption that the film has a homogeneous structure. This could introduce some error into the calculated values; however, the error is expected to be rather small for nitroxide films because they have a fairly homogeneous structure throughout most of the bulk region in the dielectric (as will be described later). Some numerical calculations are being performed to study the errors introduced into the thickness and refractive index measurements in single-wavelength ellipsometry of inhomogeneous materials such as nitroxide. Meanwhile, the data obtained from high resolution cross-sectional TEM results have been in fairly good agreement with our ellipsometry results. As a check for other sputter-induced artifacts in our profiles, we examined several samples that were chemically etched back before the Auger sputter profile analysis. The results from these etched-back samples were consistent with the profiles in Fig. 2, indicating negligible sputter-induced distortion in the Auger depth profiles.

Since the three regions were best separated in the 405Å sample, we will describe a detailed study of these samples. Three samples from each nitridation condition were analyzed to improve the reliability of the collected Auger data and give a fair statistical average. The results from these samples are shown in Fig. 3. The Auger profiles were each calibrated with respect to the standard sample of Fig. 1. The profiles for each element are plotted separately with the nitridation time as the parameter for each curve. Initially, the nitrogen peaks at the surface and at the interface grow rapidly. As will be discussed, the surface peak and the interface peak both saturate before 15 min of nitridation. The bulk nitrogen level also increases with nitridation time, but at a much

Fig. 3. The AES data for 405 Å initial SiO_2 samples nitrided at 1100°C for various nitridation times (30s-2h). The Auger profiles were each calibrated with respect to the standard sample of Fig. 1.

slower rate than at the surface or interface. Even after 2h of nitridation at 1100°C, the nitrogen level is still increasing and no apparent saturation of the nitrogen concentration is observed. This bulk nitrogen increase is also accompanied by a decrease of the oxygen concentration in the same region. The apparent increase in the oxygen level in Fig. 3 for the 2h sample is probably due to uncertainties in the normalization. Another interesting feature in the profile is the observed shift of the nitrogen profiles at the interface. The instrumental broadening effects make quantifying the physical effect in this region difficult. An attempt was made to model the interfacial nitrogen profile by assuming a superposition of a step function profile and a narrow high concentration peak at the interface, as to be discussed in the next section.

Figure 4 shows the ratio of the nitrogen to oxygen concentrations at the surface vs. nitridation time from 30s to 2h calculated from AES data. There is a rapid increase in the ratio for very short nitridation times, as shown by the data points for 30 and 60s of nitridation. However, the data for 15 min or longer nitridation times show that the surface nitrogen concentration saturates very rapidly. Also shown are two data points for 95 and 270 Å oxide nitrided at 1100°C for 15 min. Data indicate that at a given nitridation temperature the surface nitrogen concentration is almost independent of the initial oxide thickness and saturates rapidly with nitridation time.

Using the data from AES, the nitrogen to oxygen concentration ratio in the bulk was calculated vs. nitridation time for 405 Å thick oxide samples nitrided at 1100°C. The results are illustrated in Fig. 5. It shows that the bulk nitrogen concentration increases monotonically with nitridation time. After 2h of nitridation, the ratio is about 0.30. The rate of increase in the ratio in the bulk decreases with nitridation time; however, there is no saturation after 2h. The dependence of bulk oxygen concentration on nitridation time is shown in Fig. 6 for 405 Å oxide nitrided at 1100°C. For comparison, this figure also illustrates the dependence of the bulk nitrogen ($[\text{N}]$) on nitridation time. It indicates a monotonic decrease in oxygen content of the bulk due to continuing exchange reaction of bulk oxide

Fig. 4. The ratio of the nitrogen to oxygen concentrations at the surface of nitride vs. nitridation time, from 30s to 2h for 405 Å initial oxide nitrided at 1100°C for various nitridation times.

with nitridation species, similar to what is observed from Fig. 5. Another interesting feature in the nitrogen Auger profiles shown in Fig. 3 is the shift observed in the peaks of nitrogen profiles at the interface. As the nitridation time increases, the peaks shift farther away from the interface toward the surface. Instrumental broadening effects make quantifying this behavior difficult. However, as we show below, this effect cannot be completely explained by instrumental broadening and appears to correspond to the growth of an oxygen-rich layer right at the interface to the Si substrate.

Etch profile.—Precision etch profiling is an accurate measurement tool for studying the composition of the nitroxide films without significant measurement artifacts such as ion knock-on and broadening effects in AES. The etch profiles were obtained by measuring both refractive index and thickness independently until the thickness was below about 100 Å, for which the refractive index was fixed at 1.46. Our experimental ellipsometry data for subhundred angstrom nitride and nitroxide films and also some preliminary calculations based on

Fig. 5. The nitrogen-to-oxygen concentration ratio in the bulk of nitroxide vs. nitridation time. The solid curve is for 405 Å oxide nitrided at 1100°C.

Fig. 6. The bulk oxygen concentration in nitroxide vs. nitridation time. The data are for 405 \AA oxide nitrided at 1100°C for various nitridation times. The nitrogen concentration in the bulk is also shown for comparison with the oxygen concentration.

the fundamental ellipsometry equations indicate that the error introduced in the measured thickness due to varia-

tions in the refractive index is rather small, and that the thickness measurement sensitivity to refractive index becomes less as the insulator thickness is reduced. The thickness measurement based on a measured or prefixed average value for effective refractive index seems to work fairly well for the purpose of this work. The results are in close agreement with the thickness measurement with high resolution cross-sectional TEM. The original purpose of chemical etch profiling in this work was a qualitative study of the compositional changes in the nitroxide insulators; therefore, some possible small errors introduced into the ellipsometry measurement results due to the inhomogeneous nature of the films will not have any effect on our fundamental conclusions regarding the kinetics of nitridation of oxide.

Figure 7a shows a typical step-by-step etch profile for an oxide film of 405 \AA thick nitrided at 1100°C for 2h. This etch profile was obtained by a precision step-by-step etch and thickness measurement which enables us to detect the details of changes in composition of the nitroxide layer. Six different regions are observed in the nitroxide etch profile shown in Fig. 7a. The data indicate that for over 320 \AA in the bulk of the film the etch profile is fairly uniform and the etch rate is nearly constant. Figure 7b illustrates an expanded picture of the surface etch profile from the surface to the point where about 100 \AA of the film has been removed. This figure shows the three different regions including the bulk. The etch rate at the top

Fig. 7. The etch profile for the 405 \AA SiO_2 nitrided at 1100°C for 2h. a(top left): Complete profile. b(above): Expanded surface etch profile. c(left): Expanded interface etch profile. The data were obtained by step-by-step etching of the film in 50:1 DI H_2O :HF etchant and ellipsometry thickness measurement.

surface is relatively fast and is close to that for pure SiO_2 . The two dashed lines are the experimental reference etch profiles for pure thermal oxide and CVD nitride. The fast etch rate at the top surface can be due to adsorption of moisture and oxygen at the surface after unloading the wafers from the nitridation reactor and during the storage time.

Following the top layer, there is a thin layer whose etch rate is between the etch rates for pure SiO_2 and deposited silicon nitride. For this surface nitrogen-rich layer, the actual thickness is very small and just a few ($\approx 5\text{\AA}$) angstroms, as illustrated in the etch profile. The fact that the surface nitrogen-rich layer is very thin implies that the surface reaction is a result of surface reaction only on the top atomic layer, as proposed by Aucoin *et al.* (7). Finally, the expanded surface etch profile in Fig. 7b shows a transition from the surface nitrogen-rich layer to the bulk region, in which the etch rate is almost constant.

The etch profile experimental measurement results indicate that the etch rate throughout most of the bulk region is constant. For the 405\AA oxide nitrided at 1100°C for 2h, the bulk etch rate is somewhat slower than that for oxide and much faster than that for stoichiometric nitride. The change in chemical etch rate is clearly an indication of change in composition. However, the relationship between etch rate and fractional nitrogen concentration is not linear and not exactly known for nitrided oxide, and, therefore, no quantitative data regarding exact values of nitrogen concentration may be extracted from the etch-profile data. The etch-profile data can be used to estimate the thicknesses of various layers in the film.

Figure 7c shows the expanded picture of the etch profile close to the interface region for the sample with the same etch profile as that in Fig. 7a. As shown in this figure, following the relatively thick bulk region there is a thin layer ($\leq 20\text{\AA}$) whose etch rate is much slower than that for oxide and is very close to the etch rate for stoichiometric nitride. The etch profiles for pure thermal oxide and LPCVD nitride are shown in the picture for reference. The fact that the etch rate in this thin layer is very close to that for stoichiometric nitride implies that this layer is nearly stoichiometric nitride. Underneath this thin, nearly stoichiometric nitride, there is another thin layer whose etch rate is faster than that for nearly stoichiometric nitride layer but slower than that in the bulk region. The fact that the etch rate of this interfacial layer is faster than that of the top nitride layer implies that it has more oxygen. Therefore, we call this an oxide-rich layer. Finally, the etch profile ends with a region whose etch rate is somewhat slower than that of the stoichiometric nitride. The slow etch rate in this final layer may be due to high nitrogen content or high amorphous silicon content in that layer or an artifact of ellipsometry measurements. The bulk etch rate is fairly constant in more than 320\AA of nitroxide. Therefore, the bulk nitrogen concentration is fairly uniform and constant. The etch rates measured for control oxide samples grown at 900° and 1000°C was about 0.83 \AA/s and for LPCVD nitride was 0.063 \AA/s . The average bulk etch rate of this nitroxide sample is more than seven times of that for CVD nitride and about half of that for oxide.

The six different regions detected from etch-profile data are shown schematically in the insert of Fig. 8. Correspondingly, the etch-rate profile which is the derivative of the step-by-step etch profile with respect to etch time *vs.* the thickness of film remained is shown in Fig. 8. This etch-rate profile was calculated from the etch profile of Fig. 7a. Based on a nearly constant etch rate in each region, we might assume a uniform composition in each region, which is a reasonable assumption for simplified modeling of the kinetics of oxide nitridation.

Calculated according to the etch-rate profile, the approximate thicknesses of the different layers in the nitroxide sample prepared by nitridation of a 405\AA oxide at 1100°C for 2h are shown in Table I. For comparison, the thicknesses of various layers obtained from the AES data

Table I. Layer thicknesses

Layer	(Etch profile data) Etch rate (\AA/s)	Thickness (\AA)	(AES data) Thickness (\AA)
Adsorbed layer	0.69	7	—
Surface nitrogen rich	0.15	5	10
Bulk region	0.45	324	—
Interface nitrogen rich	0.09	18	9
Interface oxygen rich	0.17	27	30
Transition region	0.04	19 ^a	—

^a This thickness is partially due to the measurement offset introduced by ellipsometry.

(as will be described later) are also shown in the table. The agreement between these two sets of data is fair and reasonable.

Owing to the multilayer structure of the nitroxide, the refractive index measured by ellipsometry is an effective refractive index of the multilayer structure. For the 405\AA oxide nitrided at 1100°C , the effective refractive index was fairly constant and equal to 1.55 for all the refractive index measurement range ($400\text{--}140\text{\AA}$). However, as Fig. 9 illustrates, the effective refractive index of the 270\AA oxide sample nitrided at 1100°C for 2h is more than that of oxide. Its value depends on the thickness of the top layer removed by etching. Below about 150\AA , accurate independent measurement of refractive index was not possible. Using the simplified multilayer model and ellipsometry equations, it should be possible to simulate the dependence of the effective refractive index on thickness of the film after step-by-step etching and compare it to the experimental results. This may be another approach to verify the composition and thickness of various layers in a given model. However, because of the inhomogeneity of the nitroxide films, it would seem hazardous to draw major conclusions from effective refractive index profiles such as that shown in Fig. 9, unless all the inhomogeneity effects on single-wavelength ellipsometry measurement results are carefully taken into account.

Discussion

From the results presented, it is clear that the structure resulting from the nitridation of SiO_2 is a complicated one. In this section, we will present a comparison of the etch-rate and Auger profiling results and discuss how these relate to the findings of other investigators. Our discussion will center on the model shown in the insert of

Fig. 8. The derivative etch-rate profile of the 405\AA SiO_2 nitrided at 1100°C for 2h.

Fig. 9. The effective refractive index of the 270 Å SiO₂ nitrided at 1100°C for 2h as a function of the thickness remained after step-by-step etching.

Fig. 8. Five distinct regions plus a very thin interfacial region right at the Si substrate surface are observed. In addition, the outer region with the higher etch rate on the surface after the nitridation was completed and the sample exposed to air. This leaves four regions of interest: the surface nitrogen-rich region, the bulk, the near-interface nitrogen-rich region, and the interface oxygen-rich region. All of these regions are observed in the etch-rate data, whereas only the first three are observed in the Auger profiling results. In addition, for the thinnest sample investigated, the bulk region could not be distinctly separated. As we will show, this is due to broadening inherent in the sputter profiling experiments; when this is accounted for, agreement between the two techniques is obtained.

As a first approximation to the instrumental broadening due mainly to the sputtering process, the actual concentration profiles appear convolved with a gaussian to yield the measured profiles. Within this approximation, a step function profile produces an error function profile after the broadening, and a thin layer produces a gaussian profile. As a starting point for modeling the nitrogen profiles, we assume that the bulk nitrogen concentration is constant, and that near the interface there is a thin region of stoichiometric Si₃N₄. Although this latter assumption is clearly an idealization, it provides a lower limit on the thickness of this region. We are interested in the interface region, so the surface nitrogen peak has been neglected in this analysis. The model is shown in Fig. 10a. This profile can then be convolved with a gaussian to fit the measured profiles. A typical fit is shown in Fig. 10b for the 15 min nitrided sample. The full width at half maximum of the gaussian broadening function was 47 Å. In the fits to the other profiles, this was kept constant and the thickness of the thin nitride layer and the distance away from the interface were adjusted. A plot of the interfacial nitride thickness and the separation of the thin layer from the Si interface is shown in Fig. 11. The error bars are not shown in Fig. 11 because the curve-fittings were performed on the averaged nitrogen and oxygen profiles for each nitridation condition and as a result single values of interfacial nitride and oxide thicknesses were calculated for each nitridation condition (instead of performing three separate curve fittings for Auger depth profiles obtained from three Auger measurements of nitroxide samples having the same nitridation conditions); however, these error bars are estimated

Fig. 10. a(top): A simplified model for the structure of nitroxide. b(bottom): The fitting results for the 405 Å SiO₂ nitrided at 1100°C for 15 min.

to be a small fraction of the absolute thickness values of the interfacial oxide and nitride layers. From this figure, we see that the interfacial nitrogen-rich layer saturates (in terms of the product of the nitrogen concentration and the thickness) very quickly. However, the separation between this region and the Si interface increases monotonically with time up to 30 Å after 2h at 1100°C. These results, although somewhat ambiguous in themselves, are consistent with the etch-rate data, which give an 18 Å thickness for the nitrogen-rich region compared to 9 Å from the Auger data and a 27 Å thickness for the interfacial oxygen-rich layer compared to 30 Å for the Auger data. The discrepancy of interfacial nitride thickness values obtained from Auger and chemical-etch data may be attributed to the combination of various experimental uncertainties present in both techniques. High resolution cross-sectional TEM is being employed to study the thicknesses of these various layers in nitroxide and correlate them to those from Auger and etch-rate data. Similar fits to the oxygen profiles are also consistent with the in-

Fig. 11. The interfacial nitride thickness and its distance or the thickness of interfacial oxide layer from the Si interface vs. nitridation time.

terpretation that the region right next to the Si interface is oxygen rich.

Our findings indicate that the SiO₂ nitridation occurs by three processes. Upon exposure to NH₃, the SiO₂ surface is nitrided very rapidly (see Fig. 4). The etch rate profile in Fig. 7b indicates that the surface layer with slow etch rate is very thin, about 5Å thick. This suggests that the enhanced surface reaction occurs just on an atomic scale and is restricted to the top surface. Although the interface nitridation reaction occurs more slowly, it is clearly due to rapid diffusion of the nitrogen containing species through the SiO₂ and reaction at the interface. The average concentration of the nitrogen in this interfacial region saturates at $1.7 \times 10^{16} \text{ cm}^{-2}$ for the 1100°C case in less than 15 min.

From the etch-rate as well as Auger data it is clear that another layer between the high nitrogen concentration region and silicon grows slowly with nitridation time. If we look at the comparison of this growth rate and the rate of exchange between nitrogen and oxygen in the bulk, we see the time scales are identical (Fig. 5 and 11). Moreover, it is clear that this region is oxygen rich. These findings give strong evidence for a mechanism whereby oxygen liberated by the bulk reaction diffuses to the interface where the silicon there is oxidized.

The AES data for the nitroxide samples prepared by short-time nitridation indicate that the nitrogen peak is not located in the oxide and is in between the oxide and the silicon substrate. This is due to the fact that the interfacial nitrogen peak location is observed to be well after the position of the 50% point on the falling edge of the oxygen profile and next to the substrate Si signal. The AES data also indicate that for very short-time nitridation of oxide (≤ 60 s) there is a very thin layer of nearly stoichiometric silicon nitride at the interface. There are several reasons to believe that the interfacial nitride layer is actually "nearly stoichiometric." The obvious evidence comes from our etch-rate data that show that the etch rate for the interfacial thin nitride layer is very close to that of stoichiometric LPCVD silicon nitride. The strong possibility that the interfacial nitride layer is formed by initial reaction of ammonia (and/or nitrogen containing species) with the silicon substrate under the thin SiO₂ also suggests that this layer should be nearly stoichiometric silicon nitride (with low oxygen content). Based on oxidation resistance experiments on etched back nitroxide samples, Wong *et al.* (4) suggested that the interfacial nitride layer resembles stoichiometric Si₃N₄, which is known to be more resistant to oxidation than oxide or oxynitride layers.

For the samples nitrided at 1100°C for very short times (≤ 60 s), the AES data indicate that the bulk nitrogen content is almost negligible. This implies that the bulk reaction rate is much slower than that for interface and surface nitrogen-rich layers. In fact, at temperatures below 950°C or so the bulk reaction is not activated even for long nitridation times (4).

Figure 3 shows the AES data for 405Å oxide nitrided for 30s, 15 min, 30 min, 1h, and 2h superimposed. It can be observed that as the nitridation goes on for longer nitridation times the bulk nitrogen concentration is increased so that, for instance, after 2h of nitridation at 1100°C, more than 30% of the oxygen in the bulk has been exchanged with nitrogen. Moreover, as the nitridation goes on, the amount of oxygen in the bulk is reduced. This implies that the increase in nitrogen content of the bulk is responsible for the decrease of the oxygen concentration in the bulk. Therefore, this is a strong evidence for the exchange nature of the reaction in the bulk region which was also suggested by Ito *et al.* (3) and Habraken *et al.* (13)

where v , w , x , y , and z depend on the nitridation process. After 2h of nitridation, the bulk has acquired a nitrogen concentration of $1.42 \times 10^{22} \text{ cm}^{-3}$ vs. a loss of $0.81 \times 10^{22} \text{ cm}^{-3}$ of oxygen. This result indicates that the gain of ni-

trogen in the bulk seems to be greater than the loss of oxygen. This implies that the replacement of oxygen with nitrogen is not quite one to one. Since the Auger measurement uncertainty for the bulk oxygen loss is much greater than the uncertainty observed for the nitrogen gain in the bulk (as shown by the arrow bars in Fig. 6), more exact measurement of oxygen loss is needed to draw any firm conclusion regarding the ratio of oxygen loss to nitrogen gain in the bulk. If the nitrogen gain is actually greater than oxygen loss, it could be attributed to additional incorporation of nitrogen into the bulk of the film in addition to the replacement reaction.

Another important phenomenon observed in the AES data is that, as the nitridation proceeds for longer times, the silicon-film interface moves away from the nitrogen peak inside the oxide. A nitridation reaction at the oxide-nitride interface cannot be the reason for this phenomenon because it is fairly well known that the interfacial nitride is very thin. However, the data indicate the growth of an oxide-rich layer underneath the originally formed nitride-rich layer. The shift of the nitrogen peak implies that the thickness of this interfacial oxygen-rich layer increases slowly with nitridation time. Throughout these experiments, we tried to eliminate any possible source of oxygen or water contamination in the nitridation ambient. Because of the ultrahigh purity of the gases used for purging and nitridation, and also the fact that the reactor is closed tube and cold wall (resulting in negligible contamination from outside the quartz tube), the oxygen and water contamination of the nitridation ambient were estimated to be well below 1 ppm. Considering the fact that the nitridation ambient is very pure and oxidant free, the only source that can provide oxygen for the oxidation of the silicon substrate is the original oxide. Some of the reaction by-products of the bulk exchange reaction with the nitridation species, diffuse into the film, and further oxidize the silicon substrate. It seems that the interfacial nearly stoichiometric nitride is so thin ($\leq 20\text{Å}$) that it does not block the diffusion of these exchange reaction by-products. It is also suggested that some of the exchange reaction by-products diffuse away and go into the nitridation ambient.

Figure 12 summarizes the nitridation sequence from very short times to long nitridation times (from seconds to hours). The sequence illustrates the fast reaction of ammonia with the top surface of the oxide and also the rapid diffusion of the ammonia (and/or other nitrogen containing species such as NH and NH₃) through the oxide and the formation of a nearly stoichiometric nitride layer at the interface. For longer nitridation times, the surface nitrogen concentration saturates and the exchange bulk reaction and the oxidation of the silicon substrate by the exchange reaction by-products continue. Auger electron spectroscopy does not allow detection and measurement of the hydrogen content of nitroxide. Habraken *et al.* (17) measured the hydrogen content of nitroxide films by means of resonant nuclear reaction. Their results indicated that the hydrogen concentration amounts to less than 1-3 atom percent in the bulk of nitroxide. Hydrogen has an essential role in the bulk exchange reaction. This is also supported by the fact that, in contrast to ammonia, N₂ does not react with SiO₂ in the typical temperature range of thermal nitridation processes. Ito *et al.* (3) and Habraken *et al.* (13) suggested that the rupture of Si-O bonds in the bulk of nitroxide occurs under the action of hydrogen. Rupture of Si-O bonds results in subsequent incorporation of nitrogen atoms in the bulk of nitroxide.

Our model for the kinetics of nitridation of oxides can explain the physical mechanisms responsible for oxynitridation-enhanced diffusion of boron and phosphorus and also the growth of stacking faults. The mechanism responsible for the injection of silicon interstitials into the silicon substrate during the nitridation of oxide should be closely related to the oxidation of the silicon substrate by the exchange reaction by-products. However, according to the etch-rate data and the AES profile for the 405Å oxide nitrided at 1100°C, the thickness of the interfacial

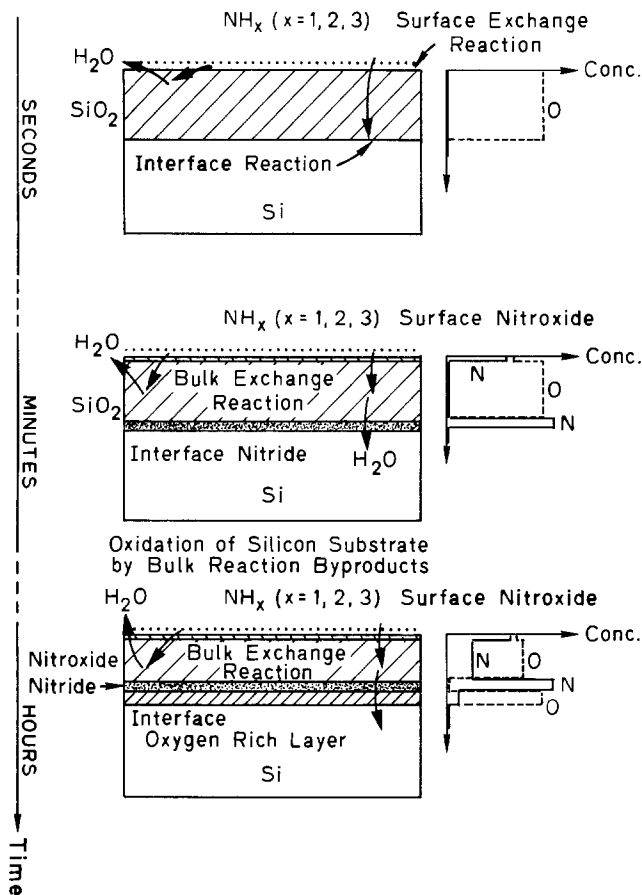

Fig. 12. The simplified model for the nitridation sequence from very short to long nitridation times.

oxide-rich layer grew to 30Å after 2h of nitridation. A comparable oxidation process for the growth of a thermal oxide with the same thickness has much less influence on impurity diffusion or stacking faults. As a result, the growth of the interfacial oxygen-rich layer during the nitridation of oxide is much more efficient in injecting interstitials into the substrate than a comparable normal oxidation process. The thickness of the interfacial oxide obtained from the position of the nitrogen peak with respect to the silicon interface and from the etch-rate data increases slowly and monotonically with nitridation time. There is no indication of saturation after 2h of nitridation.

Summary

In summary, the kinetics of thermal nitridation of SiO₂ and the composition of nitroxides have been studied. The results clearly indicated the multilayer structure of nitroxide films. The formation of the nitrogen-rich layers at the surface and interface regions occurs at the very early stage of the nitridation process. The nitrogen contents of the surface and interface regions saturate in the first few

minutes of the nitridation. Then the nitridation reaction slowly goes on in the bulk region. The movement of the interface away from the interfacial nitrogen-rich layer indicated the slow growth of an oxygen-rich layer underneath the nitrogen-rich layer. The formation of this oxygen-rich layer is due to the slow oxidation of the silicon substrate by a fraction of the oxygen containing species which are liberated in the bulk of nitroxide by the exchange reaction. The results can have important implications for understanding the effects of thermal nitridation processes on bulk and interfacial electrical characteristics of oxides and subsequent nitroxides.

Investigation of Leakage Currents in a Zinc Borosilicate Glass Passivated p-n Junction Using a Gate-Controlled Diode

S. Murakami, Y. Misawa, and N. Momma

Hitachi Limited, Hitachi Research Laboratory, Hitachi Ibaraki, Japan

ABSTRACT

A new type of gate-controlled diode to investigate the leakage currents of a thick zinc-borosilicate glass passivated p-n junction is described. Using this diode, temperature dependencies of surface and bulk components of the leakage current were measured at different values of the reverse voltage. It was revealed that the surface generation current component cannot be ignored, as compared with bulk current component, even at temperatures above 100°C. The surface recombination velocity at room temperature in glass/silicon system calculated from surface generation current component exhibited a larger value of 300-400 cm/s than did the SiO₂/silicon system, and it tended to decrease with decreases in reverse voltage or with increases in junction temperature.

Surface passivation techniques using glasses (1, 2) have been applied to the fabrication of a wide variety of power semiconductor devices. These techniques can offer such advantages as resistance against the entry of moisture and ionic impurities that affect electrical performance. Among the various glass materials, zinc borosilicate glass have been widely used because of its electrical stability at high temperatures and in high electric fields (3, 4). Properties of the silicon/glass interface have been investigated for zinc-borosilicate glasses by using metal-glass-semiconductor capacitors (5, 6). Although there have been many reports concerning those materials themselves and applications to raise breakdown voltage of p⁺-n junctions, little has been done with leakage currents and their temperature dependence. In the case of planar-diffused p-n junction having a silicon dioxide/silicon system, several types of gate-controlled diode (GCD) have been extensively used to investigate surface leakage currents (7-9). As for zinc borosilicate glass passivated p-n junctions, a GCD was applied to investigate the surface stability from the viewpoint of operational stress (3). The present work seeks to offer a suitable GCD structure with a thick glass/silicon system, which allows a more detailed examination of temperature dependence of separated surface and bulk leakage current components in a zinc borosilicate glass passivated p⁺-n junction.

Experimental

Device preparation.—A cross-sectional view of the GCD is shown in Fig. 1. This GCD was designed with the following considerations. (i) Surface depletion layer spreading would occur at the n-type silicon surface on application of a reverse voltage or a negative gate voltage. In estimating the surface recombination velocity, the surface depleted area must be defined as constant. The lateral depletion layer stopper n⁺ region shown in Fig. 1 served to hold the surface depleted area constant, thereby making it easy to measure the characteristics of the GCD without use of a guard ring voltage as was necessary in previous work (7). (ii) The deep groove structure made it possible to fabricate a GCD having a thick glass/silicon system. By controlling the amount of glass powder, the surface of the fired glass could be flattened, which made it easier to form both gate and anode electrodes using a conventional lift-off process. (iii) The gate electrode was arranged on the glass surface so as to overlap the p⁺-n and n-n⁺ junctions.

The GCD was fabricated by using 68 Ω-cm, 475 μm thick, phosphorous-doped n-type substrate with (111) orientation. The wafers were first oxidized and patterned to give a circular 70 μm selective boron diffusion, which served as the anode region. A second thermal oxidation was then performed and patterned to give an annular 40 μm selective phosphorous diffusion which served as the stopper for lateral depletion layer spreading at the surface. The back (cathode n⁺ region) was diffused simultaneously with this phosphorous diffusion. After formation

of the p⁺ region and n⁺ region mentioned above, the thermal silicon dioxide formed during the diffusion process was selectively removed. Then the exposed silicon surface was etched by U01 etchant [200 cm³ HF:800 cm³ HNO₃:19g, CO(NH₂)₂] to obtain a deep groove (20 ± 2 μm) for 45s at 10°C. An electrophoretic method was used to place glass powders of ZnO (65 weight percent [w/o]), B₂O₃ (25 w/o), and SiO₂ (10 w/o) composition into the groove. Firing was then carried out in a nitrogen atmosphere at 700°C for 30 min. The aluminum electrodes of gate and anode were formed by evaporating and subsequent patterning using the conventional lift-off process in a nitrogen atmosphere for 20 min at 470°C. The cathode electrode was formed by evaporating chromium-nickel-silver, in that order.

Measurements.—All leakage current measurements were carried out by placing the gate-controlled diode in an electrically shielded light-tight box. The currents were measured using a Takeda Riken Industry Company Limited electronic picoammeter Type TR 8641, which is capable of detecting currents as small as 5 × 10⁻¹⁴A.

Results and Discussion

Leakage current—Gate voltage characteristics at room temperature.—Figure 2 shows typical leakage current-gate voltage characteristics measured at a fixed reverse voltage, V_R = 1V. The characteristic of the SiO₂-passivated GCD in which SiO₂ was formed in the junction diffusion process is also shown. The latter structure is planar, having no groove. The fundamental leakage current I_R-gate voltage V_G characteristics have three current regions according to the values of the carrier densities at the n layer surface. General expressions of the leakage currents I_R are as follows.

Fig. 1. Cross-sectional view of the gate-controlled diode with a groove structure and n region to repress spreading of the surface depletion layer.

Fig. 2. I_R - V_G characteristics for gate-controlled diodes passivated by zinc-borosilicate glass and SiO_2 ($V_R = 1\text{V}$).

Region A: accumulation

$$I_R = I_{R,MJ} \quad [1]$$

Region B: depletion or weak inversion

$$I_R = I_{R,MJ} + I_{R,FJ}(x_d) + I_{R,S} \quad [2]$$

Region C: strong inversion

$$I_R = I_{R,MJ} + I_{R,FJ}(x_{dmax}) \quad [3]$$

In these equations, $I_{R,MJ}$ is the current flowing across the metallurgical junction, which consists of the generation current $I_{gen,MJ}$ due to electron-hole pairs generated within the junction depletion region and diffusion current $I_{diff,MJ}$ due to minority carriers generated within the neutral n and p regions. Assuming that the amount of minority carrier is negligibly small within the p⁺ region, $I_{R,MJ}$ can be expressed as follows (10)

$$I_{R,MJ} = I_{gen,MJ} + I_{diff,MJ} \\ = \frac{1}{2} q \frac{n_i}{\tau_{0,MJ}} W A_{MJ} + q \sqrt{\frac{D_p}{\tau_p}} \times \frac{n_i^2}{N_D} A_{MJ} \quad [4]$$

where $\bar{\tau}_{0,MJ}$ is the effective lifetime within a reverse biased metallurgical p⁺-n junction, W the depletion layer width of metallurgical p⁺-n junction, D_p , τ_p the diffusion constant and lifetime of minority carrier within the neutral n region, respectively, N_D the impurity concentration of n region, and n_i the intrinsic carrier density. The intrinsic carrier density n_i is expressed as following function of absolute temperature T (11)

$$n_i = 3.87 \times 10^{16} T^{3/2} \exp\left(-\frac{7.02 \times 10^{13}}{T}\right) \quad [5]$$

If the bulk generation-recombination centers are indeed located near the intrinsic Fermi level, the temperature dependence of $I_{R,MJ}$ is mainly proportional to n_i (first term) and n_i^2 (second term). When the surface under the gate electrode is inverted, the field-induced junction is formed between inverted p region and underlying substrate. Based on $I_{R,MJ}$, we obtain the following equation for the field-induced junction

$$I_{R,FIJ} = I_{gen,FIJ} + I_{diff,FIJ} \\ = \frac{1}{2} q \frac{n_i}{\tau_{0,FIJ}} x_d A_s + q \sqrt{\frac{D_p}{\tau_p}} \times \frac{n_i^2}{N_D} A_s \quad [6]$$

where $\bar{\tau}_{0,FIJ}$ is the effective lifetime within the surface depletion layer, x_d the surface depletion layer depth, and A_s the surface area of the n substrate under the gate electrode. The first term is the generation component which arises from generation carriers within the surface depletion layer. The second term is diffusion component due to minority carriers being diffused from the neutral n substrate to the surface depletion layer edge. If the surface is depleted, surface generation is caused by surface states, resulting in the flow of surface generation current $I_{gen,s}$. If the surface generation-recombination centers are located near the intrinsic Fermi level, the surface generation current is usually defined (10) as

$$I_{gen,s} = 1/2 q n_i s_0 A_s \quad [7]$$

where s_0 is the surface recombination velocity.

At the completely depleted surface, the surface leakage current $I_{R,S}$ (third term of Eq. [2]) is mainly due to $I_{gen,s}$. In the I_R - V_G curve of the GCD, the maximum leakage current is observed when the surface is depleted and the surface carrier density reaches the intrinsic. This means that the surface generation current begins to decrease as soon as the surface potential exceeds the Fermi level. Generally diffusion components of leakage currents at room temperature can be neglected as very small in comparison with generation currents. As is shown in Fig. 2, surface generation current $I_{gen,s}$ of the glass passivation is one order of magnitude larger than that of SiO_2 passivation. From the definition of s (Eq. [6]), its values are 320 cm/s for the glass passivation, and 38 cm/s for SiO_2 passivation. Although the latter system has a smaller s value, an anomalous current increase is observed with increase in positive gate voltage. This phenomenon was described previously and was attributed to inversion layer and surface crystal imperfections on the p layer surface (12).

Fig. 3. I_R - V_G characteristics at different temperatures and reverse voltages.

Fig. 4. Temperature dependence of $I_{R,MJ}$ at different reverse voltages

Temperature dependence of I_{R-V_G} characteristics.—The I_{R-V_G} measurements at various temperatures are described next. As shown in Fig. 3, leakage current in the range of the positive gate voltage exhibits the $I_{R,MJ}$ component. Leakage current begins to include the surface generation component with increasing negative gate voltages, and has its maximum value in the vicinity of $V_G =$

Fig. 5. Temperature dependence of $I_{R,FIJ}$ at different reverse voltages

–120V. This surface current component cannot be ignored as compared with bulk current component, even at temperatures above 100°C. The gate voltage value which shows the maximum leakage current does not vary significantly with the temperature and reverse voltage. This indicates that the values of the gate voltage needed to induce the inversion layer should be invariable for the temperature ranges studied.

Separated leakage currents and their temperature dependence.—Figure 4 shows the temperature dependence of $I_{R,MJ}$, which is derived from the accumulation region A of I_{R-V_G} curve shown in Fig. 3. According to Eq. [4], the currents flowing across the metallurgical junction $I_{R,MJ}$ can be separated into two components. One is the generation component in the depletion region, which shows the same temperature dependence as n_i . The other is the diffusion component, which has the same temperature dependence as n_i^2 . At low temperatures, the generation component is dominant, while the diffusion component becomes dominant at temperatures above 100°C.

$I_{gen,MJ}$ is approximately proportional to the depletion layer width W , assuming a one-sided abrupt junction

$$W = \sqrt{\frac{2\epsilon_s(V_{bi} + V_R)}{qN_D}} \quad [8]$$

where V_{bi} is the built-in voltage and ϵ_s the permittivity of silicon.

At room temperature, the value of $I_{gen,MJ}$ for each reverse voltage is approximately proportional to the square root of V_R , except for $V_R = 0.1V$. This value is 40% less than the extrapolated value from the data at $V_R = 1$ and 10V. This is attributed to the decrease in carrier generation rate within the depletion layer (13). However, since $I_{diff,MJ}$ is independent of the reverse voltage, these three curves should possess the same diffusion component as dotted line for n_i in Fig. 4. By combining the first term of Eq. [4] with Eq. [8], we estimate the effective lifetime $\tau_{0,MJ} = 33 \mu s$. However, using the second term of Eq. [4] and employing $D_p = 11.1 \text{ cm}^2/\text{s}$ (11), a value of $\tau_p = 164s$ is found.

Figure 5 shows the temperature dependence of $I_{R,FIJ}$, for data derived from the leakage currents in the strong inversion region, subtracted by $I_{R,MJ}$. The temperature dependence of $I_{R,FIJ}$ is similar to that of $I_{R,MJ}$. That is, at low temperatures the generation component is dominant, while the diffusion component becomes dominant at tem-

Fig. 6. Temperature dependence of $I_{gen,s}$ at different reverse voltages

Fig. 7. Temperature dependence of surface recombination velocity at different reverse voltages.

peratures above 100°C. Estimation of $I_{\text{gen},s}$ in conjunction with $I_{R,FIJ}$ is as follows. As we mentioned in the previous section, the maximum leakage current can be observed when the surface begins to invert. Therefore, the maximum current, which shows the peak value in the I_R-I_G curve, involves the sum of $I_{R,FIJ}$ (weak inversion), $I_{R,FIJ}$, and $I_{R,FIJ}$ (maximum). Supposing $I_{R,FIJ}$ (weak inversion) is approximately equal to $I_{R,FIJ}$ (strong inversion), $I_{\text{gen},s}$ is defined as the subtraction of the sum of $I_{R,MJ}$ and $I_{R,FIJ}$ (strong inversion) from the peak value. Figure 6 shows the temperature dependence of $I_{\text{gen},s}$ which has approximately the same temperature dependence as n_i . Using Eq. [6], surface recombination velocity s_0 is estimated as shown in Fig. 7. It tends to decrease with increases in temperature. A possible explanation is that the energy level E_i of the main surface generation-recombination center is not located exactly at the intrinsic Fermi level. Also, as is shown in Fig. 7, s_0 tends to decrease with decreases in reverse voltage. This reverse voltage dependence suggests that surface recombination velocity is subjected to a decrease in surface potential under the reverse biased nonequilibrium condition.

Conclusions

A new type of gate-controlled diode (GCD) was proposed to investigate the leakage currents of a thick zinc

borosilicate glass passivated p⁺-n junction. In this GCD, the n layer of the p⁺-n junction was surrounded by the highly doped n region which repressed lateral depletion layer spreading. Moreover, a semiplanar structure having a deep groove made possible the easy fabrication of the GCD. Using this diode, it was revealed that the surface generation current component cannot be ignored as compared with bulk current component even at temperatures above 100°C. The surface recombination velocity in the glass/silicon system, calculated from surface generation current component exhibited a larger value of 300-400 cm/s, in comparison with that of a SiO₂/Si system, and was dependent on temperature and reverse voltage.

Process-Induced Interface and Bulk States in MOS Structures

K. Hofmann and M. Schulz*

Institute of Applied Physics, University of Erlangen-Nürnberg, D-8520 Erlangen, Germany

ABSTRACT

The effect of processing on the generation of interface states and bulk states is analyzed in MOS structures. Simple process steps are simulated by postoxidation annealing in nitrogen ambient at temperatures in the range $T_A = 600^\circ\text{C}$ - 1150°C . Interface-state and bulk-trap densities are measured by constant capacitance DLTS. Interface and bulk states are strongly generated at anneal temperatures below 900°C . The interface-state density changes from a distribution showing a gradual decrease from the conduction bandedge to a distribution having a broad maximum near midgap. For the bulk traps at energy $E_c - E_T \approx 0.5$ eV, the density steeply increases within 100 nm from the interface. Densities up to $N_T = 10^{16}$ cm⁻³ are measured after 600°C annealing.

Adequate control of electronic traps in the SiO₂-Si interface region, e.g., interface states and bulk states in the silicon substrate, is an essential requirement for the production of MOS integrated circuits. Many studies have shown (1-4) that oxidation and postoxidation annealing conditions strongly affect the trap densities at the SiO₂-Si inter-

*Electrochemical Society Active Member.

face. Annealing in a H₂ containing atmosphere (1, 3-5) or other annealing procedures (6, 7) are employed for interface-state density reduction. Although the fabrication technology could be improved to achieve interface-state densities at a concentration below $D_{it} = 10^{10}$ cm⁻²eV⁻¹, the current understanding of the structure of these electronic defects and their generation kinetics is still specu-

lative, because too many interacting parameters exist in device processing. Less well studied are the interface-state and bulk-trap generation kinetics for growth and annealing sequences of the SiO₂-Si system at low temperatures as required for VLSI technology. This domain will be especially characterized in this paper.

Several models have been proposed for the microscopic structure of SiO₂-Si interface defects (1, 5, 9-11) to explain various aspects of observed annealing effects and electrical properties. For the perfect SiO₂-Si interface, *i.e.*, when all the Si surface bonds are saturated, no intrinsic defects should appear within the silicon bandgap (12, 13). At present, it is widely accepted that interface states are due to imperfections in the SiO₂-Si interface, *i.e.*, to bonding defects, such as dangling bonds or strained bonds, or to impurity atoms. In all the cases, a strong dependence of the interface-state density on different process variables is expected.

In this paper, we report a detailed experimental study of the interface-state density distribution and the bulk-state density in n-type MOS structures subjected to a postoxidation anneal (POA) in N₂ ambient at temperatures in the range 600°-1150°C to simulate simple device processing steps. Simple MOS capacitors have been employed in this investigation rather than complex devices in order to reduce the number of process steps for sample preparation.

The electronic properties of the SiO₂-Si interface have been characterized by constant capacitance deep level transient spectroscopy (CC-DLTS) (14, 15). Compared to the quasistatic capacitance voltage (CV) method (16), commonly used in MOS interface-state analysis, CC-DLTS is advantageous because of its sensitivity and ability to distinguish between interface states and bulk traps in the silicon substrate. The experimental results presented in the following sections show that interface states and bulk states of intrinsic origin are generated during POA treatment, especially at temperatures below 900°C. It appears that the annealing behavior of interface states in the vicinity of the conduction band edge is different than that of states in the midgap region.

Experimental

Sample preparation.—MOS capacitors were fabricated on (100) silicon wafers (Czochralski-grown or epitaxial) of both n- and p-conductivity type and different resistivity. The standard preoxidation cleaning sequence consists of hot NH₃/H₂O₂, hot HCl/H₂O₂, and HF with rinses in deionized water. The wafers were thermally oxidized in nominally dry oxygen atmosphere at temperatures of 920°, 1020°, and 1120°C to film thicknesses of 60-70 nm and annealed in argon for 15 min at the same temperature. The samples were pulled from the furnace and cooled in argon ambient. The gases were used as delivered by the supplier (< 5 ppm H₂O), without intentionally increasing the H₂O content. The sample and oxidation data are summarized in Table I. The other process parameters were comparable to standard MOS fabrication.

Isochronal postoxidation annealing was performed for 30 min in N₂ atmosphere at temperatures in the range of

Table I. Sample and oxidation data

Material	Oxidation temperature T _{ox} (°C)	Oxidation time t _{ox} (min)	Oxide thickness d _{ox} (nm)
n-Type Epi (1-2 Ω-cm)	920	270	70
p-Type CZ (3-6 Ω-cm)	920	270	67
n-Type CZ (0.2-0.3 Ω-cm)	1020	80	61
p-Type CZ (3-6 Ω-cm)	1020	80	58
n-Type CZ (0.2-0.3 Ω-cm)	1120	15	57.5
p-Type Epi (5-7 Ω-cm)	1120	15	58.5

600°-1150°C. The annealing time was chosen to be comparable with heat-treatments commonly used in implantation damage annealing. After annealing, the samples were pulled from the furnace at cooling rates of greater than 300 K/min. Rapid cooling was used to avoid generation or annealing of defects at intermediate temperatures.

Subsequently, gate electrodes were fabricated by E-gun evaporation of aluminum dots, 200 nm thick and of approximately 0.6 mm diam. As a substrate contact, an aluminum layer was uniformly deposited on the back surface. Finally, the Al contacts were baked at 450°C in N₂ atmosphere for 30 min. On the wafer oxidized at 920°C, additional capacitors having a guard ring with approximately 5 μm spacing from the gate electrode were fabricated.

The gate oxide was removed after metallization in an HF etch on a portion of the wafers to form Schottky diodes by Au or Al evaporation on n- or p-type substrate material, respectively, for the measurements of bulk levels and doping.

Evaluation procedure.—The density of interface states and bulk states in the SiO₂-Si interface region is determined by CC-DLTS. The measurement technique is described in detail elsewhere (14, 15, 17, 18). The basic principle is explained in Fig. 1. Interface states and bulk states are filled with majority carriers (electrons in Fig. 1), when the gate is pulsed to accumulation. After the filling pulse, the SiO₂-Si interface is biased into depletion and the initially occupied states reemit the trapped charge with a time constant, τ (19). For n-type material

$$\frac{1}{\tau} = \sigma_n v_n N_c \exp \left[-\frac{E_c - E_t}{kT} \right] \quad [1]$$

where σ_n is the capture cross section, v_n is the thermal velocity of electrons, N_c is the effective density of states in the conduction band, E_c - E_t is the trap energy in the silicon bandgap, k is the Boltzmann constant, and T the sample temperature.

In the CC-DLTS technique, the depletion capacitance, *i.e.*, the band bending is kept constant during the emission period by adjusting the gate voltage. The gate voltage transient measured at two delay times t₁ and t₂ after the filling pulse comprises the contribution of the continuously distributed interface-state density D_{it} and the bulk-trap density N_T. The CC-DLTS signal ΔV_g is given by

$$\Delta V_g(E_{FS}, T, \tau) = q \int_0^{y_x} \left(\frac{d_{ox}}{\epsilon_{ox}} + \frac{x}{\epsilon_s} \right) N_T [\exp(-t_1/\tau) - \exp(-t_2/\tau)] dx + \frac{q d_{ox}}{\epsilon_{ox}} \int_{E_{FS}}^{E_c} D_{it}(E) [\exp(-t_1/\tau) - \exp(-t_2/\tau)] dE$$

Fig. 1. Schematic band diagram of an MOS structure (n-type) in depletion, illustrating the principle of the CC-DLTS measurement. For a filling pulse to accumulation, the emission of carriers from interface states in the energy interval ΔE and from bulk states in the depth range ΔX contribute to the CC-DLTS signal. The intervals ΔE and ΔX are defined by the interface Fermi level E_{FS} and the Fermi level cross point Y_r. The width of the space charge region X_r varies with the gate voltage V_g applied to the MOS structure.

where q is the electronic charge, d_{ox} is the oxide thickness, ϵ_{ox} and ϵ_s are the oxide and substrate permittivities. For the other abbreviations, refer to Fig. 1.

In the measurement of the spectrum, the CC-DLTS signal is recorded at fixed delay times t_1, t_2 as a function of temperature. Interface states are observed in the CC-DLTS spectra as a continuum and bulk states occurring at discrete energy positions in the gap are observed as peaks. The energy position $E_0 = E_c - E_t$ of trap levels measured at temperature T_0 is calculated from Eq. [1], where the emission time constant is defined by the DLTS delay times (19)

$$E_0 = kT_0 \ln \left(\frac{\sigma_n v_n N_c}{\ln(t_2/t_1)} \right) \quad [3]$$

The interface-state density and the bulk-trap concentration can be evaluated from the CC-DLTS signal by

$$D_{it}(E_0) = \frac{\epsilon_{ox}}{d_{ox}} \frac{\Delta V_g(T_0)}{qkT_0 \ln(t_2/t_1)} \quad [4]$$

$$N_T(E_0) = \frac{2\epsilon_s C_{ox}}{q} \frac{\Delta V_{max}(T_0)}{[\exp(-t_1/\tau) - \exp(t_2/\tau)] (2\epsilon_s A y_r + C_{ox} y_r^2)} \quad [5]$$

where C_{ox} is the oxide capacitance and A is the capacitor area. ΔV_{max} is the peak maximum attributed to bulk states. In order to convert the CC-DLTS spectra recorded as a function of temperature into an energy spectrum, a constant capture cross section $\sigma_p = \sigma_n = 10^{-15} \text{ cm}^2$ is assumed in the evaluations of Eq. [3] and [4].

Results

Interface-state density distribution.—The interface-state density distribution in the silicon bandgap is shown in Fig. 2 for as-oxidized samples. States in the upper half of the bandgap are measured on n-type samples, and states below midgap on p-type samples. The peaks near midgap superimposed on the continuous spectra of interface states are caused by bulk states in the SiO_2 -Si interface space charge region. These peaks will be further discussed in the following section.

The interface-state distribution varies significantly with the oxidation temperature. For MOS capacitors oxidized at 920°C , the interface-state density decreases continuously from the conduction bandedge to the valence bandedge, while for the higher oxidation temperature of

Fig. 2. Interface-state densities in the silicon bandgap for MOS structures oxidized at 920°C , 1020°C , and 1120°C . States in the upper half of the bandgap were observed on n-type MOS capacitors, and those below midgap on p-type samples.

1120°C a broad maximum in the midgap region appears. The decrease in interface-state density towards the valence bandedge visible in Fig. 2 is frequently observed in DLTS experiments (5, 20-22). This decrease is in contrast to the U-shaped interface-state distribution observed in quasi-static CV data for the as-oxidized SiO_2 -Si interface (3). In quasi-static CV measurements taken on the samples of Fig. 2, we obtain a flat interface-state distribution in the midgap region ($E_t \pm 0.3 \text{ eV}$) at densities of $D_{it} = 1.4 \times 10^{10} \text{ cm}^{-2} \text{ eV}^{-1}$. A decrease in density below midgap is not observed. The reason for this discrepancy is still not clear. It may be caused by the limited accuracy of the CV technique or by the presence of slow states near the valence bandedge as reported by Sher *et al.* (23).

Slow states which do not emit the trapped charge at time constants of less than 100 ms do not contribute to the CC-DLTS signal, but they can still be measured by the quasi-static CV method. Near the conduction bandedge, slow states are not reported. The annealing data are therefore only presented for n-type samples.

The interface-state density distribution for MOS capacitors oxidized at $T_{ox} = 920^\circ\text{C}$ and annealed at various temperatures prior to metallization are shown in Fig. 3. The spectra were recorded at DLTS delay times of $t_1/t_2 = 2/4 \text{ ms}$ and $t_1/t_2 = 20/40 \text{ ms}$, respectively. Peaks appearing near midgap are attributed to bulk traps as mentioned above. Compared to the unannealed reference sample, the interface-state density is reduced by a postoxidation anneal in nitrogen at a temperature $T_A = 1075^\circ\text{C}$, higher than the oxidation temperature. Only a slight slope towards higher values at the conduction bandedge is observed. For annealing temperature $T_A = 600^\circ\text{C}$, POA results in an increased trap density near midgap; however, near the conduction bandedge, the interface-state density is the same as before annealing. It is noted that the shape of the

Fig. 3. Interface-state density distribution for MOS capacitors oxidized at $T_{ox} = 920^\circ\text{C}$ and subjected to different POA treatments: without POA (top), POA at 1075°C (middle), and POA at 600°C (bottom). The CC-DLTS spectra were recorded at delay times of $t_1/t_2 = 2/4$ and $20/40 \text{ ms}$, respectively. An approximate energy scale is given at the top.

energy distribution of interface-state density changes considerably with the POA temperature from a decreasing to an increasing distribution.

In order to characterize the annealing effects, we have plotted in Fig. 4-6 the interface-state density at two energy positions of $E_c - 0.4$ eV and $E_c - 0.15$ eV as a function of the POA temperature for samples oxidized at 920°, 1020°, and 1120°C, respectively.

The CC-DLTS spectra of all the samples indicate a smooth continuous interface-state distribution without any distinct structure. Independent of oxidation conditions, the lowest midgap values of D_{it} are measured for samples which received a POA at temperatures of 900°-1000°C and an increased density is observed for POA temperatures of less than 800°C and higher than 1000°C. A similar temperature dependence is observed for the shallow interface states ($E_c - 0.15$ eV) on MOS structures oxidized at 920° and 1120°C. The shallow interface states in samples oxidized at 1020°C are not affected by POA. However, in all the cases the interface-state density is lower near the conduction bandedge than near midgap after 600°C annealing. In general, the effect of a POA treatment on shallow interface states is weaker than that on deep interface states.

Midgap interface-state density and oxide charge.—Interface-state densities and flatband voltages evaluated from standard high frequency and quasi-static CV curves are shown in Fig. 7 and 8, respectively. Since reliable interface-state densities near the bandedges cannot be determined by this technique, only midgap values of D_{it} are presented in Fig. 7 for samples oxidized and annealed at various temperatures as indicated. The trap densities deduced from CV measurement agree quite well with the CC-DLTS results of Fig. 4-6 for midgap states. In the temperature range $T_A < 900^\circ\text{C}$, where the interface-state density increases, a large shift in flatband voltage up to -10V is observed. A shift in flatband voltage of $\Delta V_{FB} = -1\text{V}$ corresponds to an increase in oxide charge of approximately $Q_{ox} = -C_{ox}/A \Delta V_{FB} = 3 \times 10^{11} \text{ cm}^{-2}$, assuming that the charge centroid is located in the vicinity of the SiO_2 -Si interface (2). The CV curves taken at room tem-

Fig. 4. Interface-state densities at energy positions of $E_c - E_{it} = 0.4$ eV and $E_c - E_{it} = 0.15$ eV for samples oxidized at 920°C and annealed at temperatures $T_A = 600^\circ\text{C}$ -1150°C.

Fig. 5. Interface-state density as a function of POA temperature for MOS capacitors oxidized at 1020°C.

perature show no hysteresis and no shift in flatband voltage during bias stressing, thus indicating that only a negligible amount of mobile oxide charge is present at this temperature. A mobile oxide charge caused by sodium or hydrogen ions (2) can therefore be ruled out.

Bulk states.—Bulk states in the space charge region of the silicon substrate of MOS structures cause discrete energy levels in the bandgap and are therefore observed as peaks in the CC-DLTS spectra. The peak height of bulk levels is proportional to the measurement volume, i.e., the width of the space charge region (see Fig. 1). The peak height is therefore dependent on the surface potential ψ_s or the sample capacitance C_r . The CC-DLTS spectra shown in Fig. 9 are obtained on an MOS structure having

Fig. 6. Interface-state density as a function of POA temperature for MOS capacitors oxidized at 1120°C.

Fig. 7. Midgap interface densities measured by the quasi-static CV method for the samples of Fig. 4-6.

a guard electrode. Surface potentials are determined by high frequency CV measurements. By applying a guard electrode voltage $V_1 = -8V$, the inversion capacitance is reduced from 105 to 89 pF, thus indicating that deep depletion is achieved at the interface and that minority carrier buildup in an inversion layer can be neglected. The peak of bulk traps appearing at approximately 270 K is very sensitive to the variation of the quiescent capacitance C_i in the CC-DLTS measurement. The peak temper-

Fig. 8. Flatband voltages derived from high frequency CV measurements for the samples oxidized and annealed at different temperatures as indicated.

Fig. 9. CC-DLTS spectra for a MOS capacitor ($T_{ox} = 920^\circ C$) having a guard ring. Measurements are obtained at different sample capacitances C_i (i.e., different surface potentials). V_1 is the voltage applied to the guard electrode. The peak appearing in the spectra is due to a deep bulk trap. The energy position of the bulk trap ($E_c - E_T = 0.5$ eV) is derived from the Arrhenius plot of the emission time τ shown in the insert. The emission time τ is determined from DLTS results by the relation $\tau = (t_2 - t_1) / \ln(t_2/t_1)$.

ature position, however, is independent of the capacitance in all the three spectra, thus indicating the absence of recombination effects in the DLTS spectra. The Arrhenius plot of the peak temperature *vs.* the emission time constant is shown in the insert. A trap energy of $E_c - E_T = 0.5$ eV and a capture cross section $\sigma_n = 6 \times 10^{-14}$ cm² is derived from the slope. The bulk-trap density calculated by Eq. [5] is $N_T = 6 \times 10^{14}$ cm⁻³. A detailed analysis of the peaks observed in the CC-DLTS spectra (see Fig. 2 and 3) shows that bulk traps are present in nearly all the MOS structures used in this study. These bulk traps are located deep in the bandgap except in two samples, where two additional shallow traps are observed.

The trap level energies and the corresponding trap densities are summarized in Fig. 10 and 11. The deep bulk traps have identical energy position ($E_c - E_T = 0.5 \pm 0.03$ eV) within the overall error independent of oxidation and POA conditions. We therefore conclude that the origin of the deep traps is identical. A correlation between a special process parameter and a specific trap level could not be observed.

In MOS capacitors annealed at 900°C, no bulk traps were resolved by CC-DLTS. The detection limit for deep

Fig. 10. Energy position of the bulk traps observed in the MOS structures after various oxidation and anneal treatments.

Fig. 11. Bulk-trap density in the immediate vicinity of the SiO_2 -Si interface (< 100 nm). Only the density of the deep states ($E_c - E_T = 0.5$ eV) in Fig. 10 are depicted.

bulk traps is rather high, approximately $N_T = 5 \times 10^{13}$ cm^{-3} , because of the narrow depletion region in MOS structures. The density values in Fig. 11 represent traps located in the immediate vicinity (< 0.1 μm) of the SiO_2 -Si interface. In order to measure concentrations of bulk traps deeper in the substrate, CC-DLTS measurements were performed on Schottky diodes. These spectra show no bulk-trap densities larger than $N_T = 5 \times 10^{12}$ cm^{-3} in a depth range of 0.2-1 μm from the metal electrode. The deep traps observed in MOS structures seem to appear only in the immediate SiO_2 -Si interface region. The trap density decreases by more than three orders of magnitude within the first 2000Å from the interface in samples annealed at 600°C.

Discussion

Annealing of interface states.—Data reported in the literature show that there is still a controversial discussion on the annealing behavior of trap states at the SiO_2 -Si interface in contrast to annealing effects for oxide charges where better agreement is established. It has been emphasized by Razouk *et al.* (3, 24) that the final interface-state density distribution in the SiO_2 -Si system depends on a variety of process variables, such as oxidation and pull/cool conditions, *in situ* POA, POA in argon or nitrogen ambient, anneal time, metallization procedure, and postmetallization anneal (PMA).

The interface-state density distributions presented in this paper as shown in Fig. 2 do not represent the properties of a simple as-oxidized SiO_2 -Si interface. The 15 min *in situ* POA included in the oxidation process is believed to considerably reduce the interface-state density in the upper half of the bandgap (25), compared to that of the as-oxidized cases. Various hydrogen species needed for interface-state annihilation by complexing at low temperatures (500°C) (6) are generated by the reaction of aluminum with water vapor absorbed in the oxide (4). This assumption is supported by the observation of the flat interface-state distribution detected on samples oxidized at 1020°C (see Fig. 2). The interface-state spectra are in agreement with results published in Ref. (3) for MOS structures after a hydrogen anneal.

An oxidation temperature effect visible in Fig. 2 indicates that the PMA process is not completely controlling the interface-state distribution and that the oxidation conditions prior to the annealing affect the density. In particular, for samples oxidized at temperatures below 1000°C, an interface-state density increasing towards the conduc-

tion bandedges was also found in previous investigations of MOS structures annealed in forming gas (27) or subjected to hydrogen "layer" annealing (5, 8).

Nitrogen POA at elevated temperatures is commonly applied in device processing to reduce fixed oxide charges (Q_{ox}). However, for prolonged N_2 anneal an increase in the values of Q_{ox} after an initial decrease has been reported (24, 28-30), which is explained by the formation of Si_3N_4 at the interface. For our samples, a serious effect of such nitrogen reaction is not expected because a thick oxide layer (60-70 nm) is used and because only short annealing times (30 min) are applied.

Recently, it has been shown by Akinwande *et al.* (31) that long anneal times of up to several hours have to be used to reach steady-state values of Q_{ox} for argon annealing at temperatures below 800°C. The results presented in Fig. 8 for the flatband voltage, although showing a similar temperature dependence as the data in Ref. (31), may therefore still deviate from that for the equilibrated SiO_2 -Si interface. We believe that the same argument is probably valid for the interface-state density values of the samples annealed at temperatures $T_A < 900^\circ\text{C}$, because a strong correlation between interface-state density and oxide charges is established in Fig. 4-8. For nitrogen POA, a correlation of D_{it} and Q_{ox} values is, however, not generally observed by other authors (4, 24). We do not know the differences in the material and processing data that cause the differing behavior, and thus we cannot comment on this discrepancy.

Our results show that POA affects the residual interface-state density, even when PMA is applied. This observation is confirmed by two-step annealing experiments, where the annealing sequence consists of an initial anneal at 1150° or 700°C followed by an anneal at the oxidation temperature of 920°C. The CC-DLTS spectra of samples without POA, with one-step annealing, and with two-step annealing clearly show variations due to the various process steps. The residual interface-state density distribution is therefore determined by the entire processing history and not only by the final high temperature process. The annealing behavior of interface states illustrated in Fig. 4-6 is mainly caused by the nitrogen POA.

The essential result of our study is the difference in annealing behavior for interface states near midgap and those near the conduction bandedge. For low POA temperatures ($T_A = 600^\circ\text{C}$) the interface-state density decreases towards the conduction bandedge independent of oxidation conditions, while after high temperature POA ($T_A > 900^\circ\text{C}$) the interface-state density increases. The lowest density values were observed after POA at 900°-1000°C in accordance with observations of Yeow *et al.* (26).

Origin of interface states.—It is clear that microscopic models for the origin of interface states cannot be deduced unambiguously from electrical measurements such as CC-DLTS. We can only give some arguments to rule out unintentional impurities introduced during oxidation and annealing as an origin for the observed effects.

Contamination with alkali ions, especially Na^+ , cannot explain the large negative shift of the flatband voltage observed after low temperature annealing ($T_A < 900^\circ\text{C}$). Although there is some evidence for the presence of electrically inactive Na^+ ions in the SiO_2 -Si system (24), we do not believe that complete passivation of Na^+ occurs after annealing at high temperatures, where low negative flatband voltages are observed. Na^+ ions are also assumed to cause a band tail of interface states near the conduction bandedge (14, 32), which is not observed in our measurements. We therefore conclude that the alkali-ion contamination level is sufficiently low in our samples not to affect the interface-state density.

Other possible contaminations are metallic impurities which may act as charges in the oxide (24) or as electronic traps in the SiO_2 -Si interface region (33-35). For impurities introduced during processing, we expect an increased contamination level at elevated temperatures and diffusion of the contaminant into the substrate. If impurities

are present, the well-known trap levels related to metallic impurities should be detected in the CC-DLTS spectra of the Schottky diodes. Such trap levels were not resolved at concentrations exceeding the detection limit of $N_T = 5 \times 10^{12} \text{ cm}^{-3}$. Metallic impurities are therefore believed to cause only a negligible distortion in the interface-state distribution. The MOS structures studied in this work are assumed to exhibit the properties of the intrinsic SiO_2 -Si interface.

It is widely accepted that interface states of intrinsic type are associated with structural defects in a disordered interfacial transition layer (24, 36). The presence of interfacial layers has been demonstrated with various analytical techniques by several authors (37-39). Structural defects, e.g., strained bonds or dangling bonds residing in the interfacial region, may cause electronic traps as well as fixed oxide charges. The correlation of interface-state density and oxide charge observed during POA supports an interpretation by the same origin. According to Akinwande *et al.* (31), the distinct breakpoint at annealing temperature of $T_A \approx 900^\circ\text{C}$ for interface-state density and oxide charge observed indicates a change in the generation process, e.g., by the formation of mechanical stress. This breakpoint at about 900°C nearly coincides with the viscous flow threshold of thermal oxides $T_c \approx 965^\circ\text{C}$ (40). Stress in the oxide and interface defects related to it is not removed by elastic flow when annealing is carried out at temperatures below 900°C . It is also possible that defects are generated during annealing in the presence of mechanical stress. A direct correlation between stress distribution at the SiO_2 -Si interface and generation has been reported for radiation-induced interface states (41).

Bulk states.—We also observe a steep increase in bulk-trap density in the same temperature range ($< 900^\circ\text{C}$) where interface states and oxide charges are generated during POA. All the three types of defects, oxide charge, interface traps, and bulk traps are therefore correlated. The trap density profiles measured depict a maximum in trap density right at the interface, thus indicating that the deep trap levels ($E_c - E_t \approx 0.5 \text{ eV}$) may be attributed to a specific interface defect. At an energy position near midgap, oxidation-induced defects (42) and interface defects in MOS structures (18, 43) are frequently reported. Interstitial silicon atoms generated during oxidation may also cause a deep trap level at the SiO_2 -Si interface (44). The concentration of interstitial silicon in the interface region increases with oxidation rate (45), i.e., higher oxidation temperature. Because this dependence on oxidation temperature was not observed in Fig. 11, we conclude that the deep traps detected at energy $E_c - E_t = 0.5 \text{ eV}$ are not directly related to interstitial silicon atoms. A possible origin for the deep bulk traps associated with structural defects in the SiO_2 -Si interface region are silicon dangling bonds (12). This assumption would easily explain the strong correlation between interface states and bulk states mentioned above. At present, we can only speculate on the exact nature of bulk traps because the data are insufficient for the drawing of further conclusions.

Summary

The CC-DLTS technique was applied to study the interface-state distribution and the bulk-state density in MOS structures after oxidation and postoxidation nitrogen annealing. Oxidations were performed in dry oxygen ambient at temperatures of 920°C - 1120°C . The interface-state distribution was not found to be U-shaped in the silicon bandgap. Instead, for 920°C oxidation, the interface-state density decreases monotonically from the conduction bandedge to the valence bandedge, and, for 1120°C oxidation, a flat maximum was observed near midgap.

The postoxidation annealing behavior of interface states and bulk states in the upper half of the bandgap was investigated in the temperature range of 600°C - 1150°C . Annealing at temperatures $T_A < 900^\circ\text{C}$ generates both interface states and bulk states. The increase in interface-state density is more pronounced for states near midgap

than for states near the conduction bandedge. After a 600°C temperature treatment, the interface-state density decreases towards the conduction bandedge. For annealing at elevated temperatures $T_A > 1000^\circ\text{C}$, the slope in the energy distribution is reversed.

Deep bulk traps at an energy of $E_c - E_t \approx 0.5 \text{ eV}$ are detected in the immediate vicinity of the SiO_2 -Si interface by CC-DLTS. Specific process parameters which cause these trap levels could not be identified. The bulk-trap densities up to $N_T = 10^{16} \text{ cm}^{-3}$ have been measured in the region within 1000\AA of the interface after 600°C annealing. A strong correlation in the annealing effects of fixed oxide charges, interface-state density, and bulk-trap density has been established.

An Analysis of Particle Adhesion on Semiconductor Surfaces

R. Allen Bowling*

Texas Instruments Incorporated, Materials Science Laboratory, Dallas, Texas 75265

ABSTRACT

This paper constitutes an analysis of the forces of adhesion of small particles to surfaces, most specifically as applied to semiconductor surfaces. The primary forces of adhesion of small, less than 50 μm diam particles on a dry surface are van der Waals forces. These van der Waals forces of adhesion can increase as a function of time due to particle and/or surface deformation which increases the contact area; micron-size particles can be held to surfaces by forces exceeding 100 dyn, which corresponds to pressures of 10⁹ dyn/cm² or more. Total forces of adhesion for micron-size particles exceed the gravitational force on that particle by factors greater than 10⁶. Electrostatic forces only become important and predominate for particles larger than 50 μm diam. Immersion of the adhered particle system can, in some cases, greatly reduce the total adhesion force, first by shielding of the electrostatic and van der Waals attractions, and also by adding double layer repulsion because of dipolar alignment of liquid molecules or dissolved ions at the surfaces. Double layer interactions may, however, also add to the attractive forces if dipoles align properly for attraction. An important consideration is the possibility that if the particles are not removed by the liquid immersion, then a liquid bridge can be formed by capillary action between the particle and surface upon removal from the liquid. This would add a very large capillary force to the total force of adhesion. This capillary force has been shown to remain, in some cases, even when the system is baked at above the liquid boiling point for more than 24h. Removal of these small particles from surfaces is in theory possible but is in practice extremely difficult. It is clear that emphasis should be placed on prevention of particle deposition rather than on counting on achieving subsequent removal.

A basic understanding of particle adhesion is vital to the search for ways to insure the particle-free semiconductor processing needs of the future. It may be very important in increasing our understanding of how to better remove particulates from wafer and IC surfaces. Particles are known to have, even at present, a very dramatic effect on the manufacture of IC's and are a major yield loss factor. Particles will only become more important as the size of individual semiconductor operational units decreases (1). The present analysis was undertaken with those thoughts in mind, principally to try to understand ways of most effective particle removal from silicon wafers. As will become apparent from the presentation of the findings, it is probable that the most effective efforts may be to prevent particle adhesion in the first place. Information about particle adhesion mechanisms can also aid one in more effective particle prevention. A general summary of some basic concepts about particles is given below, followed by discussions of the forces which control basic particle adhesion to surfaces.

General particle information.—Particles are present all around us in the atmosphere in great abundance. They include, for example, pollens, dusts, fibers, metals, metal oxides, hydrocarbons, and organic matter. They are generated by several means, including mechanical abrasion, chemical reactions, and combustion processes. People are large sources of particles in a semiconductor production facility, e.g., from their clothes, from their skin and hair, and from their breath, particularly if they smoke. Particles adhere to surfaces with great tenacity. One needs only to invert a surface with adhered particles to realize that, even for particles that are quite large, the adhesion force is greater than the gravitational force on those particles. Similarly, vigorous blowing of the surface only manages to dislodge relatively few of the largest particles

(2, 3). The total adhesion force on a particle, as will be shown later in this paper, decreases approximately linearly as a function of the diameter of the particle. On the other hand, the weight of a particle decreases as a function of the diameter cubed, i.e., volume reduction. This means that, for most particles, the adhesive force is about equal to the weight of the particle for particles with diameters ranging from about 0.01 to 1 mm. For a 1 μm diam particle, the force of adhesion easily exceeds the force due to gravity by a factor greater than 10⁶ (4).

The term adhesion describes particle attachment to a surface, and general particle-particle attachment is called agglomeration. Due to adhesion of particles to each other, agglomerates are more frequently encountered than individual particles. Smaller particles, less than 0.5 μm diam, exhibit more violent Brownian motion in air and thus have greater opportunity to collide to form an agglomerate or flocculated mass (5). Particle deposition and removal are also distinctly different. Removal is further complicated over the original deposition because of deformation of the particle at the point of contact, which causes increased contact area and allows chemical bond formation (6).

Typical particles are also not spherical. They are more often agglomerated chains or flocculates of nonuniform shapes. Mechanically generated particles from abrasion processes tend to be quite large, usually greater than 1 μm diam. Vaporization generated particles, e.g., from chemical reactions and combustion processes, are generally very small, typically less than 0.5 μm diam. The distribution of particles in the atmosphere typically reflects these facts by being bimodal with a large number of particles peaking in the range 0.2-0.3 μm diam and a large number of particles peaking at 10-20 μm diam. Also, in general, the smaller the particle, the greater the number of particles of that size in the atmosphere; the number of particles increases as particle sizes decrease as a function

*Electrochemical Society Active Member.

of the reciprocal diameter cubed, d^{-3} . This increase in number of particles as particle size decreases, however, probably begins to turn down at diameters ranging from 0.01 to 0.1 μm due to agglomeration (7, 8).

Filtration of gases and liquids is very important in semiconductor production. Filtration removal of particles from gases is achieved as the result of three basic mechanisms, interception in which the particle is larger than the filter "pore" sizes, inertial impaction of particles into the filter material or strands, and diffusion, *i.e.*, Brownian statistical movement, with subsequent adhesion to the filter material. This differs drastically from fluid filtration which is achieved only by particle interception. Thus the filtration of gases is generally most effective for very small particles with high diffusive movement, and for larger particles that can be easily intercepted or impacted. The particle diameter region of least efficiency for standard HEPA¹ filters is typically around 0.3 μm or less (9, 10). Also, constant point-of-use recirculating filtration of process liquids can be vital to the reduction of particles on devices as a result of liquid processing. We already seem to realize the need for constant air refiltration and constant downward air flow in the reduction of particles from the atmosphere in clean rooms. These are both best understood by considering the gravitational settling rates of particles in solutions and in air. A typical 1 μm -diam particle would require about 50 min to settle 1 ft in air and would require over 5000 min to settle 1 ft in water. Thus, one can see that natural removal of particles by their own gravitational fall does not work. Conscious efforts must be made to remove them and to continue to remove them as new particles are being added to the processing medium.

Particle adhesion mechanisms.—There are, to date, practically no physical models of adhesion which relate adhesive strength to established fields of physics. The difficulties arise from the fact that adhesion strength is a mixture of physical and chemical forces and mechanical strains and stresses, all at and around the adhesive interface. Also, adhesion forces can only be measured destructively. Therefore, an adhesion measurement does not represent an equilibrium situation, so that a kinetic model of adhesion is required. Adhesion must thus usually be approximated geometrically by a sphere on a flat surface (11). The discussions below on adhesion mechanisms all initially assume a spherical particle on a flat surface. The effects of nonspherical particles and rough surfaces are discussed and quantified when possible. The discussions are also primarily theoretical because of the problems in making measurements of adhesive force for very small particles. A typical measurement method is to apply a force for removal by spinning the surface with the attached particles and monitoring the rotation rate at which particles are removed. Removal of 1 μm diam particles, however, are impossible by this method; they would require forces greater than 10^7g , which corresponds to rotation rates greater than 10^6 rotations per minute, a rate not obtainable for known materials. This fact emphasizes the magnitude of adhesive forces, which can be quite large for particles even as large as 10-50 μm in diameter.

Total forces of adhesion of small particles to surfaces can range from a total of 10^{-5} to 10^2 dyn. This total force can correspond to a tremendous force per unit area of up to $>10^9$ dyn/cm² for micron-size particles. Interactions between solids which bring about adhesion can be classed into several groups. Group I includes long-range attractive interactions which act to bring the particle to the surface and establish the adhesive contact area. These include van der Waals forces, electrostatic forces, and magnetic attractions. Electrostatic attractions include both bulk excess charge image forces and electrostatic contact potentials, also known as electrical double layer forces. Group II includes other forces which, along with group I forces, establish the adhesive area. This group of interfacial reactions includes sintering effects such as dif-

fusion and condensation, diffusive mixing, and mutual dissolution and alloying at the interface. This category also includes the establishment of liquid and solid bridges between particle and surface, and the consequential capillary forces associated with these phenomena. Group III includes very short range interactions which can add to adhesion only after the establishment of an adhesive contact area. It includes chemical bonds of all types and intermediate bonds such as hydrogen bonds (11, 12).

In general, the quantitative treatment of group II and III adhesive forces are very difficult because they are primarily specific to each case, being dependent upon the particle and surface materials. The sections below will thus primarily treat group I only. The effects of capillary forces, from group II, will also be discussed and quantitatively treated. This essentially ignores a general treatment of complex chemical bonding to surfaces. We do know, however, that chemical bonds play an important role in particle adhesion on silicon surfaces. For example, it has been shown that silicon particles on a silicon surface can oxidize along with the surface and effectively become entrapped in the oxide; HF cleaning can be important to the removal of the oxide, thus allowing the particle to be removed by other means. The outer surface of silicon is also known to have a large number of "dangling" —OH groups, called a silanol surface. Molecules which themselves have —OH groups can form strong estersil bonds with this silanol surface. The remaining Si—O—Si surface of silicon can also hold many species by hydrogen bonding at the electronegative oxygen atoms. All these effects must be considered when trying to remove particles, but none of these bonding factors are general enough to be treated in a quantitative manner as a function of particle size. One important factor in ignoring these in a general treatment is that bonding and interfacial reactions are not generally very active at room temperature. Higher temperatures are required for most materials before these become significant.

The primary forces which act to bring particles to a surface and then hold them there are van der Waals forces and electrostatic forces. Electrostatic forces predominate for large particles, *i.e.*, greater than about 50 μm diam. Van der Waals forces, however, predominate for smaller particles. Electrostatic forces are comprised of two types of forces, excess charge image forces and electrostatic contact potentials, also known as electrical double layer forces. For dry uncharged particles on a dry uncharged surface, only van der Waals and electrical double layer forces will act to hold the particles on the surface, *i.e.*, specifically if no bonding or other interfacial reactions can occur for the materials. Charged particles and/or charged surfaces then add an additional electrostatic image force. Wet systems can then have an additional capillary force acting to hold the particles, and immersed systems may experience a shielding of each of these forces so that the total force holding the particles is reduced. As follows, the individual forces for dry particle systems will be described followed by a treatment of wet and immersed systems.

Van der Waals Forces.—Van der Waals forces can be understood as follows. Even at absolute zero temperature, solids can contain local electric fields which originate from polarizations of the constituent atoms and molecules. Above zero degrees, additional contributions come from thermal excitations of the atoms and molecules. As explained by quantum theory, the electrons of an electrically neutral solid do not occupy fixed states of a sharply defined minimum energy which results in spontaneous electric and magnetic polarizations varying quickly with time (11). Van der Waals forces thus include forces between molecules possessing dipoles and quadrupoles caused by the polarizations of the atoms and molecules in the material. This can include both natural as well as induced instantaneous dipoles and quadrupoles. The nonpolar van der Waals forces are also referred to as London-

¹High efficiency particulate air filter.

van der Waals dispersion forces because London associated these forces with the cause of optical dispersion, *i.e.*, spontaneous polarizations (5, 13, 14). This dispersion force will make the major contribution to the intermolecular force, except in the case where the polarizability is small and the dipole moment is large. These forces are postulated by some to be additive for assemblies of atoms and molecules. This assumption has been used to calculate the van der Waals force using a microscopic approach which starts from interactions between individual atoms or molecules and calculates the attraction between larger bodies as an integration over all pairs of atoms and molecules (2, 3, 5). This method has been used by Hamaker (15). His method uses the so-called Hamaker constant, A , whose value is not measurable and is definable by order of magnitude only. This approach has severe shortcomings because linear additivity is actually not correct, as it does not consider cross correlation of charge (11, 16). One author has stated that the Hamaker approach is in certain cases "not only inaccurate but also downright misleading as to the laws of force" (6). A more satisfactory macroscopic approach was developed by Lifshitz, who started directly from the bulk optical properties of the interacting bodies (17). In this approach, the decisive material value is the Lifshitz-van der Waals constant, h , which is defined as an integral function of the imaginary parts of the dielectric constants of the adhering materials (6, 11, 16, 18).

This constant, h , depends only on the materials involved, provided the separation distance is very small. Under some conditions, the Lifshitz-van der Waals constant may be related to the Hamaker constant by the equation, $h = 4\pi A/3$ (4). This Lifshitz-van der Waals constant generally ranges from about 0.6 to 9.0 eV, depending on the materials combination (16). Qualitatively, since this constant is related to the optical absorptivity of a material, materials with strong optical absorption have strong spontaneous fields and thus should be bound by greater forces of adhesion due to van der Waals (vdW) attractions. The force per unit area between two parallel flat surfaces in contact can be exactly calculated to be

$$\frac{F(\text{vdW})}{\text{cm}^2} = \frac{h}{8\pi^2 z^3}$$

where z is the atomic separation between the surfaces (11, 16, 12). The van der Waals adhesion force between a spherical particle and a flat surface reduces in approximation to

$$F(\text{vdW}) = \frac{hr}{8\pi z^2}$$

where r is the particle radius. This formula treats the force of adhesion as the force necessary to remove the particle, and as such it is a maximum force under ideal conditions for a perfectly spherical particle on a flat surface. This formula can be further reduced by substituting $d/2$ for r , and assuming an adhesion distance, z , of about 4Å. The formula becomes

$$F(\text{vdW}) = 2hd \text{ mdyn}$$

where d is the particle diameter in microns. The constant, h , ranges from about 0.6 eV for polymers to about 9.0 eV for metals such as silver and gold. In Table I are shown some typical particle/surface van der Waals constants.

From a 1 μm-diam particle with a constant of 0.6 eV to a 100 μm-diam particle with a constant of 9.0 eV, the van der Waals force can range from about 1 mdyn to 1800 mdyn. This corresponds to a force per unit area of from about 0.2×10^9 to 3.0×10^9 dyn/cm². These are tremendous pressures, and most particles and/or surfaces can be deformed by such forces. The amount of deformation depends on the hardness of the particle and surface, and this deformation can increase with length of time that the force acts on the particle and surface. From this, it can be readily seen that the time to remove particles is as soon as possible after they are deposited. A time delay can allow

Table I. Empirically determined Lifshitz-van der Waals constants [data from Ref. (4) and (11)]

Particle	Surface	h (eV)

Cu	Cu	8.5
Ag	Ag	9.0

the force of adhesion to increase dramatically. The additional van der Waals force due to deformation is a function of the increased contact area caused by this deformation and is given by

$$F(\text{vdW deform.}) = \frac{h\rho^2}{8\pi z^3}$$

where ρ is the radius of the adhesive surface area. This reduces, for z of 4Å, to

$$F(\text{vdW deform.}) = 9.96 \times 10^3 h\rho^2 \text{ mdyn}$$

for ρ in microns. The total van der Waals force is then

$$F(\text{vdW total}) = F(\text{vdW}) + F(\text{vdW deform.})$$

If the contact of a 5 μm-diam particle is increased from point contact to a 0.05 μm radius area by deformation, and assuming h is 7 eV, the $F(\text{vdW deform.})$ can be 174 mdyn, which is much greater than the 70 mdyn normal $F(\text{vdW})$ of the system. This is only a 2% deformation of the particle, *i.e.*, the 5 μm-diam particle is flattened only to the point of having a 0.1 μm-diam contact area. The $F(\text{vdW deform.})$ would increase by a factor of five if the deformation were increased to a 0.5 μm-diam area, or 10%. This new contact area, and thus the $F(\text{vdW deform.})$, depends on the hardness of the particle and surface materials. Softer materials yield to greater deformations and thus greater forces of adhesion. In general, the constant, h , is also much smaller for soft materials. This means that the greatest forces of adhesion are generally for soft materials bound to a metal. The metal gives the combination a greater h and the soft material gives greatest added deformation. A hard oxide layer on a metal surface, on the other hand, tends to reduce adhesion of hard particles to that surface. Figure 1 is a graph of $F(\text{vdW})$ and $F(\text{vdW deform.})$

Fig. 1. $F(\text{vdW})$ and $F(\text{vdW deform.})$ as a function of particle diameter

form.) *vs.* particle diameter for materials combinations of 4 eV and 8 eV and 1% and 5% deformation. It shows the $F(\text{vdW})$ without deformation for h equal to 4 eV and 8 eV, plus the additional force due to deformation of 1% and 5% for h equal to 8 eV. It clearly shows that deformation can add tremendously to the total force of adhesion. A first look at these plots should not be incorrectly interpreted that the forces of adhesion simply decrease with decreasing particle diameter. Although the total force does decrease, the force per unit area increases with decreasing particle size, and the force of adhesion also increases relative to the gravitational force acting on the particle. These relationships will be further discussed later.

Electrostatic forces.—Two types of electrostatic forces may act to hold particles to surfaces. The first is due to bulk excess charges present on the surface and/or particle which produce a classical coulombic attraction known as an electrostatic image force. This attractive force is given by the equation

$$F(i) = \frac{q^2}{4\pi\epsilon_0 E l^2}$$

where E is the dielectric constant of the medium between the particle and surface, E_0 is the permittivity of free space, q is the charge, and l is the distance between charge centers. The distance between charge centers is in this case approximately equal to $2r$, where r is the particle radius, and q can be expressed as a function of the particle radius by the expression

$$q = CU = 4\pi\epsilon_0 rU$$

where C is capacitance, and U is the potential in volts. The capacitance has been expressed as a function of r via an approximation of the Euler equation. The expression for total image force then reduces as a function of particle diameter, d , in approximation to

$$F(i) = 3 \times 10^{-2} d^2 \text{ mdyn}$$

where d is the particle diameter in microns. This equation assumes a charge density of 10 electronic charges per square micron, what might be considered a typical large charge. The maximum charge density normally possible is about 100 electronic charges per square micron, which corresponds to a flashover potential of about 20,000 V/cm. It is important to note that for conductors, these excess charges are balanced by contact charge flow so that adhesive forces by electrostatics is small. On the other hand, for nonconductors, electrostatic attraction is significant.

The more important electrostatic force for very small particles is electrostatic contact potential induced electrical double layer forces. Two different materials in contact develop a contact potential caused by differences in the local energy states and electron work functions. Electrons are transferred from one solid to another until an equilibrium is reached where the current flow in both directions is equal. The resulting potential difference is called a contact potential difference, U , which generally ranges from 0 to about 0.5V. It sets up a so-called double layer charge region. In the case of two metals in contact, only the surface layer carries contact charges. For semiconductors and insulators, these regions may extend into the bulk up to 1 μm or deeper. For a particle on a surface, this double layer force can be calculated as

$$F(\text{el}) = \frac{\pi E_0 r U^2}{z} \text{ dyn}$$

which reduces to

$$F(\text{el}) = 4dU^2 \text{ mdyn}$$

where d is in microns and U is in volts. For a maximum of potential difference of 0.5V, $F(\text{el})$ is approximately equal to d mdyn (4, 11 19). Figure 2 is a comparison of the van der Waals forces and electrostatic forces of particle adhe-

Fig. 2. $F(\text{vdW})$ in comparison to electrostatic forces of adhesion as a function of particle diameter.

sion *vs.* particle diameter. It is clear, at least for these ideal calculations, that the van der Waals forces predominate over electrostatic forces for very small particles. Double layer electrostatic forces also generally predominate over electrostatic image forces for small particles. Materials that can carry charges high enough to allow electrostatic forces to contribute significantly to the total force of adhesion are generally polymers of poor conductivity or other extreme insulators.

It is very important in this case to point out again that these first considerations have been for spheres on flat surfaces. Electrostatic forces can in fact predominate over van der Waals forces in the case where surface asperities of the particles are significant enough to remove the bulk of the particle from the contact point. This is due to the rapid decrease in $F(\text{vdW})$ with increasing distance between the adherents. In the presence of surface asperities, calculation of the van der Waals force should not be based on the full radius of the particle, but rather on the radius of curvature of the surface elevation at which the adherents are in contact. Conversely, electrostatic forces do not change much with asperities; at not too large deviations from spherical, the effective radius for electrostatic forces is approximately equal to the true radius. This comparison can be quite complex, especially when considering that multiple asperities may be present and thus multiple contact point may be formed so that $F(\text{vdW})$ once again predominates. Also, deformation of particles and/or surfaces after a period of time may change these asperities at the contact point so that $F(\text{vdW})$ again also predominates (4, 11, 19).

For a dry system, the total forces of adhesion are thus a combination of van der Waals forces and electrostatic forces. As stated before, for particles less than 50 μm diam, this total adhesion force greatly exceeds the force due to gravity for a given particle size. For a 1 μm -diam silicon particle on a dry silicon surface, the total force of adhesion exceeds the gravitational force by a factor of greater than 10^7 . A comparison of the total force of adhesion for a dry system *vs.* the ratio of total force of adhesion to gravitational force is made in Fig. 3. The total force of adhesion line is calculated for a van der Waals constant of 8 eV and 1% particle deformation, assuming a contact potential of 0.5V and an image force from Fig. 2. The gravitational attraction is calculated for a particle density of silicon (2.33 g/cm^3) based on the equation

$$F(\text{grav.}) = 4/3\pi r^3 \rho$$

where ρ is the density and r is the particle radius. For particles less than about 20 μm diam it can be seen that

Fig. 3. Total force of adhesion of particles on a dry surface as compared to the ratio of total force to gravitational force as a function of particle diameter.

the total force of adhesion exceeds the gravitational force by a factor of at least 10^5 .

Effects of humidity and liquids on adhesion.—Due to high humidity or to an adhered particle/surface system having been immersed and then withdrawn from a liquid, a liquid film can be formed by capillary condensation or capillary action between the particle and surface. The resulting capillary force can make a large contribution to the total force of adhesion. The capillary force is a function of the particle radius and liquid surface tension (surface tension of water at 18°C is 73.0) as shown by the formula

$$F(\text{cap.}) = 4\pi r\gamma \text{ dyn}$$

where r is the particle radius, and γ is the liquid surface tension. This reduces to

$$F(\text{cap.}) = 0.63d\gamma \text{ mdyn}$$

where d is the particle diameter. There is evidence that a capillary force may remain even after baking at above the boiling point of the liquid, even for as long as 24h. If the liquid contains substances that can crystallize upon evaporation, a solid crystalline bridge might also form during

Fig. 4. Capillary force and total wet force of adhesion as a function of particle diameter.

drying. It should be pointed out that hydrophobic surfaces are not generally affected by capillary forces. Figure 4 shows the magnitude of a capillary force, for water as the liquid, in comparison to the van der Waals forces for h equal to 4 eV and for 1% deformation of the particle. It can be seen that the capillary force can be predominant over other forces for small particles. A comparison of the total wet force of adhesion, as a combination of reduced van der Waals force and capillary force, to the gravitational force is given in Fig. 5. As will be discussed later, particle forces may be reduced by immersion in liquids, particularly for large particles, but if the particles are not removed in the liquid, then the added capillary forces which remain upon removal from the liquid can increase the total adhesion force by an order of magnitude or more.

Immersion effects on adhesion.—By immersion of adherent particles in a liquid, the van der Waals force can be reduced by, in most cases, about a factor of two, since the liquid partially shields the attraction. For calculation purposes, the van der Waals constant, h , must be replaced by an immersed van der Waals constant, $h(\text{im.})$. Table II shows some typical $h(\text{im.})$ values as compared to h values (11). Electrostatic image forces are more or less eliminated by immersion, and electrostatic contact potential forces are greatly reduced. The electrostatic forces generally tend to become negligible because of the enhanced static dielectric constant of the liquid, as compared to a gaseous or vacuum environment, and because of the sorption phenomena which tend to shield the charges.

Immersion does not necessarily always cause a reduction in adhesion purely because of its shielding effect of charges. The liquid molecules and/or ionic impurities in the liquid can actually add to the total adhesive force. Likewise, in some cases, the reduction in total adhesion force by immersion is greater than predicted by shielding alone. To understand these possibilities, one must consider the interactive forces between the boundary layers present at all solid-liquid interfaces of the adherents (these same discussions can apply to the humid and wet situations described above). Molecules of a liquid are often adsorbed at the solid surfaces and are polarized and/or oriented in a certain direction so that an electrical double layer is formed at each solid-liquid interface. If the processes occur in the same way on all surfaces, dipole layers can cause repulsive forces, thus adding to the reduction in adhesive force, and in some cases actually cause removal. If the liquid itself is dissociable into ions and/or if the liquid contains dissolved species which are present as ions, again dipolar alignments on surfaces can occur to cause double layer attractions or repulsions.

Fig. 5. Comparison of the total wet force of adhesion to the gravitational force as a function of particle diameter.

Table II. Comparison of immersed and nonimmersed van der Waals constants [from Ref. (11)]

Particle-liquid-surface	h (eV)	h (im.) (eV)
polystyrene-water-polystyrene	0.6	0.1
silicon-water-silicon	6.8-7.2	3.49
copper-water-copper	8.5	4.9
silver-water-silver	9.0	7.76

These forces can be approximated by the formula for electrostatic contact potentials if the contact potential difference is determinable. For a particle on a surface, the repulsive or attractive force due to these charge double layers, for a certain charge density in solution, can be alternatively approximated by the formula

$$F = \pm 64\pi r N k T \delta$$

where r is the particle radius, T is the temperature in degrees Kelvin, N is the charge density in charges per cubic centimeter, and δ is the double layer thickness, which is typically about 50Å. This reduces to approximately

$$F = \pm 7 \times 10^{-25} d T N$$

For 0.1 g/liter NaCl, N is 2×10^{18} charges/cm³. The charge density depends on the charge of the ions as well as on the number of ions produced. Whether the force is attractive or repulsive is completely system dependent. For particles which are the same materials as the surface, charges generally form double layers the same on both surfaces so that the double layer interactions are repulsive. Different ions may, however, collect differently at unlike surfaces so that either attractive or repulsive forces are possible depending on their alignment.

Figure 6 is a comparison of the total wet and total dry adhesion forces, as given in Fig. 3 and 5, to the possible repulsive forces from double layer formation. (Although these are described as repulsive forces, they should also be considered as potentially attractive forces which would add to the total force of adhesion.) First, assuming a very large contact potential of 5V, using the contact potential force equation, the possible repulsive force exceeds either of the two total adhesion forces. This potential, however, exceeds the normal maximum possible potential difference by a factor of ten, so that this possibility is totally unreasonable, but it does effectively point out the difficulty in removal of particle by charging. In principle it would be possible to charge the particle

Fig. 6. Total wet and dry forces of adhesion compared to the calculated possible repulsive forces from double layer formation for the specified parameters.

and/or surface, unimmersed, so that repulsion would cause particle removal, so-called electrostatic removal. This is, however, quite difficult because of the large charges which must be placed on the small particles. Second, a solution with 1N ions, in which the ions align themselves correctly for repulsion, at 373 K is needed to balance the total wet force of adhesion. This is a concentrated solution which itself may cause more problems than it solves by particle removal. Also, because the solution is so concentrated, it is highly unlikely that large potential differences will result, so that this calculation is probably not valid at such high concentrations. Although unrealistic, it again points out the extremes needed for removal of small particles.

Detergency.—One final topic for consideration is aqueous and nonaqueous detergency. It is known that adhered colloidal particles below about 0.2 μ m diam are virtually impossible to remove and that removal is difficult even for particles as large as 10 μ m diam or more. One paper has reported that significant detachment of small particles can occur in nonaqueous surfactant media by polymeric detergency (20). The exact mechanism of this action is not known, but it has been referred to as an endropic repulsion mechanism where it has been hypothesized that the polymeric detergent may act as a "molecular wedge." Endropic action implies that the source of repulsion which counteracts particle adhesion is the reduction in configurational entropy of the adsorbed polymer chains when they are compressed in the space between particle and surface. The detergent molecule must not only be small enough to be able to be adsorbed between the adhered particle and solid surface, but also must be large enough to exert an effective entropic repulsion. Therefore, the size of the detergent molecule is very critical (20). These considerations imply that each particle size will be most effectively removed by a different detergent molecule size which is optimized for that particle size. Also, deformed systems in which the particle and/or surface have an extended contact area may not be so affected by this detergency, so that the longer the deformable particles are left on the surface, the less effective detergency may be.

Conclusion

It has been determined that small particles on a dry surface are primarily held by strong van der Waals forces which can increase in magnitude with time due to deformation of the particle and/or surface which increases the total contact area. Immersion generally significantly reduces the total force of adhesion while the particle/surface system is still immersed. Upon removal from the liquid, however, predominating capillary forces of adhesion may be added due to the formation of liquid bridges between particle and surface. The same phenomenon of capillary action may also occur in high humidity. The total forces of adhesion for small particles are so large that they exceed the gravitational force on those particles by many orders of magnitude. Emphasis should be placed on prevention of particle deposition rather than counting on their subsequent removal. All specific considerations of particle adhesion could not have been treated in a review such as this; however, hopefully this treatment has conveyed a general overview of the major considerations of particle adhesion. Additional references on particle adhesion not already cited in this paper appear in Ref. (21-26).

ABSTRACT

We have used a "leaky tube" diffusion system to carry out tin diffusion in p-type GaAs substrates in an attempt to produce n-p junctions with a low temperature processing technique. Solid SnS was used as the source for the tin, and the diffusions were carried out in the temperature range 650°-750°C for times varying from 2 to 24h. Both secondary ion mass spectrometry (SIMS) and Rutherford backscattering spectrometry (RBS) showed that tin had been introduced into the substrates in concentrations as high as $3.3E + 19 \text{ cm}^{-3}$ and to depths as large as $2 \mu\text{m}$. However, electrochemical carrier concentration profiling revealed that the diffused region remained p-type with net carrier concentration barely altered by the diffusion process. The reason for this anomalous behavior is not understood, but pairing or some other compensation may be taking place.

The fabrication of local p-type regions in III-V semiconductor materials is readily carried out with zinc or cadmium diffusion (1, 2) or ion implantation (3). On the other hand, a similar fabrication of local n-type areas in III-V's can only be done with ion implantation. Localized n-type diffusion in compound semiconductors has always been a difficult procedure and the development of a viable n-type diffusion technology for III-V's would be most valuable. This technology could be used to generate shallow n layers for ohmic contact formation, in self-aligned gate FET fabrication, for isolation regions in III-V bipolar circuits, and so on. The purpose of this work was to establish a low temperature n-type diffusion process for GaAs using a solid tin source in a novel diffusion system.

Various workers have carried out tin diffusion into GaAs in the past. Goldstein and Keller (4) performed tin diffusions into GaAs in closed tubes at 1060°-1260°C. Paint-on radioactive ^{113}Sn was used as the impurity source. The distribution profile was found to satisfy

Fick's equation with fixed source boundary conditions. Fane and Goss (5) also carried out closed tube tin diffusions into GaAs from an elemental tin source at 1100°-1150°C. "Slow" and "fast" components of the diffusion were observed with only the former being electrically active. Von Muench (6) used tin-doped oxides as a source of the impurity and as a protection layer for the surface. Open-tube oxide deposition and closed-tube diffusion temperatures were 700° and 1000°C, respectively. The diffusion profiles satisfied the infinite source solutions of Fick's equation. Average carrier concentrations of $3.0E + 18 \text{ cm}^{-3}$ were obtained. Gibbon and Ketchow (7) used doped-oxides and an open-tube diffusion system at 850°-1050°C. Average carrier concentrations of $6.0\text{-}8.0E + 18 \text{ cm}^{-3}$ were obtained.

More recent work has been carried out by Baligha and Ghandhi (8), who obtained planar selective diffusions from tin-doped oxides with phosphosilicate glass film masks. Diffusions were carried out in closed tubes at 1010°C. Arnold *et al.* (9) obtained step-like doping pro-

* Electrochemical Society Student Member.

files from unexhausted spin-on emulsion source layers. The diffusion coefficient was found to be a parabolic function of the concentration. Nissim *et al.* (10) also used spin-on source layers for tin diffusion. The majority of the tin was found to be electrically inactive until a further anneal was performed. Arnold and Heime (11) have employed spin-on tin emulsions and have measured surface concentrations to be $2.0E + 18 \text{ cm}^{-3}$.

In this work, we have attempted to produce n-p junctions using a so-called "leaky tube" diffusion furnace. This system has been shown to be extremely reliable for the diffusion of zinc into GaAs; details about this system have been published previously (12). A series of diffusions into p-type GaAs substrates were carried out using solid SnS as the source of tin, and the diffused wafers were characterized by optical inspection, electrochemical profiling, secondary ion mass spectrometry (SIMS), and Rutherford backscattering spectrometry (RBS). Both SIMS and RBS demonstrated that large concentrations of tin were introduced into the substrates during the diffusion, but curiously, the electrical examination revealed that no n-p junctions were formed. Further details about these experiments and speculations about the results constitute the rest of this paper.

Experimental Technique

One of the reasons why zinc diffusion into III-V's is now routine is that zinc has a large vapor pressure at relatively low temperatures. In leaky tube diffusion, elemental zinc is used as the source, and at a furnace temperature of 600°C , the zinc vapor pressure is nearly 10 torr. On the other hand, it is a well-noted property of tin that even though its melting point is rather low, its vapor pressure is miniscule at temperatures below 1600°C . Consequently, elemental tin is a poor choice for a source with this diffusion technique. There are a variety of tin compounds with high vapor pressures at temperatures in the 500°C - 700°C range which have been used as tin sources for ion implantation (13). Tin halides possess substantial vapor pressures at low temperatures, but were rejected because of the possibility of halogen etching of the substrates. Solid SnS was chosen because of its adequate vapor pressure [approximately 1 torr at 750°C (14)] and manageable toxicology.

P-type substrates with both (100) and (111) orientation were used in these experiments. They were doped with zinc to a concentration of $5.0E + 16$ - $2.0E + 17 \text{ cm}^{-3}$. After bromine-methanol polishing and degreasing, the wafers were coated with SiO_2 deposited by RF glow discharge sputtering. It has been observed that dielectric protection of the GaAs surface is required to prevent thermal decomposition in the leaky tube system. In the case of zinc diffusion at 600°C , 50 - 75\AA of SiO_2 is adequate (15). However, for the tin diffusion it was discovered that thin dielectric layers would not suffice: there was drastic etching of the wafer surface, presumably due to the formation of volatile gallium and arsenic sulfides, probably enhanced by gas convection effects. Relatively thick (1000 - 3500\AA) SiO_2 layers were deposited to prevent the decomposition of the substrate surfaces. It is interesting to note that the thick SiO_2 films did not act as diffusion masks; the tin did indeed reach the GaAs surface. As may be expected, the penetration depth of the tin into the substrates diminished with increasing SiO_2 thickness, but the tin surface concentration was not affected by the thickness. Some deterioration of the SiO_2 during diffusion was noticed, but this was inconsequential, as the dielectric films were stripped off before further testing.

After an additional cleaning step, the wafers and SnS crucible were loaded into the cold end of the furnace. Purging of the furnace in ultrapure helium was carried out for 2h, after which the boat holding the wafers and source was pushed into the hot zone of the furnace. Diffusions were performed for times varying from 2 to 24h at the temperatures of 650° , 700° , and 750°C . At the end of the diffusion, the boat was pulled back to the cold end of the

furnace and the wafers were allowed to cool for several hours before unloading.

Results

After the samples were removed from the diffusion furnace and the SiO_2 layers stripped in buffered HF, they were cleaved and stained for optical inspection. The staining fluid was a dilute solution of KOH and $\text{K}_3\text{Fe}(\text{CN})_6$ in water. The cleaved and stained (110) surface of sample LT096-B [24h, 700°C diffusion, (100) orientation] is shown in Fig. 1. The stain clearly reveals a line approximately $1.4 \mu\text{m}$ below the surface; this type of line is generally associated with a junction or a diffusion front. All of the samples in this work showed similar stain lines, and most were as regular and uniform as that displayed in Fig. 1.

The net carrier concentration ($N_A - N_D$) of each sample was measured as a function of depth with a modified Polaron electrochemical profiler. This apparatus can measure concentrations in the range $4.0E + 13$ - $4.0E + 21 \text{ cm}^{-3}$ with a depth resolution as small as 35\AA . Figures 2a, 2b, and 2c show the carrier profiles for samples LT095-A, LT096-B, and LT097-B, which were diffused at 650°C (12h), 700°C (24h), and 750°C (12h), respectively. In all three cases, the samples remained p-type. In fact, every diffused GaAs wafer (approximately thirty samples in total) remained p-type. Each of the three representative samples displayed here do show some minor alteration in the net concentration near the surface, but there are no indications of the formation of an n-type layer. These alterations, however, are related to the tin diffusion in some manner, because control samples subjected to the same heat-treatment without the tin source showed no alterations in the carrier profile whatsoever.

The atomic concentration profiles for these same samples were then measured using a secondary ion mass spectrometer (Cameca IMS3f). The primary beam consisted of positively-charged oxygen ions accelerated to 12.5 keV ; the secondary ions were accelerated to 4.5 keV . Depth profiles were obtained for arsenic (mass, 75), zinc (mass 64), and tin (mass 120). Figures 3a, 3b, and 3c are the SIMS profiles for the samples whose carrier concentrations were plotted in Fig. 2a, 2b, and 2c, respectively. The distance scale was calibrated by using a Dektak surface profilometer to measure the depth of the SIMS crater. No tin-implanted sample was available for exact calibration of the atomic concentration scale, but an approximate calibration was performed by using ratios of the dopant signals to the arsenic signal and by referring to the Rutherford backscattering spectrometry (RBS) data (to be discussed later).

Fig. 1. A photomicrograph of the cleaved and stained edge of a tin-diffused wafer (sample LT096-B).

Fig. 2. Doping profiles from three tin-diffused samples as measured with electrochemical profiling. a: 12h, 650°C. b: 24h, 700°C. c: 12h, 750°C.

The SIMS analysis clearly demonstrates that the diffusion introduced tin into the GaAs substrates, with concentrations perhaps as high as $3.0E + 19 \text{ cm}^{-3}$. The tin concentrations were significantly larger than the zinc background concentrations, and the tin penetration was as deep as $2.2 \mu\text{m}$. In addition, the shape of the tin profile (most readily observed in Fig. 3a and 3c) is quite reminiscent of the profile of zinc introduced into GaAs with the leaky tube system (12). That is, the profile has a relatively flat plateau region followed by a very steep drop-off at the diffusion front; this suggests that the tin diffusion coefficient is a function of the tin concentration and that the tin may also diffuse by means of the interstitial-substitution mechanism.

Rutherford backscattering spectrometry was also employed in the characterization of these samples. RBS was used to corroborate the SIMS measurements and to obtain an estimate of the tin concentration near the surface.

^a Estimated from SIMS.

^b RBS measurement.

Although RBS is not generally applied in trace element detection, these particular samples are well suited for the technique because of the large difference in mass between the trace element and the matrix. Helium ions with energies of 3.78 MeV were utilized, and signal-to-noise figures were enhanced by employing long counting times (~30 min), large doses (~100 μC), and pulse pile-up rejection techniques. Figure 4 shows the RBS spectrum for sample LT097-B (750°C, 12h), plotted to emphasize the tin signal. By using standard RBS analysis procedures (16), it was determined that the concentration of tin at the surface was approximately 0.15 (±0.03) atomic percent (a/o), or, $N_{Sn} \approx 3.3E + cm^{-3}$. This number was utilized in quantifying the SIMS results shown earlier.

The results of the characterization of these samples are summarized in Table I. As mentioned previously, the surface concentration was in the vicinity of $1.3.E + 19 cm^{-3}$ for each sample, and is apparently insensitive to the SiO₂ thickness. On the other hand, the tin penetration depth decreased with increasing SiO₂ thickness.

Discussion

It is clear from the above presentation that the leaky tube diffusion system does indeed introduce tin into the p-type GaAs wafers. The tin concentration is quite high and the penetration is substantial. Yet it is also just as clear that the tin has a negligible effect on the electrical properties of the diffused samples. No n-p junctions have been produced with this low temperature processing scheme. What is not clear is the reason for the discrepancy between the atomic concentration and the electrically active concentration of the tin. Figures 3a-3c demonstrated that the background dopant, zinc, was redistributed by the heat-treatment. The zinc concentration was increased at the surface by perhaps 1-2 orders of magnitude above that in the bulk. But this increase is not substantial enough to compensate the tin introduced by the diffusion.

As pointed out in the introduction, various workers have successfully diffused tin into GaAs to produce n-type layers. It is interesting to note, however, that virtually all of these diffusions have been carried out at temperatures exceeding 1000°C. In fact, Nissim *et al.* (10)

demonstrated that tin can be introduced into GaAs from a spin-on dopant source at temperatures as low as 700°C, but at low temperatures, most of the tin is electrically inactive. Furthermore, it remains inactive until a high temperature (900°C) annealing step is performed. Our results also demonstrate that a low temperature processing cycle can introduce tin, but tin that is electrically inactive. Due to equipment limitations, we did not attempt any high temperature anneals.

It appears that tin doping to produce n-type layers in GaAs is viable only at high processing temperatures. Why this is the case is not understood, but a number of scenarios are possible. (i) The tin may reside predominantly on interstitial sites and may remain electrically neutral until a high temperature step is employed to move the interstitial tin atoms to donor sites. (ii) The tin may behave in an amphoteric manner and produce self-compensation by the formation of an equal number of donors and acceptors. A high temperature step may readjust the donor/acceptor ratio in favor of the donors, as in the case of silicon in GaAs. (iii) Perhaps tin complexes are formed at low temperatures which are electrically inactive. (iv) Or perhaps the tin is being compensated by some unknown deep center that is active only at relatively low processing temperatures.

One last interesting point in this diffusion process is the behavior of sulfur. Stannous sulfide was the source in these experiments and it was expected that if sulfur were to diffuse into the wafers along with the tin, it would also contribute to the formation of an n-type layer. With the absence of n-p junctions, it was initially believed that sulfur was not introduced into the substrates during the diffusion. However, SIMS depth profiling, employing a cesium beam, revealed that sulfur was present in a very shallow surface layer, with a maximum depth not exceeding 100Å. Apparently, the dissociation of the SnS in the furnace is nearly complete, and the volatile sulfur collects at the cold end of the furnace and is unavailable for extensive diffusion.

Summary

We have endeavored to develop a low temperature n-type diffusion process for GaAs. A leaky tube diffusion system was employed using solid SnS as the source for the tin dopant. Although both SIMS and RBS demonstrated that tin did indeed diffuse into the GaAs samples, with concentrations as high as $3.3E + 19 cm^{-3}$ and to depths as large as 2.2 μm, electrical testing revealed that no n-p junctions were produced. It is suspected that the tin forms electrically active donors only when the diffusion temperature (or a subsequent annealing temperature) exceeds 1000°C (9-11). We are presently pursuing TEM and photoluminescence characterization of the diffused samples in an attempt to shed more light on this phenomenon.

Empirical Modeling of Low Energy Boron Implants in Silicon

M. Simard-Normandin and C. Slaby

Northern Telecom Electronics Limited, Ottawa, Ontario, Canada K1Y 4H7

ABSTRACT

The depth distribution of low energy boron implants in silicon are analyzed using secondary ion mass spectroscopy. The profiles for equivalent energy implants of B^+ (10-30 keV) and BF_2^+ (50-120 keV) are compared. Fluorine trapping in BF_2^+ implants is also investigated. New range parameters are extracted from the measured profiles using a least squares fitting technique. The Pearson IV distribution provides an excellent representation of the doping profile in B^+ implants, while for BF_2^+ implants the profiles are better represented using a gaussian distribution with an attached exponential tail.

The formation of shallow junctions in semiconductors using ion implantation is a well-established technique. Most process modeling aids use the results of LSS theory (1) to predict the dopant depth distribution. This technique is strictly valid for implantation into amorphous media, even though in most applications implantation is carried out into crystalline substrates. For low implantation energies, the conventional method of simulating an amorphous substrate by tilting the wafer a few degrees off normal is not sufficient and the doping profiles measured are markedly different from theoretical profiles. More sophisticated theoretical distributions are required in these cases, with parameters fitted to carefully measured experimental data. In this paper, we report on a detailed study of B^+ and BF_2^+ implants in crystalline silicon at various doses and energies of interest in VLSI applications. Similar work has already been reported by Wilson (2) and by us in a previous paper (3, 4), but for a smaller range of dose and energies, and only for Pearson IV distributions.

The doping profiles after implantation are measured using secondary ion mass spectroscopy (SIMS). Empirical range statistics are extracted from these profiles for the Pearson IV distribution and for the gaussian distribution with an attached exponential tail.

We also investigate quantitatively the problem of fluorine trapping in the damaged layer produced by BF_2^+ implants for various rapid thermal annealing (RTA) and furnace annealing conditions.

Sample Fabrication

The starting wafers were 3-7 Ω -cm n-type (phosphorus-doped) (100) CZ-grown silicon. Some wafers were oxidized in dry O_2 at 1000°C to form approximately 40 nm of SiO_2 . Implants were carried out either into bare Si or

through the 40 nm SiO_2 . The wafers that were to be annealed further received 100 nm of deposited SiO_2 at 450°C before the annealing.

The $^{11}B^+$ was implanted at 10, 15, 20, 25, and 30 keV, and the $^{10}BF_2^+$ was implanted at 25, 50, 75, 100, and 120 keV. The implant doses were between 5×10^{14} and 5×10^{15} cm^{-2} . There is a 5:1 ratio of implant energy between the BF_2^+ and the B^+ implants since the ratio of the masses is very close to 5. All implants were done using a 7° tilt angle at room temperature. The BF_2^+ implants and the B^+ implants for energies greater than or equal to 20 keV were performed in a high current implanter using postacceleration mass analysis. The remaining B^+ implants were done in a medium current implanter. In the case of the high current implanter, the wafer rotation was controlled and the rotation angle was 0° for all implants. In case of the medium current implanter, initially the rotation angle was set to 0° but it was randomly disturbed during the loading operation. No significant discrepancies in the results due to this disturbance were observed. The ion current in case of BF_2^+ implants was 1-5 mA. For B^+ implants done on the high current implanter, the current was 500-700 μA , and for those done on the medium current machine it was approximately 40 μA .

The slice temperature as determined through the use of thermal stickers attached to the back of the wafers did not rise significantly during implantation. It is estimated that the maximum temperature rise for the highest current implantations did not exceed 20°-30°C.

The wafers implanted at 3×10^{15} cm^{-2} were annealed either in a conventional furnace tube or in a tungsten halogen lamp rapid thermal annealer. Furnace anneals lasted 20 min and took place at 925°, 1000°, or 1100°C. Lamp anneals lasted 12s and were carried out at 1050° or 1150°C using a Heatpulse 210T rapid annealing system.

Measurements

For each sample, the depth distribution profile was obtained by SIMS using a Cameca IMS 3-f ion microscope with 8 keV O_2^+ as the bombarding species. The sputtering beam angle of incidence was 30° . The crater depth was measured using a Dektak stylus, and the depth scale was calibrated by assuming a constant sputtering rate. The conversion from ion counts to concentration was made by integrating the profile and equating the result to the total implant dose. There are, however, several effects which may cause deviations of the measured profile from the original dopant distribution. Wittmaack (5) points out that a depth correction of about 1.4 nm/(keV/O atom) should be applied to the profile because of the reduction in erosion rate which occurs as the sample becomes loaded with oxygen. In our case, this correction amounts to 4.85 nm. We have analyzed one sample of $3 \times 10^{15} B^+/cm^2$ at 10 keV implanted into silicon preamorphized with an implant of ^{28}Si . We found that the measured profile can be described accurately with LSS range parameters. Since the correction is small and is of the order of the accuracy to which we can measure crater depths, we have not applied it to the range parameters quoted in this paper for implantation into crystalline silicon.

For sufficiently high dose and energy BF_2^+ implantation, an amorphous region is produced. Since amorphous silicon etches slowly in concentrated HF , we can measure the thickness of the amorphous layer, $X_{amorphous}$, by soaking the samples in 49% HF for 2 days and then measuring the height of the resulting step with an interference microscope. We can also infer this quantity from SIMS measurement as described in the next section.

Results of measurements of $X_{amorphous}$, the junction depth X_j as determined from the SIMS profile, and the position of the maximum concentration X_{peak} are listed in Table I.

Results

The advantage of using BF_2^+ is that it amorphizes the surface of the silicon during implantation (at doses and energies of interest to VLSI device fabrication). This amorphous region is claimed to anneal at a lower temperature than does a heavily damaged crystalline structure (6, 7). The extent of the amorphous region can be measured before annealing by etching in HF as described previously. It can also be inferred from the SIMS profile

Note: A mnemonic has been used to describe the samples. B and BF mean a B^+ and a BF_2^+ implant, respectively. Next comes the dose (e.g., 3E15). Following the dash is the implant energy. C means implantation through a 40 nm oxide (cap), UC means implantation into bare silicon (uncapped).

after annealing. The fluorine distribution is double peaked after annealing, and the minimum corresponds to the depth of the amorphous region after implantation (Fig. 1). The peak of the as-implanted dopant distribution is always shallower than the amorphous region. After annealing, one peak corresponds approximately to the range of the implant, and one is located deeper than the depth of amorphization. This has been attributed to a plane of damage, which acts as a getter site (8). In BF_2^+ -implanted samples, both boron and fluorine show a double-peak structure after annealing. The position of these peaks is fixed with respect to the silicon surface for a given implant and does not depend on the annealing. We have investigated five very different annealing conditions, and the two maxima and the minimum are always coincident, although their amplitudes may vary.

Using the etching method, we have observed a well-delineated step in samples implanted with as little as $5 \times 10^{14} BF_2^+$ ion/cm², indicating that this low dose is sufficient to produce amorphization. Table I compares the HF and the SIMS methods of evaluating the depth of the amorphous layer; agreement is excellent.

In Fig. 2, we compare implantation of BF_2^+ into bare silicon with implantation through a 40 nm layer SiO_2 . The oxide layer was left on the sample for the SIMS analysis. The samples were not annealed. Both profiles were analyzed under the same conditions, and the silicon profiles match exactly, far from the regions very close to the surface or the Si- SiO_2 interface. The boron profiles show similar agreement. However, the fluorine count is lower for implantation through the oxide layer at every point in the silicon wafer. The evidence presented in Fig. 2 implies that the presence of SiO_2 on top of the Si substrate does not have a significant effect on the amount of boron channeling, at least at the oxide thickness used in this study, and that the range statistics presented for boron in this paper can be used for implantation through a thin layer of SiO_2 . It also suggests that in the case of BF_2^+ implants through SiO_2 a measurable fraction of the fluorine is missing from the silicon wafer. We have not attempted to calibrate the profiles in the SiO_2 layer to see whether the fluorine was trapped there or had escaped.

After annealing, the fluorine and the boron redistribute themselves differently in the wafer (2, 8). If the fluorine profile after annealing is integrated, using the unannealed profile as calibration, we find for the 925° and $1000^\circ C$ 20 min furnace anneals and the 1050° and $1150^\circ C$ 0.2 min rapid anneals that 20-100% of the fluorine is still present in the silicon. For the $1100^\circ C$ 20 min anneal, the fluorine has decreased by two orders of magnitude, leaving a fluorine dose of the order of $5 \times 10^{13} cm^{-2}$ in the crystal. The nature of the chemical bond which binds the fluorine to the silicon and the boron is currently under investigation. Depending on the annealing conditions, the

Fig. 1. Depth distribution profiles for boron and fluorine before and after annealing. The implant dose was $3 \times 10^{15} BF_2^+ cm^{-2}$ at 50 keV and annealing was carried out at $1050^\circ C$ for 12s. The fluorine dose after annealing is $6.2 \times 10^{15} cm^{-2}$.

deeper peak sometimes has a larger intensity than the first one. For boron, the second peak is always the lower one for the annealing conditions that we have studied.

Modeling

Because of the channeling tails in low energy boron implants, modeling of as-implanted profiles requires special attention. Figure 3 shows a typical SIMS profile for a low energy boron implant ($3 \times 10^{15} \text{ cm}^{-2}$, 10 keV) together with different theoretical profiles. Profiles calculated using LSS range statistics are clearly in disagreement with measurements. It is also obvious that even a gaussian distribution fitted to the measured profile cannot account for the "tail" region. Another modeling technique applied, for example, in SUPREM-II, uses a Pearson distribution with an exponential tail. Although this technique could describe the profile correctly, the current SUPREM-II model does not give good results.

A comparison of equivalent energy implantation of B^+ and BF_2^+ is presented in Fig. 4. The ranges of the distributions can be matched by adjusting the ratio of the implant energies for the two species (the factor 5:1 that we have used is not exact; therefore, the top of the profiles do not match exactly), but the shapes of the doping profiles are markedly different for B^+ and for BF_2^+ . We have found the Pearson IV distribution (9) can describe correctly B^+ and

Fig. 3. As-implanted profile of $3 \times 10^{15} \text{ cm}^{-2} \text{ B}^+$ at 10 keV (a), superimposed with the best-fit Pearson IV profile (b), the best-fit gaussian profile (c), the Pearson IV profile in SUPREM-3 (d), and the LSS gaussian profile (e).

Fig. 4. Comparison of equivalent-energy B^+ and BF_2^+ implants. The dose is $3 \times 10^{15} \text{ cm}^{-2}$ in all cases. The samples have not been annealed.

BF_2^+ profiles provided that empirically determined range parameters are used, but the parameters are different for B^+ and BF_2^+ implants of equivalent energies. We have also found that BF_2^+ implants can be modeled even better by a gaussian distribution with an attached exponential tail.

Pearson IV parameters for boron implants.—Parameters of the Pearson IV distribution for boron implants were extracted from the measured profiles through a least squares fitting procedure. The quality and accuracy of these plots are discussed in Ref. (3) and are found to be very satisfactory. Table II contains a complete set of data for 10-30 keV boron implants with doses varying from 5×10^{14} to $5 \times 10^{15} \text{ cm}^{-2}$. The data for each of the four moments of Pearson distribution are plotted separately in Fig. 5-8, together with the corresponding values currently used in SUPREM-3.

Comparing the data for the projected range (Fig. 5) and the standard deviation (Fig. 6), we observe that the empirical parameters parallel theoretical data having consistently higher values. The important difference between empirical and theoretical data is in the third distribution moment, skewness (Fig. 7), which must be positive to fit the experimental data. This results in profiles that are tilted towards the bulk and therefore properly account for

the distribution tails. As a consequence of this difference, we also observed a different behavior for the fourth moment, kurtosis (Fig. 8).

Pearson IV parameters for BF_2^- implants.—Modeling of BF_2^+ implants proved to be more complicated. Although it was possible to obtain good fits in each individual case for the Pearson IV distribution, a considerable scatter in the parameters was obtained, in particular, for skewness and kurtosis. This is because the BF_2^+ implant profiles

Fig. 8. The kurtosis of the Pearson IV distribution for boron implants compared with the LSS values.

tend to be concave towards the bulk, while the Pearson IV distribution is convex. The fitted parameters are summarized in Table III. We can reasonably describe BF_2^+ implants with this set of data which are much more accurate than the LSS data. Once R_p , ΔR_p , and skewness are determined, the shape of the profile is very insensitive to variations of the kurtosis; therefore, the high values obtained for the 75 keV implants can be replaced by an average value between the 50 and 100 keV values and the quality of the fit remains excellent.

Gaussian distribution with an exponential tail for BF_2^+ implants.—Another modeling technique used, for example, in process simulation programs such as SUPREM, uses a simple gaussian distribution with an exponential tail attached somewhere on the distribution shoulder. The drawback of this approach in SUPREM-II is the use of a fixed tail with its parameters independent of the implant energy. Our approach is to generalize the distribution which is now characterized by the projected range R_p , the standard deviation ΔR_p , the characteristic length of the tail L , and the fraction parameter F , which is the fraction of the peak concentration where the exponential tail is attached.

The following mathematical expression describes the profile used, where x_{int} is the interception point where

the exponential tail is attached to the gaussian distribution

$$y(x) = \begin{cases} \frac{A}{\sqrt{2\pi} \Delta R_p} \exp[-(x - R_p)^2/2\Delta R_p^2]; & 0 \leq x \leq x_{\text{int}} \\ \frac{A}{\sqrt{2\pi} \Delta R_p} \exp[-(x_{\text{int}} - R_p)^2/2\Delta R_p^2] \exp[-(x - x_{\text{int}})/L]; & x > x_{\text{int}} \end{cases} \quad [1]$$

and where L is the characteristic length of the exponential.

The coefficient A is determined by integrating the profile and equating the result to the implant dose. The fraction F of the peak concentration where the exponential tail is attached is given by

$$F = y(x_{\text{int}})/y_{\text{max}} \quad [2]$$

We have found that this technique is particularly useful in the case of BF_2^+ implants. Figure 9 illustrates the quality of fits obtained with this approach. The extracted parameters for this distribution are shown in Table IV, while

the energy dependence of these parameters is illustrated in Fig. 10 to 13.

Double gaussian profiles for BF_2^+ implants.—Dissociation of the BF_2^+ molecule causing abnormal boron distribution profiles has been observed previously (10). Although dissociation problems in the beam are negligible in a postacceleration mass analysis type of implanter, like the one used in this study, dissociation has been claimed to occur upon impact with the silicon wafer (6, 8). We have investigated this possibility to explain the tail of the BF_2^+ profiles. The model assumes that some BF_2^+ molecules dissociate to form an ionic form of BF . Under these conditions, boron penetrates with 11/49 and 11/30 of the implantation energy. To represent this condition, two gaussian distributions with $R_{p2} = (49/30)R_{p1}$ have been used. The standard deviations and the fraction of the dose in the second peak are left as fitting parameters. Excellent agreement with measured profiles can be obtained, as displayed in Fig. 14. This observation is in contradiction with the complete dissociation of the BF_2^+ molecule at the silicon surface. If this were the case, all the boron should have 11/49 of the implant energy.

For higher energy implants, the second profile does not match the "hump" exactly. It may be that further dis-

sociation into B and F occurs, but we have not taken this process into account as it would greatly increase the number of adjustable parameters. In all cases, the fraction of the dose in the second peak is between 0.1 and 0.5%.

Conclusion

We have compared B^+ and BF_2^+ implants in silicon at equivalent energies. Fluorine is trapped in the silicon after BF_2^+ implants, and very long anneals at high temperatures are required to drive it out. These conditions are incompatible with VLSI processing techniques.

The Pearson IV distribution fits B^+ implants into crystalline silicon at a 7° tilt angle, but range parameters different from those of LSS theory must be used. BF_2^+ implants are adequately fitted with a Pearson IV distribution, although the shape of the distribution does not match the profile exactly. A gaussian distribution to which an exponential tail is attached gives a better fit to the profile. Two gaussian profiles corresponding to BF_2^+ and ionic forms of BF can reproduce the lower energy profiles extremely well, indicating that complex dissociations are likely to happen on impact with the silicon surface.

These results significantly improve the accuracy of process simulation and are of special value when applied to such novel process techniques as rapid thermal annealing, where limited diffusion means that a precise description of the as-implanted profile is of particular importance.

Acknowledgments

We wish to thank the group at Surface Science Western for their excellent work in making the SIMS measurements. We also wish to thank B. Loro, who etched the amorphized samples in HF, I. Calder, who provided the preamorphized sample, and F. Shepherd and M. King for many stimulating discussions.

Angle-Resolved X-Ray Photoelectron Spectroscopy Study for Reactive-Sputter-Etched GaAs Surface

Norikuni Yabumoto and Masaharu Oshima

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratories, Musashino-shi, Tokyo 180, Japan

ABSTRACT

The chemical state and oxide layer structure of the GaAs surface after reactive sputter etching (RSE) with CCl_2F_2 gas were investigated by angle resolved x-ray photoelectron spectroscopy (XPS). From the XPS results taken at a low take-off angle, an As-depleted layer exists in the top surface. The RSE-GaAs surface oxide is found to be composed of two layers consisting of a Ga_2O_3 first layer and a $\text{Ga}_2\text{O}_3 + \text{As}_2\text{O}_3$ mixed second layer. The thickness of the top Ga_2O_3 layer increases with increasing bias voltage from 0 to 7Å, while the mixed layer thickness is rather likely to be reduced. The total oxide layer thickness of the RSE-GaAs surface grows gradually thicker with increasing bias voltage over the 0.2-0.8 kV region and is nearly equal to that of the native oxide before etching unless the mirror gloss of the surface is destroyed by RSE.

Dry etching technology for GaAs devices has been widely developed, *e.g.*, ion beam etching for gate formation in GaAs MESFET's (1), selective dry etching of the AlGaAs-GaAs heterojunction (2), and plasma etching of Si_3N_4 films on GaAs substrates (3). However, plasma surface treatment might cause damage to the GaAs surface as well as the Si surface (4). Various kinds of damage such as contamination, crystalline defects, and variations of the surface composition are observed on the GaAs surface after reactive sputter etching (RSE) (5) which is representative of dry etching technology.

The damage of the GaAs surface assessed by Auger electron spectroscopy (AES) was found to depend on RSE conditions, especially on the gas species and bias voltage (5). The surface stoichiometry changes from Ga-rich to As-rich with different etching gas species, and the degree of damage is affected by bias voltage. However, the extreme surface chemical state was not understood from AES study.

Many studies of GaAs surface oxides and metal-semiconductor interfaces have been reported using x-ray photoelectron spectroscopy (XPS). Since a surface oxide study is important for the MOS structure and other devices, not only the initial oxidation state of the cleaved surface in ultrahigh vacuum (6, 7), but also the oxidation states of real surfaces such as native, thermal, and plasma oxides (8-10) have been studied. Although the damage caused by RSE may affect the surface oxide state, very few studies on the reactive-sputter-etched GaAs (RSE-GaAs) surface have been reported.

The purpose of this paper is to clarify the extreme surface composition variation of the RSE-GaAs and the oxide layer structure which is formed by contact with air after RSE. It is desirable to establish the GaAs surface chemical state after contact with air because the usual device fabrication processes are carried out in an air atmosphere. Angle-resolved XPS (ARXPS) was adopted as a very surface-sensitive technique, in addition to usual XPS. The oxidation state of the RSE-GaAs surface was compared with the native oxide in order to distinguish the RSE-GaAs surface from the non-RSE-GaAs surface.

Experimental

The RSE-GaAs (100) surface was investigated with XPS and ARXPS. RSE experiments were carried out using a diode RF sputter etching apparatus with a 100 mm diam target. CCl_2F_2 gas was used as an etching gas. This gas was found to selectively remove As atoms to make the GaAs surface Ga-rich (5). Our intent is to understand the oxide structure on this reactively etched surface which is formed by contact with air. The gas pressure was set at 0.04 torr. The bias voltage was varied from 0.2 to 0.8 kV. Etching duration was 3 min, and the target material which was selected was fused quartz. After RSE, the

samples were placed in the XPS apparatus through air atmosphere.

The XPS measurements were performed using monochromatized Al $K\alpha$ x-ray from a rotating anode. For Ag $3d_{5/2}$, the signal intensity of 3000 cps was obtained with an energy resolution of 0.9 eV full width at half maximum (FWHM). The samples were rotated from a take-off angle of $\theta = 90^\circ - 25^\circ$, while the x-ray source and analyzer were fixed. Peak separation of the XPS spectra was accomplished after smoothing and subtracting the background in order to determine the Ga 3d and As 3d intensities from the surface oxide and underlying substrate.

Results and Discussion

Dependence of surface composition variation on RSE bias voltage.—The XPS spectra, as shown in Fig. 1, revealed that the oxygen content on GaAs etched with CCl_2F_2 gas was larger than for the native oxide before RSE based on the relative intensity of the O 1s to the Ga 3d and As 3d bands. This indicates that the damaged surface of RSE-GaAs is more active toward oxidation. Since the chemical state of the surface oxide formed after RSE is thought to reflect that of the RSE-GaAs surface, the Ga 3d and As 3d core levels were measured on the oxide to estimate the RSE-GaAs surface variation.

The XPS spectra of Ga 3d and As 3d core levels in the GaAs substrate were obtained at 18.5 and 40.7 eV, respectively, in binding energy. Chemical shifts of Ga 3d (+1.0 eV) and As 3d (+3.0 eV) were also observed, which corresponded to Ga_2O_3 and As_2O_3 , respectively (11), but the As 3d chemical shift of +5.0 eV corresponding to As_2O_5 (11) was not observed in this study.

Fig. 1. XPS spectra of GaAs surface before and after RSE with bias voltage at 0.6 kV.

Fig. 2. The intensity ratio of As 3d/Ga 3d which involves both GaAs and oxide states, and the intensity ratio of oxide/GaAs of As 3d and Ga 3d as a function of RSE bias voltage.

The total intensity ratio $I_{As(GaAs - Oxide)}/I_{Ga(GaAs + Oxide)}$ as well as the oxide-to-GaAs intensity ratios $I_{Ga(Oxide)}/I_{Ga(GaAs)}$ and $I_{As(Oxide)}/I_{As(GaAs)}$ were plotted as a function of RSE bias voltage in Fig. 2. The former intensity ratio indicates the intensity ratio of the sum of the As 3d photopeaks in GaAs and oxide states to that of the Ga 3d photopeaks in GaAs and oxide states. These measurements were carried out at $\theta = 90^\circ$, because the deep region was desired to be examined. $I_{As(GaAs + Oxide)}/I_{Ga(GaAs + Oxide)}$ decreases from about 0.8 to 0.6 with an increasing bias voltage, indicating that As is easily removed from the surface subjected to RSE with an ion energy higher than 0.4 keV. This energy might be the critical point at which the GaAs crystal was destroyed.

As bias voltage increases, $I_{As(Oxide)}/I_{As(GaAs)}$ drops rapidly and remains constant. On the other hand, $I_{Ga(Oxide)}/I_{Ga(GaAs)}$ increases from about 0.8 to 1.5. These results suggest that the RSE-GaAs surface oxide might consist of both an As containing oxide and an As-free oxide whose thicknesses should increase with bias voltage.

Chemical states of RSE-GaAs surface.—ARXPS was used in order to examine the oxidation state of the RSE-GaAs extreme surface region. Figure 3 shows ARXPS spectra of Ga 3d and As 3d from $\theta = 90^\circ$ – 25° where the

(a)

(b)

Fig. 5. a: Two-layer structure model of reactive-sputter-etched GaAs surface oxide. b: Calculated oxide thickness of RSE GaAs based on the two-layer structure model as a function of RSE bias voltage.

RSE bias voltage was set at 0.6 kV. No crystalline defects are found by transmission electron microscope observation, but a stoichiometric variation is observed on RSE-GaAs at this bias voltage. By increasing the bias voltage, the As 3d intensity weakens compared with Ga 3d, and the oxide photopeaks grow stronger relative to the substrate signals. This indicates that oxides cover most of the available surface area and that As_2O_3 is depleted relative to Ga_2O_3 at the extreme surface.

Both oxide and substrate As 3d photopeaks are barely

$$\frac{I_{\text{Ga(Oxide)}}}{I_{\text{Ga(GaAs)}}} = \frac{n_{\text{Ga}}^{\text{I}} \lambda_{\text{Ga}}^{\text{I}} \left[1 - \exp\left(-\frac{t_1}{\lambda_{\text{Ga}}^{\text{I}} \sin \theta}\right) \right] + n_{\text{Ga}}^{\text{II}} \lambda_{\text{Ga}}^{\text{II}} \left[1 - \exp\left(-\frac{t_2}{\lambda_{\text{Ga}}^{\text{II}} \sin \theta}\right) \right] \exp\left(-\frac{t_1}{\lambda_{\text{Ga}}^{\text{I}} \sin \theta}\right)}{n_{\text{Ga}}^{\text{III}} \lambda_{\text{Ga}}^{\text{III}} \exp\left(-\frac{t_2}{\lambda_{\text{Ga}}^{\text{II}} \sin \theta}\right) \exp\left(-\frac{t_1}{\lambda_{\text{Ga}}^{\text{I}} \sin \theta}\right)} \quad [2]$$

observable at $\theta = 25^\circ$, where the escape depth of As 3d photoelectrons is calculated to be about 5Å and surface-sensitive XPS spectra can be obtained. Therefore, the extreme surface region is found to abound with Ga_2O_3 and be very scarce in As_2O_3 and GaAs components. It is expected that the surface oxide layer after RSE splits into two layers with Ga_2O_3 in the first layer and $\text{Ga}_2\text{O}_3 + \text{As}_2\text{O}_3$ in the second layer. The fact that the As 3d substrate signal is found in a very small amount of $\theta = 25^\circ$ also suggests that GaAs patches remain even in the second oxide layer, and that the interface between the second layer and the GaAs substrate is not flat, or that the $\text{As}_2\text{O}_3/\text{Ga}_2\text{O}_3$ ratio in the second layer changes from 1 at the interface between the second layer and the substrate to 0 at the interface between the first and the second layer.

Figure 4 shows the dependence of the Ga 3d and As 3d intensity ratios of the oxide to the GaAs substrate on take-off angle, comparing the oxidation state of the RSE-GaAs surface with the native oxide before RSE in order to distinguish the RSE-GaAs surface from the non-RSE-GaAs surface. The solid line is from the present work and indicates the oxidation state on the GaAs surface after RSE with CCl_2F_2 at 0.6 kV, and the dotted line is from Kohiki *et al.*, who reported on the native oxide of the GaAs (100) surface (8). At $\theta = 90^\circ$, $I_{\text{Ga(Oxide)}}/I_{\text{Ga(GaAs)}}$ of RSE-GaAs is twice as strong as that of native oxide, while $I_{\text{As(Oxide)}}/I_{\text{As(GaAs)}}$ is almost the same value in both RSE-GaAs and native oxide. This indicates that the oxide layer of RSE-GaAs differs from the native oxide on two points, *i.e.*, that the oxide thickness on the etched wafer is thicker than that of the latter and that it also contains a higher mole fraction of Ga_2O_3 .

The comparison of RSE-GaAs surface oxide with the native oxide at the small θ region shows that the former is more easily oxidized than the latter. Because the GaAs surface is attacked by ions and radicals derived from CCl_2F_2 during RSE, and As atoms are removed selectively from the surface region, many As-removed holes surrounding the Ga atoms exist in the surface region. This results in the surface becoming an active state, where oxygen molecules are easily dissociated and adsorbed.

Although the $I_{\text{As(Oxide)}}/I_{\text{As(GaAs)}}$ of RSE-GaAs is almost the same as that of native oxide at $\theta = 60^\circ$ - 90° , it begins to increase more than the $I_{\text{As(Oxide)}}/I_{\text{As(GaAs)}}$ of native oxide with a decreasing θ from about 40° . This result implies that As atoms are also easily oxidized because a small amount of Ga atoms are also removed and O atoms intrude the neighborhood of As atoms.

Oxide layer structure.—The oxide layer thickness of the RSE-GaAs surface was estimated from the model as shown in Fig. 5a. Here we assumed that a Ga_2O_3 homogeneous layer exists in the first layer and a mixed layer of Ga_2O_3 and As_2O_3 exists in the second layer. The RSE-GaAs surface and the interface between the two layers are supposed to be flat. The intensity of photoelectrons I is given by Eq. [1] as

$$I = C \int_0^\infty n(x) \exp[-x/\lambda(x) \sin \theta] dx \quad [1]$$

where C is a proportional constant, $n(x)$ is the number of atoms per unit volume at a depth x , σ is the ionization cross section, $\lambda(x)$ is the photoelectron escape depth of each layer, and θ is the take-off angle. The λ of both Ga 3d and As 3d in Ga_2O_3 are 13Å and that in As_2O_3 is 21Å; they are calculated by the method of Penn (12). For the λ of Ga 3d and As 3d in GaAs, 16 and 19Å were adopted, respectively (8).

The intensity ratio equations of oxide to GaAs concerning Ga 3d and As 3d were made from Eq. [1] as

$$\frac{I_{\text{As(Oxide)}}}{I_{\text{As(GaAs)}}} = \frac{n_{\text{As}}^{\text{II}} \lambda_{\text{As}}^{\text{II}} \left(1 - \exp\left(-\frac{t_2}{\lambda_{\text{As}}^{\text{II}} \sin \theta}\right) \right)}{n_{\text{As}}^{\text{III}} \lambda_{\text{As}}^{\text{III}} \exp\left(-\frac{t_2}{\lambda_{\text{As}}^{\text{II}} \sin \theta}\right)} \quad [3]$$

Here, t_1 and t_2 are the thicknesses of the first and second layers, and Roman numbers I, II, and III mean the first layer, second layer, and substrate, respectively. The t_1 and t_2 were calculated by the least squares method using Eq. [2] and [3] and the measured values.

Figure 5b shows the calculated oxide thickness of RSE-GaAs based on the two-layer structure model as a function of bias voltage. The Ga_2O_3 top layer enlarges to about a 7Å thickness with bias voltage, though it is apparent that an As-free oxide top layer does not exist on the native oxide before RSE. On the other hand, the mixed layer thickness of Ga_2O_3 and As_2O_3 is reduced from 20 to 13Å by 0.2 kV RSE, and remains about 13Å for the bias voltage increase.

The total oxide thickness on the RSE-GaAs surface becomes slightly thinner at 0.2 kV than the native oxide, growing gradually thicker with a bias voltage of more than 0.4 kV. This tendency will accelerate with increasing bias voltage above 0.8 kV, because the damaged layer spreads deeper and the mirror gloss of the surface is lost. The reason the total oxide thickness becomes thinner at 0.2 kV may be explained by the fact that only the native oxide on the GaAs wafer is etched by 3 min RSE at 0.2 kV.

The GaAs surface after RSE was oxidized immediately by contact with air because of its activity. The oxide layer thickness was equal to that of the natural oxide layer before RSE if the mirror gloss of the surface was maintained under RSE conditions. However, the oxide layer after RSE with CCl_2F_2 split into two layers, which were composed of the Ga_2O_3 top layer without As atoms and the $\text{Ga}_2\text{O}_3 + \text{As}_2\text{O}_3$ mixed underlying layer. This suggests that during RSE of GaAs using CCl_2F_2 , As atoms break away first and then the remaining Ga atoms are released.

Here the layers I and II were assumed to be homogeneous and flat. However, in the real surface, the interface between the layers I and II, or the layers II and III, may not be flat. The $\text{As}_2\text{O}_3/\text{Ga}_2\text{O}_3$ ratio in the layer II may not be constant, and the layer II may contain bare GaAs patches.

In this paper, the chemical states of GaAs surfaces etched with CCl_2F_2 and air oxidized were determined. These results imply that the oxide layer structure of the RSE-GaAs surface etched with CF_4 and CCl_4 (which makes the GaAs surface Ga rich) as well as CCl_2F_2 is $\text{Ga}_2\text{O}_3/\text{Ga}_2\text{O}_3 + \text{As}_2\text{O}_3$, and that the surface etched with CHCl_3 (which makes the GaAs surface As rich) is $\text{As}_2\text{O}_3/\text{Ga}_2\text{O}_3 + \text{As}_2\text{O}_3$.

Conclusion

The air-exposed GaAs surface following RSE with CCl_2F_2 gas was investigated using angle-resolved XPS. The surface oxide layers split into a two-layer structure consisting of a Ga_2O_3 top layer and a mixed layer of $\text{Ga}_2\text{O}_3 + \text{As}_2\text{O}_3$, *i.e.*, no As atoms are found to exist in the top layer. The thicknesses of these layers were calculated by means of photoelectron intensity ratios and estimated es-

cape depths of Ga 3d and As 3d. The top Ga₂O₃ layer thickness enlarges with bias voltage, whereas the mixed layer thickness of Ga₂O₃ + As₂O₃ diminishes somewhat. The total oxide thickness grows gradually thicker with a bias voltage over 0.4 kV, and is nearly equal to that of the native oxide before etching unless the mirror gloss of the GaAs surface is lost by RSE.

When GaAs is reactive-sputter-etched with CCl₂F₂ gas, Ga and As do not break away at the same time, but rather Ga is released later following the release of As from the surface, which is exposed to a CCl₂F₂ plasma. Consequently, many As vacancies exist in the surface region and the RSE-GaAs surface becomes active to oxygen uptake.

Silicon Layers Grown by Differential Molecular Beam Epitaxy

H.-J. Herzog and E. Kasper

AEG-TELEFUNKEN Forschungsinstitut, D-7900 Ulm, Germany

ABSTRACT

We report on molecular beam epitaxy (MBE) of Si layers at 750° and 550°C onto (100) Si substrates covered with a patterned oxide mask. Within the exposed substrate windows epitaxial growth and on the oxide-covered areas polycrystalline growth take place at both temperatures. Different ratios of MBE film thickness to oxide thickness have been realized. The lattice perfection of the epitaxial layers, the grain size of the poly-Si, and the boundary between the single-crystalline and the polycrystalline Si at the oxide edges were investigated by scanning and transmission electron microscopy complemented by Nomarski microscopy and Secco etching. These differential MBE layers reproduce the oxide pattern and, with MBE films thinner than the oxide, the layer on top of the oxide can be removed by a lift-off step. The electrical conductivity of Sb-doped differential MBE layers is measured by means of spreading resistance. As an example of device application, a molybdenum Schottky diode is prepared and electrically characterized.

At present, the molecular beam epitaxy of silicon (Si-MBE) is capable of growing uniform layers on large area substrates (1, 2) with high crystal quality and, in particular, with arbitrary doping profiles (3, 4). However, in integrated device fabrication, the uniform planar epitaxy is a very early step and subsequent high temperature processes for preparation of lateral device dimensions limit or even destroy the advantage of the low temperature MBE process. Therefore, and also with respect to novel devices it may be promising to define lateral structures by the epitaxy process itself (5). This can be achieved by Si-MBE on a suitable prepatterned substrate surface without any change in growth parameters compared to uniform MBE layers. With VPE, for example, selective growth on a substrate with a SiO₂ pattern can be attained when the growth conditions are balanced near equilibrium by adding an etching gas such as SiCl₄ (6). Near-equilibrium nucleation takes place only on the Si; it does not on the SiO₂. With MBE, the situation is completely different because growth always takes place under heavy supersaturation. At the usual Si-MBE temperatures, the growth rate is temperature independent, the desorption is negligible, and the condensation coefficient is near unity (7, 8). On the SiO₂ surface, two reactions are possible: (i) impinging Si atoms react with SiO₂, forming volatile SiO, and the velocity of this oxide consuming reaction being strongly dependent (9); and (ii) above a critical growth rate, the nonconsumed Si condenses on the SiO₂ surface and suppresses reaction (i) by growing a polycrystalline layer on top of the oxide. A sketch of the possible results is given in Fig. 1.

At high substrate temperatures (Fig. 1a) reaction (i) dominates up to growth rates ranging from 0.03 nm/s at

850°C to 2 nm/s at 1000°C. An epitaxial layer grows on the Si surface, whereas the oxide thickness decreases. Depending on the initial oxide height, the resulting surface can be flat or the oxide layer can be consumed completely.

At the usual MBE temperature, reaction (i) is slow (Fig. 1b and 1c). On the oxide surface, a polycrystalline layer forms, whereas on the substrate an epitaxial layer grows (10-12). For this growth mode of uniform deposition on SiO₂ and Si but selective epitaxy on Si, the terms differential epitaxy (10) or patterned epitaxy (11) are used. Here, two cases can be distinguished: with thick oxides (oxide layer thicker than epitaxial layer, Fig. 1b) the poly- and single-crystalline layers are separated and, if necessary, the poly-Si can be removed by a lift-off procedure (11). With thin oxides (Fig. 1a), there is an interface between the epitaxial layer and the poly-Si film. Employing additional technological steps (etching, ion implantation), the poly-Si layer can be utilized for structures such as resistors and contact connections.

In the present study, differential epitaxial growth of undoped and Sb-doped films was carried out at growth temperatures of 750° and 550°C onto Si substrates provided with a patterned mask of SiO₂. Particular attention was directed to the two cases: MBE layer thinner than the SiO₂ and MBE layer thicker than the SiO₂.

The lattice perfection of the epitaxial layers, the grain size of the polycrystalline Si, the boundary between the single- and polycrystalline films, and the pattern distortion, *i.e.*, change of lateral dimensions of the mask pattern after layer deposition, were investigated by scanning electron microscopy (SEM) and transmission electron microscopy (TEM) assisted by Nomarski interference micros-

copy and Secco etching. The strain of a poly-Si film was determined by means of x-ray diffraction. The electrical conductivity of Sb-doped layers was examined by spreading resistance measurement. As an example of device applications, a molybdenum Schottky diode was prepared.

Sample Preparation

Standard 3 in. diam (100) silicon substrates of 1000 $\Omega\text{-cm}$ p-type and 1 $\text{m}\Omega\text{-cm}$ n-type resistivity were used. Thermally grown SiO_2 with thicknesses ranging from 0.1 to 0.5 μm was chosen as masking material. Two different mask patterns, one consisting of a simple layout of circles ranging from 3 to 10 μm in diameter and another more complex memory-test layout, were transferred by optical lithography. The 0.1 μm thick SiO_2 was only wet chemically etched. In contrast, the 0.5 μm thick SiO_2 was reactive ion etched in a fluorine plasma to achieve oxide walls as vertical as possible. The plasma etching was stopped 30-50 nm before reaching the oxide-substrate interface. Thus, any contamination and damage caused by the reactive etch was avoided. A final wet chemical etching step using buffered HF was performed to completely open the windows. Before loading into the MBE apparatus, all wafers were subjected to a conventional cleaning procedure [RCA etch (13)].

The high throughput MBE apparatus used for these experiments is described in detail elsewhere (2). A brief description is as follows. A separately UHV-pumped storage chamber with a ten-wafer cassette for 3 in. standard substrates is connected with the growth chamber by a pneumatic gate valve. The main elements of the epitaxy chamber are a UHV-pump system, a radiation-heated substrate heater, an electron gun for silicon, effusion cells for dopant evaporation (all beam sources provided with shutters), and *in situ* control facilities such as a thickness monitor, a quadrupole mass spectrometer, charged particle detectors, and temperature sensors. After loading a

substrate from the cassette into the substrate heater, the epitaxy process starts at a total pressure in the 10^{-8} Pa range with an annealing step (5 min at 900°C). The substrate temperature is then reduced to the desired epitaxy temperature and the shutters above the preadjusted molecular beam sources are opened.

Results

MBE layers were grown at epitaxy temperatures of 750° and 550°C and with different ratios of layer thickness to oxide thickness. As an essential result, it is found that at both epitaxy temperatures single-crystalline growth takes place onto the exposed substrate areas. The layers on top of the oxide exhibit polycrystalline growth, as shown by TEM analysis. The grain size was found to depend on epitaxy temperature and layer thickness as well. In Fig. 2, typical TEM micrographs of layers grown at 750°C are inset in the diagram showing an almost linear increase of the average grain size from $0.1 \mu\text{m}$ at a layer thickness of $0.2 \mu\text{m}$ to $0.75 \mu\text{m}$ at a thickness of $3 \mu\text{m}$. At 550°C , the average grain sizes range from 30 nm at a layer thickness of $0.2 \mu\text{m}$ to 40 nm at $0.7 \mu\text{m}$. A similar dependency of grain size on film thickness was reported recently by Lu and co-workers (14) for LPCVD poly-Si layers grown at 620°C on thermal oxide. On fused quartz, Matsui *et al.* (15) reported growth of polycrystalline films by molecular beam deposition (MBD) down to 400°C .

One goal of this work was to study the transition regions between the single-crystalline layer in the windows and the polycrystalline layer on top of the oxide. In Fig. 3, two top-view SEM micrographs of differential MBE layers are shown with an oxide thickness of $0.5 \mu\text{m}$ and a layer thickness of $0.2 \mu\text{m}$ grown at epitaxy temperatures of 750° (Fig. 3a) and 550°C (Fig. 3b) representing the case of layer thickness smaller than the oxide thickness. Both single-crystalline films are completely smooth and, as revealed by Secco etching, free of detectable crystal de-

Fig. 5. Cross-sectional SEM micrographs of differential MBE layers around an oxide step with layer thickness ($0.8 \mu\text{m}$) larger than oxide thickness ($0.5 \mu\text{m}$). Epitaxy temperatures are 750° (a) and 550°C (b).

fects. Owing to the difference in grain sizes the poly-Si in Fig. 3a exhibits a rather grainy surface structure, whereas the poly-Si in Fig. 3b shows a fine roughness only. A subsequent treatment in an ultrasonic HF acid bath for 10-20 min completely lifts off the poly-Si layer parts by dissolving the SiO_2 and produces mesa-like single-crystalline islands on the substrate. The lift-off with the circular patterned SiO_2 is shown in Fig. 4a and Fig. 4b for layers grown at 750° and 550°C , respectively. The mask pattern is exactly reproduced leaving epitaxial disks of $3 \mu\text{m}$ diam and $0.2 \mu\text{m}$ height on the substrate surface. The notches at the rim of the mesa in Fig. 4a may be due to a shadowing effect during the growth by overhanging grains.

As a second important case, we prepared samples with oxide thickness smaller than the MBE layer thickness. In Fig. 5, SEM micrographs of the cross section of MBE layers grown at 750° (Fig. 5a) and 550°C (Fig. 5b) are given. The thicknesses of the masking oxide and the MBE layer amount to 0.5 and $0.8 \mu\text{m}$, respectively. That means that above the oxide edge the single-crystalline film comes in contact with the polycrystalline layer. After polishing the cross section, the samples were treated by Secco etch for 5s to intensify the contrast in the micrographs. The MBE layers reveal on the surfaces an exact replica of the oxide step without any significant pattern distortion equally in the lateral direction and in the vertical direction. The microscopic structure of the transition region polycrystalline/single-crystalline layer is demonstrated by the top-view TEM micrograph in Fig. 6. The layer sequences are $0.1 \mu\text{m}$ thick oxide and $0.2 \mu\text{m}$ thick MBE film grown at 750°C . There is a sharp transition between the polycrystalline and the single-crystalline Si. With exception of some small stacking faults or twin faults at the boundary, no crystal defects were found within the crystalline film. By preparing a sample with a patterned oxide layer of $0.14 \mu\text{m}$ followed by a $3 \mu\text{m}$ thick MBE layer grown at 750°C , it is illustrated that the pattern distortion is by far smaller than the film height. In Fig. 7 a top-view Nomarski micrograph of this differential MBE layer and a correspond-

Fig. 6. Top-view TEM micrograph showing some stacking faults or twin faults at the single-crystalline/polycrystalline boundary. Layer thickness: $0.2 \mu\text{m}$. Oxide thickness: $0.1 \mu\text{m}$. Epitaxy temperature: 750°C .

ing cross-sectional SEM micrograph are given. The cross-sectional sample has been etched for 5s in Secco etch. Of course, there is a strong interlocking between the single-crystalline and polycrystalline layer, but the boundary runs almost vertically from the oxide edge to the layer surface. From the SEM micrograph, the pattern distortion on the layer surface can be estimated to be about $0.5 \mu\text{m}$.

With a wafer having the same thickness sequence as in Fig. 7, but an unpatterned oxide, an analysis of the strain in the layer was performed. Since a strained layer causes a bending of the substrate-overgrowth structure, the curvature k of the sample was measured by means of x-ray diffraction (16, 17) before and after Si-MBE. The film strains ϵ_f were calculated in terms of substrate thickness t_s and film thickness t_f using the relation (18)

$$\epsilon_f = \frac{kt_s^2}{6t_f}$$

It is found that both the SiO_2 film and the polycrystalline layer are under compressive strain of -2.85×10^{-3} and -0.5×10^{-3} , respectively. Accordingly, the strain in the poly-Si layer is more than a factor five smaller than in the oxide film.

With respect to the preparation of Schottky diodes as an example for device application of this differential growth technique, Sb-doped layers with thicknesses ranging from 0.2 to $0.8 \mu\text{m}$ were grown at 550°C on n^+ substrates. The pattern in the $0.5 \mu\text{m}$ thick masking oxide consisted of circular windows. The conductivity of these layers was measured using a spreading resistance probe. The resistivity within the single-crystalline parts amounts to $6.5 \times 10^{-2} \Omega\text{-cm}$ corresponding to a doping level of $1.5 \times 10^{17} \text{cm}^{-3}$. In contrast, the spreading resistance of the poly-Si layers on top of the oxide was found to be beyond the measuring range ($10^9 \Omega$) of the apparatus used. Hence it follows that the resistivity of the poly-Si is as much as five orders of magnitude higher than that of the adjoining single-crystalline Si. This considerably deviates from the result of differential MBE given by Ota (10), who reported a change in resistivity of about two magnitudes. However, this may be due to the higher epitaxy temperature of 800°C and/or the other dopant type and doping technique, namely, B doping by ion implantation. The doping profile as calculated from the spreading resist-

ance in the single-crystalline areas is shown in Fig. 8, demonstrating that an abrupt transition occurs at the interface between substrate and MBE layer followed by a flat Sb profile of $n = 1.5 \times 10^{17} \text{ cm}^{-3}$ within the layer.

As Schottky barrier material, a Mo-Ti-Au metallization was deposited onto differential MBE layers and structured by optical lithography and chemical etching. A cross-sectional view of a Schottky diode with a 0.2 μm thick MBE film grown at 550°C is sketched in Fig. 9a. The I-V curve of such a Schottky diode is shown in Fig. 9b, clearly revealing forward and reverse characteristics. The reverse breakdown voltage is typical for the film thickness and doping density.

Conclusion

Si-MBE layers were grown at two different temperatures on Si substrates covered with a mask oxide. Thicknesses of the Si and SiO₂ films ranged from 0.2 to 3 μm and from 0.14 to 0.5 μm , respectively. The following results are obtained from these differential MBE layers.

At both epitaxy temperatures of 750° and 550°C epitaxial growth with good crystal perfection takes place on the exposed substrate areas.

On the oxide polycrystalline growth is obtained. The grain sizes of layers grown at 750°C are found to increase almost linearly from 0.1 μm at 0.2 μm film thickness to

0.75 μm at 3 μm film thickness. At 550°C, the grain sizes amount to 30 nm at 0.2 μm film thickness and 40 nm at 0.7 μm , respectively.

With layer thickness smaller than the oxide thickness, the single-crystalline film is separated from the surrounding polycrystalline layer provided that the oxide walls are nearly vertical. If desired, the poly-Si can be lifted off by dissolving the oxide. By that means mesa-like epitaxial layers are obtained which exactly reproduce the pattern of the oxide.

With layer thickness larger than the oxide thickness, the single-crystalline film is interlocked with the surrounding oxide overlayer. However, the boundary proceeds almost vertically from the oxide edge to the layer surface. Hence, the pattern distortion is by far smaller than the film height even if the thickness ratio between MBE and oxide is 3-0.14 μm .

The poly-Si is under compressive strain. This strain for 3 μm thick layers grown at 750°C amounts to 5×10^{-4} , which is more than five times smaller than the compressive strain in the underlying oxide.

Differential Si-MBE layers intentionally doped with Sb to $n = 1.5 \times 10^{17} \text{ cm}^{-3}$ were analyzed by spreading resistance. A sharp transition and a flat profile are obtained in the single-crystalline regions. On the other hand, in the polycrystalline films up to a thickness of 0.8 μm the resistivity is found to be as much as five decades higher in comparison to the adjoining single crystal.

Acknowledgments

The authors wish to thank H. Kibbel for MBE work. They would also like to thank H. Jorke, S. Lindenmaier, D. Gruchmann, Dr. K. Strohm, C. Adamek, A. Schaub, and W. Pilz for technical assistance. Support by the Ministry of Research and Technology of Germany is acknowledged.

Instrumental Neutron Activation Analysis of Processed Silicon

Joseph A. Keenan,* Bruce E. Gnade, and John B. White

Texas Instruments, Incorporated, Materials Science Laboratory, Dallas, Texas 75265

ABSTRACT

Instrumental neutron activation analysis has been applied to the surfaces of processed silicon wafers with analytical sensitivity down to parts per million of a monolayer. Residual contamination with gold, copper, and sodium has been shown to be consistently present in the range 4-500 ppm of a monolayer. Copper and sodium are added to the surface from oxidation furnaces.

The electrical properties of Si, and, therefore, the yield of usable devices fabricated from Si, are dependent upon impurity concentrations in the range of subparts-per-billion to parts-per-million. In order to determine impurity concentrations at these levels in small samples, it is necessary to use a very sensitive analytical technique. Instrumental neutron activation analysis (INAA) fulfills most of the requirements necessary for this analysis. The present work is an application of INAA as a monitor for silicon device processing.

The sensitivity of INAA for key elements such as gold, copper, and sodium allows detection at concentration levels which are too low to distinctly impact device performance. Therefore, it is desirable to determine an acceptable base line of impurity levels in manufacturing. This base line was established by collecting data over a 2.5 yr period, incorporating data from a wide range of cleanup and oxidation process steps. The great sensitivity of INAA allows for the realization of changes in impurity concentrations before they cause measurable yield loss in a monitored process. As might be expected, there is a great deal of scatter in the data when very low concentrations are measured. Nevertheless, enough data have been acquired to justify a statistical analysis. This provides a basis for understanding when a contamination level is out of control as well as a means of determining when trends arise or when significant changes in contamination levels have occurred.

Neutron activation is especially applicable for samples in which the matrix does not become highly activated, such as high purity Si or graphite. More than 40 elements undergo neutron capture to produce radioactive products which are readily detectable by gamma-ray spectroscopy. Quantitation in INAA requires a knowledge of the neutron flux to which the samples are exposed. The flux can be determined using one of several single-flux monitor procedures (1-4). In the present work, the average flux was initially derived from the use of a single Au and Co monitor (2). This method of flux determination, in conjunction with the Westcott formalism (5) for obtaining effective (thermal/epithermal) neutron cross sections, has been shown to be a valid quantitative technique (2), if the energy distribution of the reactor's neutron flux is stable.

Experimental

The utilization of INAA as a monitor for wafer processing is done best using relative measurements to compare unprocessed wafers (as controls) with processed wafers. Both N<111> and P<100> 3 in. wafers were monitored. Pilot wafers were processed in several different types of equipment for each procedure so that individual oxidation furnaces and cleanup apparatus could be compared.

It is important to remember that any contamination introduced after the irradiation will not affect the analysis, since it is not radioactive. Handling through completion of the test up to the irradiation is the critical step. A set of pilot wafers was selected from N<111> and P<100> unprocessed starting material, with controls for each group being set aside at this point. The pilot wafers were prepared for testing in a class 100 clean room. Some of these

wafers were used to test the effectiveness of the various clean-up procedures and apparatus. The remaining wafers were then subjected to the standard preoxidation cleanup, which is described below, and used to test oxidation furnaces. The flow of test wafers is depicted in Fig. 1.

Upon completion of the tests, the wafers were scribed, broken, and placed in a clean 2 in. quartz dish. This work was done in an area with less than 1500 particle/ft³. Prior to use, the quartz dish was cleaned by (i) soaking in H₂SO₄:H₂O₂ (7:4) mixture for 10 min, (ii) rinsing with de-ionized (DI) water for 10 min, (iii) soaking in 10% HF for 1 min, (iv) rinsing with DI water for 10 min, (v) soaking in HCl:H₂O₂:H₂O (4:1:5) for 2 min, and (vi) finally rinsing for 10 min in DI water. The individual wafers were separated by clean 2 in. Si slices. The wafers were held in place by a piece of compressed Zr foil to minimize breakage. The quartz dish was then wrapped in Al foil and placed inside an Al irradiation container. The Al container was sealed with epoxy to avoid leakage of reactor cooling water onto the samples.

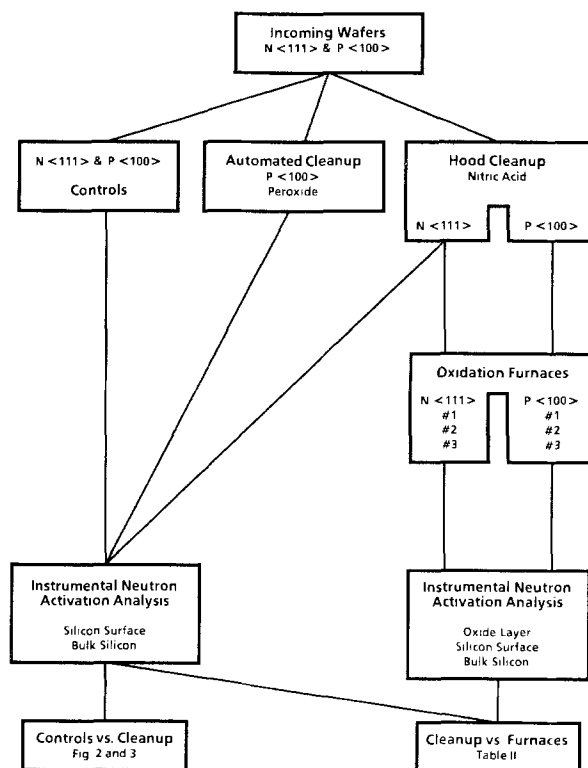

Fig. 1. A diagram of the materials flow for INAA testing. Incoming N<111> and P<100> wafers were sampled as controls. P<100> wafers went through an automated cleanup using peroxide-based chemicals. N<111> and P<100> wafers went through a conventional cleanup hood in which nitric acid served as the inorganic cleanup step, and then went on to test oxidation furnaces. Some N<111>, but no P<100>, wafers were tested by INAA following the hood cleanup, but the control wafers are compared to cleaned wafers in Fig. 2 and 3. Cleaned wafers are compared to wafers from oxidation furnaces in Table II.

*Electrochemical Society Active Member.

The samples were irradiated at the Texas A&M Nuclear Science Center research reactor for 14h at a nominal flux of 1.5×10^{13} neutron/cm²-s. The maximum sample size is a cylinder approximately 5 cm in diameter by 2.5 cm in height. Analysis begins about 12h after irradiation, allowing the detection of short-lived isotopes such as ⁶⁴Cu and ²⁴Na in the oxide and surface layers. This decay time allows the activity of the ³¹Si ($t_{1/2} = 2.62$ h) matrix and ²⁸Al ($t_{1/2} = 2.24$ min), which is formed from ²⁸Si, to decay to a safe level. Once the samples are received, they are rinsed three times with an HCl/CH₃OH mixture to remove any surface contamination that may have inadvertently been introduced during the packaging procedure. If the surface of the sample is to be analyzed, the back of the sample is protected with acid-resistant tape. The oxide layer, if any, is removed with 50% HF, and the etch solution is analyzed to determine contamination levels in the oxide. Next, approximately 2 μm of material is removed by etching the sample for 30s in planar etch (2HF:15HNO₃:5 acetic acid). This etch solution, which represents a sample of the surface contamination, is then analyzed. The remainder of the sample is etched three times in an HF:HNO₃ (1:3) solution, and then in a warm Aura etch solution (1% NaOH, 1% EDTA, 2.5% p-nitrobenzoic acid, and 1% NaCN) to remove and complex any further surface contaminants. The etched wafer is then analyzed as a solid, giving a good measure of the quality of the bulk material.

The oxide and surface solutions are counted at approximately 15h after the end of irradiation, while the bulk samples are counted at 30h and again at 60h after the end of irradiation. The bulk samples are counted at two different times to give maximum sensitivity for both short- (⁶⁴Cu, ²⁴Na, etc.) and long-lived (⁵⁹Fe, ⁶⁰Co, etc.) species, as well as to ensure that the elemental identification is correct. (Elements are identified by both half-life and gamma-ray energy.)

The samples are counted for periods of 8000s each on each of three large volume Ge(HP) detectors. These detectors have > 20% relative efficiency at 1.3 MeV, with an energy resolution of 1.8 keV FWHM at 1332 keV. The solutions are counted in a standard geometry, which is directly against the face of the detector. Each detector is housed inside a graded Pb shield to minimize background radiation. The systems are calibrated for energy and efficiency with an absolutely calibrated mixed-radionuclide source of the same geometry as the etch solutions. The data are acquired with a computer-based multichannel analyzer, and stored on local floppy disk. Once acquisition is complete, the spectral data are transferred from the multichannel analyzer to a VAX 11-750, where the data reduction is performed.

Concentrations of contaminants are determined by calculating the volume of Si present from the amount of ³¹Si activity (4). This eliminates the need to precisely determine the neutron flux for each irradiation, since everything is measured relative to the counting rate of the 1266 keV gamma ray from the decay of ³¹Si. The drawback to this technique is that the absolute accuracy of contamination levels is only as good as the accuracy of the ³⁰Si

thermal cross section and resonance integral, as well as the Cd ratio. We feel these errors are constant and insignificantly larger than the errors encountered in measuring the flux with external monitors (2). For bulk silicon samples, this method also avoids the experimental errors generated in determining the absolute counting efficiency for each different sample shape. Surface contaminations in units of atoms per square centimeter were computed using the concentrations derived from INAA (atoms per cubic centimeter) and the measured weight and thickness of the sample, assuming a density of 2.32 g/cm³ for silicon. Contamination levels measured in these units were found to be independent of the thickness of "surface sample" removed by etching.

Results and Discussion

Surface contaminants can be broadly classified as either organic or inorganic. Most organic contaminants are residual materials such as waxes, resins, oils, and trace residues from solvents. Layers of such organic impurities are usually chemisorbed to the surface. However, inorganic contaminants such as sulfate ion, sodium, copper, and gold are either physically adsorbed, electrochemically deposited on the surface or entrapped in the oxide film (6).

The sequence of surface cleaning must follow a logical course: (i) organic contaminants must be removed before subsequent reagents can contact the underlying surface; (ii) next, the native oxide on bare silicon or the outer 100-200Å of oxide on an oxide film must be removed; (iii) then it is possible to remove inorganic contaminants (7).

In the processes tested here, a mixture of sulfuric acid and hydrogen peroxide was routinely used for the removal of organic contaminants. Oxide removal was done with hydrofluoric acid diluted 10:1 with deionized water. Inorganic removal was done with one of two alternate methods. The first method used nitric acid preceded and followed with extensive rinses in deionized water. The second method used a sequence of ammonium hydroxide with hydrogen peroxide and hydrochloric acid with hydrogen peroxide (7).

All N<111> wafers and all P<100> wafers being prepared for furnace tests received the first method for removal of inorganic contamination. This process is identified in Fig. 1 as the "hood cleanup" since all of these cleanups were performed manually in traditional cleanup hoods. The P<100> wafers tested after cleanup received the second method for removal of inorganic contamination. This step was carried out in automated equipment manufactured by FSI Incorporated and is identified in Fig. 1 as the automated cleanup.

In order to place the levels of contamination being measured in perspective, consider that one atomic layer on a <100> silicon surface should ideally consist of 6.8×10^{14} at./cm², while one atomic layer on a <111> silicon surface should consist of 7.8×10^{14} at./cm² on the basis of a purely geometric argument. Normalizing to units of monolayers shows that the surface concentrations measured in INAA are ppm of a monolayer. The following discussion will make use of these units.

The bulk contamination levels for Cu, Au, As, and Sb ranged from a low of 1×10^{10} at./cm³ for Au to a high of 6×10^{13} at./cm³ for As. The bulk detection limits for Fe and Zn are 1×10^{16} and 2×10^{14} at./cm³, respectively. These levels of contamination in the bulk are consistent with the reported concentration gradient (13) between surface and bulk material which is maintained during high temperature processing. Since the purpose of this work was to study the introduction and removal of surface contamination, only the oxide and surface data will be discussed here. Eight elements, listed in Table I, were detected in these samples. Table I lists the frequency with which these elements were detected and the maximum and minimum surface concentration detected. Based on Table I, gold, copper, and sodium were selected for statistical analysis. Chromium, cobalt, arsenic, and tungsten were detected far too inconsistently for statis-

Table I. The frequency of detection of eight elements in silicon surfaces (times detected/times analyzed). The top two rows list the maximum and minimum level detected in parts per million of a monolayer

	Au	Cu	Na	As	Sb	Cr	Co ^a	W

^a The detection limit for iron under these conditions for INAA is approximately 700 times worse than for cobalt.

tical analysis. Antimony was usually detected near the minimum value given in Table I, with the stated upper limit being an isolated occurrence.

An important dimension of any trace element analysis technique is the determination of a detection limit when an element is not observed. The formulation of Currie (8, 9) is used to calculate both a limit of qualitative detection, as well as a limit of quantitative determination. Detection limits were not entered into the data sets for statistical analysis. The number of data points analyzed for any particular set, therefore, is less than or equal to the total number of irradiations carried out during the test period. The statistical interpretation and presentation of the INAA data are based on the methods presented in Ref. (10).

Figure 2 compares the N<111> control wafers with the N<111> wafers after water-nitric-water inorganic cleanup with respect to the elements, sodium, copper, and gold. For both the long- and the short-term t-test, no significant difference is observed for the levels of copper and gold before and after cleanup. A significant improvement after cleanup is observed for sodium in the long term. The short-term difference is less clearly established. Figure 3 presents the same comparison for P<100> material. For these wafers, the peroxide-based inorganic cleanup was used in an automated system. Again, the elements sodium, copper, and gold are presented. Over both the short and the long term, significant improvement after cleanup is seen for sodium and gold. The short-term difference for copper is also significant.

With respect to the initial points, the last few points are "out of control" for all three elements on the P<100> control wafers (Fig. 3). These last points reflect a change in polishing procedures by the wafer supplier which appears to have had a favorable impact. Both the N<111> wafers and the P<100> wafers report points out of control for copper. The loss of control over copper is especially important for the P<100> process since it is this which casts doubt upon the long-term difference between control and post-cleanup samples.

Fig. 2. A comparison of surface contamination on cleaned N<111> wafers with "as-received" control wafers. The vertical scale is logarithmic with the labels in units of parts per million of a monolayer. The horizontal scale is linear in time. Asterisks indicate points which are "out of control" on a statistical basis. For sodium, a t-test shows an 80% probability of a true difference between the control wafers and cleaned wafers in the short term and 90% probability of a true difference in the long term. For copper and gold, the same test shows no significant difference.

Fig. 3. A comparison of surface contamination on cleaned P<100> wafers with "as-received" control wafers. The vertical scale is logarithmic. Asterisks indicate points which are "out of control" on a statistical basis. The points out of control for the control wafers reflect a change in polishing procedure by the wafer supplier. For sodium and gold, a t-test shows 99.9% probability of a true difference between the cleaned wafers and the control wafers in both the short and the long term. For copper, the significance of the difference is 90% in the short term and 80% in the long term.

A comparison of the N<111> control wafers (Fig. 2) and the P<100> control wafers (Fig. 3) suggests that the P<100> wafers were consistently more contaminated up until the change in polishing procedures. Schmidt *et al.* (11) observed that P<100> wafers are most prone to contamination during polishing, while N<111> wafers appeared to be the less readily contaminated. That trend is reflected here. Since the chemicals used in the cleanups and the method of applying those chemicals (manual *vs.* automated) differs, the impact of orientation or type upon ease of cleanup cannot be determined. In general, the cleanups were successful. The impurity levels observed on cleaned <111> and <100> slices are comparable and appear to represent very clean silicon surfaces.

Table II compares average results over the test period from the monitoring of three furnaces used to process

Table II. Surface impurity concentrations in parts per million of a monolayer for gold, copper, and sodium in cleaned wafers, and for test wafers from six oxidation furnaces

Wafer type process step	Gold	Copper	Sodium
N<111> hood cleanup	13	140	120
P<100> automated cleanup	23	100	200
Average cleaned wafer	18	120	160
Furnace N-type 1 oxide	0.2	19	180
Surface	3.5	86	81
Total	3.7	105	261
Furnace N-type 2 oxide	0.3	15	280
Surface	5.0	100	70
Total	5.3	115	350

Surface	8.0	190	86
Total	8.1	212	286

Fig. 4. Variations in time of copper contamination on pilot wafers processed in six furnaces. The data are for the silicon surface under the oxide layer. Three furnaces were used to process N<111> wafers, and three processed P<100> wafers. The vertical scale is logarithmic. Asterisks indicate points which are "out of control" on a statistical basis.

N-type <111> wafers and three furnaces used to process P-type <100> wafers with cleaned wafers. The results for cleaned wafers are the data from Fig. 2 and 3. P-type <100> wafers were cleaned along with the N-type <111> material for furnace tests (Fig. 1). However, no P-type wafers were set aside after cleanup.

After irradiation, the oxide layers and the silicon under the oxide were separated by etching and individually analyzed. Both results are included in Table II. Sodium appears mostly in the oxide sample, while copper and gold appear to a greater extent in the silicon surface sample. This result is produced during the oxide removal step by the tendency of copper and gold to deposit on a silicon surface from acid solution (6, 11). Sodium, being readily water soluble, is effectively removed with the oxide. Non-radioactive copper and gold carriers added to the planar etch used for silicon removal helped reduce this "plate-back" effect during the surface sampling. Nevertheless, the measured copper and gold levels are probably consistently underestimated due to this effect. Since the comparison here is between cleaned surfaces and processed surfaces, which were all analyzed in a consistent manner, any error due to "plate back" or sample preparation prior to irradiation should be systematic.

One would usually expect surface contamination carried into the furnace on the wafers or deposited on the wafers during the furnace step to appear in the oxide sample. Because of the sampling problem during oxide removal, it is preferable to compare the cleaned surfaces with the sum of impurities in the oxide and the surface samples. This is done in rows labeled "total" in Table II.

After oxidation, the level of gold contamination is consistent with cleaned wafers. Sodium is clearly high compared to cleaned wafers for N-type 3 and N-type 2. Two furnaces used for N-type <111> wafers, N-type 1 and 2 in Table II, maintain copper levels similar to cleaned wafers. The remaining four furnaces give evidence of copper contamination. The variations in copper contamination with time for the six furnaces are shown in Fig. 4. The time dependence of sodium contamination is shown in Fig. 5.

Fig. 5. Variations in time of sodium contamination on pilot wafers processed in six furnaces. The data are for the oxide layer. Three furnaces were used to process N<111> wafers, and three processed P<100> wafers. The vertical scale is logarithmic. Asterisks indicate points which are "out of control" on a statistical basis.

Changes over the test period such as copper in P-type 1 are readily seen, but the t-test used on Fig. 2-3 provides a firm basis for determining when there is a real difference. Figure 6 compares copper observed on the silicon surface for P-type 1 and sodium observed in the oxide layer from P-type 2 in the period March-November 1981 and December 1981-May 1983. The exact month in which

Fig. 6. A comparison of copper and sodium contamination on pilot wafers processed in furnace P-type 1 and P-type 2. The left-hand side represents the period from May 1981 to November 1981. The right-hand side represents the period from December 1981 to May 1983. The date chosen to define subsets of the test period is not exact. The t-test indicates that the level of copper is different for the two time periods with a 90% significance in the short term and 80% significance in the long term. The difference for sodium is 99.9% certain in the short term and 98% certain in the long term. The vertical scale is logarithmic.

Table III. Operating conditions for the six furnaces tested by INAA. Column 1 lists the furnaces. Column 2 lists the gas flowing between the inner and outer quartz liner. Column 3 lists the maximum operating temperature in the center zone in degrees C. Columns 4-7 list the sequence of gasses used in each oxidation

1	2	3	4	5	6	7
N-type 1	Oxygen-HCl	1100	Oxygen	Oxygen-HCl	Nitrogen	Oxygen
N-type 2	Oxygen-HCl	1100	Oxygen	Oxygen-HCl	Nitrogen	Oxygen
N-type 3	Oxygen-HCl	950	Oxygen	Steam	Nitrogen	Oxygen
P-type 1	Nitrogen	900	Oxygen	Steam	Nitrogen	
P-type 2	Oxygen-HCl	1100	Oxygen	^a	Nitrogen	
P-type 3	Oxygen-HCl	1100	Oxygen	^a	Nitrogen	

^a Occasional use of POCl₃.

one period ends and another begins is not clear. The t-test confirms that there is a real difference between the average values for the selected periods. While differences with time were seen for several furnaces, the differences of greatest significance are shown in Fig. 6. The t-tests also show that copper levels in P-type 2 increased between March-November 1981 and December 1981-May 1983 and sodium increased in N-type 1 between March 1981-January 1982 and February 1982-May 1983. None of these changes marked a clear transition from "clean" (as compared to cleaned wafer) to contaminated, as is the case with P-type 1 and P-type 2.

Contamination could arise from the quartz furnace liners, the heating elements (by diffusion through the quartz liners), boats, or rods introduced into the furnace, or ambient gases. INAA tests indicate that the cleanups are not at fault. There is no strong evidence to indicate that the quartz furnace liners are at fault. INAA of quartz confirms this belief (11).

The operating conditions for the six furnaces are listed in Table III. If a diffusion mechanism is the cause of contamination, the furnaces operating at higher temperatures should be most effected. As can be seen in Table III, this is not the case. An oxygen-HCl gas ambient between the inner and outer liner is often used to block such diffusion (12). A comparison of N-type 3 and P-type 1 shows that more contamination resulted when an oxygen-HCl barrier was in use than when it was omitted. This is true for sodium throughout the test period and for copper during the early portion of the test period. The observed trends are opposite of what might be expected if impurity diffusion from sources outside the quartz liner were a major source of contamination for these furnaces.

If ambient gases are a factor, trends in contamination should correlate with column five of Table III, which lists the differences in gases used. With respect to sodium, the most contaminated furnace is N-type 3, followed by N-type 2, and P-type 1. From Table III, the best results for sodium contamination were obtained in furnaces using POCl₃ and oxygen-HCl. Results not so good were obtained in furnaces using oxygen-HCl and steam. For copper, the most contaminated furnace is N-type 3. The next worst is P-type 1, but only for the latter portion of the test period. P-type 2 and 3 show slight copper contamination, and N-type 1 and 2 are consistently clean. Again from Table III, the lowest copper contamination was seen in furnaces using oxygen-HCl and steam. The highest levels of copper contamination occur where steam is used. Slight copper contamination appears where POCl₃ is used.

Summary and Conclusion

Table I indicates that gold, copper, and sodium are the most consistently occurring contaminants, as seen by INAA, followed by antimony and arsenic. Other transition metals such as chromium and cobalt were detected, but not as consistently as copper. It is reasonable to assume that iron and zinc are also present below the detection limit for INAA in these experiments. The levels re-

ported here constitute a base line which production of 2.5-5.0 μm geometry NMOS and PMOS devices tolerated.

The worst results for both copper and sodium correspond to the use of steam. The best results with respect to copper correspond with the use of oxygen-HCl. The removal of copper from a silicon surface requires oxidation and a complexing agent (7). Therefore, oxygen-HCl would be expected to show cleaning action, as these data suggest.

The ambient gases may impact contamination as corrodors, transporters, or cleaners. There is evidence for all three processes in this case. Surface contamination from sodium is water soluble and therefore readily transportable by steam. These results suggest that steam introduces sodium rather than removes it. POCl₃ is not a likely cleaning agent. There is no evidence that it introduces sodium. The mixed results for sodium in furnaces using oxygen-HCl suggests that there was no casual connection with sodium contamination. In the presence of water vapor, either HCl or POCl₃ should initiate corrosion of metals such as brass or steel, or even stainless steel. The corrosion products could then be transported, perhaps as very fine particles by the more common gases such as nitrogen and oxygen.

Acknowledgments

The authors wish to thank R. Martin for the sample preparation, and S. Halfacre and C. Blackburn for the analysis of the activation data. A special debt of gratitude is owed to G. Larrabee for valuable comments and discussion.

Self-Compensation in Rapid Thermal Annealed Silicon-Implanted Gallium Arsenide

S. K. Tiku and W. M. Duncan

Texas Instruments, Incorporated, Central Research Laboratories, Dallas Texas 75265

ABSTRACT

This paper describes the regrowth and activation characteristics of Si-implanted GaAs resulting from rapid thermal annealing (RTA) using optical radiation heating. Activation of Si in GaAs by RTA is observed to increase with temperature up to a maximum value, then decrease sharply for additional increases in temperature. The optimum annealing temperature is dependent on both implant dose and annealing time. This activation behavior in RTA time regimes is explained by the competition between kinetic and thermodynamic factors. From Arrhenius plots of the activation data, regrowth under these conditions is shown to be a thermally activated process. Electrical and photoluminescence measurements demonstrate that Si self-compensation limits activation at high annealing temperatures.

Ion implantation has become the most viable method available for controllably and reproducibly introducing shallow conductive layers into GaAs for application to digital and monolithic microwave integrated circuit fabrication. A requisite step in ion implantation processing is a high temperature anneal to reduce the ion damage produced in the crystal during implantation and to activate the implanted dopant. Furnace annealing at about 850°C for 15-20 min with the use of arsenic overpressure or encapsulating layers is normally employed for activating implants. Rapid thermal annealing (RTA) has been shown to yield higher peak carrier concentrations and sharper dopant profiles than furnace annealing (1). More importantly, RTA has greater application for annealing self-aligned n^+ implants in MESFET and HEMT devices and for implanted contact layer activation in other structures where long duration furnace anneals can cause degradation. Silicon has been studied here, as it is the most commonly employed n-type species for GaAs implantation. Because of the amphoteric nature of Si in GaAs, its activation behavior can be strongly dependent on the parameters of the annealing process. In this work, the regrowth and activation characteristics of Si-implanted GaAs and the carrier loss due to self-compensation under RTA conditions are studied and discussed.

Experimental

In the present work, a tungsten halogen lamp system (HEATPULSE, A.G. Associates) was used to activate $^{29}\text{Si}^+$ in semi-insulating LEC GaAs. Figure 1 shows a schematic diagram of the rapid annealing system. An extra quartz plate has been introduced in the system for better uniformity and to collect As lost from slice backsurfaces during anneal. The GaAs wafers were placed face up on a 4 in. Si wafer during the anneal. The temperature was measured using a thermocouple attached to a small Si wafer placed near the substrate. The thermocouple was calibrated using glasses of known melting point (Omegalag, Omega Engineering, Incorporated). Plasma-deposited silicon nitride and reactively sputtered aluminum nitride encapsulants were used; both were about 500Å thick. Both materials had excellent adhesion to GaAs and retained their integrity during anneal. After annealing, the encapsulants were stripped using HF or phosphoric acid to yield undamaged mirror surfaces.

A RF cold cathode discharge source was employed for $^{29}\text{Si}^+$ ion generation from implantation-grade SiF_4 . Diagnostic mass scans of the SiF_4 source plasma were examined to assure ion beam purity. The implants were carried out in a random equivalent orientation to avoid axial channeling. All implants were performed at room temperature. Implant activations were determined using a contactless sheet conductivity probe (Model 1200XR, Lehighton Electronics, Incorporated). For some samples, contactless conductivity values were checked using transmission line (2) and van der Pauw Hall effect (3) measurements. Reported mobility values were also determined

using Hall effect measurements. Photoluminescence (PL) measurements were carried out at 4.2 K using an argon ion laser at 488 nm as the excitation source. Spectra were recorded at 10 W/cm² excitation power densities using a 1m Czerny-Turner monochromator at 0.3 nm resolution. A S-1 photocathode photomultiplier tube and synchronous demodulation electronics were used for signal detection.

Results and Discussion

Figure 2 shows the sheet conductivity vs. temperature behavior of samples implanted over a range of doses, after RTA for 10s. From the figure it can be seen that the Si activation increases to a maximum value and then decreases sharply on the high temperature side of the maximum. The optimum annealing temperature is seen to shift to higher temperature with increasing dose. As lattice damage increases with increasing dose, the optimum anneal time-temperature product is expected to increase with increasing dose. The decrease in activation observed at temperatures above the optimum is more abrupt than is found for furnace anneals where Si activation remains constant or decreases slightly at temperatures above 850°C. Similar behavior is seen in uncapped anneals. However, very high temperatures are not generally used in uncapped anneals for fear of arsenic loss; therefore, the effect is less prominent. This decrease in activation above the optimum temperature in thermal pulse anneals has been attributed to As loss by some authors (1). However, Auger measurements on these samples do not show As in the encapsulant after RTA. Furthermore, photoluminescence measurements do not show any evidence of arsenic vacancies in the RTA samples. The absence of As loss from the front sample surface has been confirmed in both Si_3N_4 - and AlN-encapsulated annealed samples. Activation results are nearly identical for the two encapsulants.

From thermodynamic considerations, the decrease in activation at temperatures above the optimum annealing temperature can be explained due to an increase in Si self-compensation. Under equilibrium conditions, the concentration of Si on Ga, Si(Ga), and Si on As sites, Si(As), is related to the corresponding vacancy concentrations. Thus the ratio, R , of Si on As sites to those on Ga sites is directly related to the ratio of As vacancy, $V(\text{As})$, to Ga vacancy, $V(\text{Ga})$, concentration

Fig. 1. Schematic diagram of the HEATPULSE annealing system

Fig. 2. Sheet conductivity of ²⁹Si implants as a function of anneal for 10s anneals.

$$R = \frac{[Si(As)]}{[Si(Ga)]} \times \frac{[V(As)]}{[V(Ga)]}$$

As excess As vapor pressure is not involved in these anneals, it is assumed that the vacancy concentrations at equilibrium are for the Ga-rich side of the liquidus line. The concentrations of V(Ga) and V(As) under these conditions are given by (4)

$$[V(Ga)] = 3.33 \times 10^{18} \exp(-0.4/kT)$$

$$[V(As)] = 2.22 \times 10^{20} \exp(-0.7/kT)$$

or

$$R = [Si(As)]/[Si(Ga)] = 66 \exp(-0.3/kT)$$

Therefore, at equilibrium, the ratio R increases exponentially as a function of temperature. Regrowth is expected to drive the lattice toward the equilibrium vacancy concentrations. At high temperatures, Si should have an increasing tendency to occupy As sites, and at very high Si concentrations the material should be almost

Fig. 3. Conductivity and mobility as a function of annealing temperature for 10s anneals.

Fig. 4. Photoluminescence spectrum of a sample Si implanted at 180 and 50 keV with doses of 1.25×10^{12} and $0.35 \times 10^{12} \text{ cm}^{-2}$, respectively, after 10s anneals.

fully compensated (5, 6). Transport and photoluminescence measurements demonstrate conclusively that self-compensation is responsible for the decrease in activation on the high temperature side of maximum activation. Figure 3 shows the sheet conductivity and average mobility of a sample after annealing over a range of temperatures. The drop in average mobility which tracks the drop in conductivity confirms an increase in compensation, although the compensation ratio cannot be computed from these data alone (7). Additional confirmation of self-compensation comes from photoluminescence measurements. Figure 4 shows a characteristic PL spectrum of a Si-implanted, RTA sample. The free electron-to-Si acceptor band [F-A(Si)] at 1.4843 eV is of primary interest in the current analysis. The band at 1.515 eV is an envelope of bound exciton states which are not resolvable under these conditions, and the band at 1.4915 eV is donor to acceptor in nature. The Si acceptor band is found to increase monotonically with annealing temperature for a given dose under RTA conditions. This behavior of the F-A(Si) band with RTA temperature is shown in Fig. 5 for two implant conditions.

Figure 6 shows an Arrhenius plot of donor activation vs. anneal temperature for three Si doses. The data fit the Arrhenius form at low temperatures, indicating that silicon activation under RTA conditions is kinetically limited on the low temperature side of the maximum activa-

Fig. 5. Free-to-silicon acceptor [F-A(Si)] normalized to bound exciton (X) band intensity vs. annealing temperature for 10s anneals.

Fig. 6. Arrhenius plot of donor activation vs. anneal temperature for 10s anneals.

tion temperature. The activation energy for the rate-limiting step as determined from Fig. 6 is 0.76 eV. This activation energy cannot correspond to vacancy generation, as the value is too low, and vacancies are present in large numbers in ion-implanted material. Diffusion in the damaged material may be important for maximizing Si donor activation; however, the contribution of enhanced diffusion in damaged material containing local stoichiometric disturbances (8, 9) cannot be assessed, as these activation barriers are not known. Activation energies for self-diffusion and vacancy diffusion in single-crystal GaAs (10, 11) are, however, clearly too large for these processes to contribute to the rate-determining step. The activation energy of 0.76 eV may therefore correspond to local reordering needed for regrowth. In summary, at low temperatures, Si activation is kinetically limited, as is shown by the Arrhenius activation behavior. At high temperatures Si activation does not show Arrhenius behavior, as the Si starts to prefer As sites, because of thermodynamic reasons described earlier. The overall activation behavior of Si in GaAs is a competition between kinetic and thermodynamic factors.

Shown in Fig. 7 is the optimum anneal time needed for maximum donor activation as a function of anneal temperature for a range of Si doses. Also included in the figure are literature data points plotted in the same format. It is interesting that the slope of these lines is nearly equal over the large range of schedules shown in Fig. 6. This is evidence that the activation process is independent of dose and is not affected by damage and stoichiometric disturbances.

Conclusions

This paper provides the first mechanistic explanation of the activation behavior of Si in GaAs as a competition between kinetic and thermodynamic factors. Arrhenius fits of the activation data provide information about the

Fig. 7. Optimum anneal times as a function of optimum anneal temperature for a range of Si doses. Numbers enclosed by circles are literature data points.

kinetics of the activation process. Also, guidelines for annealing conditions over a range of implant conditions are presented. Finally, electrical and photoluminescence measurements demonstrate that Si self-compensation limits activation at high annealing temperatures.

Ambient Gas Effects on the Reaction of Titanium with Silicon

Subramanian S. Iyer,* Chung-Yu Ting, and Peter M. Fryer

IBM T. J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Because of its low resistivity and excellent thermal stability, TiSi_2 is finding widespread application as an interconnect material in novel schemes such as the salicide structure. The Ti-Si reaction is complex and has been studied previously in certain regimes. This investigation shows that the ambience in which the reaction is conducted influences the reaction considerably. We show that after the commencement of the interfacial reaction, *i.e.*, after reduction of interfacial oxides, the initial stage of the reaction proceeds rapidly. The extent to which it proceeds depends on the nature of the Ti ambient gas interaction. A final stage of the reaction begins when the silicide phase and the ambient species phase interfere; the reaction then proceeds relatively slowly at a rate depending on the nature of the ambient species. Some important implications of these observations for device processing applications are pointed out.

Scaling of VLSI devices into the submicron domain, puts increased demands on the contact and interconnect technologies. In MOS devices, one needs to simultaneously reduce the sheet resistance of the polysilicon gate and areas of the single-crystal source and drain diffusions, as well as the contact resistance associated with the source and drain. One method that has been proposed (1) is the self-aligned silicide (salicide) technology. In this method, metal deposited over a FET structure with oxide sidewall insulation along the gate, is reacted with the exposed silicon areas on the source and drain, as well as the exposed polysilicon areas on the gate, to form a silicide. The unreacted metal is then selectively etched away. TiSi_2 proposed by Ting *et al.* (2) and also pursued by Lau *et al.* (3) and Park *et al.* (4), is by far the most promising material for this technology. This is due to its low resistivity, high thermal stability, a demonstrated contact metallurgy, and compatibility with submicron processing technology. We have, therefore, investigated the Ti-Si interaction in more detail in order to determine the important parameters that govern the reaction.

The Ti-Si reaction has been studied in various aspects. Bower and Mayer (5) concluded that the Ti-Si reaction followed diffusion-limited kinetics. Chu *et al.* (6) showed that silicon was the dominant moving species. Recently, Hung *et al.* (7) investigated the reaction with both amorphous and single-crystal silicon in vacuum, and confirmed the diffusion-limited reaction. Bene and Yang (8) and Kato and Nakamura (9) have reported on the phases that are nucleated during the interaction including some metastable phases observed at low film thickness. Butz *et al.* (10) have also reported on the initial stages of silicide formation and silicon motion to the surface in UHV conditions.

It is clear from the above work that the Ti-Si interaction is very complex. This, to a major extent, is due to the extreme reactivity of Ti. As a result, it not only readily absorbs various gases, but can also reduce other compounds (11). Furthermore, analysis of the Ti-Si reaction by conventional means is often rendered difficult because of the nonuniformity of the interface.

This study was undertaken to examine the influence of the ambient gas on the Ti-Si reaction. As is recognized by all workers in the field, the purity of the reacting gas is very important. Impurities such as oxygen have been observed to cause an increase in resistivity of the TiSi_2 film and also reduced thermal stability. However, we have found that the influence of the ambient gas is much more far reaching and subtle. Even so-called inert gases like He appear to exert considerable influence on the nature, rate, and extent of the Ti-Si interaction. The extent of the reaction both in the growth direction and laterally, the dependence on film thickness, and the effect of the ambience on the resistivity discussed in terms of the three-stage reaction model we propose.

Experimental

P-type silicon wafers with a (100) orientation and a resistivity between 2 and 10 $\Omega\text{-cm}$ were used in this study.

*Electrochemical Society Active Member.

The wafers were cleaned using standard processes and dipped in buffered hydrofluoric acid prior to loading in the evaporator. High purity Ti was then evaporated onto the wafers. The base pressure used was about 25 μPa . The substrates were held at 150°C during evaporation. The evaporation was done by resistive heating, the deposition rate was between 0.8 and 1.2 nm/s. Film thickness between 30 and 400 nm were used in this experiment.

The Ti-Si samples were then annealed in an ultraclean furnace. Different ambient gases were used. He that was purified by passing over heated Ti granules, 99.999% pure argon also purified by passing over Ti granules, and house nitrogen were used in this study. The samples were annealed in these ambiences for times between 30 and 120 min at temperatures between 600° and 800°C. In addition, some samples were soaked in nitrogen at 500°C and subsequently annealed in helium. Some general comments regarding the purity of the ambient gas are in order here. Using a residual gas analyzer (mass spectrometer type) it is observed that at high enough flow rates, as used in these experiments, no oxygen is detectable. This translates to less than 10^{-1} Pa partial pressure of oxygen. Clearly, therefore, we cannot exclude the effect of these impurities.

The reacted films were analyzed by Rutherford backscattering spectroscopy, and the amount of silicide phase formed was determined using standard techniques. In the Ti-Si reaction, the various interfaces, which are used to determine the amount of silicide and of unreacted Ti are not easily delineable because of the nonuniformity of the interfaces and the consequent smearing of the backscattering spectra. The nonuniformity of the silicide-silicon interface, easily seen by stripping off the TiSi_2 and also in cross-sectional transmission electron spectroscopy, is believed to arise because of the importance of the nucleation mechanism in the process of silicide formation (16). In order to increase the accuracy of the RBS analysis, we have developed a novel technique of selective etching of the unreacted Ti. In this method, the films are reacted and first analyzed by RBS in the conventional manner,

Fig. 1. RBS spectra of 200 nm Ti on Si annealed at 600°C for 120 min.

i.e., the total amount of Ti present is estimated from the number of counts under the Ti peak. The sample is then etched in a selective etch described previously (2) which dissolves all the unreacted Ti, leaving behind only the reacted phase. This is analyzed by RBS again, and the counts under the Ti peak now represent the reacted Ti. Figure 1 shows the RBS spectra for a 200 nm Ti film reacted with Si at 600°C for 120 min, both before and after etching. The clean etching of the unreacted Ti is clearly seen. The etching procedure takes off the nitride phases of Ti (when present) as well.

In addition, we have also monitored the sheet resistance of the reacted films after annealing in various ambient gases at different temperatures and for various spans of time.

Finally, the ambience also influences the lateral formation of silicide which is examined by electron microscopy.

Results and Discussion

On the basis of our studies, we have formulated a model for the Ti-Si interaction in the presence of an ambient species. We shall first present this model and point out the consequences. We shall then present experimental results to support the model including some kinetic data. The effect on resistivity of the film will also be discussed. Finally, the effects of the ambient gas on the lateral formation of TiSi_2 will be discussed.

The model.—We propose that the Ti-Si reaction proceeds in three stages. The first stage is the initiation of the reaction. Since the silicon surface is usually covered with a native oxide, typically 1-2 nm thick, this has to be reduced prior to the direct silicide formation. Generally, the reduction can take place at temperatures below the silicide formation temperature. At the silicide formation temperature, the thin native oxide is consumed quite swiftly; the oxide reduction time depends on the nature of the surface treatment prior to the deposition of the metal.

The second stage of the titanium silicide reaction begins now. Here, we recognize that there are actually two interfaces to consider. This is shown in Fig. 2a. At the bottom, we have the Ti-Si interface, and at the top we have the Ti-A interface, where A refers to the ambient species. At this point, the entire Ti film is substantially free from any ambient gas impurities (other than those which were incorporated during the evaporation of the film and those which diffused in during the first stage). As time proceeds, however, two interactions progress. One, of course, is the Ti-Si interaction at the bottom interface resulting in the formation of the silicide phase. Simultaneously, the ambient gas species interacts with the Ti film at the top interface. The nature and extent of this top interface interaction depends on the species A. We shall discuss this in more detail below. Thus, we have two interactions proceeding from opposite directions towards each other. The final stage of the reaction is when the Ti-Si and the Ti-A phase interact. Of course, the interac-

tion depends on the A species and we recognize that one of three possibilities may occur: (i) the silicide phase grows at the expense of the Ti-A phase; (ii) the Ti-A phase grows at the expense of the silicide phase; or (iii) the two phases interact to form a third new phase. This is shown schematically in Fig. 2d.

The outcome depends on both thermodynamic and kinetic considerations. Our interest here is primarily those situations where the silicide phase grows. The details of this third stage of the reaction depend on the nature of the species A and how well it is bound to the Ti. In the third stage, one needs to recognize that the ambient species may have reacted physically; for instance, it may be in solution. Thus, for example, in the case of nitrogen, which not only dissolves in Ti but also reacts with it to form a variety of phases, the third stage would be much more complex.

We now discuss in more detail the second and third stages of the reaction with the help of our experimental results. This is shown in Fig. 2b, where the pure Ti is bounded by the Ti-A phase on the top and the Ti-Si phase at the bottom. The important characteristic of this second stage of the reaction is that the silicon is reacting with a relatively pure Ti film.

The extent to which this stage of the reaction proceeds depends on how fast the Ti-A interface advances. When the two interfaces meet, as shown in Fig. 2c, this stage of the reaction is terminated.

Helium anneals.—In Fig. 3, we have shown the RBS spectra for a 100 nm film annealed in helium at 600°C for 30, 60, and 90 min, respectively. It is clearly seen that the reaction is not complete even at 90 min. Using backscattered counts under the Ti peak to determine the total amount of Ti and our selective etching method to determine the amount of reacted Ti, we have plotted in Fig. 4 for two different initial Ti thicknesses, the equivalent thickness squared of Ti reacted (which is proportional to the silicide thickness squared) vs. the reaction time. This type of scaling (rather than linear scaling) provides the best fit to our data and indicates a diffusion-controlled reaction. More interesting is the fact that the reaction rate is almost twice as fast for the 200 nm film as for the 100 nm film.

Nitrogen and argon anneals.—In Fig. 5, we show the RBS spectra for a 100 nm film annealed in N_2 at 600°C for 30, 60, and 90 min. In Fig. 6, we show the spectra for annealing at 650°C for the same thickness and times. In this figure, we clearly see a distinct surface phase which was identified by Auger spectra to be nitridized. In the case of argon anneals, we see results very similar to the N_2 case.

The influence of a noble gas species on the Ti-Si reaction is, indeed, quite surprising. It is well known (12) that the noble gas species are unstable in most metals. In fact, the equilibrium concentration of He in Ti at these temperatures is not expected to be significant, although the

diffusivity of He through the film may be quite high. Furthermore, it is known (12) that the He atom binds very strongly to vacancies with energies of several electronvolts. Therefore, we can only speculate on the reason for our results. Since the silicide reaction is diffusion limited, the ambient species obviously interferes with Si diffusion through the already formed TiSi_2 , perhaps by tying up vacancy sites. We must not exclude the possibility of unknown impurities causing the observed effects. For example, hydrogen, which can occur in He, has significant solubility (~8%) in Ti (12) and may also produce similar results. Certainly, more experiments are needed to verify the details of the mechanisms involved.

The dependence on thickness in the helium case suggests that the top surface plays an important role. We believe that the top surface is sealed, perhaps by impurities that, unfortunately, always occur in the ambience, in a short time. Thus, the impurity that affects the reaction is trapped in the film and occurs in different concentrations in films of different thicknesses. Thus, thicker films with a lower impurity concentration may react faster. This implies that the Ti-Si reaction in this case occurs predominantly during the third stage.

What is more important is that argon, another inert gas, behaves quite differently. Size differences may play a role here. Although nominally of the same purity, we cannot exclude the probability that argon may contain higher concentration of nitrogen.

The behavior of nitrogen is perhaps most logical. Diffusion of N_2 into the film occurs rapidly to solid solubility limits ~19% (12). Simultaneously, a nitridized phase grows at the surface. Nitrogen occupies interstitial sites in Ti and has been observed to segregate outside the silicide phase (15), similar to the observations of Berti *et al.* (14)

Fig. 5. RBS spectra for 100 nm Ti on Si annealed at 600°C for 30 min (filled squares), 60 min (open squares), and 90 min (triangles) min, respectively, in N_2 .

Fig. 6. RBS spectra for 100 nm Ti on Si annealed at 650°C for 30 min (closed squares), 60 (open squares), and 90 (triangles) min, respectively, in N_2 .

for oxygen. The reaction occurs extremely fast until the interface reaches the nitridized phase. Thereafter, the reaction does not proceed at all; in fact, thermodynamic considerations favor the growth of the nitride phase.

Comparison of different ambiances.—Figure 7 shows the RBS spectra for a 100 nm film annealed at 600°C for 30 min in He, N_2 , and Ar. The tremendous impact of the two types of ambiances is clearly seen. In the case of He, the silicide/Ti interface is less clearly defined. The reaction in the case of N_2 and Ar is more uniform. The silicide reaction in the N_2 and Ar cases has also proceeded to a much greater extent. Figure 8 shows the results of an interesting annealing sequence. We first soak the samples at 500°C in nitrogen for 60 min. Figure 8a shows for a 100 nm thick Ti film that the effect of the soak is to convert the top Ti layer into a nitridized phase. This is seen from the decrease in the surface peak of the Ti spectrum. No noticeable silicide phase has formed. In Fig. 8b is shown the RBS spectrum of a 200 nm film annealed in He at 600°C for 30 min and also one when the sample is first soaked in N_2 at 500°C for 60 min and then annealed in He at 600°C for 30 min. It is seen that the soaked sample shows signs of silicide reaction to a greater extent than does the unsoaked one. This is understood from the fact that the nitridized surface layer screens the rest of the Ti layer from the ambient gas (in this case He) and thus extended the second-stage reaction. In Fig. 8c and 8d are shown the spectra after 60 and 90 min annealing, respectively, in He. It is seen that the reaction has proceeded into the third stage. In the case of the nitrogen soak, the reaction has slowed down much more (as would be expected with a strong Ti-N bond) than in the case of the pure He anneals. The reaction continues, until at 90 min the two cases are almost identical.

Effect of film thickness.—The effect of the ambience also introduces a dependence of the extent of the reaction

Fig. 7. RBS spectra for 100 nm Ti on Si annealed at 600°C for 30 min in various gases.

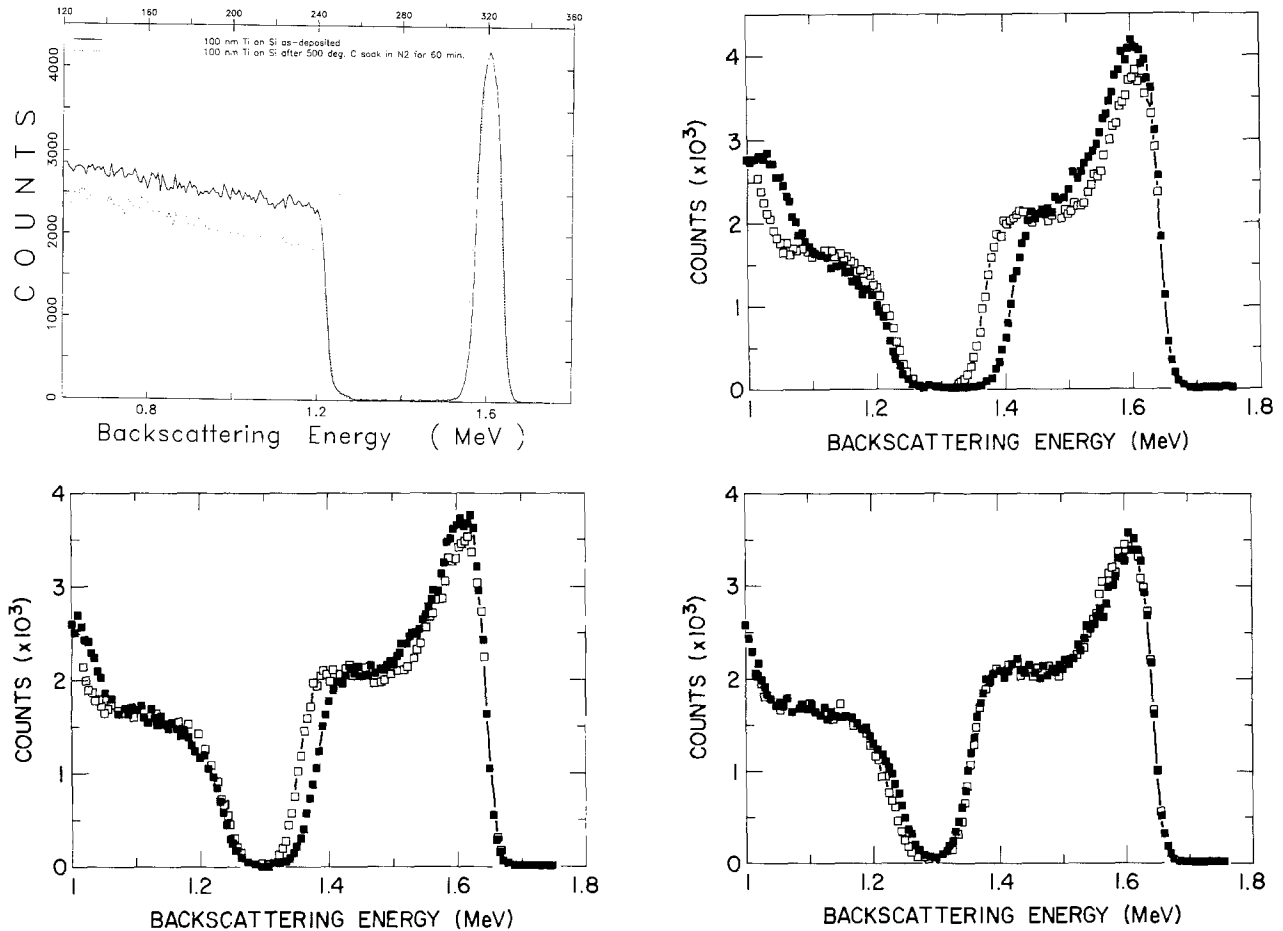

Fig. 8. a: RBS spectra showing as-deposited 100 nm Ti film and after 500°C soak for 60 min in N₂. Note surface nitridation and that no significant silicide phase is formed. b, c, and d: Comparisons of RBS spectra for 200 nm samples annealed in He with (open squares) and without (filled squares) N₂ presoak for 30 min (b), 60 min (c), and 90 min (d) at 600°C. Spectra for the presoaked samples are shifted left by three channels.

on the thickness of the film. This is clearly seen in Fig. 9, where the RBS spectra for 100 and 200 nm thick films annealed in N₂ at 600°C for 30 min are shown. Note that the surface nitridized layer is about the same in both cases. Thus the pure Ti layer is much greater in the case of the thicker film than in the case of the thinner one. In the thermal cycles considered here, we find that the amount of silicide formed is limited only by the nitridized surface phase. We have already mentioned that in the case of He the reaction rate depends on the film thickness which is also the case for films annealed in Ar. Figure 10 shows that by using the selective etching technique of analysis and plotting the Ti counts representing the reacted Ti with film thickness for different thermal cycles. An almost linear increase of reacted Ti on film thickness is seen in the regime investigated. A temperature depen-

dence is also noted, indicating that at higher temperatures thicker films react to a greater extent.

Effect on resistivity.—The sheet resistance of the reacted films is also expected to reflect the effects of the ambience. However, interpretation of the sheet resistance data is not a reliable method of studying the reaction. The aggregate sheet resistivity is sensitive to (i) the amount of the silicide phase, (ii) the extent of the Ti-A phase, (iii) the free Ti, (iv) defects in all of these films, and (v) other unaccounted impurities. Figure 11 shows the sheet resistivity behavior for different thermal cycles and different ambiances for a 200 nm Ti film on Si.

The 600°C data are considered here. In the case of He anneals, a slow but steady drop in sheet resistivity after a slight initial increase is seen. In the case of Ar, the initial increase is not significant and the subsequent drop oc-

curs fairly rapidly. In the case of nitrogen anneals, the initial increase is not seen in the time resolution here. There is first a rapid decrease in sheet resistivity, and then a slower decrease. In the case of He anneals with a pre-anneal nitrogen soak the results are similar qualitatively to that of the nitrogen anneals, as discussed earlier.

The effect on lateral diffusion.—In IC processing, it is necessary to limit the extent of silicide formation to a certain exposed silicon area. This is true in the case of Schottky or ohmic contacts as well as in the silicide case, where lateral diffusion must be minimized to prevent bridging (short circuiting) of the gate with the source or drain areas. The ambience in which the reaction proceeds plays an important role in determining the lateral extent of the reaction.

Consider the situation shown in Fig. 12a, where we have a window in the oxide exposing silicon. Ti is then evaporated over this structure and reacted. While most of the reaction occurs in the window, since the reaction proceeds predominantly by silicon motion, the silicon may diffuse through the already formed silicide laterally onto the oxide, leading to silicide formation there. As we have seen, the diffusivity of silicon as well as the reactivity between Si and Ti is dependent on the nature of the impurity in the Ti film. On the SiO₂, the reaction of silicon is different; the ambient species does not have to compete with free silicon for the Ti. Hence, the Ti film contains much more of the ambient species, and that is well bound. The Ti film on the oxide is thus either stuffed with nitrogen or forms tin on the top and no longer reacts with silicon easily. Consequently, lateral silicide formation is inhibited.

In the case of inert species such as He, we observe that lateral diffusion proceeds fairly rapidly. The presence of impurities such as O₂ in the helium has the effect of slowing the lateral extent of the reaction somewhat, and the conductivity of the TiSi₂ formed is poor. Reactive species have an inhibiting effect on the lateral extent of the reaction.

In this case, a 400 nm film of Ti was used. After reaction, the unreacted Ti was selectively etched away and the samples examined in an electron microscope. This reaction was done at 600°C for 8h. Clearly, there is significantly less lateral diffusion in the case of the N₂ anneals. The inhibiting effect of N₂ over He is also seen in electrical data, and the beneficial effect of N₂ in localizing the reactions has been reported in other laboratories as well (3, 4).

Summary and Conclusions

We have shown that the gas ambience plays a subtle and important role on the Ti-Si interaction. This is due to the extreme reactivity of Ti and also the ability of the interacting ambient species to alter the properties of the film. This results in a reduction of the number of diffusion paths in the Ti, surface passivation of the Ti film as some of the effects of ambience. Consequently, these effects affect reaction rate and extent both in the film and

Fig. 12. Lateral formation of TiSi₂. a: Structure. b: SEM micrographs for 4000Å Ti on a 1000Å thick SiO₂ window after 8h at 600°C and Ti etch. The N₂ annealing arrests lateral migration completely, as compared to He annealing. Note that the N₂ annealed surface exhibits a rough surface morphology.

lateral formation as well. They also introduce a thickness dependence.

The effect of oxygen impurities on our interpretations needs to be evaluated more carefully. Our analysis shows that oxygen if present occurs only in trace quantities. Its effect is qualitatively at least, similar to that of nitrogen. We have also observed that oxygen contamination in more than trace amounts results in silicide films with very poor electrical characteristics. The films used in our analysis had excellent electrical characteristics, and the ambient effects we have observed are certainly not attributable to any significant level to inadvertent impurities.

The above effects have an effect on the film quality, resistivity, and thermal stability. For silicide applications, N₂ or N₂-based forming gas are attractive annealing ambiances. They offer the advantage of greater process reproducibility, small sensitivity to impurities in the gas, besides being crucial in preventing lateral diffusion. They also allow for the reaction of a greater part of the film in a given time than helium leading to lower sheet resistivity.

In addition, the above work also stresses the importance of the initial purity of the film and the deposition methods. Silicides formed from films deposited by sputtering usually loaded with the sputtering gas, often Ar, and therefore to have different properties from silicides formed from films deposited by evaporation (sputter deposition are usually preceded by an energetic surface cleaning step, and this must be taken into account). The choice of the gas ambience will be dictated by the considerations discussed in this paper, and proper control of the

ambience is crucial to process reproducibility and reliability.

Properties of Tungsten Film Deposited on GaAs by RF Magnetron Sputtering

Nobuhiko Susa, Seigo Ando, and Sadao Adachi

Nippon Telegraph and Telephone Corporation, Musashino Electrical Communication Laboratory, Musashino-shi, Tokyo 180, Japan

ABSTRACT

The crystalline and electrical properties of W films are studied with regard to their relation to Ar sputtering pressure. An α -W phase is formed at a pressure below 5×10^{-2} torr, and its density is 19.2 g/cm^3 , independent of the pressure. Above 5×10^{-2} torr, the β -W phase and WO_3 are detected by x-ray diffraction, and the oxygen and carbon are detected by SIMS. The RIE etching rate is found to be independent of the pressure for the α -W phase. This rate increases with Ar pressure after β -W phase formation, and the etching characteristic suffers from aging after deposition. Resistivity is found to be related to density rather than grain size. The W-GaAs Schottky characteristics are somewhat influenced by the pressure. Degradation in carrier density, barrier height, and dark current caused by sputtering damage can be recovered by annealing.

Refractory metals such as tungsten are attractive for use as interconnections in VLSI's because of their low resistivity and fine patternability (1-4). Recently, W films have also been used as bases embedded in a GaAs epitaxial layer, thus facilitating the fabrication of GaAs permeable base transistors (PBT) (5, 6). In these papers, no changes in W Schottky characteristics were observed at MO-CVD growth temperatures of $600^\circ\text{--}800^\circ\text{C}$ (7). Although W films have received much attention as interconnections for LSI's, only a few studies have been carried out on their electrical properties when applied as Schottky contacts deposited on GaAs (8, 9).

Tungsten films have been fabricated by CVD (10, 11), electron-beam evaporation (12), and sputtering (13, 14). The properties of W films deposited by sputtering are known to depend on the sputtering pressure. In the present experiment, the crystalline and electrical properties of W films prepared by RF magnetron sputtering were studied, especially the characteristics of W Schottky contacts. The observed characteristics were then analyzed in terms of their relations to the Ar sputtering pressure.

Film Deposition and Crystalline Properties

Film deposition.—The W films were prepared by RF magnetron sputtering (ULVAC, SBR-1304E) at an Ar pressure ranging from 1×10^{-2} to 2×10^{-1} torr. Prior to

Ar gas introduction, the chamber was evacuated on the order of 10^{-7} torr with a He cryogenic pump. The W target was cleaned by presputtering for 30 min at 200W. During deposition, the RF power was set at 50W. The substrate bias was 0 V, and no substrate was intentionally heated.

At a 50W input, however, the substrate temperature increased to about 100°C during the deposition. Film thicknesses were measured with a mechanical stylus. The W films on the substrates were partially lifted off by photolithography in order to measure the thickness. Film thicknesses were in the range of $500\text{--}6000\text{\AA}$.

The deposition rate increased with Ar pressure, as shown in Fig. 1a. When the Ar pressure exceeded 1×10^{-1} torr, the deposition rate increased sharply. This is primarily due to the increase in the ion flux rather than the reduction in density, because the films deposited above 1×10^{-1} torr were heavier than those prepared at low pressures for an identical deposition time.

It is well known that stress in W films is compressive at low Ar pressures, while being tensile at high pressures (4). Cracks are sometimes observed in thick W films deposited on GaAs substrates due to this stress. The use of thick films, however, is required to control the device characteristics of a PBT, which has a W Schottky electrode embedded in the GaAs as described before. The existence of cracks was examined in relation to Ar pressure

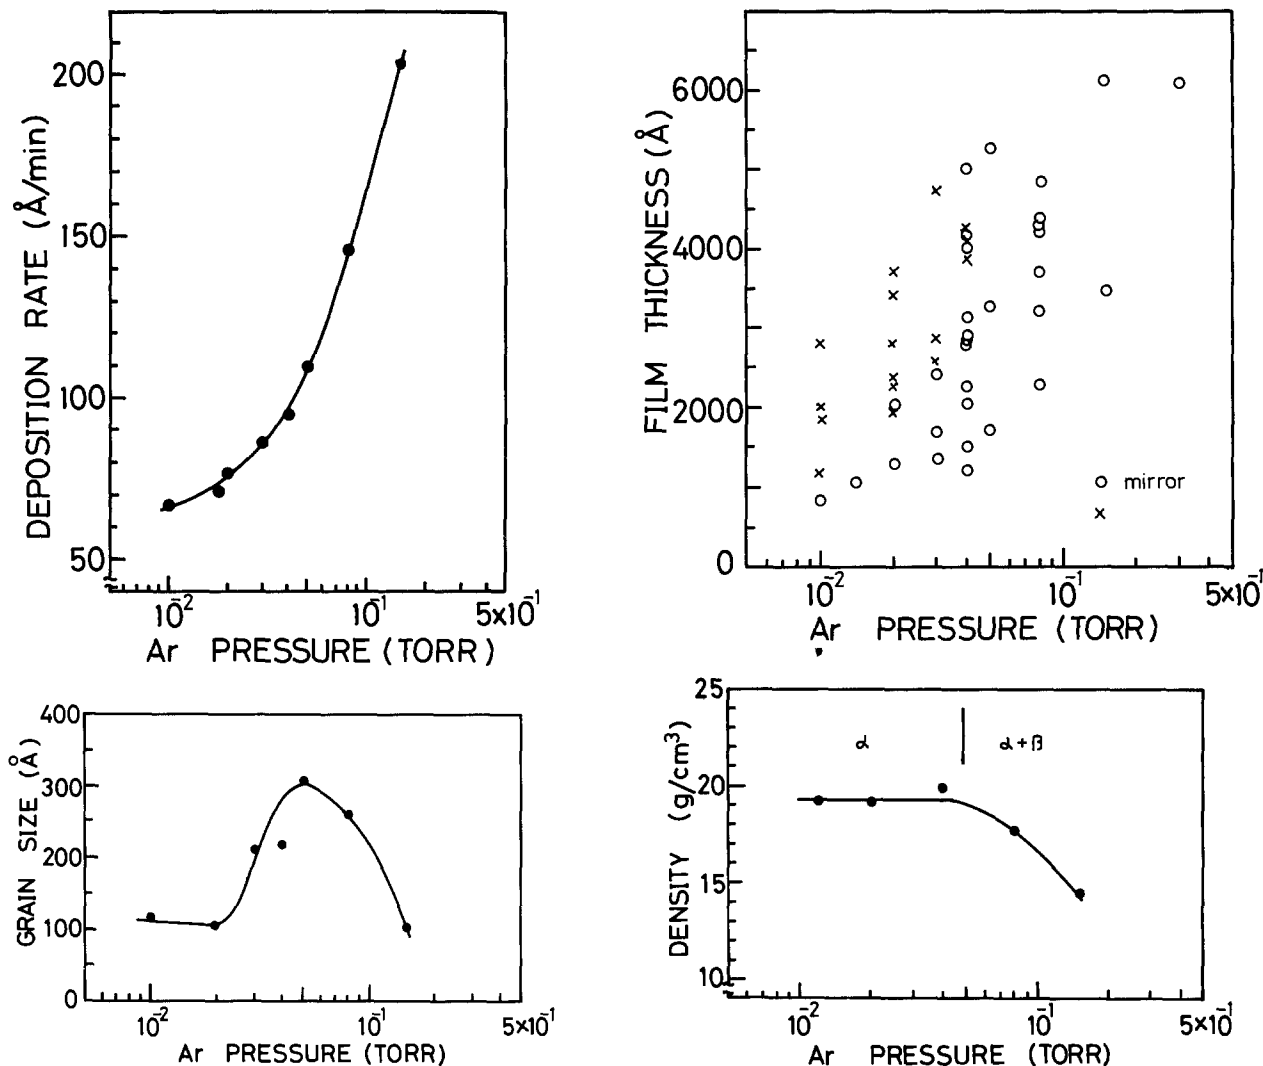

Fig. 1. Deposition rate (a, top left), existence of cracks (b, top right) density (c, bottom left), and grain size (d, bottom right), as functions of sputtering pressure.

and film thickness, and the results are shown in Fig. 1b. Films thicker than 1000 \AA cannot be obtained at low Ar pressures, while thick films containing no cracks can be deposited at higher pressures.

The reason for this is not clear. The substrate temperature rose to about 100°C, even when the substrate was not intentionally heated. Thermal expansion coefficients are 4.2×10^{-6} and $6.0 \times 10^{-6} \text{ } ^\circ\text{C}^{-1}$ for W (15) and GaAs (16), respectively. Since the temperature of the substrate is cooled from 100°C to room temperature after deposition, compressive stress, caused by the difference in thermal expansion coefficients between W and GaAs, is induced in the W films. The compression initially existing in the W film deposited at a low Ar pressure, due to the peening effect, increases during this cooling period. However, tension in the films prepared at the higher pressure was reduced after deposition. The W films deposited at the lower pressures suffer from larger compressive stress and may contain cracks. The densities of the films deposited at the higher pressures were smaller than those for the lower pressure, as will be described in the following section. Films prepared at higher pressures may be porous and may withstand greater stress than films prepared at the lower pressures.

Density and grain size.—Densities of the W films deposited on glass plates are shown in Fig. 1c as a function of the sputtering pressure. The density was obtained from the weight increase and film volume after W deposition. Densities were 19.2 g/cm^3 and were independent of the Ar pressure in the range of 1.5×10^{-2} torr; however, they decreased above this range. The W films were revealed to be in the α -W phase for the Ar pressure of 1.5×10^{-2} torr,

while the β -W phase was formed above 5×10^{-2} torr, as shown in Fig. 2.

The smaller density obtained for the high Ar pressure is related to the existence of the β phase rather than the grain size. This is because the W films having the α phase and prepared at 1.2×10^{-2} torr showed a large density of 19.2 g/cm^3 even when the grain size was small, as shown in Fig. 1d. However, the existence of the β phase alone cannot explain the lower density, as described below. The α -W phase has a body-centered cubic structure with a 3.16 \AA lattice constant. The β -W phase structure is an A-15-type structure having a 5.04 \AA lattice constant, and is body-centered cubic having two atoms on each of its {100} planes (17). Densities calculated from the above parameters for the α and β phases are quite similar: 19.4 and 19.1 g/cm^3 , respectively. Thus, the presence of the β phase alone cannot cause the lower density.

Since WO_3 has a lower density than that of metal, it is possible that the WO_3 , which was always detected by x-ray diffraction for samples consisting mainly of the β -W phase, is responsible for the low density. The larger deposition rate may also cause the low density by making the deposited film porous.

The grain sizes of the W films were determined from x-ray line broadening analysis and are plotted in Fig. 1c. The (110) α phase diffraction patterns were used for analysis. The grain size became small when the β -W phase was formed, as reported in a previous paper (14). Grain size, however, was also small for the films prepared at 1.2×10^{-2} torr, in spite of the presence of the α -W phase. The influence of grain size on resistivity will be discussed later.

Fig. 2. X-ray diffraction patterns for W films deposited on GaAs at 4×10^{-2} , 8×10^{-2} , and 1.5×10^{-1} torr.

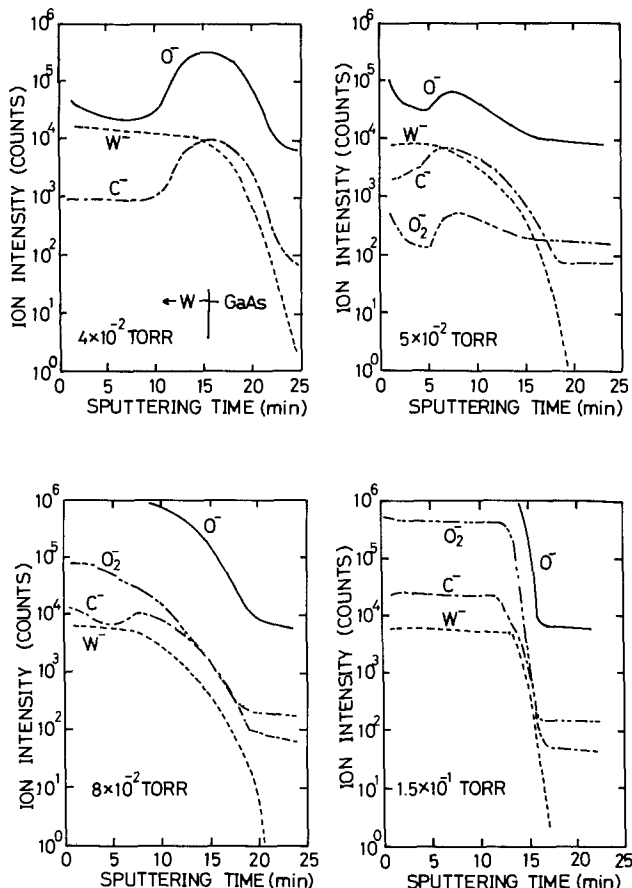

Fig. 3. Impurity profiles measured by SIMS for W films prepared on GaAs at 4×10^{-2} , 5×10^{-2} , 8×10^{-2} , and 1.5×10^{-2} torr.

Orientation and impurity. The x-ray diffraction pattern for the W films deposited on GaAs changed when the Ar sputtering pressure was varied, as shown in Fig. 2. Below a 5×10^{-2} torr Ar pressure, diffraction from the $\alpha(110)$, $\alpha(211)$ planes was observed. The intensity ratios of $\alpha(211)$ to $\alpha(110)$ x-ray diffractions were 0.08 and 0.2 for the present experiment and for the ASTM data on W powder, respectively. This implies that the films deposited at below 5×10^{-2} torr were well oriented in the $\langle 110 \rangle$ direction.

The $\beta(200)$ diffraction was observed for films prepared at above 5×10^{-2} torr, and WO_3 diffraction also was observed. The WO_3 was always detected when the β -W phase was formed. These results are consistent with previous reports suggesting that oxygen stabilizes the β phase (12, 13, 18). Etching characteristics, density, grain size, and impurity content changed owing to the existence of the β -W phase, as will be described below.

Impurities in the W films deposited on the GaAs such as oxygen and carbon were analyzed by secondary ion mass spectroscopy (SIMS), and the films were bombarded by a Cs^+ ion beam. The bombarded area was $60 \mu\text{m}$ in diameter. The results are shown in Fig. 3. The W films with a $2000\text{-}6000\text{\AA}$ thickness were sputtered by Cs^+ ions. Data on the W-GaAs interface were not very accurate, because the W film surface, sputtered by the Cs^+ ions, became rough during the sputter etching. When the W film was deposited at a high Ar pressure, oxygen and carbon contents increased. In particular, oxygen increased rapidly with an increase in the Ar pressure. The existence of oxygen was also detected by the x-ray diffraction as a part of the WO_3 .

At the W-GaAs interface, C and O concentrations were large, as in the case for GaAs epitaxial layers grown on a GaAs substrate. They are probably due to the existence of the GaAs surface oxide layer and also due to C contamination before W deposition.

For the application to device fabrication, the etching rate for reactive ion etching (RIE) using CF_4 was studied with respect to the W deposition pressure dependence. The etching rate for RIE is shown in Fig. 4 as a function of pressure. The W films were etched under the conditions of 50W and 10 Pa (7.5×10^{-2} torr). The etching rate was constant for the W films deposited at below 5×10^{-2} torr Ar pressure and was independent of time after deposition. On the other hand, the etching rate increased with an increase in the sputtering pressure above 5×10^{-2} torr. This etching rate, however, decreased after 2 months. The etching rate increased when the β -W phase was formed and the film density decreased. Although the reason for the reduction in the etching rate after 2 months is not clear, it seems to be related to the existence of the β -W phase.

Fig. 4. Etching rates of RIE measured immediately after and 2 months after W deposition and resistivity, as functions of sputtering pressure.

Fig. 5. Resistivity as a function of density and grain size

Electrical Properties

Resistivity.—The resistivity of W films deposited on semi-insulating GaAs is also shown in Fig. 4. A four-point probe was used for the measurement. These results were similar to those for W films prepared on glass plates. The α -W films exhibited lower resistivity than those in the β -W phase (14, 19). Resistivity decreased slightly when the deposition pressure increased in the range of $1\text{--}2 \times 10^{-2}$ torr. This was probably due to the smaller grain size as shown in Fig. 1c.

Resistivity is plotted in Fig. 5 as a function of W film density. It can be seen that resistivity is related to the film density as well as volume fractions of β - and α -W phases.

Figure 5 shows resistivity as a function of grain size calculated from the x-ray diffraction pattern. Data for the α -W phase are somewhat influenced by the grain size, contrary to a previous report (14). The resistivity is $5 \times 10^{-5} \Omega\text{-cm}$ when grain size is extrapolated to zero. Since this value is larger by about one order of magnitude than that for the bulk, it is concluded that scattering resulting from impurities and defects is larger than that caused by the grain boundary.

Schottky characteristics.—When the W film is applied to devices such as a PBT, Schottky characteristics are important for realizing good device performance. Tungsten film was deposited on a GaAs epitaxial layer grown on a

Fig. 6. Ideality factor and barrier height as a function of sputtering pressure.

n^+ -GaAs substrate. The epitaxial layer was $2.6 \mu\text{m}$ thick, and its carrier concentration was $1 \times 10^{17} \text{cm}^{-3}$. Ohmic contacts (alloyed Au-Ge-Ni) were formed on the n^+ -GaAs substrates. A W Schottky contact of $200 \mu\text{m}$ diam was deposited through metal mask. Ideality factor, n , and barrier height, ϕ_{Bn} , obtained from the forward current and voltage characteristics (20), are shown in Fig. 6. The ideality factor increased from 1.03 to 1.06 when the sputtering pressure was varied from 1×10^{-2} to 2×10^{-1} torr. However, the barrier height was 0.6 eV, and was constant in the range of $1\text{--}5 \times 10^{-2}$ torr, where the α -W phase existed. The barrier height increased to 0.64 eV for a 2×10^{-1} torr Ar pressure.

Leakage currents for diodes were larger at a reverse bias voltage by several orders of magnitude than those for diodes with a Au Schottky contact prepared by Au vacuum evaporation. The carrier concentration profile, calculated from the C-V characteristics, showed that the carrier density decreased at the W-GaAs interface as a result of sputtering damage to the epitaxial layer surface during the deposition. In order to improve the crystal quality, an attempt to anneal GaAs deposited with W film was carried out at 430°C .

Annealing.—The GaAs diodes having W Schottky contacts were annealed at 430°C in a 10% H_2 -90% He gas flow.

Carrier concentration profiles obtained from the C-V characteristics are shown in Fig. 7. A sample was annealed for 3 min at 430°C . The carrier density was reduced at the W-GaAs interface by sputtering damage for the as-deposited diodes. After annealing, the reduction in the carrier was recovered by performing a relatively short annealing process.

Dark currents for diodes with as-deposited and annealed (2 min) W contacts as well as a reference (Au Schottky) contact are shown in Fig. 8a as a function of reverse bias voltage. The dark current can be reduced by about one order of magnitude as a result of annealing. However, no further dark current reduction was observed for annealing of over 2 min. The dark currents for annealed diodes, however, were still larger than those for the reference.

Forward currents for diodes with as-sputtered and annealed W contacts are shown in Fig. 8b. The W film was prepared at 4×10^{-2} torr. Data for the diode having the Au evaporated Schottky contact are also shown for reference. The barrier height increased from 0.55 to 0.61 eV owing to annealing. A similar improvement in barrier height has been reported by Sinha (9). The barrier height obtained from the I-V characteristics agreed with that calculated from the C-V characteristics. However, barrier height for as-deposited diodes calculated from the C-V characteristics (0.66 eV) was higher than that obtained from the I-V characteristics (0.55 eV). The values obtained

Fig. 7. Carrier concentration profiles for GaAs diodes with as-sputtered and annealed W contacts.

Fig. 8. Reverse (a, left) and forward (b, right) currents for diodes with as-sputtered and annealed W Schottky contacts as functions of bias voltage. Currents for diode having Au evaporated Schottky contact are shown for reference.

Fig. 9. Ideality factor and barrier height as a function of annealing time.

from the C-V measurement became much larger than those for the C-V characteristics when the damage was seriously increased. This suggests that an insulator layer was formed by sputtering deposition (21).

The ideality factor decreased slightly from 1.08 to 1.04 owing to annealing. No further improvement in the ideality factor or barrier height was observed for a heat-treatment of longer than 3 min, as shown in Fig. 9.

Conclusion

Properties of W films deposited by RF magnetron sputtering were investigated in terms of their relation to Ar sputtering pressure, which ranged from 1×10^{-2} to 3×10^{-1} torr. Below 5×10^{-2} torr, an α -W phase was formed and the density was 19.2 g/cm^3 , independent of the Ar pressure. The β -W phase and WO_3 were detected by x-ray diffraction for films prepared at pressures above 5×10^{-2} torr. Oxygen and carbon contained in the W films as impurities increased with the pressure. The RIE etching rate was found to be independent of the pressure for the α -W film. This rate increased with an increase in β -W phase content in W films and was dependent on time after deposition.

Resistivity increased sharply when the volume fractions for the β -W phase and WO_3 were increased. Density rather than grain size was found to affect the resistivity.

The Schottky characteristics of W-GaAs diodes were studied. The barrier height and ideality factor were in-

fluenced somewhat by the sputtering pressure. Degradation of barrier height, carrier concentration, as well as the increase in dark current due to sputtering damage, can be recovered by carrying out annealing at 430°C for 2-3 min.

Acknowledgments

The authors would like to express their gratitude to Dr. Kenji Kamabe, Dr. Hideo Sugiura, and Dr. Yoshifumi Takanashi for their helpful discussions. They are also grateful to Hiromitsu Asai for the x-ray diffraction measurements and Yoshikazu Homma for the SIMS measurements.

An Experimental and Theoretical Study of the Infrared Reflectance of Thin Oxide Films on Metals

David K. Ottesen

Sandia National Laboratories, Livermore, California 94550

ABSTRACT

External reflectance infrared spectroscopy has been used to study the formation of oxide films on chromium and iron alloys. Experimental data have been acquired with an FTIR spectrometer using a polarized beam at high angles of incidence to the surface normal. Theoretical calculations have been made for these systems and are compared with the experimental results. Particular attention is given to the quantitative calculation of film thickness. Complications which arise from distortions in band shape, frequency shifts, the appearance of additional reflectance minima, and beam divergence and state of polarization are discussed in detail.

This paper presents an experimental and theoretical study on the applicability of Fourier transform infrared (FTIR) reflectance spectroscopy for the study of oxide films formed on binary iron-chromium alloys. A thorough understanding of these results is a vital step leading to the study of more complex ferrous alloys, such as the stainless steels. The quantitative study of metal alloy oxidation and corrosion using this technique requires a detailed understanding of the physical processes governing the optical properties of such layered systems. We have also sought to determine the effect of nonidealities, such as the roughness of films and substrate, and variations in experimental parameters, such as the angle of incidence, beam divergence, and state of polarization.

Infrared spectroscopy has played an increasingly important role over the past few years in the chemical characterization of surfaces. In particular, external reflection spectroscopy at large angles of incidence has been of special value in examining thin, dielectric films on metallic substrates. The usefulness of this technique was first noted by Berreman (1) and later popularized by Greenler under the name "reflection-absorption spectroscopy" (2,4).

Reflection-absorption spectroscopy has much in common with ellipsometry, another surface-sensitive optical technique. While both approaches utilize linearly polarized light, visible wavelength ellipsometry has generally been acknowledged to be the more sensitive technique to small changes in surface coverage. This is due to the clearly observed changes in phase angle of light reflected from a substrate covered by a dielectric film only a few angstroms thick. This advantage, however, has been offset somewhat by recent developments in double-modulation FTIR reflectance spectroscopy (5).

The outstanding advantage of reflection-absorption spectroscopy lies in the positive identification of chemical species in surface films through the spectral structure in the observed reflectance. In general, ellipsometry suffers from the lack of spectral data in single wavelength measurements, with the consequent assumption of surface species and their optical constants. Even scanning ellipsometric measurements in the visible region can be relatively featureless, resulting in unavoidable ambiguities in the determination of surface species (6).

Reflection-absorption spectroscopy has been successful in a large number of recent qualitative investigations. Interest has centered primarily on the characterization of chemisorbed gases (5, 7) and thin layers of organic compounds deposited on metals (7-13). Reference (7) is a particularly useful review article of results up to 1976.

Investigations of inorganic thin films on metallic substrates have also been numerous (1, 4, 14-24). These results are qualitatively quite different from the studies of chemisorption and thin organic films. The interpretation of the resulting reflectance spectra for these systems is complicated by distorted band shapes and frequency shifts for thin films when compared to absorption spectra of the pure, bulk material. This behavior is generally caused by the large values of refractive index and absorption coefficient associated with the absorbing film and the metallic substrate and the complex interaction of these optical properties with the electric field of the incident infrared beam. In addition to our own experimental work on metal oxides, we will draw on earlier spectroscopic studies of the high temperature oxidation of iron (14, 18) and chromium (24).

Theoretical

We will adopt the nomenclature of Heavens (25) in our treatment of the interaction of light with a thin film on a bulk substrate. This is shown for an n -layer film in Fig. 1. Here n_m and k_m are the refractive index and absorption coefficient, respectively, d_m is the thickness of the layer, and Φ_0 is the angle of incidence, while Φ_m ($m > 0$) is the angle of refraction within a layer, m . For absorbing media, we also note that the refractive index and angle of refraction are in general complex. In this case, the so-called complex refractive index is defined as

$$\hat{n}_m = n_m - ik_m \quad [1]$$

The amplitude of the electric field both incident and reflected from this system of layers can be expressed by solving Maxwell's equations in terms of these quantities. Using the boundary conditions that the tangential components of both the electric and magnetic vectors be continuous at each layer interface, we arrive at the expression shown in Eq. [2] and [3] for the ratio of the electric field amplitudes in the plane where layer m is in contact with layer $m + 1$

$$E^-_{mp}/E^+_{mp} = [(\hat{n}_m \cos \Phi_{m+1}) - (\hat{n}_{m+1} \cos \Phi_m)] / [(\hat{n}_m \cos \Phi_{m+1}) + (\hat{n}_{m+1} \cos \Phi_m)] \quad [2]$$

$$E^-_{ms}/E^+_{ms} = [(\hat{n}_m \cos \Phi_m) - (\hat{n}_{m+1} \cos \Phi_{m+1})] / [(\hat{n}_m \cos \Phi_m) + (\hat{n}_{m+1} \cos \Phi_{m+1})] \quad [3]$$

These ratios are more commonly known as the Fresnel reflection coefficients, r_{mp} and r_{ms} , where P and S refer to the polarization of the light. The change in phase of the

Fig. 1. Nomenclature for reflectance in a multilayer system

light, δ_m , within layer m as a function of wavelength, λ , is defined as

$$\delta_m = (2\pi/\lambda)\hat{n}_m d_m \cos(\Phi_m) \quad [4]$$

For a single absorbing layer on a substrate, the reflected electric field amplitude can then be expressed

$$\mathcal{R} = [r_1 + (r_2 e^{-2i\delta_1})]/[1 + (r_1 r_2 e^{-2i\delta_1})] \quad [5]$$

where it is understood that \mathcal{R} will be appropriate for either P- or S-polarized light, depending upon the values of the Fresnel coefficients used in Eq. [5].

The experimentally measured reflectance is the energy of the reflected beam, and this is related to \mathcal{R} by

$$R = \mathcal{R}\mathcal{R}^* \quad [6]$$

We have written a computer program to calculate the reflectance as a function of optical constants for up to three absorbing dielectric layers on an absorbing substrate. The method can be easily extended to additional layers, since Eq. [5] is evaluated from a product of matrices, each matrix corresponding to one layer in the film. Values for the refractive index and absorption coefficient are supplied for each layer and the substrate. The films may be either optically isotropic or anisotropic. In the case of an anisotropic medium, however, the Fresnel coefficients must be redefined (Eq. [2] and [3]). These relations are given in Ref. (25) and they are, as that author states, "complex and depressingly complicated." Other input data are the angle of incidence and state of polarization of the infrared beam. These are determined by the experimental conditions which are discussed below.

We have also included the capability of averaging the calculated reflectance over a number of angles of incidence to simulate an incident beam which has been focused to a small image on the sample surface. In these calculations, we assume that our experimental infrared source is a lambertian emitter. This implies that the intensity of the light incident on a sample at an angle θ from the principal optical axis will be attenuated by a factor equal to $\cos \theta$. The divergence of the infrared beam from the optical axis is determined experimentally for each set of auxiliary reflectance optics.

A provision has been made to model losses in the reflected light due to scattering on a rough surface by including a frequency dependent term. The effect of scattering is especially noticeable in the decrease of reflectance with increasing wave number. Our data are fit well by multiplying the calculated reflectance at a given frequency by a term which is proportional to $1/[1 + (c\nu)^2]$, where c is a constant. Since the size of the crystallites formed on the metal surfaces is, at most, on the order of a few micrometers in our study, this behavior of the scattering coefficient is in good agreement with previous studies of diffuse reflectance (26). This approach is simi-

lar to that taken by Allen and Swallow in their study of oxide films on Cr substrates (24).

Another characteristic of real thin films is a variability in the layer thicknesses. Our model takes this into account by performing a weighted average of calculations for a given distribution of layer thickness. The general effect of this refinement is to broaden and shift the position of reflection minima. Particularly striking changes may occur for various spectral features, and this is discussed in some detail for iron oxide films.

The calculated reflectance is optimized with respect to the experimental data by varying the order of the layers, their thicknesses, and the coefficient in the scattering term. For situations where good data were available for the optical constants of the absorbing layers, the use of experimental measurements at different angles of incidence and polarization produced rapid and unambiguous fits of the observed spectra.

Experimental

Specular reflectance of oxidized metals and alloys was measured using a Digilab FTS-14 spectrometer equipped with a CsI/Ge beamsplitter, TGS detector, and wire grid polarizers. This arrangement permitted a usable bandwidth of 250-1500 cm^{-1} . Two auxiliary optical attachments were used to provide a single reflection at angles of incidence of 22° and 73° relative to the surface normal. Mounting the sample holder on translation stages allowed the precise centering and focusing of the incident beam on the sample. The minimum dimension of the beam on the sample was 4-6 mm, depending on the focusing optics. Half-angles of divergence for the two attachments were 20° and 12°, respectively (21). All data presented here were acquired with a spectral resolution of 4 cm^{-1} .

Samples were prepared from the following high purity metals and metal alloys [all percentages are given as weight percent (w/o)]: Cr, Fe-10% Cr, and Fe-15% Cr. After being cut to a typical 12 mm square size, the samples were polished to at least 600 grit finish and ultrasonically cleaned in acetone. Pure chromium substrates were oxidized in air at 700°C, while the Fe-10% Cr and Fe-15% Cr binary alloys were oxidized in air at 850°C. Oxidation times varied from a few minutes to several hours.

Reference reflectance spectra were obtained using either unoxidized metal samples polished to a 600 grit finish, or first surface mirrors of gold or aluminum. The use of gold or aluminum reference mirrors is preferable for calibration purposes, since the reflectance values for these materials are well known and are very close to 1. However, this approach sometimes produced a residue of uncompensated curvature and structure in the base line due to nonlinear aberrations in the reflectance attachment optics. In those cases, ratioing sample spectra to that of an unoxidized substrate gave relative reflectance values in which the spectrometer instrument function was largely eliminated.

The experimental reflectance values we present in this paper are those data which exhibited the least uncompensated instrument function. They have been scaled linearly so that nonabsorbing regions of the spectrum at low wave number yield reflectance values in agreement with our theoretical calculations. This normalization procedure may produce a systematic offset of the base line by a few percent, but should have little or no effect on the relative behavior of the absorbing regions of the spectrum.

Results and Discussion

Theoretical calculations for single-phase thin films.— Before considering the complexities of real thin films with many absorption modes, it is profitable to note the effect of angle of incidence, film thickness, and state of polarization on the reflectance of a simple, single-phase thin film. It is important to be aware of these relationships since the resulting reflectance of a highly absorbing oxide film may result in rather bizarre "distortions" of band shape and position.

For the purposes of illustration, we consider a hypothetical material having two active infrared modes with

Table I

Resonance center (cm^{-1})	Damping constant (cm^{-1})	Band strength
400	15	0.30
600	25	0.05

the optical properties shown in Table I. These values are representative of many metal oxides. We calculate n and k values as a function of wave number using the classical dispersion equation

$$e = e_1 - ie_2 = e_\infty + \sum_j \frac{4\pi\rho_j\nu_j^2}{(\nu_j^2 - \nu^2) + i\gamma_j} \quad [7]$$

and the relation of the refractive index and absorption coefficient to the dielectric constants

$$\hat{n} = n - ik = (e_1 - ie_2)^{1/2} \quad [8]$$

In this formulation, e_∞ is the value of the high frequency dielectric constant, ν_j is the frequency at the band center, ρ_j is a dimensionless band strength, and γ_j is a constant damping coefficient associated with mode j . Values of n and k used for the substrate are those of metallic chromium (27). This is perhaps the simplest model for deriving values of n and k from the optical constants, and it has the advantage that the damping constants can be related to bandwidths at half-height for the imaginary portion of the dielectric constant, e_2 . Calculated values for n and k are shown in Fig. 2.

We calculate the reflectance for a P-polarized beam at normal incidence for three different thicknesses as shown in Fig. 3. The two thinner films produce reflection minima near the mode centers, as one would intuitively expect. We do observe a shift in the band centers toward lower energy as the thickness increases from 0.5 to 1.0 μm . The film of 2.0 μm thickness, however, produces additional minima which have no apparent connection with the two specified vibrational modes. In addition, no reflectance minimum is observed at the 600 cm^{-1} mode center of the second band. This situation becomes more confusing and complex as the thickness of the layer increases.

As pointed out by Swallow and Allen (23), this phenomenon is caused by the rapidly changing values of n and k in the region of the mode centers. As the value of n increases, interference due to multiple reflections occurs, and for sufficiently thick films one or more fringes may be observed near the band centers. This effect should always be considered as a possibility when complex spectral features appear as surface films increase in thickness. The assumption that additional observed bands are due to different chemical species may not be warranted in many cases.

Fig. 3. Calculated P-polarized reflectance of a thin film showing the effect of layer thickness.

Swallow and Allen present a detailed and lucid examination of these effects and their dependence on mode frequency, band strength, and damping coefficient, and the reader is referred to their article (23). Their treatment is based on approximate equations for normal incidence, however, and they did not consider the effects of angle of incidence and state of polarization. These variables profoundly influence the resulting reflectance, and they are examined below.

The effect of angle of incidence is shown in Fig. 4. We consider here films of 0.5 μm thickness and a P-polarized beam incident at angles of 0° , 22° , and 73° (the latter two values corresponding to our experimental conditions). Two additional reflection minima appear and grow in intensity as the angle increases from normal incidence. Berreman (1) has shown that these features are coincident with the longitudinal optic (LO) phonon modes which are infrared forbidden for bulk crystalline material at any angle of incidence. The boundary conditions imposed by the thin film-substrate geometry on Maxwell's equations allow these modes to be observed as reflection minima for P-polarized light when the angle of incidence is greater than zero.

These additional modes are not predicted to occur for either polarization at normal incidence. Hence, some authors who have used simpler, approximate equations for reflectance at normal incidence (23, 24) have found it necessary to postulate a scattering effect in order to produce these minima. This is not necessary, since they are a natural consequence of reflectance calculations at non-normal incidence for P-polarized light at even rather small angles of incidence. Thus the straightforward re-

Fig. 4. Calculated P-polarized reflectance of a thin film showing the effect of angle of incidence.

flectivity equations for normal incidence are not adequate to interpret all features of the experimental results.

Experimental measurements for chromium oxide forming alloys.—Accurate determinations of optical constants are available for several transition metal single-phase oxides. We have used previous work on metal oxides for our calculations on Cr_2O_3 (28) and Fe_2O_3 (29), and data for chromium and iron metals (27).

Reflectance spectra at near-normal incidence for Cr_2O_3 grown on bulk chromium substrates by thermal oxidation in air have been reported by Allen and Swallow (24) for relatively thick films (0.3–7.5 μm), and by Mertens (18) for films between 0.05 and 0.4 μm thick. In fitting their experimental data, Allen and Swallow found it necessary to modify the literature values of optical constants for chromium oxide given by Renneke and Lynch (27). These changes were quite small and resulted in a set of constants which effectively assumed that the oxide was isotropic in its optical properties. We have also measured the reflectance of thermally grown oxide films on chromium substrates in the same thickness range as Mertens. Estimates of thickness were made by weight-gain measurements and ranged from 0.04 to 0.40 μm .

Reflectance measurements for these very thin films were made using P-polarized light at an angle of incidence of 73° . Agreement with Allen and Swallow's results for films of 0.4 μm thickness at near normal incidence is relatively good, with the exception of the intensity of the band at 735 cm^{-1} . Since this band is coincident with an LO optical phonon, its intensity is expected to greatly increase with increasing angle of incidence as shown above. Our data agree more closely with those of Mertens, and this is expected since he utilized an experimental angle of incidence similar to ours.

The set of optical constants used by Allen and Swallow also fit our observed data very well over the entire range of thickness, and a plot of experimental and calculated spectra are shown in Fig. 5 for a thickness of 0.39 μm . Optical constants for metallic chromium (27) were used for the substrate. Agreement between calculated and measured frequencies and their relative intensities is quite good for these films. The observed bands, however, are generally broader than their calculated counterparts and are asymmetric. Broadening reduces the observed splitting between bands near 415 and 600 cm^{-1} , and the 735 cm^{-1} band is noticeably asymmetric on the low energy side.

Other investigators have pointed out (25) that this broadening probably stems from large anharmonicities in the thin film lattice modes in contrast to bulk crystals from which the optical constants were taken. These differences tend to arise from imperfections in the oxide structure and may broaden the lattice phonons considerably. Band asymmetry has been shown (1) to result from the use of a frequency-dependent damping term, $\gamma(\nu)$, in

contrast to the constant term used in Eq. [7] above. This results from the rapid fluctuation in the value of γ near the mode center. Furthermore, large changes of γ in regions not near lattice mode frequencies resulted in the observation of weak reflection minima for a thin film of LiF on silver (1). This may be an additional cause of the pronounced asymmetry in the 735 cm^{-1} band for our thin Cr_2O_3 films.

The calculated thickness for a given film may be obtained in a straightforward manner by the comparison of the theoretical and experimental minimum reflectance for several bands. This is a rather simple process for very thin films where the base line is well defined. However, for increasingly thicker layers it becomes more difficult to precisely locate the base line in the region of the strong bands (for instance, see Fig. 5). Our experimental data for the thicker chromium oxide films generally possess a rather flat character in the transparent regions below 400 and above 800 cm^{-1} , and linear base lines were drawn connecting these two regions.

Some authors (18) suggest that a logarithmic relation (analogous to absorbance) in some cases would offer a linear correlation with film thickness. In Fig. 6, we show a plot of calculated $-\log R_{\min}$ values for the band near 735 cm^{-1} . Evidently, a linear increase in this function does exist for films thinner than 0.1 μm . This reflectance function goes through a maximum for films near 0.18 μm , and gradually rolls off with increasing thickness.

We also present experimental data for oxide films grown on bulk chromium in air at 700°C . These are given in Fig. 6 as circles, and they also exhibit an initial linear region with a slope identical to that of the theoretical plot. A positive linear offset in the measured film thickness from the theoretical curve is clearly observable. The thicknesses for these films were calculated from weight gain measurements, and it is quite probable that enhanced growth at the sample edges caused an overestimation of the average thickness on the flat surface. This seems especially likely in that the experimental values do not extrapolate to 0.03 (the value for bare chromium) at thickness equal to zero. We therefore attribute the systematic positive offset in experimental points from the theoretical curve to this cause.

In performing these calculations for thin films, it is of crucial importance to include the effects of infrared beam divergence. Most experimentalists use a highly focused beam in order to improve sensitivity and minimize sample dimensions by reducing the spot size to a few millimeters in cross section. This means, however, that the infrared radiation will be incident on the sample over a range of angles rather than a single value. The theoretical curve presented in Fig. 6 was evaluated using an angle of incidence of 73° and a half-angle of divergence of 12° . The effects of disregarding beam divergence are shown in Fig. 7. The reflectance minimum is extremely sensitive to the

Fig. 5. Experimental and calculated P-polarized reflectance of 0.39 μm film of Cr_2O_3 on Cr.

Fig. 7. Calculated P-polarized reflectance for the 735 cm^{-1} band of Cr_2O_3 films on Cr showing the effect of beam divergence.

angle of incidence, and the value of $-\log R_{\min}$ is shown to strongly increase around a thickness of $0.18\ \mu\text{m}$ for a beam which is collimated at 73° angle of incidence.

Other bands in the reflectance spectrum also exhibit characteristic increases in intensity with film growth, and they may also be used to calculate film thicknesses. In Fig. 8, we show the composite theoretical and experimental behavior for three vibrational modes: the mode coincident with the bulk LO phonon discussed above, and two transverse optic (TO) modes near 530 and 415 cm^{-1} .

The 530 cm^{-1} mode seems to be especially well suited for thickness determinations. Indeed, the scatter in experimental data for films greater than $0.2\ \mu\text{m}$ thick is considerably less than that for the much more intense 735 cm^{-1} band discussed above. We note, however, that this band exhibits a very different characteristic behavior and shows no linear region of growth for $-\log R_{\min}$. Although the data for the band near 415 cm^{-1} also seem to agree well with theory, its use is more problematic for two reasons. First, it is of quite low intensity, and, second, it is a "forbidden" mode (27) and shows a considerable intensity variation in relation to the other bands depending on the conditions of film preparation.

Finally we observe that for layers thinner than $0.05\ \mu\text{m}$, only the band at 735 cm^{-1} is observed with any substantial intensity. Thus any departure of the film's optical constants from the input values will have a serious effect on calculated thicknesses since only one band is being fit.

Air oxidation of Fe-15% Cr alloys at high temperatures tends to form an oxide scale which is predominantly Cr_2O_3 . The P-polarized reflectance spectrum of the sample heated for 3h is shown in Fig. 9. The resemblance

Fig. 8. Calculated P-polarized reflectance for three bands of Cr_2O_3 films on Cr.

Fig. 9. Experimental and calculated P-polarized reflectance for a $0.31\ \mu\text{m}$ film of Cr_2O_3 on Fe-15% Cr.

to the films grown on pure chromium substrates is obvious, and we fit the observed spectrum to the calculated reflectance for a $0.31\ \mu\text{m}$ thick layer of Cr_2O_3 . The principal deviation of the calculated curves from the measured spectra is again the breadth of the bands and the asymmetry of the 735 cm^{-1} band. We note, however, that the degree of asymmetry for this band is far more pronounced than in the spectra of the oxides grown on the pure chromium substrates.

An additional mechanism for producing absorbance in the region between 660 and 735 cm^{-1} is the substitution of Fe for Cr in the Cr_2O_3 layer. Chang and Mitra (30) have studied the behavior of optic mode frequencies in certain classes of mixed crystals. They have shown that these frequencies vary continuously and approximately linearly with concentration from the frequency characteristic of one end member to that of the other end member for several mixed oxides. Unpublished work by Ottesen and Nagelberg at this laboratory has confirmed that the mixed oxide, $(\text{Fe}, \text{Cr})_2\text{O}_3$, exhibits this behavior. The presence of a small amount of iron in our thin chromium oxide films would be expected to produce absorptions precisely in the region between 660 and 735 cm^{-1} . The exact nature of the resulting reflectance spectrum would depend on the manner in which the iron atoms were distributed throughout the predominantly Cr_2O_3 thin film.

We now wish to determine layer thicknesses for these films grown on Fe-15% Cr alloys and to fit the calculated thicknesses to an experimental kinetic rate law plot. While optimum fits of theoretical calculations to experimental data are obtained by using a nonlinear least squares analysis, an approach based on minimum band reflectance has much to recommend it in terms of both simplicity and speed. Provided that the limits of applicability can be accurately quantified, this method of determining film thicknesses is of great potential value to a variety of users.

Using the theoretical curves for $-\log R_{\min}$ determined above for bands near 735 and 530 cm^{-1} , we calculate thicknesses for our six samples. Assuming that the oxidation process is diffusion controlled, the calculated thickness data are plotted vs. the square root of oxidation time in Fig. 10.

Initially the fit to a parabolic rate law is reasonably good (indicated by the straight line). However, as the film thickness increases, this interpretation becomes less clear. This is primarily due to the scatter of the data points for the four greatest thicknesses determined using the 735 cm^{-1} band. This scatter is not unexpected. Traditional analytical methods (31) have shown that the maximum accuracy in spectroscopic measurements is obtained for linear absorbance measurements in the vicinity of 0.43 . Accuracy for our $-\log R_{\min}$ measurements is expected to degrade seriously below 0.2 and above 0.7 , and the four points mentioned above all have values above 0.8 .

Fig. 10. Parabolic rate law plot for Cr_2O_3 film thickness as formed during air oxidation of Fe-15% Cr in air at 850°C .

Using this criteria for accuracy, acceptable limits for determining film thickness using the 735 cm^{-1} band are $0.01\text{--}0.07\text{ }\mu\text{m}$. For the 530 cm^{-1} band, these limits are $0.20\text{--}0.38\text{ }\mu\text{m}$. This also avoids the major uncertainty in the determination of the experimental base line discussed above. The area of greatest uncertainty lies in the vicinity of the 530 cm^{-1} band when it is quite weak and therefore unreliable for thickness determinations.

Thus we may expect a reasonably accurate determination of Cr_2O_3 film thicknesses using these two bands over a range of $0.01\text{--}0.38\text{ }\mu\text{m}$ with somewhat greater uncertainty in the intermediate range of $0.07\text{--}0.20\text{ }\mu\text{m}$.

For thicker films, it may be best to use the interference fringes in the transparent region for thickness determinations. These become more closely spaced and increase in intensity as the oxide film grows in thickness, and their use in such determinations has been demonstrated elsewhere for chromium oxide (24), and will be described below for iron oxide forming alloys. For layers thinner than $0.01\text{ }\mu\text{m}$, considerable care must be taken in determining thicknesses using infrared reflectance data. Our approach is predicated on the underlying assumption of uniform surface coverage and optical constants which do not change with film thickness. Both of these criteria become increasingly debatable for such thin layers, and the quantitative use of external reflectance must be buttressed by careful calibration and independent measurements by other surface science methods.

Experimental measurements for iron oxide forming alloys.—Binary alloys containing smaller amounts of chromium exhibit strikingly different behavior during thermal oxidation. Previous work has shown that the oxidation mechanism and oxide film composition for a given alloy depend strongly on the chromium content of the substrate, the temperature, and the oxygen partial pressure (32).

We have studied the oxidation of an Fe-10% Cr alloy in air from 700° to 850°C . At 850°C , much thicker films are grown on this alloy compared to Fe-15% Cr. The reflectance spectra of a coupon oxidized for 1h are shown in Fig. 11 and 12. Note the strong features in the S-polarized spectrum as compared to the flat, featureless curves which occur for very thin films (2). The oscillations in both S- and P-polarized spectra above 700 cm^{-1} are due to interference fringes. The spacing between the fringes decreases in the vicinity of 700 cm^{-1} due to the rapid variation in the film's refractive index.

These experimental spectra were fit using calculated data for hematite ($\alpha\text{-Fe}_2\text{O}_3$). Optical constants of iron were used for the substrate (27), and optical constants for hematite were obtained from the literature (29). Since this material is strongly anisotropic, we were not able to construct a set of "average" optical constants, as was the case for Cr_2O_3 . Our computer program accommodates anisotropic, uniaxial absorbing media as long as the symmetry

Fig. 11. Experimental and calculated P-polarized reflectance for an $8.4\text{ }\mu\text{m}$ film of $\alpha\text{-Fe}_2\text{O}_3$ on an Fe-10% Cr substrate.

axes of the crystal are aligned normal or parallel to the surface. Since hematite possesses trigonal crystal symmetry, we approximated a random orientation of microcrystals on the surface by averaging calculations for layers with the crystal c axis parallel and perpendicular to the surface (shown schematically in Fig. 13).

If the two conditions with the crystal c axis parallel to the surface are equivalent, then the interaction of the incident infrared radiation would result in the electric vector's being perpendicular to the c axis twice as often as it would be parallel to the c axis. Accordingly, we cal-

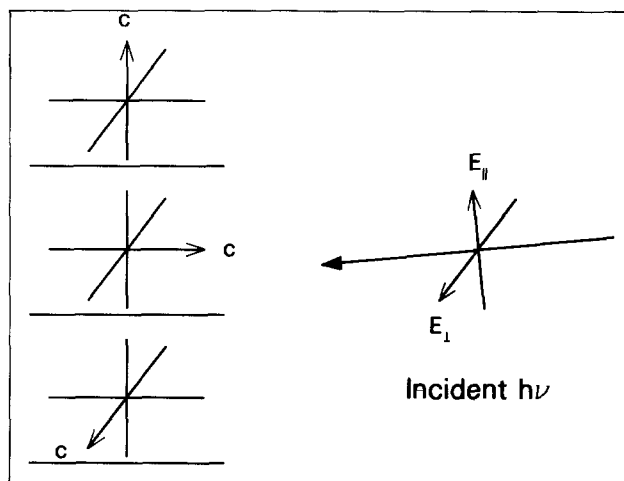

Fig. 13. Schematic orientation of $\alpha\text{-Fe}_2\text{O}_3$ crystal symmetry axis with respect to the substrate and incident infrared beam.

culated reflectance spectra for these different orientations and performed a weighted average in our comparison with experimental results.

The calculations for P- and S-polarizations for a 0.67/0.33 mixture of the orientations given above are also shown in Fig. 11 and 12. The agreement between calculated and experimental data in the absorption region is extremely good with two exceptions. A weak, broad band in the experimental spectra at 620 cm^{-1} is not present in the calculated curves. Also, the detailed structure of the strong doublet centered at 710 cm^{-1} in the P-polarized experimental spectrum is calculated as a slightly narrower singlet. We attribute these differences primarily to a small amount of $(\text{Fe}_{3-x}\text{Cr}_x)\text{O}_4$ oxide phase in the experimentally grown oxide film. Previous work (32) suggests that this phase should be present as a thin layer between the hematite film and the substrate.

Earlier experimental studies of similar oxide films (21) noted the lack of reliable optical constants in the reference literature for complex oxide phases, and the present theoretical treatment of these systems serves to emphasize this deficiency. This situation prevents a complete interpretation of our external reflectance measurements.

The calculated spectra presented in Fig. 11 and 12 also include an assumption of $\pm 0.4\text{ }\mu\text{m}$ standard deviation in film thickness. This was modeled by assuming a gaussian distribution of layer thicknesses about the mean, and performing a weighted average of five calculations in which the layer thickness was varied in equal increments from 7.9 to $8.9\text{ }\mu\text{m}$. The assumption of surface roughness was necessary to adequately fit the shape of the experimentally observed interference fringe region. This was particularly important for the S-polarized component, and a comparison of the rough surface calculation and a smooth surface calculation is shown in Fig. 14. This shows that the assumption of a uniformly thick oxide layer would be seriously in error for this system.

We find, however, that the assumption of a single angle of incidence of the infrared beam results in a very good approximation to the observed data in contrast to the results for thin chromium oxide films discussed above. Calculated spectra for a P-polarized spectrum taken at 73° angle of incidence assuming no angular spread and $\pm 12^\circ$ half-angle of divergence show no significant difference.

Finally, we note that although the correct spacings and shapes of the interference fringes are calculated by our present model, their relative intensities and the treatment of the base line leave something to be desired. The principal cause for this is most likely our simple approach to modeling scattering phenomena with a single ν^2 term. While this may be satisfactory for the thinner chromium oxide films presented earlier, electron micrographs for these thicker films clearly show a complex microcrystalline morphology which might be expected to exhibit behavior intermediate between specular and diffuse reflection.

Fig. 14. Calculated S-polarized reflectance for $\alpha\text{-Fe}_2\text{O}_3$ on an Fe-10% Cr substrate showing the effect of surface roughness.

Quantitative film thickness determination.—One of the most significant uses of external infrared reflectance would seem to be the monitoring of film thickness during an industrial process. In a previous paper, Mertens (18) addressed precisely this feature of the method, and a set of calibration factors was derived for four transition metal oxides which related thickness to the measured negative logarithm of reflectance for the most intense band in the spectrum. As we noted above, this band corresponds to the position of the highest LO mode in the bulk oxide, and its $-\log R_{\min}$ function exhibits roughly linear behavior for very thin layers.

We derive analogous calibration factors from our experimental data and calculated spectra for chromium oxide and from a theoretical treatment for the oxides of iron and nickel. The calculations for chromium and iron have been discussed in detail above; optical constants for NiO and Ni metal have been taken from the literature for similar calculations (33, 27). The results for each oxide's highest energy mode are shown in Fig. 15 for films between 0.001 and $0.5\text{ }\mu\text{m}$ in thickness. All three of these modes show similar qualitative behavior: linearly increasing $-\log R_{\min}$ for thin films with a gradually increasing negative deviation from this straight line behavior. Slopes of the initial portion of the curve are taken, and calibration factors analogous to those of Ref. (18) in units of angstroms per $-\log R_{\min}$ are derived. Those values are expressed in units of angstrom/absorbance/reflection, where the term "reflection" refers to the number of external reflections in a multiple-pass experimental apparatus.

These values are compared in Table II, and we see that there is a very large discrepancy between the two sets. The disagreement becomes progressively less as the linear region for $-\log R_{\min}$ increases. Thus the values for chromium oxide differ by a factor of 10, those for nickel oxide by a factor of 2.7, and those for iron oxide by a factor of 3. One factor which complicates the earlier results (18) is the calculation of intensity factors using data from films whose thicknesses have entered the nonlinear region for $-\log R_{\min}$. This is especially the case for chromium oxide and may account for the astounding degree of difference between the two approaches.

This may account for much of the disagreement for nickel oxide and iron oxide calibration factors as well. It is not a simple matter to quantitatively reconcile this previous study with our present investigation, however. The principal obstacle to this lies in Mertens' use of multiple reflectance sampling optics which were designed to maximize optical sensitivity for extremely thin films (18, 19). That experimental arrangement consists of two rectangular sample (or reference) surfaces which are arranged parallel and very close to each other. The infrared beam is then focused on the space between the two surfaces, and the resultant reflected light is collected at

Fig. 15. Calculated P-polarized $-\log R_{\min}$ of the highest energy infrared active mode for thin films of transition metal oxides on metallic substrates.

Table II

Metal oxide	Infrared band (cm ⁻¹)	Calibration factor (Å/-log R _{min})	
		Ref. (18)	This work
α-Fe ₂ O ₃	655	5000	1695
NiO	582	5900	2200
Cr ₂ O ₃	733	9800	1030

the other end. Since the beam is incident on the sample surface over a range of angles, the number of reflections at the sample surface depends on both the angle of incidence and the spacing between the surfaces.

The angles of incidence used in that experiment thus range about 72° for the initial reflection. The net effect is to accentuate the lower angles of incidence which experience more reflections for a given sample length than the higher angles of incidence. We noted above that the incorporation of a range for the angle of incidence generally results in a lowering of the peak -log R_{min} values (see Fig. 7). We assume that the effective skewing of this distribution to lower angles, as would be the case for the multiple reflectance apparatus, would lower the resulting peak values even more.

Whatever the specific behavior of the measured "absorbance" might be, the lower values of -log R_{min} would certainly result in correspondingly higher values for the calibration factors than those which we obtain from the strictly linear region of -log R_{min} and a complete reflection calculation. The present work thus serves as a warning to experimentalists using multiple reflectance optics. Although these sampling attachments do indeed enhance the sensitivity of the technique, the resulting measurements are not simply related to single reflectance measurements, and they will certainly have a depressingly complicated dependence on the beam angular divergence.

Potential users should keep in mind that linear calibration factors derived from external reflectance studies will be transferrable to other measurements only when precisely similar sampling optics are used. This is true of our single reflection measurements as well, although in this case theoretical confirmation is much more straightforward.

Conclusions

External reflectance infrared spectroscopy has been shown to be a reliable technique for the study of thin oxide films formed on air oxidized Fe-Cr alloys. A computer program has been written to calculate the external reflectance for these films using optical constants from the reference literature for the oxides. This method is useful in the determination of both composition and film thickness of simple oxide films, and extends over a wide range of layer thickness (0.01-10 μm for Cr₂O₃).

Many of the features observed in the reflectance spectra of these thin films can be misleading when compared to absorption spectra. These complications arise primarily from the large (and rapidly varying) indexes of refraction for metal oxides, the rough nature of the oxide films, the presence of complex oxide phases, and several experimental parameters (angle of incidence, angle of divergence, beam polarization).

Finally, theoretical calibration factors for the determination of film thickness have been derived for three transition metal oxides. These factors utilize the most intense oxide reflectance band and are useful in a region where the negative logarithm of the reflectance band increases

linearly with film thickness. These values are in marked contrast to those of an earlier study (18), and this discrepancy is attributed to differences in the experimental reflectance optics used in the two investigations.

Acknowledgments

I would like to thank Karen Siegfried, who prepared many of the experimental samples for this investigation, and who also collected some of the experimental data in addition to incorporating several modifications in the reflectance optics. I would also like to thank John Hamilton for kindly providing the thin chromium oxide films grown on bulk chromium substrates, and Alan Nagelberg for his helpful discussion of metal oxidation. This work is supported by the U.S. Department of Energy under Contract DE-AC04-76DP00789.

Electrochemical Determination of Standard Gibbs Energies of Formation of Rare-Earth Oxysulfides and Oxysulfates

Norihiko Fukatsu,¹ Noriyuki Shidawara,² and Zensaku Kozuka

Department of Metallurgical Engineering, Faculty of Engineering, Osaka University, Suita, Osaka 565, Japan

ABSTRACT

The oxygen chemical potentials established by the equilibrium reactions between the rare-earth (La, Ce, Nd, Gd, and Y) oxysulfide and the corresponding rare-earth oxide or oxysulfate were measured in the temperature range 1200-1500 K using the cell

where S-O gas represents the gas mixture whose species consist of only sulfur and oxygen. The sulfur chemical potentials were determined by calculations on the complex equilibrium reactions among gas species under the restriction of the constant total pressure. The standard Gibbs energy changes for the reactions were calculated from these results regarding that the activities of the participating solid components were unity. The standard Gibbs energies of formation of $\text{Ce}_2\text{O}_3\text{S}$, $\text{Nd}_2\text{O}_3\text{S}$, $\text{Gd}_2\text{O}_3\text{S}$, $\text{Y}_2\text{O}_3\text{S}$, $\text{Nd}_2\text{O}_2\text{SO}_4$, and $\text{Gd}_2\text{O}_2\text{SO}_4$ were determined from these data. The standard Gibbs energies of formation of $\text{Ce}_2\text{O}_3\text{S}$ obtained in this study were slightly more negative than that determined with gas equilibrium method by Fruehan. The Gibbs energies of formation of oxysulfides estimated by Gschneidner *et al.* were found to agree fairly well with the present experimental results.

Rare-earth elements have been widely used in the industrial material production processes as additives to improve the properties of the product. In these applications, rare-earth elements are sometimes used in the environment where the oxygen and sulfur are both contained as the components. For example, they are used as deoxidizer, desulfurizer, and modifier of the morphology of inclusions in the steel production, are used to control the graphite morphology in the production of cast iron, and are used as the additives to improve the high temperature corrosion resistance properties. To use them efficiently in these applications, it is important to understand the thermodynamic aspects of the system containing both sulfur and oxygen. However, thermodynamic data of rare-earth compounds with sulfur and oxygen are very limited. Especially, the temperature dependence of the Gibbs energies of formation of rare-earth oxysulfides are not known except for $\text{Ce}_2\text{O}_3\text{S}$ (1), in spite of those industrially important as rare-earth-doped phosphors.

It has been ascertained that the EMF method employing the stabilized zirconia solid electrolyte is a useful tool for investigating the thermodynamic properties of the systems containing both sulfur and oxygen as the components. The present authors have utilized this method on the thermodynamic studies of the system Bi-S-O (2, 3), Ag-S-O (4), and Pb-S-O (5) and have gotten satisfactory results. In the present work, the same method was applied to RE-S-O systems (RE = La, Ce, Nd, Gd, and Y) to determine the Gibbs energies of formation of oxysulfides and oxysulfates of these elements.

Recently, Dwivedi and Kay (6) measured the oxygen partial pressures corresponding to the oxysulfide/oxysulfate equilibrium using a similar EMF method; they determined the Gibbs energy changes for the reactions between the oxysulfides and the respective oxysulfates. However, the Gibbs energies of formation of either compound could not be determined. For Ce and Y, they also measured the oxygen partial pressures corresponding to the oxide/oxysulfide equilibrium in the condition that Ag and Ag_2S coexisted (7); the Gibbs energies of formation of $\text{Ce}_2\text{O}_3\text{S}$ and $\text{Y}_2\text{O}_3\text{S}$ were determined based on those of oxides, but their temperature dependences could not be obtained because the cells operated successfully over a very limited temperature range.

In the present experiment, the oxygen partial pressures corresponding to the oxide/oxysulfide equilibrium were

¹Present address: Department of Material Engineering, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466, Japan.

²Present address: Nippon Steel Corporation, Tokai, Nagoya 476, Japan.

measured in "quasi isobaric closed" conditions. The equilibrium sulfur pressures were determined by calculations on the complex equilibrium reactions among gas species. The Gibbs energies of formation of oxysulfides, therefore, could be determined directly from those of oxides for more wide temperature range. The Gibbs energies of formation of oxysulfates were also determined from these data.

Theory

A metal-sulfur-oxygen system at a constant temperature may be thermodynamically characterized by the equilibrium oxygen and sulfur partial pressures. In these two variables, the oxygen partial pressure may be measured preferentially with the coexisting sulfur partial pressure by using oxygen galvanic cell employing stabilized zirconia as solid electrolyte (8). When the equilibrium oxygen partial pressure is known, the equilibrium sulfur partial pressure may be determined by calculation if the gas phase consists of the species made only from oxygen and sulfur atoms and if its total pressure was known. Since this method was first used by Larson and Elliott (9) to determine the Gibbs energies of formation of several sulfides, it has been used to measure the Gibbs energies of formation of sulfates (10-13), to measure the activities of sulfur in liquid melts (2, 4), and to study the phase equilibria in metal-sulfur-oxygen systems (5, 14, 15). In those experiments, it was most of the cases that the gas phase may be substantially regarded to be pure SO_2 or S_2 . Even if this condition is not satisfied, sulfur partial pressure can be determined by calculation when the thermodynamic data of all coexisting gas species is known, as is explained below.

According to the phase rule, the degree of freedom is two when three phases are contained in a system which is composed of three elements, RE, S, and O (RE = La, Ce, Nd, Gd, and Y). In these systems, the unique oxygen partial pressure is, therefore, established when the two condensed phases and a gas phase coexist in the equilibrium state at a given temperature and a given total pressure. The oxygen partial pressure established over the two condensed phases may be measured by the following galvanic cell

Pt, Au, oxysulfide, oxide or oxysulfate,

When the ionic transport number of the solid electrolyte may be considered to be 1—and this condition is satisfied in the present experiment (16)—EMF of the above cell is given as

$$E = -(1/4F) RT \ln (P_{O_2}/0.21) \quad [2]$$

where, E is the reversible cell, EMF, R is the gas constant, T is the temperature of the cell, and P_{O_2} is the equilibrium oxygen partial pressure of the left electrode (17). Therefore, the oxygen partial pressure at the left electrode may be determined by measuring the EMF of the cell. The partial pressures of other gas species, S_mO_n , (e.g., SO_2 , SO_3 , etc.) may be represented in a function of sulfur partial pressure and oxygen partial pressure using the following equilibrium relations

$$P_{S_mO_n}/(P_{S_2})^{m/2}(P_{O_2})^{n/2} = \exp(-\Delta G^0_3/RT) \quad [4]$$

where, ΔG^0_3 is the standard Gibbs energy of formation of S_mO_n . On the other hand, from the condition that the total pressure is kept constant

$$\sum P_{S_mO_n} = P_{total} \quad [5]$$

The sulfur pressure may, therefore, be calculated by solving Eq. [4] and [5] simultaneously. The detail of this calculation was already reported elsewhere (2).

When pure condensed phases $RE_{x_1}S_{y_1}O_{z_1}$ and $RE_{x_2}S_{y_2}O_{z_2}$ are in equilibrium with gas phase of the total pressure P_{total} , the equilibrium reaction may be represented by

The Gibbs energy change of this reaction may be given in terms of the chemical potential of oxygen and the chemical potential of sulfur by

$$\Delta G^0 = [(x_1y_2 - x_2y_1)/2x_2] RT \ln (P_{S_2}/P_{total}) + [(x_1z_2 - x_2z_1)/2x_2] RT \ln (P_{O_2}/P_{total}) \quad [7]$$

In the present calculations, SO_2 , S_2O , SO_3 , S , S_2 , S_3 , S_4 , S_5 , S_6 , S_7 , S_8 , O , O_2 , and O_3 are considered as the coexisting gas species. The Gibbs energies of formation of these gas components, except that of SO_2 , were adopted from the compiled data of Barin and Knacke (18). For the free energy of formation of SO_2 , the calculated values based on the CODATA key values ΔH^0_{298} and ΔS^0_{298} (19) and the data of ΔC_p compiled by TPRC (20) were used. These data are shown in Table I.

Experimental

Materials.—Rare-earth oxides (La_2O_3 , CeO_2 , Nd_2O_3 , Gd_2O_3 , and Y_2O_3) were all supplied from Shinetsukagaku Company Limited. The purities of these oxides are 99.99% for La and Y and 99.9% for Ce, Nd, and Gd. Main impurities were the other rare-earth oxides. All rare-earth oxysulfides except La_2O_2S were prepared by holding the respective oxide powders in the alumina crucible at 1473 K for 10,800s under flowing H_2S atmosphere. The product phases are identified by x-ray diffraction analysis. For lanthanum, oxysulfide phase was not formed by the above conditions, but La_2S_3 was obtained by holding at 913 K for 3600s with the same procedure. Therefore, for

the La-S-O system, oxide and sulfide phases were used as the charging materials.

Apparatus.—The schematic diagram of the apparatus and the cell assembly are illustrated in Fig. 1. An 11 mole percent (m/o) CaO stabilized zirconia tube (5 mm id, 8 mm od, and 300 mm length) closed at one end supplied from Nippon Kagaku Togyo Company Limited was used as the solid electrolyte of the cell. Air-Pt reference electrode was prepared on the outside of the closed end of the tube by painting platinum paste and heating it in air at 1300 K. Air was flowed at the rate 0.8 cm³/s over the reference electrode. Gold, which is virtually inactive to both sulfur and oxygen, was used for the material of the working electrode because the electric conductivities of these samples are very low. Iridium wire spot-welded to Kanthal wire was used as the lead wire to the working electrode, which was protected from corrosion by sulfur and oxygen using alumina sheath and alumina cement. Temperature was measured by the Pt-Pt 13% Rh thermocouple in the protecting tube which is touched to the bottom of the zirconia tube. A Kanthal-wound furnace and an electronic controller were used to maintain the temperature of the cell within ± 1 K to the selected values.

Procedure.—In the present work, all measurements are on the two-condensed phase equilibria. It is not necessary that the ratio of the amounts of charge materials be chosen rigidly to a certain value. The ratio of oxysulfide to oxide is selected to be about 2:1, because the sulfur is transferred to gas phase by sublimation or the reaction with the oxygen permeated through the zirconia electrolyte owing to its small electronic conduction. A slight amount of pure sulfur was added to them in the several systems exhibiting the relative high partial pressure of sulfur to check the reliability of the EMF data. They were well mixed in a mortar, and 0.6g of them were used as the charge material. About 1g of pure gold bead was loaded at the bottom of the zirconia tube, and the lead wire was set to touch it. The sample was then charged over the gold and the zirconia crucible was well tapped to ensure the dense packing.

The reaction compartment of the cell was first evacuated at 473 K to a vacuum of 0.1 Pa, and then purified SO_2 was introduced. SO_2 was allowed to overflow

Fig. 1. Schematic diagram of cell assembly

through the liquid paraffine bubbler located near the gas inlet of the apparatus as shown in Fig. 1 to keep the total pressure equal to the atmospheric pressure. In such "quasi isobaric closed" conditions, the cell was heated to the temperatures to be studied. The condition mentioned in the theoretical section, *i.e.*, gas phase must be made from the species which consist of only sulfur and oxygen and the total pressure must be kept constant, could be satisfied by this method. This is ascertained in other works of the authors by comparing the data by this method with those by other methods (2-5). The cell should first be heated to the temperature over the melting point of gold to establish the good contact between gold and zirconia solid electrolyte; the lead wire was lowered until it touched the liquid gold electrode; the temperature was changed to the preselected one; and the EMF measurement was started. The EMF was recorded with time, and, when at a given temperature EMF maintained a constant value within 0.2 mV for at least 1800s, the value was adopted as a data. The measurement was performed within the temperature range 1200-1500 K. Thermoelectromotive force between Kanthal and platinum lead wires was measured beforehand, and the EMF of the cell was corrected according to the data. All EMF values in this paper are these corrected values. The atmospheric pressure was measured by a mercury manometer. The total pressure of the reaction compartment of the cell was taken to be equal to the atmospheric pressure. The effect of the daily change of atmospheric pressure on the EMF of the cell was found to be negligibly small. After the measurement was completed, the cell was pulled out from the furnace at appropriate temperature and cooled swiftly in air. The quenched samples were subjected to the x-ray analysis for the identification of the phases at each equilibrium.

Results and Discussion

Cell performance.—When the cell was first heated from the room temperature to the preselected one about 1350 K, it took approximately 12,000s to get a stable EMF after the cell temperature was stabilized. Afterwards, the equilibrium time was about 2000s for the subsequent change of temperature by about 30 K in either ascending or descending direction. The inner resistance of the cell was evaluated by measuring the EMF change when a small current was impressed from an external power source through it. Most of the cells had the inner resistances below 1 k Ω ; stable values of EMF were obtained using these cells. A few cells exhibit the inner resistance more than 100 k Ω ; stable EMF's were not obtained with these cells, and the resulting data were discarded. The reversibility of the cell was checked by passing a current for a short time through the cells exhibiting the stable EMF; the EMF was observed to return to the original value in a short time.

The whole gas phase does not come to the equilibrium in this measurement because it extends to the room temperature zone. The condition of the measurement is satisfied when the gas phase around the condensed phase comes to equilibrium. To confirm it was the case, the flow rate of the overflowing SO₂ was varied and the location of the gas outlet was changed; the EMF's were not affected by these matters. Furthermore, in some experiments, the quantities of the pure sulfur added to the specimens were varied in separate runs; the resulting data did not exhibit the significant differences among these runs. The measurements were performed with both ascending and descending temperatures; the overall reproducibility of the EMF values was excellent. From these facts, it was concluded that the equilibrium between the specimen and the gas phase around it were established under 1 atm total pressure.

The gas composition around the specimen may be estimated by calculations on the complex equilibrium reactions. Typical examples of the result are indicated in Table II. Case 1 is for the measurement on Ce-S-O at 1191 K; it is the most reduced state among the present ex-

periments; the main gas species is S₂. Case 2 is for the measurement on Nd-S-O at 1400 K; it is a more oxidized state; SO₂ is the most predominant species.

The specimens of the quenched cells were easily separated from its electrolyte; careful inspection of them showed that no reactions between the specimen and the electrolyte occurred. For all the related compounds, the x-ray patterns obtained from the specimens after the measurements corresponded closely to the standard ASTM Index patterns noted. This evidence indicates that the activities of the condensed phases did not deviate so greatly from unit ones after the reactions in the measurements. In view of the fact that the errors introduced from the contamination of the condensed phase are relatively small, all the compounds were regarded to be at unit activity in the calculation of the Gibbs energy change for the reactions.

The results for the individual system will be stated separately below.

La-S-O system.—Powdered La₂S₃ and La₂O₃ were used as the charge materials. The EMF measured is shown in Fig. 2 and the equation of least square regression analysis is given in Table III. It was ascertained from x-ray analysis that the phases existing at the equilibria were La₂O₂S and La₂O₂SO₄. The equilibrium reaction may be represented by

Fig. 2. Variations of EMF with temperature for the cells [Pt, CeO₂, Ce₂O₂S][ZrO₂(+CaO)]air, Pt and [Pt, La₂O₂SO₄, La₂O₂S][ZrO₂(+CaO)]air, Pt. The different symbols represent the separate runs of experiments.

When both phases were considered to be pure, the Gibbs energy change may be represented by

$$\Delta G^\circ_8 = 2RT \ln P_{\text{O}_2} \quad [9]$$

These values were calculated from the measured oxygen partial pressures and are represented as a function of temperature in Table IV.

This system was recently studied by Dwivedi and Kay (6) based on the method similar to ours. They measured the equilibrium oxygen partial pressures of reaction [8] under the coexistence of La_2O_3 . The total pressure of S_mO_n in their experimental condition must be very low as compared with the present measurement. Their data are also shown with a dashed line in Fig. 2. As is seen in the figure, the agreement between two measurements is very good, which shows that the "quasi isobaric closed" conditions mentioned in the Theory section are satisfied in the present measurement.

In the temperature range studied, La_2O_3 was not in equilibrium with oxysulfide phase. The Gibbs energies of formation of either $\text{La}_2\text{O}_2\text{S}$ or $\text{La}_2\text{O}_2\text{SO}_4$, therefore, could not be determined in this study.

Ce-O-S system.— CeO_2 and $\text{Ce}_2\text{O}_2\text{S}$ were used as the charge materials. The measured EMF's are shown in Fig. 2; the result of the regression analysis is given in Table III. The x-ray analysis of the quenched specimen showed that the coexisting phases were CeO_2 and $\text{Ce}_2\text{O}_2\text{S}$. The equilibrium reaction is represented as³

As both condensed phases may be considered to be pure, the Gibbs energy change of the reaction may be represented by

$$\Delta G^\circ_{10} = -RT \ln (P_{\text{O}_2}/P_{\text{S}_2}^{1/2}) \quad [11]$$

The values of ΔG°_{10} were evaluated using the measured oxygen partial pressure and the sulfur partial pressure calculated by the method mentioned earlier. The least squares analysis gave the equation as a function of temperature listed in Table IV. The standard Gibbs energy of formation of $\text{Ce}_2\text{O}_2\text{S}$ was calculated from these results using the Gibbs energy of formation of CeO_2 recom-

³Strictly speaking, cerium oxide must be represented by CeO_{2-x} , where x is a function of the equilibrium oxygen partial pressure. It was ascertained, however, that the error introduced from neglecting this effect is so small that CeO_2 was assumed in this study.

Table IV. Standard Gibbs energy changes of the reactions determined in the present work

Reaction	ΔG° (J)	Estimated uncertainty (J)	Temperature range (K)
$\text{La}_2\text{O}_2\text{S} + 2 \text{O}_2 = \text{La}_2\text{O}_2\text{SO}_4$	$-905,880 + 317.2 \cdot T$	± 3800	1190-1510
$2\text{CeO}_2 + (1/2)\text{S}_2 = \text{Ce}_2\text{O}_2\text{S} + \text{O}_2$	$423,910 - 104.5 \cdot T$	± 2300	1180-1530
$\text{Nd}_2\text{O}_3 + (1/2)\text{S}_2 = \text{Nd}_2\text{O}_2\text{S} + (1/2)\text{O}_2$	$60,800 + 10.10 \cdot T$	± 4600	1400-1510
$\text{Nd}_2\text{O}_2\text{S} + 2 \text{O}_2 = \text{Nd}_2\text{O}_2\text{SO}_4$	$-875,400 + 307.4 \cdot T$	± 600	1170-1400
$\text{Gd}_2\text{O}_3 + (1/2)\text{S}_2 = \text{Gd}_2\text{O}_2\text{S} + (1/2)\text{O}_2$	$73,060 + 12.89 \cdot T$	± 6500	1250-1510
$\text{Y}_2\text{O}_3 + (1/2)\text{S}_2 = \text{Y}_2\text{O}_2\text{S} + (1/2)\text{O}_2$	$65,330 + 33.87 \cdot T$	± 5800	1190-1500

Table V. Standard Gibbs energy changes of formation for oxysulfides and oxysulfates

Reaction	ΔG° (J)	Estimated uncertainty (J)	Temperature range (K)
$2\text{Ce(l)} + \text{O}_2(\text{g}) + (1/2)\text{S}_2(\text{g}) = \text{Ce}_2\text{O}_2\text{S(s)}$	$-1,753,500 + 311.4 \cdot T$	$\pm 25,000$	1180-1530
$2\text{Nd(l)} + \text{O}_2(\text{g}) + (1/2)\text{S}_2(\text{g}) = \text{Nd}_2\text{O}_2\text{S(s)}$	$-1,753,400 + 300.0 \cdot T$	$\pm 14,000$	1400-1510
$2\text{Gd(s)} + \text{O}_2(\text{g}) + (1/2)\text{S}_2(\text{g}) = \text{Gd}_2\text{O}_2\text{S(s)}$	$-1,741,000 + 288.7 \cdot T$	$\pm 19,000$	1250-1510
$2\text{Y(s)} + \text{O}_2(\text{g}) + (1/2)\text{S}_2(\text{g}) = \text{Y}_2\text{O}_2\text{S(s)}$	$-1,828,000 + 312.5 \cdot T$	$\pm 16,000$	1190-1500
$2\text{Nd(s)} + 3 \text{O}_2(\text{g}) + (1/2)\text{S}_2(\text{g}) = \text{Nd}_2\text{O}_2\text{SO}_4(\text{s})^a$	$-2,616,300 + 599.5 \cdot T$	$\pm 15,000$	1170-1289

$2\text{Gd(l)} + 3 \text{O}_2(\text{g}) + (1/2)\text{S}_2(\text{g}) = \text{Gd}_2\text{O}_2\text{SO}_4(\text{s})^a$	$-2,631,700 + 615.6 \cdot T$	$\pm 21,000$	1000-1250 ^b

^a Phase transformations observed in solid Nd_2O_3 , Nd, and Y_2O_3 are ignored because the accompanied enthalpy changes are too small compared with the experimental errors.

^b Based on the standard Gibbs energy change for the reaction $\text{Gd}_2\text{O}_2\text{S} + 2 \text{O}_2 = \text{Gd}_2\text{O}_2\text{SO}_4$ measured by Dwivedi and Kay.

Fig. 3. Standard Gibbs energies of formation of $\text{Ce}_2\text{O}_2\text{S}$ and $\text{Y}_2\text{O}_2\text{S}$ as a function of temperature.

mended by Gschneidner *et al.*; the results are shown in Fig. 3, and the least squares equation is listed in Table V. In the figure, the measured value by Fruehan (1), who used gas-equilibrium method, is also shown with a dot-dashed line. The present results are 7.5 kJ negative than theirs. The dotted line shows the estimated value by Gschneidner *et al.* (21). Agreement with the present result is fairly good in view of the large estimated uncertainty (60 kJ) given to their values. In Fig. 3, the value reported by Dwivedi and Kay (7) is also shown. They used the reaction between Ag and Ag_2S to fix the partial pressure of sulfur. The reliability of the value, therefore, depends on the data of the Gibbs energy of formation of Ag_2S . However, the extrapolated value of the present result agrees with it very well within the error of only 4 kJ.

Nd-S-O system.—The charge materials were Nd_2O_3 and $\text{Nd}_2\text{O}_2\text{S}$. The measured EMF's are shown in Fig. 4; the result of the regression analysis is given in Table III. As can be seen from this figure, there is found a marked break in the temperature dependence of EMF around 1400 K. One may infer that one of the equilibrium phases is trans-

Fig. 4. Variations of EMF with temperature for the cell [Pt, $\text{Nd}_2\text{O}_2\text{SO}_4$] or $[\text{Nd}_2\text{O}_3, \text{Nd}_2\text{O}_2\text{S}/\text{ZrO}_2(+\text{CaO})/\text{air}, \text{Pt}]$. The different symbols represent the separate runs of experiments.

formed to another at the temperature. The x-ray analysis was performed for the specimens quenched from higher and lower temperatures than this point; it was found that the equilibrium phases were Nd_2O_3 and $\text{Nd}_2\text{O}_2\text{S}$ for higher temperature and $\text{Nd}_2\text{O}_2\text{SO}_4$ and $\text{Nd}_2\text{O}_2\text{S}$ for lower temperature, respectively. The equilibrium reactions may, therefore, be represented by

The Gibbs energy changes for reactions [12] and [13] were calculated from the measured oxygen partial pressures and the calculated sulfur partial pressures and are listed in Table IV as a function of temperature. The Gibbs energy of formation of $\text{Nd}_2\text{O}_2\text{S}$ was calculated using the data of Gibbs energy of formation of Nd_2O_3 , recommended by Gschneidner *et al.* and is shown in Table V. By extrapolating this value to lower temperature, the Gibbs energy of formation of $\text{Nd}_2\text{O}_2\text{SO}_4$ was also determined by combining the measured value for reaction [13] and is listed in Table V.

The EMF values measured by Dwivedi and Kay on the reaction between the oxysulfide and the oxysulfate with the coexistence of the oxide (6) are shown in Fig. 4. The good agreement between two measurements shows also that the conditions mentioned in the Theory section were satisfied in the present experiments.

Gd-S-O and Y-S-O system.—The oxides and the oxysulfides were used as the charge materials in both systems. The measured EMF's for Gd-O-S system and Y-S-O system are shown in Fig. 5. The results of regression analysis

Fig. 5. Variations of EMF with temperature for the cells $[\text{Pt}, \text{Gd}_2\text{O}_3, \text{Gd}_2\text{O}_2\text{S}/\text{ZrO}_2(+\text{CaO})/\text{air}, \text{Pt}]$ and $[\text{Pt}, \text{Y}_2\text{O}_3, \text{Y}_2\text{O}_2\text{S}/\text{ZrO}_2(+\text{CaO})/\text{air}, \text{Pt}]$. The different symbols represent the separate runs of experiments.

are given in Table III. In the measured temperature range, the experimental points show the linear dependence on temperature. It was ascertained from the x-ray analysis of the quenched samples that the equilibrium phases were the oxysulfide and the sesquioxide of each element for both systems. The equilibrium reactions may be written, respectively, as

The Gibbs energy changes for these reactions were calculated from the measured oxygen partial pressures. The calculated sulfur partial pressures are listed in Table IV. The Gibbs energies of formation of oxysulfides of these elements were calculated based on the Gschneidner's recommended values for the Gibbs energies of formation of oxides and are shown in Table V. For the Gd-S-O system, Dwivedi and Kay (6) have reported the data of the Gibbs energy change for the reaction

Based on their value and the present results, the Gibbs energy of formation of $\text{Gd}_2\text{O}_2\text{SO}_4$ was determined. The calculated value is shown in Table V.

The Gibbs energy of formation of $\text{Y}_2\text{O}_2\text{S}$ is shown in Fig. 3. The data of Dwivedi and Kay (7) are 9.4 kJ more positive than ours. The broken line indicates the estimated value by Gschneidner *et al.*, which agrees fairly well with the present result in view of the large uncertainty given in their report.

Estimated uncertainty.—In the present measurements of the Gibbs energy changes of the reactions, some errors are introduced from the uncertainties of the thermodynamic data used in the calculation of sulfur chemical potentials. These errors are estimated as follows. First, we assumed the errors of the formation energies of SO_2 , S_2O , and S, which are considered to have the most serious effect on the result of the calculations, to be ± 4200 , ± 2100 , and ± 2100 J, respectively. Then, the uncertainties of the calculated results were evaluated. The typical values introduced from this effect were ± 4150 J for Nd (reaction [12]) and ± 450 J for Ce (reaction [10]). The uncertainties introduced from the EMF measurement were added to these values and the total uncertainties are shown in Table IV. The uncertainties of the free energies of formation of oxysulfide and oxysulfate given in Table V are considerably large. The main reason for this large uncertainty comes from the low accuracy of the Gibbs energy

Fig. 6. Standard Gibbs energies of formation of $\text{Ce}_2\text{O}_2\text{S}$, $\text{Gd}_2\text{O}_2\text{S}$, $\text{Nd}_2\text{O}_2\text{S}$, $\text{Y}_2\text{O}_2\text{S}$, $\text{Gd}_2\text{O}_2\text{SO}_4$, and $\text{Nd}_2\text{O}_2\text{SO}_4$ as a function of temperature.

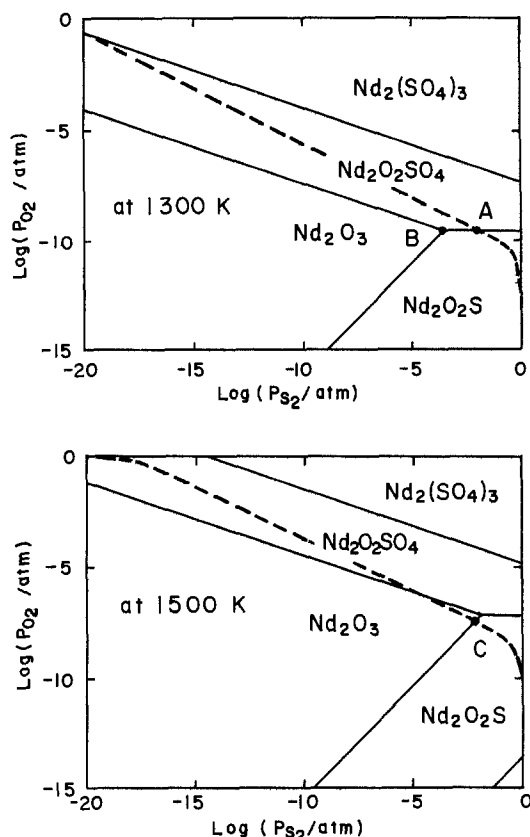

Fig. 7. P_{S_2} - P_{O_2} potential diagrams of the system Nd-O-S for 1300 and 1500 K. The broken lines represent the condition of $P_{total} = 1$ atm.

of formation of oxides used as the basis of the calculations.

The thermodynamic stabilities of oxysulfides and oxysulfates.—The Gibbs energies of formation of oxysulfides and oxysulfates determined in this study are summarized in Fig. 6. The standard entropies of formation of oxysulfide and oxysulfate do not vary significantly from one rare-earth element to another, and have values of about -300 and -610 J/K-mol, respectively. Gschneidner *et al.* estimated that the stability of oxysulfide increases as the atomic number of the constituent rare-earth element increases. The present data also may show essentially a similar trend, but it is not much clearer. On the other hand, the stability of $Nd_2O_2SO_4$ is almost the same or a little larger than that of the heavier rare-earth oxysulfate $Gd_2O_2SO_4$. Considering that the oxysulfate of lanthanum did not decompose at the highest temperature of the present measurement, it appears that the stability of oxysulfate decreases as the atomic number of the constituent rare-earth element increases. These considerations explain the fact that the stability of the oxysulfate with respect to the oxysulfide shows the more obvious dependence on the atomic number of the constituent, which was reported by Dwivedi and Kay (6).

The phase equilibrium relations.—The P_{S_2} - P_{O_2} potential diagrams for Nd-S-O system, in which the free energies of formation of oxysulfide and oxysulfate were determined

in the present work, were made for 1300 and 1500 K, as shown in Fig. 7. The thermodynamic data for normal sulfate are based on the recommended value by Kellogg (22). In Fig. 7, the condition of $P_{total} = 1$ atm is shown by the dashed line. The present experimental condition is represented by point A for 1300 K and by point C for 1500 K. The experiment of Dwivedi and Kay (6) is of the three condensed phase equilibria. Their experimental condition for 1300 K may be represented by point B. At 1500 K, the condition represented by point D is located at the total pressure of more than 1 atm. The decomposition of oxysulfate observed by Dwivedi and Kay (6) may be explained by the above considerations.

Acknowledgments

The authors would like to thank Dr. S. Otsuka for the helpful advice and Mr. K. Utata for his help in the experimental work.

Hot Corrosion of Nickel in Na₂SO₄-CaSO₄ Mixtures

M. Arbab and S. R. Shatynski¹

Department of Materials Engineering, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

The hot corrosion of pure nickel was studied in Na₂SO₄-CaSO₄ salt mixtures at 900°C in purified oxygen. The kinetics of the reactions and the microstructures of the reaction products were examined. The effect of pure CaSO₄ was shown to be only slightly different than simple oxidation. The addition of Na₂SO₄, which resulted in lower melting deposits, significantly enhanced the corrosion. Both V₂O₅ and PbO additions to the salt resulted in reduced corrosion compared with the Na₂SO₄ salt. These results are correlated with existing models for hot corrosion.

Nickel-based superalloys have been proposed as candidate materials for heat-transfer tubes in fluidized bed coal combustors (fbcc) (1). Sulfur emissions in fbcc's can be minimized by adding limestone, which reacts with sulfur impurities to form the stable solid CaSO₄, which condenses on the heat-transfer tubes and forms a dense, adherent deposit. In one test fbcc, a 50 μm thick deposit was formed after only 500h of operation (2). Accelerated corrosion of heat-transfer tubes has been observed in some test fbcc's. In one test fbcc, nickel-based superalloy and stainless steel tubes were found to corrode with a linear rate (3). Significant amounts of CaSO₄ deposit were found above the corrosion product. The extent to which CaSO₄ itself is responsible for the observed corrosion in fbcc's is not clear. Also contributing may be a reducing/sulfidizing environment, which is thought to result from a low oxygen potential at the deposit/scale interface or from high carbon concentration due to uneven coal/air distributions in the fbcc (4). The reducing/sulfidizing environment may be solely responsible for the observed corrosion or may increase the corrosive activity of the CaSO₄ deposit. Other corrosive impurities found in coal itself, such as sodium, potassium, lead, and vanadium may also play a role (5).

The study of high temperature corrosion of transition metals in the presence of molten salts, particularly Na₂SO₄, has been the subject of many investigations (1, 6, 7). A variety of different models have been proposed, among which the acid-basic fluxing model of Goebel *et al.* (12) that was extended later by Rapp and Goto (7) appears the most promising. Goebel *et al.* (12) have proposed a model based upon the fluxing or dissolution of the protective scale by the basic or acidic component of Na₂SO₄. Basic fluxing is associated with the generation of a high concentration of oxide anions (O⁻²), whereas acidic fluxing is generally achieved by the dissolution of MoO₃, WO₃, or other acidic oxide from the corrosion products on the alloy. Rapp and Goto (7) suggested that fluxing of an oxide can only be self-sustained by the establishment of a negative solubility gradient at the oxide/salt interface. Localized electrochemical half-reactions spatially separated are used to describe the corrosion reactions.

This study compares the corrosion due to CaSO₄ and Na₂SO₄-CaSO₄ mixtures with that due to Na₂SO₄. Pure nickel was chosen as the test alloy for a number of reasons. First, nickel is the base metal of most superalloys. A complex superalloy B-1900 was also studied for a comparison; the results are reported in a separate publication (17). Second, nickel is an excellent model system, because only a limited number of reaction products (NiO, Ni₃S₂, and NiS) are possible.

Experimental Procedure

Standard thermogravimetric analysis (TGA) supplemented with scanning electron microscopy (SEM) and energy dispersive x-ray analysis (EDAX) were employed in the experiments. Samples were prepared from high purity nickel rods (Table I). The rods were cut into disks of 0.5 cm diam and of approximately 0.22 cm thickness.

¹Deceased.

Each sample had a 0.16 cm hole drilled for suspending in the TGA rig. Typical total area of each sample was 0.80 cm²/g. Samples were then annealed at 900°C for 1h (in static air) to remove the residual stresses. They were subsequently ground to 600 grit and degreased. Samples were finally preheated to 300°C and sprayed with an aqueous salt mixture, producing a salt coating layer corresponding to 2 mg/cm².

The effects of four chemical compounds, *i.e.*, Na₂SO₄, CaSO₄, V₂O₅, PbO, and mixtures thereof, on the corrosion of nickel were studied. Among the four, only Na₂SO₄ is highly soluble in distilled water. The solubility of CaSO₄ is only about 2.09 g/liter of H₂O. In order to obtain a homogeneous solution, the ratio of CaSO₄ to water was closely controlled. Solubilities of PbO and V₂O₅ in water are very low. Therefore, a solution of the former in acetone was used and the mixture of the latter in water was carefully homogenized prior to each application.

Since the first few minutes of high temperature exposure of samples to an oxidizing atmosphere were found to be extremely critical in these experiments, all samples were kept out of the hot zone of furnace (at 300°C) and in 1 atm of purified argon during the elementary steps of preparing the system for a run. After a run was completed, corroded samples mounted and cross sections through the corrosion product were polished to 3 μm grit for morphological studies. All samples were oxidized in 1 atm of oxygen.

Results and Discussion

For pure Na₂SO₄-coated samples, extensive corrosion was noticed when the samples were exposed to 1 atm oxygen at 900°C. The melting point of Na₂SO₄ is 884°C. Samples coated with 2 mg/cm² had weight gains in excess of 20 mg/cm² before the accelerated growth came to an end (Fig. 1). Goebel *et al.* (6) have obtained similar results for the hot corrosion of Ni in the presence of 0.5 mg/cm² Na₂SO₄ at 1000°C. That study shows a similar termination after a weight gain of only 4 mg/cm². This significant difference emphasizes the role of salt quantity in determining the extent of hot corrosion (6). It was also noticed that when a sample was exposed to additional Na₂SO₄ coating after the termination of the first accelerated growth and initiation of stage three (after 70 min), rapid linear growth was again observed. These results are in agreement with the point of view expressed by Stringer (1), who noted that even though the basic fluxing model is not self-sustaining, it should not be excluded as a possible explanation for catastrophic hot corrosion of alloys.

Table I. Concentration of impurities in the nickel samples

Element	ppm
Iron	<3
Aluminum	<1
Calcium	<1
Chromium	<1
Copper	<1
Magnesium	<1
Silicon	<1
Silver	<1

Fig. 1. Variations of weight gain with time for nickel samples exposed to 1 atm of oxygen at 900°C. A: coated with 2 mg/cm² of Na₂SO₄. B: simple oxidation.

Samples coated with 2 mg/cm² of CaSO₄ and in 1 atm of oxygen did not experience any considerable hot corrosion attack. The TGA results in this case were comparable to that of simple oxidation, which is shown as curve B in Fig. 1. The crucible experiments with 2g of CaSO₄ produced similar results. The melting point of this salt is 1450°C, *i.e.*, considerably above the experimental temperature of 900°C, and molten salt was not observed at any time in these experiments. Thus, according to any of the fluxing models, the occurrence of extended hot corrosion is not expected at 900°C.

The TGA results for nickel coated with 2 mg/cm² of Na₂SO₄-CaSO₄ mixtures are shown in Fig. 2 and 3. The curves indicate that as the CaSO₄ content in the mixture increases, the extent of weight gain decreases. For 40% CaSO₄-60% Na₂SO₄,² however, the extent of weight gain compared to the immediate curves is higher, *i.e.*, for this mixture, a relative maximum of attack exists. Beyond the above mixture, the degree of attack decreases uniformly, and for mixtures containing 80% or more of CaSO₄, the TGA results correspond to that of simple oxidation. According to the CaSO₄-Na₂SO₄ phase diagram (16), for compositions greater than 3% CaSO₄, a liquid phase does not

²Unless otherwise specified, numbers preceding a compound indicate its weight percentage in the mixture.

Fig. 2. Variations of weight gain with time for nickel samples exposed to 1 atm of oxygen at 900°C and coated with 2 mg/cm² of 100% Na₂SO₄ (A) and 90% Na₂SO₄-10% CaSO₄ (B).

Fig. 3. Variation of weight gain with time for nickel samples exposed to 1 atm of oxygen at 900°C and coated with 2 mg/cm² of: A, 80% Na₂SO₄-20% CaSO₄; B, 70% Na₂SO₄-30% CaSO₄; C, 60% Na₂SO₄-40% CaSO₄; D, 50% Na₂SO₄-50% CaSO₄. Note the existence of a relative maximum weight gain for the eutectic salt composition.

exist at 900°C. The eutectic composition of this system is a 39% CaSO₄-61% Na₂SO₄ mixture which melts at 913°C. Therefore, the phase diagram indicates that the salt deposit should have remained solid and that hot corrosion of nickel beyond 3% CaSO₄-Na₂SO₄ should have been quite low. However, the possibility of the presence of other compounds has not been included in the above analysis.

If the salt does not melt at 900°C, then the high temperature oxidation of the sample will proceed initially and the formation of NiO will introduce a third compound in addition to Na₂SO₄ and CaSO₄. Gupta and Rapp (13) have shown that there is a high degree of solubility of NiO in Na₂SO₄ when $\alpha_{\text{NiO}} > 10^{-4}$ at 927°C. These basic conditions have been shown to exist in Na₂SO₄ melts at 900°C under certain conditions (6, 7). The dissolution of NiO in the salt may lead to a decrease in the melting point of the Na₂SO₄-CaSO₄ mixture, which in turn will result in the accelerated attack to the sample. Considering that most CaSO₄-Na₂SO₄ mixtures are solid salt layers at 900°C, in contrast to pure Na₂SO₄, Ni transport must occur in the solid layer or at local regions where there is melting of Na₂SO₄ for the above argument to be valid.

Even though a simple binary phase diagram did not suggest the presence of a liquid phase, molten salt was observed both in the crucible experiments and on the surface of those samples coated with a variety of Na₂SO₄-CaSO₄ mixtures, including those containing more than 40% CaSO₄. An EDAX analysis of the latter samples showed that the solid salt remaining on the surface of the samples did not contain any detectable amount of Na₂SO₄. This suggests that the presence of CaSO₄, only increases the melting temperature of the salt mixture, but otherwise it does not influence the hot corrosion mechanism at 900°C.

A relative maximum weight gain was recorded for a nearly eutectic salt mixture (Fig. 1-3), while at all other experimental salt compositions there was a uniform decrease of weight gain as the ratio of CaSO₄ to Na₂SO₄ increased. Therefore, the extent of attack is an increasing function of the concentration of Na₂SO₄ mixture and is enhanced if a liquid phase is formed.

The weight gain *vs.* time curves are generally composed of three distinct regions: (i) the incubation period, (ii) the linear accelerated period, and (iii) the plateau. It was not possible to determine a common equation which could fit all three regions. It was concluded that the mechanism of scale growth differs from one period to another.

Fig. 4. Micrograph of a nickel coated with Na_2SO_4 and exposed to 1 atm of oxygen at 900°C for 24h (SEM secondary electron image) (right). Sulfur $K\alpha$ plot illustrating the sulfur distribution in the area shown (left).

The incubation stage was most pronounced in the case of pure Na_2SO_4 , while in the case of 100% CaSO_4 its absence is compatible with the attribution of the observed corrosion to simple oxidation. In most cases, the incubation period lasts up to 2 min, while for pure Na_2SO_4 an average incubation period of 10 min was observed. The linear accelerated period occurs for $2 \leq t \leq 4.5$ min of the experiment, with an exception for the case of pure Na_2SO_4 , where the longer incubation period shifts it to $10 \leq t \leq 16$ min. The rate of oxygen uptake in this stage is in the range of 1.3×10^{-3} to 3.6×10^{-3} $\text{mg}/\text{cm}^2\text{-s}$. This region becomes less distinct as the CaSO_4 content of the salt mixture increases. The rate of weight gain in the accelerated stage continuously decreases until a plateau is reached. This transition shows a parabolic behavior, and it continues for up to 14-16 min. The slopes of the plateaus for different curves are between 3.3×10^{-5} and 4.5×10^{-5} $\text{mg}/\text{cm}^2\text{-s}$. The behavior of the attack after the accelerated stage resembles that of simple oxidation. It is observed that simple oxidation of nickel consists of two stages:³ an initial parabolic growth and a plateau. The parabolic stage lasted for 13 min (comparable to 14-16 min of the former situation) and the slope of the plateau was 2.5×10^{-5} $\text{mg}/\text{cm}^2\text{-s}$. Thus, it may be concluded that the termination of the accelerated stage corresponds to the onset of simple oxidation of the corroded sample, *i.e.*, a protective scale forms beneath the nonprotective scale. However, a considerable difference between the slopes of the parabolic regions of the transition period in the presence of salt and simple oxidation of salt-free samples is noticed. In the former case, the slopes assume an average value of $0.4 \text{ mg}/\text{cm}^2\text{-s}^{1/2}$, while in the latter it is as low as $0.04 \text{ mg}/\text{cm}^2\text{-s}^{1/2}$.

The slope of the plateaus remained constant for a period of 48h except for a few instances when it slightly increased. This increase was found to be due to the cracking of the scale, as determined by the optical analysis.

Metallographic analyses indicated that a protective and coherent oxide layer (NiO) is formed adjacent to the nickel substrate during high temperature simple oxidation and its thickness is nearly uniform everywhere. The results of corrosion in pure Na_2SO_4 are shown by Fig. 4, where a typical portion of the corroded sample has been

photographed. A layer of nickel sulfide formed immediately adjacent to the nickel substrate. The physical formation of the layer, *i.e.*, its coherent contact with both the substrate and the oxide layer above it, as well as its ability to fill all gaps, suggests that at 900°C the sulfide is melted. Based on this observation and EDAX results, the sulfide layer is thought to be essentially Ni_3S_2 .

Above the sulfide layer, a thick layer of NiO has been formed. The porosity of this layer is less than what is expected from the literature (6), and its thickness increases at certain limited areas. These areas of higher corrosion differ morphologically from other parts of the scale (Fig. 5). The outer NiO is layered and porous, and further inward a more uniform and compact oxide similar to that found in the rest of the scale exists. Goebel and Pettit (6) have reported this latter type of scale to be dominant for

Fig. 5. Area of higher corrosion on a nickel sample coated with Na_2SO_4 and exposed to 1 atm of oxygen at 900°C for 24h (SEM secondary electron image). This morphology is typical of high corrosion areas on different samples.

³A completely parabolic growth of the scale in the case of simple oxidation was not registered owing to the lack of apparatus precision for small weight gains. However, since both cases are affected equally, a comparison of the results is possible.

Na_2SO_4 corroded nickel base alloys, and their theory of basic fluxing is partly based on similar observations. As in the case of pure Na_2SO_4 , the scale for any of the salt mixtures with a CaSO_4 content of less than 80% consists of a sulfide and an oxide layer. The uniformity of the scale generally increases as the amount of Na_2SO_4 in the salt decreases. The NiO regions closer to the nickel substrate are less porous than the outer sections. This is in accordance with our earlier discussion, where a comparison with the TGA results for simple oxidation of nickel showed that after the accelerated attack, which results in the formation of a porous oxide, a more protective thick oxide layer similar to the scale on the salt-free samples is formed. Also, the scale includes some sulfide particles, which are nonuniformly dispersed. This indicates that the oxygen partial pressure in the oxide layer can be low enough to permit the formation of intermixed scales (14, 15).

For those salt mixtures containing 80% or more CaSO_4 , the sulfide layer was virtually absent and sulfide particles were dispersed in the oxide layer. Therefore, we concluded that for such salt mixtures the sulfur diffusing through the initial oxide was totally consumed by nickel sulfide (Ni_3S_2) formation within the oxide layer and did not reach the Ni-NiO interface. This suggests that the initial formation of Ni_3S_2 occurs in the oxide layer, probably creating an easy path for sulfur diffusion, as pointed out by Giggins and Pettit (14) and Birks (15), in previous cases where a sulfide layer was formed. The extent of corrosion for high CaSO_4 salts and especially in the case of pure CaSO_4 resembles simple oxidation of nickel except for some sulfidation, which implies limited solid-state decomposition of CaSO_4 at the salt/scale interface.

The occurrence of the local areas of higher attack may be due to one or more of the following reasons.

1. During the coating of the sample with a salt mixture, it was noted that upon the complete evaporation of water more salt remained in the hole drilled through the sample than any other place. The extent of corrosion in this region was high and the overall morphology resembled that of Fig. 5 and 6. Therefore, some geometrical variation on the surface, caused during the sample preparation (such as a pit), may lead to a region of high salt buildup and eventually into a region of more extensive hot corrosion.

2. Since Na_2SO_4 is soluble in water and CaSO_4 is not, the latter will precipitate on the surface of the preheated sample before the complete evaporation of water. This

can result in the local segregation of the two compounds; local regions rich in Na_2SO_4 may suffer enhanced attack. However, the uniform thickness of the salt layers left on the corroded sample, the absence of such areas of higher corrosion on samples coated with salt mixtures containing V_2O_5 and PbO (see below), and the increase in the uniformity of the scale with increasing the CaSO_4 concentration as mentioned above indicate that additional factors may be involved.

3. Finally, sample variations such as different grain structures can have a strong effect on the extent of hot corrosion attack and on the final corrosion morphology.

The general morphology of the samples contradicts certain aspects of the theory of simple basic fluxing based on sulfidation. This theory assumes that sulfur is generated from the melt and is transported to the metal where sulfidation occurs. As a consequence, the melt increases in oxygen anion activity and attacks the protective NiO. An examination of the areas of higher corrosion shows that the thickness of the sulfide layer is either less than or equal to that of other regions where the attack was uniform and slower (Fig. 6). However, according to simple basic fluxing, the contrary is expected; *i.e.*, higher corrosion rates should be accompanied by higher sulfidation. Thus, sulfidation is one of the reduction reactions, but not the only one. This view is consistent with the treatment of Rapp and Goto (7).

The effects of V_2O_5 and PbO impurities.—A CaSO_4 : Na_2SO_4 ratio of 1.5, which is close to the eutectic composition, was selected for this part of the study. Other mixtures were shown to produce similar results.

V_2O_5 .—In order to preserve a Na_2SO_4 : CaSO_4 ratio of 1.5 in the presence of the impurity, mixtures of 57% Na_2SO_4 -38% CaSO_4 -5% V_2O_5 and 59% Na_2SO_4 -39% CaSO_4 -2% V_2O_5 were used. For 2% V_2O_5 , no differences in the TGA or the metallographic analysis were noticed compared with the vanadium-free mixture. With 5% V_2O_5 , the extent of attack was reduced to a level comparable to simple oxidation (Fig. 7). The micrographs of such samples also indicated a very limited attack. Immediately above the substrate, a thin layer of NiO was formed. This scale was coherent and compact and consisted of three regions. The interior layer, adjacent to the substrate, was pure NiO. Above it was a second layer containing Ni, V, and O, presumably nickel vanadate. The third layer, adjacent to the salt phase, was again NiO, but it contained considerable amounts of calcium and sulfur as solid solutions. The V_2O_5 -NiO phase diagram (16) indicates that at 900°C for more than 75% NiO a solid nickel vanadate

Fig. 6. Area of higher corrosion on a nickel sample coated with 85% Na_2SO_4 -15% CaSO_4 and exposed to 1 atm of oxygen at 900°C for 24h (SEM secondary electron image). The thickness of Ni_3S_2 layer in such areas is either less or equal to that of the same layer in less corroded areas.

Fig. 7. Variations of weight gain with time for nickel samples exposed to 1 atm of oxygen at 900°C and coated with 2 mg/cm² of: A, 60% Na_2SO_4 -40% CaSO_4 ; B, 57% Na_2SO_4 -38% CaSO_4 -5% V_2O_5 ; C, 59% Na_2SO_4 -39% CaSO_4 -2% PbO .

$\text{Ni}_3(\text{VO}_4)_2$ and nickel oxide phase exists. Also, based on a study of the effects of V_2O_5 on the high temperature oxidation of nickel, Bornstein and DeCresente (10) have reported that in 1 atm of oxygen the formation of a nickel-vanadium oxide on nickel samples coated with V_2O_5 , considerably decreased the extent of oxidation. Therefore, in the case of the present study, the formation of a solid and compact $\text{Ni}_3(\text{VO}_4)_2 + \text{NiO}$ layer is considered to be similarly responsible for the protection of the sample from an otherwise accelerated attack. No localized areas of enhanced corrosion were detected.

Finally, it must be noted that even though the presence of 2% V_2O_5 also results in the formation of $\text{Ni}_3(\text{VO}_4)_2$, the quantity of the product is not high enough to form a protective layer.

PbO.—A mixture of 59% Na_2SO_4 -39% CaSO_4 -2% PbO was used for this experiment. According to the TGA results (Fig. 7) and the SEM analysis, the extent of corrosion is reduced to that of simple oxidation in the presence of a 2% PbO mixture. The reasons for an inhibiting effect have not been understood yet, especially since it was observed that pure PbO enhances the high temperature oxidation of nickel, both in the present study and elsewhere (11). On the other hand, Chatterji *et al.* (9) have noticed the same inhibitory effect of PbO when they studied the hot corrosion of nickel samples coated with 1% PbO-99% Na_2SO_4 (mole percentages are indicated). The morphology reported from their investigation resembles the morphology observed in the present study, *i.e.*, the presence of a sulfide-free, dense oxide layer.

Summary

The high temperature corrosion of nickel induced by various salt deposits was studied at 900°C in an environment of pure oxygen by the use of TGA and metallographic techniques. The salt deposits were Na_2SO_4 , CaSO_4 , various mixtures of Na_2SO_4 - CaSO_4 , and mixtures of the Na_2SO_4 - CaSO_4 eutectic to which small amounts of V_2O_5 or PbO were added. Enhanced attack relative to simple oxidation was observed when the deposit, or a portion of it, melted. Thus, fast attack was observed for pure Na_2SO_4 and mixtures containing up to 50% CaSO_4 . Pure CaSO_4 and 80% CaSO_4 -20% Na_2SO_4 did not melt and did not exhibit enhanced attack. The addition of 2% PbO or 5% V_2O_5 to the eutectic Na_2SO_4 - CaSO_4 mixture greatly inhibited the rate of attack. In the case of the V_2O_5 addition,

a protective layer of nickel vanadate formed. PbO apparently plays a different, but as yet not understood, inhibitory role.

Carburization Mechanisms of High Chromium Alloys

T. A. Ramanarayanan* and D. J. Srolovitz¹

Exxon Research and Engineering Company, Corporate Research Science Laboratories, Annandale, New Jersey 08801

ABSTRACT

Carburization is a major mode of corrosive degradation of high chromium alloy materials in many high temperature processes. The process generally involves the transfer of carbon from the gas phase onto the alloy surface followed by diffusion of carbon to the alloy interior with concurrent precipitation of chromium-rich carbide phases. The kinetics of this overall process has been determined by thermogravimetry in the temperature range 1173-1373 K using Fe-20 Cr and Ni-30 Cr model alloy systems and H_2 - CH_4 gas mixtures to provide the carburizing medium. Mathematical expressions for the overall kinetics have been developed in terms of surface reaction and diffusion steps. Both processes contribute to carburization, the influence of the surface reaction step increasing with increase in temperature. Additions of sulfur as H_2S to the gas phase slows down the surface reaction step sufficiently so that the whole carburization process can become surface reaction controlled.

High chromium alloys used in high temperature service are susceptible to carburization in environments with high carbon activity. This form of corrosion leads to the precipitation of chromium-rich carbide phases, M_{23}C_6 and M_7C_3 , in the alloy interior with resultant degradation of

the high temperature mechanical properties of the alloy (1, 2). Schnaas and Grabke (3-5) have described the carburization process in H_2 - CH_4 gas mixtures, in the absence of a surface oxide layer, as being controlled by the diffusion of carbon in the alloy, the kinetics obeying a parabolic rate law.

Grabke and co-workers (6-11) have also investigated the kinetics of decomposition of CH_4 on iron surfaces at ele-

vated temperatures using extremely thin foils so as to avoid diffusion as a rate limiting step. Additions of small amounts of sulfur as H_2S to CH_4 - H_2 gas mixtures had a retarding effect on the methane decomposition kinetics.

In the present work, the kinetics of carburization of model Fe-20 Cr and Ni-30Cr alloys have been determined in the 900°-1100°C temperature range, using H_2 - CH_4 gas mixture as the carburizing medium. Further, the effect of adding small quantities of H_2S below the stability limit of CrS was investigated. The aim of the study is to develop an understanding of the contribution from surface reaction and diffusion to the overall corrosion.

Experimental Procedure

The investigations were conducted on two model alloys, Fe-20 Cr and Ni-30 Cr. The former has a body-centered cubic structure, while the latter is face-centered cubic. Further, the tendencies of Fe and Ni to partition between the metal matrix and the carbide precipitates is expected to be different. The alloys were obtained in the cast form; Fe-20 Cr alloy samples were cut from a region having an average grain size of $\sim 100 \mu m$. In the Ni-30 Cr alloy samples, the grain size varied from about $50 \mu m$ near the sample surface to $\sim 250 \mu m$ in the sample center. The samples had rectangular geometry with dimensions of $2 \text{ cm} \times 1 \text{ cm} \times 2 \text{ mm}$. The samples were ground to a 600 grit SiC finish and cleaned ultrasonically in acetone.

The procedure used in the study was to first establish the kinetics of carburization of the selected alloys in a purely carburizing environment and then add predetermined amounts of sulfur as H_2S and redetermine the carburization kinetics. The investigations were carried out in the temperature range, 1173-1373 K. Since small amounts of oxygen in the environment can lead to the formation of Cr_2O_3 on the surface of high chromium alloys, it was essential to remove trace oxygen impurity from the carburizing gas. This was done by passing the gas over an activated copper catalyst at $\sim 200^\circ C$ and subsequently drying by passing through a column of anhydrous calcium sulfate. The H_2 -2000 ppm H_2S stream was dried only and then mixed with the carburizing gas. The formation of a chromia layer would decrease the carburization rate of the alloy and would make it difficult to separate the influence of sulfur on the carburization rate from that of chromium oxide.

A H_2 - CH_4 gas mixture was used as the carburizing medium. The carbon activity in this gas mixture is fixed by the equilibrium

whereby

$$a_C = K_1 p_{CH_4} / p_{H_2}^2 \quad [2]$$

where K_1 is the equilibrium constant for reaction [1]. The gas mixtures used in this investigation had a carbon activity of 0.9 relative to pure graphite as the standard state.

When it was desired to fix a partial pressure of sulfur in the carburizing gas mixture, a preselected amount of H_2S was added. The sulfur pressure is then fixed by the H_2 - H_2S equilibrium

whereby

$$p_{S_2} = K_2^2 p_{H_2S}^2 / p_{H_2} \quad [4]$$

Precisely controlled gas mixture compositions were obtained by controlled flow of H_2 -10% CH_4 , H_2 -2000 ppm H_2S and H_2 through Tylan mass flow controllers.

The kinetics of carburization in the presence and absence of sulfur were determined thermogravimetrically in a Cahn 1000 thermogravimetric unit shown in Fig. 1. The alloy sample was hung from the Cahn Electrobalance by a Pt suspension wire. A vertical quartz reactor tube surrounded the sample. A preheated platinum resistance furnace could be moved up to surround the quartz reactor tube and bring the specimen to the reaction temperature

Fig. 1. Thermogravimetric assembly used for the determination of carburization kinetics.

in minutes. The reactive gases entered the quartz reactor at the bottom and exited at the top along with an argon stream used to provide an inert environment within the electrobalance. At the start of an experiment, the sample was suspended from the electrobalance and an argon stream was introduced into the quartz reactor tube. When the furnace temperature reached the desired value, the argon stream was replaced by the carburizing gas stream and after an interval of ~ 30 min the furnace was raised to heat the sample. Sample weight gain data were collected and analyzed using a Hewlett Packard 9845 T computer.

Results

Investigations on Ni-30 Cr alloys.—Most investigations of Ni-30 Cr alloys were carried out at 1173 K at a carbon activity of 0.9. The carburization kinetics in the absence of H_2S , and for three different H_2S levels, are shown in Fig. 2.

The carburized microstructure corresponding to the sulfur-free case in Fig. 2 is shown in Fig. 3. The attack is internal; carbide precipitates can be seen both within alloy grains and at alloy grain boundaries. The grain boundary carbides have penetrated much deeper into the alloy. The grain boundaries can act both as preferred nucleation

Fig. 2. Carburization data for Ni-30 Cr at 1173 K and $a_C = 0.9$ as a function of p_{H_2S}/p_{H_2} .

Fig. 3. Typical carburized microstructure of Ni-30 Cr

sites for carbides and high diffusivity paths for carbon transport.

The composition of the carbide phase at various depths was determined using a scanning Auger analyzer. The carbide composition was found to be independent of depth within the sample; a typical Auger spectrum is shown in Fig. 4. The carbon-to-chromium ratio as determined from the Auger spectrum corresponds to Cr_7C_3 .

Upon adding H_2S to the carburizing gas medium, the rate of carburization weight gain (Fig. 2) decreased, which is also reflected as a decrease in the depth of carburization. In Fig. 2, the kinetic carburization curves changed from a nearly parabolic time dependence in the absence of sulfur to a linear rate at higher levels of sulfur. At a $p_{\text{H}_2\text{S}}/p_{\text{H}_2}$ ratio of $\sim 9 \times 10^{-5}$ in the gas, a thin layer of chromium sulfide, CrS , precipitated on the alloy surface as detected by energy dispersive x-ray analysis. Thus the line in Fig. 2, corresponding to a $p_{\text{H}_2\text{S}}/p_{\text{H}_2}$ ratio of 9.4×10^{-5} does not describe carburization alone. For the kinetics plot for $p_{\text{H}_2\text{S}}/p_{\text{H}_2} = 5 \times 10^{-5}$ in Fig. 5, no CrS formation occurred; the extremely small linear weight gain in this case only resulted from carburization. For a ratio of 7.5×10^{-5} (Fig. 5), which is also below the stability limit of CrS ,

Fig. 4. Auger spectrum of Cr_7C_3 carbide

Fig. 5. Carburization kinetics of Ni-30 Cr alloy at 1173 K at higher $p_{\text{H}_2\text{S}}/p_{\text{H}_2}$ values.

no carburization weight gain could be detected. Upon exceeding a $p_{\text{H}_2\text{S}}/p_{\text{H}_2}$ ratio of 10^{-4} , the alloy corroded by sulfidation (Fig. 6). Kinetic curves for carburization of Ni-30 Cr at 1273 K are shown in Fig. 7; only one $\text{H}_2\text{S}/\text{H}_2$ ratio was investigated at this temperature.

Investigations of Fe-20 Cr alloys.—The experiments on Fe-20 Cr alloys covered three different temperatures, namely 1173, 1273, and 1373 K. Carburization kinetics at 1173 K in sulfur-free and sulfur containing environments are presented in Fig. 8. Figure 8 bears some similarities to Fig. 2 in the sense that at higher sulfur levels, the carburization weight gain approaches a linear rate law. At $p_{\text{H}_2\text{S}}/p_{\text{H}_2} = 7.5 \times 10^{-5}$ some carburization was observed in the Fe-20 Cr alloy, but none for Ni-30 Cr (Fig. 2). The car-

Fig. 6. Sulfidation of Ni-30 Cr alloy at 1173 K at $p_{\text{H}_2\text{S}}/p_{\text{H}_2} = 1.75 \times 10^{-4}$.

Fig. 7. Carburization kinetics of Ni-30 Cr at $a_C = 0.9$ at 1273 K

Fig. 8. Carburization kinetics of Fe-20 Cr alloy at 1173 K at various p_{H_2S}/p_{H_2} ratios.

burized microstructure for Fe-20 Cr, Fig. 9, was similar to that for the Ni-30 Cr except that the carbide was of the $M_{23}C_6$ type, M comprised of ~75% Cr and ~25% Fe. The carbide particles at the surface (Fig. 9), however, were M_7C_3 type. Upon introducing a gas mixture with $p_{H_2S}/p_{H_2} = 1.5 \times 10^{-4}$, CrS was formed at the alloy surface (Fig. 10).

When the temperature was raised to 1273 K, the kinetic curves obtained were similar to those at 1173 K, but higher H_2S levels were required to limit carburization to the same level as shown in Fig. 11. Again, the approach to a linear kinetics at higher H_2S levels is evident. Upon exceeding a H_2S/H_2 partial pressure ratio of 1.5×10^{-4} at 1273 K, sulfidation occurred in addition to carburization, leading to larger weight gains. The effect of sulfur on carburization becomes less pronounced upon increasing the reaction temperature to 1373 K (Fig. 12).

A comparison of the kinetic curves at 1173, 1273, and 1373 K for the sulfur-free experiments (Fig. 8, 11, 12) shows that there is a deviation from parabolic kinetics with increase in temperature even in the absence of sulfur.

Discussion

In the high temperature carburization of an alloy, three distinct kinetic steps are involved. 1. The transfer of car-

Fig. 9. Typical carburized microstructure of Fe-20 Cr alloy

Fig. 10. Formation of chromium sulfide phase on Fe-20 Cr alloy at $p_{H_2S}/p_{H_2} = 1.5 \times 10^{-4}$ at 1173 K.

bon from the gas phase to the alloy surface and the formation of an adsorbed, carbon containing complex. 2. The diffusion of carbon from the alloy surface into the alloy interior. 3. The reaction of carbon with chromium to form chromium carbide phases in the alloy interior.

Kinetics controlled by diffusional processes with time independent boundary concentrations have a parabolic time dependence, whereas kinetics controlled by a surface reaction obey a linear rate law. The parabolic nature of the carburization weight gain *vs.* time curves in the absence of sulfur at the lower temperatures (Fig. 2 and 8) suggests that under these conditions carbon diffusion into the alloy controls the rate of carburization. The gradual approach to linear kinetics upon sulfur additions (Fig. 2, 7, 8, and 11) or increase in carburization temperature (Fig. 12) indicates that step 1 in the aforementioned sequence of steps becomes increasingly important. Thus, sulfur tends to retard the kinetics of step 1 sufficiently so that it becomes the slowest step in the sequence. Sulfur cannot penetrate the alloy rapidly enough to influence the kinetics of step 3. Further, one can conclude that an increase in temperature has a larger influence on the diffusion step as compared with the surface reaction step.

Fig. 11. Carburization kinetic data for Fe-20 Cr alloy at 1273 K

Fig. 12. Carburization kinetic data for Fe-20 Cr alloy at 1373 K

It is assumed in the discussion below that the overall process of carburization is controlled by the carbon transfer reaction at the alloy surface and carbon diffusion into the alloy bulk, step 3 being relatively rapid. The overall surface reaction transferring carbon onto the alloy surface can be represented as

where C represents carbon dissolved in the alloy. The kinetics of reaction [5] can be represented by the expression (7)

$$\frac{dn_c}{dt} = A(k_1 p_{\text{CH}_4} \cdot p_{\text{H}_2}^{-\nu} - k_2 p_{\text{H}_2}^{2-\nu} \cdot a_c^e) \quad [6]$$

where k_1 and k_2 denote the forward and backward rate constants for reaction [1], a_c^e is the activity of carbon on the alloy surface, dn_c/dt is the number of moles of carbon transferred to the alloy from the gas phase per unit time, A is the surface area, and the value of ν depends upon which of several possible rate limiting steps is controlling. Under conditions of thermodynamic equilibrium, $dn_c/dt = 0$, so that

$$k_1 p_{\text{CH}_4} p_{\text{H}_2}^{-\nu} = k_2 p_{\text{H}_2}^{2-\nu} a_c^e \quad [7]$$

where a_c^e is the equilibrium activity of carbon on the alloy surface. Substituting Eq. [7] into Eq. [6]

$$\frac{1}{A} \frac{dn_c}{dt} = k(a_c^e - a_c^s) \quad [8]$$

where k equals $k_2 p_{\text{H}_2}^{2-\nu}$.

The differential equation describing carbon diffusion into the alloy can be expressed in terms of Fick's second law as

$$\frac{\partial c_c}{\partial t} = D_c \left(\frac{\partial^2 c_c}{\partial x^2} \right) \quad [9a]$$

where D_c is the diffusivity of carbon in the alloy and x is the distance coordinate perpendicular to the surface. Equation [9a] assumes a concentration-independent diffusion coefficient, D_c . Further, if a concentration-independent activity coefficient, γ_c , is assumed, Eq. [9a] can be rewritten

$$\frac{\partial a_c}{\partial t} = D_c \left(\frac{\partial^2 a_c}{\partial x^2} \right) \quad [9b]$$

During carburization, the carbon furnished by the surface reaction in accordance with Eq. [8] must diffuse into the alloy interior. Mathematically stated

$$\frac{1}{A} \frac{dn_c}{dt} = k(a_c^e - a_c^s) = -\frac{D_c}{\gamma_c} \left(\frac{\partial a_c}{\partial x} \right)_{x=0}$$

or

$$\left(\frac{\partial a_c}{\partial x} \right)_{x=0} = \frac{-k\gamma_c}{D_c} (a_c^e - a_c^s) \quad [10]$$

where $x = 0$ represents the surface of the alloy. Additionally, one has the initial condition

$$a_c = 0 \text{ at } x \geq 0, t = 0 \quad [11]$$

The solution which satisfies Eq. [9-11] is given by

$$a_c = a_c^e \left\{ \operatorname{erfc} \left(\frac{x}{2\sqrt{D_c t}} \right) - \exp \left(\frac{k\gamma_c x}{D_c} + \frac{k^2\gamma_c^2 t}{D_c} \right) \left[\operatorname{erfc} \left(\frac{x}{2\sqrt{D_c t}} + k\gamma_c \sqrt{\frac{t}{D_c}} \right) \right] \right\} \quad [12]$$

where erfc is the complementary error function. The activity of carbon at the surface is obtained by setting $x = 0$ in Eq. [12]. Thus

$$a_c^s = a_c^e \left\{ 1 - \exp \left(\frac{k^2\gamma_c^2 t}{D_c} \right) \operatorname{erfc} \left(k\gamma_c \sqrt{\frac{t}{D_c}} \right) \right\} \quad [13]$$

Upon combining Eq. [10], [12], and [13]

$$\frac{1}{A} \frac{dn_c}{dt} = k a_c^e \exp \left(\frac{k^2\gamma_c^2 t}{D_c} \right) \operatorname{erfc} \left(k\gamma_c \sqrt{\frac{t}{D_c}} \right) \quad [14]$$

Equation [14] can be transformed into an expression for carburization weight gain per unit area using the relation

$$\frac{\Delta W}{A} = \frac{12}{A} \int_0^t \frac{dn_c}{dt} dt \quad [15]$$

where $\Delta W/A$ is the weight gain by carburization per unit area of the specimen. On combining Eq. [14] and [15] and performing the necessary integration

$$\frac{\Delta W}{A} = \frac{12 D_c}{k\gamma_c^2} a_c^e \left[\exp \left(\frac{k^2\gamma_c^2 t}{D_c} \right) \operatorname{erfc} \left(k\gamma_c \sqrt{\frac{t}{D_c}} \right) + (2/\sqrt{\pi}) k\gamma_c \sqrt{\frac{t}{D_c}} - 1 \right] \quad [16]$$

Two limiting cases of Eq. [16] can now be examined. When the rate of carbon transfer reaction at the alloy surface is extremely fast, i.e., $k^2\gamma_c^2 t \gg D_c$, one has diffusion-controlled carburization and Eq. [16] simplifies to

$$\frac{\Delta W}{A} = \frac{24}{\pi} \frac{a_c^e}{\gamma_c} \sqrt{D_c t} \quad [17]$$

When the surface reaction is slow compared with diffusion, i.e., $k^2\gamma_c^2 t \ll D_c$, then

$$\frac{\Delta W}{A} = 12 k a_c^e t \quad [18]$$

Equation [17] applies to the situation where, in the absence of sulfur in the environment, and at the lower temperatures, parabolic kinetics have been observed. At relatively high sulfur levels where linear kinetics have been observed, Eq. [18] applies. At intermediate levels of sulfur or higher carburization temperatures, one must take into account both surface reaction and carbon diffusion in describing the kinetics of carburization and Eq. [16] must be used. Figure 13 shows the carburization weight gain vs. time plot for such a "mixed control" situation at a $p_{\text{H}_2\text{S}}/p_{\text{H}_2}$ ratio of 10^{-5} for Fe-20% Cr carburized at 1173 K. Also shown in Fig. 13 are the calculated points using Eq. [16]; the agreement is very good. A similar situation for the carburization of Ni-30% Cr at 1173 K is shown in Fig. 14.

It was pointed out earlier that sulfur retards carburization as long as the level of sulfur in the gas is below that at which chromium sulfide forms as a surface phase.

Fig. 13. Comparison of experimental carburization data with prediction based on mathematical model for Fe-20 Cr at 1173 K.

Fig. 14. Comparison of experimental carburization data with prediction based on mathematical model for Ni-30 Cr at 1173 K.

Above this critical sulfur level, rapid sulfidation can occur since chromium sulfide does not form a protective scale. Based on thermodynamic grounds, the critical sulfur activity at which chromium sulfide formation is initiated increases with temperature.

The surface of alloys exposed to carburizing environments at sulfur concentrations below the critical level was examined using Auger spectroscopy. The Auger spectrum indicated the presence of adsorbed sulfur in all the cases. A typical example is shown in Fig. 15.

The above findings lead to the hypothesis that adsorbed sulfur on the alloy surface blocks potential sites where the carbon transfer reaction occurs, thereby reducing the speed of this reaction. A similar conclusion was reached by Grabke and co-workers (10, 11), who studied CH_4 decomposition on thin foils of iron in the presence of H_2S . A schematic representation of the sulfur effect is shown in Fig. 16. In the absence of sulfur (Fig. 16a) there is a high concentration of carbon in the adsorption layer; thus carburization is controlled by the rate at which carbon diffuses from the alloy surface into the bulk. At sulfur concentrations just below the level at which chromium sulfide formation is possible, there is a high concentration of sulfur in the adsorption layer (Fig. 16b). The concentration of carbon in this layer is therefore extremely small and is limited by the rate of the carbon transfer reaction at the surface. No significant gradient in

Fig. 15. Auger spectrum for adsorbed sulfur on Fe-20 Cr alloy exposed to carburizing environment containing sulfur.

Fig. 16. Schematic mechanism of inhibition of carburization by sulfur

carbon concentration exists between the surface and the bulk and the overall carburization process is surface reaction limited.

Summary

The influence of sulfur on the carburization of high temperature alloys has been investigated by exposing model Ni-30 Cr and Fe-20 Cr alloys to high carbon activity (~ 0.9) environments in the temperature range 1173-1373 K at predetermined levels of sulfur as H_2S . The following conclusions are reached from the present study. 1. Sulfur inhibits the carburization of high temperature alloys; this effect becomes less pronounced at higher temperatures. 2. The extent of inhibition increases with increase in the amount of sulfur added until the thermodynamic stability limit of chromium sulfide, CrS , is reached. At higher concentrations of sulfur, sulfidation attack is initiated. 3. Sulfur inhibits carburization by decreasing the kinetics of the reaction which transfers carbon from the gas phase into the alloy surface.

Chemical Vapor Deposition of Erosion-Resistant TiB₂ Coatings

A. J. Caputo, W. J. Lackey, I. G. Wright,¹ and P. Angelini

Oak Ridge National Laboratory, Metals and Ceramics Division, Oak Ridge, Tennessee 38731

ABSTRACT

Erosion- and wear-resistant coatings are needed for numerous applications, including valve and pump components for coal liquefaction and gasification plants. Titanium diboride is unusually hard and stable and offers considerable promise for use in highly erosive and corrosive environments. We deposited TiB₂ coatings by hydrogen reduction of TiCl₄ and BCl₃. Our objective was to correlate process variables with coating structure and properties, with emphasis on obtaining coatings having high erosion resistance. We varied deposition temperatures from 750° to 1050°C and the TiCl₄ and BCl₃ flow rates. Commercial cemented carbides and experimental nickel-bonded TiB₂ were used as substrates. After structural characterization, the resistance of the deposited coatings to erosion was determined by a hot coal-oil slurry impingement test. The deposition rate was very temperature dependent, ranging from 0.1 to 2.9 μm/min between 750° and 950°C. The surface of the coatings showed nodules increasing in size with temperature. The coatings were dense and adherent. The grain size varied with deposition conditions. Often, the grains were too small to resolve optically, but transmission electron microscopy showed the grain size to be very small (2-300 nm) and to increase with distance from the substrate. Electron microscopy and x-ray diffraction showed only single-phase TiB₂, and ion microprobe analysis revealed a constant Ti:B ratio across the coating thickness. Energy-dispersive fluorescence analyses showed more chlorine in coatings deposited at 800°C than in coatings deposited at higher temperatures. The Knoop microhardnesses of coatings deposited at 800° and 900°C were 15 and 33 GPa, respectively. Coatings deposited at 850°C or below eroded extensively (up to 30 μm deep craters during a 1h test), while those deposited at 900°C showed very little or no erosion (0-3 μm).

In the past several years there has been an increasing interest in the use of titanium diboride (TiB₂), in the form of both ceramic bodies (1) and coatings prepared by chemical vapor deposition (CVD) (2-4). This interest is the result of favorable properties: high hardness; moderate strength, toughness, and electrical conductivity; and excellent resistance to erosion, wear, and corrosion. These desirable properties are retained by TiB₂ even at high temperature. Such properties make the application of TiB₂ desirable in several areas of coal conversion plants, but especially so in coal liquefaction plants, where erosion of letdown valves is still one of the most serious materials problems. In this case, a high flow of a coal-oil slurry must pass through a small orifice to produce the required 10-15 MPa (1500-2000 psi) pressure drop. In this application, the life of valve trim and seat material may be hours, days, or a few weeks. Their high hardness, wear resistance, and chemical stability also make TiB₂ coatings attractive for use as metal cutting tools and other applications.

Previously, hot-pressed nickel-bonded TiB₂ substrates produced at Oak Ridge National Laboratory (Oak Ridge, Tennessee) were coated with CVD TiB₂ at Sandia National Laboratories (Albuquerque, New Mexico) (5). In erosion tests of these coatings, some samples eroded rapidly, while others experienced essentially no erosion. The low erosion results were extremely encouraging, but the inconsistency of the results (all specimens were coated in the same run) indicated the need for further development.

The TiB₂ coatings were deposited according to the reaction

This reaction has been used by various researchers (2-4, 6) to deposit TiB₂. The thermodynamics and kinetics of the reaction have been studied extensively (7, 8). Lower depo-

sition temperatures are possible by use of TiCl₄ and diborane as reactants (9), but diborane is very toxic and can burn explosively in air. The lower deposition temperatures were not judged to be a sufficient advantage for this study to offset the safety hazard.

The purpose of our work was to investigate by use of a statistically designed experiment the influence of deposition conditions and substrate type on the structure and properties, particularly erosion resistance, of the TiB₂ coatings.

Materials, Experimental Apparatus, and Procedure

The coating runs were made with the equipment shown schematically in Fig. 1. The graphite coating chamber was heated with a graphite resistance heating element within a water-cooled, metal-wall furnace. The substrate was held by a support rod in the center of the coating chamber. The temperature of the outside surface of the coating chamber wall at the same elevation as the specimen was measured with an optical pyrometer sighted through a silica glass window. Because blackbody conditions were closely approximated (viewing the graphite chamber through a slot in the graphite heating element), no emissivity correction was made. The flow of TiCl₄ out of a heated reservoir was controlled by the flow rate of hydrogen carrier gas and the temperature of a reflux condenser on the exit line from the reservoir. Hydrogen in excess of that needed for the TiCl₄ flow was added separately. The heated BCl₃ flow was controlled by a flowmeter, and the header of mixed inlet gases was heated to prevent condensation until entry into the coating chamber.

This study was divided into three sets of coating runs. The first set of 18 runs was a statistically designed experiment as shown schematically in Fig. 2 and Table I. From prior work and several exploratory coating runs, the "center point" process gas flow rates (cm³/min) for this design were established: TiCl₄, 40; BCl₃, 240; and total H₂, 2200.

¹Battelle Columbus Laboratories, Columbus, Ohio 43201

Fig. 1. Equipment for TiB₂ deposition

Variables in the experimental design were temperature (800° and 900°C), TiCl₄ flow rate (20, 40, and 60 cm³/min), and BCl₃ flow rate (120, 240, and 360 cm³/min). These process conditions result in boron-to-titanium ratios for the reactants ranging from 2 to 18 and hydrogen-to-titanium ratios of 34 to 117, which prior work had indicated would be worthy of investigation. Erosion testing of selected samples of this series (see Table I) indicated the deposition temperature to be the most significant variable affecting the erosion performance. Thus, a second series of eight runs was made, in which the deposition temperature was varied in 50°C increments from 750° to 1050°C. The data for this temperature series are shown in Table II. The substrate type for each coating run in the first and second set of runs was a commercially available² cemented carbide (WC-TaC-TiC-Co) machining tool insert. These inserts are square in cross section (12.7 mm edge length and 4.8 mm height). A third set of three coating runs was made at 900°C to study the effect of substrate type. The data are shown in Table III.

^a For each coating run, the substrate was Type GE-370 cemented carbide, and the run time was 20 min.

^b Calculated from weight gain.

^c Three additional runs (one of which used a nickel-bonded TiB₂ substrate) were made at this condition, except longer run times were used to produce thicker coatings. Erosion crater depths ranged from 23 to 33 μm, comparable to the coating thicknesses.

^d Crater depths were of the same order of magnitude as surface roughness, so the detection limit is in the range of 0-2 μm.

Fig. 2. Statistically designed experiment for TiB₂ deposition

The substrates studied are described in Table III and included various grades of commercially available cemented carbides and two experimental formulations of hot-pressed, nickel-bonded TiB₂. These substrates permitted investigation of the influence of substrate thermal expansion coefficient and composition on coating structure and properties.

The erosion test procedure and equipment are more fully described elsewhere (10). In summary, it is a 1h test in which a hot (315°C) high velocity (100 m/s) coal-oil slurry (8% solids in anthracene oil) is impacted on the test specimen at an angle of 20° (Fig. 3). Erosion resistance was determined by measuring (using profilometer traces) the depth of the erosion crater. For those coatings that exhibit very little wear, distinguishing the crater depth from the normal fluctuations of the as-deposited coating surface was difficult, and distinguishing between crater depths in the range of 0-2 μm was sometimes difficult.

Results and Discussion

Deposition rate.—The deposition rate of TiB₂ was most dependent on the temperature. The change in deposition rate as a function of temperature is shown in Fig. 4. The

EROSION BEHAVIOR OF TiB_2 COATINGS WAS DETERMINED BY HIGH-VELOCITY COAL-OIL SLURRY EXPOSURE (350°C, 1 h, 100 m/s, 20° INCIDENCE ANGLE)

Fig. 3. Schematic diagram of the specimen fixturing for the slurry erosion test.

data points represent runs in which the centerpoint $TiCl_4$ and BCl_3 flow rates were used, i.e., 40 and 240 cm^3/min , respectively. The bars represent the variation in deposition rate for the runs using other flows of $TiCl_4$ and BCl_3 (see Table I). Although the gas flow rate affects the deposition rate at a given temperature, the dominant effect is that of temperature. The deposition rate increased with increasing temperature up to 950°C and then decreased. The decrease in deposition rate above 950°C was probably caused by deposition on the hot wall of the reaction chamber and gas phase reactions which depleted the $TiCl_4$ and BCl_3 contents of the gas mixture before contact with the substrate. Indeed, a considerable amount of TiB_2 powder was formed in these runs, especially at 1050°C.

Table II. Deposition conditions^a and erosion results of second series of TiB_2 coatings—temperature variation

Run	Deposition temperature (°C)	Deposition time (min)	Weight gain (mg)	Coating ^b thickness (μm)	Erosion crater depth (μm)

^a Reactant flows (cm^3/min): $TiCl_4$, 40; BCl_3 , 240; H_2 , 2200. Deposition time, 20 min; deposition temperature, 900°C. Coating thicknesses were in the range 15-20 μm .

^b For comparison, the thermal expansion coefficient of chemically vapor-deposited TiB_2 is $8.0 \times 10^{-6} K^{-1}$.

^c Crater depths were of the same order of magnitude as surface roughness, so the detection limit is in the range of 0.2 μm .

Fig. 4. Influence of temperature on the TiB_2 deposition rate

Surface morphology.—The coatings deposited at and below 850°C were bright and smooth, while those deposited at 900°C and above tended to be dull and rough, especially, the 1000° and 1050°C coatings. Scanning electron microscopy clearly showed the surface morphology to depend on temperature. Figure 5 shows the surface nodules to be small (2-3 μm) at 800°C, somewhat larger (5-10 μm) at 900°C, and large (20-40 μm) platelets at 1000°C. Reactant gas flow rates had less effect on surface morphology, as shown in Fig. 6. At 900°C and a $TiCl_4$ flow rate of 40 cm^3/min , the surface morphology became finer textured as the BCl_3 flow rate increased.

Microstructure.—Optical microscopy showed the coatings to be dense and well bonded³ to the substrate, as shown in Fig. 7. Coating thickness was surprisingly uniform at sharp corners but sometimes varied from one side of a specimen to another.

The TiB_2 grains were typically columnar and generally small (<2 μm in width). The grain size, however, varied considerably from one specimen to another (Fig. 8) and was not correlated with deposition temperature or reactant gas flow rates. The grain size for the finer grained material was in the range 2-300 nm. Generally, the

Coating adherence was not evaluated quantitatively, but debonding was neither observed in the metallography specimens nor experienced during handling, erosion testing, or reheating to 1000°C. Debonding was, however, sometimes observed during attempts to use the coated specimens as machine tool inserts.

Fig. 5. Surface morphology of TiB₂ coatings are temperature dependent. Flow rates (cm³/min): TiCl₄, 40; BCl₃, 240; and H₂, 2200. (a) 800°C. (b) 900°C. (c) 1000°C.

Fig. 6. The BCl₃ flow rate influences coating surface texture. Deposition temperature, 900°C; TiCl₄ flow rate, 40 cm³/min. BCl₃ flow rate (a) 120, (b) 240, (c) 360 cm³/min.

Fig. 7. The TiB₂ coatings were dense, adherent, and of uniform thickness. Deposited at (a) 900°C, (b) 800°C

Fig. 8. Polarized light shows (a) no grain structure, (b) some structure, and (c) structure throughout the TiB_2 coatings

grain size increased with distance from the substrate (Fig. 9). Sometimes, however, the grain size changed abruptly (either decreased or increased) across the thickness of the coating, producing a banded or striated structure (Fig. 8). Fortunately, as will be apparent later, these variations in grain size did not appear to influence the erosion resistance of the coatings.

X-ray diffraction and transmission electron microscopy results showed only single-phase crystalline TiB_2 to be present. Preferred orientation occurred in most specimens, but the preferred plane and the degree to which a given crystallographic plane was preferred varied with deposition conditions.

Selected-area electron diffraction patterns of thin sections parallel to the substrate of a fine-grained specimen deposited at 800°C (Fig. 10) showed preferred orientation of the grains. The extent of preferred orientation and grain size increased with distance from the substrate. The diffraction patterns also showed the TiB_2 to be highly crystalline and rather defect free.

Chemical homogeneity, composition, and impurity content.—Ion microprobe analyses indicated a constant titanium-to-boron ratio across the coating thickness. The only impurity detected by energy-dispersive x-ray fluorescence analysis was chlorine. Although actual concentrations were not obtained, the chlorine-to-titanium intensity ratio for coatings deposited at 800° , 900° , and 1000°C were 0.187, 0.021, and 0.008, respectively. We do not know if this is free chlorine or a subchloride of the reactants in a concentration too low for x-ray diffraction to detect. This is one of the few differences in the coatings deposited at 800° and 900°C , and the possible influence of chlorine content on hardness and erosion results is discussed in a later section.

Microhardness.—Knoop microhardness data for the first set of coatings deposited at 900°C (coatings deposited at 800°C were too thin for measurement) are shown in Fig. 11. The data show that the TiB_2 coatings at the center point process condition (TiCl_4 and BCl_3 flow rates of 40 and $240\text{ cm}^3/\text{min}$) had a hardness of 33 GPa, as compared

Fig. 9. Transmission electron microscopy shows that the grains are small and increase in size with distance from the substrate. (a) Grain size 2-20 nm, $0.2\text{ }\mu\text{m}$ from substrate. (b) 20-30 nm at $3\text{ }\mu\text{m}$.

with the cemented carbide substrate of 19 GPa at the same indenter load of 100g. The data in Fig. 11 also show the following.

1. The maximum hardness values occurred at the centerpoint process conditions.
2. At a TiCl₄ flow of 40 cm³/min changing the BCl₃ flow from 240 to either 120 or 360 cm³/min had little effect on hardness.
3. At TiCl₄ flows of 20 or 60 cm³/min, the hardness values were lower and were significantly affected by the BCl₃ flow.
4. As expected, the hardness values were influenced by the load on the hardness indenter. The hardness values at the 25 and 50g load are higher than normally reported but are shown to emphasize the fact that the indenter load must be known before hardness values can be compared and to show the general trend of hardness at the various flow conditions.

Additional measurements indicated that coatings deposited at 800°C were not nearly as hard as those deposited at 900°C (15 vs. 33 GPa for a 100g indenter load). The hardness data for the second set of runs (the temperature series) again showed that deposition temperature affects hardness. Coatings deposited at 850°C and below were not as hard as those deposited at the above 900°C. For deposition temperature in the range 900°-1000°C, hardness values are in the range 32-44 GPa for a 50g indenter load. It is not clear whether 900° or 1000°C yields the harder coatings, but it should be noted that all coatings deposited in the 900° to 1000°C range were very hard. However, coatings deposited at 900°C are preferred because they are smoother.

Fig. 11. Microhardness of TiB₂ coatings deposited at 900°C as a function of reactant gas flow rates and indenter load. For comparison, the curve labeled WC-TaC-TiC-Co shows data for the GE-370 substrate.

Erosion resistance.—Six specimens from the first series were chosen for erosion testing. These were the three samples coated with a TiCl₄ flow rate of 40 cm³/min at 800°C and the three with the same flow rate at 900°C (see Fig. 2 and Table I). However, the 800°C samples had a coating thickness of only 4-7 μm as compared with 20-30 μm for the 900°C samples. Therefore, three more runs were made at 800°C with the centerpoint flow rates, but the run time was increased from 20 min to 2 to 4h. This provided samples coated at 800°C with coating thickness in the same range as the 900°C coatings. Also, one of these runs was made with a hot-pressed, nickel-bonded TiB₂ substrate.

As shown in Table I, all the coatings deposited at 800°C were completely penetrated during the test, regardless of the coating thickness (4-25 μm), gas flow rate, or substrate type. In contrast, none of the coatings deposited at 900°C showed up appreciable erosion for the coating thicknesses (22-29 μm) or gas flow rates investigated.

The second series of coating runs was made to permit further investigation of the influence of deposition temperature. The deposition conditions and erosion results for this set of samples are shown in Table II. These results again indicate an effect of deposition temperature on coating erosion resistance. Coatings deposited at 850°C or lower (4-14 μm thick) were essentially completely penetrated, but coatings deposited at 900°C and above were only partially penetrated. For coatings deposited at 900°C and above, the crater depths were greater than expected from the first set of results. However, some of the discrepancy is probably due to the measurement technique, in which crater depths are determined from profilometer traces. Coatings deposited at the higher temperatures are erosion resistant but have rougher surfaces, so the crater depth to be measured is small and close to the magnitude of the variation in the surface of the as-deposited coating. This increases the uncertainty of the crater depth measurement.

The third series of coatings was made to investigate the effect of substrate on coating erosion resistance. The substrates tested were five commercially available grades of cemented carbides and two experimental formulations of nickel-bonded TiB₂ (see Table III). The coating conditions, substrates, and erosion results are summarized in Table III. Note that in each of the coating runs 452, 453, and 454 three substrates were simultaneously coated and that, for each of these runs, one of the substrates was the GE-370 grade of cemented carbide, which served as a standard. The erosion results for the coatings deposited on the standard GE-370 substrate indicated that coating runs 452 and 453 were normal, good runs, but run 454 was somewhat suspect. Substrate type does not appear to strongly influence erosion resistance, although this conclusion is clouded by scatter in the data. There is some indication that the GE-370 grade of cemented carbide and the nickel-bonded TiB₂ may be preferable. Examination

of the data in Table III leads to the conclusion that erosion resistance does not appear to correlate with how closely the thermal expansion coefficient of the substrate matches that of TiB_2 .

Summary and Conclusions

The most significant conclusion that can be reached from this investigation is that properly deposited CVD coatings of TiB_2 have shown little or no erosion during accelerated testing. Thus TiB_2 coatings appear to be very promising for highly erosive environments such as those encountered by valve trim material and pump components in coal liquefaction processes. Low erosion rates were demonstrated for TiB_2 coatings deposited on different substrates (various grades of cemented carbides and nickel-bonded TiB_2) for a range of temperatures and flow rates of reactants.

Deposition temperature is the most important process variable in determining the erosion performance of the coatings. Coatings deposited at 900°C or higher exhibit very low erosion rates, but coatings deposited at 850°C or lower exhibit very high erosion rates. The property that most obviously correlates with the deposition temperature and therefore with erosion resistance is hardness. Coating hardness increased with increasing deposition temperature, at least up to 900°C and perhaps to 1000°C. Coatings deposited at 900°C had hardness values of about 33 GPa, whereas coatings deposited at 800°C had hardness values of about 15 GPa for a 100g indenter load.

Another significant difference between the 800° and 900°C coatings was the chlorine content. Raising the deposition temperature from 800° to 900°C lowered the chlorine content by a factor of 9. Increasing the temperature from 900° to 1000°C further lowered the chlorine content by a factor of 2.6. Whether or not the chlorine content is a significant factor affecting the erosion performance of the coating is not yet known.

Other conclusions follow.

1. The deposition rate increased as the temperature increased from 750° to 950°C, but then decreased as the temperature continued to increase to 1050°C.

2. The surface morphology of the coatings was strongly temperature dependent. The coating surface had small nodules at the lower temperatures (800°C), somewhat larger nodules at the intermediate temperatures (900°C), and a platelet structure at the higher temperatures. Changing the gas flows had only slight effect on the surface morphology.

3. The coatings were fine-grained, adherent, and of uniform thickness. Varying degrees of preferred grain orientation were observed. The grain size did not appear to correlate with any of the process variables. Both fine-grained and coarser-grained specimens exhibited excellent erosion resistance.

4. X-ray diffraction indicated the presence of only TiB_2 , with no unidentified peaks, and ion microprobe analyses

indicated a constant titanium-to-boron ratio across the coating thickness.

Optical Properties of CuInSe_2 and Related Compounds

P. Lange, H. Neff, M. Fearheiley, and K. J. Bachmann*

Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27695-8204

ABSTRACT

Reflectivity and photoluminescence (PL) spectra of stoichiometric CuInSe_2 and of two nonmolecular defect structures tied to the liquidus composition $\text{Cu}_3\text{In}_3\text{Se}_9$ and $\text{Cu}_2\text{In}_4\text{Se}_7$ are presented. At room temperature the fundamental gap and high energy features in the reflectivity spectra show only a very weak dependence on the stoichiometry of the compounds, while the PL spectra exhibit distinct differences. The PL of the stoichiometric material is dominated by free exciton emission, but the defect structures are characterized by broad deep luminescence bands of currently unknown origin.

The ternary compound semiconductor CuInSe_2 has attracted attention in the context of photovoltaic devices, optical detectors, and light emitting diodes (1, 2). In particular, CuInSe_2 -based solar cells with power conversion efficiencies in excess of 10% at AM1 and excellent resistance against degradation under operating conditions have been reported (3-5). Conflicting experimental data and analyses of the experimental results have been published (6-10) concerning the relation between the optical properties of copper indium diselenide and point defects in this material that is characterized by a wide homogeneity range. In the opinion of the authors, the primary cause for this confusion is a lack of control over the point defect chemistry and surface preparation conditions. In this paper, we report on the reflectivity and photoluminescence (PL) of stoichiometric CuInSe_2 and of related defect structures of well-defined composition.

Experimental Procedure

Bulk single crystals of stoichiometric CuInSe_2 , which is an incongruently melting material, were grown from the appropriate liquidus composition as described elsewhere (11). In addition, single crystals of the defect structures tying to the liquidus compositions $\text{Cu}_3\text{In}_3\text{Se}_9$ and $\text{Cu}_2\text{In}_4\text{Se}_7$ were prepared. Crystals prepared from these liquidus compositions were previously described as separate solid phases of same composition (12, 13). This contention is certainly wrong, since detailed phase diagram studies (11) show no evidence for the existence of a solid phase $\text{Cu}_3\text{In}_3\text{Se}_9$. As determined by electron microprobe analyses, both liquidus compositions tie to different solidus compositions, *i.e.*, $\text{Cu}_3\text{In}_4\text{Se}_7(\text{l})$ to $\text{Cu}_{0.19}\text{In}_{0.29}\text{Se}_{0.52}(\text{s})$ and $\text{Cu}_3\text{In}_5\text{Se}_9(\text{l})$ to $\text{Cu}_{0.21}\text{In}_{0.29}\text{Se}_{0.51}(\text{s})$ corresponding to atom ratios $\text{Cu}:\text{In} = 0.66$ and 0.72 and $(\text{Cu} + \text{In}):\text{Se} = 0.92$ and 1.00 , respectively.

Samples for the optical measurements were prepared by cleaving on (110) for the stoichiometric CuInSe_2 . As-grown natural (112) faces were used for the evaluation of the defect structures. Cutting, mechanical polishing, and chemical etching significantly alter the surface composition and optical response of the samples and was avoided in our work. The PL spectra were recorded in the temperature range $9 \text{ K} \leq T \leq 60 \text{ K}$ using a closed cycle He cryostat. The 514.5 nm Ar ion laser line at 150 mW incident power was used as excitation source and the emitted PL radiation was analyzed by means of an Instruments SA Model HR 320 monochromator. A 1200 g/mm holographic grating affording a spectral resolution of $\approx 3 \text{ \AA}$ was utilized in conjunction with either a Ge photodiode or a S1 photomultiplier tube. The data acquisition/signal processing system consisted of a PAR Model 192 chopper, a PAR Model 5206 lock-in analyzer, and a Tek 4052 computer. A similar setup was used for the reflectivity measurements using a Xe lamp as light source and, in the UV region, an alternative holographic grating with 1800 g/mm plus a R955 photomultiplier tube.

Results and Discussion

Figure 1 shows the reflectivity of CuInSe_2 and of the defect structure materials. The fundamental gap and the

*Electrochemical Society Active Member.

transitions at 3.9 and 4.5 eV do not show significant shifts for all samples, while the feature near 2.9 eV exhibits a dependence on composition. The nature of the high energy transitions is presently not understood. In Ref. (14) and (15), they are characterized as transitions from Cu d levels to the conduction band or E_1 -like transitions from the upper valence band or pseudodirect transitions. The above result indicates that the bandgap at room temperature is not significantly affected by deviations from molecularly. This finding is corroborated by the location of the low energy cutoff in the spectral response of liquid junction solar cells of the defect structure materials tied to liquidus compositions $\text{Cu}_3\text{In}_3\text{Se}_9$ and $\text{Cu}_2\text{In}_4\text{Se}_7$, respectively, shown in Fig. 2.

Figure 3 shows the PL spectra of stoichiometric CuInSe_2 at four different temperatures. A dominant peak at 1.03 eV and four additional peaks at 1.02, 0.97, 0.94, and 0.90 eV are observed. Note that the FWHM for the peak at 1.03 eV decreases upon increase of the temperature from 10 to 30 K. This shows that the 1.02 eV transition visible as a shoulder on the low energy side of the peak at 1.03 eV is strongly quenched. The 9 meV FWHM peak at 1.03 eV is assigned to the free exciton that is located 20 meV below the conduction band edge (CBE) (17). The bandgap is 1.05 eV in agreement with the previous data of Ref. (7) and (8). The absence of significant deep emission features in the PL spectrum of the stoichiometric CuInSe_2 sample of this study shows that it has substantially lower concentration of point defects than the heretofore reported CuInSe_2 crystals. For such high purity material, the transition probability for the free exciton is much higher than for band-to-band transition, which could be

Fig. 1. Reflectivity vs. photon energy of CuInSe_2 (solid line) and related compounds tied to the liquidus composition $\text{Cu}_3\text{In}_3\text{Se}_9$ (dashed line) and $\text{Cu}_2\text{In}_4\text{Se}_7$ (dot-dash line).

Fig. 2. Spectral response of defect structure materials tied to $\text{Cu}_2\text{In}_4\text{Se}_7(\text{l})$ and $\text{Cu}_3\text{In}_5\text{Se}_9(\text{l})$ in a $\text{V}^{++}/\text{V}^{+++}$, HCl, aqueous redox system. The position of the fundamental gap of CuInSe_2 is denoted by an arrow.

observed in the high energy region (16), but is not resolved in Fig. 2. A temperature increase by 50 K shifts the free exciton peak position by 5 meV, which is in good agreement with the previous results of Won Yu (8).

Fig. 3. Photoluminescence spectra for CuInSe_2 from a cleaved (110) surface for different temperatures showing five transitions.

Fig. 4. Energy level diagram for CuInSe_2 indicating the acceptor and donor levels, the position of free exciton level (FE), and the fundamental gap.

In a previous communication (19), we reported complementary features in the PL and photoconductivity spectra of a sample of atom ratios $\text{Cu}:\text{In} = 1.01$ and $(\text{Cu} + \text{In}):\text{Se} = 1.04$ that were explained by the presence of two acceptor states at 40 and 80 meV above the valence bandedge (VBE) and one donor state at 70 meV below the CBE. These states were related to Cu on In antisites, In vacancies, and Se vacancies, respectively. In accord with this model, the 0.94 and 0.90 eV transitions observed for the stoichiometric compound are interpreted as D-A transitions between the Se vacancy level and the Cu_{In} antisite and the In vacancy levels, respectively. The small peaks at 0.90 and 0.94 in Fig. 1 are probably of the same origin. The additional peak at 0.97 eV is interpreted as a CBE to the 80 meV acceptor level as indicated in the energy level diagram, Fig. 4. It has been observed in other samples of CuInSe_2 previously and has been characterized as a D-A transition by others (8, 18).

Fig. 5. Photoluminescence spectra of nonstoichiometric crystals tied to $\text{Cu}_3\text{In}_5\text{Se}_9$ liquid from the free (112) surface for different temperatures showing broad-band emission.

Fig. 6. Photoluminescence spectra of nonstoichiometric crystals tied to $\text{Cu}_2\text{In}_4\text{Se}_7$, liquid from the (112) surface for different temperatures showing broad emission.

Figures 5 and 6 show the PL spectra for the nonmolecular samples grown from $\text{Cu}_3\text{In}_3\text{Se}_8$ and $\text{Cu}_2\text{In}_4\text{Se}_7$, liquidus compositions, respectively. In both cases, the PL is dominated by broad deep emission, the location of which with regard to the bandedges cannot be assigned at this time. Since the solidus composition of the two cases considered correspond to Cu:In ratios < 1 and to metal:selenium ratios ≤ 1 , other defects are likely to dominate the recombination in this case than those considered in the discussion of Fig. 1. Both Cu-vacancy acceptors and In on Cu antisite donors are likely contributing defects, but need positive identification. Clearly, at low temperature the bandgaps of the two nonmolecular crystals are shifted to significantly higher energy than observed for stoichiometric CuInSe_2 , which is consistent with the observations of others who reported larger energy gaps for crystals of nominal composition CuInSe_2 grown from melt compositions that could have tied into In-rich material (11, 20).

Summary

Reflectivity and photoluminescence data have been reported for stoichiometric CuInSe_2 and for nonmolecular defect structures tied to the liquidus compositions $\text{Cu}_3\text{In}_3\text{Se}_8$ and $\text{Cu}_2\text{In}_4\text{Se}_7$. At room temperature, the location of the critical points corresponding to high energy transitions at 3.9 and 4.5 eV and the fundamental gap are not significantly affected by the point defect chemistry. However, substantial differences in both the bandgaps

and the dominant PL features are observed for stoichiometric CuInSe_2 and nonmolecular defect structures at low temperature.

Photoelectrochemical Defect Delineation in GaAs Using Hydrochloric Acid

R. Bhat*

Bell Communications Research, Murray Hill, New Jersey 07974

A number of different defect delineation techniques — chemical (1, 2), electrochemical (3), and photoelectrochemical (PEC) (4) — have been reported for gallium arsenide. The advantage of an electrochemical and PEC etch over a chemical etch is that the depth of etching is easily monitored and controlled. This enables one to evaluate thin layers and also specific layers in a multilayer structure. In this note, we report on a PEC technique using dilute hydrochloric acid and illumination. Hydrochloric acid was chosen as the electrolyte because (i) it is commonly available, (ii) the anodic oxide which is formed continuously dissolves in it, and (iii) it does not attack gallium arsenide appreciably.

Experimental

A Polaron profile plotter¹ (Model PN4100) was used to monitor the current-voltage behavior of an n⁺-GaAs electrode in 1HCl:10H₂O electrolyte. The same instrument was also used for defect delineation. The sample was held against a sealing ring mounted on one side of an electrochemical cell made of Teflon by a spring-loaded plunger. The sealing ring exposed approximately 0.1 cm² of the sample surface to the electrolyte. Ohmic contacts were formed on the back of the sample by applying a 40V, 60 Hz supply, through a current limiting resistor, for 150 ms to two tin-plated probes contained within the plunger. The cell contained a saturated calomel reference electrode and a carbon cathode. Light from a 150W tungsten lamp was filtered using a short pass filter with a cutoff wavelength of about 550 nm and then focused on to the sample through a Plexiglas window on the cell. The optics were adjusted to give uniform illumination over an area with a diameter of approximately 1 cm. The arrangement is similar to that reported in Ref. (5). Some experiments were also done using a 250W high pressure mercury arc lamp from a photoresist exposure system and a larger cell. This enabled defect characterization of entire wafers as large as 50 mm in diameter.

A typical plot of current-voltage characteristics is shown in Fig. 1. For defect revelation, we selected a bias point such as A in Fig. 1. The etching was more selective when it was done with an unsaturated photocurrent (point A) rather than with a saturated photocurrent (point B). This result is similar to that reported by Faktor and Stevenson (3) for PEC etching of GaAs using 0.5M Tiron. A Nomarski interference contrast photomicrograph of an etched, Si-doped ($N \approx 2 \times 10^{18} \text{ cm}^{-3}$) GaAs substrate oriented 6° off the (100) toward the (111)A is shown in Fig. 2. The etching was done under conditions similar to point A in Fig. 1 by appropriately choosing the bias and light intensity. The etching time was 30-35 min, resulting in an etched depth of approximately 0.6 μm of GaAs. Figures 3a and 3b show the same region of the wafer etched using molten KOH (2) and PEC etches, respectively. A one-to-one correlation between the hexagonal and conical pits in Fig. 3a and the raised features in Fig. 3b is seen. However,

*Electrochemical Society Active Member.

¹Polaron Equipment Limited, England.

some linear features such as the rectangular-shaped one located close to the left-hand edge of the photograph (Fig. 3b) appear only as two hexagonal pits in Fig. 3a. The reason for this difference is not clear at present. In addition, it is seen that the PEC technique not only reveals dislocations but also reveals bands or striations. Finally, we have found that work damage such as that caused by chemi-

Fig. 1. Typical current-voltage characteristics of an n⁺-GaAs electrode in 1 HCl:10 H₂O electrolyte. Voltages are measured with respect to a saturated calomel electrode.

Fig. 2. A Nomarski interference contrast photomicrograph of a photoelectrochemically etched n⁺ GaAs substrate (approximately 0.6 μm of GaAs has been etched).

Fig. 3. Nomarski interference contrast photomicrographs of the same region of an n^+ GaAs substrate showing defects revealed by molten KOH etching (top) and photoelectrochemical etching (approximately $0.5 \mu\text{m}$ of GaAs has been removed) (bottom).

mechanical polishing can also be revealed. This damage shows up as a network of raised, criss-crossed lines, al-

though no such pattern is visible prior to etching even with a Nomarski interference contrast microscope.

The PEC technique is sensitive to all hole traps and recombination centers (4) regardless of their origin. These regions are not etched as rapidly as the rest of the region, since the holes needed for the reaction are not readily available at these centers due to recombination or trapping of holes. Hence, the PEC technique delineates dislocations and work damage as raised features. Further, the variation in hole lifetime caused by a fluctuation in the impurity incorporation during crystal growth is also revealed, and this appears as bands or striations as seen in Fig. 3b (4). In contrast, the molten KOH etch reveals dislocations only as pits. Further, the electrochemical technique also reveals dislocations as pits because etching occurs primarily at defect sites where holes are generated by impact ionization. This technique, however, has been shown not to be as sensitive as the PEC technique (4). Therefore, the PEC etch is preferred to the molten KOH and electrochemical etches.

Conclusions

In summary, a simple defect delineation technique using dilute hydrochloric acid has been shown to be a sensitive technique to evaluate n-type GaAs wafers. A correlation between the commonly used molten KOH etch and the electrochemical technique has been established.

Dry Cleaning of Contact Holes Using Ultraviolet (UV) Generated Ozone

H. Norström, M. Östling,* R. Buchta, and C. S. Petersson*

Institute of Microwave Technology, Stockholm, Sweden

The reduction in minimum feature size of circuit elements to below $2 \mu\text{m}$ in modern IC technology has made dry etching a well-established technique for pattern transference. However, to further exploit the inherent potential of dry processing, many of the presently used wet cleaning steps must be replaced or completed with gas phase cleaning techniques, because a high surface tension together with a tendency to bubble formation within liquid agents will result in an ineffective cleaning of narrow openings. Consequently, immersion of silicon wafers in an oxygen glow discharge has been used for removing polymer formations as well as for photoresist trimming (decumming) and removal (ashing).

*Electrochemical Society Active Member.

In the following, we will show that UV-ozone equipment can be a versatile complement or replacement for the more expensive and "muscular" plasma ashers.

Experiments and Results

Two types of commercially available UV-ozone systems¹ were evaluated. Both were equipped with low pressure mercury UV lamps. No significant differences in performance could be observed for the two systems under identical conditions.

Ozone was generated by the mercury lamps through the

¹Model TO306, UVOCS, Incorporated, Montgomeryville, Pennsylvania 18936; Model 88-9660-02, BHK, Incorporated, Monrovia, California 91016.

interaction of 185 nm radiation and oxygen in the air (1-4). As shown by Vig (1), the UV intensity on a surface positioned at a distance d from the lamp is related to the source intensity (I_0) according to the expression

$$I = I_0 \exp(-130pd) \quad [1]$$

where p equals the average partial pressure of ozone between the lamp and the substrate. Consequently, a low power UV source can be used, presuming the samples to be cleaned are positioned in close vicinity to the lamp.

In view of the foregoing, all wafers to be ozone treated were placed at a fixed distance of 5 mm from the lamp. Prior to any wafer cleaning, the interior of the enclosure, fixtures, etc., were ozone cleaned in a "dry run" for 15 min to remove any possible organic contamination.

Reactive sputter etching (RSE) was performed in a homemade system equipped with a 150 mm diam quartz covered cathode, capacitively coupled to a 13.56 MHz RF power supply (5). Before admission of the CHF_3 gas, the system was evacuated to below 10^{-6} torr, using a 750 liter/s diffusion pump. All experiments were performed at a constant flow rate of 20 sccm, a partial pressure of 20 mtorr, and a power density of 0.5 W/cm^2 .

Two sets of samples were used in the experiment. For the initially performed nuclear resonance measurements, bare p-type, 16-24 $\Omega\text{-cm}$ (100)-oriented silicon wafers were reactively sputter etched for 10 min in CHF_3 .

Immediately after reactive sputter etching, the reference samples were sputter coated with a thin layer of titanium (800Å) to seal the interfacial carbon from any further contamination (6) during transportation to the accelerator. The same procedure was repeated for the ozone-treated specimens.

The carbon analysis was carried out in a tandem van de Graaff accelerator using the $^{12}\text{C}(\alpha, \alpha)^{12}\text{C}$ resonance at 4.26 MeV. A thorough description of the technique has been the subject of a paper by Ostling *et al.* (7). This technique increases the relative sensitivity for a light element, such as carbon, in a heavier matrix by a factor of 200 compared to conventional Coulomb scattering.

The results of the carbon analysis for two typical samples, *viz.*, one reference and one for 15 min treated specimen, are depicted in Fig. 1a and 1b. The energy of the α -particles was increased to 4.28 MeV to compensate for an energy loss caused by the surface titanium layer, thereby fulfilling the conditions of resonance at the silicon-titanium interface. The labeled arrows included in the graphs indicate the surface position of the respective elements, and the inset shows the analyzed structure. As the scattering cross section no longer follows the simple relation of Coulomb scattering, an irregular behavior of the silicon signal can be observed.

In Fig. 1a, two carbon peaks are easily distinguished. The one with a slightly lower intensity at higher energy is due to surface carbon on the titanium film. A lower detected intensity for the surface carbon film does not necessarily indicate a lower content, but is solely due to a lower scattering cross section, as resonance occurred for interfacial carbon. A similar peak belonging to surface carbon is also seen on the second sample, Fig. 1b; it results from contamination during transportation and installation into the accelerator as well as carbon buildup by the beam during analysis.

As pointed out above, the resonance scattering cross section no longer follows the relation of Coulomb scattering (*i.e.*, is inversely proportional to the energy square); instead, its dependence on the energy of the incoming α -particles is much more complex. A calibration procedure, similar to the one described in Ref. (7) — using plasma-deposited amorphous carbon films (8, 9) with various thicknesses as an internal standard — was therefore performed to render it possible to estimate the carbon film thickness.

The low energy carbon signal (Fig. 1a) possessing a larger intensity originates from carbon at the silicon titanium interface. The thickness of this carbon layer was estimated to be roughly 40Å. As verified by Fig. 1b, this low

Fig. 1. a (top): Backscattering spectrum of a reference sample, *i.e.*, sample without ozone treatment. The energy of the alpha particles was 4.28 MeV. This corresponds to a carbon resonance energy of 4.26 MeV at the titanium-silicon interface. b (bottom): Backscattering spectrum of a sample after a 15 min ozone treatment. The alpha particle energy was the same as in 1a. Only surface carbon on the titanium film can be observed.

energy peak has vanished after a 15 min ozone treatment. However, similar results were obtained for a shorter (10 min) ozone treatment. It is therefore anticipated that if this technique results in the removal of roughly 40Å of carbon within 10 min, the longer time (15 min) would produce a practically clean surface.

To further evaluate the effectiveness of ozone cleaning of carbon residues, holes were patterned with a photoresist mask and defined by RSE through a 6000Å SiO_2 layer. Two sets of samples were compared: one set received only the standard wet cleaning (10), whereas the other was completed with a 15 min O_3 cycle. After the cleaning, both sets were metallized in parallel with a titanium/titanium nitride layer (300/1000Å) (11). The samples were then examined under a light microscope. The results are shown in Fig. 2a and 2b. It is evident that the samples which did not receive the ozone treatment exhibited a weak metal-to-silicon bond, whereas the ozone-treated ones showed an excellent adhesion. This shows that the originally present polymer film in the contact openings was removed by the O_3 treatment.

Considering device operation, it is essential that the resultant oxide layer subsequent to the ozone treatment should not be too thick, as this would result in a poor metal-semiconductor contact with high intrinsic series resistance.

To confirm that no embarrassing oxide growth occurred as a result of the ozone treatment, the SiO_2 film thickness was monitored with an automatic ellipsometer using a program with fixed refractive indexes. The recorded data are presented in Fig. 3 in the form of differences. These were obtained by subtracting the previously measured native oxide thickness from the one recorded

Fig. 2. a (top): Optical micrograph of a Ti/TiN (300/1000Å) metallized water following RSE in CHF_3 and standard wet cleaning. The marker is equal to 250 μm . b (bottom): The same preparation and scale as in the previous figure, but cleaning completed with a 15 min ozone treatment.

after ozone cleaning. It should be pointed out that the presented data are limited by the accuracy in the measurements, but the tendency was justified by several repetitive measurements.

For short cleaning times, up to 10 min, a decreasing thickness can be observed. This is due to the removal of a thin organic layer originally present on the silicon surface. However, after a prolonged treatment, a positive difference, indicating a minute oxide growth, is observed. It is therefore concluded that even an extensive ozone treatment will cause only vanishingly small oxide thickening, which should be of no harm if a proper metallization scheme is selected. This is, however, not always true for the much more intensive plasma strippers, where a significant oxidation can occur.

Conclusion

It is shown that ozone, generated via the interaction of 185 nm UV radiation with oxygen in the air, is an effective carbon scavenger and therefore can be used to clean narrow contact holes defined by RSE in CHF_3 .

Fig. 3. The difference in oxide film thickness as a function of the ozone cleaning time.

The oxidation of silicon caused by the ozone treatment was found to be very small and is therefore anticipated not to cause any contact resistance problems. An improved metal-to-silicon adhesion was observed if the standard wet cleaning technique was completed with a 15 min ozone treatment. We have, however, not examined whether the UV radiation will have any detrimental effects on the properties of the MOS system, not being annealed out during subsequent processing. Neither have any contact resistance measurements comparing plasma- and UV-O₃-cleaned contact openings been performed. Further investigations regarding this eventual problem should therefore be undertaken.

Boron Diffusion Profile in Silicon and Data Analysis

F. Găiseanu

Research and Development Center for Semiconductors (CCSIT-S), R-72996 Bucharest, Romania

On the basis of the assumption that a vacancy mechanism should operate during the boron diffusion in silicon, it has been suggested (1) that the diffusion coefficient D would depend linearly on the boron concentration C , for $C > n_i$ (n_i being the intrinsic carrier concentration). How-

ever, it has been shown recently that the high concentration profile (2), the diffusion depth, and the boron amount after the diffusion from a liquid BBr_3 source (3) is well described if $D \sim C^{1/2}$. In this paper, an analysis of the boron profile obtained after diffusion from a solid source

(BN) by the H_2 injection technique is presented. The results are compared with those of the diffusion from a BBr_3 source.

Experimental

Dislocation-free, (111)-oriented, phosphorus-doped, 5 Ω -cm silicon wafers were used. The wafers were polished on both sides and underwent the following deposition cycle: 5 min $O_2 + N_2$, 2 min $H_2 + O_2 + N_2$, and 120 min flowing N_2 , at 1100°C. After the removal of the borosilicate glass (BSG), successive sectionings by chemical etching in a mixture of HF, HNO_3 , and CH_3COOH suitable to maintain the luster of the silicon surfaces were made. The sheet resistivity was measured each time by the four-point method and converted afterward into a corresponding concentration value (4).

A chemical method consisting of dosing of the boron amounts from the etching solutions by emission spectrography (5) was also applied for the profile determination.

Data Analysis and Discussion

Diffusion profile.—The measured concentration profile is shown in Fig. 1. The agreement (within $\pm 7\%$ error limits) between the two data sets allows a unique representation of the curve. One may, consequently, consider that within the experimental error limits the whole boron amount present in silicon is electrically active.

The Boltzmann-Matano analysis was applied to the diffusion profile. This proved to be, in this case, sufficiently accurate because of the particular shape of the profile. The result is presented in Fig. 2, showing a linear variation of D in the concentration range of about $(6 \times 10^{19} - 2 \times 10^{20}) \text{ cm}^{-3}$. This result experimentally supports Fair's earlier assumption (1), *i.e.*, $D \sim C$, and is characteristic of a diffusion mechanism by single charged monovacancies (1).

An approximate solution of the diffusion equation in this case is (6)

$$1 - 1.25y = 0.78(C/C_0) + 0.152(C/C_0)^2 \quad [1]$$

where $y = z/2(D_0t)^{1/2}$, $D_0 = D(x=0)$, and t is the diffusion time, allowing an easy determination of the depth x of an isoconcentration plane.

A deviation of the boron concentration profile near the silicon surface with respect to the boron diffusion profile

Fig. 1. Experimental boron profile obtained by sheet resistivity (dots) and emission spectrography (crosses) measurements.

Fig. 2. Dependence of the boron diffusion coefficient on the boron concentration deduced from the Boltzmann-Matano analysis of the experimental diffusion profile.

in the silicon bulk region may be noticed (Fig. 1), showing a rapid increase of the boron concentration to the silicon surface. This increase is correlated with a corresponding decrease of the boron diffusion coefficient (Fig. 2).

Comparative data analysis.—In spite of the two different results — (i) $D \sim C^{1/2}$ (2, 3), and (ii) $D \sim C$ (in this analysis) — the boron diffusion into the silicon bulk should be described by a single dominant mechanism, independent of the doping source and of the ambient atmosphere of the deposition process. This point may be discussed as follows.

In the analysis leading to result (i), the measured surface concentration was considered as a reference value (2, 3). For the discussion of result (ii), we dispose of two types of experimental data: some of them obtained after diffusion from the BN source by different techniques [that of this paper and, for instance, that of Ref. (7), where it clearly appears that the boron diffusion depends on the ambient atmosphere in the furnace tube], and others obtained by diffusion from BBr_3 source. Whereas, for some experimental data belonging to the first type, a diffusion "kink" near the silicon surface may be observed [Fig. 1 and Fig. 1 of Ref. (7)] that for the second type is not evident. Therefore, considering that the specific properties of the BSG-Si system perturb the boron diffusion near the silicon surface in both cases (*i.e.*, the profile near the surface is a product of this perturbation) then an analysis of all these data in terms of solid solubility of boron in silicon may be done.

In Fig. 3, some collected experimental data (8) and our own are represented as C/C_0 vs. x/x_0 , where $C_0 = C(x=0)$ and x_0 is depth for which $C = 10^{18} \text{ cm}^{-3}$. If one considers that C_0 would be the measured surface value, then the collected data may be represented by the dashed curve plotted in Fig. 3. This curve was deduced from Fair's universal curve [relation [5] in Ref. (1)], and it is close to the curve obtained after a proper solving of the diffusion equation (2), by using the result (i) [see Fig. 1 of Ref. (2)]. Considering now that C_0 would be the solid solubility of boron in silicon at the diffusion temperature, then both the collected and our experimental data are this time well described by the curve plotted as a full line in Fig. 3. This curve was deduced from Eq. [1] by using the result (ii), and it is very close to the curve obtained from Guo's computed curve [Eq. [16] of Ref. (9)].

Fig. 3. Normalized boron diffusion profile for Co representing: the measured surface value (broken line) and the solid solubility (solid line). The experimental conditions of the collected data (8) were: 7.2% O_2 , 0.04% BBr_3 (squares), and 1.8% O_2 , 0.04% BBr_3 (triangles).

The solid solubility $C_0 = 1.2 \times 10^{20} \text{ cm}^{-3}$ of boron in silicon at the diffusion temperature $T = 1000^\circ\text{C}$ previously reported (8) was taken into account as a reference value to represent in Fig. 3 the collected experimental data. These data resulted from successive sheet resistivity measurements after the boron diffusion from a liquid BBr_3 source, carried out under two different ambient conditions (see the legend of Fig. 3). The reference value $C_0 = 2.2 \times 10^{20} \text{ cm}^{-3}$ obtained by the best fitting of the curve deduced from Eq. [1] with our experimental data represented as C/C_0 vs. x/x_j as in Fig. 3 considered as solid solubility of boron in silicon at the temperature $T = 1100^\circ\text{C}$.

The result of this analysis brings into accord Fair's previous assumption (*i.e.*, $D \sim C$) with the experimental data exhibiting the boron diffusion profile in silicon bulk.

Summary and Conclusions

A chemical dosing method was applied as a technique for the boron profile determination after the boron diffusion in silicon from a BN solid source by H_2 injection. Direct comparison between the experimental results and those obtained by electrical measurements shows that the boron atoms in silicon might be considered as wholly ionized.

From the analysis of the experimental diffusion profile, a dependence, $D \sim C$, characteristic to a diffusion mechanism by monocharged vacancies for $C > n_i$ was emphasized in a silicon bulk region. An approximate solution of the diffusion equation under these conditions is given, allowing the estimation of the boron diffusion profile. An increase of the boron concentration and a corresponding decrease of the boron diffusion coefficient near the silicon surface with respect to their behavior in the silicon bulk were also pointed out.

The comparative analysis of the data resulting from the boron diffusion from the BN solid source and those obtained after the boron diffusion from a liquid BBr_3 source under different ambient conditions shows that the boron diffusion in the silicon bulk may be described considering that $D \sim C$, irrespective of the doping source and/or of the atmosphere of the deposition process, if one admits that the specific properties of the BSG-Si system perturb the diffusion near the silicon surface in all these cases.

Electrochemical Intercalation of Lithium in an Active Carbon

Yoshio Takasu, Masao Shiinoki, and Yoshiharu Matsuda

(pp. 959-960, Vol. 131, no. 4)

A. N. Dey:¹ In this paper, the authors suggested that the cathodic electrolysis of 1.0 mol-dm⁻³ of LiClO₄ in an equivolume mixture of propylene carbonate (PC) and 1,2 dimethoxyethane produces an intercalation compound of lithium and carbon, LiC₅, when "active carbon" is used as a cathode. The experimental evidences provided in the paper are (i) x-ray diffraction spectra of the active carbon electrode before and after discharge and (ii) the relation between the amount of Li⁺ detected in the cathode and the charge passed.

Let us first consider the x-ray diffraction spectra of the discharged carbon. A critical examination of the spectra indicates that all the new peaks that appeared as a result of discharge coincide with the major peaks of Li₂CO₃. We found earlier² that cathodic electrolysis of LiClO₄ in PC on graphite resulted in the decomposition of PC to form Li₂CO₃ and CH₃-CH=CH₂ quantitatively. Therefore, we suspect that the same reaction is occurring in this case as well and that the reaction product is Li₂CO₃ and not LiC₅. I recommend that the authors test their discharged cathode for evolution of CO₂ on acidification in order to confirm this possibility.

The evidence in regard to the relationship between the amount of Li detected in the cathode and the charge passed may be fortuitous, since the authors used Pt disk for establishing electrical contact with the carbon pellet. We discovered earlier³ that Pt formed intermetallic compound with Li when subjected to cathodic electrolysis in organic electrolyte. It is quite possible that the linear region of Fig. 3 of this paper corresponds to the decomposition of PC according to

and the subsequent nonlinearity is due to the loss of Li as Li₃Pt₂ intermetallic compound which has not been analyzed for Li. I recommend that the authors immerse their Pt disk in water after the discharge and test the aqueous solution for alkalinity in order to verify the possible formation of Li₃Pt₂ intermetallic compound.

Y. Takasu, M. Shiinoki, and Y. Matsuda:⁴ Dr. Dey has attempted to explain our result on the cathodic behavior of the active carbon electrode⁵ based on his investiga-

⁵Y. Takasu, M. Shiinoki, and Y. Matsuda, *This Journal*, **131**, 959 (1984).

tions using a graphite cathode.^{6,7} However, his explanations are not in conformity with the findings in our study.

When we used a graphite cathode for comparison, the electrode potential dropped rapidly and showed *ca.* -1.94V (*vs.* SCE) with the discharge as shown in Fig. 2, curve b, in the previous paper.⁵ During the galvanostatic discharge, a substantial evolution of gas was also observed on the graphite cathode. Both the cathodic performance of the graphite electrode and the gas evolution correspond to the result reported by Dey and his co-workers.⁶ But, we found no indications of gas evolution on the active carbon cathode. Moreover, the potential dropped gradually with discharge to *ca.* 0.3 Ah-g⁻¹ of discharge (Fig. 2) curve b.⁵ It must also be noted that the potential did not drop below -1.4V. To check the influence of carbonate ions, we performed the galvanostatic discharge of the active carbon electrode in various electrolyte solutions, *i.e.*, DME (1,2-dimethoxyethane), THF (tetrahydrofuran), PC, and PC · DME (1:1), each of which contained 1.0 mol-dm⁻³ of LiClO₄. The cathodic performance of the active carbon electrode in the THF-LiClO₄ was not much inferior to those of PC-LiClO₄ and PC · DME (1:1)-LiClO₄; moreover, that in the DME-LiClO₄ was also much better than that of the graphite electrode in PC · DME(1:1)-LiClO₄. It is difficult to assume that carbonate ions are formed easily by decomposition of either THF and DME. These findings show that the main cathodic reaction of the active carbon cathode was not the formation of Li₂CO₃. As pointed out by Dey, the new peaks on the x-ray diffraction spectrum of the discharged active carbon electrode⁵ coincide with the major peaks of Li₂CO₃. We think that such Li₂CO₃ must be formed either by a side reaction at the cathode or by the reaction of the intercalated (or adsorbed) lithium with carbon dioxide in air because the discharged cathode was analyzed by the x-ray diffractometry in air.

As to the lack of evident increase in lithium detected in the discharged cathode beyond *ca.* 0.3 Ah-g⁻¹, we have confirmed that this phenomenon was caused by decomposition of the electrolyte solution at the platinum anode as described in the previous paper.⁵ That is, the gradual increase of the cathode potential beyond *ca.* 0.3 Ah-g⁻¹ discharge⁵ could not be found when we used a lithium plate as the anode. In order to reveal the effect of some organic species, which might be formed at the platinum anode, the following experiment was made. The electrolyte solution of PC · DME(1:1)-LiClO₄ (1.0 mol-dm⁻³) was pre-electrolyzed with an H-type cell having a nickel net cathode and a platinum plate anode separated by a cation exchange membrane. The quantity of electricity passed corresponded to that passed before the potential of the active carbon cathode began to increase, *i.e.*, *ca.* 0.4 Ah-g⁻¹ discharge. Then only the pre-electrolyzed anolyte was used as the electrolyte solution

⁶A. N. Dey and B. P. Sullivan, *ibid.*, **117**, 222 (1970).

⁷A. N. Dey, *ibid.*, **118**, 1547 (1971).

of the galvanostatic discharge of the active carbon electrode. On discharge, the cathode potential immediately dropped to -0.5V and then increased to *ca.* -0.2V after $3.0\text{ Ah}\cdot\text{g}^{-1}$ discharge. The x-ray diffraction spectrum of this discharged cathode ($3.1\text{ Ah}\cdot\text{g}^{-1}$) gave no evident new peaks, and the amount of lithium detected in the discharged cathode was only $4.7 \times 10^{-3}\text{ mol}\cdot\text{g}^{-1}$ (active carbon). These findings strongly suggest that some organic ions formed by the decomposition of the electrolyte solution at the platinum anode mainly took part in the reaction on the cathode after the intercalation of lithium (or adsorption) into the active carbon reached saturation ($Q \approx 0.3 - 0.4\text{ Ah}\cdot\text{g}^{-1}$). The UV spectrum of PC · DME(1:1)-LiClO₄ electrolyte solution after the electrolysis using the active carbon cathode and platinum anode showed that PC was partly decomposed; *i.e.*, the peak at 243 nm , which is characteristic peak of PC, was reduced after the electrolysis. On the other hand, the used electrolyte solution using the active carbon cathode and the lithium anode gave little evidence of decomposition. The formation of Li₃Pt₂ on the platinum disk, which was used for the electrical contact with the active carbon pellet, was not confirmed by our experiment.

Electrochemical Conversion of CrO₂

D. Fousse, V. Jovancicevic, and F. Tissier

(pp. 2734-2736, Vol. 131, no. 11)

F. Beck:⁸ The cyclovoltammograms Fig. 1 and 2 have been performed with pressed powder layers 0.1 mm thick on platinum in phosphate buffer of pH 7. This corresponds to about $0.5\text{ mmol CrO}_2/\text{cm}^2$, and, with a total $1\text{ e}^-/\text{mol}$ conversion, about $50\text{ As}/\text{cm}^2$. The measured reduction charges have been $5 \times 10^{-7}\text{ As}/\text{cm}^2$, if the ordi-

⁸Gesamthochschule Universität, Duisburg, D-4100 Duisburg 1, Germany.

nate reads in $0.01\text{ }\mu\text{A}/\text{cm}^2$ units, or $5 \times 10^{-3}\text{ As}/\text{cm}^2$ if $100\text{ }\mu\text{A}/\text{cm}^2$ is the correct scale. Nevertheless, in both cases conversion of oxide is extremely low, *i.e.*, 10^{-6} or $10^{-2}\%$. By this way, an impurity effect seems to be reasonable.

I do not know what SSE-standard electrode means. If it means "standard silver chloride electrode" or "saturated silver chloride electrode," then the oxidation potential for $\text{Cr}_2\text{CO}_3 \rightarrow \text{CrO}_3$ follows from Fig. 1 and 2 to be about $+0.3\text{V vs. SHE}$. However, we have found at pH 7 $+0.93$ and $+1.58\text{V}$.⁹

D. Fousse,¹⁰ V. Jovancicevic,¹¹ and F. Tissier:¹⁰ CrO₂ is a quite new material from an electrochemical point of view, and its behavior is not yet fully understood. Nevertheless, the evidence for electrochemical stability and oxidation-reduction processes taking place at the oxide surface seem to be very convincing.

The calculations given by Beck concerning the amount of charge for the conversion of 0.1 mm thick CrO₂ is correct. However, we disagree with his interpretation to account for a small conversion of oxide where the impurity effect is put forward. On the one hand, it is highly unlikely that impurity effects are the same in CrO₂ and Cr₂O₃. It is also improbable that impurity is responsible for the two-step reversible oxidation-reduction process observed in voltammograms. On the other hand, the conversion is ascribed as a surface and not bulk reaction and, consequently, the participation of only $10^{-2}\%$ of CrO₂ in the reaction seems to be reasonable. The consecutive oxidations of reduced CrO₂ back to Cr(IV) and Cr(VI) are consistent with observed results.

The reference electrode SSE means "Saturated mercurous sulfate electrode."

On the Preferred Dissolution of Iron from Thin Films of Permalloy

M. Köhler, A. Wiegand, and A. Lerm

Akademie der Wissenschaften der DDR, Physikalisch-Technisches Institut, 6900 Jena, Germany

The spontaneous dissolution behaviour of alloys is of importance in corrosion processes and etching technology. Electrochemical investigations show that selective dissolution of single components is possible. The enrichment of Mo at the surface was observed in electrochemical dissolution experiments with steel (1). Zn is selectively dissolved at the beginning of the anodic dissolution of a copper/zinc alloy in a chloride containing bath (2). Studies on rotating ring disk electrodes of a Cu-Ni alloy show selective dissolution of Ni at low potentials (3).

Preferred dissolution is observed when dissolving Fe-Ni-alloy thin layers in an etching bath under open circuit conditions. The dissolution behaviour of such films is characterised by a typical time dependence of the open circuit potential. Alterations in the open circuit potential are caused by inhomogeneous dissolution of components of the alloy. The etching process was interrupted after different time intervals in order to investigate the dissolution behaviour. The resulting etching solutions were analyzed polarographically. The relative concentrations of iron and nickel in these etching solutions differ considerably from the composition of the alloy (Fig. 1a). The measurements show that at the beginning of the dissolution process iron is the component which is dissolved preferentially (stage I). In the second stage (II) the rates of dissolution of iron and nickel remain nearly constant, but a somewhat higher dissolution rate of iron is observed. During the last stage (III) only nickel is dissolved, because all iron

had been dissolved during stages I and II.

The analytical data of the etching solutions correlate with the observed open circuit potentials (Fig. 1b). At the beginning of the first stage the potential decreases. This decrease is connected with a preferred dissolution of iron. In this way nickel is enriched at the surface. The dissolution of nickel begins after a fifth of the etching time, whereby the potential increases slowly. The following constant potential is caused by constant dissolution rates of iron and nickel, respectively. Probably, the ratio of iron and nickel at the surface remains constant in this stage. This means that the enriched nickel is dissolved with a slower specific rate than iron. The rapidly increasing potential at the end of the etching process is caused by the complete consumption of iron. The increasing potential causes an increasing rate of dissolution of the remaining nickel.

Measurements of the open circuit potential during the etching of thin permalloy films of various thickness are shown in Fig. 2. As may be seen the duration of stage I is nearly independent of the film thickness. In contrast, the length of stages II and III increases with the thickness. Stage II is missing when 0.3 μm thick films are etched. Thus, we can conclude that the enrichment of nickel is a surface effect. Obviously, the preferred dissolution of iron takes place in the upper 0.2 to 0.3 μm of the film.

Fig. 1a. Relative amount of dissolved iron and nickel, respectively, in dependence on the normalized etching time. $\Delta t/t = 1$ is equivalent to a completely dissolved permalloy film.

Fig. 1b. Open circuit potential versus normalized etching time $\Delta t/t$.

Fig. 2. Open circuit potential ϵ in dependence on the etching time t for three permalloy films of different thickness.

It is possible to estimate the amount of nickel at the surface during stage II by comparison of the open circuit potential with the current-voltage dependence of bulk pure iron or nickel, respectively. From such measurements a nickel concentration of about 80% was estimated.

EXPERIMENTAL

The thin FeNi-films (50/50 wt %) on copper coated glass substrates were prepared by high rate sputtering. The open circuit potential was measured in aqueous solutions containing 0.1 M NH_4F and 0.45 M $(\text{NH}_4)_2\text{S}_2\text{O}_8$ at room temperature. The concentrations of the dissolved metals were determined by means of the polarograph OH 105 (Radelkis). Cyclovoltammograms for the estimation of the nickel enrichment were recorded by means of the potentiostat PS 4 (Meinsberg).

Loading Effect of Ashing Rate Observed in Cr Mask Fabrication

Fumio Mizuno, Yoshihiko Okamoto, Makoto Kato, and Katsuro Sugawara*

Hitachi Limited, Device Development Center, Kodaira, Tokyo 187, Japan

INTRODUCTION

For LSI's with higher density and higher performance, precise control of mask making has been required in addition to that of wafer processing. One problem is how to control the etching of Cr masks. An accurate "in process" method was reported in the case of the mask making using spray etching (1). Another problem is how to remove the residue of the resist which is often observed after developing the resist film. An ashing treatment is used to remove this kind of the residue. It gives influence on the thickness of the resist film and also on dimension of the mask through thinning the resist. In this treatment, a new phenomenon was observed which showed that Cr film on the mask acted as a load for the ashing rate in the case of Cr mask making. In this note, this novel effect and experimental results will be reported in the following.

RESULTS AND DISCUSSION

Specimens used in this experiment were low expansion glass substrates of 5 inches in square with electron-beam negative resist, PGMA, polycidylmethacrylate (2) of 4000Å in thickness and with or without Cr film of 800Å in thickness. Ashing conditions were as follows. Ashing was carried out in a reactor of parallel plate type which consisted of 200mm diameter stainless steel watercooled electrodes run at 13.56MHz and RF power of 40W. The reactor was evacuated, ashing gas, O₂ was fed in and the pressure was kept at 67 Pa (0.5 Torr). Ashing was done for 2 min. Ashing rate was determined as a difference of the resist film before and after the ashing treatment, measured by using an automatic thin film thickness measurement system for selected small area, NANOSPEC/AFT.

Manuscript received June 3, 1985.

Figure 1 is the ashing rate of the resist film coated on Cr mask. It shows the ashing rate increased as area ratio of the resist pattern on the mask increased. This tendency was also observed under different ashing conditions such as moistured air instead of O₂ and a barrel type reactor instead of the parallel reactor. This trend is quite contrary to the usual loading effect observed in plasma etching (3).

Fig. 1 Dependence of ashing rate to area ratio of resist pattern in the case of Cr mask.

To explain this new phenomenon, following experiments were tried. At first, the difference between Cr mask and glass substrate of the mask was examined. Fig. 2 is the result of the ashing rate in the case of the glass substrate of the mask done under the same ashing condition. As the area of the resist pattern on the glass substrate increased, the ashing rate decreased. This tendency was quite similar to that of the conventional plasma etching (3). The second evidence was the result of Auger electron spectroscopy analysis.

Fig. 2 Dependence of ashing rate to area ratio of resist pattern in the case of glass substrate.

Fig. 3 shows sputter profiles of chromium and oxygen measured with Ar sputtering. There was a remarkable difference of the oxygen distribution before and after the ashing treatment; Fig. 3(a) and 3(b) are the profiles before and after the ashing, respectively. After the ashing, oxygen content increased at the surface of the Cr mask. This phenomenon may be explained as follows. In the case of the glass substrate, PGMA, $(C_7H_{12}O_4)_n$ may be reacted by the excited O^* as

As the area of the resist patterns increases the ashing rate becomes decreased as the result of consuming larger amount of the excited O^* . In the case of the Cr mask, following reactions may be occurred in addition to Eq. [1]

At the large ratio of the Cr pattern = the small ratio of the resist pattern, the excited O may be more reacted by Eq. [2] and Eq. [3] than by Eq. [1], therefore, the increasing tendency of the ashing rate may be brought about.

SUMMARY

In Cr mask fabrication, an ashing process was adapted to remove the residue of the resist and novel loading effect was observed, which showed Cr film acted as the load. This may be explained by a stronger reaction between Cr and oxygen radical than the conventional reaction between the resist film and oxygen radical.

Transient Photoconductivity Profiles of Electrochemical Interfaces: The α -Si:H Aqueous Electrolyte Contact

R. Könenkamp and H. J. Lewerenz

Hahn-Meitner-Institut für Kernforschung Berlin, Bereich Strahlenchemie, D-1000 Berlin 39, Germany

Transient photoconductivity measurements using the technique of the time-of-flight (TOF) method¹ are demonstrated for the hydrogenated amorphous silicon (α -Si:H)/aqueous electrolyte junction. Our results indicate that local surface variation achieved by in situ alteration of the interfacial oxide by solution composition is clearly reflected in the time dependence of the photoconductivity.

A block diagram of the experimental arrangement is shown in fig.1. A voltage pulse (typical duration $t_V=300\mu s$) is applied to the working electrode via a pulse generator. Within a period considerably shorter than the dielectric relaxation time of the α -Si:H films (here typically 1ms) a nanosecond laser pulse (Excimer Laser, Lambda Physics) of 8ns duration with $\lambda=308nm$ falls onto the sample. The generation of electron-hole pairs occurs in the surface near region due to the high absorption of the semiconductor at that wavelength. One type of carrier (electrons when the working electrode is positive) then drifts in the applied field to the back contact giving rise to a photocurrent which is recorded using a Tektronix 7912AD digitizer. The photogenerated charge is not greater than $\sim 10^{-10} Ccm^{-2}$ per pulse which is low enough to avoid space charge effects.

The electrochemical cell, especially designed for photocurrent transient measurements², consists of the α -Si:H working electrode, a carbon counterelectrode ring and a saturated calomel electrode (SCE). Solutions were prepared from analytical grade chemicals and distilled water. The α -Si:H films were prepared in a conventional rf glow discharge in SiH_4 ³ onto stainless steel; substrates were held at $T=270^\circ C$. The films were undoped but were provided with a 200Å thick n^+ layer to establish an ohmic contact. The film thickness ranged between 2.5 and $3\mu m$.

Hahn-Meitner-Institut für Kernforschung Berlin assisted in meeting the publication costs of this article.

The time dependence of the photocurrents in a solution made of 1M NH_4F in H_2O ⁴ is displayed in fig.2 for a series of bias voltages. Similar results have been obtained in a solution made of 5M LiCl and 1M NH_4F . We note that a distinct voltage dependence of the photocurrent transients is observed. The general shape of the $\log I$ vs. $\log t$ plots is characterized by a constant current, a bend and a pronounced current decrease at larger t . The time regime of constant photocurrent is interpreted as the collection of the drifting photogenerated excess carriers in the applied field. The bend indicates the termination of the primary carrier drift and the tail at larger t is considered to arise from detrapping and subsequent drift. Up to $\sim 4V$, a linear increase of I with bias voltage is observed. For $V_b > 4V$ the photocurrent saturates. The transit times, t_T , show the expected behavior, i.e. faster drift at higher fields. The changes of I with V_b and the differences in t_T indicate that the external voltage drops across the semiconductor bulk. The existence of a current at 0V bias can be attributed to an internal electric field at the interface most likely due to trapped charge. From the transient behavior at high voltages the drift mobility of electrons can be determined. With $\mu_D = l^2 / V t_T$ where l denotes the semiconductor thickness we obtain $\mu_D \approx 3 cm^2 / Vs$ in accordance with measurements using evaporated metal contacts¹.

A pronounced change in transient behavior is noted in the absence of NH_4F . Fig.3 shows measurements equivalent to those in fig.2 but performed in supporting electrolyte (5M LiCl) only. Here, photocurrent saturation occurs already at external voltages of $\sim 1V$ and no transit time dependence is observed. The comparison with fig.2 shows that the transit time for 1V in fig.3 corresponds to the expected value in fig.2 but beyond that voltage no decrease in t_T is achieved in fig.3.

In a first tentative interpretation, these results indicate different electric fields to be effective at the surface and in the bulk of the sample, depending on solution composi-

tion. Electrochemical measurements on single crystalline and amorphous silicon show pronounced differences in electrode behavior in the presence or absence of NH_4F 4,5. In particular, a dark current is observed in NH_4F after immersion of the electrode, whose magnitude and time dependence is linked to the thickness of interfacial $\text{SiO}_2\text{-SiO}_x$ species. In a separate combined electrochemical and XPS experiment⁴ it was found that a-Si:H in supporting electrolyte LiCl is covered by SiO_2 mainly. In NH_4F , however, the surface appears to be free of oxygen and fluorine within the XPS resolution limit. We therefore attribute the differences observed with TOF to the different surface conditions with and without oxide. Although the determination of the actual field distribution has to await further detailed investigation, we have shown the applicability of TOF for analysis of microscopic interfacial changes. The applicability appears, however, to be restricted to intrinsic or almost intrinsic material and, in the case of monitoring surface or interface changes, to effects of these surface conditions on the internal field distribution in the intrinsic semiconductor. Since the field distribution in semiconductors is sensitive to even small changes in the surface, the TOF method in this form might be successfully applied in situ in a variety of suitable systems.

Indium Oxide, Oxygen Photoanode of High Quantum Efficiency

Lynn C. Schumacher, Susanne Mamiche-Afara, and Michael J. Dignam*

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario, Canada M5S 1A1

To date, high quantum efficiencies ($\sim 100\%$) for transition-metal-oxide oxygen-photoanodes have been reported only for TiO_2 (1), WO_3 (2), SrTiO_3 (3) and SnO_2 (4). To this list we now add a thin film form of In_2O_3 .

We have formed thin films of indium oxide by thermal oxidation of thin indium metal films which reproducibly display quantum efficiencies close to 100% at the absorption maximum of 310 nm (4.0eV). The technique used for making these thin oxide electrodes involves depositing indium metal films by sputtering from a 6" diameter indium metal target. The films are deposited in 1.0×10^{-2} torr of argon to an average thickness of about 800Å onto indium tin oxide (ITO) substrates held at 350°C. Following deposition of the metal, the plasma is shut off, the argon flow stopped and oxygen bled into the bell jar. The substrates are then left in 1.0×10^{-2} torr of oxygen for 30 minutes at 350°C after which the oxygen flow is stopped, the bell jar evacuated, and the substrates cooled down to room temperature over 4 hours. An indium metal-film of mean thickness of about 800Å will oxidize to form an In_2O_3 film of mean thickness $\sim 1000\text{Å}$. However, SEM studies show that the resulting oxide is not flat but consists of a series of hemispherical structures of mean radius $\sim 3.0 \times 10^{-5}$ cm. Transmission studies of these films deposited directly onto quartz showed less than 10% transmission of the incident light for $\lambda < 325\text{nm}$.

Photoelectrochemical and impedance properties of these films have been determined using a PAR model 170 Electrochemical System along with a focused xenon lamp carefully calibrated using the iron oxalate actinometer system. The experimental arrangement has already been described in some detail (5,6). The quantum efficiency, (ϕ), was calculated using the expression $\phi = 1.2408 J / I_0$, where J is the photocurrent density in $\mu\text{A}/\text{cm}^2$, 1.2408 a conversion

*Electrochemical Society Active Member.

factor relating photon flux density to power flux density and I_0 is the power flux density in mW/cm^2 at wavelength λ (expressed in nm) incident upon the photoelectrode surface. No corrections were made for reflection and transmission losses at the electrode. As a further check on the accuracy of our quantum efficiencies, such measurements were made for a thin film TiO_2 electrode which had previously been compared to a single crystal electrode (7). Our present calibration places the maximum TiO_2 single crystal quantum efficiency at 80%, in good agreement with the value of 81% obtained by Mavroides et. al. (1).

Figure 1 shows the measured quantum efficiency for a thermally oxidized indium metal layer at a bias potential of + 0.50 V(SCE) in 0.10 M NaOH. Figure 2 shows the d.c. photocurrent response at 310 nm of this same electrode. The photocurrent onset of -0.25 V(SCE) agrees very well with that reported for single crystal n- In_2O_3 (8), -0.20 V(SCE) in 1.0M NaOH. While the maximum in the quantum efficiency for these thermally oxidized metal films occurs at the same wavelength (310 nm) as that for the only single crystal studied (8), the increase in quantum efficiency from 25% for the single crystal to 90% for these thermally oxidized films is quite dramatic. The electrode response was stable under constant illumination for 3 days at +0.5 V(SCE) bias in 0.10 M NaOH. Measurements on a blank ITO substrate showed no photocurrent indicating that the observed photoresponse is due entirely to the thermally oxidized In_2O_3 . They were checked periodically over several weeks and no sign of corrosion or instability was detected. The poor behaviour of the single crystal has been attributed by Bockris et. al. (8) to high recombination rates due to the presence of a high density of impurity centres incorporated

into the crystal lattice during crystal growth. The technique used to produce these thin $n\text{-In}_2\text{O}_3$ films, has advantages over single crystal growth. These oxide films can be formed within at most 30 minutes of metal deposition, compared to several days, and at the much lower temperature of 350°C , compared to 950°C for single crystal growth. Furthermore, the fabrication procedure minimises contamination. Further studies are underway to characterise the photoelectrochemical, optical, morphological and impedance properties of indium oxide films produced in this way.

Physical and Chemical Characteristics of Hermetically Sealed High Rate Li/SOCl₂ C-Cells

K. M. Abraham* and L. Pitts

EIC Laboratories, Incorporated, Norwood, Massachusetts 02062

William P. Kilroy*

Naval Surface Weapons Center, White Oak Laboratory, Silver Spring, Maryland 20903-5000

ABSTRACT

Pressure-temperature-voltage relationships in hermetically sealed high rate Li/SOCl₂ cells have been studied using specially instrumented C-size cells. The cells generated considerably lower pressures than those expected on the basis of established discharge reactions. This is believed to be due to the SO₂ generated being complexed by LiAlCl₄ and/or absorbed by the carbon cathode. Li-limited cells produced lower internal temperatures and pressures towards the end of discharge and during voltage reversal than cathode-limited cells. In high rate discharge involving >10 mA/cm², Co-TAA-catalyzed cathode cells exhibited higher capacities and lower IR heating than uncatalyzed cells. Li-limited Co-TAA catalyzed cathode cells appear to be a desirable design for high rate applications.

The Li/SOCl₂ battery is a very attractive high energy density system for many high power applications since it can provide load voltages near 3.0V under high current drains. However, high rate applications are generally limited by safety hazards that occur under certain conditions of operation such as forced overdischarge or by poor cathode performance. Several recent papers have examined some of the factors that can affect cell performance and safety in SOCl₂ cells. Cell design is one such factor. Early studies with spirally wound cells revealed that some anode-limited cells exhibited hazardous behavior during forced overdischarge at low rates (1, 2). These cells were considered anode limited rather than Li limited since substantial amounts of Li remained on the anode despite anode potentials greater than 4.0V. This was attributed to poor electrical contact between the Li and the anode grid. Recent studies confirm that during high rate cell reversal, cathode-limited cells were more hazardous than those of Li-limited design (3).

A great deal of work has also been devoted to improving cell performance via the use of catalysts. Studies show that both organic macrocyclic (4) and inorganic (5) additives substantially improve cathode performance, especially at low temperatures. Recently, the use of cobalt tetraazaannulene complexes as catalysts has been proposed to enhance the safety of the SOCl₂ system by altering the discharge mechanism so that no pressure building SO₂ product is generated (6).

The presence of water as a safety factor in SOCl₂ cells has received little attention. Studies have primarily addressed the effect of water on voltage delay or hydrolysis reactions that produce HCl or H₂ gas (7-9). Water has been shown to increase cell capacity of reverse polarity SOCl₂ cells following storage at room temperature (10).

Despite the fact that no energetic products capable of causing detonations have been found, occasionally SOCl₂ cells have exhibited explosive behavior. Indeed the mechanism of generating safety hazards is still not well understood.

*Electrochemical Society Active Member.

To date, very little has been reported on the physicochemical characteristics of Li/SOCl₂ cells discharged under high rate regimes. In particular, a detailed knowledge of the cell's internal pressure-temperature-electrode potential behavior and its dependence on discharge rates, depth of discharge, and environmental temperatures are extremely important for the ultimate description of safe cells.

By using specially instrumented cells, we have reexamined the effects of cell design, catalysis, and water on the performance-chemistry-safety relationship of Li/SOCl₂ cells.

Experimental

Cell construction.—Specially instrumented, spirally wound C-size Li/SOCl₂ cells, manufactured by Hellekens Battery Engineering, Incorporated (Hyde Park, Massachusetts), were used in this study. Each cell contained a vent mechanism designed to vent at ~250 psig. A stainless steel threaded bushing fitted with a removable plug was incorporated into the cell top. This allowed electrolyte sampling and the installation of a pressure transducer (Precise Sensor, Incorporated, Monrovia, California) capable of measuring the internal pressure of the cell in the 0-500 psig range. The temperatures at two different points on a horizontal plane perpendicular to the cell wall were measured using internal and external iron-constantan thermocouples. The internal thermocouple was 0.010 in. diam with a 304 stainless steel sheath placed in a 0.020 in. id-0.040 in. od closed tube positioned at the core of the spiral electrode package halfway down the electrode length. This permitted the thermocouple to be isolated from the electrolyte yet provided rapid response to temperature changes. The cell skin temperature was measured by an external thermocouple held in place at the middle of the cell height by the heat-shrinkable cell jacket. Each cell contained a Li reference electrode to enable measurements of individual electrode potentials during discharge. All other components had conventional characteristics of commercial cells.

Cell specifications.—Cells were designed as cathode and Li limited. The specifications of the cathode-limited cells were as follows: dimensions of the Li anode were $0.058 \times 29.2 \times 3.8$ cm; Li weight of 2.4 ± 0.2 g. The dimensions of the cathode were $0.064 \times 25.4 \times 3.8$ cm; the carbon weight was 3.3 ± 0.5 g. The electrolyte was $1.8M$ $LiAlCl_4$ in $SOCl_2$; its weight was 19.5-20g. The void volume was 1.5-1.8 ml based on electrolyte deletion. The average weight of the cathode-limited cell was 63g. The cell volume was 29.5 cm^3 .

The specifications of the Li-limited cells were as follows. The dimensions of the Li anode were $0.023 \times 37.5 \times 3.8$ cm; the Li weight was 1.10 ± 0.15 g. The dimensions of the cathode were $0.064 \times 33 \times 3.8$ cm; the carbon weight was 4.3 ± 0.5 g. The electrolyte was $1.8M$ $LiAlCl_4$ in $SOCl_2$, and its weight was 24.5-25g. The void volume was 1.5-1.8 ml based on electrolyte deletion. The average weight of the Li-limited cell was 68g, and the cell volume 29.5 cm^3 .

Dry electrolyte, containing less than 10 ppm of water, was used for all cells. The "dry" cells contained ~ 50 ppm water. "Wet" cells containing ~ 500 ppm of water were prepared by adding water to the dry electrolyte in a controlled manner.

Catalyst.—Cathodes were prepared from Shawinigan acetylene black. In addition to the regular cathodes, those containing 5 weight percent of dibenzotetraazaannulene complex of cobalt (Co-TAA) as a catalyst additive were used. The catalyzed cathodes were prepared by mixing the carbon with the catalyst and then heat-treating the mixture at $500^\circ C$ under inert gas. After cooling, this mixture was made into a paste with water, isopropanol, and Teflon binder, and then dried below $100^\circ C$. The mixture was cured by heating to $\sim 275^\circ C$ under inert gas. At no time was the catalyst heated above $100^\circ C$ in air. The possibility exists that the catalyst undergoes structural perturbations during the heat-treatment at $500^\circ C$; however, we did not investigate this.

Testing and analysis.—Prior to electrochemical experiments, the cell was housed inside a specially designed test chamber (11) provided with feedthroughs for electrical connections and ports for collecting gases and liquid. A stainless steel capillary tubing with 0.5 cm^3 of void volume connected the pressure transducer located on the outside of the chamber to the cell inside. The chamber was housed in a constant temperature environmental chamber prior to electrochemical tests. Standard electrochemical equipment was used. Data collection and retrieval were done with Bascom-Turner Instruments Series 8000 recorders equipped with microprocessor accessories.

Cell postmortem and sample collection for analyses were done in a Vacuum Atmospheres dry box maintained with an Ar atmosphere. Infrared (IR) spectra were recorded on a Beckman Acculab-5 double-beam spectrometer. X-ray data were obtained by the Debye-Scherrer technique. Gas chromatographic (GC) analysis of volatile materials from the cells were performed on a Varian 920 Gas Chromatograph equipped with a thermal conductivity detector and a 6 ft chromosorb Analabs column.

The water content of the cells was measured by removing electrolyte samples from cells stored one week. The hydrolysis products present were analyzed using infrared spectroscopy and quantitatively measured against IR calibration curves prepared from samples of the dry electrolyte containing known amounts of water.

Results and Discussion

The discharge and overdischarge data and the related pressure-temperature behavior for cathode-limited cells containing uncatalyzed cathodes are given in Fig. 1 and 2. The temperature and pressure changes which accompany the discharge and overdischarge at $0.2A$ (~ 1 mA/cm^2) are rather minor. The temperature and pressure increase slightly at the end of discharge when the cell potential approaches 0 V. The internal pressure after the voltage reversal remains at a slightly higher value than that during

Fig. 1. Temperature, pressure, and voltage data for an uncatalyzed cathode-limited $Li/SOCl_2$ cell discharged at $0.20A$ at room temperature.

normal discharge. The data in Fig. 2 for the discharge and overdischarge at $2A$ (~ 10 mA/cm^2) show that the internal temperature increased to $\sim 50^\circ C$ during the course of the first 15% of discharge and remained at this value until the end of the normal discharge. The internal pressure increased slightly during the course of the normal discharge, but attained a maximum of only ~ 25 pounds per square inch (psi) at the 100% depth-of-discharge stage to a $2.0V$ limit.

By using the following information and the cell geometry and specifications given in the Experimental section, we have calculated the internal pressure of the cells on the basis of the generally accepted cell discharge reaction given below

The vapor pressure of SO_2 at $50^\circ C$ is about 130 psi (12). The solubilities of SO_2 in $SOCl_2$ and $SOCl_2/LiAlCl_4$ are given in Ref. (13). The calculated volume reduction which accompanies the $Li/SOCl_2$ cell discharge is 0.56 ml/Ah (14).

The pressure of the cell discharged at $2A$ was calculated to be at least 130 psi from the 75% depth-of-discharge stage onwards. The observed pressures were much lower. In addition, the internal temperature increases to $\sim 115^\circ C$ during the early stages of voltage reversal. At this temperature, an amount of SO_2 produced according to Eq. [1] would have generated a pressure of at least 500 psi. The measured maximum pressure is only ~ 140 psi, slightly lower than the cell venting pressure of ~ 250 psi. As the data in Table I show, the internal pressures are significantly lower than that expected on the basis of the

Fig. 2. Temperature, pressure, and voltage data for an uncatalyzed cathode-limited $Li/SOCl_2$ discharged at $2.0A$ at room temperature.

^d At a 3.0A rate, cell became cathode limited and vented after ~3 Ah overdischarge.

SO₂ stoichiometry of Eq. [1]. Complexation of the SO₂ by LiAlCl₄ (15), the absorption of SO₂ by carbon (10), and/or the presence of a significant amount of the low volatile (SO)_x rather than its decomposition products S and SO₂ may be occurring (16). The minimum amount of LiAlCl₄ in our cells is ~0.02 mol, which is sufficient to complex all the SO₂ produced at the 2.0A rate according to Eq. [1] to form an adduct of the composition [Li⁺(SO)₂AlCl₄⁻]. Raman spectroscopic studies have revealed the existence of such complexes in LiAlCl₄ solutions in SO₂ (15). However, there is strong evidence for significant absorption of SO₂ by Shawinigan carbon (10). The desorption of this SO₂ gas is reflected in the rapid pressure rise accompanying the temperature increase seen in the early stages of overdischarge. If it were not for a built-in SO₂ scavenging mechanism, the Li/SOCl₂ cell would produce excessive internal pressures capable of potentially violent venting, especially during early stages of cell reversal. If the scavenging mechanism involves the formation of SO₂ adducts with LiAlCl₄, then the salt concentration is critical: cells with higher salt concentrations should be safer. However, a lower salt concentration is a widely recognized remedy for alleviating voltage delays in the Li/SOCl₂ cell (16).

Some typical data for uncatalyzed cells are given in Table I. The temperature and pressure maxima reached in the Li-limited cells were considerably lower than the cathode-limited cells as illustrated by a comparison of the data in Fig. 2 and 3. A substantial fraction of the internal

heating at the end of cell life in cathode-limited cells at both 20° and -12°C was associated with cathode polarization. Very little cathode polarization occurred in Li-limited cells.

The effects of environmental temperature and the addition of 500 ppm H₂O on uncatalyzed cell performance are also tabulated in Table I. The data are averaged over five discharges for each type of cell. Some of the observations follow.

1. Addition of water showed no adverse affect on voltage delay at either 20° or -12°C. Cells with and without the added water showed substantial voltage delays when discharged at >10 mA/cm² at -12°C. In both types of cells, the voltage delay exceeded 60s of time to recover to 2.0V. Previous studies have examined the effects of smaller additions of water on voltage delay after storage at 23° and 55°C. Subsequent to room temperature storage for 1 month, cells containing an additional 100 ppm water displayed a decreased delay and attained their running potentials faster (10). Interestingly, partially discharged and stored cells behaved as well as fresh cells. Thus cells discharged for 1 Ah at 2.0A and stored 4 months at ambient room temperature experienced no voltage delay on redischarge at 2.0A (14 mA/cm² Li) at room temperature. The same type of cells redischarged at 3.0A (27 mA/cm² Li) did exhibit a voltage delay.

2. The internal temperature and pressure maxima at 2A at -12°C were substantially lower than that found at 20°C. The internal temperature of cathode-limited cells was always higher in the presence of added water. Data for a cathode-limited cell overdischarged at -12°C are illustrated in Fig. 4.

3. As seen in Table I, the capacity of the Li-limited cells was decreased ~11% at 20°C and ~18% at -12°C by addition of the water.

4. Two cells each from the four types of uncatalyzed cells were stored 4 months after having been discharged for 1 Ah at 2.0A current. The pressure generated after 4 months storage was 42% greater in the "wet" cells.

In general, the uncatalyzed cathode- and Li-limited cells exhibited safe behavior during extended periods of forced overdischarge at both the 0.2 and 2.0A rates. No cells vented.

Effect of Co-TAA catalyst.—The benefits of Co-TAA catalysis in 1/2 AA Li/SOCl₂ cells have been recently cited. These include superior cell performance, significant reduction in voltage delay, and a new SO₂-free reduction mechanism (6, 17). Our studies revealed that the addition of Co-TAA affected the behavior of Li/SOCl₂ cells in the following manner.

1. *Increased voltages.*—The catalyst gives rise to higher load voltages at the 2.0A and higher discharge rates. Typical discharge and overdischarge data at 2.0A at 20°C for

Fig. 3. Temperature, pressure, and voltage data for an uncatalyzed Li-limited Li/SOCl₂ cell discharged at 2.0A at room temperature.

Fig. 4. Temperature, pressure, and voltage data for an uncatalyzed cathode-limited Li/SOCl₂ cell containing 500 ppm H₂O discharged at 2.0A at -12°C. Because of the poor response of the transducer, the pressure reading may not be accurate.

cathode and Li-limited cells are depicted in Fig. 5 and 6, respectively. The cathode potential profiles vs. the lithium reference electrode indicate that the higher voltage results largely from improvements in cathode load voltages—polarization of the catalyzed cathodes at the higher currents is considerably lower than in the uncatalyzed cells. In general, for both wet and dry cells discharged at -12° and 20°C, the average mid-discharge voltage was ~10 and 20% higher in cathode- and Li-limited cells, respectively, when the catalyst was present.

2. Increased performance.—The effect of catalyst on increasing the average cell capacity is shown in Table III. The data indicate that wet cathode-limited cells discharged at high rates and low temperatures benefit most from the catalyst.

The cells discharged at low temperatures exhibited the most pronounced effect of the catalyst. Even at low rates, where no beneficial effect was expected, cathode-limited cells discharged at -12°C at 0.2A (0.8 mA/cm²) showed a 55% improvement in cell capacity. As Table III indicates,

Fig. 5. Temperature, pressure, and voltage data for a catalyzed cathode-limited Li/SOCl₂ cell discharged at 2.0A at room temperature.

at the 2.0A rate at -12°C these cells had approximately a 74% average increase in cell capacity. At double the rate, 4.0A, the same cells containing catalyst had a 28% larger average capacity at -12°C than uncatalyzed cells discharged at only a 2.0A rate. Indeed, the catalyst was most effective at higher discharge rates. Dry cathode-limited cells discharged at 20°C at 0.2, 2.0, and 3.0A rates showed a 8.6, 20.3, and 61.2% increase, respectively, in cell capacity with added catalyst.

Interestingly, as Table III indicates, the catalyst was most effective in enhancing the capacity of cells containing 500 ppm H₂O. In Li-limited cells, the catalyst appears to have negated the detrimental effect of water, perhaps by inhibiting corrosion of the anode. The water or hydrolysis products may play a role in the catalysis mechanism to increase the capacity of cathode-limited cells.

3. Lower internal temperatures and pressures.—Catalyzed cells exhibited lower average internal temperatures (~40°C) during discharge compared with uncatalyzed cells (~50°C). This difference was also reflected in the temperature maximum accompanying cell reversal. The

data in Tables I and II reveal that addition of catalyst to cathode-limited wet cells reduced the average internal temperature ~28% during overdischarge at room temperature.

Cells which experienced lower internal temperatures also displayed lower pressure maxima. Upon addition of the Co-TAA catalyst, the average pressure maxima in type A-D, A-W, C-D, and C-W cells were reduced 19, 25, 46, and 52%, respectively.

Our results so far indicate that the catalyst is ineffective in reducing the resistive heating which accompanies the steep drop in cell voltages at the end of discharge and during early stages of cell reversal. On the other hand, the catalyst appears to be effective in lowering cell polarizations during high rate discharge. As a result, the catalyzed cells maintain an overall lower internal temperature profile relative to uncatalyzed cells.

Indeed, the pressure-temperature profiles which accompany cell reversal at high rates were significantly better in the Li-limited cells. Since Co-TAA catalyzed cells exhibited lower cathode polarizations and higher capacities, Li-limited catalyzed cells are a highly desirable design for high rate applications with practically attractive capacities. It should be noted that our Li-limited test cells were not optimized. Larger anodes would have provided additional capacity.

Discharge data for one of the lithium-limited catalyzed cells tested at a constant current of 4.0A are given in Fig. 7. None of the dry Li-limited cells vented at the 4.0A rate. Similar cells have been discharged and forced overdischarged at currents up to 5.0A to monitor their pressure-temperature profiles and safety characteristics.

Co-TAA catalyzed cathode-limited cells have also shown higher useful capacities and lower polarizations at the 3.0 and 4.0A discharge rates. However, in this design, the internal temperature during reversal at 4.0A rises to very high values, approaching the melting point of Li. One of the catalyzed cathode-limited cells tested at 3.0A

Fig. 7. Temperature, pressure, and voltage data for a catalyzed Li-limited Li/SOCl₂ cell discharged at 4.0A at room temperature.

and two cells tested at 4.0A vented following reversal. The venting occurred during the high temperature excursion. Typically, the cells first vented relieving the internal pressure. Soon after, a second highly exothermic reaction seemed to take place increasing the internal temperatures to excessively high values (Fig. 8). A number of products have been identified in the gases collected from vented cells (*vide infra*).

Constant current vs. constant load discharge.—The pressure-temperature behavior observed at the end of cell discharge would be different in constant current and constant load discharges. Since the current decreases substantially as the voltage falls towards 0.0 V in a constant load discharge, cell heating would be much less compared to a constant current discharge. This is illustrated in Fig. 9 for a catalyzed cell discharged through a 1.0Ω load. The constant current data are most relevant to cells in series connected batteries.

Cell chemistry.—Gas analysis.—Vapor phase IR spectra and GC analysis were performed on collected gases. The results indicate: (i) SO₂ is a discharge product of catalyzed cells; (ii) HCl gas was most often found in wet cells with high internal temperatures; and (iii) cells exhibiting the largest temperature rise generated the largest amount of the carbonaceous gases, COS, CO₂, and CS₂; specifically, they were cells discharged at high rates, cathode-limited

^c The diffuse lines at high d values are carbon background lines.

cells, and cells that vented. Comparison of Fig. 7 and 8 reveals cathode-limited cells have higher internal temperatures.

Gases collected from cathode-limited cells forced overdischarged at > 3A showed small amounts of COS and CO₂, in addition to SOCl₂ and SO₂. Appreciable quantities of these carbon containing gases and some CS₂ were found in all cells that vented during forced overdischarge. The cells that vented at high discharge rates generally were those containing the 500 ppm of water. These cells displayed the greatest amounts of HCl.

The formation of these gases typically accompanied or followed the large temperature increase which occurred in the early stages of voltage reversal. It appears the carbonaceous gases are produced in thermally initiated reac-

tions of carbon with S and SO₂. Evidently, rather high temperatures are required for the formation of these materials. Hence, the carbon cathode seems to play a major role in the safety hazards.

Analysis of solids.—Tables IV and V summarize x-ray data on cathodes taken from various discharged and overdischarged uncatalyzed and catalyzed cells. Recent x-ray studies on overdischarged (19) and 100% discharged (20) cells have been interpreted to involve the formation of Li₂O₂ under those circumstances. It should be noted that the x-ray data for Li₂O₂ can be accounted for by the combined x-ray powder patterns of LiCl and rhombohedral sulfur. It has been proposed that the Co-TAA catalyst alters the mechanism of SOCl₂ reduction to form Li₂O (6).

The x-ray data in Table V give little evidence for this and are generally in good agreement with the x-ray patterns for LiCl and S.

In general, the catalyzed and uncatalyzed cells exhibit the same discharge products. While the relative intensities of the LiCl peaks show good agreement to the literature data, the sulfur peaks do not. This may be due to poor crystallinity of the sulfur and/or the existence of more than one allotropic form of S. Furthermore, S exhibits substantial solubility in SOCl₂ and, as a result, only small amounts would probably be present in the solid state in partially discharged cells.

Additional x-ray lines are present in the cathodes of partially discharged cells. These may arise from crystallized solvates of LiAlCl₄ containing SO₂, SOCl₂, or SO₂Cl₂. Evidence for solvates in overdischarged Li-limited cells comes from both the x-ray data and IR spectra.

When the electrolyte solution from overdischarged cells was collected and dried by pumping off the volatiles under vacuum, a glassy solid formed. These extracted salts were examined by IR analysis. Catalyzed and uncatalyzed cells gave identical spectra. However, as observed with the x-ray data, the Li-limited cells displayed a more complex spectral pattern than cathode-limited cells. The IR spectrum of the salt extracted from an overdischarged Li-limited cell is given in Fig. 10. The major absorptions at 1330 and 1070 cm⁻¹ are attributed to the complex Li⁺[(SO₂)_x(SO₂Cl₂)_yAlCl₄]⁻. Such a complex has recently been proposed (18). The peak at 1195 cm⁻¹ may be the S—O absorption associated with Li⁺(SOCl₂)_rAlCl₄⁻ and agrees with the strong band reported for LiAlCl₄ · 2SOCl₂ (21). The fact that SO₂Cl₂ is commonly reported in overdischarged Li-limited cells supports the proposed first complex. Additionally, the 1070 and 1195 cm⁻¹ bands were not present in the IR spectra of the salts extracted from the overdischarged cathode-limited cells. The peaks at 825 and 695 cm⁻¹ are probably due to an oxychloroaluminate salt (18, 22). Studies indicate that the relative amounts of the various materials formed during anode-limited reversal depend on a number of factors including the amount of electrolyte (*i.e.*, flooded or starved cells), the extent of overdischarge, and current density (2, 18, 23).

We also identified Li₂S₂O₄ in the cathodes of some overdischarged cathode-limited cells via qualitative tests with naphthol yellow-S (24). IR spectra of the cathode did not show the characteristic absorptions of Li₂S₂O₄ (11, 25), indicating it was a minor product. A band at 1015 cm⁻¹ appeared only in catalyzed overdischarged cathode-limited cells and may be associated with the catalyst.

Fig. 10. Infrared spectrum of the glassy solid obtained by evaporating the liquid products from forced overdischarged "dry" cells. Curve A: cathode limited. Curve B: Li limited.

Infrared spectra of the liquid collected from extensively overdischarged cells, with or without catalyst, did not differ from the spectra obtained prior to the overdischarge. SO₂ was the only product in the liquid. Previous studies on electrolyte flooded cathode-limited cells showed evidence for LiAlSCl₂ formation (2).

The ability of Li-limited cells to sustain extensive periods of overdischarge, as evidenced by their overdischarge voltage profiles, seem to indicate regenerative processes similar to those previously characterized (2).

Cathode-limited cells that were forced overdischarged for extended periods exceeding the amount of Li originally present in the cell suggests cell short-circuiting accompanying plating of lithium onto the cathode. The short-circuited cell apparently shunts current as if it were a resistor. The fact that a substantial amount of Li remains on the anodes of extensively overdischarged cells supports this hypothesis.

Several cathode-limited cells experienced premature anode polarization during discharge. A typical pattern of behavior can be seen in Fig. 4. Polarization of the anode begins after achieving ~1 Ah capacity, initiates a corresponding temperature rise, and appears to trigger the onset of cathodic polarization. This phenomenon was unpredictable, and most frequently occurred in uncatalyzed cells discharged at low temperatures (-12°C) and usually at 2.0A rates or higher. Occasionally, the anode polarized at low rates as shown in Fig. 11. This event was frequently characterized by a subsequent (ganging) or possibly simultaneous (mimicking) failure of the cathode and by the unexplained recovery of the anode to 0 V. It appears that a continuously growing LiCl anode film during discharge or crystallized LiAlCl₄ on the surface of the anode as a result of ionic concentration gradients in the cell increases the resistance to Li⁺ transport across the anode/solution interphase. Higher current densities and low temperature increase the associated resistance polarization of the anode. Eventually, the voltage of the Li anode recovers, indicating that a disruption or dissolution of the film has occurred. However, the mechanism of this interesting process is not well understood. Lithium has been recently shown to undergo anodic passivation in research cells (26). It has also been shown that a greater passivation occurs when LiCl films are grown quickly (27). A temporary film has been recently shown to exist during anodization of lithium in the SO₂ system (28). Additional studies are warranted to characterize this interesting phenomenon.

Conclusions

The pressure generated in Li/SOCl₂ cells has been found to be significantly less than that predicted on the

Fig. 11. Temperature and voltage data for an uncatalyzed cell discharged at 0.2A at -12°C.

basis of the accepted discharge reaction. This is believed to be due to the complexation of the generated SO_2 by LiAlCl_4 and/or the absorption of SO_2 by the carbon cathode. The highest internal heating was observed towards the end of constant current discharge and during early stages of cell reversal. Cathode polarization was identified as the major contributing factor to this type of internal heating. Runaway reactions and venting were observed in some cathode-limited cells in which the heating caused the internal temperature to exceed the melting point of Li. The generation of CO_2 , COS, and CS_2 appeared to be a function of internal temperature—the higher the temperature, the greater the amount of the carbonaceous gases that were produced. Li-limited cells show very little or no cathode polarization towards the end of cell discharge, and they produce considerably less heat than cathode-limited cells. Premature anode polarization has also been observed. This is proposed to be due to a growing anode film or ionic concentration gradients which increases the resistance of Li^+ transport across the anode-solution interface. The addition of water appeared to have no significant effect in voltage delay but generally lowered the capacity of uncatalyzed Li-limited cells, generated greater pressures in stored cells, increased the temperature of cathode-limited cells, and enhanced venting at high rates. Cells incorporating Co-TAA catalyzed cathodes exhibited higher capacities and less internal heating than uncatalyzed cells, especially at low temperatures. Li-limited cells with Co-TAA-catalyzed cathodes appear to be highly desirable for high rate applications.

Acknowledgment

We wish to express our appreciation to N. Marincic and his associates at Hellesens Battery Engineering for the preparation of the Co-TAA catalyst. We are grateful for the continued financial support provided by the Independent Research Program at NSWC and for the High Energy Batteries for Weapons Block Program.

Manuscript received April 22, 1985.

Electronmicroscopic Examination of Corroded Aluminum-Copper Alloy Foils

D. Y. Jung,* I. Dumler, and M. Metzger*

Department of Metallurgy and Mining Engineering and Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

ABSTRACT

The formation of particles of copper through selective dissolution of dilute Al-Cu solid solutions in sulfuric acid was studied by transmission electron microscopy of foils prethinned before corrosion. A technique was employed for prethinning without surface enrichment. At -500 mV vs. SCE, a significant fraction of the copper made available by selective dissolution appeared as particles, but not at -100 mV vs. SCE. The results are discussed with reference to concurrent AES observations on the Cu-enriched solid solution beneath the anodic film over the main body of the electrode.

Selective dissolution during corrosion of Al-Cu alloys may lead to the formation of metallic copper on the surface and a large enhancement of the cathode reaction rate

* Electrochemical Society Active Member.

(1). In HCl solutions, this is displayed through rapid and accelerating pitting corrosion (2, 3). One of the surface reactions in the selective dissolution was recently identified by Strehblow and co-workers (4, 5), who showed by

Rutherford backscattering and ion scattering spectrometry that anodic sweeps of Al-Cu alloys in buffer solutions of pH 5.0-9.2 produced an undoped alumina film with enrichment in Cu of the substrate beneath the film. The observations reported in this paper, which are part of a study that included electrochemical and AES measurements, were concerned with the formation of particles of copper metal on the surface. The identification, distribution, and crystallography of these particles can be examined by TEM with high spatial resolution. The corrosion was performed in sulfuric acid in order to maintain passive conditions and with the intent to employ the body of information on anodic films as an aid in interpreting film behavior. Specimens were thinned to near electron transparency and then exposed to corrosion to a small depth. A problem of specimen preparation arises with these alloys in that electropolishing, which is required to thin specimens properly for microscopy, itself produces surface enrichment in Cu. A procedure was devised to deal with this.

Experimental

The high purity binary alloys, in the form of 1 or 0.1 mm sheet, contained 0.06, 0.20, 0.60, or 2.0% Cu. They were given a final anneal at 580°C to yield solid solutions of grain size >2 mm and water quenched. Testing was done in 2.4M H₂SO₄ at 25.0° ± 0.2°C, without deaeration or stirring, at -500 or -100 mV vs. SCE. Before switching on the control potential, the rest potential was monitored for a few minutes as a check on specimen surface cleanliness. In all cases, the initial rest potential was ≈ -950 mV vs. SCE and near that of 99.999% Al, there being negligible corrosion in this interval. Specimens for electrochemical testing were polished mechanically to avoid initial surface copper enrichment. Mechanical polishing cannot be employed to thin specimens for TEM. Several electropolishing baths were tested and all produced severe surface enrichment in Cu. It was found that the enriched region could be removed by sputtering. This was possible because of the apparent absence of preferential sputtering under the conditions employed, as seen in the AES work. A procedure for thinning from one side, as diagrammed in Fig. 1, was developed. After dishing a 0.12 mm sheet just to perforation by electropolishing in a

Fig. 1. Preparation of aluminum-copper corrosion specimens for transmission electron microscopy.

HNO₃-H₂O bath, the specimen was inserted into the Physical Electronics 545 Auger unit and sputtered with 1 keV Xe⁺ over a region larger than the dish. The Cu peak at 918 eV was monitored, and the sputtering continued until the Cu signal was indistinguishable from the bulk value as determined on a mechanically polished specimen. After sputtering, both sides of the sheet were exposed in sulfuric acid for a period which would make the equivalent of a few monolayers of Cu available by selective corrosion of the solid solution. In the 0.60% Cu alloy, on which most of the work was done, this required only a fraction of a micrometer depth of corrosion. This, being small and relatively uniform, enlarged the original hole but usually left sufficient thin region for examination.

Observations were made either on a Phillips 400 microscope at 120 kV or a JSEM 200B microscope at 200 kV, both equipped with EDS capability for chemical analysis.

It was confirmed by electron diffraction of the matrix material that a single-phase solid solution was retained by quenching in all the alloys. Even the 2.0% Cu alloy aged one week at room temperature showed a diffraction pattern in the [100] orientation with no streaking indicative of the formation of Guinier-Preston zones. With this alloy, difficulties were anticipated in completely removing severe surface enrichment without metallurgical changes in the foil corrosion specimens, and it was not examined.

Results and Discussion

-500 mV vs. SCE.—At this potential, no loss of Cu from the solid solution by direct dissolution would be expected. Cu particles or rounded patches were visible in the thinner regions of the corroded foil as dark areas 4-35 nm across (Fig. 2a and 2b). These remained visible during tilting, i.e., they were visible by mass thickness contrast even in the absence of diffraction contrast and thus had thicknesses substantial fractions of their diameters. The particle density was relatively uniform from one field to another and from one foil to another though showing local variations within one field (Fig. 2). There was a tendency for alignment or clustering of particles in the walls of a topographic cell structure.

Figure 3a is a micrograph of the alloy of Fig. 2b after twice as much corrosion. It is seen that the particle density increased but the range of particle diameters remained about the same.

EDS observations in the thinner regions of the foil, employing the ratio of the Cu K α peak height to that of the Al, readily confirmed the presence of Cu in excess of the bulk value. Observations with selected areas of 0.1 μ m diam (Fig. 3) confirmed that local regions of higher particle density gave higher Cu/Al ratios (Fig. 3b and 3c).

The micrographs of copper particles were similar in general appearance to micrographs shown by Tomashov *et al.* (6) of palladium particles in extraction replicas from a steel containing 25% Cr and 0.5% Pd. These were, however, produced under different conditions, i.e., by a few minutes of active dissolution in sulfuric acid.

Selected-area diffraction in regions containing a number of particles (Fig. 4) showed full rings of very fine

grained Cu_2O and spotty rings of Cu together with the single-crystal spot pattern (incomplete cross grating) from the selected grain of the aluminum substrate. A layer of Cu_2O would have formed on the surface of the Cu when the specimen was removed from the acid bath and rinsed with water. Al_2Cu was not observed. Darkfield micrographs employing portions of Cu rings imaged the particles. All diffraction patterns represented regions well within a single grain of the substrate so that the observation of closely spaced spots on the Cu rings indicated that a large number of Cu particle orientations arose from a single orientation of the Al-Cu solid solution substrate.

-100 mV vs. SCE.—A second test potential of -100 mV vs. SCE was chosen as one at which there is a small corro-

Fig. 4. Diffraction pattern in an area containing many particles and indexing of the rings as Cu and Cu_2O . 0.60% Cu, -500 mV vs. SCE, 4h.

sion current for pure Cu, i.e., $\approx 80 \mu\text{A}/\text{cm}^2$ as indicated by data of Ghandehari *et al.* (7). Thus, any metallic Cu exposed to the acid would suffer some corrosion and would be removed unless it grew faster than it dissolved. The severest case examined was that of the 0.60% Cu alloy exposed 4h at -100 mV vs. SCE with a depth of corrosion $0.66 \mu\text{m}$ and with the amount of Cu which would have been made available by selective corrosion of the Al equivalent to a 1.2 nm thick layer, far greater than in Fig. 2b or 3a. No Cu particles were detected in electron micrographs (Fig. 5a), and an intensive search of thin regions of the foils failed to reveal any Cu or Cu_2O rings in the diffraction pattern.

The topographic cell structure seen in Fig. 5a for 0.60% Cu is characteristic of the potential rather than the copper content since it appeared also with 99.999% Al (Fig. 5b). Impedance data showed that the presence of this structure did not indicate severe surface roughening, as may accompany selective dissolution in some cases (8).

Further Discussion

Quantity of copper in particles.—In many of the micrographs, particles were visible down to projected diameters of about 4 nm. Examination of the micrographs indicated that any smaller particles present probably would have been indistinguishable from the faint phase contrast background, owing to the presence of the amorphous alumina surface film. The distribution of particle diameters had a maximum at 11-14 nm and fell more or less sharply for smaller diameters. It was concluded that in any case only a small fraction of the volume of copper would have been in undetected particles below 4 nm diam.

An estimate of the amount of copper appearing as particles was made from the measured distribution in bright field images. The particles being mainly noncircular in section, a diameter was assigned to each particle to give an equal area. For purposes of estimation, the particles were assumed to be hemispheres and the volume of particles in each size class was calculated and summed. The results for three specimens are compared in Table I with the total copper which would have been made available by selective dissolution. The latter was obtained by integrating the partial anode current during the exposure at -500 mV vs. SCE. The estimates show that under the conditions of these experiments a significant fraction up to perhaps one-half of the available copper appeared as particles. It may be noted that an analogous calculation was made for the total surface area of the copper particles in the micrographs. The results were in rough agreement with copper area figures deduced from capacitance measurements and from cathodic polarization data, thus supporting the validity of the TEM data.

An additional portion of the copper made available by selective corrosion should be in the Cu-enriched solid solution beneath the film over the main body of the electrode, according to the results of Strehblow *et al.* (4). To discuss this point, some pertinent results are cited below from the companion AES study, which will be reported separately.

AES observations.—Figure 6 presents for illustration some AES depth profiles for the 0.60% Cu alloy. The enrichment in Cu of surfaces of Al-Cu alloys prepared by electropolishing, which has been noted previously for an alloy of higher copper content (9), is shown in Fig. 6a. This enrichment appears greater than that of the mechanically polished specimen exposed to sulfuric acid at -500 mV vs. SCE (Fig. 6b), but the efficiency of enrichment was actually much greater in the latter case, which was produced by corrosion to a depth two orders of magnitude smaller. The depth profiles in Fig. 6 show a maximum in the copper signal at the oxide-metal interface, indicative of an enriched zone beneath the film. These data do not reveal the lateral distribution of copper or the phases present. In interpreting these depth profiles, it must be borne in mind that the enriched zone will appear thicker than it actually is. The mixing effect of ion bombardment (i) causes the enriched zone to be sensed before the nominal sputtered depth has actually reached the outer limit of the zone, and (ii) drives some of the excess copper inward so that an excess copper signal persists beyond the original maximum depth of the enriched zone.

Surface at -500 mV vs. SCE.—The Cu particles formed at this potential were up to 25 nm across and thus were too large to be covered by the alumina film (estimated as ≥ 4 nm thick). Even if they had originally formed beneath it, the overlying film would disappear by slow chemical dissolution in the acid since the copper blocks its renewal. The exposed copper metal would be stable at this immune potential. The alloy surface at a particular exposure time is then modeled, as shown schematically in Fig. 7a, as isolated patches of copper covering a few percent of

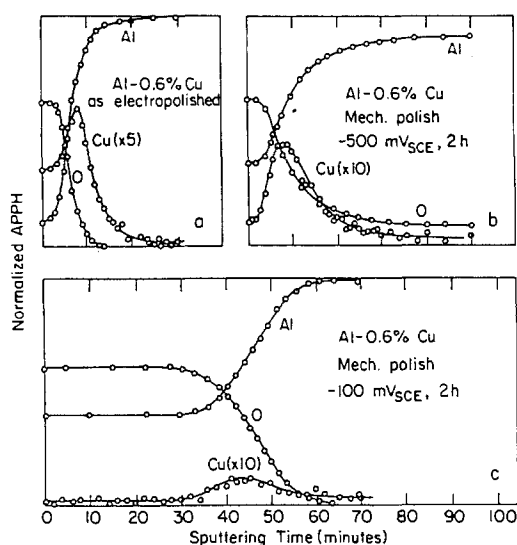

Fig. 6. Auger depth profiles of 0.60% Cu alloy after various treatments. the surface with the remainder, in line with Strehblow's model, consisting of an undoped alumina film overlying a few layers of enriched solid solution. An AES depth profile of such a surface with a 0.03 mm² electron-beam sampling many particles would show a copper concentration of a few percent at the external surface concurrent with the oxide film signals and there would be a maximum at the film-substrate interface, consistent with Fig. 6b. The copper depth profile does not yield a separation of the contributions from particles and enriched zone. Estimates of the total excess copper in these profiles are subject to some uncertainty, but do suggest that a substantial or large fraction of the copper made available by corrosion remains on the electrode at this potential.

Although the copper metal particles are immune at this potential, there would be a tendency for them to be undercut and released in the course of continued corrosion. The smallest particles would be most susceptible to undercutting, the ones which achieve larger diameters surviving longer. This could explain why the particle size frequency decreases at the smaller diameters.

Surface at -100 mV vs. SCE.—The processes occurring at this potential are considered to be the same as at -500 mV vs. SCE, except for the presence of a significant dissolution current for copper. The cell current was higher and the film thicker.

Consideration is given first to the special case of the 0.60% Cu alloy. The AES depth profile in Fig. 6c shows a Cu-enriched zone beneath the film, but also shows a small copper signal concurrent with the oxygen signal through the film region. The latter would be contrary to Strehblow's model if such signified doping of the film structure with copper ions. The copper signal from within the film cannot be attributed simply to copper metal particles of the size and nature discussed in the previous section because no Cu or Cu_2O was detected in the TEM observations and the cathode polarization data were also not consistent with this. The behaviors of 99.999% Al and 99.999% Cu in this acid are such that an area fraction of exposed copper of only 10^{-5} would produce cathode currents an order of magnitude greater than those of the pure aluminum. It is conceivable that the film formed on this alloy contains fragments of copper, or of copper-aluminum alloy from the enriched zone, which have been undercut from the substrate and trapped in the film, which at this potential is ≥ 20 nm thick. Such fragments are presumably suffering slow corrosion in the porous film. The model is represented schematically in Fig. 7b. Some small particles or clusters yielding the small ($\leq 0.6\%$) Cu signal in Fig. 6c could be undetected by electron microscopy, and, being isolated from the substrate by an alumina film of low electronic conductivity, they would not be effective cathodes.

In the 0.20 and 0.06% Cu alloys exposed at -100 mV vs. SCE, the AES depth profiles showed no detectable copper signal from within the film (0.20% Cu still showed copper enrichment beneath the film). This is interpreted as a consequence of a lower rate of particle formation and growth in these alloys so that any copper or copper-containing patches exposed at the surface would have dissolved before they could be undercut. Overall, it is concluded that the presence of a Cu signal from within the film may arise from processes other than doping of the

film structure with copper ions and that the present AES observations are not necessarily inconsistent with Strehblow's model.

Orientation relationships.—The dissolution in this system is highly selective at -500 mV vs. SCE and it would be expected that the nucleus of a particle of copper metal would have to form by a solid-state process from copper atoms in the alloy and would thus tend to be coherent with the substrate and of the same crystal orientation. This is expected whether the nucleation occurs through aggregation of copper atoms in the enriched zone under the film or if it occurs in conjunction with film breakdown and transient pitting processes. The orientation would persist during growth although misfit dislocations would form. Forty and Durkin (10) made a TEM study of selective dissolution in (111) orientation thin foils of Ag-Au solid solutions and found the substrate orientation retained in the gold-enriched regions; it may be noted that this is a system with minimal coherency strains because the lattice parameter varies by less than 0.2%. However, in the well-formed copper particles noted in the present work, many orientations were present within a single grain of the alloy. Also, in many cases (e.g., Fig. 2b), the particle images showed internal structure indicating that they were not generally monocrystalline. Multiple orientations could have come from nuclei forming in twin relation to the substrate and from growth twinning. The copper requires a strain of 12% to remain coherent with the substrate. It is conceivable that the copper particles do not necessarily nucleate as thin coherent plates but may nucleate in the enriched solid solution beneath the film as incoherent entities too thick to be coherent. The distribution of orientations of the copper particles and its origin needs further study. It is thought unlikely that nucleation at this potential involves transport through the electrolyte. Mechanisms of particle growth will be discussed elsewhere.

Anodic Oxide Films on CrSi₂

A. J. Barcz,¹ M. Bartur,* T. Banwell, and M-A. Nicolet*

California Institute of Technology, Pasadena, California 91125

ABSTRACT

Oxide layers on chromium disilicide of thicknesses up to several thousand angstroms are formed by constant current anodization in ethylene glycol containing different amounts of water. For low H₂O concentrations (1-10%), the films have essentially uniform composition of about 92% SiO₂ and 8% Cr₂O₃; the chromium being dissolved in the electrolyte during the anodic oxidation at a rate of one Cr atom per seven oxygen atoms incorporated. Greater H₂O content leads to increased current efficiency and higher angstrom per volt values for the anodization. In a 50% H₂O electrolyte, Cr-free SiO₂ films can be grown up to a limited thickness. These results are compared with the anodic oxidation of Si and the thermal oxidation of CrSi₂.

It is expected that silicides will be applied to interconnection lines in VLSI technology due to silicides, low resistivity relative to the commonly used polysilicon (1) as well as their ability to form insulating layers upon thermal oxidation (2). An exciting feature of the oxidation of most silicides is that the growing oxide appears to be pure SiO₂ while the integrity of the silicide is being preserved. From a purely thermodynamic point of view, assuming equilibrium and unlimited supply of the reactants, one might expect that both silicon and the metal will oxidize since the heat of formation of the silicides is small compared to those of the respective metal oxides [see, for example, the data tabulated per metal atom in Ref. (1)]. The calculations fall closer to the experimentally observed results when the corresponding heats of reaction are taken per one oxygen atom (3). Neverthe-

less, it seems that kinetic factors such as oxygen transport through the oxide and the rapid migration of Si and metal atoms through the silicide at the temperature of oxidation play a key role in the mechanism which leads to the formation of the metal-free oxide. Several possibilities concerning the mass transport across the silicide layer are discussed in Ref. (2).

In this paper, we report on a study of the formation of anodic oxides on CrSi₂ grown in an ethylene glycol containing small quantities of KNO₃ and H₂O, an electrolyte known to produce high quality, compact SiO₂ films when applied to silicon (4). This study gives an interesting opportunity to verify concepts adopted to explain the thermal oxidation processes and, specifically, to identify what is common and what is different in the thermal vs. electrochemical mechanism of the oxidation of silicides. First, in anodic oxidation carried out at room temperature any atomic transport across the remaining silicide can be ignored. Second, ionic movement in the high electric

* Electrochemical Society Active Member.

¹ Present address: Institute of Electrical Technology, 02-668 Warsaw, Poland.

field within the oxide includes usually both cationic and anionic components (5), in contrast to the thermal oxidation of Si, in which the mobile species in the oxide is an oxygen containing molecule.

Finally, we point out that the potential advantages of using anodic *vs.* thermal oxides of a silicide could be (i) a higher dielectric constant results if the metal oxide is present in the SiO₂ film, and (ii) that the silicon-silicide interface is not being affected by the high temperature treatment.

Experimental Procedure

Chromium films about 750Å thick were deposited in an oil-free vacuum of $\sim 10^{-7}$ torr by electron-beam evaporation onto Si <111> substrates. The wafers were then heat-treated in a vacuum furnace (600°C, 20 min, 10^{-7} torr range) to form $\sim 2300\text{\AA}$ of the stoichiometric chromium disilicide. The samples to be oxidized were degreased with trichloroethylene, rinsed in deionized water, and blown dry prior to being placed as anodes in an electrolytic cell. The samples were masked so that a limited area (0.3 cm²) was in contact with the electrolyte. A platinum cathode was positioned about 2 cm from the anode, and the electrolyte was stirred. The solution used in the present experiment was anhydrous ethylene glycol containing 0.5 weight percent (w/o) KNO₃ with different quantities of water: 1, 2, 10, 20, and 50 w/o. Oxidations were performed at a constant anode current density of 3 mA/cm² up to a predetermined voltage (V_{\max}) followed by a current decay at the maintained voltage V_{\max} down to one-quarter of its initial value. After the oxidations, the samples were rinsed in acetone and high resistivity water. Also, some oxidations were made using either 2 atom percent KNO₃ in the electrolyte or 0.5 mA/cm² current density. No detectable influence of these parameters changes on the composition of the films was found. Complementary thermal oxidations of CrSi₂ were performed in an open-tube furnace at 900°C by steam oxidation. The samples were introduced into the furnace with high N₂ flow to minimize oxidation during the temperature rise of the sample. After the sample had reached the desired temperature, O₂ bubbled through 96°C water was introduced.

It is important to note that the as-evaporated Cr contains about 7 a/o oxygen (6). Also, after thermal oxidation a thin layer of Cr oxide was always observed on the sample surface.

Elemental analysis of the oxidized layers was performed using 2 MeV ⁴He⁺ backscattering spectrometry (BS). Samples were positioned normal to the primary beam, and backscattered ions were detected at an angle of 170°. The backscatter analysis provides full information about the composition of the films, since, owing to a large mass difference, signals corresponding to the three components Si, Cr, and O can be independently observed. From these, we derive such quantities as stoichiometric ratios and overall oxygen content. Also, owing to the existing reference plane at the Si-CrSi₂ interface, it is possible to detect the loss of Si or Cr atoms by comparing the respective count integrals before and after the anodic processing. The masked edge enables reliable comparison of oxidized and unoxidized CrSi₂ at adjacent spots on the sample.

Results

Most oxidations were performed with either 1 or 10 w/o H₂O electrolytes. In these conditions, laterally uniform anodic films were reproducibly grown up to cell voltages of about 125V. Occasionally, it was possible to obtain V_{\max} as high as 200V (1% H₂O) before the initial reaction ceased. Typical voltage-time curves for CrSi₂ and pure Si substrates oxidized in the above electrolytes are shown in Fig. 1. There is a pronounced difference in the slope of the two curves corresponding to CrSi₂, while the curves for Si seem to overlap except for the initial potential rise. Figure 2 depicts the BS spectra of the CrSi₂ oxide resulting from the oxidation in the 10% H₂O glycol to $V_{\max} = 50\text{V}$; the solid line represents the spectrum of the initial silicide. First, we noticed that the surface film contains

Fig. 1. Voltage-time curves for CrSi₂ and Si anodization in glycol with water percentage of either 1 or 10% at constant current density of 3 mA/cm².

oxygen, silicon, as well as chromium atoms. The integral over the O peak yields 1.2×10^{18} at./cm² of incorporated oxygen. Furthermore, the stoichiometry ratios calculated on the basis of the signal heights give O/Si = 2.27 and Cr/Si = 0.17. It is thus clear that the oxide grows deficient in chromium with regard to the elemental proportions in the silicide (Cr/Si = 0.5). The difference in the Cr integrals confirms the net loss of chromium atoms equal to 1.8×10^{17} at./cm², *i.e.*, one Cr atom lost per seven O atoms incorporated. No loss of silicon atoms is detected. We also note that the composition profile is uniform and that the oxide-silicide interface is, and Si-silicide interface remains, sharp. A similar picture presented in Fig. 3 concerns the anodization to $V_{\max} = 75\text{V}$ in a solution containing smaller amounts of water (1 w/o). Here, the resultant oxygen content is 4.9×10^{17} at./cm² with a stoichiometry profile comparable to the previous case. A slight Cr enrichment at the surface becomes more evident for the anodic runs in which the electrolyte was not stirred (broken line in the figure). Without

Fig. 2. 2 MeV ⁴He⁺ backscattering spectra of CrSi₂ on Si before (solid line) and after anodically oxidized in 10% H₂O electrolyte to a voltage of 50V (full dots).

Fig. 3. Backscattering spectrum corresponding to CrSi_2 oxide obtained by oxidation in glycol containing 1% water to $V_{\text{max}} = 75\text{V}$ (dots), when no stirring was applied to the electrolyte (broken line), and with CrSi_2/Si substrate (solid line).

stirring, the current decay stage proceeded down to one-tenth (instead of one-quarter) of its nominal 3 mA/cm^2 , and the Cr appeared at even higher concentrations reaching the ratio of $\text{Cr/Si} = 0.5$.

Considering the above two figures, it is evident that the water content has a large effect on the outcome of the anodization: the sample oxidized in 10% H_2O to a lower voltage contains 2.4 times more oxygen than the one oxidized to the higher voltage in the 1% H_2O electrolyte. This trend is clearly appreciable in Fig. 4, where the oxygen content in atoms per square centimeter is plotted against the maximum effective potential drop ΔV in the oxide ($\Delta V = V_{\text{max}}$ minus initial potential rise). For comparison, data for pure Si are also shown. In all cases, the dependence appears to be linear; for CrSi_2 , the slope for oxidations carried out at 10% H_2O is significantly higher than that for the 1% H_2O electrolyte. Both slopes for CrSi_2 are greater than that of Si, which oxidizes at a rate which is nearly independent of the H_2O content. These slopes can be expressed in terms of convenient "electrochemical" units of angstroms per volt by assuming atomic concentration of the oxygen atoms equal to that of pure SiO_2 which is justified by a relatively small contribution of the Cr oxide. The corresponding values are 5.2 \AA/V for Si, 18.5 \AA/V for CrSi_2 (1% H_2O), and 65 \AA/V for CrSi_2 (10% H_2O).

Anodization in solutions of increasingly aqueous character leads to further increase in the angstroms per volt value and to a more efficient Cr dissolution. At the same

Fig. 5. Backscattering spectra of CrSi_2 (solid line) and CrSi_2 oxide (dots) produced in 50% H_2O glycol; $V_{\text{max}} = 12\text{V}$.

time, the maximum voltage that the film can sustain is reduced to 10-20V. An example of this type of behavior is shown in Fig. 5, where the anodic growth proceeded only to $V_{\text{max}} = 12\text{V}$ (from the starting potential of 7.5V , $V = 4.5\text{V}$). The oxide layer is practically free of Cr and constitutes a pure SiO_2 of a thickness of about 850 \AA . This result is thus similar to thermally grown oxides except that the silicide is not preserved as a whole, and Cr is lost into the solution.

Additional information about the growth mechanism can be acquired by analyzing an oxide layer produced by anodic followed by thermal oxidation. In Fig. 6, backscatter spectra are shown for the individual oxidations of CrSi_2 : anodic oxidation (10% H_2O , $V_{\text{max}} = 30\text{V}$ producing incorporation of $5 \times 10^{17}\text{ O at./cm}^2$), thermal oxidation (900°C , wet, 30 min) resulting in an oxide with $8.5 \times 10^{17}\text{ O at./cm}^2$, together with the spectrum resulting from thermal oxidation of the already preformed anodic

Fig. 6. Schematic BS spectra of chromium disilicide oxides. Anodic: 10% H_2O ; $V_{\text{max}} = 30\text{V}$. Thermal: 90°C , wet, 30 min. Anodic followed by thermal.

oxide (11.5×10^{17} O at./cm² incorporated). A most interesting feature in these spectra is the observation of the Cr exclusion within the films. As far as the concentration level of Cr in the anodic oxide is concerned, only a trace amount is detected at the surface in the thermal case. In the double-oxidized sample, the Cr profile in the oxide seems to be divided into two regions: a surface region (1.4-1.45 MeV) with similar Cr concentration as in the anodic oxide, and a chromium-free layer underneath (1.35-1.4 MeV). The deleterious effect of the heat-treatment on the Si-CrSi₂ interface is also visible in the bottom spectra as broadening of the step at 0.85 MeV.

For a sample that was initially oxidized thermally, followed by anodic oxidation and finally thermal oxidation again, Cr was not detected in the oxide layer.

Discussion and Conclusion

The experiment described in this paper gives evidence that thick uniform oxides can be grown on chromium disilicide by anodic oxidation in ethylene glycol + potassium nitrate + water electrolyte. This may be regarded as the main result of this work. In view of a still inadequate understanding of the anodic processes, it is not possible to rigorously predict whether a given material in a given oxidizing medium will yield substantial oxide films (7, 8). Apart from valve metals such as Al, Hf, or Ta that oxidize with 100% current efficiency to voltages of at least 200V and sustain high electric fields ($>10^6$ V/cm), there exist many other materials that only partially fulfill these criteria. Such behavior is exhibited by silicon, which in organic electrolytes can be oxidized to several hundreds volts, though exhibiting a poor current efficiency suggesting the evolution of an appreciable amount of oxygen (9). On the other hand, chromium, which passivates to form Cr₂O₃ (10), has not been reported to produce thick oxides. In the electrolytes employed here, anodization of a pure Cr film does not induce any potential buildup, and creates a black spot on the Cr film surface containing no oxygen detectable by He backscatter spectrometry. Consequently, the CrSi₂ compound seems to be a rather complicated system as far as its anodic behavior is concerned. It is known that compounds or single phase alloys composed of valve or near-valve metals oxidize easily (11). The general situation becomes more complicated. Extensive studies on the anodization of GaAs (12), for example, show that several factors (*e.g.*, current density, oxide thickness) determine the composition and quality of the compound oxide formed. As for silicides, data on anodic oxidation are not available; the corrosion study of Cu, Co, and Ni silicides published in Ref. (13) was oriented primarily toward electrorefining and electrowinning from ores.

Summarizing the oxidation of CrSi₂ in glycol with a water content ranging from 1 to 10%, it can be concluded that the oxide has a fixed composition with a relative concentration of the constituents given by O/Si = 2.27 and Cr/Si = 0.17. Assuming that the film is composed of SiO₂ and Cr₂O₃ molecules, these numbers are consistent with a composition of 92% SiO₂ and 8% Cr₂O₃. This indicates that during the film formation, a substantial segregation takes place; preservation of the Cr/Si proportion in the silicide would require an oxide composition of 83% SiO₂, and 17% Cr₂O₃. Undoubtedly, the excess Cr is dissolved in the electrolyte. From the corrosion behavior of chromium, it is known that at higher potentials Cr atoms enter the electrolyte as CrO₄²⁻ anions (14). Also, chromium tends to lose its passivity rather easily in the presence of certain contaminants, especially chloride ions (9). The accumulation of Cr at the oxide surface observed when the 1% H₂O electrolyte was not stirred during the anodization suggests that the dissolution could be further reduced by saturating the solution with Cr ions. Alternatively, more Cr atoms are leached out of the film for electrolytes with greater water content. Hence, the Cr-to-Si ratio in the oxide can be controlled by choosing adequate experimental conditions.

The current efficiency for oxide formation on CrSi₂ increases from 3 to 16% when the H₂O content of the electrolyte is raised from 1 to 10%. This is probably associated with enhanced field-assisted ionic transport across the (porous) oxide. It is unlikely that there is suppression of the current contribution from parasitic reactions and/or electronic conduction, since the oxide breakdown voltage dropped with increasing H₂O content as one might anticipate (15). The ionic current associated with Cr dissolution also degrades the current efficiency.

Anodic vs. Thermal

Comparison between anodic and thermal oxidation gives further insight to the prevailing processes.

1. In both cases, the silicide dissociates readily. In thermal oxidation, the excess Cr diffuses through the silicide to the Si substrate, where it reacts and reforms silicide, hence preserving the silicide (16). But, during anodic oxidation, Cr diffuses through the growing oxide and a fraction of the dissociated Cr oxidizes while the rest is dissolved in the electrolyte.

2. Increasing the water content in the oxygen gas during thermal oxidation increases the oxidation rate. In anodic oxidation, a higher water content also results in a higher oxide formation rate. Possibly, it has to do with the oxygen containing molecule that diffuses through the oxide. In the thermal oxidation case, the effective diffusion coefficient changes, while in anodic oxidation it may be only the boundary condition at the oxide/electrolyte interface.

3. With the assumption that the heat capacity of the reactants and products are similar, the heat of the reaction ΔH at room temperature and at high temperatures (for thermal oxidation) never exceeds 3 kcal/gatom (17). So the thermodynamic predictions (3) are the same by definition for anodic and thermal oxidation. The observed different results are due to different kinetic limitations.

4. From the sequential thermal/anodic oxidation results, we conclude that (i) chromium cannot diffuse through thermal SiO₂ (see Fig. 6 and also the results of thermal/anodic/thermal), and (ii) an oxygen containing molecule diffuses through the anodic oxide driving wet oxidation faster than through thermal oxide. This conclusion is reached with the assumption that the thermal oxidation is parabolic rate limited. The predicted oxygen content of anodic and thermal oxides, assuming the same diffusion coefficient in anodic and thermal oxides, is $10^{17} (5^2 + 8.5^2)^{1/2} = 9.9 \times 10^{17}$ O at./cm²; while we get 11.5×10^{17} O at./cm², which is indicative of a faster diffusion rate in the anodic oxide.

Since no electrical characterization of the layers was conducted and no data on insulating properties of anodic Cr₂O₃ have been published, it is difficult to predict dielectric constant ϵ or breakdown voltage of the films. There are indications, however (9), that the anodic oxide of Cr, having a low formation field, should have a high ϵ value (> 40), as it is known that low ϵ values (*e.g.*, SiO₂) tend to be associated with high anodization fields and vice versa. Additionally, the breakdown voltage can be roughly estimated from the angstrom per volt values because they are nearly linearly correlated (18). (However, it is uncertain how the individual properties of SiO₂ and Cr₂O₃ will contribute in the mixed oxide.)

Application of Kramers-Kronig Transforms in the Analysis of Electrochemical Systems

I. Polarization Resistance

Digby D. Macdonald* and Mirna Urquidi-Macdonald

Chemistry Laboratory, SRI International, Menlo Park, California 94025

ABSTRACT

A Kramers-Kronig transform that is useful for validating electrochemical and corrosion impedance data is employed to calculate the polarization resistance from the frequency-dependent imaginary component. Applications of the transform in the analysis of experimental impedance data for TiO₂-coated carbon steel in HCl/KCl solution at ambient temperature and for aluminum and Al-0.1P-0.1In-0.2Ga-0.01Ti alloy in 4M KOH solution at 25°C are discussed.

Electrochemical techniques are now used extensively for investigating the mechanisms of electrochemical and corrosion processes, and for the measurement of corrosion rates (1-4). With respect to the latter, the advantages offered by electrochemical methods are that they can be applied *in situ* in hostile environments and that they require minimal manipulation of samples or post-test analyses. In all electrochemical methods for estimating corrosion rates, the objective is to measure the polarization resistance (R_p), from which the corrosion current and corrosion rate may be calculated using the Stern-Geary relationship (5, 6), provided that the Tafel constants are known.

A widely used technique for measuring R_p is impedance spectroscopy (1-3), in which the impedance of the corroding interface is measured over an effectively infinite bandwidth. The polarization resistance is therefore given by

$$R_p = |Z(j\omega)|_{\omega \rightarrow 0} - |Z(j\omega)|_{\omega \rightarrow \infty} \quad [1]$$

$$= \text{Re} [Z(j\omega)]_{\omega \rightarrow 0} - \text{Re} [Z(j\omega)]_{\omega \rightarrow \infty} \quad [2]$$

where Re denotes the real part of the complex impedance $Z(j\omega)$. In other words, the polarization resistance may be obtained from only the real component of the impedance, provided that it is measured over a sufficiently wide frequency range.

A critical problem in any impedance analysis involves validation of the data. This is particularly true because of the need to employ low amplitude excitations, and when working with inherently "noisy" systems. In this paper, we describe how Kramers-Kronig transforms may be used to estimate R_p from the imaginary component of the impedance. We also argue that comparison of the R_p value computed from the imaginary component via the K-K transforms with that derived directly from Eq. [2] represents a simple and convenient test of the validity of corrosion impedance data.

*Electrochemical Society Active Member.

Kramers-Kronig Transforms

Derivation of the Kramers-Kronig transforms (7-11) is based upon four quite general conditions of the system being fulfilled.

Causality.—the response of the system is due only to the perturbation applied, and does not contain significant components from spurious sources.

Linearity.—the perturbation/response of the system is described by a set of linear differential laws. Practically, this condition requires that the impedance be independent of the magnitude of the perturbation.

Stability.—the system must be stable, in the sense that it returns to its original state after the perturbation is removed.

Impedance values.—the impedance must be finite valued at $\omega \rightarrow 0$ and $\omega \rightarrow \infty$, and must be a continuous and finite valued function at all intermediate frequencies.

Provided that the above conditions are satisfied, the K-K transforms are purely a mathematical result, and do not reflect any other physical property or condition of the system. The transforms have been used extensively in the analysis of electrical circuits (9), but only rarely in the case of electrochemical systems (10-14).

Two of the more important transforms may be stated as follows (9, 11)

$$Z'(\omega) - Z'(\infty) = \left(\frac{2}{\pi}\right) \int_0^{\infty} \frac{xZ''(x) - \omega Z''(\omega)}{x^2 - \omega^2} dx \quad [3]$$

$$Z'(\omega) - Z'(0) = \left(\frac{2\omega}{\pi}\right) \int_0^{\infty} \left[\left(\frac{\omega}{x}\right) Z''(x) - Z''(\omega)\right] \cdot \frac{1}{x^2 - \omega^2} dx \quad [4]$$

where Z' and Z'' are the real and imaginary components of the impedance, respectively. Therefore, according to Eq. [2], the polarization resistance simply becomes

$$R_p = \left(\frac{2}{\pi}\right) \int_0^{\infty} \left[\frac{Z''(x)}{x}\right] dx \approx \left(\frac{2}{\pi}\right) \int_{x_{\min}}^{x_{\max}} \left[\frac{Z''(x)}{x}\right] dx \quad [5]$$

The forms of Eq. [3]-[5] deserve brief comment. First, it is evident that if the integral in Eq. [5] is to be convergent and finite, then $Z''(x)/x \rightarrow 0$ as $x \rightarrow x_{\min} \rightarrow 0$ and $x \rightarrow x_{\max} \rightarrow \infty$. The approximation is valid when the integrals from $x = 0$ to x_{\min} and from x_{\max} to ∞ are negligible compared with the integral from x_{\min} to x_{\max} . Second, it appears that the functions beneath the integrals in Eq. [3] and [4] contain singularities at $x = \omega$. However, as we show later (16), expansion of $(x^2 - \omega^2)^{-1}$ reveals that no singularity actually exists, and hence that the precision of integration is not compromised on passing through $x = \omega$, as is sometimes claimed.

In this study, we evaluate the integral in Eq. [5] in a piece-wise fashion by fitting a fifth-order polynomial to experimental Z'' vs. frequency (x) data using a least squares technique

$$Z''(x) = a_0 + a_1x + a_2x^2 + a_3x^3 + a_4x^4 + a_5x^5 \quad [6]$$

The segments over which the integral is evaluated are chosen to coincide with changes in the sign of $Z''(x)$ and/or with changes in the gradient of $Z''(x)$ vs. frequency. The total integral is then evaluated as

$$R_p \approx \left(\frac{2}{\pi}\right) \sum \left[a_0 \ln x + a_1x + \frac{a_2x^2}{2} + \frac{a_3x^3}{3} + \frac{a_4x^4}{4} + \frac{a_5x^5}{5} \right]_{x_i}^{x_{i+1}} \quad [7]$$

where i is the segment number. The limitation on the size of the segment is that the number of data points must exceed the highest order of the polynomial; we have found that a fifth-order polynomial is well suited for the cases discussed later in this paper.

The use of Eq. [5] in the analysis of impedance data for corroding systems has also been proposed by Kendig and Mansfeld (12) and was subsequently used by Mansfeld *et al.* (13). However, these workers propose that this equation is a basis for estimating polarization resistance data from the imaginary component of the interfacial impedance at high frequencies, thus avoiding the need to obtain impedance data at time consuming low frequencies. As noted by Kendig and Mansfeld (12), this approach is valid only if the plot of Z'' vs. $\log \omega$ (e.g., see Fig. 2) is symmetrical. This is true only for those systems that exhibit single semicircles in the complex plane that are either depressed or centered on the real axis; it is generally not valid for systems that exhibit multiple resistive/capacitive or resistive/inductive relaxations or for those systems that are best described in terms of a diffusional impedance or a transmission line. Accordingly, the method described by these workers is not expected to be generally applicable to experimental impedance data, except in those cases for which the condition noted above holds.

In this work, we adopt a more general approach in the application of Eq. [5], in that the integration is carried out over the entire frequency range and not just over the high frequency arm of the Z'' vs. $\log \omega$ region, as proposed by Kendig and Mansfeld (12). Accordingly, our analysis is not restricted by the shape of the Z'' vs. $\log \omega$ correlation, but should be applicable to all impedance data, provided that the four general conditions for a valid impedance are fulfilled and that the integral in Eq. [5] can be evaluated. This then forms the basis for using Eq. [5] as a diagnostic criterion for determining the validity of impedance data.

Analysis of Experimental Data

In order to illustrate the application of the K-K transformation method for validating polarization resistance measurements in particular and for verifying impedance data in general, we consider three systems: TiO_2 -coated steel in a HCl/KCl solution of pH = 2 at 25°C, Al-0.1P-0.1In-0.2Ga-0.01Tl alloy in 4M KOH at 25°C, and pure aluminum (99.99%) also in 4M KOH at 25°C. The first system was

chosen because it is characterized by an extensive (Z' , Z'') vs. frequency data set that appears to satisfy the four conditions listed previously for a valid impedance. The second and third systems are included because aluminum corrodes rapidly in KOH solution, so that the condition of stability may not be satisfied. Furthermore, the third system exhibits characteristics that suggest the presence of experimental artifacts in the experimental impedance data. Accordingly, this system affords an opportunity to examine the sensitivity of the transform currently being considered to apparently "bad" data.

The complex plane plot for TiO_2 -coated carbon steel in HCl/KCl solution, pH = 2, at 25°C is shown in Fig. 1. The high frequency region exhibits a slope of $\sim \pi/4$, indicating that the interfacial properties are dominated by a mass-transfer process. At lower frequencies, the locus of data points curls over and ultimately intercepts the real axis at a frequency of less than 0.01 Hz. The measured polarization resistance is readily computed from the high frequency and low frequency intercepts as $R_p = 158.48 - 1.35 = 157.13 \Omega$. The experimental Z'' vs. $\log_{10} x$ (x = frequency in hertz) data are plotted in Fig. 2, and demonstrate that this system exhibits a single dispersed relaxation centered about $x = 0.58$ Hz. Also plotted on this figure are data calculated from the least squares piecewise fit of Eq. [6] to the experimental data. In this case, five segments were used, corresponding to one for $x < 0.58$ Hz and four for $x > 0.58$ Hz. The value of R_p calculated from the integral (Eq. [7]) was found to be 158.20 Ω which differs from the experimental value noted above by less than 0.7%. This error is of the same order (1-1.5%) as that found by transforming data calculated from equivalent electrical circuits; systems that we know *a priori* satisfy the conditions for a valid impedance. Thus, the observed error may be attributed principally to the algorithm itself.

In the second case Al-0.1P-0.1In-0.2Ga-0.01Tl alloy in 4M KOH at 25°C, (Fig. 3 and 4), both the complex plane and the Z'' vs. $\log_{10} x$ plots demonstrate the existence of resistive/capacitive and resistive/inductive relaxations at high and low frequencies, respectively. The data plotted in Fig. 4 were analyzed in three segments: A-B, B-C, and C-D. Agreement between the experimental data and that recalculated from Eq. [6] is clearly less exact in this case than in the previous one. Also, it was necessary to use much wider segments in the evaluation of the integral in Eq. [5]. The calculated R_p value was found to be 82.4 Ω compared with $90 \pm 5 \Omega$ obtained by extrapolating the

Fig. 4. Plot of Z'' vs. $\log x$ (x in hertz) for Al-0.1P-0.1In-0.2Ga-0.01Ti alloy in 4M KOH at 25°C under open-circuit conditions ($E = -1.76V$ vs. Hg/HgO). Dashed line: polynomial fit (Eq. [6]). Solid line: experimental data.

measured impedance to intercept the real axis in the limit of zero frequency. We believe that the difference is significant, and that it reflects not only an overall lower quality of data, as expected for a rapidly corroding system, but also a less extensive data set, particularly in the critically low frequency region. Nevertheless, the transform is quite satisfactory, considering the dubious fulfillment of the stability condition.

The final case considered in this paper (Fig. 5 and 6) was chosen because the system apparently exhibits a negative resistance at high frequencies and multiple intersecting loops at low frequencies. This latter characteristic is frequently observed experimentally, and is predicted

Fig. 5. Complex plane impedance plot for pure Al (99.99%) in 4M KOH at 25°C. $E = -1.56V$ vs. Hg/HgO. Numbers next to the experimental points are frequencies in hertz.

Fig. 6. Plot of Z'' vs. $\log_{10} x$ (x in hertz) for Al in 4M KOH at 25°C. $E = -1.56V$ vs. Hg/HgO. Dashed line: polynomial fit (Eq. [6]). Solid line: experimental data.

theoretically for certain dissolution reactions (12), so that verification that data of this type correctly transform is a matter of considerable interest. The negative resistance at high frequencies is almost certainly an experimental artifact, presumably arising from poor cell design. In carrying out the transformation, a three-segment (A-B, B-C, C-D, Fig. 6) integration was used to yield an R_p value of 7.55Ω. This value is significantly lower (by 18%) than the value of 9.2Ω obtained by extrapolating the high and low frequency arms to the real axis. Part of the difference may be due to the fact that the data were not obtained at a sufficiently low frequency to detect an inductive loop; note that the data point at 0.01 Hz does in fact lie below the real axis. However, a more likely explanation is that the real component of the impedance is distorted by some cause that results in the appearance of an apparent negative resistance at high frequency. Indeed, if it is assumed that the high frequency data intersects the real axis at the origin, then an experimental value for R_p of $8.2 \pm 0.5\Omega$ is obtained. This value is in much better agreement with that calculated above using the K-K transform.

Discussion

The analyses described above demonstrate that the Kramers-Kronig transform, as embodied in Eq. [5], is an accurate and convenient tool for assessing the validity of electrochemical impedance data.

From the present analysis, it is evident that the quality of electrochemical impedance studies depends heavily upon the size and accuracy of the experimental data set, as exemplified by the first example analyzed in this study. It is also apparent that pseudoinductive impedances (second case), and possibly those exhibiting intersecting loops (third case), also transform correctly, and hence may be regarded as valid characteristics of an observed impedance function. Finally, the transform apparently is sensitive to experimental artifacts that may, for example, lead to the distortion of one component; in the third case analyzed here, the distortion results in negative resistance at high frequencies. It is important to note, however, that the entire weight of the validation test afforded by Eq. [5] is placed on a knowledge of the real and imaginary components of the impedance over an effectively infinite frequency bandwidth. Since reliable impedance data for the low frequency region are not always available, considerable care must be exercised in applying Eq. [5] as a quantitative validity test. It is possible that more accurate and convenient validation analyses might be developed by considering the full set of K-K transforms, including Eq. [3] and [4], in order to de-emphasize the importance of the low frequency region. This possibility is currently being explored, and will be discussed in the second part of this series (16).

Acknowledgments

Financial support of this work from the Department of Energy and Eltech Systems, Incorporated, through Contract LNL-1806205, is greatly appreciated. The authors also thank Dr. M. C. H. McKubre for supplying data on TiO₂-coated carbon steel and Ms. Silvia Real for some of the experimental data for aluminum.

Anodic Oxide Growth on Aluminum in the Presence of a Thin Thermal Oxide Layer

Walter J. Bernard* and Steven M. Florio

Sprague Electric Company, North Adams, Massachusetts 01247

ABSTRACT

The presence of a thin film of thermal oxide on the surface of aluminum promotes the growth of additional crystalline (γ' - Al_2O_3) oxide during subsequent anodization in an aqueous phosphate solution. It was shown through the use of phosphorus-32 tracer and chemical thinning procedures that the anodic crystalline oxide is formed beneath a discrete, continuous layer of amorphous oxide, and that the original thermal oxide is incorporated in the anodic crystalline film. The concentration of phosphorus in the amorphous layer is greater than that which occurs in the absence of crystalline oxide. Evidence is given that the occluded phosphorus species has some ionic mobility in both oxides.

The anodic oxidation of aluminum in aqueous borate or phosphate solutions generally results in the growth of oxide films that appear amorphous by x-ray or electron diffraction. Under some conditions, however, these dielectric films may display some degree of crystallinity. For example, if the metal is treated with hot water before anodic oxidation to a high voltage in aqueous borate, a portion of the dielectric contains crystals of γ' - Al_2O_3 (1, 2). This has been studied in some detail. Low voltage films grown in citric acid after a boiling water treatment have also been shown to have a partial crystalline character (3).

Crystalline oxide growth may also be promoted by the use of a brief thermal oxidation prior to the anodic oxidation (4, 5). The thermal oxide, identified as γ - Al_2O_3 (6), has been shown (7, 8) to consist of small crystallites that nucleate below the pre-existing amorphous oxide, spreading laterally to cover the entire metal surface.

The presence of the thermal oxide modifies the mechanism of anodic oxidation so that the growth of additional crystalline oxide is promoted, and it may also affect the composition of the layers of oxide that comprise the overall complex film structure. That such compositional modification can be brought about by the presence of an existing film was shown (9) in the case of anodic oxidation of aluminum in an aqueous phosphate solution. When the surface is free of oxide the dielectric contains substantial amounts of phosphorus (10, 11), but when the foil is first covered with a hydrous oxide layer the subsequently formed anodic oxide is essentially free of phosphorus. One purpose of this study was to see if the thermal oxide behaves analogously.

The location of the thermal oxide during anodization may be conveniently observed by the use of a pretreatment of the foil in hot phosphoric acid containing ^{32}P . As a result of this treatment, the aluminum surface becomes covered with a monolayer of the acid (or other phosphate species). This phosphorus is retained during thermal oxidation, becoming incorporated into the thin thermal film and thereby acts as a marker during the following anodization. The location of the tagged thermal oxide may be determined by measuring the amount of residual ^{32}P during chemical sectioning of the composite films.

Further information on the mechanism of the reaction was obtained by carrying out the foil pretreatment in non-

radioactive phosphoric acid; in this case, the thermal step was followed by anodization in a radioactive solution of ammonium dihydrogen phosphate.

Experimental

The aluminum specimens were cut from 76 μm thick Alcoa foil of 99.99% purity. Prior to phosphoric acid treatment, the specimens were electropolished in a perchloric acid/acetic anhydride mixture for 150s at 10 mA/cm^2 , and then rinsed with distilled water and dried with acetone. This electropolishing procedure produces a smooth metal surface covered with a very thin ($<20\text{\AA}$) oxide film (12).

Carrier-free ^{32}P isotope was obtained from New England Nuclear as H_3PO_4 in water. A 2.0 mCi portion of this acid was incorporated into a 0.01M solution of H_3PO_4 ; a similar 0.01M H_3PO_4 solution without tracer was also prepared. A second 2.0 mCi portion of the radiolabeled acid was incorporated into a 0.01M solution of ammonium dihydrogen phosphate (ADP); a similar 0.01M ADP solution without tracer was also prepared.

Standards for determining activity were prepared by the uniform distribution of an aliquot (either 50 or 100 μliter) of the active solutions, in small droplets, over an area of aluminum equivalent to that used for counting experimental specimens. The phosphoric acid for these standards was neutralized with 0.01N NaOH before use. The foils were then dried at 60°C before counting.

For all radioactive specimens, a circular area of 7.9 cm^2 was measured with a Geiger-Müller counter. A tantalum mask, 0.76 mm thick, served to define the counting area. The aluminum foil itself was transparent to β -radiation emitted by ^{32}P , and hence both sides of the experimental samples were counted simultaneously.

Acid pretreatment was carried out in vigorously boiling solutions of 0.01M H_3PO_4 for 90s. These foils were then thoroughly washed with distilled water, dried with acetone, weighed, and counted when applicable. The weight changes for this step and all subsequent operations were determined with a digital microbalance. Specimens were oxidized in air at 600°C for 5 min, and then reweighed and counted.

After thermal oxidation, the active specimens were anodized in nonactive 0.01M ADP solution; foils that had been pretreated with nonradioactive H_3PO_4 , on the other hand, were anodized in ADP solutions containing the ^{32}P tracer.

*Electrochemical Society Active Member.

Anodizations were performed in glass-jacketed cells, using Teflon supports for platinized-platinum counter-electrodes. Stirring of the electrolyte was accomplished with a magnetically driven stirring bar. A constant-temperature liquid pumped through the cell jacket maintained the anodizing solution at $85^\circ \pm 0.2^\circ\text{C}$. The current density was 1.0 mA/cm^2 , and during the constant-voltage period it was allowed to decay to 0.05 mA/cm^2 .

Measurements of series capacitance, at 120 Hz, were made in a similar cell using aqueous ammonium borate at 25°C .

The distribution of radiotracer in the films was determined by dissolving the films stepwise in a stirred solution of 2% $\text{CrO}_3/5\% \text{H}_3\text{PO}_4$ at 65°C . This solution has been shown to attack amorphous Al_2O_3 uniformly at a moderately fast rate, with extremely little attack on the metal (13). However, the rate of attack on crystalline Al_2O_3 has been shown to be much slower (14, 15). As such, this procedure is effective for discriminating between the two types of oxide.

In addition to the determination of weight loss and residual radioactivity following the chemical sectioning steps, capacitance and remaining barrier voltage were obtained to give a measure of the film thickness. The barrier voltage was determined by applying a small constant current (i.e., 10% of the formation current density) in the original anodizing electrolyte, and observing the knee of the V-t curve. The point which is taken as V_b is the beginning of the constant slope corresponding to the calculated rate of new film growth. This is found by extrapolation of the straight line to the point of curvature, and is indicated by vertical lines on the tracings in Fig. 3. For short chemical treatment times, the break in the curve is satisfactorily sharp, and observations were reproducible to a volt or two. For longer periods, where film undercutting may occur, there is correspondingly less certainty in the value.

Results and Discussions

The amount of thermal oxide grown on aluminum depends on both the temperature and the reaction time. Crystalline oxide can be formed at temperatures as low as 450°C (6), but more complete coverage of the foil is achieved under more vigorous conditions; this, in turn, increases the amount of crystalline anodic oxide. Five minutes at 600°C gave satisfactory results for the work reported here.

Under the experimental conditions used, it is believed that after thermal treatment the oxide present on the metal surface is almost entirely crystalline. The exposure to dilute phosphoric acid serves to dissolve the natural amorphous oxide as well as to create an adsorbed layer of phosphate. The oxide-free aluminum is thus largely protected from regrowth of oxide until exposure to temperatures which permit the growth of crystalline oxide. This sequence of events is supported by weight measurements showing that the loss in weight during exposure to phosphoric acid corresponds to the removal of the original amorphous film; no substantial weight gain occurs until high temperature oxidation takes place. Only a small fraction of the resulting film is soluble in phosphoric acid. Details will be given in a future publication.

In the first series of experiments foil samples were treated with active H_3PO_4 , thermally oxidized, and then anodized in nonactive ADP. When these foils were subjected to the chemical sectioning procedure, the ^{32}P activity and oxide weight varied with time, as shown in Fig. 1.

The duplex nature of the anodic films can be deduced from these results. It is apparent from the weight loss curve that a soluble oxide is positioned above an insoluble layer, as shown by the abrupt reduction in weight loss after 2 min. The insoluble layer was identified by electron diffraction as $\gamma'\text{-Al}_2\text{O}_3$, confirming earlier reports (14, 16). In addition, the fact that only about 10% of the original activity is lost during chemical stripping shows that the bulk of the original adsorbed species has become a constituent of the insoluble crystalline oxide. This can only have come about by nearly complete incorporation

Fig. 1. Loss of activity and weight during chemical sectioning of 100V ADP films. Pretreated with active H_3PO_4 and then thermally oxidized.

of phosphorus in the thermal oxide that was grown at 600°C ; upon anodization this thermal oxide, which enhances the anodic growth of $\gamma'\text{-Al}_2\text{O}_3$, occupies the same location in the complex film as the thicker crystalline film.

It is not clear why the thermal oxide failed to tie up the entire layer of adsorbed phosphoric acid, allowing about 10% of the phosphorus to be removed during the early stage of the chemical sectioning. It might have been reasonable to expect the $\gamma'\text{-Al}_2\text{O}_3$ film to have sufficient mass to accommodate all the phosphorus available; using a density of 3.6 g/cm^3 (5) and an oxide weight of $5.7 \mu\text{g/cm}^2$, the film thickness is estimated to be about 160\AA .

The very small amount of phosphorus introduced as a marker has apparently no significant effect on the mechanism. From activity data, it was calculated that only about $0.035 \mu\text{g/cm}^2$ was present before thermal treatment, and that about $0.030 \mu\text{g/cm}^2$ remained in the final duplex oxide before chemical sectioning. These figures were essentially independent of the anodization voltage, as shown in Table I.

The curves of weight loss and residual activity do not show the limiting horizontal lines which would be anticipated for ideal behavior. This is most likely a result of the incompletely continuous nature of the crystalline oxide, which permits some degree of penetration and undercutting of the crystalline particles, followed by mechanical dislodging of these grains.

The curves in Fig. 2 provide further evidence for the layered structure of the dielectric film. Separate foil specimens were chemically stripped and reanodized to determine the amount of barrier remaining (V_b), as well as the capacitance of the remaining film. The shape of the V_b curve is similar to that of the weight loss curve of Fig. 1, and for a 100V film it indicates that about 35% of the original barrier consists of the easily soluble amorphous oxide. The remainder of the film appears to be largely crystalline, although the presence of an additional thin amorphous layer at the metal/oxide interface is likely (3), and is supported by the manner in which the crystalline

film may be undercut after extended chemical stripping. When carried out for sufficiently long periods, it was possible to observe minute particles of insoluble oxide suspended in the stripping solution.

Reanodization curves also demonstrate that the crystalline layer is not a completely impenetrable barrier, but consists, in part at least, of some defects and channels in which amorphous film is grown. A typical reanodization curve, shown in Fig. 3, demonstrates that a small but significant charge is required to refill gaps in the crystalline layer when chemical sectioning approaches the amorphous/crystalline interface. A 30s stripping (curve I) required only 6.8 mC/cm² to recharge the film to 97V, corresponding to 3.6% of the charge passed during the original formation to that voltage. A longer reaction time of 120s,

Fig. 3. Recorder tracings of reanodization of 100V ADP films chemically stripped for 30s (curve I) and 120s (curve II). Foils pretreated as in previous figures.

on the other hand, required the passage of 9.3 mC/cm² to reach the residual barrier level of 71V (curve II); in terms of anodization charge, this amounts to 6.6% of that needed to form a 71V film.

Figure 2 also shows the dependence of reciprocal capacitance on stripping time; a constant value of 1/C is reached after about 120s, the same point at which V_B becomes constant. The data in this plot represent measurements made immediately after reanodization, which gave stable reproducible values. If measured before reanodization, however, capacitances were unstable and fictitiously high, either through the dissolution of intergranular amorphous oxide, or because of some degree of dielectric instability revealed by the chemical treatment. This type of dielectric relaxation is commonly observed in high voltage films that have been formed in the presence of a hydrous oxide layer, but has also been observed with low voltage films of the type described here (2, 17).

The two forms of anodic oxide differ not only in their degree of crystallinity, but also in other properties. The growth constant (reciprocal field strength) of the crystalline layer is obviously greater than that of the amorphous film, and it should be possible to estimate its value from the curves in Fig. 2 and from the appropriate physical constants of the amorphous oxide, i.e., 14.8 Å/V¹ and ε = 8.5 (18).

The voltage across the crystalline film is 71V (assuming that there is only a negligible amount of amorphous oxide at the metal interface), while its reciprocal capacitance is only 54% of the total film. If its dielectric constant is 8.6, as reported (5), its growth rate is calculated as 7.2 Å/V. This suggests that the field in the crystalline oxide is much higher than has been reported previously; weight measurements, on the other hand, lead to different results. From the curve in Fig. 1, and using an oxide density of 3.61 g/cm³ (5) for the crystalline layer, the growth rate is calculated to be 9.2 Å/V, in good agreement with Alwitt and Takei (5).

These discrepant results could perhaps be reconciled if a higher value of ε for γ'-Al₂O₃ were used. In view of the relatively high values that have been published for polycrystalline aluminas—10.5 and higher (19)—it would not be surprising to find the value for γ'-Al₂O₃ to be somewhat greater than 8.6.

The second set of experiments involved the use of active phosphorus in ADP solution to tag the growing anodic film. The amount of phosphorus take-up (Fig. 4) was constant with formation voltage up to 150V, as was ob-

¹The cited paper reported 12.3 Å/V at a current density of 0.05 mA/cm² at 25°C. From this value, we have made an estimate of the thickness of the amorphous film at 85°C.

Fig. 4. Weight of phosphorus incorporated into films during anodization in active ADP. Foils previously treated with inactive H₃PO₄, followed by thermal oxidation.

Fig. 5. Loss of activity and weight during chemical sectioning of 100V films anodized in active ADP. Foils pretreated as in Fig. 4.

served earlier in films formed in the absence of a thermal oxide (10), but the distribution was quite different. Figure 5 shows the rate at which activity was lost in the chemical stripping solution; the rate of weight loss is also depicted, in good agreement with the previous independent set of measurements. The bulk of the phosphorus (about 65%) is in the outer amorphous layer, but a significant amount is incorporated in the crystalline film.

The concentration of phosphorus in the amorphous layer is influenced by the presence of the underlying crystalline material. When anodization conditions are chosen so that a fully amorphous oxide is grown, a 100V film has a [P] of 640 ng/cm² (20, 21). But since phosphorus is found only in the outer 70% of the film, where it is homogeneously distributed (10), the concentration may be better expressed as 9.1 ng/cm² for each volt of film. In the case of the duplex film described in the paper, however, the outer amorphous layer does not appear to be as homogeneous, judging from the absence of a sharp transition in the rate of activity lost during chemical sectioning, and the phosphorus concentration is much greater. From the activity data, it was calculated to be 19 ng/cm²-V or about twice that found in the conventional film. The crystalline portion of the film, on the other hand, has a [P] of only 4.4 ng/cm²-V.

These data suggest that the crystalline oxide acts as a conductor not only for aluminum ions during film growth, but also for oxygen and phosphate ions. The presence of phosphorus in that portion of the dielectric cannot come about by direct occlusion from solution as it does for the outer amorphous film, since the crystalline layer is never in contact with the solution once the first contribution to film growth by metal ion migration takes place. The results cannot therefore be reconciled to the picture of P as an inert marker, but rather as a film component with ionic mobility.

The difference in the phosphorus concentration in the amorphous and crystalline oxide forms can thus be attributed to its lower mobility in the γ' -modification. In the case of a wholly amorphous film, it was found (10) that

the rate of phosphorus incorporation from the advancing oxide/solution interface is constant at constant current density; the rate of phosphorus diffusion into the phosphorus-free region grown at the metal/oxide interface is such that a uniform distribution results in the outer layer of the duplex film. In the present case, however, because the diffusing ions encounter the environment of γ' -Al₂O₃ in which mobility is sharply reduced, the concentration in the amorphous layer is increased.

It is also significant that the total amount of phosphorus in the overall film structure is greater than the parallel case with an all-amorphous film, the figures being 950 and 640 ng/cm², respectively. This can be accounted for if the contribution to film growth by aluminum ion motion is greater in the presence of the crystalline film, since this would lead to greater growth at the electrolyte interface and increased inclusion of phosphate ion.

A more detailed description of the process—in particular, the transport numbers of the ions—is not justified by the available data. If the P species is not an immobile marker, the measurement of its profile in the outer layer alone cannot be used to estimate transport numbers. A concentration profile of P in the crystalline films by means other than chemical sectioning might do much to throw more light on the overall process.

Anodic Oxidation of Reductants in Electroless Plating

Izumi Ohno,¹ Osamu Wakabayashi,² and Shiro Haruyama

Tokyo Institute of Technology, Faculty of Engineering, O-okayama, Meguro-ku, Tokyo 152, Japan

ABSTRACT

The anodic oxidation of reductants (hypophosphite, formaldehyde, borohydride, dimethylamine borane, and hydrazine) was studied on different metal electrodes (Au, Pt, Pd, Ag, Cu, Ni, and Co) at various temperatures, with special interest in the catalytic aspect of electroless plating. The rate of the anodic oxidation strongly depended on the pH value, the concentration of reductants, and the nature of the metal electrode. The catalytic activities of the metals for the anodic oxidation of different reductants were evaluated by the potentials at a reference current density. The order of the catalytic activity with metal varied depending on the nature of the reductants. The catalytic activity series thus obtained can be utilized for choosing the reductant suitable for the metal to be deposited. Arrhenius plots of the anodic currents on different metals at a reference potential yielded their respective straight lines. Some correlations were observed between the catalytic activity and the activation energy. The catalytic activity series was discussed in connection with that for hydrogen electrode reaction.

It is widely accepted that electroless plating proceeds along the electrochemical mechanism as the simultaneous reaction of cathodic metal deposition and anodic oxidation of reductant (1-5). The electrochemical conditions for electroless plating taking place are, first, the oxidation potential of the reductant's being less noble to the reversible potential of the metal to be deposited, and, second, the metal's having enough catalytic activity for the anodic oxidation taking place with reasonable rate. The first condition can be readily provided by simple thermodynamic consideration. Therefore, the rate of anodic oxidation of the reductant is, in some sense, a dominant factor in electroless plating.

The reductants used in electroless plating have a special feature. A limited variety of reductants is used in an electroless process, e.g., hypophosphite, formaldehyde, borohydride, dialkylamine borane, and hydrazine. Electroless plating usually accompanies hydrogen evolution, the rate of which is not directly related to that of metal deposition. Different reaction mechanisms have been proposed to account for the hydrogen evolution during electroless plating: (i) the proton discharge mechanism (6, 7), (ii) the hydroxide mechanism (8, 9), and (iii) the hydride ion mechanism (10, 11) and atomic hydrogen mechanism (12, 13). It was found by Gorbunova *et al.* (14) and Holbrook *et al.* (15) that the hydrogen evolved during electroless plating was originated mainly from the reductant molecule. Electroless plating proceeds mostly on certain metals that are known to be hydrogenation-dehydrogenation catalysts. It was reported by Gorbunova *et al.* (16) and Pearlstein *et al.* (17) that the poison for hydrogenation catalysts such as thiourea and mercaptobenzothiazole functions as stabilizer in an electroless process.

Various reaction mechanisms were presented for respective electroless processes (18-25). It was suggested by several workers that the key step in the reaction is the dissociative chemisorption to form adsorbed atomic hydrogen and an adsorbed anion radical. Van der Meerakker (26) claimed that all the electroless plating processes can be explained by a universal mechanism with the dehydrogenation of the reductant as the first step, thus

where RH represents the reductants. Reactions [3] and [4] represent the recombination and ionization of adsorbed atomic hydrogen, respectively, which can occur in paral-

lel. Van den Meerakker also advocated that the catalytic aspect in electroless plating is originated from the catalytic property of the metal for reaction [3]. There are, however, only a few works on the anodic oxidation of the reductant in connection with the catalytic activity of the metal.

The aim of this paper is to establish the anodic oxidation behavior of the reductants on different metal electrodes with special interest in the catalytic activities of the metals in electroless plating.

Experimental Details

Polarization experiments were carried out on gold, platinum, palladium, silver, copper, nickel, and cobalt electrodes in the appropriate complex solutions containing sodium hypophosphite, formaldehyde, sodium borohydride, dimethylamine borane, and hydrazine, respectively. The standard compositions of the baths and the experimental conditions are summarized in Table I. Platinum, gold, and silver plates of surface area 0.4 cm² were used as the working electrodes. A platinum plate of the same surface area plated with the metal under investigation was also used as the working electrode. The counter-

* Dimethylamine borane.

electrode was a platinum plate of surface area 18 cm². The electrolytic cell was a Pyrex cylinder 5 cm in diameter and 8.5 cm in height. The potential of the working electrode was measured against a saturated calomel electrode (SCE) via a Luggin capillary and a salt bridge. Polarization measurements were made in potentiodynamic mode with a sweep rate of 0.002 V/s using an electronic potentiostat and a function generator. The experiments were carried out without agitation at 298.2 K unless otherwise noted. Some of the experiments were performed by using a rotating disk electrode. The rotating electrode was a platinum disk 0.3 cm in diameter plated with the metal under investigation. It was found, however, that the rotation of the electrode had no significant effect on the polarization behavior.

Results and Discussions

The anodic and cathodic reactions in electroless plating are more or less interdependent when they occur simultaneously (27, 28). The rate of the anodic oxidation of the reductant is in many cases accelerated in the presence of the cathodic deposition of the metal. As a first approximation, however, it can be assumed that the anodic polarization curve obtained in the absence of the metallic ion represents the true partial anodic reaction that would occur in the complete baths. In order to understand the catalytic aspect in electroless plating, the anodic polarization experiments were carried out on gold, platinum, palladium, silver, copper, nickel, and cobalt electrodes in the baths containing the reductants as listed in Table I. Similar polarization experiments were carried out in the baths in the absence of the reductant to distinguish the anodic current attributable to the dissolution of the metal.

Effect of pH and the concentration of reductant.—The rate of the anodic oxidation of the reductants increases with increasing either pH value or the concentration of the reductant. As the examples, the effects of the concentration on the anodic polarization curve of nickel in the solution containing hypophosphite are shown in Fig. 1. The polarization curves exhibit a maximum in current

Fig. 1. Current-potential curves of anodic oxidation of hypophosphite on nickel at different concentrations. Bath composition: 0.2M Na-citrate + 0.5M H₃BO₃ + NaH₂PO₂ (varied), pH 9.0, 343 K. Concentration of NaH₂PO₂ (mol/dm³): open circles, 0.40; open squares, 0.20; open triangles, 0.10; solid circles, 0.06; solid triangles, 0.03.

Fig. 2. Current-potential curves of anodic oxidation of hypophosphite on nickel at different pH values. Bath composition: 0.2M NaH₂PO₂ + 0.2M Na-citrate + 0.5M H₃BO₃, 343 K. pH: open circles, 9.5; open squares, 9.0; open triangles, 8.5; solid circles, 8.0; solid squares, 7.5; solid triangles, 7.0.

which increases with increasing the concentration. Although the depression of current after the maximum has been often attributed to the formation of an oxide film on surface, it occurs sometimes on noble metals and the depression potentials are mostly less noble compared to the reversible potentials for the oxide formation of the metals.

Figure 2 shows the effect of pH value on the anodic oxidation of hypophosphite on nickel. The current increases with increasing the pH value, shifting the current maximum to less noble potentials. The effects of the concentration of hypophosphite and the pH value on the anodic current at a fixed potential are summarized on logarithmic diagrams in Fig. 3 and 4, respectively. The slopes of the current-concentration diagram in Fig. 3 scattered between 0.44 and 0.80, depending on the nature of metal. The reaction orders with respect to hydroxyl ion were obtained from Fig. 3 to be approximately 0.25, except that for platinum (29).

Polarization experiments similar to those described above were carried out in the other baths shown in Table I. The dependencies of the current on pH value and the concentration of reductant in the other baths were very complicated, and the logarithmic plots of the relation similar to Fig. 3 and 4 did not exhibit a straight line (30, 31). Summarizing all the results, the reaction orders with respect to the reductants seem to scatter between 0.4 and 0.8, regardless of the natures of metal and reductant. The reaction orders regarding hydroxyl ion ranged from 0.2 to 0.4. Since the anodic oxidation of the reductants in the complex solutions is affected by pH in various ways, however, the apparent reaction orders may not be so helpful for the diagnosis of the reaction mechanism.

Effect of the nature of metals.—The polarization curves for the anodic oxidation of hypophosphite on different metals in sodium citrate solution are shown in Fig. 5. Anodic current attributable to the oxidation of hypophosphite was not observed on copper and silver electrodes, which simply dissolved anodically as indicated by the dotted line in Fig. 5. The polarization curve on palladium electrode exhibits a monotonous increase in current with

Fig. 3. Dependency of the anodic oxidation current at constant potential on the concentration of hypophosphite. Bath composition: 0.2M Na-citrate + 0.5M H_3BO_3 + NaH_2PO_2 (varied), pH 9.0, 343 K. Potentials (vs. SCE): $-0.80V$ (for Pd, Au, Ni, Co), $+0.20V$ (for Pt).

shifting the potential to noble direction. The polarization curve on gold shows three maxima of current, and the current falls off finally at around 0 V. The current on nickel electrode reaches a maximum at $-0.7V$ and falls off at $-0.4V$. Cobalt electrode dissolved anodically at the potentials noble to the current maximum. It is readily seen in Fig. 5 that platinum is less active for the anodic oxidation of hypophosphite.

Fig. 4. Dependency of the anodic oxidation current of hypophosphite on pH value. Bath composition: 0.2M NaH_2PO_2 + 0.2M Na-citrate + 0.5M H_3BO_3 , 343 K. Potential (vs. SCE): $-0.80V$ (for Au, Ni), $-0.70V$ (for Pd, Co), $+0.20V$ (for Pt).

Fig. 5. Polarization curves for the anodic oxidation of hypophosphite on different metals. Bath composition: 0.2M NaH_2PO_2 + 0.2M Na-citrate + 0.5M H_3BO_3 , pH 9.0, 343 K. Dotted line: current attributable to the anodic dissolution of Ag and Cu electrodes.

The polarization curves for the anodic oxidation of formaldehyde on different metals in a EDTA solution are shown in Fig. 6. Cobalt and nickel electrodes exhibit the anodic current attributable to oxidation of formaldehyde only at the potentials noble to 0.3V. The anodic current on copper starts to rise at $-0.95V$ and falls off at $-0.3V$, exhibiting a maximum in current. The polarization curves on gold, silver, platinum, and palladium electrodes obey the Tafel relation at less noble potentials, exhibiting a limiting current at noble potentials. The limiting current was scarcely affected by the rotation of the electrode.

Fig. 6. Polarization curves for the anodic oxidation of formaldehyde on different metals. Bath composition: 0.1M HCHO + 0.175M EDTA, 2Na, pH 12.5, 298 K. Dotted line: current attributable to the anodic dissolution of Cu and Co electrodes.

It is seen in Fig. 6 that the apparent oxidation potential of formaldehyde on copper is less noble than that on the other metals.

The polarization curves for the anodic oxidation of borohydride on different metals are shown in Fig. 7. Most of the polarization curves obey the Tafel relation exhibiting an asymptotic behavior at noble potentials, whereas those on cobalt and nickel electrodes show a current maximum.

Figure 8 shows the polarization curves for the anodic oxidation of dimethylamine borane on different metals. Copper electrode simply dissolved without exhibiting the current attributable to anodic oxidation of dimethylamine borane. The current maximum behavior was observed on nickel, cobalt, and platinum electrodes.

The polarization curves for the anodic oxidation of hydrazine on different metals are shown in Fig. 9. The polarization curves on cobalt and nickel show a maximum current behavior, whereas those on platinum, palladium, copper, gold, and silver exhibit well-defined Tafel lines.

Referring to the results shown in Fig. 5-9, it is seen that the shapes of the polarization curves can be classified into three categories: the Tafel type, the Tafel type with limiting current, and the volcano type. The limiting current has been attributed to a limited diffusion of reactant in solution, whereas it is less sensitive to agitation of solution. Occurrence of the volcano type of polarization curve has been often attributed to the formation of anodic oxide film on surface, although the potential of falling off of current is usually less noble than the reversible potential of oxide formation. It is highly probable that these polarization behaviors reflect the mechanism of anodic oxidation of reductants as such. It is also noted that electroless plating usually takes place at the potentials corresponding to the less noble branch of the polarization curves.

Effect of temperature.—The anodic polarization experiments similar to those described above are carried out on various metals and reductants at different temperatures. The Arrhenius plots of the currents on different metals at appropriate potentials for the anodic oxidation of hypophosphite, formaldehyde, borohydride, dimethylamine borane, and hydrazine are shown in Fig. 10, 11, 12, 13, and

Fig. 7. Polarization curves for the anodic oxidation of borohydride on different metals. Bath composition: 0.03M NaBH_4 + 0.175M EDTA.2Na, pH 12.5, 298 K. Dotted line: current attributable to the anodic dissolution of Co electrode.

Fig. 8. Polarization curves for the anodic oxidation of dimethylamine borane (DMAB) on different metals. Bath composition: 2.0 g/dm³ DMAB + 0.2M Na-citrate + 0.5M H_3BO_3 , pH 7.0, 298 K. Dotted line: current attributable to the anodic dissolution of Cu and Co electrodes.

14, respectively. The reference potential was so selected in the Tafel region at less noble potentials in Fig. 5-9 that the temperature dependency of the current on different metals could be evaluated on the basis of a common potential. Because of difference in the shape of polarization curves and in its temperature dependency, however, all the data on different metals could not be covered by

Fig. 9. Polarization curves for the anodic oxidation of hydrazine on different metals. Bath composition: 1.0M N_2H_4 + 0.175M EDTA.2Na, pH 12.0, 298 K.

Fig. 10. Arrhenius plots of the anodic oxidation current of hypophosphite at a reference potential. Bath composition: 0.2M NaH_2PO_2 + 0.2M Na-citrate + 0.5M H_3BO_3 , pH 9.0. Reference potential (vs. SCE): -0.80V (for Au, Pd, Ni, Co), $+0.20\text{V}$ (for Pt).

single reference potential. The apparent activation energies and the frequency factors obtained from Fig. 10-14 are summarized in Table II, together with the reference potentials. The activation energies (kJ/mol) hitherto published on the rate of electroless plating in the net electroless baths are 74.1 for NiP-hypophosphite (18), 49.0 for

Fig. 11. Arrhenius plots of the anodic oxidation current of formaldehyde at a reference potential. Bath composition: 0.1M HCHO + 0.175M EDTA.2Na, pH 12.5. Reference potential (vs. SCE): -0.70V (for Au, Cu), -0.65V (for Ag), -0.50V (for Pt), -0.35V (for Pd), 0.40V (for Ni), 0.45V (for Co).

Cu-formaldehyde (32), 44.4-64.0 for NiB-dimethylamine borane (33), 80 for Au-borohydride (22), and 66.5 for Co-hydrazine (34). The activation energies for the anodic oxidation of reductants shown in Table II seem to be appreciably low in comparison with those for the rate of electroless plating in the net electroless baths, probably because the latter values involve the temperature depend-

Fig. 12. Arrhenius plots of the anodic oxidation current of borohydride at a reference potential. Bath composition: 0.03M NaBH₃ + 0.175M EDTA.2Na, pH 12.5. Reference potential (vs. SCE): -0.95V (for Pt, Pd, Ni, Co), -0.70V (for Au, Ag, Cu).

encies of the rate of cathodic metal deposition and of the dissolution equilibrium of complex ion.

Hydrogen evolution during anodic oxidation of reductant.—Before the polarization experiments start, evolution of hydrogen gas was observed on some electrodes at open-circuit condition, especially in the solutions containing either hypophosphite or borohydride or dimethylamine borane. With shifting the potential to noble potentials, however, hydrogen evolution on cobalt, nickel, palladium, and platinum electrodes decreased and finally ceased. Therefore, it is probable that the hydrogen evolution in open circuit is attributable to the cathodic proton discharge under mixed potential control, thus

On the other hand, the rate of hydrogen evolution on copper, silver, and gold electrodes increased with shifting the potential to noble direction, regardless of the nature of the reductant. This means that the reductants are anodically oxidized on copper, silver, and gold electrodes accompanied by evolution of hydrogen gas that is originated from the reductant molecule. Accordingly, it is likely that the anodic oxidation of the reductants proceeds mainly along the hydrogen evolution mechanism on copper, silver, and gold, and the hydrogen ionization mechanism predominates on cobalt, nickel, palladium, and platinum.

Catalytic activity of the metal.—As is shown in Fig. 5-9, the shape of the polarization curves of anodic oxidation of the reductants varies in a complicated way depending on the natures of metals and reductants, probably because of complexity in reaction mechanism. Therefore, it seems difficult to evaluate the catalytic activity of the metal for respective reductants on the basis of a unified theoretical standard. As a first approximation, however, it can be assumed that the catalytic activities of the metals are char-

Fig. 13. Arrhenius plots of the anodic current of dimethylamine borane (DMAB) at -0.55V (vs. SCE). Bath composition: 2.0 g/dm³ DMAB + 0.2M Na-citrate + 0.5M H₃BO₃, pH 7.0.

acterized by the potential at a reference current density on the polarization curves shown in Fig. 5-9. The characteristic potentials at 1.0×10^{-4} A/cm² are summarized in Fig. 15. The oxidation-reduction potentials of the reductants and the reversible hydrogen potentials in respective solutions are also indicated in Fig. 15.

Fig. 14. Arrhenius plots of the anodic oxidation current of hydrazine at a reference potential. Bath composition: 1.0M N₂H₄ + 0.175M EDTA.2Na, pH 12.0. Reference potentials (vs. SCE): -0.75V (for Pt, Pd, Ni, Co), -0.50V (for Au, Ag, Cu).

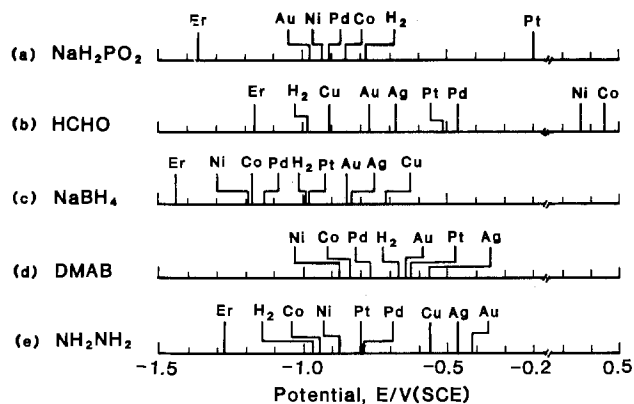

Fig. 15. Catalytic activities of metals (the potentials at 10^{-4} A \cdot cm $^{-2}$), for anodic oxidation of different reductants. E_r : oxidation-reduction potentials of reductants. H_2 : reversible hydrogen potentials. Conditions: (a) 0.2M NaH $_2$ PO $_2$ + 0.2M Na-citrate + 0.5M H $_3$ BO $_3$, pH 9.0, 343 K; (b) 0.1M HCHO + 0.175M EDTA.2Na, pH 12.5, 298 K; (c) 0.03M NaBH $_4$ + 0.175M EDTA.2Na, pH 12.5, 298 K; (d) 2.0 g/dm 3 DMAB + 0.2M Na-citrate + 0.5M H $_3$ BO $_3$, pH 7.0, 298 K; (e) 1.0M N $_2$ H $_4$ + 0.175M EDTA.2Na, pH 12.0, 298 K.

It can be seen in Fig. 15 that the catalytic activity of the metals for the anodic oxidation of different reductants decreases in the following order, respectively: Au, Ni, Pd, Co, and Pt for hypophosphite, Cu, Au, Ag, Pt, Pd, Ni, and Co for formaldehyde, Ni, Co, Pd, Pt, Au, Ag, and Cu for borohydride, Ni, Co, Pd, Au, Pt, and Ag for dimethylamine borane, Co, Ni, Pt, Pd, Cu, Ag, and Au for hydrazine. Although there is no simple rule governing these orders, it is noted that the order of the catalytic activity for borohydride is almost the same as that for dimethylamine borane. This fact seems to imply that the anodic oxidation of these two boron containing reductants involve the same adsorbed intermediate in the rate determining step as was suggested by Okinaka (3). It must be also pointed out that copper, silver, and gold are very active for the anodic oxidation of formaldehyde, whereas they are less active for the other reductants.

The requisite kinetic condition for the electroless plating taking place with a reasonable rate is the characteristic potentials being less noble to the reversible potential of the metal to be deposited. According to this approach, Fig. 15 can be utilized for choosing the reductant suitable for electroless process of respective metals. Since the reversible potentials of metals in the complex solutions that are utilized in electroless processes are mostly in the range from -0.65 to -0.45 V (SCE) (35, 36), it is said that the reductants available for depositing the metals are hypophosphite for Au, Ni, Pd, and Co, formaldehyde for Cu, Au, Ag, (Pt), and (Pd), borohydride for Ni, Co, Pd, Pt, Au, Ag, and (Cu), dimethylamine borane for Ni, Co, Pd, and (Pt), and hydrazine for Co, Ni, Pt, Pd, and (Cu). It can be seen that borohydride can be utilized for the electroless process of most metals and formaldehyde is substantially the only reductant which can be used in high speed electroless copper process. Such speculations based on Fig. 15 are in accord with the conventional usage of the reductant in electroless process.

The characteristic potentials at 1.0×10^{-4} A/cm 2 are listed in Table II, together with the activation energies. The activation energies are plotted against the characteristic potentials in Fig. 16. For the anodic oxidation of hypophosphite and dimethylamine borane, the characteristic potential shifts, except for platinum, to noble potentials with increasing the activation energy. Somewhat similar correlation is observed on hydrazine. Although the physical meaning of the activation energy is not clarified yet, the observed parallelism between the catalytic activity and the activation energy is quite acceptable from the usual understanding of chemical reaction. On the other hand, the correlation as described above is not observed for borohydride and formaldehyde. The activation energies for borohydride and formalde-

Fig. 16. Relation between activation energies and the potentials at 10^{-4} A \cdot cm $^{-2}$.

hyde scatters around 42 and 30 kJ/mol, respectively, regardless of the nature of metal.

Since the electroless plating accompanies hydrogen evolution originated from the reductant molecule, the catalytic nature in electroless plating has been often discussed in connection with that in hydrogen electrode reaction (12, 13, 16). According to Van den Meerakker (26), the anodic oxidation of the reductant proceeds along four elementary steps: dissociative adsorption, anodic oxidation of adsorbed radical, and recombination and/or ionization of adsorbed hydrogen. Namely, the adsorbed atomic hydrogen formed by dissociative adsorption of reductant is removed by either recombination or ionization, as similar with that in hydrogen electrode reaction. It is known (37) that the exchange current density of hydrogen electrode reaction decreases in the following order with metal: Pt, Pd, Ni, Co, Cu, Ag, and Au. It is probable that the anodic oxidation of the reductants proceeds mainly along the hydrogen evolution mechanism on copper, silver, and gold electrodes which are less active for hydrogen electrode reaction. Thus, it seems likely that the preferential reaction path for removing the adsorbed atomic hydrogen is related to the activity of metal for hydrogen electrode reaction. However, there is no simple correlation between the order of catalytic activity with metal for hydrogen electrode reaction and that for the anodic oxidation of the reductants. Therefore, it is not likely that the rate of anodic oxidation of the reductants is controlled by the removal of the adsorbed hydrogen. Much attention should be focused on the electrochemical step for removing the adsorbed anion radical.

Summary

The catalytic activity of metals for the anodic oxidation of different reductants in electroless plating was evaluated by the potentials at a reference current density. The catalytic activity series thus obtained serve to choose the reductant suitable to the metal to be deposited. Some correlations were observed between the catalytic activity and the apparent activation energy.

It is suggested that the anodic oxidation of the reductants proceeds mainly along hydrogen evolution mechanism on copper, silver, and platinum, whereas the hydrogen ionization mechanism predominates on cobalt, nickel, palladium, and platinum. It is found, however, that the catalytic activity series of metal for anodic oxidation of reductants does not coincide with that for hydrogen electrode reaction.

ABSTRACT

The electrodeposition of Cu from aqueous $\text{CuSO}_4\text{-H}_2\text{SO}_4$ electrolyte onto a high resistance moving substrate has been studied. Substrate speeds of 0.5-2.0 cm/s, average current densities of 12-50 mA/cm², input Cu thicknesses of 0.1-0.5 μm , and cell depths of 30-74 cm were employed. Measured Cu metal thickness distributions showed good agreement with those predicted by a steady-state "terminal effect" model.

The production of printed circuits by additive methods (1) is initiated by the electroless deposition of a thin (0.1 μm) conductive coating of Cu onto an insulating substrate. This coating may be patterned (1) or may be a uniform deposit over the dielectric. The thickness of this coating can then be increased to practical values (ca. 35 μm) by electrodeposition of Cu. The patterned electroless coating may be built up by electrodeposition (if the pattern is continuous) or by high speed electroless plating. The unpatterned electroless deposit will most often be used as a cathodic connection for pattern electrodeposition through a plating mask. The latter process is usually referred to as "semiadditive" plating.

Additive production methods permit an inventory of Cu metal which is smaller than that required by standard printed-circuit production methods, where the starting material is (typically) an insulating substrate clad with 35 μm thick Cu foil. The additive printed-circuit production method minimizes reliance on etching processes, which thereby enhances the process capability for definition of fine-line patterns.

Continuous or semicontinuous production of flexible printed circuits may be carried out by passing a sheet of substrate material through a series of processing tanks, using rollers to guide the substrate along its desired path.

*Electrochemical Society Active Member.

A schematic diagram of the electrodeposition portion of such a continuous processing machine is illustrated in Fig. 1. Electrodeposition apparatus similar to that shown might be expected to increase the thickness of the Cu deposit from 0.1 to 5 μm . The apparatus, with dimensions as shown in Fig. 1, accommodates substrate speeds of 1-5 cm/s in order to be compatible with the remainder of the additive process. Economic constraints dictate that the apparatus should be compact and have the capability of operating at high current densities.

Previous studies by D'Amico *et al.* (2) showed that practical current densities in the electrodeposition apparatus (Fig. 1) were well below mass-transfer-limited values. Measurements of Cu thickness distributions indicated that this limitation was a consequence of highly nonuniform current distributions; the local current density was a strong function of axial position of the substrate in the apparatus. This highly nonuniform current density distribution was attributed to the so-called "terminal effect" (3), caused by the relatively high resistance (small Cu thickness) of the substrate on which the Cu metal is electrodeposited. Another source of nonuniform current distribution is the uneven division of current between different loops of Cu-clad substrate connected to one or more metallic rollers that are held at the same cathodic potential. Proportionately more current is distributed to sub-

Fig. 1. Schematic diagram of a continuous, multipass electrodeposition apparatus. The five top rollers (stainless steel) are parallel-connected cathodes. The (hanging) copper bars are parallel-connected anodes. A side view of the complete apparatus is shown. A plan view of a single section is similar to that presented in Fig. 2. All dimensions are in centimeters.

strate loops with thicker Cu deposits; *i.e.*, higher currents are observed closer to the location where the substrate exits the electrodeposition apparatus. D'Amico *et al.* evaluated several designs that provided more even current density distributions, including "field shields," additional cathode connections located within the electrolyte phase, and shorter loops near the location where the substrate enters the electrodeposition apparatus.

The purpose of the present work is to apply basic models of current density distribution to evaluate measured Cu deposit thickness variations in a pilot-scale continuous electrodeposition apparatus. It is expected that these models can be used as a predictive basis for the design of full-scale electrodeposition equipment employed in the production of printed circuits by additive methods.

Other investigators have studied the problem of non-uniform current density distribution during electrodeposition onto a substrate of high ohmic resistance. Both steady-state (3) and transient (4) analyses of the current density distribution on resistive, stationary plane-parallel electrodes have been performed, and the transient current density distribution on a resistive, stationary wire electrode has been studied (5). The problem of nonuniform current density distribution during electrodeposition onto a moving wire electrode of high ohmic resistance has been analyzed (6, 7). Both steady-state (8) and transient (9) analyses of forced-convection mass transfer to a moving sheet electrode of negligible resistance have been performed. None of these investigations has studied the problem of nonuniform current density distribution along resistive, moving plane-parallel electrodes.

Experimental

Electrodeposition apparatus.—Copper electrodeposition was carried out in the "single-pass" cell shown in Fig. 2. This cell is intended to model a single loop of a "multipass" apparatus, such as that shown in Fig. 1. The anodes were 0.64 cm thick, 15.2 cm wide oxygen-free, high conductivity Cu sheets of various lengths. The 6.5 cm wide, 0.05 mm thick polyimide (du Pont Kapton®) flexible substrate material, initially coated with a 0.1-2.5 μm layer of Cu (unpatterned), passed over 3.5 cm diam stainless steel rollers, which served not only to guide the substrate through the cell, but also to make electrical contact to the substrate. Electrical connection to the substrate on the side not in contact with these rollers was made through numerous Cu-plated through-holes in the

Fig. 2. Schematic diagram of electrodeposition cell. A side view of the cell is shown in the lower portion of the figure, and a plan view of the cell is shown in the upper portion of the figure. All dimensions are in centimeters.

substrate, as described previously in Ref. (2). Anode/cathode spacings were 1.9 and 5.7 cm, as shown in Fig. 2. A mean electrode separation of 3.8 cm was employed in the subsequent analysis. Average electrolyte flow velocities were 2.8-3.8 cm/s.

Electrolyte.—The electrolytes used were acid copper sulfates, having compositions and conductivities as listed in Table I. Electrolytes I and II were proprietary compositions, Cubath I® and Cubath II® supplied by Sel-Rex Company (Nutley, New Jersey). Electrolyte III was a 50-50 (volume percent) mixture of I and II. In addition to the sulfate ingredients listed, these baths contained trace amounts of electroplating additives, including 30 ppm Cl^- . These additives are expected to have little effect on the electrolyte conductivity.

The conductivities reported in Table I were measured with a direct reading conductance bridge (Industrial Instruments, Incorporated) at 1 kHz. The conductance cell was platinum-glass, with a cell constant of 1.0 cm^{-1} . Measurements were made at 22°-24°C in reagent-grade $\text{CuSO}_4 \cdot \text{H}_2\text{SO}_4$ mixtures. The conductivity of electrolyte III was not measured, so an interpolated value $\kappa = 0.319$ was used in subsequent calculations.

Table I. Electrolyte properties

Electrolyte	Concentrations (mol/liter)		Conductivity ($\Omega^{-1}\text{-cm}^{-1}$)
	CuSO_4	H_2SO_4	
I	0.27	1.76	0.475
II	0.90	0.57	0.162
III	0.59	1.17	—

The electrolyte temperature was maintained at 22°–25°C, and it was continuously pumped through polypropylene and carbon filters in a recirculation loop. The electrolyte composition was monitored by periodic measurement of Cu^{2+} , pH, and Cl^- . Electrolyte losses due to water evaporation and mechanical loss (*i.e.*, the small amount of electrolyte that adhered to the substrate) were compensated for by periodic additions of H_2O , CuSO_4 , H_2SO_4 , and/or HCl, as necessary.

Electrodeposition experiments.—Electroless Cu-clad substrate was passed through the electrodeposition cell shown in Fig. 2. After setting the substrate speed and cell current, the cell was operated for an interval corresponding to three to four times the substrate residence time within the electrolyte, in order to assure that steady-state conditions were reached. The cell circuit was then opened and the substrate movement was simultaneously halted. The two locations where the substrate rested at the top of the stainless-steel rollers were marked on the substrate, and the substrate was then fed out of the cell at 3 cm/s. This procedure resulted in an open-circuit residence time within the electrolyte of not more than 1 min. Other experiments showed that during a 1 min interval, not more than 0.01 μm of Cu would be etched by the $\text{CuSO}_4/\text{H}_2\text{SO}_4$ electrolyte. This amount of etching could create errors as high as 10% (near the entrance to the cell) in subsequent determinations of Cu thickness.

Copper thicknesses were determined by weighing the deposited metal. The substrate was cut in to 3.2 cm long specimens, which were then weighed on a Mettler H-15 balance (accuracy of approximately 0.1 mg). The specimens were then dipped in dilute HNO_3 solution to remove the Cu metal, and the substrate was dried and reweighed to arrive at the net weight of Cu metal. The weight of the 3.2 cm long Cu-free substrate was 135 mg. The standard bulk Cu density of 8.93 g/cm^3 and the measured specimen area of 40 cm^2 (both sides) was used to calculate the average Cu metal thickness on the specimen.

Analysis

A complete analysis of the electrodeposition cell used in this study would necessarily consider the interrelated electric-field, kinetic, hydrodynamic, and mass-transfer effects, as well as the spatially and temporally variable ohmic resistance of the cathode substrate. However, consideration of the conditions that exist in a continuous electrodeposition cell suggests that the following approximations may be made (refer to the cell geometry shown in Fig. 3). (i) The anode/cathode separation is typically much smaller than the depth and width of electrodes, so the primary current density distribution (in the limiting case where the cathode substrate resistance is zero) is fairly uniform. (ii) The electrolyte is continuously agitated by pumping, so that concentration and temperature gradients within the cell are relatively small. Mass-transfer limiting conditions are not approached anywhere in the cell. (iii) The net thickness change ($\leq 35 \mu\text{m}$) of electrodeposited metal in a multiloop electrodeposition apparatus (Fig. 1) is much smaller than the anode/cathode separation. Therefore, provided that electrodeposition conditions lead to a uniformly smooth metal deposit, the anode/cathode separation is constant. (iv) The net Cu electrodeposit thickness change (0.5–5 μm) over the cathode substrate length L (which corresponds to one-half of a loop in a multiloop electrodeposition apparatus) is small relative to the local electrodeposit thickness (0.1–35 μm). This approximation is most likely to be valid near the exit of the electrodeposition apparatus where the metal deposit is relatively thick, and it is least likely to be valid near the entrance to the device where the metal deposit is relatively thin. However, it has been shown (2) that it is appropriate to use lower currents and shorter loops (smaller values of L) where the metal deposit is relatively thin, which leads to a smaller net Cu electrodeposit thickness change per loop near the entrance to the device. This approximation permits the effective resistance of the

Fig. 3. Cell coordinate system

cathode substrate to be defined by a single value that is characteristic of the average (*i.e.*, averaged over the Z-direction) thickness of the Cu deposit at some location $0 \leq x \leq L$. (v) Because the Cu metal is either shielded (upward facing side of the cathode substrate) or remote (downward facing side of the cathode substrate) from the anodes, little metal deposition (or dissolution) occurs as the cathode substrate passes around the lower guide roller ($x > L$). (vi) Negligible rates of metal deposition (or dissolution) occur after the cathode substrate leaves the electrolyte phase and enters air. (vii) The electrode kinetics for Cu electrodeposition on the cathode substrate and Cu electrodisolution from the anode may be described by linear expressions. This should be a good approximation if the cell design leads to a fairly uniform current density distribution, because even if the levels of current density correspond to operation in the Tafel region, the Tafel expression can be linearized if there are only small excursions from average current density values. (viii) The electrodeposition process is 100% efficient, *i.e.*, there are no side reactions such as H_2 evolution. (ix) Steady-state conditions prevail.

By making the nine approximations listed above, it is possible to treat each half-cell as a classical steady-state "terminal effect" problem, solved by Tobias and Wijnsman (3). They found the current density distribution to be a strong function of a single parameter ϕ (defined in Eq. [2]), that represents the ratio of the electrode resistance to the electrolyte resistance, and identified conditions under which a simplified model could be applied. Their results show that the simplified model can be used when $d/L < 0.1$, $(\lambda_o + \lambda_a)$ is not $\gg 1$, and $(\mu_o + \mu_a)$ is not $\gg 1$. For the conditions employed in the present work, $0.05 < d/L < 0.12$, $0.04 < (\lambda_o + \lambda_a) < 4.0$, and $0.02 < (\mu_o + \mu_a) < 0.06$. Even when $d/L = 0.12$, the computed results shown in Fig. 10 of Ref. (3) suggest that the simplified model will predict values of local current densities that fall within about 2% of those calculated for the exact solution, $0.05 < x/L < 1$. The simplified model is easier to apply than the exact model, and it thereby permits rapid estimation of the current density distributions that will result from various designs of the electrodeposition apparatus. The simplified Tobias-Wijnsman model can now be ap-

Fig. 4. Dimensionless current per unit cathode substrate width for various values of the parameter ϕ .

plied directly. The dimensionless current J per unit width (in the Z -direction) of Cu is given by

$$J(X) = 1 - \frac{\sinh[\phi(1 - X)]}{\sinh \phi} \quad [1]$$

where

$$\phi^2 = \frac{\rho_e \kappa L^2}{T(d + 2\kappa b)} \quad [2]$$

is a parameter related to the ratio of the X -direction potential gradient in the resistive cathode substrate to the potential gradient in the electrolyte phase. The corresponding local current density distribution is given by

$$\frac{i(X)}{i_{avg}} = \phi \frac{\cosh[\phi(1 - X)]}{\sinh \phi} \quad [3]$$

Fig. 5. Dimensionless current density distributions for various values of the parameter ϕ .

Equations [1] and [3] are plotted in Fig. 4 and 5, respectively, for various values of the parameter ϕ . Small values of ϕ correspond to uniform local current densities and a linear variation of J vs. X . Large values of ϕ correspond to nonuniform local current densities and a nonlinear variation of J vs. X .

The local Cu metal thickness can be related to the local current density through Faraday's law

$$T(x) = T(0) + \frac{M}{nF\rho v} \int_0^x i(x) dx \quad [4]$$

or it may be equivalently related to the current per unit width (in the Z -direction) of Cu

$$T(x) = T(0) + \frac{M}{nF\rho v} j(x) \quad [5]$$

Equations [1] and [5] can be combined to predict the axial distribution of Cu metal thickness in the electrodeposition cell.

Results and Discussion

Electrolyte composition, loop depth, substrate speed, cell current, average cathodic current density, and entering Cu deposit thickness are listed for ten separate experiments in Table II. The measured steady-state axial Cu thickness distributions are shown as the filled circles in Fig. 6-10.

Fig. 6. Axial Cu thickness distributions. Lower abscissa: distance along cathode substrate (cm). Upper abscissa: dimensionless axial distance x/L . Left ordinate: Cu thickness (μm). Right ordinate: dimensionless Cu thickness $J(X)$. Dashed line: dimensionless thickness distribution $J(X)$, computed using the Cu thickness at the lower guide roller location $x = L$ to calculate the effective substrate resistivity ρ_e . Solid line: dimensionless thickness distribution $J(X)$, computed using the Cu thickness where the substrate enters the electrolyte (for the portion of the solid curve to the left of the inflection point), or where the substrate leaves the electrolyte (for the portion of the solid curve to the right of the inflection point). Solid circles: measured axial Cu thickness distributions. The experimental parameters employed for the data shown in the upper half (A) and lower half (B) of the figure are listed in Table II.

The Cu deposit resistivities were measured using the standard four-point probe method. Strips 1.27 cm wide and 15.2 cm long were cut from sections of the plated substrate, and their resistances were measured on a special fixture designed to accommodate these specimens. The copper thickness of the same specimens was then determined using the weighing method previously described. This method requires that the deposit density be known, and the literature value for electrolytic copper was used for both electroless and electroplated Cu. The density of electroless Cu is reported (10) to be only a few percent lower than that of electrolytic Cu.

Electroplated Cu deposit resistivity ρ_e was 2.0×10^{-6} Ω -cm, which is close to the literature value of 1.8×10^{-6} Ω -cm. Electroless Cu deposit resistivity was three times higher, 6.0×10^{-6} Ω -cm. The linear polarization parameter $b = 1.3$ Ω -cm² was estimated by linearizing Cu electrode kinetic data, reported by Turner and Johnson (11), about the average cathode current density. The use of a single polarization parameter will not account for asymmetry of the anodic and cathodic polarization curves, nor will it apply when there are large variations in local current density [see approximation (*vi*) above]. However, the effect

Fig. 7. Axial Cu thickness distributions. Designations are identical to those listed in the caption for Fig. 6.

Fig. 8. Axial Cu thickness distributions. Designations are identical to those listed in the caption for Fig. 6.

of electrode kinetics on the current density distribution is expected to be relatively small. This effect can be estimated from the magnitude of the last term in the denominator of Eq. [2]; even if this term is neglected, there results only a 5-15% error in the value of ϕ , which corresponds to a similar error in the associated current density distribution Eq. [3]. The assumption that both the anode and cathode exhibit the same linear electrode kinetic behavior, which is consistent with the assumptions made in the derivation of Eq. [2], is therefore expected to lead to small errors in calculated current density distributions and metal thickness distributions. Values of the computed dimensionless parameter ϕ ranged from 0.7 to 6.0.

Computed dimensionless thickness distributions $J(X)$ are plotted as the dashed and solid curves in Fig. 6-10. The dashed curves correspond to the value of ϕ calculated using the measured Cu deposit thickness at the bottom guide roller. The solid curves to the left of the inflection points correspond to the value of ϕ calculated using the measured Cu deposit thickness on the substrate as it enters the electrolyte [*i.e.*, $T(0)$ listed in Table II]. The solid curves to the right of the inflection points correspond to the value of ϕ calculated using the measured Cu deposit thickness on the substrate as it leaves the electrolyte. The solid and dashed curves therefore represent extremes of effective cathode substrate resistivity along a single half-loop. The spread between the solid and dashed curves indicates the uncertainty associated with employing a single value of Cu deposit thickness to characterize the effective resistance of the cathode substrate.

Fig. 9. Axial Cu thickness distributions. Designations are identical to those listed in the caption for Fig. 6.

Fig. 10. Axial Cu thickness distributions. Designations are identical to those listed in the caption for Fig. 6.

For example, the large spread between the solid and dashed curves to the left of the inflection point on Fig. 9B suggests that the use of a single value of Cu deposit thickness to compute a characteristic value of ϕ may lead to considerable error. In this case, the experimental parameters give rise to an increase in Cu deposit thickness from 0.08 to 0.55 μm , which violates the conditions leading to approximation (iv). The failure of the present analysis to accurately predict the measured axial Cu thickness distribution to the left of the inflection point in Fig. 9B is, therefore, not unexpected.

Another case where the predicted axial thickness distributions do not agree well with the measured distributions is in Fig. 8B, where the measured thickness distribution is more uniform than that predicted. Note that a relatively high average current density of 41.5 mA/cm^2 was employed with the low Cu^{++} -concentration electrolyte, and a discolored ("burned") Cu electrodeposit was observed near the location where the substrate exits the cell. These observations suggest that mass-transfer limiting conditions were approached, which violates approximation (ii). Again, therefore, it is not surprising that in Fig. 8B the measured axial thickness distributions do not agree well with those predicted.

Figures 6-10 show that the "terminal-effect" model provides a good basis for predicting axial metal thickness distributions (and the associated current density distributions Eq. [4]) under a range of electrolyte compositions, cell depths, substrate velocities, average current densities, and initial Cu thicknesses. The uniformity of current density distribution (linearity of Cu thickness distribution) is enhanced by: (i) more shallow loops (cf. Fig. 7A and 10A), (ii) thicker initial Cu deposits (cf. Fig. 6B and 7B), (iii) slower substrate speeds (which leads to thicker Cu electrodeposits) (cf. Fig. 7A and 7B), (iv) higher average current densities (which leads to thicker Cu deposits) (cf. Fig. 9A and 9B), and (v) lower electrolyte conductivity (see Eq. [2]).

Conclusions

The steady-state "terminal effect" model has been shown to provide a good basis for the prediction of axial metal thickness distributions along a resistive cathode substrate in a continuous electrodeposition cell. Good agreement between predicted and measured thickness distributions is found for a wide range of experimental parameters; for example, the dimensionless parameter ϕ ranged from 0.7 to 6.0. These results indicate that the current density distribution is typically determined by the value of ϕ , which includes several factors: ohmic potential drop in the resistive cathode, ohmic potential drop in the electrolyte, kinetic overpotential at the electrodes, and cell geometry. Other factors, such as the concentration overpotential, are of secondary importance. Conditions leading to cases where the model may not apply have been identified; these conditions can correspond to cell designs and operating parameters (e.g., those leading to local mass-transfer limiting currents) that can produce electrodeposited metal exhibiting undesirable properties.

Electrochemical Production of Potassium Carbonate

F. Hine,* M. Yasuda,* Y. Ogata, and T. Kojima

Nagoya Institute of Technology, Nagoya 466, Japan

ABSTRACT

Direct production of potassium carbonate by electrolysis of potassium chloride solution with the membrane cell was studied. The current efficiency was high since the hydroxyl ion concentration in the cathode compartment was low, resulting in minimum back-migration of OH^- through the membrane. The reduction of the cell voltage is discussed in some detail. The anode and cathode materials having low overvoltages were studied, and Nafion 423 was used as the separator. The operation of a separate reactor for carbonating the catholyte liquor is also described briefly.

Although the production capacity and the market of caustic and carbonate potash are small in comparison with the soda products, they are still important chemicals. Potassium carbonate is produced only by absorption of carbon dioxide with caustic potash, and there is no direct route from chloride such as the Solvay process for making soda ash because of the large solubility of potassium carbonate: 127g/100g H_2O compared to 46g/100g H_2O of Na_2CO_3 at 60°C (1).

Caustic potash is produced by electrolysis of potassium chloride solution. However, the current efficiency of the membrane cell is said to be low somewhat caused by small transport number of K^+ in the membrane compared to the case of NaCl electrolysis (2).

There are several publications on the electrolytic production of sodium carbonate where the caustic catholyte is carbonated to keep the OH^- concentration low, resulting in high current efficiency (3, 4). In fact, it is troublesome since sodium carbonate and bicarbonate deposit in the cathode compartment.

In the case of potassium salts, on the other hand, this process would be desirable because of no unwanted deposition (5). This paper deals with a small cell experiment and a pilot test for the direct electrolytic production of potassium carbonate from potassium chloride solution with a membrane cell followed by absorption of carbon dioxide with the catholyte effluent.

Flowsheet and Reaction Sequence

A proposed flowsheet is illustrated in Fig. 1. Concentrated and purified KCl solution is pumped to the anode compartment of the membrane cell, and its effluent is sent back to the reservoir through the gas-solution separator where chlorine gas is recovered. Polishing of the feed brine with the chelating resin column is of great importance in eliminating a trace of hardness ions so as to keep the cell performance high and in extending the membrane service life (6, 7). The depleted brine is sent to the brine treatment yard. It is not shown in this figure.

The catholyte liquor flows down from the top of the CO_2 absorption tower packed with the Raschig rings to carbonate caustic solution into carbonate, then bicarbonate after separation of hydrogen. A part of the catholyte liquor is bypassed to the second stage of the absorption tower, where carbonate is converted into bicarbonate.

Water is supplied to the catholyte reservoir to adjust the water balance and the solution concentration.

The reaction sequence is simple. In the electrolytic cell, chlorine and hydrogen are liberated at the anode and the cathode, respectively

and

Since the catholyte contains bicarbonate ions, reaction [3] takes place in the bulk of solution

The catholyte effluent is further carbonated in the absorption tower to keep the OH^- concentration low, but the bicarbonate content in the product should also be controlled.

An excess solution absorbs more CO_2 to convert into bicarbonate in the second stage of the tower

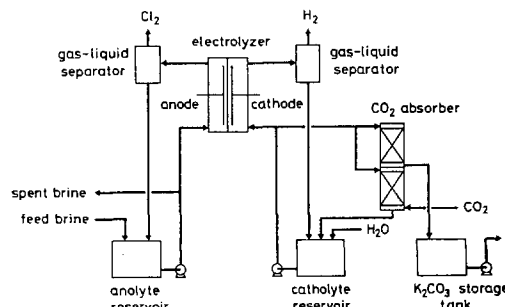

Fig. 1. Flowsheet for the electrolytic production of potassium carbonate

Fig. 2. A small Lucite cell

Experimental Procedure

A small Lucite cell, shown in Fig. 2, was fabricated to determine the electrode polarization, the IR drop through the membrane, and the cathode current efficiency in the batch-wise system. That is, four Luggin-Haber probes were positioned on the front of the anode and cathode, and both sides of the membrane. The Luggin probes located at the cathode compartment were connected with respective reference electrodes composed of $Hg/HgO/1M$ KOH, while the probes in the anode side were referred to the saturated calomel electrodes (SCE).

The solution gaps in both the anode and cathode compartments were large enough for the convenience of experiment.

The DSA-type ($RuO_2 + TiO_2$) anode was prepared by a conventional manner, and another material—named MODE—was also used. The MODE is a platinized Ti mesh loaded with IrO_2 as the electrode catalyst (8). A nickel sheet was used as the cathode.

The solutions, 0.2 liter each in volume at the anode and cathode sides, were agitated by the magnetically driven stirrer, and the temperature was controlled at $60^\circ C$ by electric heater.

The flowsheet of the pilot experiment was almost the same as shown in Fig. 1, with some exceptions. A major difference was the separate operation of the electrolyzer from the gas absorber.

A vertical and rectangular-type electrolytic cell, also made of Lucite resin, is illustrated in Fig. 3. The Nafion membrane of 5 cm wide and 40 cm long was flanged by two frames, and supported by the anode mesh. The

Fig. 3. A vertical cell

membrane-to-cathode gap was adjusted by a frame of a certain thickness. A MODE mesh was employed with this cell. A plain Ni sheet was mostly used as the cathode, and some experiments were conducted with an activated mesh cathode consisting of a steel coated with the Raney nickel. An alloy composed of 50% Ni and 50% Al was plasma-sprayed on a steel mesh substrate, then aluminum was leached out with hot concentrated caustic soda for a day. The apparent electrode area was about the same as of the membrane, so that the current density on both electrode and membrane was *ca.* $40 A/dm^2$ at 80A in total amperage. The current density presented in this paper is referred to the membrane surface.

Nafion membranes 315, 417, and 423 were employed. Most experiments were conducted with 423. These membranes were treated with boiling water for about an hour prior to experiment.

The temperature was controlled by the electric heater immersed in the reservoir. The solution volume was 8 liters each side. The anolyte flow was kept constant at 3 liter/min, and was large enough to keep the solution composition to be unchanged during experiment. On the other hand, the catholyte flow rate was varied in a wide range, 0.04-3.0 liter/min. All the catholyte flows through the gap between the membrane and the flat plate cathode. On the other hand, a part of the catholyte and hydrogen bubbles evolved may pass through the back-space when the mesh cathode is provided.

Potassium chloride of 4.2M in concentration was fed to the anode compartment. The catholyte was composed of a mixture of $KHCO_3$ and K_2CO_3 . The total molarity was kept constant at 2.0M, and the concentration ratio of the constituents was varied in a wide range. Its composition and concentration are not optimum, but it is just for the convenience of experiment. In practice, the higher the catholyte concentration, the higher is the performance of the cell. Potassium hydroxide was also added to the catholyte if necessary. These electrolytes were prepared with reagent-grade chemicals and deionized water. Also, the anolyte was further treated by passing through the chelating resin column when the hardness content reached unacceptable levels.

The catholyte was titrated with HCl solution and the indicator composed of methyl red and bromocresol green before and after electrolysis to evaluate the current efficiency for the cathode products. The solution composition was determined by pH titration.

A vertical cell was normally operated continuously for 30 Ah at various current densities, while a small batch cell was operated for 2.1 Ah.

Results and Discussion

As is shown in Eq. [3] and [4], the reaction of KOH with $KHCO_3$ is just a neutralization, so that OH^- and CO_3^{2-} may exist in alkaline solution. On the other hand, the solution containing excess CO_2 or HCO_3^- is composed of $KHCO_3$ plus K_2CO_3 , but no KOH. In consequence, a parameter α shown by Eq. [5] is used to represent a nature of the mixed solution or the $KOH-K_2CO_3-KHCO_3$ system instead of the molar concentration C of the components

$$\alpha = \frac{C_{CO_3^{2-}} + C_{OH^-}}{C_{HCO_3^-} + C_{CO_3^{2-}}} \quad [5]$$

At $\alpha = 1$, neither OH^- nor HCO_3^- exist in the solution; that is, the solution contains only K_2CO_3 . If $\alpha < 1$, the solution contains excess $KHCO_3$, but no KOH. On the other hand, OH^- remains in the solution, but there is no $KHCO_3$ when $\alpha > 1$. It is useful to compare the electrolyte of different composition and concentration.

Figure 4 shows an example of the current efficiency and the terminal voltage of a small cell shown in Fig. 2 as functions of α . It is clear that the current efficiency decreases when α increases, especially in the region larger than unity of α caused by a significant migration of OH^- from the cathode compartment to the anode side through the membrane. On the other hand, the cell voltage goes down with the increase of α because the IR drop between

Fig. 4. Current efficiency and voltage of the small cell as functions of the solution composition. Closed points: solution containing carbonate. Open points: solution free of carbonate. Anode: DSA. the cathode and the membrane decreases with the increase of the ionic strength and/or the KOH concentration. The cell voltage in this figure is very large and is shown as reference because the solution gaps in both the anode and cathode sides are large.

This figure also shows the current efficiency and the cell voltage obtained with the KOH catholyte free of carbonate. The current efficiency is almost equal to that of the cell operated with mixed solutions. It represents that the back-migration of OH⁻ through the membrane is not affected significantly by carbonate ions. The cell voltage was, of course, very high in weak solutions whereas it was almost the same as of the cell filled with mixed solutions in the concentration range of OH⁻ more than 1.5M.

The current efficiency and the voltage of the vertical cell equipped with Nafion 423 as functions of the catholyte composition are shown in Fig. 5. The current density was 20 A/dm², and the solution temperature was kept constant at 60°C. The catholyte flow was 3 liter/min or ca. 16.7 cm/s in a 6 mm gap between the flat plate cathode and the membrane. As is shown by the top draft in this figure, the current efficiency of the vertical cell was almost equal to that of the small cell described above. The cell voltage in this case is relatively low in comparison with that of the small cell because the membrane touches on the anode mesh and the cathode gap is small, but is still insufficient. The flow rate was a small factor on the current efficiency as shown in Fig. 6. Of course, electrolytic hydrogen bubbles associate with forced circulation to agitate the catholyte and to keep the solution composition uniform across the vertical cell.

At the flow rate lower than 0.1 liter/min or 0.6 cm/s, the OH⁻ concentration in the cathode compartment increases and causes the current inefficiency.

Figure 7 illustrates that the current efficiency is almost independent of the current density in the range 10-40 A/dm² if α does not exceed unity. Also, the current efficiency did not change in the temperature range 40°-70°C. The cell voltage is almost linear with the current density in the range 10-40 A/dm² (see bottom of the figure), which represents that the major factor of the cell voltage is the ohmic component, either membrane or electrolyte, rather than the overvoltage.

From the viewpoint of product quality, potassium carbonate is contaminated by either caustic potash or bicar-

bonate depending on α , and hence α must be controlled as exactly as possible.

Table I shows the breakdown of the terminal voltage of the small cell and the vertical cell at a given current density (20 A/dm²) and temperature (60°C). The figures for the small cell were obtained by experiment with the exception of the catholyte IR drop. Its IR drop was calculated with an assumption of 6 mm for the electrolysis gap to compare the voltage drop in two cells under the same conditions. The solution conductivity was measured with a separate cell for this treatment. The anolyte IR drop of the small cell was dropped from the list for the same reason. Both cells were equipped with a mesh-type MODE anode, a plain Ni cathode, and Nafion 423. As shown in Fig. 2, since the solution gaps in both the anode and cathode compartments of the small cell are large enough, the gas voidage is small, and hence it is concluded that the experimental results do not contain any bubble effect of hydrogen and chlorine in this case.

In the vertical cell, on the other hand, Nafion membrane is supported by the anode mesh while the cathode plate is located at 6 mm from the membrane, and the catholyte is circulated in between at a constant rate (3 liter/min). Therefore, detachment of chlorine bubbles from the anode-membrane structure is delayed, and the

Fig. 7. Current efficiency and voltage of the vertical cell as functions of the current density. Operating conditions were the same as in Fig. 5, except for $\alpha = 0.9-1.0$.

catholyte in the electrolysis zone is crowded by hydrogen bubbles to some extent. As a result, the overvoltages at the anode and the cathode, and also the membrane IR drop, increase considerably depending on the blinding of these surfaces.

The reversible potentials for the hydrogen and chlorine electrode processes under operating conditions of solution composition and temperature were measured with the small cell and agreed with theory. These results were used to break down the cell voltage shown in Table I.

The overvoltages obtained with the small cell are also shown in Fig. 8. In this case, the IR drop between the working electrode and the Luggin probe was calibrated by the current interruption technique. However, the anode potential of the vertical cell in Table I contains some IR drops between the anode and the Luggin probe.

The membrane IR drop in the small cell was some 0.6V, as shown in Table I, and did not contain any disturbance as the vertical cell was affected. However, it is still very large in comparison to the IR drop of similar Nafion employed in the NaCl cell: ca. 0.3V at 80°C with Nafion 427 (9) due to different conductivity in both cases.

As is shown in Table IIA as example with Nafion 315, the resistance of Nafion membranes immersed in potassium electrolyte is larger than that in sodium salt solution due to different permeability of K^+ and Na^+ . Also, the specific resistance in carbonate solution is large compared to hydroxide solution. These factors reflect directly the IR drop through the membrane in potassium

Table I. Breakdown of the cell voltage at 20 A/dm². Membrane: Nafion 423. Anode: MODE mesh. Cathode: plain Ni plate. Cathode-to-membrane gap: 6 mm. Flow rate: 3 liter/min. $\alpha = 1$. Temperature: 60°C

carbonate cell under discussion. Table IIB lists the nominal resistance of Nafion membranes in a dilute KCl solution (0.6N KCl at 25°C, reported by du Pont) and the test results obtained in the small cell under operating conditions.

On the other hand, very large IR drop through the membrane positioned in the vertical cell was recorded as shown in Table I. Because the membrane was supported by the anode mesh, chlorine bubbles liberated from the anode were disturbed to escape, and hence the membrane surface was covered by gas bubbles to a great extent. This causes large IR drop through the membrane, and also the anode overvoltage. It is known that gas bubbles can detach from the membrane if the surface is hydrophilic.

Uneven current distribution in the membrane attached to the mesh electrode is also a factor on high voltage drop; that is, the effective area for passing electrolytic current reduces to some extent, which is a common problem for the membrane cell technology. Consequently, an adequately designed electrode must be employed to eliminate, or minimize at least, these troubles.

The cathode overvoltage is the second largest factor of the terminal voltage after the membrane IR drop when the plain Ni cathode is used. Several cathode materials showing low hydrogen overvoltage are available in the market. The hydrogen overvoltage of a Raney-type porous Ni cathode is very low (see Fig. 8), and its Tafel slope is somewhat small, ca. 110 mV/decade, in comparison with 142 mV/decade of a plain Ni cathode.

The solid line labeled 423 in Fig. 9 shows the volt-ampere curve of the cell equipped with Nafion 423 and a porous Ni-coated mesh cathode attached with Nafion. The voltage saving from the cell with a plain Ni cathode (see dotted line) is ca. 0.6V at 20 A/dm². The experimental

results with other membranes are also shown. The cathode current efficiency at 20 A/dm² was, of course higher than 95% in all cases.

The solution temperature is an important factor for cell operation. The higher the temperature, the lower is the cell voltage. The cell voltage could be reduced further by 0.2V when the operating temperature is raised from 60° to 90°C, whereas only few experiments were conducted under such conditions since the plastic cell was affected by chemical attack.

Most experiments described here were conducted with the catholyte of 2M total concentration and at the current density of 20 A/dm² for the convenience of experiment. Of course, the higher the concentration, the lower was the cell voltage. The current efficiency was almost independent of the total catholyte concentration. Therefore, the concentration must be kept as high as possible. Also, we estimate that an optimum current density may exist at higher levels than 20 A/dm², so that the investment or the fixed charge is lowered while further experiment and engineering considerations are required for evaluating the economy of this process.

Absorption of carbon dioxide with potassium hydroxide solution (reaction [6]) followed by reaction [4] or [7] is a typical process of gas absorption accompanied with chemical reaction (10-12), and is very fast, especially at high temperatures

and

The catholyte can be carbonated by introducing CO₂ gas into the cathode compartment, while the cell configuration is complicated somewhat (4). However, use of a sepa-

rate reactor in parallel with the electrolyzer is preferable for easy operation and reduction of the energy consumption, as is illustrated in Fig. 1.

Excess caustic in the catholyte effluent is neutralized in the upper column of the absorption tower (see Fig. 1), and a part of solution is recovered as an intermediate of the product, which is concentrated or evaporated, depending on the market. Remains flow down to the second stage of the tower where the solution absorbs more CO₂ to obtain bicarbonate (reaction [4A]) to prepare the catholyte liquor.

In conclusion, electrochemical production of potassium carbonate with a membrane cell was studied. The cathode current efficiency was high at almost 100% in a wide range of the operating conditions since the OH⁻ concentration in the cathode compartment was low. The IR drop through the membrane was the largest factor of the terminal voltage. Although Nafion 423 was employed most often in this experiment, any membrane having lowest resistivity is preferable since the OH⁻ concentration in the catholyte liquor is sufficiently low, and further reduction of the cell voltage is thus anticipated. The flowsheet shown in Fig. 1 is applicable to practice because of easy operation of the whole process of interest.

Acknowledgments

The Nafion membranes were supplied by the Experimental Station of E. I. du Pont de Nemours and Company, Wilmington, Delaware, by arrangements of Mr. S. Higuchi of du Pont Japan, Tokyo. The Raney-type Ni-coated cathode was prepared by Showa Company, Nara, Japan. The authors wish to thank Y. Ishida, A. Kuroyanagi, and N. Yamauchi for their laboratory efforts.

Analysis of Laboratory Data in Early Stages of Evaluation of Electro-Organic Reactions

Edward K. Yung^{*,1} and Richard C. Alkire^{*}

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

The production of 1,2-dichloroethane and ethylene chlorohydrin by electrolysis of ethylene containing hydrochloric acid solutions was studied with a bench-scale continuous-flow undivided parallel-plate cell. The product distribution was independent of electrolyte flow rate and current density, but was significantly influenced by the chloride ion concentration. The cell current-voltage curves were found to be independent of electrolyte flow rate. Engineering models which included consideration of the chemical environment in the electrolysis zone were developed from fundamental principles of mass transport, ohmic resistance, and reaction kinetics. The models were verified by comparison with experimental findings, and were subsequently used to explore engineering aspects of scale-up and optimization. These models were incorporated with economic analyses to study the influence of design and operating parameters on the cost of 1,2-dichloroethane. A successive quadratic programming method was used to identify optimal operating conditions as well as the most sensitive parameters of the system.

Development of new electro-organic synthesis processes depends on knowledge of chemical mechanism as well as on engineering design trade-offs. The unification of these perspectives at an early stage of development can promote a more cost-effective exploration of those factors which control the candidate process. The purpose of the present study was to provide methodology by which small-scale experiments can be exploited to evaluate process limitations at an early stage. The emphasis of the work was on a methodology which is simple and portable to other applications, and not on development of a specific candidate process.

The process chosen for study was the production of 1,2-dichloroethane (DCE) and ethylene chlorohydrin (EC) by electrolysis of hydrochloric acid solutions containing ethylene. The synthesis was an indirect electrochemical process in which chlorine was produced at the anode, and products were generated by electrophilic addition of chlorine to ethylene

where R is the product ratio defined as $R = [\text{EC}]/[\text{DCE}]$. The reaction mechanism consists of formation of a chloronium ion intermediate followed by attack from nucleophiles (1).

A series of feasibility studies for electrochemical chlorination of ethylene was carried out by Tedoradze *et al.* (2-5). Experiments were carried out in ethylene-sparged beaker cells with planar electrodes. Parameters investigated included purity and concentration of HCl solutions, temperature, current density, electrode materials, and ethylene feed rate. The dependence of yield and product spectrum upon these parameters was reported. These studies made their contribution in demonstrating feasibility and identifying the proper chemical environment for the process.

Early aspects of process evaluation also require quantitative data obtained in well-characterized experimental systems. The scope of the present work included bench-scale experiments, formulation of models of the reaction chemistry and of the electrolytic cell, scale-up, cost evaluation, optimization, and sensitivity analysis.

Fundamental analyses of the parallel-plate cell geometry have been reported (6). For the system under study, however, gas evolution on both electrodes complicated

the mass transfer and ohmic resistance aspects. The influence of gas bubbles on the current distribution in electrolytic cells has been reported (7, 8) for situations where the population distribution of bubbles was uniform. A review of gas evolving electrodes has been provided by Vogt (9).

The scale-up of electrochemical processes has recently been reviewed (10) with emphasis on the value of engineering models to exploit limited bench-scale laboratory data. Capital costs for electrochemical cells have become available (11), and examples of economic evaluations have been reported (12).

Methods for optimization of electrochemical processes (13) are beginning to emerge for analysis of individual cells (14, 15) as well as entire electrolytic processes (16). In general, optimization considerations should be based on the entire flowsheet, since in some cases it is worthwhile to accept cell modifications in order to achieve better downstream operations.

Experimental

Apparatus.—The electrochemical cell was of undivided parallel-plate geometry and consisted of two cell housing pieces and a spacer, all of polypropylene. The electrodes were mounted flush with the flow channel surfaces, opposite each other, and were held in place by the spacer which also served to establish the gap distance between electrodes. The anode material was Karbate[®] no. 22 (Union Carbide), a graphite material impregnated with a standard phenolic resin, impervious to liquids. [Results of auxiliary limiting current experiments (17) for chlorine reduction with a Karbate[®] rotating disk electrode indicated that deviation of the active surface area from the apparent surface area was less than 5%.] The cathode was platinized graphite (17) on a substrate of Poco AXF-5Q (Union Oil) graphite. The exposed electrode surface had a dimension of 10.2 × 2.54 cm. A hydrodynamic entrance length (43.2 cm) was provided for flow development upstream from the electrodes. For a typical cell gap of 0.635 cm, this hydrodynamic entrance length was adequate up to a Reynolds number of 1700, where the Reynolds number was based on the cell gap (18). The downstream calming region was 10.2 cm long. Current feeders consisted of threaded oxygen-free copper rods (1/8 in. diam) connected to the back side of the electrodes.

The flow system is shown schematically in Fig. 1. A bubble column (4 ft length) was included for ethylene (Air Products, C.P. Grade, 99.8%) absorption. The ethylene stream eventually passed through a Dry Ice cold trap for recovery of residual 1,2-dichloroethane. The liquid stream passed through flow measurement devices (Gilmont, F1500 and F1300), flow stabilizer, the electrochemical cell, and then returned to the reservoir. The function of the flow stabilizer was to collect the gradually released

ethylene gas so that a steady, bubble-free electrolyte would enter the cell. For electrolysis experiments, the cell pressure was monitored at 1.2 atm, for which release of ethylene gas was found to be sufficiently slow. Tubing and piping were of 1/2 in. polypropylene.

Flow electrolysis experiments were carried out in constant current mode. A current controlling resistor (Koolohm®, 10W, 1Ω) was connected to the power supply (PAR, 371) for cell current monitoring. Current readout was given by a digital multimeter (Keithley, 179A). For cell current-voltage measurements, a function generator was connected to the potentiostat to provide the voltage scan, and the cell current was recorded by an X-Y recorder (Houston Instrument, 2000). HCl (Mallinckrodt, AR) and deionized water were used in electrolyte preparation.

A rotating disk (Pine Instrument, AFDD 20) was used to determine charge transfer parameters. A Karbate® disk (0.318 cm diam) was used for chlorine evolution, and a platinized graphite disk (0.159 cm diam) for hydrogen evolution. The disk sizes were chosen so that the current distribution would be uniform to within 20% up to a current density of 100 mA/cm² (25).

Procedures.—Prior to each electrolysis experiment, ethylene was bubbled for at least 20 min with electrolyte circulation. The period of electrolysis was typically 2h, following which the bulk solution and cold trap were sampled and analyzed by gas chromatography (Varian 3740 Chromatograph and Vista 401 Data Station). The combinations of operating parameters which were investigated included three electrolyte flow rates (95, 328, 1380 ml/min) and four current levels (200, 400, 800, 1600 mA). Four electrolyte concentrations (1, 2, 4, 8M HCl) were used to study the effect of chloride ion concentration on the product spectrum. Temperature range was (25 ± 4)°C.

No organic impurities were found in the electrolyte that would interfere with the chemical analysis. The column was 2 mm glass, 6 ft length, and packed with 1% SP-1000 on 60/80 Carboxpack (Supelco, Incorporated). A prepacking of sodium bicarbonate was used to retard attack of HCl on the packing. Helium was the carrier gas; the flow rate was 30 ml/min at an inlet pressure of 50 psig. The flame ionization detector was held at 210°C, while the flash injector was held at 180°C. For analysis, the column was held at 50°C for 2 min and then subjected to temperature programming at a ramp rate of 10°C/min to a final temperature of 150°C. Ethanol was used as the internal standard.

Cell current-voltage curves were recorded for various combinations of cell gap and flow rate. Voltage sweep

rate was 10 mV/s, which appeared to be slow enough to minimize double-layer charging effects as well as to allow the cell to operate at pseudo-steady state.

Results and Discussion

The amount of the two major products, 1,2-dichloroethane (DCE) and ethylene chlorohydrin (EC), was a linear function of the electrolysis period. For most experimental runs, the material yield (*Y*)

$$Y = \frac{\text{sum of the amount of EC and DCE}}{\text{total amount of chlorine generated at 100\% current efficiency}}$$

was in the range of (100 ± 5)%. Therefore, the current efficiency for chlorine evolution was 100% at all current densities investigated. Electrolyte flow rate and cell current were found to have little influence on the product spectrum.

Chloride ion concentration was found to have significant influence on the product distribution. As the chloride ion concentration was increased, the product spectrum shifted towards 1,2-dichloroethane. Supplementary experiments for the study of solution phase reaction between ethylene and chlorine were carried out with a chemical flow reactor having no electrodes. To within experimental error, it was found that the product distribution was practically identical to that from the electrolysis experiments. It was concluded that, even in the presence of electrodes, the reaction was still occurring in the solution phase. Figure 2 shows the dependence of the product distribution upon the ratio $[H_2O]/[HCl]$. The equation which fits these data is

$$R = \frac{[EC]}{[DCE]} = -0.102 + 0.132 \frac{[H_2O]}{[HCl]} \quad [1]$$

The product distribution results in Fig. 2 agree with the commonly accepted mechanism of chlorination of olefins (1)

According to this mechanism, the slope of the straight line would be the ratio (k_3/k_4) of the two rate constants leading to the formation of the two major products. Evidence given by Serguchev and Konyushenko (19, 20) indicated that the ratio k_3/k_4 was relatively independent of the reactivity of the unsaturated compounds. The number obtained in our experiments (0.132) compares favorably with that for chlorination of styrene in aqueous system (0.133) as well as that for chlorination of allyltrimethylammonium perchlorate (0.156). The activity of styrene has been estimated to be 1.2×10^5 times that of allyltrimethylammonium perchlorate. However, there was evidence (20) that the ratio depended upon the solvent composition. Therefore, extension of the experimental finding to systems other than aqueous hydrochloric acid would not be recommended.

The product ratio resulting from thermodynamic equilibrium between the two products following the reaction

$$K_{eq} = \frac{[C_2H_5OCl][HCl]}{[C_2H_4Cl_2][H_2O]}$$

would be expected to be pH dependent. However, supplementary experiments with mixed electrolytes of HCl and NaCl showed that the product distribution depended upon total chloride ion concentration but not upon HCl concentration. It was therefore concluded that the product distribution was controlled by the kinetics of the homogeneous reaction.

It was found that the same I-V curve was recorded for both 1M HCl and for ethylene-saturated 1M HCl as long as

Fig. 2. Determination of the ratio of rate constants (k_3/k_4)

the cell was kept continuously active. If the power was turned off, the I-V curve from the first subsequent voltage scan would then be different, but subsequent scans eventually reverted to the curve found in ethylene-free electrolyte. These observations suggest that as long as the cell is continuously activated, there will be no possibility for the adsorption of ethylene to occur and the electrode will not respond to the presence of ethylene. These results support the interpretation that rapid reaction between ethylene and chlorine occurs in the solution phase and that the cell plays only the role of a chlorine source.

For a fixed cell gap, the I-V curves were found to be independent of the electrolyte flow rate over a range from 50 to 2000 ml/min. The I-V curves recorded for various cell gaps ranging from 0.323 to 1.892 cm are shown in Fig. 3. It can be seen from the slope of the high current portion of the curves that at the same cell voltage the cell current is smaller for larger cell gap, owing to larger ohmic loss in solution phase. Also, the cell gap influences the overall shape of the curves; the curves become straight lines at lower current levels for larger cell gaps. These measurements were clarified by visual observations described in the following paragraphs.

For visual observation of flow pattern in the electrolysis region, a transparent Plexiglas® spacer 1.224 cm thick was used. While the results are qualitative in nature, the phenomena which were observed were essential for resolution of I-V data.

Gas evolution was observed at both electrodes. Three distinct regions were seen. Next to the anode surface, a thin layer containing a chlorine bubble swarm was observed. All bubbles seemed to move at the same velocity. Coalescence of bubbles was not apparent. A similar bubble layer containing hydrogen bubbles was seen adjacent to the cathode. The central portion of the flow channel was free of bubbles. The diameter of hydrogen bubbles was estimated to be 200 μm and that of chlorine bubbles was estimated to be 100 μm . Bubble size distribution seemed to be narrow. Neither cell current nor electrolyte flow rate seemed to influence the bubble sizes. The thickness of the moving bubble layers was not uniform

Fig. 3. Experimental cell current-voltage curves for different cell gaps

over the entire electrode length; it increased with the distance from the leading edge. The thickness of the moving bubble layers increased slightly with decreasing electrolyte flow rate. The current level was found to have little influence on the thickness. The hydrogen layer was thicker than the chlorine layer. For a flow rate of 1560 ml/min, hydrogen layer thickness at the center of the electrode was estimated to be 0.05 cm, while the corresponding chlorine layer thickness was estimated to be 0.02 cm. The thickness of the moving bubble layers, δ_{avg} , is represented by

$$\delta_{\text{avg},a} = 0.02(Q/26.0)^{-0.5} \quad [2]$$

$$\delta_{\text{avg},c} = 0.05(Q/26.0)^{-0.5} \quad [3]$$

The rise velocity of bubble swarms was not influenced by the change of electrolyte flow rate for a fixed cell current. Over the cell current range under study (1-3A), the rise velocity varied nearly proportionally with the cell current for fixed electrolyte flow rate, while the layer thickness did not change. For a cell current of 1A, the rise velocity of hydrogen bubble swarm was estimated to be 6 cm/s. The corresponding value for chlorine bubbles was 2 cm/s. These values were in reasonably good agreement with values calculated on the assumption of Stoke's law (21) for an isolated bubble without internal circulation. The rise velocity of bubble swarms was therefore represented as

$$u_{g,\text{Cl}_2} = 2I_{\text{cell}} \quad [4]$$

$$u_{g,\text{H}_2} = 6I_{\text{cell}} \quad [5]$$

According to observation of others on bubble formation at solid surfaces (9), it is reasonable to expect that a layer of small stationary bubbles exists underneath each moving bubble layer. This immobile layer would not be expected to be affected by liquid flow, owing to its thinness and the attachment of the bubbles to the electrode surfaces.

A schematic of the flow pattern in the electrolysis region, based on visual observation, is summarized in Fig. 4. This flow pattern will play a central role in formulation of the cell model which follows.

Fig. 4. Schematic of the flow pattern in the experimental cell. Layer 1: Fixed hydrogen layer. Layer 2: Moving hydrogen layer. Layer 3: Bubble-free liquid layer. Layer 4: Moving chlorine bubble layer. Layer 5: Fixed chlorine bubble layer.

Charge transfer measurements with the rotating disk electrode were carried out at four concentrations (1, 2, 4, and 8M HCl), and were corrected for the ohmic component by assuming that the reference electrode was infinitely far away. The data for both reactions followed the Tafel equation

$$i_c(x) = i_{c0} \left\{ \frac{[H^+]_s(x)}{C^*} \right\}^2 \exp \left\{ \frac{-\alpha_c n_c F}{RT} [-E_{eq,c} - \phi_{s,c}(x)] \right\} \quad [6]$$

$$i_a(x) = i_{a0} \left\{ \frac{[Cl^-]_s(x)}{C^*} \right\} \exp \left\{ \frac{\alpha_a n_a F}{RT} [V_{cell} - E_{eq,a} - \phi_{s,a}(x)] \right\} \quad [7]$$

By examination of the data represented by Eq. [7], a value of 1.05V vs. SCE was assigned to $E_{eq,a}$, and the exchange current density (i_{a0}) was therefore evaluated at a reference concentration ($[Cl_2]_0$) for each electrolyte such that the combination of $[Cl^-]$ and $[Cl_2]_0$ yielded a value of 1.05V for $E_{eq,a}$. By examination of the data represented by Eq. [6], a value of -0.123V vs. SCE was assigned to $E_{eq,c}$; the exchange current density (i_{c0}) was then evaluated at a reference concentration ($[H_2]_0$) which yielded a value of -0.123V for $E_{eq,c}$. These data are listed in Table I.

Theoretical

Reaction chemistry near the anode.—Chlorine produced at the anode reacts homogeneously with ethylene which is dissolved in the solution. The concentration profiles near the electrode were investigated theoretically with use of a transport model, described in the Appendix. Calculations were carried out for combinations of flow rates (3, 10, 20 ml/s) and current densities (8, 16, 32, 64, and 128 mA/cm²). A rate constant of 2×10^5 cm³/mol-s was used since this value had been reported for the uncatalyzed reaction (23); the actual overall rate constant is probably larger since the HCl-catalyzed reaction path would also be available. Details on computation aspects are available in Ref. (17).

Results of these calculations indicated that the homogeneous reaction takes place in a very sharply defined zone

at a distance from the anode. At this reaction plane, the chloride ion concentration is essentially identical to that in the bulk solution. Therefore, the product distribution would be expected to be the same as if the chlorine had been bubbled directly into the solution, in agreement with experimental findings. Also, it was computed that the product distribution varied by less than 0.5% for all combinations of flow rates and current densities. These results supported the experimental finding that the product distribution was not affected by either flow rate or current density. Also, the calculations demonstrated that the ethylene concentration between the reaction plane and the anode would be zero, supporting the view that ethylene is not adsorbed on the anode as long as the electrode is maintained in the active state.

The discussion in the first paragraph of the Appendix suggests that the effect of gas bubbles is to increase the rate of transport in comparison with the rate of homogeneous reaction. One simple way to achieve such alteration in relative rates in the present model is to decrease the reaction rate constant (or to increase the diffusion coefficient). When calculations were carried out with rate constants which were 10⁶-fold smaller (that is, a value of 2×10^{-1} cm³/mol-s), it was found that the qualitative features of behavior described in the previous paragraph remained valid. It was therefore concluded that the general features described above would not be qualitatively different had a more detailed treatment of bubble evolution been carried out.

Analysis of the electrolytic cell.—An undivided parallel-plate reactor was modeled. The present analysis differs from previous treatments of parallel-plate flow cells owing to the presence of gas bubbles which requires consideration of flow pattern in the formulation of effective electrolyte conductivity. Phenomena under consideration included charge transfer, ohmic resistance, and mass transfer. Parameters for each phenomena were determined experimentally or were obtained from the literature for use in model calculations; these parameters are compiled in Table I. The mathematical articulation of these components into a unified representation of the entire cell constitutes an important task. While each element of the following overall model could be represented in a more sophisticated manner, it is rarely cost effective to do so in early stages of process evaluation. By the method described below, the most sensitive features of an optimized simple model can be identified. In turn, these components can then be upgraded in order to improve in a selective manner the most important features of the cell model.

The charge transfer characteristics of the chlorine and hydrogen evolution reactions on the electrode materials used in this study were obtained experimentally as discussed in the presentation of Eq. [6] and [7] above.

The solution phase ohmic resistance was assumed to be the sum of the resistance of each layer represented in the flow pattern depicted in Fig. 4. The effective conductivity of the bubble curtains was assumed to be 1/5 of the bulk value (27). A thickness of 50 μm was assigned to the chlorine bubble curtain, and a value of 60 μm was assigned to the hydrogen bubble curtain (27).

Bruggeman's equation (28) was used to describe the effective conductivity of the moving bubble layers on each electrode

$$\kappa_{avg,a} = \kappa_0 \left[1 - \frac{RT(I_{cell}/2)}{2FP_{cell}\delta_{avg,a}u_{g,Cl_2}W} \right]^{3/2} \quad [8]$$

$$\kappa_{avg,c} = \kappa_0 \left[1 - \frac{RT(I_{cell}/2)}{2FP_{cell}\delta_{avg,c}u_{g,H_2}W} \right]^{3/2} \quad [9]$$

The total solution phase ohmic resistance was expressed as

$$R_s = 5(0.005)/A\kappa_0 + 5(0.006)/A\kappa_0 + \delta_{avg,a}/A\kappa_{avg,a} + \delta_{avg,c}/A\kappa_{avg,c} + (h - 0.005 - 0.006 - \delta_{avg,a} - \delta_{avg,c})/A\kappa_0 \quad [10]$$

Table I. System parameters used in the modeling of the experimental cell

Parameter	Physical meaning	Value or functional	Ref.
C	HCl concentration	Variable (M), normally $1M$	
h	Cell gap	Variable (cm)	
L	Cell length	10.16 cm	
W	Cell width	2.54 cm	
Q	Flow rate	Variable (ml/s)	
V_{cell}	Cell voltage	Variable (V)	
C_0	C_2H_4 concentration	$5.0 \times 10^{-3}M$	
T	Temperature	298.15 K	
P_{cell}	Cell pressure	1 atm	
i_{a0}	Exchange current density for Cl^-/Cl_2 redox pair	4.78×10^{-4} A/cm ² for $1M$ HCl	(17)
i_{e0}	Exchange current density for H_2/H^+ redox pair	4.523×10^{-5} A/cm ² for $1M$ HCl	(17)
i'_{a0}	Exchange current density for H_2O/O_2 redox pair	1.0×10^{-6} A/cm ²	(17)
$\alpha_a n_a$	Anodic transfer coefficient for chlorine evolution	0.2779 for $1M$ HCl	(17)
$\alpha_c n_c$	Cathodic transfer coefficient for hydrogen evolution	1.2986 for $1M$ HCl	(17)
$\alpha'_a n'_a$	Anodic transfer coefficient for oxygen evolution	0.30	(17)
$E_{\text{eq. a}}$	Equilibrium potential for Cl^-/Cl_2	$1.05V$	(17)
$E_{\text{eq. c}}$	Equilibrium potential for H_2/H^+	$-0.123V$	(17)
$E'_{\text{eq. a}}$	Equilibrium potential for H_2O/O_2	$1.01V$	(17)
d_{b, Cl_2}	Chlorine bubble departure diameter	50 μm	(27)
d_{b, H_2}	Hydrogen bubble departure diameter	60 μm	(27)
κ_0	Electrolyte conductivity	$\kappa_0 = 0.0126143 + 0.380292C - 0.0591346C^2 + 0.00365068C^3 - 0.0000842448C^4$ (mho/cm)	(35)
D_{HCl}	Diffusion coefficient of HCl	$D_{\text{HCl}} = (2.87445 + 0.58244C) \times 10^{-5}$ (cm ² /s)	(35)
ρ	Density	$\rho = 0.999802 + 0.0159094C$ (g/ml)	(35)
η	Viscosity	$\eta = (0.896375 + 0.0393314C + 0.00251171C^2) \times 10^{-2}$ (g/cm-s)	(36)
t_{H^+}	Transference number of H^+	$t_{H^+} = 0.811794 + 0.0302287C - 0.00525897C^2 - 0.000472662C^3 + 0.0000514969C^4$	(35)
D_{Cl_2}	Diffusion coefficient of chlorine	$D_{Cl_2} = 1.44T/(293.15\eta) \times 10^{-7}$ (cm ² /s)	(17)

Note: Range of applicability: 1-8M HCl.

A correlation for mass transfer in the presence of microconvection owing to bubble growth on an electrode surface (24) was used

$$Sh = 0.93 Re^{0.5} Sc^{0.487} \quad [11]$$

The equations governing mass transfer were

$$i_a(x) = Fk_{\text{mt,a}}[C_b(x) - [Cl^-]_s(x)] \quad [12]$$

$$i_c(x) = Fk_{\text{mt,c}}[C_b(x) - [H^+]_s(x)] \quad [13]$$

Variation of bulk concentration of HCl was obtained from a differential mass balance

$$C_b(x) = C^* - \frac{W}{2FQ} \left(\frac{R_0 + 2}{R_0 + 1} \right) \int_0^x i_a(x') dx' \quad [14]$$

The solution phase potential on both electrode surfaces were related by the following equations

$$\phi_{s,a}(x) = \phi_{s,c}(x) + i_c(x)AR_s + \eta_{c,c}(x) + \eta_{c,a}(x) \quad [15]$$

The concentration overpotentials were formulated on the assumption of dilute solution theory as well as linear concentration profile in the mass-transfer boundary layer (29)

$$\eta_{c,c}(x) = \frac{2RT}{F} \ln \left[\frac{C^*}{[H^+]_s} - t_{H^+} \left(1 - \frac{[H^+]_s}{C^*} \right) \right] \quad [16]$$

$$\eta_{c,a}(x) = \frac{2RT}{F} \ln \left[\frac{C^*}{[Cl^-]_s} - t_{Cl^-} \left(1 - \frac{[Cl^-]_s}{C^*} \right) \right] \quad [17]$$

The last equation needed is for current balance

$$i_c(x) = i_a(x) \quad [18]$$

Equations [1]-[18] constitute a system of 18 independent equations for 18 variables at each location of the cell. The variables are i_a , i_c , $k_{\text{mt,a}}$, $k_{\text{mt,c}}$, $[Cl^-]_s$, $[H^+]_s$, $\phi_{s,a}$, $\phi_{s,c}$, $\eta_{c,a}$, $\eta_{c,c}$,

$\delta_{\text{avg,a}}$, $\delta_{\text{avg,c}}$, u_{g,Cl_2} , u_{g,H_2} , $\kappa_{\text{avg,a}}$, $\kappa_{\text{avg,c}}$, R_s , and C_b . This set of equations contains parameters the values of which are set according to literature sources or laboratory measurement as well as estimations when literature values were unavailable. Table I lists the values used in the present study.

Method of solution.—It is convenient to arrange the integral in Eq. (14) by approximating it as

$$\int_0^x i_a(x') dx' \cong \sum_{j=1}^{m-1} i_a(j) \frac{L}{N} + \left(x - \frac{L}{N}(m-1) \right) i_a(m) \cong \sum_{j=1}^{m-1} i_a(j) \frac{L}{N} \quad [19]$$

where

$$(m-1) \frac{L}{N} < x \leq m \frac{L}{N}$$

since no iterations were then required for the solution of the equations. Integration was carried out by dividing the cell into N sections along the flow direction, and proceeding section-wise starting from the upstream end of the cell. The set of equations was combined into two nonlinear algebraic equations, and IMSL subroutine ZSPOW was used on the Cyber 175 computer to solve them. Subsequently, the cell current was evaluated by

$$I_{\text{cell}} = W \int_0^L i_c(x) dx = W \sum_{j=1}^N i_c(j) \frac{L}{N} \quad [20]$$

Results

The calculated cell current-voltage curves for various cell gaps and flow rates are listed in Table II and their comparison with experimental curves is shown in Fig. 5. The discrepancy at low current densities is probably the result of errors in evaluation of kinetic parameters. However, for current densities above 100 mA/cm² ($I_{\text{cell}} > 2.6A$),

the error between experimental and calculated curves was less than 30 mV. The model also indicated that the cell current-voltage curves will be insensitive to the flow rate change (see Table II), a phenomenon also observed during the experiments. Reasonable variation in the choice of values of δ_{avg} and u_g (Eq. [2]-[5]) did not affect this conclusion. For a comparison, formulation of the cell model based on a commonly used flow pattern, namely, homogeneous gas-liquid mixture with no slip between phases, was done; the results showed strong dependence of I-V curves on flow rate. The comparison demonstrates that understanding of flow pattern, which in turn can vary with design considerations and operating conditions, is essential for predicting cell behavior of gas evolving systems.

Scale-up and cost analysis.—The application of the cell model to scale-up was made with the following modifications to the foregoing model.

1. The flow pattern was assumed to be a homogeneous gas-liquid mixture over the entire cell domain because of the merging of bubble layers in cells of very large length/gap ratio.

2. Pumping power requirement was included in the scale-up. A correlation proposed by Vogt (30) was used for pressure drop estimation for gas-liquid mixture.

3. The mass-transfer rate was described by a correlation proposed by Vogt (31) which considered the mass transfer to be jointly controlled by gas evolution and hydrodynamic flow.

4. Oxygen evolution following Tafel kinetics was included as an anodic side reaction.

Analyses were carried out for a hypothetical production facility operating at 10^4 metric tons of DCE per year. The overall cost was composed of three components: capital cost, operating cost, and raw material cost. The capital cost was evaluated to the cell battery limit, i.e., cell banks together with their peripheries including rectifiers and bus bars, pumps, piping, instrumentation, etc. Equipment cost of upstream feed preparation and downstream product recovery operations was not included. Operating cost, which included energy cost, labor, and maintenance, was also considered to cell battery limit. Economic information by Keating and Sutlic (11) and supplementary data by Danly (32) for electrochemical cells was used. All cost information was corrected to March 1983 prices. Electricity cost was assumed to be 5 ¢/kWh.

The raw material cost included reactant cost and credit for useful by-products. A price (12 ¢/lb), or half the market price for ethylene glycol, was arbitrarily assigned for ethylene chlorohydrin credit. Credit was also given to hydrogen based on its heat of combustion at an assumed thermal efficiency of 90%. A payback time of seven years was selected. The production cost of DCE was determined so that the total revenue would be equal to the total cost at the end of the payback period.

Calculations were carried out initially for 1M HCl to investigate the influence of design and operating parameters on DCE cost. Two parameters, cell gap and flow rate, showed pronounced effects. The variation of DCE cost with cell gap is shown in Fig. 6. A sharp minimum can be seen. For smaller cell gaps, unit cell production rate was higher at a fixed cell voltage, which would lead to smaller capital investment. However, pumping power, as a fraction of operating cost, was strongly influenced by the cell gap ($\Delta P \sim h^{-3}$, approximately) so that pumping cost dominated the operating cost and outweighed gains in capital investment. For larger cell gaps, unit cell production rate was lower at fixed cell voltage due to larger ohmic loss in the solution phase.

The variation of DCE cost with flow rate is shown in Fig. 7. Since over the range under investigation mass-transfer rate was mainly dominated by gas evolution phenomenon, increase of electrolyte flow rate would not substantially increase the production rate. Instead, operating cost would be significantly increased owing to pumping power. For very low flow rate, ohmic loss in the solution phase owing to the high gas content lowered the unit cell production rate which resulted in higher capital investment. However, the effect of high gas content was not very strong and, therefore, the minimum seen in Fig. 7 is not very sharp.

Fig. 5. Comparison of experimental and calculated cell current-voltage curves.

Fig. 6. Influence of cell gap on 1,2-dichloroethane cost

Results shown in Fig. 6 and 7 were carried out for 1M HCl because of the more distinct variation with the parameters under study.

The market price of DCE was 17 ¢/lb (July 1983 price) which is substantially lower than these calculated costs. It has been shown in Fig. 2 that the product distribution depends on $[Cl^-]/[H_2O]$. In particular, DCE cost will de-

Fig. 7. Influence of electrolyte flow rate on 1,2-dichloroethane cost

crease as HCl concentration increases. For example, when 8M HCl is used as the electrolyte, a calculated cost of 22 ¢/lb for DCE is obtained at a current density less than 1 A/cm².

Optimization.—An enhanced successive quadratic programming (SQP) method (14) was applied to the cost model described in the previous section in order to locate the optimal design parameters and operating conditions. The SQP method was chosen because it is known to be successful in situations where a large number of function and derivative evaluations are required, a category to which our system belongs. The SQP method has only recently been reported for electrochemical applications (15), and the present study represents the first known application of its use in directing bench-scale studies.

Starting with an initial set of values for the independent variables, a quadratic programming problem was formulated by taking a quadratic approximation of the objective function as well as linearization of the constraint functions. Solution of this problem by the Han-Powell algorithm (33) produced a search direction. Improvement of the objective function value was attempted along this search direction, and a new set of values was thereby obtained. The same procedure repeated itself until no further improvement was made. Five independent variables (cell gap, cell length, electrolyte flow rate, cell voltage, and cell width) were considered in the present analysis. The objective was minimization of DCE cost. Other more sophisticated objectives could be chosen for evaluation, but the general method would be the same. Three constraint functions were implemented: an upper limit was set on the maximum current density for anode protection, an upper limit (0.40) was also set for gas volume fraction at the outlet of the cell to prevent development of hot spots, and the maximum electrode area was set to be 0.8 m².

The software package SQPHP for solving nonlinear programming problems using an enhanced version of the Han-Powell method for successive quadratic programming was developed by Chen (33, 34), and is available commercially.² The program requires 41.4K words of core on the CDC Cyber 175 computer.

Results of optimization calculations for 1M HCl are summarized in Table III. It was found that the major fraction of computer time was consumed in function and derivative evaluations, not in the optimization procedure. For example, in Run no. 10, 120.526 CP seconds were consumed, of which only 0.154 CP seconds were used for 19 calls of SQPHP. Most runs terminated when there was lack of improvement of objective function value along the final search direction. In these cases, the final solution is believed to be very close to a local minimum. The results of Runs 1-4 suggest the possibility of local minima since different initial guesses ended up with different sets of optimal values for the variables.

Sensitivity analysis was carried out by finite difference evaluation of the cost change for small changes in each independent variable at the optimal condition. The strong influence of cell gap and cell voltage on the economy was demonstrated by the sensitivity analysis results shown in the footnote of Table III.

A simplified method for determining which phenomenon controls the cell resistance is to calculate the cell current that would pass if the entire driving force (cell voltage) were consumed by the particular phenomenon under consideration. That phenomenon which gives the smallest current is the limiting process. When such calculations were done for the optimal conditions corresponding to a maximum current density of 0.5 A/cm² (Run no. 4 of Table III), values of 2.12, 20.73, and 1.84 for dimensionless cell current were obtained in response to charge transfer, mass transfer, and ohmic resistance-controlled system, respectively. Therefore, it was concluded that mass transfer will not control the cell; measures towards

enhancement of mass-transfer rate, such as implementation of turbulence promoters, would not be expected to improve the cell economic performance. The present system is controlled primarily by ohmic resistance and, to a lesser degree, by a charge transfer resistance. Increasing the solution conductivity with a different electrolyte seems unlikely since the most mobile cation, H⁺, is already present in the electrolyte. Development of a more active electrode surface for enhancement of charge transfer rate would represent only a limited contribution to process improvement. Further improvement in yield would be achieved by increasing the total chloride ion concentration beyond that obtainable with pure HCl electrolyte, such as by addition of chloride ion containing salts.

Conclusions

Because electrochemical processes can be complex, early stages of process evaluation must be guided so that efficient use is made of development efforts. Simple methods need to be used for modeling cells, their scale-up properties, and their economic features, and for predicting their optimal configuration. The incorporation of such methods along with bench-scale laboratory data can be carried out with numerical software available commercially on most mainframe systems.

In the present investigation, the most sophisticated numerical computations were those used to clarify the chemical reaction sequence which occurred near the electrode surface, summarized in the Appendix. The development of a model of an entire cell involved a few dozen equations, primarily nonlinear algebraic equations, which in the present study were easily solved by commercial software. Optimization and identification of the most sensitive parameters were also found to be readily accomplished with successive quadratic programming methods. While the present study did not include aspects of the process flow sheet other than the electrolytic cell, methods for flowsheet simulation and optimization represent an area of active research where rapid advances may be anticipated in the near future.

As a model system for the investigation of these methods, the electrochemical process for 1,2-dichloroethane production by electrolysis of ethylene containing hydrochloric acid solutions was studied with a bench-scale continuous-flow undivided parallel-plate cell. Ethylene chlorohydrin was the only by-product. The product spectrum was found to be independent of both electrolyte flow rate and cell current, but was found to be significantly influenced by the chloride ion concentration. Product distribution data supported the reaction mecha-

nism involving a chloronium ion intermediate and subsequent attack by nucleophiles (chloride ion and water molecule).

An approximate model which considered the chemical environment in the electrolysis zone was developed from fundamental principles of mass transport and reaction kinetics. The calculations supported the view that the cell served to generate chlorine, and that reaction of ethylene occurred solely by homogeneous chemical reaction.

The cell current-voltage curves were found to be independent of electrolyte flow rate. The flow patterns arising from gas evolution in the cell were observed experimentally and were used to establish a mathematical model of the cell. The cell model took into account mass transfer, charge transfer, and solution phase ohmic resistance. When a correlation was constructed for solution phase ohmic resistance based on the observed gas bubble flow pattern, the model characterized the experimental cell accurately, particularly the observation that the I-V curve was independent of flow rate.

Economic analyses were carried out for a hypothetical production facility. Influence of key operating and design parameters on the balance of capital cost and operating cost was demonstrated. An enhanced successive quadratic programming code was applied to locate the optimal operating conditions and to identify the most sensitive variables. The methods developed in this study are portable and can be applied to a wide variety of electrolytic processes.

APPENDIX

Reaction Chemistry Near the Anode

A two-dimensional representation of the reaction zone, illustrated in Fig. A-1, was used to calculate concentration profiles near the anode. Reference (17) contains a complete discussion of the summary which follows. The primary assumptions were (i) constant physical properties, (ii) well-developed laminar flow with a linear velocity field in the thin reaction region, (iii) homogeneous reaction which is first order in both chlorine and ethylene concentrations, (iv) 100% current efficiency for chlorine evolution, and (v) transport by convection along the electrode and by diffusion normal to the electrode. The last assumption represents a limiting case of behavior which does not include the effect of gas bubbles. The presence of such bubbles would serve to increase mass transfer of Cl^- and ethylene toward the anode, and to transport Cl_2 into the bulk at rates faster than given by the model. That is, the consequence of gas bubbles would be to increase rates of transport with respect to rates of chemical reaction, a point to which discussion will return.

The differential mass balances for chlorine and ethylene

$$D_{\text{Cl}_2} \frac{\partial^2 [\text{Cl}_2]}{\partial y^2} - u_x(y) \frac{\partial [\text{Cl}_2]}{\partial x} = k[\text{Cl}_2][\text{C}_2\text{H}_4] \quad [\text{A-1}]$$

$$D_{\text{C}_2\text{H}_4} \frac{\partial^2 [\text{C}_2\text{H}_4]}{\partial y^2} - u_x(y) \frac{\partial [\text{C}_2\text{H}_4]}{\partial x} = k[\text{Cl}_2][\text{C}_2\text{H}_4] \quad [\text{A-2}]$$

where the linear velocity field is represented by

$$u_x(y) = 6\langle u \rangle \left(\frac{y}{h} - \frac{y^2}{h^2} \right) = 6\langle u \rangle \frac{y}{h} \quad [\text{A-3}]$$

The six boundary conditions are

$$[\text{Cl}_2] = 0 \text{ at } y = \delta_R \text{ for all } x \quad [\text{A-4}]$$

Fig. A-1. Basis of the reaction chemistry model. N_1 : chlorine flux at anode. N_2 : convective flux of chlorine into the reaction zone. N_3 : diffusive flux of chlorine into bulk solution. N_4 : convective flux of chlorine out of the reaction zone. S : rate of consumption of chlorine in the reaction zone.

$$[\text{C}_2\text{H}_4] = C_0 \text{ at } y = \delta_R \text{ for all } x \quad [\text{A-5}]$$

$$-D_{\text{Cl}_2} \frac{\partial [\text{Cl}_2]}{\partial y} = \frac{i}{2F} \text{ at } y = 0 \text{ for all } x \quad [\text{A-6}]$$

$$\frac{\partial [\text{C}_2\text{H}_4]}{\partial y} = 0 \text{ at } y = 0 \text{ for all } x \quad [\text{A-7}]$$

$$[\text{C}_2\text{H}_4] = C_0 \text{ at } x = 0 \text{ for all } y \quad [\text{A-8}]$$

$$[\text{Cl}_2] = 0 \text{ at } x = 0 \text{ for all } y \quad [\text{A-9}]$$

Different concentration profiles will be obtained for different values of reaction layer thickness δ_R . The value of δ_R must be chosen so that it satisfied a chlorine mass balance

$$\frac{iWL}{2F} = W \int_0^{\delta_R} [\text{Cl}_2](y) \Big|_{x=0}^{x=L} u_x(y) dy + W \int_0^L \int_0^{\delta_R} r(x, y) dy dx \quad [\text{A-10}]$$

The differential mass balance for chloride ion is

$$D_{\text{HCl}} \frac{\partial^2 [\text{Cl}^-]}{\partial y^2} - u_x(y) \frac{\partial [\text{Cl}^-]}{\partial x} + \frac{R}{R+1} r = 0 \quad [\text{A-11}]$$

where r is the local reaction rate, which can be calculated after the concentration profiles for both chlorine and ethylene have been obtained. Diffusion coefficient of HCl molecule, D_{HCl} , is used in Eq. [A-11] because of the binary nature of the electrolyte (22). The last term accounts for chloride generation following the stoichiometric reaction

The local product ratio was

$$R(x, y) = \frac{[\text{EC}]}{[\text{DCE}]}(x, y) = -0.102 + 0.132 [\text{H}_2\text{O}][\text{Cl}^-](x, y) \quad [\text{A-12}]$$

The boundary conditions associated with Eq. [A-11] are

$$D_{\text{HCl}} \frac{\partial [\text{Cl}^-]}{\partial y} = \frac{i}{F} \text{ at } y = 0 \quad [\text{A-13}]$$

$$[\text{Cl}^-] = [\text{Cl}^-]_0 \text{ at } y = \delta_R \quad [\text{A-14}]$$

$$[\text{Cl}^-] = [\text{Cl}^-]_0 \text{ at } x = 0 \quad [\text{A-15}]$$

where $[\text{Cl}^-]_0$ is the chloride ion concentration in the bulk solution.

The overall product ratio can be calculated by

$$R_{\text{overall}} = \left(\frac{[\text{EC}]}{[\text{DCE}]} \right)_{\text{overall}} = \frac{\frac{iLfR_0}{2F(R_0 + 1)} + \int_0^L \int_0^{\delta_R} \frac{r(x, y)R(x, y)}{R(x, y) + 1} dy dx}{\frac{iLf}{2F(R_0 + 1)} + \int_0^L \int_0^{\delta_R} \frac{r(x, y)}{R(x, y) + 1} dy dx} \quad [\text{A-16}]$$

where R_0 is the ratio obtained from reaction in the bulk solution and f is the fraction of chlorine being carried out of the reaction layer by convection

$$f = \int_0^{\delta_R} u_x(y)[\text{Cl}_2](y)|_{x=L} dy / \left(\frac{iL}{2F} \right) \quad [\text{A-17}]$$

Concentration profiles were computed by a finite difference method (IMSL subroutine ZSPOW) implemented on a Cyber 175 computer. Additional details are available in Ref. (17).

LIST OF SYMBOLS

A	electrode area (cm^2)
C_b	bulk concentration of HCl (mol/cm^3)
C_0	ethylene concentration in electrolyte (mol/cm^3)
C^*	bulk concentration of HCl at cell inlet (mol/cm^3)
d_b	bubble departure diameter (cm)
D_i	diffusion coefficient of species i (cm^2/s)
E_{eq}	equilibrium potential (V)
f	fraction of chlorine flux out of the reaction layer
F	Faraday's constant (96,487 C/eq)
h	cell gap (cm)
i	current density (A/cm^2)
i_0	exchange current density (A/cm^2)
I_{cell}	cell current (A)
k	reaction rate constant for chlorination of ethylene ($\text{cm}^3/\text{mol}\cdot\text{s}$)
k_3	rate constant for ethylene chlorohydrin formation ($\text{cm}^3/\text{mol}\cdot\text{s}$)
k_4	rate constant for 1,2-dichloroethane formation ($\text{cm}^3/\text{mol}\cdot\text{s}$)
k_{mt}	mass transfer coefficient (cm/s)
L	cell length (cm)
n	number of electrons involved in the electrochemical reaction
$N_1 - N_4$	chlorine fluxes in Fig. A-1 ($\text{mol}/\text{cm}^2\cdot\text{s}$)
P_{cell}	cell pressure (atm)
Q	electrolyte flow rate (cm^3/s)
R	product ratio ($[\text{EC}]/[\text{DCE}]$); gas constant (8.3144 J/g-mol-K), when appearing as RT
R_0	product ratio in bulk electrolyte
R_s	solution phase ohmic resistance (Ω)
Re	$V_g d_b / A \nu$, Reynolds number (dimensionless)
S	amount of chlorine reacted in the reaction layer per unit time (mol/s)
Sc	ν / D_{HCl} , Schmidt number (dimensionless)
Sh	$\kappa_{\text{mt}} d_b / D_{\text{HCl}}$, Sherwood number (dimensionless)
t_i	transference number of ionic species i
T	temperature (K)
$\langle u \rangle$	average velocity of electrolyte flow, (cm/s)
u_g	rise velocity of bubble swarm, (cm/s)
V_{cell}	cell voltage (V)
V_g	volume rate of gas bubble formation (cm^3/s)
W	cell width (cm)

Greek Symbols

α	symmetry factor in Butler-Volmer equation
δ_{avk}	average thickness of moving bubble layer (cm)
δ_R	reaction layer thickness (cm)
η_c	concentration overpotential (V)
κ_{avk}	effective conductivity of moving bubble layer (mho/cm)
κ_0	conductivity of gas bubble-free electrolyte (mho/cm)
ν	kinematic viscosity (cm^2/s)
ϕ_s	solution phase potential (V)

Subscripts

a	anodic
c	cathodic
s	surface

Charge-Discharge Behavior of Polyacetylene Electrodes

Fritz G. Will*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The charge-discharge and open-circuit behavior of polyacetylene electrodes, p-doped with BF_4 , is examined. Discharge curves for controlled current are interpreted quantitatively in terms of a model involving slow dopant diffusion and slow discharge at the polymer/electrolyte interface. The open-circuit potential is measured as a function of mean dopant level. It is shown that, due to the slow dopant diffusion, no steady-state potentials are attained. The coulombic efficiency of pristine polyacetylene electrodes in identical states of doping is determined as a function of discharge current. Discrepancies among results of different authors are related to different dopant states near the polymer surface. A quantitative relationship between efficiency and current is derived which is shown to be valid for small polarizations and short discharge times.

Polyacetylene $(\text{CH})_x$ can be doped and undoped electrochemically (1) with a variety of ions and can, therefore, principally be used as novel electrode material in rechargeable batteries. Certain aspects of repetitively charging (p-doping or anion incorporation) and discharging (undoping) polyacetylene electrodes have been described in the literature. Nigrey *et al.* (1) applied controlled current charges and discharges of short duration to polyacetylene films in solutions of LiClO_4 in propylene carbonate. This resulted in ClO_4 dopant level changes of the order of 0.5 mole percent (m/o). Kaneto *et al.* (2) described the open-circuit voltage behavior following consecutive controlled potential charge and discharge pulses and determined the coulombic and energy efficiency of ClO_4 -doped polyacetylene at various constant current discharges. They observed an unexplained increase in coulombic efficiency from 74 to 87% for a ten-fold increase in discharge current. Farrington *et al.* (3) found quite different open-circuit voltage behavior after p-doping with ClO_4 or AsF_6 , characterized by a pronounced voltage step at 2 m/o doping level and a linear increase in voltage at higher doping levels. Furthermore, coulombic efficiencies reported in Ref. (3) for controlled current discharge from identical dopant levels as in Ref. (2) are only approximately half of the values reported in Ref. (2), that is, only 41-51%.

In the present paper, we study the open-circuit voltage behavior of polyacetylene electrodes p-doped with BF_4 , following consecutive controlled current charges and discharges of 0.1-100s duration. Furthermore, we establish the coulombic efficiency of pristine polyacetylene film electrodes for various controlled current charges and discharges of typically 1h duration. We show that the coulombic efficiency is determined by slow dopant diffusion (4, 5) in the polyacetylene structure. The anomalies of efficiency *vs.* discharge current observed by others (2) and the discrepancies among the efficiency values reported by different groups (2, 3) can be reconciled by the nonsteady-state nature of dopant diffusion and concentration in polyacetylene.

Experimental

Polyacetylene films had been prepared by the Rohm and Haas Company and shipped in sealed glass vials, filled with inert gas. Prior to electrochemical experiments, films were predominantly in the *cis* form as evidenced by infrared spectroscopy (6). They had an apparent density of 0.56 g/cm^3 , corresponding to 48% of the theoretical density and a true surface area of 40-50 m^2/g . The internal void space of 52% consists of interconnected micropores of a few hundred to a few thousand angstroms diameter between individual polyacetylene fibers of a few hundred angstroms diameter. This microfibrillar structure of polyacetylene is well established (7, 8).

Details of the film preparation and characterization have been described elsewhere (6). Circular electrodes A of 2 cm^2 area with 89 μm thickness and B of 1.25 cm^2 area

with 68 μm thickness were cut from the films. The former corresponds to 2.7 m/o dopant per $\text{A-s}/\text{cm}^2$ charge, the latter to 3.5 m/o/ $\text{A-s}/\text{cm}^2$. Electrodes were provided with 1000 \AA sputtered Au films on the back side. Contact was made by attaching Au wires with Au-epoxy cement. Experiments were carried out in PTFE cells using Li counter and reference electrodes. Approximately 1 cm^3 electrolyte was employed, consisting of 30% by weight solutions of LiBF_4 in sulfolane for electrodes A and 10% solution for electrodes B. These electrolytes have very high viscosity. Handling of and experimentation with the polyacetylene were carried out in a high quality dry box.

Coulombic efficiency studies were performed for each different discharge current on a pristine polyacetylene electrode, charged with identical current density of 0.24 mA/cm^2 .

Controlled currents were generated with a PAR Model 175 Universal Programmer and applied with a PAR Model 175 Galvanostat/Potentiostat equipped with Digital Coulometer Model 179. Voltage-time traces were recorded on a Nicolet Model 206 Storage Oscilloscope or a Hewlett-Packard Model 17501A Recorder, depending on pulse duration.

Results

Nonsteady-state polarization behavior.—Figure 1 shows polarization-time transients for electrode A, subjected to short-duration discharge and charge pulses separated by open-circuit periods. Electrode A had been previously charged to 7 m/o BF_4 dopant level. The polarization data are corrected for the ohmic voltage drop between test and reference electrode and are referred to the open-circuit potential of 3.8V obtained after 7 m/o doping. It is seen from Fig. 1 that discharge and charge with current densities as small as 0.05 and 0.5 mA/cm^2 yield low polarizations which do not appear to change significantly after the first few hundredths of a second.¹ Open-circuit stand for 0.1s following discharge or charge with 0.05 mA/cm^2 for 0.1s results in negligible remaining polarization, whereas a current density of 0.5 mA/cm^2 for 0.1s al-

¹ Closer examination of the curves and charging or discharging for longer periods of time, however, reveals that the polarizations do not attain steady-state values.

Fig. 1. Short-term charge, discharge, and open-circuit behavior of BF_4 -doped polyacetylene electrodes; doping and undoping with 0.1s current pulses.

* Electrochemical Society Active Member.

Fig. 2. Short-term polarization behavior of BF_4 -doped polyacetylene electrodes; doping and undoping with 100s current pulses.

ready produces a perturbation which does not dissipate completely on open circuit in 0.1s. Charge or discharge with 0.5 mA/cm^2 for 0.1s corresponds to a dopant injection or removal of $3.1 \times 10^{14} \text{ BF}_4$ molecule/ cm^2 .

Figure 2 shows polarization-time transients for pulse lengths and open-circuit periods of 100s each. Thus, dopant injection or removal corresponds to 3.1×10^{16} and $3.1 \times 10^{17}/\text{cm}^2$ in a single 0.05 and 0.5 mA/cm^2 pulse. It is seen that even for the small current density of 0.05 mA/cm^2 steady-state polarizations are never attained. This is even more pronounced for the 0.5 mA/cm^2 pulse. During the 100s open-circuit periods following current pulses, the perturbations caused by the charge injection or removal do not relax. Slow diffusion (4, 5) prevents steady state from being attained.

Open-circuit potential-dopant level relationship.—Prior to establishing the open-circuit potential-dopant level relationship, electrode A had been cycled several times, discharged to 1.3V, and left on open circuit for 1h, which led to recovery of the potential to 3.33V. The electrode was then p-doped in a series of 100s charging pulses of 0.25 mA/cm^2 , each followed by an open-circuit period of 100s (part a of curve). In part b of the curve, the open-circuit period was increased from 100 to 500s. The potential-time transients were equivalent to those shown in Fig. 2. The charge input and the open-circuit potential were both recorded and the potential at the end of the open-circuit stand plotted in Fig. 3 against the incremental charge input. The upper abscissa shows the incremental dopant level if the dopant were uniformly distributed throughout the entire polyacetylene film.² It is appreciated from the discussion in the preceding paragraph that the potentials plotted in Fig. 3 are nonsteady-state values. The open-circuit potential increases monotonically from 3.35 to 3.72V for a mean dopant level change of 1.5 m/o. The decrease at 3.62V is due to the change of open-circuit stand from 100 to 500s. Discharge in a series of 100s pulses of 0.25 mA/cm^2 with 500s stand after pulses results in decreasing open-circuit potentials as shown in Fig. 3. The relevant curve exhibits considerable hysteresis such that the open-circuit potentials on discharge are by an average of 0.2V lower than those on charging at identical mean dopant levels. Under the conditions applied, namely, charging with 100s pulses of 0.25 mA/cm^2 followed by open circuit for 500s and discharging with the same pulse regime, polyacetylene electrodes do not behave reversibly, and no unique relationship between open-circuit potential and mean dopant level is established.

Charge-discharge cycling simulating battery applications.—The charge-discharge curves of Fig. 1 and 2 are of little interest to practical battery operation as the discharge times are too short and the doping level changes too small to yield energy densities competitive with other batteries. Figure 4 shows the results of three consecutive charges and discharges of longer duration. Pristine film was charged initially at controlled potentials of 3.5, 4, and 4.5V for a total of 2h. A charge of 1.5 A-s/cm^2 was thus injected over a time period of 2h, corresponding to a mean

² Referred to as mean dopant level or mean concentration from here on.

Fig. 3. Open-circuit potential of BF_4 -doped polyacetylene vs. incremental state of charge or mean dopant level. a: 100s on open circuit after $0.25 \text{ mA/cm}^2 \times 100\text{s}$ charging pulses (doping). b: 500s on open circuit after doping. c: 500s on open circuit after $0.25 \text{ mA/cm}^2 \times 100\text{s}$ discharge pulses (undoping).

dopant level of 4 m/o. Subsequent discharges were performed at 0.25 mA/cm^2 to a lower voltage limit of 1.3V and alternate charges at 0.25 mA/cm^2 for 1-2.5h. The charging, discharging, and open-circuit conditions are summarized in Table I, as are the coulombic efficiencies. The latter values vary greatly, from 19 to 55%, in spite of identical current densities during charge and discharge in these three cycles. It appears from Table I that a short open-circuit period between charge and discharge leads to high coulombic efficiencies and vice versa.

Coulombic efficiency of pristine polyacetylene.—The nonreproducibility of consecutive charge-discharge curves of polyacetylene films subjected to different open-circuit periods prior to discharge suggests that the film is in different dopant states. This makes an evalua-

Fig. 4. Consecutive charge-discharge curves of BF_4 -doped polyacetylene. First charge potentiostatically at 3.5, 4, and 4.5V; subsequent charges and discharges galvanostatically at 0.25 mA/cm^2 . Additional details in Table I.

Table I. Coulombic efficiencies in consecutive cycling

Charging			Open circuit <i>t</i> (min)	Discharging			Open circuit <i>t</i> (min)	Efficiency Q_{out}/Q_{in}
<i>i</i> (mA/cm ²)	<i>t</i> (min)	Q_{in} (A-s/cm ²)		<i>i</i> (mA/cm ²)	<i>t</i> (min)	Q_{out} (A-s/cm ²)		
Const. V	120	1.45	10	0.25	54	0.80	30	0.55
0.25	160	2.39	50	0.25	31	0.46	60	0.19
0.25	120	1.75	10	0.25	54	0.82	60	0.47

tion of the effect of current density on discharge performance difficult or impossible.

Therefore, a comparative study of the very first charge and discharge on pristine polyacetylene films was undertaken with discharges performed at different current densities. This enables determination of the coulombic efficiency as a function of current density for polyacetylene identically pretreated and hence presumably in identical initial dopant states. Figure 5 shows charge-discharge curves for three pristine film electrodes B. Charging was carried out with 0.24 mA/cm² for 70 min, equivalent to 1 A-s/cm² or a dopant level of 3.5 m/o. The charging curves for all three films were identical. Discharging was performed after 1h open-circuit stand with current densities of 0.08, 0.24, and 1.2 mA/cm², respectively. A voltage plateau occurs with inflection points at 3.5, 3.45, and 3.03V, respectively. The coulombic efficiencies for discharge to 2.5V decrease from 70% at 0.08 mA/cm² to 64% at 0.24 mA/cm² and to 30% at 1.2 mA/cm².

Reproducibility of the charge-discharge curves was ascertained at 0.24 mA/cm² by employing a fourth pristine film. A charge-discharge curve identical to the relevant curve in Fig. 5 was obtained.

Discussion

Nonsteady-state polarization behavior.—Polarization-time transients of short duration such as those shown in Fig. 1 and 2 are quantitatively interpreted (4) in terms of a semi-infinite linear diffusion model with charge transfer through the polyacetylene/solution interface superimposed on the very slow diffusion (5) of dopant in the polyacetylene. Applicability of semi-infinite linear diffusion to the microporous structure of polyacetylene films is tantamount to the assumption that only the exterior surface of the film is wetted by the electrolyte and that the large interior surface (2000 times larger than the projected area) remains essentially electrolyte free. This assumption is justified by the fact that the observed

double-layer capacitance (4, 5) is 14 and 22 μ F for electrodes B and A, respectively. Such values yield 11 μ F/cm² if only the exterior surface is wetted and 0.005 μ F/cm² if the large interior surface is also wetted. Clearly, only the former value is in agreement with generally accepted double-layer capacitance values. Considering the high viscosity of the electrolytes used in this study, the nonpenetration of the micropores is not surprising. This condition may not apply to electrolytes with low viscosities, especially if the electrodes are carefully vacuum impregnated. Vacuum impregnation, however, has not been applied in this study or, apparently, in other studies (1-3).

The mathematical model further assumes a solid slab of homogeneous physical properties. This means that the fibrous structure is neglected and that an isotropic diffusion coefficient is assumed. In fact, however, the diffusion coefficient is expected to be different parallel and perpendicular to the fiber axis. More complex future models may take these features into account and future experiments may establish the diffusion coefficients parallel and perpendicular to the fiber axis.

The effect of charging the double-layer capacitance is only significant in the first few milliseconds of the transient and can be neglected thereafter. For times short compared to the time constant for diffusion through the entire film and for small polarizations η , the transient is given (9) by

$$\eta = (RT/F) (i/i_0 + 2i \sqrt{t}/\sqrt{\pi D} F c_0) \quad [1]$$

where i is the applied current density, i_0 the exchange current density, t the time, c_0 the initial dopant concentration, D the dopant diffusion coefficient, R the gas constant, T the temperature, and F the Faraday constant. The current densities are related to the wetted exterior (or projected) surface area where ion charge and discharge is thought to occur.³

Validity of Eq. [1] assumes that the dopant concentration is nearly constant (c_0) over a distance from the exterior surface into the interior comparable to the diffusion depth relevant to the subsequent transient. Whether or not this is the case depends on the duration of the pulses and open-circuit periods. Figure 6 shows the polarization transients of Fig. 2 for both charge and discharge at 0.5 mA/cm² in a plot of η against \sqrt{t} . The curves exhibit the straight line behavior required by Eq. [1]. The slope of the straight line yields the diffusion coefficient, and the intercept with the axis $\sqrt{t} = 0$ yields the exchange current density. It is, therefore, clear that the nonsteady-state behavior of polyacetylene electrodes results from the very slow diffusion of dopants into and out of the polymer.

The concentration gradients relevant to a pulse sequence are qualitatively shown in Fig. 7. Figure 7a corresponds to charging (doping) of a pristine or well-equilibrated film. The constant value of dc/dx is dictated by the constant applied current density. Figure 7b shows the partial relaxation of the concentration profile during open circuit. At the interface, $dc/dx = 0$ as the current is zero. Figure 7c shows commencement of discharge with concentration gradients from the preceding charging event still present. Figure 7d shows the relaxation on open circuit of the concentration gradients left from the previous discharge. For comparison with Fig. 7c, Fig. 7e shows the concentration profile for discharge of a well-equilibrated film, kept on open circuit for a long time.

³ It is for this reason that we refer to doping and diffusion of BF_4^- rather than BF_4^- ions in the polyacetylene structure.

Fig. 5. First charge-discharge curves of pristine BF_4^- -doped polyacetylene at various discharge currents; 1h on open circuit following charging to 3.5 m/o.

Fig. 6. Polarization-time transients of polyacetylene, BF_4 -doped to 7 m/o, during charging and discharging with $0.5 \text{ mA/cm}^2 \times 100\text{s}$ current pulses; η plotted against \sqrt{t} according to Eq. [1].

Open-circuit potential-dopant level relationship.—The open-circuit potential is dependent on the activity or concentration of dopant at the polyacetylene/solution interface. In view of the small diffusion coefficients of dopants in polyacetylene, very long times of equilibration are required after charging or discharging before steady-state open-circuit potentials are obtained which correspond to uniform dopant concentration throughout the polyacetylene. For a $70 \mu\text{m}$ thick film, equilibration times are in excess of 300h, and for a $7 \mu\text{m}$ film, in excess of 8h. The open-circuit potential vs. charge data in Fig. 3 are thus nonsteady-state data, and the dopant levels near the surface deviate considerably from the mean levels in Fig. 3. The surface values decrease or increase toward the in-

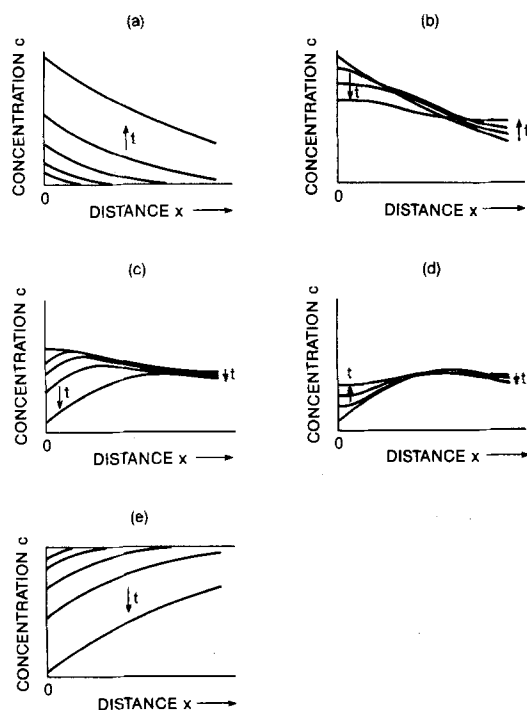

Fig. 7. Dopant concentration profiles in polyacetylene electrodes (qualitatively) at different times during consecutive (a) charging, (b) 1. open circuit, (c) discharging, and (d) 2. open circuit; (e) discharge of previously equilibrated charged film.

terior after charge or discharge, respectively, in a way qualitatively shown in Fig. 7. The decrease in open-circuit potential with longer open-circuit time and the hysteresis of the curves on charge and discharge, as shown in Fig. 3, are thus explained in terms of nonsteady-state diffusion.

Kaneto *et al.* (2) determined the open-circuit potential as a function of dopant level at different times after charging with a series of potential steps. Their results after 2s and 24h open-circuit stand are plotted in Fig. 8 together with the present results. Straight lines result in a semilog plot with slopes between 300 and 400 mV/decade. The open-circuit potentials are highest after the consecutive $0.25 \text{ mA/cm}^2 \times 100\text{s}$ current pulses and 100s open-circuit times employed in this study, since the surface concentration of dopants is highest. The consecutive voltage pulses applied by Kaneto *et al.* allowed more time for the dopant to diffuse into the interior. Hence, the open-circuit potentials are lower after only 2s open-circuit time. The values after 24h open-circuit time are lower yet, but still cannot be regarded as steady-state values. Farrington *et al.* (3) employed 0.05 mA/cm^2 current pulse charges of various durations. Discharge for more than 16h had preceded charging. Open-circuit potentials were observed at unspecified time after charging. The data are also shown in Fig. 8. The high mean dopant levels employed in this study correspond to exceedingly large dopant levels near the surface. Such high dopant levels, in the region of 10-50 m/o, may result in formation of a second phase which would explain the step change in open-circuit potential at 3 m/o mean dopant level.

The large observed slopes of 300-400 mV/decade in Fig. 8 are not readily explained in terms of simple solution behavior as it applies, for example, to the alkali intercalates of graphite (10). Such large changes in open-circuit potential with doping have, however, been observed (11) in other intercalation compounds, such as Li_xTiS_2 and Na_xTaS_2 ; they are consistent with a salt-like model, requiring lattice rearrangement energy, and may also be associated with shifts in the Fermi level energy brought about by the donation of p-type charge carriers from the dopant molecules to the conduction band.

It appears that the slow diffusion of dopants in polyacetylene is responsible for the different behaviors observed by different authors. The boundary conditions established at the surface depend on the previous history of the polyacetylene, such as potentiostatic vs. galvanostatic conditions, applied current density, duration of open-circuit periods, etc. The open-circuit potential, in turn, depends only on the surface concentration. In all studies to date, open-circuit times have been too short to establish the true steady-state relationship between open-circuit potential and dopant level.

Fig. 8. Open-circuit potential of p-doped polyacetylene vs. logarithm of mean dopant level at specified times after charging. (a) 100s after BF_4 doping with 0.25 mA/cm^2 pulses; (b) unspecified time after ClO_4 doping with 0.05 mA/cm^2 ; (c) 2s after ClO_4 doping with increasing voltage pulses; (d) 24h after ClO_4 doping with voltage pulses.

Charge-discharge cycling.—Short-duration charge and discharge curves such as those shown in Fig. 1 and 2 can be readily interpreted in terms of the simple Eq. [1]. For such short times, the polarization η remains small and the linearization of the exponential terms in the discharge equation leads to cancellation of the terms containing the transfer coefficient α .

However, for longer charge and discharge times, as they are of interest to battery applications, the polarization becomes large enough so that the expression

$$\eta = -[RT/(1 - \alpha)F] [\ln(-i/i_0) - \ln(1 - \sqrt{t/\tau})] \quad [2]$$

must be used (12). The transition time τ is given by

$$\tau = \pi D F^2 c_0^2 / 4 i^2 \quad [3]$$

and signifies the time at which the dopant concentration at the polyacetylene surface has become zero; τ must not be confused with the time constant for dopant diffusion through the entire film.

When τ has been reached, η increases rapidly; this is the case for $\tau = 7200$ s for the discharge curve at 0.08 mA/cm^2 on pristine polyacetylene, shown in Fig. 5. From Eq. [3] with $D = 5.7 \times 10^{12} \text{ cm}^2/\text{s}$, we calculate a dopant concentration of $3.1 \times 10^{-2} \text{ mol/cm}^3$. This corresponds to 34.8 m/o doping when averaged over the penetration depth \sqrt{Dt} of approximately $3 \mu\text{m}$ during 1h charging and 1h on open circuit. Figure 9 shows the discharge curve for 0.08 mA/cm^2 of Fig. 5 in a plot of η vs. $-\log(1 - \sqrt{t/\tau})$. A straight line results at large η as required by Eq. [2]. The slope yields an α value of 0.77 and the intercept with the ordinate at $\sqrt{t/\tau} = 0$ results in an i_0 value of $3.6 \times 10^{-5} \text{ A/cm}^2$. Discharge curves published by Kaneto *et al.* (2) for discharge of polyacetylene doped with 7 m/o ClO_4 also yield straight lines for large η when plotted in terms of η vs. $-\log(1 - \sqrt{t/\tau})$. As an example, the lower curve in Fig. 9 corresponds to discharge at approximately 0.5 mA/cm^2 with $\tau = 2400$ s. The slope yields $\alpha = 0.93$, and the intercept $i_0 = 2.1 \times 10^{-4} \text{ A/cm}^2$. To arrive at these numbers, we have made the reasonable assumption that the diffusion coefficients of BF_4 and ClO_4 are approximately the same. Hence, the model of slow diffusion and discharge explains the present data and those of Kaneto *et al.* equally well. We find no support for the recent model of field-enhanced diffusion of Kaufman *et al.* (13), which they employ to explain a perceived three orders of magnitude discrepancy between observed discharge currents and currents predicted on the basis of a standard diffusion model. The perceived discrepancy is based upon an estimate of the diffusion coefficient which is six orders of magnitude in error [see Ref. (5)]; in addition, the model of field-enhanced diffusion which has been applied to O_2

diffusion in thin SiO_2 films on Si (14) is not applicable to highly doped polyacetylene, as the Debye length for such high charge-carrier densities is far too small.

Coulombic efficiency as function of discharge current.—In consecutive cycling of polyacetylene electrodes with 0.25 mA/cm^2 , we have observed variations of the coulombic efficiency from 19 to 55% (Table I) and have found that long open circuit results in low efficiencies and vice versa. This behavior is due to a larger fraction of the dopant diffusing into the bulk of the polyacetylene during longer open-circuit stand. Figure 7 shows the relevant time-dependent concentration profiles.

Farrington *et al.* (3) observed variations in efficiency from 21 to 46% in three consecutive cycles with approximately identical mean dopant levels of 3 m/o and charge/discharge currents of $0.05/0.5 \text{ mA/cm}^2$. The open-circuit time between charge and discharge was not specified, and we speculate that the variations in their efficiency values too may have been caused by different open-circuit periods.

A study of the effect of current density on coulombic efficiency also requires identical previous history and, hence, identical states of doping. This was assured in the present study by employing pristine polyacetylene and identical charging conditions and open-circuit times prior to discharge. According to the results in Fig. 4, the coulombic efficiency of pristine film, charged and discharged once, decreases significantly with increasing discharge current density. Such behavior may be suspected again to result from the slow diffusion of dopants in polyacetylene. The effect of slow diffusion and simultaneous slow discharge on the coulombic efficiency can be predicted from Eq. [1] or [2], for small or large values of η , respectively. For discharge performed at various current densities i_d to small fixed polarization η_F , the relevant discharge times t_d follow from Eq. [1] as

$$\sqrt{t_d} = (\sqrt{\pi D} F c_0 / 2) (F \eta_F / RT i_d - 1/i_0) \quad [4]$$

The mean dopant concentration c_0 is related to the input charge $q_{in} = i_c t_c$ by

$$c_0 = q_{in} / F \delta \quad [5]$$

where i_c , t_c are charge current density and time, respectively, and δ the film thickness. The coulombic efficiency $e_{\text{coul}} = q_{\text{out}}/q_{\text{in}}$ then follows from Eq. [4] as

$$e_{\text{coul}} = (\pi D q_{in} i_d 4 \delta^2) (F \eta_F / RT i_d - 1/i_0)^2 \quad [6]$$

According to Eq. [4], for discharge to a fixed small polarization η_F , a plot of $\sqrt{t_d}$ vs. the reciprocal discharge current ($1/i_d$) should yield a straight line. Figure 10 shows a plot of this type for $\eta_F = 50 \text{ mV}$ and 100s discharge pulses applied to electrode A. A straight line is indeed obtained, and the observed discharge times are predicted very well for a doping concentration near the surface of 5 m/o, which is somewhat smaller than the 7% derived from the charge input under the assumption of a flat concentration profile throughout the polyacetylene.

No quantitative agreement between observed and predicted coulombic efficiencies is obtained for large polarizations as they apply to the discharge curves in Fig. 4 and 5. Only the general trend is predicted correctly; namely, that for polyacetylene in identical dopant state just prior to discharge, the efficiency decreases significantly (70, 64, and 30%) with increasing current density (0.08, 0.24, and 1.2 mA/cm^2).

On polyacetylene in different dopant states prior to discharge, Kaneto *et al.* (2) observed an unexplained increase in coulombic efficiency (74, 79.3, and 86.7%) with increasing current (0.1, 0.55, and 1.0 mA). Charging in all three cases had been carried out to a mean dopant level of 7 m/o but for times of 12, 7, and 5.5h, respectively. The results of the present study provide a ready explanation for the anomalous observed behavior: during longer charging time, a larger fraction of the total amount of dopant diffuses into the polyacetylene, thus leaving a smaller dopant concentration near the surface for reduction dur-

(a) 1h discharge of pristine 3.5 m/o BF_4 -doped polyacetylene with 0.08 mA/cm^2 (see Fig. 5); $\tau = 7200$ s; (b) 0.7h discharge of 7 m/o ClO_4 -doped polyacetylene with $\sim 0.5 \text{ mA/cm}^2$, $\tau = 2400$ s.

Fig. 10. Discharge time $\sqrt{t_d}$ vs. reciprocal discharge current density to fixed polarization of -50 mV according to Eq. [4]; evaluation of transients from 0.05 to 0.5 mA/cm² shown in Fig. 2.

ing subsequent discharge. This behavior is evident from the time-dependent concentration profiles shown in Fig. 7.

Conclusions

The behavior of BF₄-doped polyacetylene electrodes during charge, discharge, and open circuit is controlled by slow solid-state diffusion of the dopant in the polymer. Steady-state potentials are therefore usually not attained, unless the amount of charge (dopant) injected or removed is of the order of only 0.01 mA-s/cm² or open-circuit times between charges or discharges are exceedingly long, *i.e.*, in excess of 300h for a 70 μ m thick film. Since such long times have not been employed in this or other studies, no unique relationship between open-circuit potential and state of charge or dopant level has been established as yet.

Discharge curves of BF₄-doped polyacetylene reported here and of ClO₄-doped polymer obtained by others are interpreted quantitatively by a model involving slow diffusion and discharge. There appears to be no need to invoke a field-enhanced diffusion model.

Coulombic efficiencies observed on pristine polyacetylene electrodes, identically BF₄-doped for 1h with

0.24 mA/cm² to 3.5 m/o followed by 1h on open circuit, are 70, 64, and 30% for discharge with 0.08, 0.24, and 1.2 mA/cm², respectively. The dependency of efficiency on current is predicted quantitatively by a semi-infinite diffusion model if the discharge polarizations and times are small. The anomalous increase in efficiency with increasing discharge current observed by other authors is readily explained by different dopant concentrations near the surface caused by very different charging times.

Kinetic Investigation on the Mechanism of the Photoelectrochemical Oxidation of Water and of Competing Hole Processes at the TiO₂(Rutile) Semiconductor Electrode

F. Vanden Kerchove, A. Praet, and W. P. Gomes*

Rijksuniversiteit Gent, Laboratorium voor Fysische Scheikunde, B-9000 Gent, Belgium

ABSTRACT

The competition between the oxidation of H₂O and that of Br⁻ ions at the illuminated surface of the semiconducting rutile anode was studied as a function of the Br⁻ concentration at the surface, the light intensity, the electrode potential, and the surface pretreatment by means of the rotating ring-disk electrode (RRDE) technique. The results allow one to propose a mechanism for the multistep oxidation of H₂O to O₂ as well as for the oxidation of Br⁻, the latter reaction being assumed to occur with the surface intermediate H₂O₂ of the former. The data also indicate the occurrence of a surface electron-hole recombination process involving intermediates of the H₂O oxidation, and demonstrate the influence of surface imperfections upon the competition studied.

The anodic oxidation of water to oxygen by photo-generated holes at the semiconducting TiO₂ (rutile) electrode is the reaction which led, more than a decade ago, to the concept of solar-to-chemical energy conversion in photoelectrochemical cells (1). However, the mechanism of this important reaction is not known in detail yet. Indeed, the saturation photocurrent density only depends on the light intensity. Therefore, data on the reactivity of water for holes and on the different steps of this oxidation are not directly accessible by kinetics, and can only be obtained by studying the competition between different reagents for the holes at the electrode surface. One possible method, which was formerly used for TiO₂ (2) and SrTiO₃ (3), consists of the measurement of the photocurrent under the addition of so-called current doubling reagents to the photoelectrochemical cell. A more recent technique uses the rotating ring-disk electrode (RRDE): the reaction product of one of the competitive photoreactions at the semiconductor disk electrode is detected specifically at the metal ring electrode. A competitive reagent, which is well suited for this study, is the bromide ion. Its oxidation product, Br₂, is stable in acid solutions and can be easily detected at the ring electrode.

Other investigators have already presented results, obtained by means of this method at monocrystalline TiO₂ electrodes, where Br⁻ competed with water for holes. Kobayashi *et al.* (4) observed at pH = 2 that Br⁻ was very reactive as compared to water. At high concentrations of Br⁻ ($c \geq 10^{-2}$ mol-dm⁻³), the fraction n of the photocurrent that oxidizes Br⁻ appeared to be independent of the light intensity. At lower bromide concentrations, n decreased when the light intensity increased, apparently because of the diffusion limitation of the bromide transport to the electrode. Also, Fujishima *et al.* (5) studied the competition between Br⁻ and H₂O. They also stated that n was independent of the light intensity, without mentioning, however, at which values of pH and c this observation was made. Both groups of investigators found that the reactivity of Br⁻ decreases with respect to that of water when the pH of the solution is increased. Hence, higher concentrations of bromide can be used for competition studies in less acid solutions, so that the oxidation of Br⁻ at the anode is no longer limited by the diffusion rate. However, at higher pH, several complications must be taken into account: dismutation of Br₂ to hypobromite and bromide is possible (6); in unbuffered solutions, the pH at the photoanode changes because of the photo-oxidation of water; and in buffered solutions, the buffer (*e.g.*, acetate) may react with the holes (7).

Therefore, we preferred to confine our measurements to solutions of a pH less than 2, so that the addition of buffers could be avoided and nevertheless changes in pH could be neglected. At these pH values, the range of bro-

mid concentrations, in which changes of n can be observed without the influence of diffusion limitation, is rather small; however, the concentration range can be considerably extended by exploiting the properties of the RRDE. By varying the rotation speed of the RRDE, the flux of bromide to the disk can be monitored. By application of the diffusion laws, c_s (the concentration of bromide at the disk surface) can be calculated (see results). Thus, n can be measured as a function of c_s under different circumstances of light intensity, electrode potential, and surface pretreatment. Such measurement may yield interesting indications on reaction mechanisms, as was recently shown in the case of III-V semiconductor electrodes [see, *e.g.*, Ref. (8) and (9)]. By measuring n at different stages of the photoetching procedure, the influence of the surface pretreatment on the photoelectrochemical behavior of TiO₂ can be studied.

Experimental

All TiO₂ electrodes were cut from one monocrystalline sample, purchased from NL Industries (South Amboy, New Jersey). The sample was doped with 0.05 weight percent (w/o) Nb₂O₅. The electrodes were worked to a cylinder with a height of 5.0 mm and a diameter of 5.0 mm. The front side was the (001) face. Before the TiO₂ sample was mounted as the disk electrode, indium was evaporated on the back and then it was heated in a nitrogen flow during 20 min at 400°C. After cooling, the disk was fitted in a Teflon® tube, which was in turn fitted in a copper tube, on top of which a platinum ring was soldered. Around the ring and the copper tube, a PVC shaft of a suitable shape was mounted. In order to avoid leaks to the back of the electrodes, Cyanolit® 202, a cyanoacrylate ester, was applied between the electrodes and the Teflon and solidified there. Before any measurement, the electrode surface was successively polished with abrasive papers and Al₂O₃ powders of decreasing grain size (0.3 μm final polish) and the previously described photoetching procedure (10) was applied.

Six electrodes were assembled in this way. All but one, exhibiting an inhomogeneous surface, showed very similar behavior. The results reported below were all obtained on two of them, indicated by A and B, respectively. The dimensions of the RRDE r_1 , r_2 , r_3 (being the radius of the disk, and the inner and the outer radius of the ring, respectively), and the theoretical collection efficiency N are given in Table I. For the calculation of N from the dimensions of the RRDE, the theoretical treatment of Albery and Bruckenstein (11) was followed.

The combined ring-disk electrode was fixed in the cover of the perspex electrochemical cell. In the cell, an auxiliary electrode made of platinized platinum gauze was present; a saturated K₂SO₄-Hg₂SO₄ reference electrode (Radiometer K601) was connected to the cell

* Electrochemical Society Active Member.

Table I. Characteristics of the electrodes used

Specimen	r_1 (mm)	r_2 (mm)	r_3 (mm)	N
A	2.37	3.47	3.88	0.213
B	2.40	3.45	3.92	0.232

through a saturated K_2SO_4 salt bridge. The four electrodes were connected to a bipotentiostat (Bipad Tacussel). The potential of the disk or the ring could be swept by a homemade voltage programmer. All electrode potentials will be expressed in volts vs. the saturated sulfate electrode (SSE). The cell was installed in an earthed metal case. The ring-disk electrode could be rotated by means of an electric motor (Tacussel); the rotation speed could be varied between 0 and 2400 rpm. The speed was measured by means of an opto-digital tachometer.

The disk was illuminated by a 450W xenon arc lamp with a stabilized power supply (Oriol). The light was entering the electrochemical cell through a Pyrex window. By placing neutral density filters (Balzers) in the light beam, different light intensities were obtained. No absolute measurement of the light intensity was performed. The saturation photocurrent was always proportional to the light intensity for each state of the electrode surface and was hence considered as a measure of the light intensity for the electrode state considered. All electrodes were mounted in the same position relative to the lamp; thus, the saturation photocurrent under full light intensity can be used as a reference for the measurement of the light intensity at the different states (damaged or etched) of the surface.

All solutions were prepared with reagent-grade chemicals (Merck) in deionized water. During the measurements, pure N_2 (99.98%) was bubbled through the electrolyte solution in order to remove the dissolved and formed oxygen.

The value of N was checked experimentally by dark reduction of $Fe(CN)_6^{3-}$ at the disk and reoxidation of the resulting $Fe(CN)_6^{4-}$ at the ring. The mean experimental value of N differed from the calculated one by less than 0.2% for electrode A and by less than 0.1% for electrode B.

Results on the competition between Br^- and H_2O are expressed by the competition ratio n . The value of n is calculated from the currents at the ring-disk electrode

$$n = I_{Br}/I_D = |I_R|/NI_D \quad [1]$$

where I_{Br} is the photocurrent associated with the oxidation of bromide, and $|I_R|$ and I_D the absolute increase of the (negative) ring and the (positive) disk current, respectively, resulting from the illumination of the disk. Unless otherwise stated, the disk was kept at +1.00V, i.e., in the saturation region of the photocurrent, and the ring at -0.20V, i.e., in the saturation region of the bromine reduction.

Results

Fully etched electrodes.—Influence of the light intensity and of the bromide concentration on n .—In accordance with the results of Kobayashi *et al.* (4) and Fujishima *et al.* (5), it is a general observation that, for relatively high concentrations of Br^- , n is independent of the light intensity, while for lower concentrations a strong dependence of n on the light intensity is observed. This is illustrated in Fig. 1, when n is given as a logarithmic function of the saturation photocurrent density i for three different concentrations of Br^- . These curves are very similar to those presented by Kobayashi *et al.* (4). As part of these curves are influenced by diffusion limitation of Br^- , we will, in order to isolate the effect of the light intensity, consider in what follows the concentration of Br^- ions at the surface, c_s . Under circumstances of diffusion control, c_s is smaller than the bromide concentration in the bulk, c . In the steady state, the flux of material reacting at the electrode surface must equal the flux being transported through the diffusion layer. Hence

Fig. 1. The competition ratio n as a function of the logarithm of the total photocurrent density i at different concentrations c of bromide. $n-TiO_2$ (specimen A), surface area 17.6 mm^2 , disk potential +1.0V vs. SSE, ring potential -0.2V vs. SSE, rotation speed 600 rpm, supporting electrolyte $0.33 \text{ mol}\cdot\text{dm}^{-3} \text{ HClO}_4$. Bromide concentration $c/\text{mol}\cdot\text{dm}^{-3}$: (□) 0.1; (×) 0.01; (○) 0.001.

$$i_{Br} = \frac{I_{Br}}{A} = \frac{FD(c - c_s)}{x_D} \quad [2]$$

i_{Br} being the part of the photocurrent density corresponding to the oxidation of Br^- , A the surface area of the disk, F the Faraday constant, x_D the thickness of the diffusion layer, and D the diffusion constant of Br^- . The value of x_D (in SI units) is given by (12)

$$x_D = 0.643 W^{-1/2} \nu^{1/6} D^{1/3} \quad [3]$$

with W the rotation speed of the RRDE (in revolutions per second) and ν the kinematic viscosity of the solution ($\nu = 0.9 \times 10^{-6} \text{ m}^2\cdot\text{s}^{-1}$).

The value of D can be calculated from the slope of the plot of I_{Br} vs. $W^{1/2}$ under circumstances of pure diffusion control. Indeed, when $c_s = 0$ and c is kept constant, I_{Br} is a function of the rotation speed only (see Eq. [2] and [3]). A value of $D = 1.56 \times 10^{-9} \text{ m}^2\cdot\text{s}^{-1}$ was obtained in $0.33 \text{ mol}\cdot\text{dm}^{-3} \text{ HClO}_4$ as the supporting electrolyte, which is in good agreement with that measured by Johnson and Bruckenstein (13) in $1 \text{ mol}\cdot\text{dm}^{-3} \text{ H}_2\text{SO}_4$ ($D = 1.58 \times 10^{-9} \text{ m}^2\cdot\text{s}^{-1}$).

From Eq. [1]-[3], Eq. [4] can be derived, which shows that c_s can be varied by varying the rotation rate and the bulk concentration of Br^- , and can be determined by measuring $|I_R|$ at given c and W , the values of N , A , ν , and D being known

$$c_s = c - \frac{0.643\nu^{1/6}}{NFAD^{2/3}} \cdot \frac{|I_R|}{W^{1/2}} \quad [4]$$

Values of n were measured at three different light intensities as a function of c_s . The results for the etched electrode A are plotted in Fig. 2(a). At high values of c_s , n tends to a constant value, but at lower values of c_s , n appears to be a function of both c_s and of the light intensity and, hence, of the total photocurrent density i .

Influence of the electrode potential on n .—The photocurrent at the disk remains nearly unaffected by variations of the disk potential, if larger than +0.25V. However, when the potential is decreased gradually to -0.5V, the photo-

Fig. 2. The competition ratio n as a function of the logarithm of the bromide concentration at the surface c_s at different light intensities corresponding to three values of the disk current density $i/\mu\text{A}\cdot\text{cm}^{-2}$: (○) 142; (×) 568; (●) 2840. Surface pretreatment: (a) photoelectrochemically etched; (b) damaged by polishing on Al_2O_3 powder of $0.3\ \mu\text{m}$ grain size; (c) as in (b), but $1.0\ \mu\text{m}$ grain size. $n\text{-TiO}_2$ (specimen A), disk potential $+1.0\ \text{V}$ vs. SSE, ring potential $-0.2\ \text{V}$ vs. SSE, supporting electrolyte $0.33\ \text{mol}\cdot\text{dm}^{-3}\ \text{HClO}_4$.

current declines to almost zero because of the recombination of holes with electrons, and simultaneously n is observed to increase. In Fig. 3, the top curve represents results obtained at a fully etched electrode. In order to avoid complications by diffusion limitation, the light intensities were kept low enough. It can be noticed that the photocurrent can be decreased by decreasing either the light intensity or the disk potential, the effect on n being generally more pronounced in the latter case. This phenomenon is illustrated clearly in Fig. 4, by plotting n as a

Fig. 3. The competition ratio n as a function of the disk potential V , with a limiting photocurrent density (at $V = +1.0\ \text{V}$ vs. SSE) of $616\ \mu\text{A}\cdot\text{cm}^{-2}$, after different periods of photoetching: (a) 20h (fully etched); (b) 13h; (c) 6.5h. $n\text{-TiO}_2$ (specimen B), ring potential $-0.2\ \text{V}$ vs. SSE, rotation speed 600 rpm, supporting electrolyte $0.33\ \text{mol}\cdot\text{dm}^{-3}\ \text{HClO}_4$, bromide concentration $0.01\ \text{mol}\cdot\text{dm}^{-3}$.

Fig. 4. Plot of n vs. the total photocurrent density i , changed by either varying the electrode potential (□) (same data as in curve (a) of Fig. 3) or the light intensity (■).

function of the photocurrent density. The full line shows the change of n when the photocurrent is varied by a change of the light intensity. As the broken line indicates, the variations of the photocurrent, due to changes of the disk potential, are by far more considerable; in that case, n can rise to its maximum value of 1.

Damaged electrodes.—Influence of the light intensity and of the bromide concentration on n .—After the measurements represented in Fig. 2(a), the electrode was polished with Al_2O_3 powder of $0.3\ \mu\text{m}$ so that damage was induced to the surface and to the underlying region. As a consequence of the ensuing enhanced electron-hole recombination (10), the light intensities had to be increased by a factor of 2.1 in order to obtain nearly the same photocurrents as in Fig. 2a. Then the dependence of n on the light intensity and on c_s was studied again [see Fig. 2b]. Finally, the polishing was repeated with Al_2O_3 powder of $1\ \mu\text{m}$. As a result of the larger degree of damaging, the light intensities had to be increased again, now by a factor of about 5 relative to those used for Fig. 2(b). Even with full illumination, it was no longer possible to produce a photocurrent of $500\ \mu\text{A}$ in this case. The results obtained after the final polish are plotted in Fig. 2(c).

For damaged surfaces, the concentration range where the influence of the light intensity on n is observed, is extending to higher values of c_s ; this effect is very pronounced in Fig. 2c. By comparing parts a, b, and c of Fig. 2, it is obvious that the more the surface has been damaged, the lower the value of n is for each pair of parameters (i and c_s).

Influence of the electrode potential on n .—Similarly, as with fully etched electrodes, it is observed with damaged disks that in the onset region of the photocurrent-voltage curve, n increases significantly as the potential is decreased. In Fig. 3, below curve a representing data for the fully etched electrode B, two other curves (b and c) are given, representing data, obtained before the photoelectrochemical etching of the electrode was completed. The values of n , corresponding with curve c were measured after about 6.5h of photoetching (the limiting photocurrent was at that moment $100\ \mu\text{A}$ with full illumination). The values of curve b were measured after another 6.5h of etching; the limiting photocurrent had risen to $300\ \mu\text{A}$, while the complete etching lasted 20h and led to a maximum photocurrent of $400\ \mu\text{A}$.

In all cases, n decreases with increasing V to reach a constant value in the voltage region where, also, the photocurrent is almost constant.

Discussion

Other investigators (4) obtained results, similar to those shown in Fig. 1, but ascribed the decrease of n at increas-

ing light intensity in dilute bromide solutions fully to the diffusion limitation of Br^- transport. The measurements reported here, however, reveal a clear influence of the light intensity and hence of the total photocurrent density on n , at given concentration of Br^- at the surface, for etched as well as for damaged electrodes. Such influence shows that the competing anodic oxidation reactions, *i.e.*, those of H_2O and Br^- , do not occur through parallel pathways involving consecutive one-hole steps, since in that case n should be independent of the light intensity.

In several recent publications by our research group, the kinetics of competing hole processes at semiconductor photoanodes have been analysed (8, 9, 14, 15). Although stabilization of photocorroding n-type III-V semiconductor electrodes is particularly stressed, the kinetic models developed there can be easily adapted to the treatment of the competition between the oxidation of H_2O and that of Br^- at the TiO_2 surface. With III-V compounds as well as with TiO_2 , one reagent is always present in large excess (*i.e.*, the electrode material itself in the case of III-V compounds and H_2O in the case of TiO_2) and is oxidized in a multistep reaction, whereas another reducing agent is added to the solution, oxidized in a relatively simple reaction, and detected in a quantitative way. The analysis of competing electrode reactions mentioned leads to the conclusion that those mechanisms, which lead to a light-intensity-dependent competition ratio, are grouped kinetically into two classes, in which n is either a function of the single variable c_s/i or of c_s^2/i . The present experimental results were found to belong to the latter class, as is illustrated by Fig. 5, where the data of Fig. 2a have been replotted as n vs. $\log(c_s^2/i)$, leading to one single curve. All but one (a chemically improbable one) of the previously derived kinetic relationships in which n is a function of (c_s^2/i) are of the type $n^2/(1-n) \sim c_s^2/i$. This relationship appears not to be obeyed in the present case, however.

Therefore, in order to account for the experimental kinetics of the H_2O vs. Br^- competition on the TiO_2 electrode, we propose a reaction mechanism which is to a certain extent analogous to mechanisms devised earlier for cases in which the competition ratio is a function of c_s^2/i and which is furthermore based upon various literature data on the photooxidation of H_2O on TiO_2 . By spin trapping and electron spin resonance techniques, Jaeger and Bard (16) revealed the existence of adsorbed hydroxyl and perhydroxyl radicals on illuminated TiO_2 powder, which were dispersed in aqueous solutions. Wilson (17) proposed associating intermediates of the O_2 evolution process with surface states within the bandgap of TiO_2 . It is presently accepted that OH^\cdot radicals and adsorbed H_2O_2 molecules are involved as intermediates and as surface states in the photo-oxidation of H_2O on TiO_2 ; in a number of recent papers, Salvador and Gutierrez dealt with this subject (18-20). These authors proposed the following mechanism for the photo-oxidation of H_2O to H_2O_2 : (i) capture of a photogenerated hole by a Ti-OH -surface group, creating a surface OH^\cdot radical; (ii) electron transfer from an OH^- ion, physisorbed from solution, to a

Fig. 5. Plot of n vs. $\log(c_s^2/i)$. Same data as in Fig. 2(a).

surface OH^\cdot radical; (iii) formation of H_2O_2 from two OH^\cdot radicals. Oxygen is then suggested to be formed either by decomposition of H_2O_2 or by further capture of two holes. Details about these eventual reactions are not given in the references cited. Neither of both these proposed pathways for further reaction of H_2O_2 can account for the n vs. c_s^2/i relationship describing the competition between H_2O and Br^- (see below), so that we propose the following mechanism for the photoanodic oxidation of H_2O

Hence, the overall reaction is

Reaction [7] was already considered by Jaeger and Bard (16) as a possible source of the observed OOH^\cdot at TiO_2 surfaces. Reactions [7] and [8] are assumed to occur during the gas phase decomposition of H_2O_2 (21).

The general kinetic analysis mentioned above (8) suggests consideration of the reaction of Br^- with the surface intermediate H_2O_2 , which is known to proceed in the case of a homogeneous liquid phase and to take place according to (22)

followed by the much faster reaction

Note that in this mechanism (reactions [5]-[8], [10], and [11]), the competition between the formation of O_2 and that of Br_2 is actually a competition for H_2O_2 between OH^\cdot radicals and Br^- ions, as expressed in Eq. [7] and [10], and that the light-intensity dependence originates from the fact that the OH^\cdot radicals are formed by holes (Eq. [5]) and hence by light. The intermediates OH^\cdot , H_2O_2 , and OOH^\cdot are assumed to be adsorbed to the surface. The OH^\cdot radical is considered as being mobile along the surface (a layer of adsorbed H_2O can be conceived in which the OH^\cdot radical captures an electron from a neighboring H_2O molecule). The adsorbed H_2O_2 is assumed to react with a bromide ion from the adjacent solution layer (reaction [10]).

Under steady-state conditions, the concentrations of the intermediates OH^\cdot , H_2O_2 , and OOH^\cdot are constant, resulting in Eq. [12]-[14]

$$\frac{dx_1}{dt} = k_1 p_s - 2k_2 x_1^2 - k_3 x_1 x_2 - k_4 x_1 x_3 = 0 \quad [12]$$

$$\frac{dx_2}{dt} = k_2 x_1^2 - k_3 x_1 x_2 - k_{\text{Br}} x_2 c_s = 0 \quad [13]$$

$$\frac{dx_3}{dt} = k_3 x_1 x_2 - k_4 x_1 x_3 = 0 \quad [14]$$

Here x_1 , x_2 , and x_3 represent the surface concentrations of OH^\cdot , H_2O_2 , and OOH^\cdot , respectively, and p_s the concentration of holes at the electrode surface.

The total steady-state current density is proportional to the light intensity and is given by the following expression, in view of Eq. [5] and considering the surface H_2O concentration to be constant

$$i = ek_1 p_s \quad [15]$$

where e is the absolute value of the elementary charge. According to Eq. [10] and [11], the part of i corresponding to the oxidation of Br^- is given by

$$ni = i_{\text{Br}} = 2ek_{\text{Br}} x_2 c_s \quad [16]$$

Elimination of the unknown quantities p_s , x_1 , x_2 , and x_3 from Eq. [12]-[16] leads to the expression

$$\frac{n^2(1+n)}{(1-n)^2} = \frac{ek_2k_{Br}^2}{k_s^2} \cdot \frac{c_s^2}{i} \quad [17]$$

which conforms to the experimental result that n is a function of the single variable c_s^2/i (Fig. 5).

It should be remarked that, in this equation, k_1 and k_4 are absent: only reactions [6], [7], and [10] determine the competition. It has been found that the shape of the function (Eq. [17]) is not changed if reaction [5] is assumed to be reversible. Neither is it changed when reaction [8] is replaced by another plausible reaction (21)

Under the latter assumption, only the ratio of the reaction constants in Eq. [17] must be adapted. On the other hand, if further oxidation of H₂O₂ by a hole instead of reaction [7] were assumed, an expression would result in which n is a function of (c_s/i) instead of (c_s^2/i) ; if decomposition of H₂O₂ were assumed, an i -independent expression for n would be obtained.

When the experimental results are plotted as $n^2(1+n)/(1-n)^2$ vs. c_s^2/i , the linearity is not completely satisfactory. However, it can be improved by inserting, instead of n , a quantity n' defined by

$$n' = n/n_{\max} \quad [19]$$

and in which n_{\max} represents the observed maximum value of n (in Fig. 2, n_{\max} is equal to 0.90, 0.86, and 0.59 for parts a, b, and c, respectively). In Fig. 6, the data of Fig. 2 have been replotted as $\log[n'^2(1+n')/(1-n')^2]$ vs. $\log(c_s^2/i)$. It is seen that the sets of data a, b, and c can be represented in a very satisfactory way by linear plots with slope 1, demonstrating that Eq. [17] holds for n' and hence indicating that the proposed competing reaction mechanism (Eq. [5]-[7], [10], and [11]) is valid.

Kobayashi *et al.* (23) already remarked that, at damaged TiO₂-electrodes, n does not tend to 1 when the concentration of bromide is increased. This was explained by the assumption that polishing results in the creation of special surface sites (*e.g.*, Ti³⁺-Ti³⁺ pairs), where the formation of O₂ (and surface electron-hole recombination) would occur by preference. Hence, the surface might be conceived as being composed of two parts, *i.e.*, a nondamaged one, where the competition between the formation of Br₂ and that of O₂ proceeds according to reactions [5]-[11], and a damaged one, where only O₂ is formed. This reasoning would be compatible with the correction of n by the factor $(1/n_{\max})$. Also, with the fully etched electrode, the limiting value of n remains less than 1. It is therefore supposed that even after prolonged etching, a certain fraction of the surface consists of special Ti³⁺-Ti³⁺ sites.

The foregoing considerations refer to situations in which surface electron-hole recombination can be excluded because of the large band bending. Recombination mechanisms, in which conduction band electrons are captured in surface states, associated with intermediates of the anodic decomposition of the semiconductor, have

Fig. 6. Plot of $\log [n'^2(1+n')/(1-n')^2]$ vs. $\log(c_s^2/i)$. Same data as in Fig. 2 (a, b, and c).

been treated kinetically in a recent paper (9). Specifically it was shown that, if the intermediate involved in recombination corresponds to a higher degree of oxidation than that involved in the competing reaction with the solved reducing agent, then decreasing the voltage in the photocurrent onset (*i.e.*, increasing the conduction band electron concentration at the surface) should result in a change in the competing rates in favor of the solved reducing agent. This conclusion has very recently been verified experimentally on the system n-GaAs/Fe²⁺ (24). In an analogous way, the results presented in Fig. 4 may be interpreted by assuming the occurrence, not only of ordinary electron-hole surface recombination, but also of a recombination step in which conduction band electrons are captured by OOH[•] radicals according to

It can be easily seen from a simplified reaction scheme (Fig. 7, in which protons and ordinary surface recombination have been omitted) that this recombination step prevents the oxidation of H₂O₂ to O₂ and hence leads to the enhancement of the competition ratio n . Reaction [20] is conceivable to occur in view of the energetic position of the OOH[•]/H₂O₂ redox couple [$U^0 = 1.5\text{V vs. SHE at pH} = 0$ (16), corresponding to an energy level at -1.5 eV vs. SHE , *i.e.*, about midgap].

Another recombination step, in which conduction band electrons are captured by H₂O₂, adsorbed at the TiO₂ surface, has been suggested in the literature (19). The occurrence of this step is in principle not excluded by the present results, but may contribute to a minor extent only when H₂O₂ is much more reactive with respect to bromide ions than to conduction band electrons.

It should be remarked that, also, Kobayashi's concept (23) of special sites for preferential H₂O oxidation and surface recombination may explain the influence of the electrode potential upon V : when V is decreased and hence the conduction band electron concentration at the surface increased, surface recombination competes in these sites only with the H₂O oxidation, resulting in an increase in the observed value of n .

Conclusions

The present study on competing hole processes has allowed us to propose a mechanism for the oxidation of water molecules at the TiO₂ photoanode, in which hydroxyl radicals are assumed to be involved in at least three of the subsequent reaction steps. The results also indicate that the hole processes occurring simultaneously with the H₂O oxidation reaction, *i.e.*, oxidation of Br⁻ and to a certain extent also surface electron-hole recombination, do not occur in parallel with the water oxidation, but that these three processes are linked through the intermediates of the latter, analogously to what has previously been observed on n-type III-V electrodes. In particular, the oxidation of Br⁻ ions appears to occur by reaction with the surface intermediate H₂O₂ of the H₂O oxidation. If this type of oxidation mechanism for reducing agents at the TiO₂ photoanode were general, this would evidently have important implications as to the factors which determine the reactivity and selectivity behavior of this electrode: these factors would then be connected with the thermodynamics and kinetics of reactions between solved reducing agents and adsorbed hydrogen

Fig. 7. Reaction scheme for processes occurring at the illuminated TiO₂ electrode.

peroxide. Experimental work with reducing agents different from bromide will be needed in order to clarify this point.

Ellipsometry of the Growth and Dissolution of Anodic Oxide Films on Aluminum in Alkaline Solution

R. Greef* and C. F. W. Norman**

Department of Chemistry, The University, Southampton, England SO9 5NH

ABSTRACT

Ellipsometry has been used to study the growth of anodic films on superpure aluminum in sodium hydroxide of concentration range 0.1-4M. The ellipsometer used was a self-nulling type, and all experiments were performed *in situ* at a constant wavelength of 632.8 nm. The results are explained by the growth and dissolution of anodic films that are duplex in nature. During the dissolution process, at certain potentials, a highly reproducible transient effect in the optical signal is seen. This effect has been related to roughening of the underlying aluminum substrate, followed by subsequent smoothing upon completion of the dissolution process. The latter is indicated by the optical signal returning close to its initial value prior to film growth.

Until comparatively recently, interest in oxygen containing films on aluminum has focused largely on their protective and decorative properties. Newer applications for aluminum and aluminum alloys include their use in corrosion control as sacrificial anodes, and as primary battery anodes (1-3). In the latter role, the presence of passivating oxide films is detrimental to the primary function of the substrate, which is to dissolve electrochemically at the lowest possible overpotential.

Aluminum used in these applications is alloyed with such elements as zinc, tin, indium, and gallium, the effect of which is to improve reactivity (4-7). The full reasons for the effect of alloying with these metals is not yet clear, and recent work (8) with zinc-tin and zinc-indium alloys in 0.1M NaOH has shown the system to be complex. To help understand the mechanisms involved, it was acknowledged that investigation with super-pure aluminum would be of fundamental importance.

A method of monitoring the surface condition of the metal under working conditions with the metal *in situ* in the electrolyte was required. Ellipsometry provides such a technique (9, 10) and allows precise monitoring of the electrode surface by measuring the change in the state of polarization of a beam of light specularly reflected from the surface. These changes can be interpreted in terms of

the thickness and refractive index of overlayers on the metal surface.

Previous ellipsometric studies of pure aluminum are available and are concerned with anodic film growth in acidic or buffered solutions (11-14) or in hot water (15). This paper describes an ellipsometric study of aluminum in sodium hydroxide solutions, in which aluminum oxide is soluble, and which for this reason is a medium of importance in battery applications.

Ellipsometry is shown to be capable of monitoring the growth and dissolution of surface films over a range of potentials and alkali concentrations, and the results can be interpreted in terms of the porosity of the films. The results are explained with a detailed model of changes in density profile through the thickness of the film as a function of time.

When the surface film dissolves, it does so finally to leave a smooth aluminum surface, but an unexpected and large transient optical signal is observed just before the last of the porous film disappears. This is explained by the short-lived presence of a microrough metal surface formed by exposure and corrosion of the substrate as the overlying layer becomes discontinuous. When all the protective layer dissolves, the peaks of the rough metal surface are preferentially attacked and dissolve, and the substrate again becomes smooth, as is shown by a return of the optical signal to a point closely corresponding to its starting point before the initiation of anodic film growth.

Experimental Method

Materials.—Aluminum rods (99.999% Al) were cut into cylindrical electrodes of 6 mm diam. Electrical connection was made with a copper wire attached with thermosetting silver-loaded epoxy resin. The samples were mounted in epoxy resin.

Smoothing.—The electrodes were ground on 400 grit, then mechanically polished for 6 min on 6 μm diamond, and finished on alumina (0.05 μm). The powder was mixed with distilled water.

Cell.—The electrodes were mounted in a polypropylene cell, designed to support the surface horizontally at the optical center of the ellipsometer. The cell contained a platinum counterelectrode and a reversible hydrogen reference electrode. The reference electrode consisted of a platinized platinum electrode sealed into a tube with a closed upper end and an open lower end immersed in the electrolyte. It was prepared by passing a cathodic current of approximately 10 $\text{mA}\cdot\text{cm}^{-2}$ until a bubble of hydrogen formed enveloping half of the platinum. Electrode potentials are reported throughout *vs.* this reversible hydrogen electrode in the same solution. The electrolyte was air-saturated, AR-grade sodium hydroxide solution.

Electrochemical measurement.—The electrode potential was controlled by a Wenking potentiostat (70TS1) coupled to a Wenking voltage scan generator (VSG72). Cyclic voltammograms were recorded on an analog X-Y recorder.

Optical measurements.—The ellipsometer is a self-nulling fully automated type, employing Faraday modulation

Fig. 1. a, top: Cyclic voltammetry of super pure aluminum in 0.1M NaOH, sweep rates 40 $\text{mV}\cdot\text{s}^{-1}$ (bold line) and 25 $\text{mV}\cdot\text{s}^{-1}$ (dashed line). Potentials throughout are against the reversible hydrogen electrode in the same solution. b, bottom: Cyclic voltammetry as in 1a in 1.0M NaOH.

and compensation. The optical and mechanical parts of the ellipsometer have been described elsewhere (16).

The ellipsometer was used in the monochromatic mode, the source being a He-Ne laser of wavelength 633 nm. The time constant for the self-nulling process is of the order of 0.1s.

The ellipsometer is linked to a SWTPC M6809 micro-computer which controls the operation and data acquisition. The computer is interfaced with a Hewlett-Packard Type 7470A plotter, which enables direct monitoring of the results while the experiment is running. Data points consisting of readings of time, the ellipsometric parameters Δ and ψ , and the working electrode potential and cell current were recorded on diskette.

Electrochemical results.—Cyclic voltammograms for super-pure aluminum in 0.1 and 1.0M NaOH are given Fig. 1a and 1b.

On the forward anodic sweep, at a potential close to -0.5V there is a region where little hydrogen evolution occurs together with no film growth. Here we have a small net anodic current and, ellipsometrically, an almost steady signal.

At higher anodic potentials there is an increase of current and the resulting broad plateau is characteristic of film growth. Currents are slightly lower on the reverse sweep and indicate a continuation of film growth.

Current time transients were recorded by stepping the potential from -0.5V to other more anodic potentials. The resultant transients shown in Fig. 2 show a fall of current with respect to time indicative of the growth of a porous film. Hurlen and Haug (17) have recently obtained transients that are similar in structure, but the potential steps are much smaller than in our experiments.

When the potential is stepped back to -0.5V , the current becomes zero very quickly and after several seconds rises to the small anodic value it had prior to the anodic pulse. This time period is known as the recovery time, and previous accounts of similar phenomena in acidic electrolytes are available (18-21).

The recovery time depends upon the electrolytic concentration and the height of the anodic peak. The recovery time is longer for more dilute concentrations and higher anodic pulses.

Optical terminology.—Ellipsometry measures the quantity ρ , which is the ratio of the reflection coefficients parallel to (p component) and perpendicular to (s component) the plane of incidence. Each of these reflection coefficients is a complex quantity which is an expression of the fact that it contains both amplitude and phase information. The ellipsometer measures two angular quantities Δ and ψ which are related to ρ by the equation

$$\rho = \tan \psi e^{i\Delta}$$

The possible range of Δ is 0° - 360° , and of ψ is 0° - 90° . Oxide films on aluminum are transparent, and the theory

for an idealized uniform film model shows that as the film grows, a cyclic change in both Δ and ψ is traced, (see Fig. 3) the size of which depends upon the refractive index of the oxide.

Pretreatment and growth potentials.—On immersing the electrode in the electrolyte, the potential was quickly adjusted to -1.0V in the hydrogen evolution region to cathodically protect the polished surface. After 10s, the potential was shifted to -0.5V , where the optical signal is steady. A pipette was used to disperse the remaining hydrogen bubbles before the potential was stepped to the higher anodic growth potential. A diagram of this potential cycle is shown in Fig. 4.

Optical measurements during cyclic voltammetry.—Figure 5 shows the Δ - ψ signature obtained during a cyclic sweep of potential at 25 mV/s in 0.1M NaOH . The starting point A is at -0.5V , where the optical signal is stable. As the potential was scanned positive, a distorted egg-shaped curve was produced, as shown in section A-B. Point B represents a potential of 2.0V , and section B-D is the return scan to -0.5V .

Only a qualitative interpretation of this result was attempted. The anodic sweep A-B evidently results in the formation of a film, but because of the distorted egg shape of the curve, this cannot be a layer of constant optical properties increasing in thickness. During the negative sweep the film continues to grow for a time, but then as point C is approached the Δ - ψ curve turns back on itself and traverses around an inner curve until a position near the starting point is reached.

The optical signal at A did not move appreciably until a potential of 0.1V was reached. The signal at C corresponds to 1.3V . It is possible that the general shape of the Δ - ψ signature in Fig. 5 could be attributed to two entirely different processes: film growth, which accelerates as the

Fig. 4. Potential profile for anodic growth and dissolution of oxide layers.

potential increases, and chemical dissolution of the film as the potential is reduced.

This experiment suggests that the refractive index of the film is dependent on potential, so the effect of the formation potential was explored in detail.

Constant potential experiments.—A series of films was formed using the potential profile already described (see Fig. 4), in which the pretreatment at -1.0 and -0.5V was held constant, while formation potentials between 1.5 and 3.5V were applied, until approximately one whole Δ - ψ "egg" had been traced.

The eggs traced out at high potentials tended to form nearly closed curves, characteristic of a uniform transparent film. When plotted on common axes (see Fig. 6), the formation curves form a very striking set or "nest" of eggs, which is strongly suggestive of an oxide film increasing in refractive index very regularly with formation potential. The smoothly variable composition of the film implied by this increasing refractive index is most plausibly explained by a film of varying porosity, which fits well with the electrochemical results of Fig. 2.

Another series of eggs (see Fig. 7) was obtained by keeping the anodic growth potential constant ($+2.5\text{V}$) and varying the concentration of the sodium hydroxide. Increasing the concentration decreased the size of the egg, and this implies that the refractive index of the transparent film also decreases, corresponding to the increasing solubility of Al oxides and hydroxides at higher pH's.

Dissolution at open circuit.—In Fig. 8, two curves are shown for growth at $+2.5\text{V}$ in 0.1M NaOH . The maximum

Fig. 6. Family of anodization curves at the indicated growth potentials with data points every 5s. Each run was carried out with a freshly polished electrode.

Fig. 7. A family of growth curves at +2.5V, for NaOH concentrations of 0.1M (A), 1.0M (B), and 4.0M (C). Curves B and C have points at intervals of 1s; the time interval between points for curve A is 2s.

current density for this electrolyte is about 50 mA/cm². When a certain film thickness was obtained, the film was allowed to dissolve at open circuit. The potential decreased quickly at first until it reached -0.9V at a position close to the starting position. The potential approached E_{corr} , but in the duration of the experiment never completely stabilized.

During the dissolution phase, the optical signal did not even begin to retrace the formation curve but departed immediately on a totally different path, which nevertheless brought the curve back closely to the starting point.

Dissolution at -0.5V.—A family of curves is shown in Fig. 9 for growth at 2.5V but with interruption of the growth at different stages to show the dissolution signal at -0.5V. All of these curves were obtained with the same electrode, the oxidation potential being reapplied as soon as the dissolution process had brought the $\Delta\psi$ values closely to the starting position. Each point was recorded at a time interval of 1s.

It is convenient to reduce this rather complex picture into three main regions: (i) the film growth region, (ii) the dissolution pathway until the point D_L (D_L = dissolution limit) is reached, and (iii) the remaining part, which we will call the "loop," which finally returns the optical signal to the starting point.

The corresponding current-time transients are identical in structure compared with those in Fig. 2. Examination in three stages shows, first, the falling transient after the anodic pulse which indicates porous film formation; second, a region where after stepping the potential back to

Fig. 8. Growth curves for +2.5V in 0.1M NaOH interrupted at different film thicknesses (G), and their resultant dissolution curves at open circuit (D). The time interval between points is 4.5s.

Fig. 9. A family of curves for growth +2.5V (G), interrupted at different stages to show the dissolution signal at -0.5V (D). D_L corresponds to the dissolution limit in the text. The time interval between points is 1s.

-0.5V negligible current flows and the process occurring is attributed to chemical dissolution of the film by the electrolyte; and last, the rising current when the recovery time is complete, the onset of which coincides with the point marked D_L in Fig. 9. The return of the net anodic current accompanies the optical signal which traverses the loop before returning to the starting position.

The formation of the loop is very reproducible even after three growth-dissolution cycles and is fast, taking only about 8s from the point marked D_L to the starting position.

Dissolution at other potentials.—The result of the open-circuit dissolution and the dissolution at -0.5V seem to indicate that the behavior of the loop region of the dissolution process is potential controlled. Further experiments where the dissolution potential was varied can be seen in Fig. 10 and 11. In Fig. 10, the potentials -1.0 and -0.8V were very close to the open-circuit potential (see Fig. 8) and the dissolution behaviors are very similar. Increasing the dissolution potential (Fig. 11) to more anodic potentials than -0.8V leads to the appearance of the loop, which increases in size with an increase of dissolution potential up to about 0.0V where, as seen in Fig. 5, at this potential the rate of film growth exceeds that of film dissolution. Therefore, at this potential no net film dissolution would be expected.

Discussion

It is possible to make qualitative conclusions based purely upon the general shape of the $\Delta\psi$ signatures. It is

Fig. 10. Optical signal for film growth at +2.5V (G), with dissolution at -1.0V (asterisks) and -0.8V (open circles) (D). The time interval between points is 5.5s.

Fig. 11. Growth curves as in Fig. 10, with dissolution at -0.6V (open circles), -0.4V (X's) and -0.2V (asterisks). The time interval between points is 5.5s.

clear that a porous film grows (see Fig. 5) on the aluminum substrate above potentials of about 0.1V and that the refractive index of the film, and hence its density, increases regularly with increasing formation potential and decreasing electrolytic concentration. Films formed in this way dissolve to leave a clean surface which is still smooth even after several growth-dissolution cycles.

The conclusions can be tested in a quantitative way by calculating the $\Delta\psi$ response, using a single-film or multi-film model, measured or estimated values of the various optical constants, and a computer program such as that of McCrackin and Colson (22).

Optical constants of the substrate.—The condition of the surface at -0.5V before anodization is stable and has been used as a reference state. It is not a film-free surface, however, as a film of oxide formed in air during the polishing process is not removed even at -1.0V . Values of n and k for bare, pure aluminum surfaces are available (11, 12, 15, 23, 25), but not for the polished aluminum substrate immersed in a caustic electrolyte. The values of the bare surface optical constants were therefore estimated by assuming that a thin layer (0.5 nm) of oxide of refractive index 1.65 exists initially on the aluminum. The effect of "removing" this layer in the calculations is to increase Δ and decrease ψ . Using this new starting point in the film calculation does give a noticeable change in the $\Delta\psi$ signatures predicted, but none of the conclusions is changed by using the initial measured $\Delta\psi$ values as if they represented a clean surface. Using this and the fact that the surfaces are mechanically polished and are never exactly reproducible, approximate optical constants of the aluminum used were $n = 1.5 \pm 0.15$ and $k = 5.5 \pm 0.4$. These values can be compared with those for aluminum deposited under UHV conditions (23) of $n = 1.43$ and $k = 7.28$. Under our conditions these values correspond to "bare surface" Δ and ψ values of 131.08° and 40.90° , which lie close to the observed starting points.

Film growth models.—The simplest model is the single-film model Fig. 3, in which a uniform oxide film lies between the alloy substrate and the immersion medium. This model suffices for films grown on pure aluminum under certain conditions (14, 15). When the model is applied to these results, however, it is obvious from Fig. 12 that a uniform film model is inadequate (25). Initially, the experimental data indicate a constant refractive index, but as the film thickens the refractive index seems to decrease, implying that the film is increasing in porosity.

Two multilayer models were therefore explored (26), having a linear and an exponential fall in the refractive index with distance from the electrode. Neither model yielded $\Delta\psi$ signatures that fitted any substantial part of the experimental curves.

A two-film model similar to that used by Dell'Oca and Fleming(11) was then tried in which there was a dense ox-

Fig. 12. Comparison of calculated uniform film models (value for the oxide refractive index as indicated), with an experimental growth curve $+2.0\text{V}$ in 0.1M NaOH (open circles). S corresponds to the initial experimental point, with further points taken at 2s intervals.

ide layer next to the electrode and a more porous layer in contact with the electrolyte. The model was refined by proposing a smooth transition between the two refractive indexes rather than a sudden step (see Fig. 13). This was done by dividing the film up into many thin slices and generating a function with which to define the refractive index of each slice. The function used was

$$n = n_{\min} + (n_{\max} - n_{\min}) \exp(-x) / [\exp(-x) + \exp(-x_{\max}/f)]$$

where n_{\min} and n_{\max} are the values of refractive index in contact with the electrolyte and metal, respectively, and x_{\max} is an arbitrary number which controls the sharpness of the refractive index transition between the two extreme values. The value of x varies from 0 to x_{\max} in equal increments for each slice from the metal to the outer film boundary. The fraction $1/f$ determines the distance at which the step from n_{\max} to n_{\min} is half complete. So for Fig.13, the theoretical parameters are film thickness = 420 nm, slice thickness = 4 nm, $n_{\min} = 1.45$, $n_{\max} = 1.50$, $x_{\max} = 60$, and $f = 2.2$, which implies the dense part of the film is 190 nm thick.

The calculation of the $\Delta\psi$ response is started with a bare surface, and the slices are added one at a time until the total film has been assembled. The result shown in Fig. 13 is a set of $\Delta\psi$ points tracing out the simulated characteristics.

Fig. 13. Comparison of the refined duplex model for film growth (dashed line) superimposed upon the experimental curve from Fig. 12 (open circles) and the uniform film model curve in Fig. 12 (bold line). Theoretical parameters: film thickness = 420 nm, $n_{\min} = 1.45$, $n_{\max} = 1.50$, $x_{\max} = 60$, and $f = 2.2$. The inset shows the smooth transition for the refined model; the start and end of the transition between the two layers are indicated by X and Y, respectively.

Fig. 14. A calculated anodization curve (G) with two dissolution curves (D), $x_{\max} = 60$, film thicknesses 320 nm (point A) and 210 nm (point B). B_s corresponds to the bare surface.

Film dissolution models.—Accepting that the growth curves can only be explained by a graded-film model, it is clear that a dissolution process quite different from the reverse of the formation process is needed to explain the dissolution trajectory in the Δ - ψ plane. A model in which all of the oxide layers begin to relax toward a lower refractive index at the end of the growth phase was found to give the correct kind of shape. Out of many curves produced by trial and error, Fig. 14 shows the main features seen in the open-circuit dissolution experiment (see Fig. 8).

It therefore seems clear that the outer layers of the oxide are porous enough to allow attack of the inner, dense layers to start immediately upon cessation of the anodization process.

Figure 15 shows a three-dimensional plot indicating how the refractive index of the film changes with thickness and time. At the point marked A, the potential is pulsed anodically and a film of uniform refractive index starts to form. At B, the film becomes duplex in nature and as the thickness increases so the refractive index profile through the film changes until the lower refractive index limit is reached. At C, the potential is stepped back to its initial value and the film chemically dissolves. Note that the thickness remains constant but the refractive index diminishes until at D the whole of the film reaches a predetermined refractive index which represents the point D_L in Fig. 9.

This simple dissolution model is capable of reproducing qualitatively the open-circuit dissolution curve in Fig.

Fig. 15. A three-dimensional plot indicating how the refractive index of the film varies from A (the initial anodic pulse) to D (the dissolution limit D_L in Fig. 9), with both time and film thickness.

8. However, from Fig. 9 and 11 it is obvious that the model is insufficient in explaining the complete dissolution process which contains the loop phenomenon. A more complex model is therefore required.

At the position D_L (see Fig. 9), the Δ - ψ value(s) corresponding to this portion clearly indicates that a film of finite thickness still remains on the substrate. At this position, subsequent dissolution causes the current to rise (see Fig. 2) and the Δ - ψ response to depart from the dissolution curve and traverse the loop before returning close to the starting position.

The net anodic recovery current must be due to the chemical breakdown of the film at random sites, thus exposing bare metal and allowing preferential metal dissolution. The metal dissolution process would result in appreciable roughening of the metal surface.

The large Δ - ψ excursion from the dissolution curve cannot be explained by a continuation of the dissolution process alone, nor by the growth of another transparent film or by a mixture of both. The optical constants of the transparent system cannot produce any Δ - ψ values for any film thickness in this region of the Δ - ψ plane, where $\Delta < \Delta_{\text{starting position}}$ and $\psi < \psi_{\text{starting position}}$, assuming reasonable values for the refractive index of the film ($1.4 \leq n \leq 4.0$). This region is therefore "out of bounds" for a transparent film on a smooth aluminum substrate. It very quickly becomes obvious that we must introduce a k (extinction coefficient) value into the optical constants of the system to force the Δ - ψ response into this region. The appreciable roughening caused by the aluminum dissolution reaction must now be taken into account.

The model used so far has assumed a perfectly smooth interface between the substrate and the film (9), such that the reflection from which can be described by the Fresnel complex reflection coefficients and the Drude equation. The problem of microscopically rough surfaces can be treated however by using simple models to characterize the roughness of the surface. The simplest optical model that approximates to a rough substrate is to represent the rough layer as an effective medium of intermediate optical properties, sandwiched between a perfect substrate and a perfect ambient (27). There are several effective-medium models that represent a heterogeneous dielectric mixture by a single parameter. The Maxwell-Garnett (MG) and the Bruggeman effective-medium approximation (EMA) are two of the most popular theories used.

Aspnes *et al.* (27) have shown that the MG treatment is inconsistent in its definition of the volume fractions of the substrate and ambient media, and they recommend as being self-consistent the Bruggeman theory (EMA). The equation that relates the volume fraction of the inclusions (V_2) in the ambient medium (film) (1) can be written as

$$(1 - V_2) \frac{\epsilon_1 - \langle \epsilon \rangle}{\epsilon_1 + 2\langle \epsilon \rangle} = -V_2 \frac{\epsilon_2 - \langle \epsilon \rangle}{\epsilon_2 + 2\langle \epsilon \rangle}$$

where $\langle \epsilon \rangle$ is the effective dielectric function of the rough layer and ϵ_1 and ϵ_2 are the dielectric functions of the film material and bulk substrate, respectively. The effective dielectric function is a complex quantity.

The rough layer was divided into a number of slices of equal thickness, and various structural models (27) describing the inclusion of the substrate into the film were employed. These models were triangular ridges (model 1), close-packed cones (model 2), hemispheres (model 3), inverse cones (model 4), and inverse hemispheres (model 5). Figure 16 shows a section through a rough layer structure using model 1 as the geometric shape with the layer divided into equal slices. From this geometric shape, it is easy to calculate the volume fraction of the base material in each slice of the rough layer. The EMA theory allows the calculation of the optical constants of each slice, knowing the volume fraction of the inclusions, and from these values a new curve is produced in the Δ - ψ plane.

Fig. 16. A schematic diagram showing the rough layer section using rough model 1 (triangular ridges) to describe the inclusion of substrate into the film, and the division of the rough layer into slices of equal thickness.

In Figure 17, the simulated dissolution reaction is stopped at D_L and the rough layer for model 1 is grown for two different rough layer thicknesses. Both curves move into the out-of-bounds region, and increasing the thickness of the rough layer causes the curve to deviate further from the point D_L .

From the $\Delta\psi$ curves in Fig. 9, the $\Delta\psi$ response, having traversed the loop, returns very close to the starting position. Here the film will be very thin, and the optical constants of the system will approach the initial values of the substrate before the first anodic pulse. This can only be explained by the roughened substrate becoming smooth again. With the chemical dissolution of the film near completion, a preferential "leveling off" process of the rough layer, via the aluminum dissolution reaction, would seem to occur. This process may be akin to the leveling and brightening effects observed in electropolishing (28).

The leveling-off process is a simple process to model, as one slice at a time in the rough layer starting from the film boundary has its optical constants changed to those of the medium (1.34, 0) until the underlying substrate boundary is reached. Figure 18 shows how the extinction coefficient varies with time and the rough layer thickness. Initially $k = 5.5$ and is representative of the substrate, whereas at B, when the rough layer is completely grown, k tends to 0, representing the transparent film. From B, the removal shows k progressively made equal to 0 from the outermost slices at the film boundary until at C the removal of the rough layer is complete.

To allow the film dissolution to continue while the roughening process is occurring, the computer program was adapted so that a suitable constant could be included which represents the ratio of roughening to dissolution in the system. So for example, if the constant was equal to 3, the computer simulation would represent the growth of three slices in the rough layer for every one small reduction in the refractive index of the film (representing film

Fig. 17. A calculated growth (G) and dissolution curve (D); parameters are refractive index of film = 1.5, film thickness = 100 nm, and slice thickness = 10 nm. The calculation is stopped when the film refractive index reaches 1.4 (D_L). Simulated roughening using model 1 is then calculated with different rough layer thickness, 10 nm (A) and 20 nm (B).

Fig. 18. A three-dimensional plot showing how the extinction coefficient varies with time and the rough layer thickness during the processes of growth (A to B) and dissolution (B to C) of the rough layer.

dissolution). When the rough layer was completely grown, its removal via the leveling-off process was simulated. The initial rate was still used, and three rough layer slices were removed for every one step in the reduction in the refractive index of the film. The best results for all five models used were found when the roughening occurs quickly compared to the film dissolution.

Figure 19 shows a theoretical response for model 1. The saw tooth appearance to the shape of the loop is present to show the two separate parts of the calculation, although this curve could be made smooth by modeling both processes in the same step of the calculation.

All five of the models have a theoretical $\Delta\psi$ response which moved into the out-of-bounds region when the rough layer was grown and produced a loop when coupled to the film dissolution and the smoothing process. However, models 1 and 2 produced loops that showed the greater resemblance to the experimental curves in Fig. 9. Experimentally, film breakdown leading to the substrate roughening would occur at random sites across the substrate and the highly structured rough layer models used here would only be an approximation to the real system.

Finally, another result that can now be explained is the dependence of the loop size upon potential (see Fig. 11). In Fig. 1a and 1b the cyclic voltammograms show that as the potential is raised from -1.0 to -0.2 V the current also increases. Therefore, when film breakdown occurs at a more anodic potential in this range, the aluminum disso-

Fig. 19. The complete theoretical model depicting film growth and dissolution to D_L , and the growth and dissolution of the rough layer together with the continued dissolution of the film until point B_S is reached (bare surface). Parameters for the film as in Fig. 17, with rough layer parameters of model = 1, thickness = 20 nm, slice thickness = 0.33 nm.

lution reaction can occur at a faster rate and the effect of the roughening will be greater. Figure 17 shows that an increase in the rough layer thickness, possibly caused by more vigorous aluminum dissolution reaction at higher anodic potentials, would lead to an increase in the size of the loop.

Conclusions

1. The density of anodic oxide films on aluminum in alkaline conditions depends upon the potential of formation and the electrolyte concentration. The films increase in porosity toward low formation potentials and high electrolytic concentrations.

2. The films are not of uniform density throughout their thickness, being denser at the metal surface. A model consisting of a duplex film with a smooth transition in refractive index between the two layers produced a good fit with the experimental results.

3. The dissolution process is not the reverse of the formation process. The oxide layer begins to dissolve throughout its thickness upon cessation of anodization until a critical point is reached where the underlying metal is preferentially dissolved due to film breakdown.

4. Dissolution of the underlying metal and the incomplete oxide layer proceed in parallel, giving a $\Delta\psi$ signal that departs from the dissolution curve and moves into a region in the $\Delta\psi$ plane that is "forbidden" for any reasonable transparent film system.

5. The preferential dissolution of the underlying metal leads to appreciable roughening which has been modeled by constructing a layer between the substrate and the film where inclusions of metal into the film (and vice versa) are used to represent the rough layer.

6. Having now moved into this forbidden region, the $\Delta\psi$ response traverses a loop and returns close to the starting position. The optical constants of the system are now very similar to those before the initial anodic pulse. This implies that the anodic oxide film has been removed and that the rough substrate has become smooth again via some form of leveling-off process.

Electrochemical Formation of Graphite-Sulfuric Acid Intercalation Compounds on Carbon Fibers

Yasuhisa Maeda,* Yasuo Okemoto, and Michio Inagaki

Department of Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi 440, Japan

ABSTRACT

The cyclic voltammograms in 98% H₂SO₄ were measured on the mesophase-pitch-based carbon fibers heat-treated at various temperatures. They showed a marked dependence on the heat-treatment temperature of the carbon fibers. The electrochemical formation of graphite-sulfuric acid intercalation compounds was confirmed by x-ray diffraction. The change of graphite layer planes in the carbon fibers due to electrolysis was examined by Raman spectra.

Graphite forms intercalation compounds by the insertion of various ions, atoms, and molecules into its interplanar space. Recently, graphite intercalation compounds (GIC's) have attracted attention because of their unique properties. For a number of new GIC's synthe-

* Electrochemical Society Active Member.

sized by different methods, their structure, physicochemical properties, and applications have been studied actively (1-3).

Graphite is electrochemically oxidized in a concentrated sulfuric acid to form graphite-sulfuric acid intercalation compounds as follows

A bisulfate ion and sulfuric acid molecules are inserted between graphite layers. The positive charge of the oxidized graphite network is balanced by the negative charge of the intercalated ions. In this case, intercalation occurs in the anodic process and deintercalation in the cathodic process.

There are several papers (4-8) reporting electrochemical formation of graphite-sulfuric acid intercalation compounds on the graphite electrodes with high crystallinity, natural graphite, and highly oriented pyrolytic graphite. However, extensive studies on carbon electrodes are uncommon, although carbon materials have wide varieties in structure, in texture, and in shape. Carbon fibers have different textures and different degrees of perfection in structure according to their precursor and heat-treatment (9-11). Therefore, carbon fibers are interesting host materials of GIC because they may give much information on the GIC formation behavior in relation to crystallinity of host materials and also on the development of applications.

In this paper, the electrochemical formation behavior of graphite-sulfuric acid intercalation compounds was examined on the mesophase-pitch-based carbon fibers (11) heat-treated at various temperatures.

Experimental

The electrode materials were the mesophase-pitch-based carbon fibers (Kureha Chemical Industry Company) heat-treated at temperatures of 1800°, 2100°, 2400°, 2700°, and 3000°C for 30 min in argon atmosphere. Figure 1 shows the SEM micrograph of a cross section of the 3000°C treated carbon fibers. It is well known that the degree of graphitization of carbon materials is higher with the rise of heat-treatment temperature (HTT). The average interlayer spacing $\bar{d}(002)$ determined from 002 x-ray diffraction line by using inner standard of silicon is usually used as graphitization degree. The $\bar{d}(002)$ values of the heat-treated carbon fibers are summarized in Table I. The value decreases to the value for the natural graphite, 3.354Å, with the rise of HTT as has been found in various carbon materials.

A bundle of carbon fibers (weight of about 40 mg) attached to a copper lead wire with conducting silver epoxy was prepared as a working electrode. A platinum wire

2700	3.362
2400	3.383
2100	3.405
1800	3.426

and a saturated calomel electrode were used as a counter and a reference electrode, respectively. An electrolyte was 98% sulfuric acid. Cyclic voltammograms were measured by using a potentiostat (Hokuto Denko, Model HA-501) and a function generator (same company, Model HB-104).

The x-ray diffraction pattern of the carbon fibers electrolyzed at a certain potential was measured in order to confirm the formation of graphite-sulfuric acid intercalation compounds. Because of instability of intercalation compounds in air, the electrolyzed carbon fibers were taken out from the electrolyte in nitrogen atmosphere and mounted to the x-ray sample holder with a cover of 0.5 mm thick polyethylene film. The x-ray diffraction measurement was made with a diffractometer (Rigaku Denki, Model Geigerflex-2028).

Raman spectra were measured in order to examine the change of graphite layer planes in the carbon fibers due to electrolysis. In this case, the electrolyzed carbon fibers were taken out from the electrolyte, rinsed repeatedly with pure water, and dried in air. The Raman measurement was made with a Raman spectrometer (JRS, Model 400D) using 4880Å line (150 mW) of Ar-ion laser (NEC, Model GLG-3200). The angle between the incident beam and the fiber axis was 45°, and the scattered light was collected under 90° with the fiber axis. The slit widths at entrance, intermediate, and exit were 500, 600, and 500 μm , respectively.

Results and Discussion

Figure 2 shows the cyclic voltammograms (CV's) on the mesophase-pitch-based carbon fibers heat-treated at

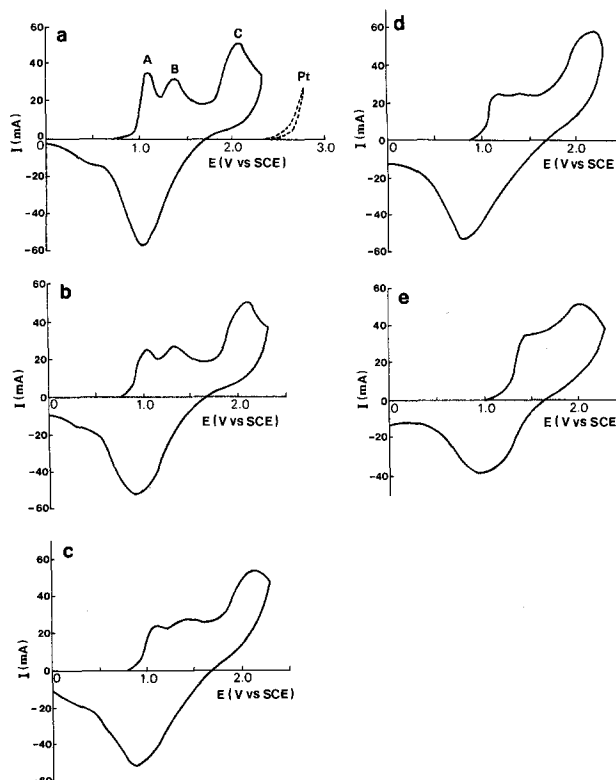

Fig. 2. Cyclic voltammograms (first scan) on the mesophase-pitch-based carbon fibers in 98% H_2SO_4 . a, b, c, d, and e: The carbon fibers heat-treated at 3000°, 2700°, 2400°, 2100°, and 1800°C, respectively. Scan rate: 10 $\text{mV}\cdot\text{s}^{-1}$. Pt: Platinum.

3000°, 2700°, 2400°, 2100°, and 1800°C. The CV's in a concentrated sulfuric acid showed a remarkable dependence on HTT. In Fig. 2a on the 3000°C treated carbon fibers, three anodic current peaks A, B, and C were observed at potentials of about 1.1, 1.4, and 2.1V, respectively. A cathodic peak appeared at about 1.0V. A platinum working electrode gave no anodic and cathodic peaks in the potential range of 0.0-2.3V in 98% H₂SO₄. The CV on the 2700°C treated carbon fibers (Fig. 2b) is similar to that on the 3000°C treated carbon fibers. From the CV's on the 2400°C and the 2100°C treated carbon fibers (Fig. 2c and 2d), it is indicated that both the anodic current peaks corresponding to A and B peaks in Fig. 2a become broad with the decrease in HTT. In contrast with peaks A and B, peak C seems to be almost independent of HTT. In the CV on the 1800°C treated carbon fibers (Fig. 2e), only two anodic current peaks were observed.

Figure 3 shows the x-ray diffraction patterns of the 3000°C treated carbon fibers for original (a) and 60 min electrolysis at the potential of 1.1, 1.4, and 2.1V (b, c, and d, respectively). On the electrolyzed carbon fibers, 001 diffraction lines from graphite layer planes disappear and new lines due to the formation of GIC are observed. The diffraction lines in Fig. 3b can be indexed by the stage 2 graphite-sulfuric acid intercalation compound with the identity period along the c-axis I_c of 11.33Å, as shown in the figure, and those in Fig. 3c by the stage 1 compound with I_c of 7.98Å. Therefore, anodic current peaks A at the potential of 1.1V and B at 1.4V observed in the CV (Fig. 2a) are attributed to the formation of the stage 2 and the stage 1 compounds, respectively. As shown in Fig. 3d, the product obtained by the anodic oxidation up to the potential of 2.1V has two diffraction lines at almost the same

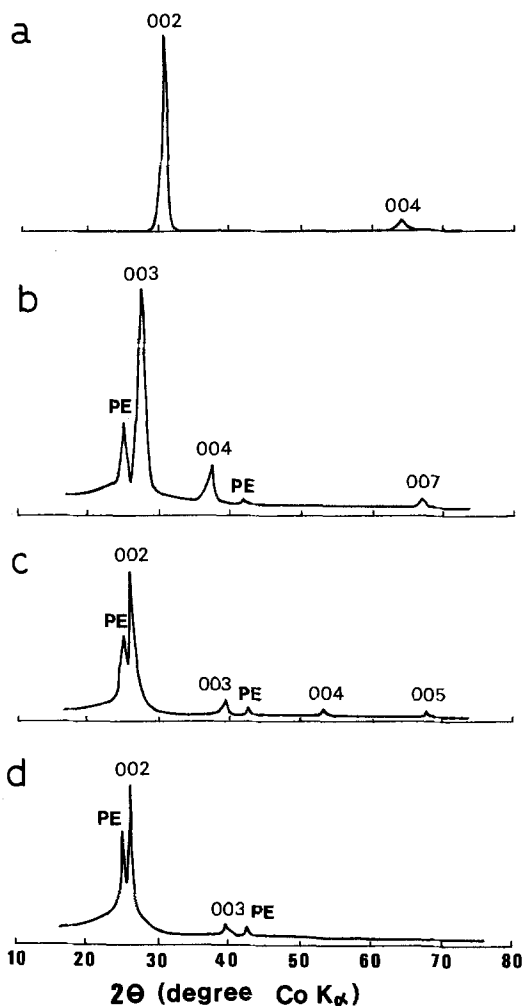

Fig. 3. X-ray diffraction patterns of the 3000°C treated carbon fibers. a: Original. b, c, and d: After electrolysis for 60 min at the potential of 1.1, 1.4, and 2.1V, respectively. PE: Polyethylene.

Fig. 4. Dependences of onset potential and of interlayer spacing $\bar{d}(002)$ on heat-treatment temperature.

diffraction angles as the stage 1, but two higher-order diffraction lines are missing. Since the stage 1 GIC which has the maximum content of intercalant is already formed at the potential of 1.4V, anodic current peak C is supposed to be due to the formation of graphite oxide (12, 13). Besenhard *et al.* (8) mentioned the formation of graphite oxide following that of the stage 1 compound on the highly oriented pyrolytic graphite electrode in 96% H₂SO₄. In the CV's on the carbon fibers, the anodic current peak C is quite different from the peaks A and B with regard to HTT dependence. The broadening of the peaks A and B with the decrease in HTT suggests that a distinction in staging of GIC formed gets obscure on the carbon fibers with lower degree of graphitization.

Figure 4 shows the dependences of the onset potential (OP) and of the interlayer spacing $\bar{d}(002)$ on HTT of the carbon fibers. The OP is denoted as the threshold potential which shows the beginning of the anodic current flow in the first scan. The OP value of the carbon fibers treated at the higher HTT is less positive. A striking similarity between the HTT dependences of OP value and $\bar{d}(002)$ suggests that the OP value is closely related to the crystallinity of the host carbon fibers, the higher degree of graphitization facilitating the formation of GIC.

Figure 5 shows the CV on the 3000°C treated carbon fibers in the range of 0.0-1.4V. In this potential range, only the formation of GIC occurs, as shown by two anodic current peaks at 1.1 and 1.4V, but not the forma-

Fig. 5. Cyclic voltammogram (first scan) on the 3000°C treated carbon fibers in 98% H₂SO₄. Scan rate: 10 mV·s⁻¹.

Fig. 6. Raman spectra of the 3000°C treated carbon fibers. a: Original. b and c: After ten times cyclic electrolysis in the range of 0.0-1.4V and 0.0-2.3V, respectively.

tion of graphite oxide. This CV characteristically shows two cathodic peaks at the potential of about 0.4 and 0.8V, which correspond to the reduction of the stage 2 and the stage 1 graphite-sulfuric acid intercalation compounds, respectively. These waves are not clearly detected with scans up to the potential of 2.3V, as shown in Fig. 2a. The CV's (0.0-1.4V range) on the 2700°, 2400°, and 2100°C treated carbon fibers also showed two cathodic current peaks. The potential of these peaks shifted to less positive values with the decrease in HTT. This dependency seems to imply a relation between the deintercalation process and the crystallinity of the carbon fibers.

Figure 6 shows Raman spectra of the 3000°C treated carbon fibers before and after electrolysis. It has been known that carbon materials have two Raman bands at 1580 and 1360 cm^{-1} (14-16), the former being due to the in-plane motion of carbon atoms in the hexagonal graphite layers, and the latter being related to the presence of structural defects in the graphite layer planes. As shown in Fig. 6a, the original carbon fibers without electrolysis give a strong sharp band at 1580 cm^{-1} but only a weak one at 1360 cm^{-1} . The ten times cyclic electrolysis in the range of 0.0-1.4V did not affect the spectrum (Fig. 6b). This suggests that graphite layer planes of the original carbon fibers retain their perfection after the electrochemical formation of the stage 1 graphite-sulfuric acid intercalation compound. In the spectrum of the carbon fibers after the ten times cyclic electrolysis in the range of 0.0-2.3V (Fig. 6c), however, a marked increase in the relative intensity of 1360 cm^{-1} band is observed. Thus the formation of graphite oxide seems to give rise to various

defects in graphite layer planes, which may be related to puckering of layer planes due to the carbon-oxygen bond in graphite oxide (12, 13). The introduction of the defects in layer planes by the formation of graphite oxide may cause the disappearance of the higher-order diffraction lines of the stage 1 intercalation compound, as shown in Fig. 3d.

Summary

The results obtained can be summarized as follows. The CV's in 98% H_2SO_4 were measured on the mesophase-pitch-based carbon fibers heat-treated at the various temperatures. Three anodic current peaks at the potential of about 1.1, 1.4, and 2.1V in the CV's were attributed to the formation of the stage 2 and the stage 1 graphite-sulfuric acid intercalation compounds and of the graphite oxide from the measurements of x-ray diffraction patterns and Raman spectra. The CV depended strongly on HTT of the carbon fibers; the onset potential shifting to the positive value, and the anodic current peaks due to the formation of GIC becoming broad with the decrease in HTT. Thus the electrochemical behavior showed a marked dependence of the GIC formation on the crystallinity of the host carbon fibers. For the Raman spectra of the 3000°C treated carbon fibers, the graphite layer planes of the original fibers were found to retain their perfection even after ten times cyclic electrolysis up to 1.4V, that is, ten times repetition of formation and decomposition of the stage 1 compound, but various defects were introduced in the layer planes by the formation of graphite oxide.

Open-Circuit Reduction of Oxygen Coverage on Au by Allyl Alcohol in Aqueous Electrolytes

R. Celdrán and J. González-Velasco

Departamento de Electroquímica, Facultad de Ciencias, Universidad Autónoma de Madrid, 28049 Madrid, Spain

ABSTRACT

An open-circuit study of the reduction of oxygen coverage on Au by allyl alcohol was made. The experimental results have been interpreted using Christov's scheme (15). The gold oxide coverage appears to be removed via a chemical, an electrochemical, or a mixed mechanism, depending on different potential values which characterize the diverse zones appearing in the $E-t$ curves. Gold oxide reduction seems to take place through two steps in acidic electrolytes and through three in neutral ones. The first step appears to be the reduction of Au_2O_3 to Au_2O , the second a reduction of Au_2O to Au, while the third has been interpreted as a reduction of an aged form of Au_2O .

In previous papers, (1, 2), we have reported on the oxidation mechanism of allyl alcohol on gold in aqueous solutions. The oxidation of the organic substance would interfere with that of the electrode itself. The oxide coverage can then interact with the organic molecules giving rise to a fairly rapid oxygen coverage removal, depending on oxidation level, structure, and stability of the oxide layers. The aim of the present study is to clarify the mechanism of the interaction between the organic reducing agent and the oxide coverage. The study could also provide indirect evidence for the composition and structure of superficial oxygen coverage on gold.

The open-circuit potential decay technique was applied. In this way, it is possible to follow the changes in potential under null net current conditions. The $E-t$ curves recorded after anodic polarization of a gold electrode in the bulk electrolyte and in the presence of allyl alcohol give information on the interaction mechanism between electrolyte and oxide layer.

Various authors have used this method to study the development and evolution of oxide coverage on metal electrodes (3-10). The influence of stirring (6, 7) and of diverse reducing agents (6-12) was also investigated. Few papers have appeared on the reduction of oxygen coverage on gold by organic reducing agents (13, 14).

Experimental

Procedures.—Cell, electrodes, apparatus, and activation method have been described elsewhere (1, 2). The reactants were NaOH, K_2SO_4 , H_2SO_4 (Merck, P.A.). Allyl alcohol (Fluka, P.A.), was also used. Experiments were carried out under N_2 atmosphere and in unstirred solutions. Temperature (except in experiments for determination of the activation energy) was kept constant at $25.0^\circ \pm 0.1^\circ C$. Two series of experiments were carried out under the following conditions.

In the first series, a potential $E_a = 1.15 V_{SCE}$ was applied to the working electrode (WE) in the bulk solution for a given time t_a . The circuit was then opened and the $E-t$ curve recorded. The electrode was then activated (1) in the bulk solution and the I/E curve was recorded and compared with a standard I/E curve in order to check its catalytic activity. Thereafter, the electrode was polarized at E_a and allyl alcohol was added in N_2 atmosphere, immediately prior to opening the circuit. The resulting $E-t$ relationship was recorded. Measurements were made in unbuffered solutions (H_2SO_4 , NaOH, and $10^{-1}M$ and $5 \times 10^{-1}M$ K_2SO_4), and in buffer solutions (Britton-Robinson) for the complete pH range. The allyl alcohol concentration was varied from $c = 10^{-2}$ to $5 \times 10^{-2}M$. The time during which the polarization was applied, t_a , was changed from 5 to 20 min.

In the second series, the WE was activated in the bulk solution ($0.1M$ H_2SO_4 ; $\mu = 1$ with K_2SO_4) then introduced into a second, previously deoxygenated cell containing a solution of allyl alcohol. The solution was stirred with N_2 for 2 min and then left for 30s. Finally, a potential E_a was applied to the WE for a time, t_a , before opening the circuit

and recording the $E-t$ curve. For this series, the allyl alcohol concentration, c , was varied from 10^{-3} to $10^{-1}M$, and t_a was varied from 4 to 45s. The catalytic activity of the WE was checked after each experiment as described (1). All potential values are expressed *vs.* SCE.

Both series of experiments gave rise to similar $E-t$ responses. In acidic medium, the different values of the transition times which can be deduced from Fig. 2 and 5 are due to the different t_a and E_a applied.

The experimental determination of τ according to Ref. (15) was made, either as the time corresponding to the intersection of the tangents to AB and CD (Fig. 1) or as the time at which characteristic potential is reached. This po-

Fig. 1. Open-circuit $E-t$ curve of $0.1M$ H_2SO_4 + 10^{-2} allyl alcohol. ($E_a = 1.16 V_{SCE}$, $t_a = 5$ seconds, $T = 25^\circ C$) showing the different gold oxide reduction zones (9), and a description of the processes supposed to be implied in every section (b).

tential, which corresponds to zero oxygen coverage is given by $E = 0.62 V_{SCE}$ for Au in acidic medium (1, 18, 26). In this case, the potential value corresponding to the tangent intersection point is $0.86 \pm 0.01 V_{SCE}$ and the values of τ obtained from both methods do not differ by more than 5%.

Results.—Figures 2, 3, and 4 show $E-t$ curves obtained in different media: acid, neutral, and basic (18). In all media, a marked decrease in τ is brought about by the presence of allyl alcohol. The decrease is larger in unbuffered than buffered solutions for all pH values. In alkaline medium, at $t = \tau$ the potential drops sharply to values close to that for H_2 evolution and then increases. Similar behavior is observed for allyl alcohol on other metals (1).

The theoretical treatment (15-17) was applied to the $E-t$ curves obtained in the second series of experiments. Table I summarizes the results for the different sections of the $E-t$ curves (see Fig. 1) in the second series of experi-

Fig. 2. Open-circuit $E-t$ curves in acidic medium at different adsorption times (t_a). Solution = $0.1M H_2SO_4$ ($\mu = 1$) + $10^{-2}M$ allyl alcohol. 1: $t_a = 45s$. 2: $t_a = 30s$. 3: $t_a = 25s$. 4: $t_a = 20s$; $E_a = 1.20 V_{SCE}$.

Fig. 3. Open-circuit $E-t$ curve in (a) $0.1M K_2SO_4$ + $10^{-2}M$ allyl alcohol ($t_a = 5$ min, $E_a = 0.91 V_{SCE}$), (b) $0.1M K_2SO_4$ and the values for t_a and E_a given in (a).

Fig. 4. Open-circuit $E-t$ curves in (1) $0.1M OHNa$, (2) $0.1M NaOH$ + $10^{-2}M$ allyl alcohol. $t_a = 20$ min. $E_a = 0.3 V_{SCE}$.

Fig. 5. Open-circuit $E-t$ curves for different E_a values. Solution: $0.1M H_2SO_4$ + $10^{-2}M$ allyl alcohol. $EdS = 10s$. $T = 25^\circ C$.

ments. In addition to the results summarized in Table I, the following were determined. The dependence of τ on the different experimental parameters is as follows. τ decreases with increasing allyl alcohol concentration [plots of $(\log \tau / \log c)_{E_a, t_a}$ are linear and show a slope value of $b' = -0.48 \pm 0.02$ ($E_a = 1.22 V_{SCE}$, $t_a = 45s$, and an intercept of $+0.90$). τ shows an exponential increase with increasing E_a and a linear increase with increasing intermediate values of t_a (Fig. 6). τ decreases with increasing temperature values. From the slope of the $(\log \tau / T^{-1})_{t_a, E_a}$ plot, the value of the apparent activation energy (E_A) of the overall process can be obtained: $E_A = 73.6 kJ \cdot mol^{-1}$ (Fig. 6).

In general, it can be said that the results are similar to those obtained by Christov (15) for the interaction between organic substances and the platinum oxides.

Theoretical Treatment of Data

Christov *et al.* (15-17) have proposed a general mechanism to interpret the complete open-circuit reduction of oxygen coverage on Pt by organic reducing agents. It was assumed that two parallel processes take place at the electrodes, and this assumption can be essentially kept for the case of the gold oxides, considering the following equations for the interaction between allyl alcohol and the gold oxides

Fig. 6. Plot of $\log \tau$ vs. E_a . $T = 39.8^\circ C$; $t_a = 10s$. $0.1M H_2SO_4$ + $10^{-2}M$ allyl alcohol. (E_a) critical = $1.25 V_{SCE}$.

The partial reactions [1], [2a], and [2b] correspond to chemical oxidation of the reducing agent by the oxygen coverage, electro-oxidation of the reducing agent on the free electrode surface, and electrochemical oxidation and reduction of the electrode, respectively. The e^- produced in reaction [2a] take part in reaction [2b]. k_1 , k_2 , k_3 , and k_4 represent the rate constants of the respective processes.

Although both the structure and the composition of the oxide layers are different for Au and Pt, the kinetic assumptions upon which Cristov (15) based his theory apply to both metals.

The dependence of E on t in every region of Fig. 1 can be theoretically deduced on the assumption that the chemical interaction of the reducing agent and the oxygen coverage is rate determining and the adsorption can be described by a Temkin isotherm. On this basis, a general analytical $E-t$ dependence is derived for the overall process. In order to achieve the direct determination of the kinetic parameters, some particular cases are examined.

High coverage (section A-B of Fig. 1).—The theoretical treatment (16) gives rise to the following relations for a chemical mechanism

$$(\partial E/\partial \log t)_c = \frac{-2 \times 2.303}{f} \approx 0.12V \quad [3]$$

$$(\partial t/\partial \log c)_E = -1 \quad [4]$$

where $f = F/RT$, t = time after opening the circuit, E the electrode potential, c the bulk concentration of reducing agent (allyl alcohol), and α the transfer coefficient

$$(\partial E/\partial \log t)_c = -2 \times 2.303/f(1 - \alpha) \approx 0.24V \quad [5]$$

$$(\partial t/\partial \log c)_E = -3/2 \quad [6]$$

For high coverage and an electrochemical mechanism, the following values should be obtained

$$(\partial E/\partial \log t)_c = -2.303/\alpha f \approx 0.12V \quad [7]$$

$$(\partial t/\partial \log c)_E = 0 \quad [8]$$

Low coverage (section C-D of Fig. 1).—The resulting equations (16) take the form

$$(\partial E/\partial \log(\tau - t))_c = 2 \times 2.3/(1 - \alpha)f \approx 0.24V \text{ when } k_2c \gg k_4 \exp(\alpha FE) \quad [9]$$

$$(\partial E/\partial \log(\tau - t))_c = 2 \times 2.3/f \approx 0.12V \text{ when } k_2c \ll k_4 \exp(\alpha FE) \quad [10]$$

where τ = time required for the complete reduction of oxygen coverage. The concentration interval over which [9] or [10] is valid, is determined by the slope of the plot $(\log(\tau - t)/\log c)_E$. This slope gives values of $-1/2$ and -1 for Eq. [9] and Eq. [10], respectively.

Medium coverage (section B-C of Fig. 1).—According to Ref. (17), the mathematical analysis predicts the appear-

ance of one or more inflections in the $E-t$ curves, depending on the value of α . This case can be characterized by the concentration dependency of the potential in the region of the inflection

$$E_i = (2.3/f) \log(k_2k_3/k_1k_4) \text{ when } (1 - \alpha)k_2c \ll k_4 \exp(\alpha E_i) \quad [11]$$

$$E_i = (2.3/(1 - \alpha)f) \log(k_3/k_1) - (2.3/(1 - \alpha)f) \log c \text{ when } (1 - \alpha)k_2c \gg k_4 \exp(\alpha FE_i) \quad [12]$$

and by the slope of the plateau in the $E-t$ curve

$$\log(-dE/dt)_{E=E_i} = \log[4g(k_1k_2)^{1/2}/qf] + \log c \text{ when } (1 - \alpha)k_2c \ll k_4 \exp(\alpha FE_i) \quad [13]$$

$$\log(-dE/dt)_{E=E_i} = \log[4g(k_1k_2)^{1/2}/(1 - \alpha)qf] + \log c \text{ if } (1 - \alpha)k_2c \gg k_4 \exp(\alpha FE_i) \quad [14]$$

where g is inhomogeneity factor from Temkin's isotherm and q the charge required for the formation of a monolayer of oxygen coverage on gold. An additional relation between $(-dE/dt)_{E=E_i}$ and $\log \tau$ can be obtained. The re-

$$\left. \begin{aligned} (\partial E/\partial \log t)_c &= \frac{-2 \times 2.303}{f} \approx 0.12V \\ (\partial t/\partial \log c)_E &= -1 \end{aligned} \right\} \text{for } k_2c \ll k_4 \exp(\alpha FE) \quad [3]$$

sulting slope and intercept are predicted to be independent of the kinetic parameters. The effect of various factors (t_a , E_a , c , ...) on τ is also considered (17).

Discussion

The results obtained in the first series of experiments confirm the existence of alcohol-gold oxide interaction observed in other studies (1, 2). Under experimental conditions that differ slightly from those described before, the $E-t$ curves show that the reduction occurs in more than one step (more than one plateau from which more than one transition time can be measured) or show the co-existence of more than one type of adsorbed species. In alkaline medium, results suggest that only one type of oxide [possibly $\text{Au}(\text{OH})_3$] is present at sufficiently high anodic potentials.

As said above, the second series of experiments leads to results similar to the first. This can be explained on the basis of the results (1, 2) obtained for the direct oxidation of allyl alcohol on gold. In that case, an inhibition of the oxidation of the organic substance at the potentials at

which gold oxides were formed was observed (E_p , peak potential for the allyl alcohol oxidation appears at 1.03 V_{SCE} and E_p for gold oxide at 1.15 V_{SCE}). It could be argued that a part of allyl alcohol can be oxidized and reduced by electron tunneling through the Au oxide film, analogous to electron tunneling in the case of oxygen evolution at Pt oxide covered Pt electrodes. This contribution could take place at more anodic potentials (E_a) than those applied in this work. At these potentials the electron tunneling contribution should be too small to be considered. A chemical interaction between allyl alcohol and the gold oxides can take place during anodic polarization, but the initial conditions at the moment of open circuit seem to be similar to those obtained for the first series.

The results for this second series show a slow change in the slope in the section C-D of the $E-t$ curve (Fig. 1). This suggests that the removal of the oxide layer occurs in steps. This has also been observed by other authors (4), and attributed to changes occurring in the nature of the adsorbed species. At $E = 0.86 V_{SCE}$ the same oxygen coverage is achieved for any value of c , while at $E = 0.62V$, the whole oxide layer is removed.

In order to evaluate the $E-t$ curves, the diagnostic criteria derived from Christov's treatment (15, 17) were used.

The first section (A-B) of the $E-t$ curve is characterized by high potential values and high oxygen coverages. High anodic potentials would enhance the electro-oxidation of the alcohol. High oxygen coverages would hinder its adsorption on the bare metal surface, and hence electro-oxidation, while it would facilitate the chemical interaction between the oxide layer and the alcohol in solution.

The values of the slope $\alpha = (\partial E / \partial \log t)_c$ (Table I) tend to increase with increasing c and this result, similar to that for Pt (20), suggests a chemical interaction between the gold oxide and the alcohol which requires that $k_2c \ll k_4 \exp(\alpha f E)$ be satisfied (Eq. [3]). This condition does appear to hold, since at high anodic potentials the electro-oxidation of the electrode surface predominates over that of the alcohol. Moreover, Eq. [11] predicts that for low c values, $E_i \neq f(c)$, while for higher c , E_i would decrease with increasing c , according to Eq. [12]. The E_i values obtained from the experimental $E-t$ curves, show that for $c < 10^{-2}M$, $E_i \neq f(c)$, while a slight decrease in E_i is observed for $c > 5 \times 10^{-2}M$. Moreover, the value of the slope α is the same as that obtained for a purely electrochemical mechanism (Eq. [7]). To choose between chemical or electrochemical interaction, it is necessary to resort to the value of b (Table I). A purely electrochemical mechanism would give $b = 0$ (Eq. [8]), while a chemical one would give $b = -1$ (Eq. [4]).

Table I gives two values of b for section A-B of the curve, depending on the c concentration range. For $c \approx 10^{-3}$ - $10^{-2}M$ $b = -0.30$, but -0.50 when c varies between 5×10^{-2} and $10^{-1}M$. Both values are intermediate between 0 and -1 , which suggests that the reduction proceeds through a mixed mechanism with approximately 30% of the reduction being chemical. The higher relative contribution of chemical reduction with increasing c could be expected. The above interpretation is in agreement with previously observed potentiodynamic curves (1, 2). These show that, if c is increased, the electroreduction oxide peak decreases until it disappears at sufficiently high c . At the same time, the allyl alcohol oxidation peak in the cathodic sweep increases with c . This is due not only to its direct oxidation but also to the faster appearance of bare gold surface enhanced by the direct chemical reaction between alcohol (in higher concentrations) and the most oxidizing oxide form. It can be seen in Ref. (21) that a species possibly implied in the process, Au_2O_3 , can chemically oxidize the alcohols.

When the section B-C is reached, the oxygen coverage on the electrode has decreased. Thus, chemical oxidation of the alcohol is expected to be slower than in section A-B. Also, the allyl alcohol might encounter a larger bare metal surface, which would increase its electro-oxidation rate. The theory predicts the appearance of an inflection

point when both chemical and electrochemical oxidation rates become of the same order.

The experimental potential, E_i , corresponding to the inflection point is independent of c (Table I), for low c values. Equation [11]-[12] predict that, for low values of c , $E_i \neq f(c)$ (Eq. [11] is followed), while for higher values of c , E_i decreases with increasing c according to Eq. [12]. A slight decrease in E_i is observed for $c > 5 \times 10^{-2}M$.

The electro-oxidation of the alcohol should make the electrode potential more negative. The potential value, however, shows only a very slight decrease in this section of the decay curve.

Thus, another mechanism for the elimination of negative charge from the electrode must accompany e^- transfer from the alcohol. The only negative species on the electrode would be the O^- ions, which can react with the H^+ ions in solution. This elimination would yield zero net current and explains why the potential value remains almost unchanged.

The proposed electrochemical mechanism should be responsible for the elimination of the oxide coverage, as suggested by the similarity between the experimental values in Table I— -1.10 and -0.72 (slope and intercept, respectively, of the $\log [(-dE/dt)/\log \tau]_{E=E_i}$ plot—and the theoretically predicted— -1.00 (slope) and -0.81 (intercept) (20).

Furthermore, if this mechanism is correct, influence of H^+ concentration on the reaction rate and, consequently on the $E-t$ curves, should be observed. It is to be expected that the elimination rate of O^- would decrease with decreasing H^+ concentration, giving rise to an increase in τ . This is the result obtained (Fig. 3) for $E-t$ curves recorded at near-neutral pH values.

There is a disagreement between the theoretically (20) predicted slope of the plot of $(-dE/dt)$ vs. $\log c$ (at $E = E_i$) and the experimental ones (1.00 and 0.42, respectively).

It should be pointed out that for oxygen coverage reduction of PtO by organic substances it has been assumed (22) that both chemical and electrochemical reactions follow the same path, i.e., via dehydrogenation of α -H atoms. For gold oxide-alcohol interaction (1, 2), the reaction may follow different paths, giving rise to different reaction rates.

In the section C-D, the theoretical treatment supposes that the electro-oxidation of the organic substance is much faster than its chemical oxidation. The low oxygen coverage makes the chemical oxidation rate too low to be considered. The decreasing potential values in this section are due to electrochemical oxidation of the alcohol.

The experimental values for this section are summarized in Table I. The experimental value for $(\partial \log(\tau - t) / \partial \log c)_E$ coincides with the theoretically predicted (-0.5) when $C_{allyl} \gg 5 \times 10^{-2}M$, and shows that Eq. [9] should be valid. The plot of Eq. [9] gives in fact a value for $(\partial E / \partial \log(\tau - t))_c$ of $0.224 \pm 0.005V$, in a very good agreement with the theoretical value $0.220V$. The derived value of α should be 0.48 ± 0.01 .

The observed discrepancy between experimental and theoretical values for low values of c is similar to that obtained for the reduction of PtO by organic substances (20). This fact could be explained if the condition $k_2c \gg k_4 \exp(\alpha f E)$ in Eq. [9] is no longer satisfied due to the decrease of c .

The variation of τ with the different experimental parameters (c , t_a , E_a , T , ...) is similar to that for Pt and agrees with the proposed interaction mechanism. The decrease in τ with increasing c implies an alcohol-gold oxide interaction whose rate increases with c , according to potentiodynamic studies (1, 2). This decrease of c cannot be attributed to a smaller oxygen coverage due to the presence of the alcohol during anodic polarization (in the second series of experiments), because the same result is obtained in the first series of experiments, in which the WE was polarized before the addition of the alcohol. The linear relation between $\log \tau$ and E , as well as between τ and t_a , can be deduced by supposing a mixed chemical and electrochemical reduction mechanism of the oxygen cov-

erage. At sufficiently positive potentials but not too high coverage, the rate of oxygen coverage formation will be much greater than the reduction rate. Assuming that the oxygen coverage increase can be described by means of a Temkin isotherm, the linear terms in θ can be neglected. In this way the following equation (17) can be derived

$$[1 - 2g(k_1 k_2)^{1/2} c \tau / \pi q]^{-1} = 1 + (k_1 / k_2)^{1/2} (\pi g k_4 t_a / 2q) \exp(\alpha f E_a) \quad [15]$$

where g represents the interaction coefficient in the Temkin isotherm and q is the charge required for the formation of a monolayer of oxygen coverage.

In order to obtain an idea about the value of the $2g(k_1 k_2)^{1/2}$ factor, plots of Eq. [13] and [14] were made. From the slope value it was deduced that $4g(k_1 k_2)^{1/2} / qf = 0.01778$, and taking (27, 28) $q = 850 \mu\text{C}\cdot\text{cm}^{-2}$, gives $g(k_1 k_2)^{1/2} = 1.47 \times 10^{-4}$. This value is very similar to that deduced from the intercept of the $(\log \tau / \log c)_E$ plot (17). In this case, $\log(\pi q / 2(k_1 k_2)^{1/2} g) = \text{intercept} = 0.9$, and $g(k_1 k_2)^{1/2} = 1.68 \times 10^{-4}$. [Incidentally, this value provides an additional test for the validity of Christov's treatment for the case of gold oxides, since it is very similar to that obtained for that case (15).]

A rearrangement of Eq. [15] can be easily made by supposing that $\pi q \gg 2g(k_1 k_2)^{1/2} c \tau$, as is obtained from the value for $2g(k_1 k_2)^{1/2}$ formerly deduced. Finally, the following expression can be obtained for the relation between τ and t_a and E_a

$$\tau = (\pi^2 k_d / 2ck_2) \exp(\alpha f E_a) t_a \quad [16]$$

Plots of $\log \tau$ vs. E_a at different temperatures were made (Fig. 6). At 25.2°C and $t_a = 10\text{s}$ the intercept¹ value leads to a k_d/k_2 ratio of 7×10^{-6} , i.e., the oxidation reaction of allyl alcohol is faster than the gold oxide formation. At 39.8°C , the intercept gives a value of 3.5×10^{-6} for this ratio. It seems that with an increase in the temperature k_2 increases more rapidly than k_d . The exponential increase of τ with E_a could be in agreement with the idea of the differential characteristics of the adsorbed species, supposedly formed at different potential values.

Figure 7 gives the τ vs. t_a plots at $T = 25.0^\circ\text{C}$ and $E_a = 1.22 \text{ V}_{\text{SCE}}$. The result indicates that, the higher the allyl alcohol concentration, the faster would be the oxide layer elimination. The rate of change of τ with t_a is also dependent on c and can be attributed to a change in the value of α in Ref. (16) induced by the different participation of chemical and electrochemical reactions in the mixed mechanism proposed. These changes of α can be followed by substituting the k_d/k_2 values obtained from the plots of Fig. 6.

Substituting the k_d/k_2 ratio obtained in Eq. [11], ($E_1 = 0.95 \text{ V}_{\text{SCE}}$), one obtains a value of $k_3/k_1 = 5.86 \times 10^{12}$, the same order of magnitude as found in the PtO study (15). This would mean that the chemical interaction [1] between allyl alcohol and gold oxide would be much slower than the electrochemical one (Eq. [2a] and [2b]).

The decrease of τ with stirring for $c < 10^{-2} \text{ M}$ (Fig. 10) shows the influence of convective diffusion on the process. Faster transport of the alcohol to the surface would accelerate the chemical and electrochemical reduction rates. For $c > 10^{-2} \text{ M}$, the slightly higher values of τ can be explained supposing the formation of adsorbed intermediates, which would be partly eliminated by stirring, thus making slower the rate of production of electrons (by oxidation of the allyl alcohol molecules initially present). This fact is reflected in potentiodynamic curves taken in almost neutral solutions (Fig. 10). Under stirring, a second reduction peak is recorded which can be attributed to the reduction of a gold oxide produced in a first reduction step. When stirring is stopped, only a reduction peak (Fig. 11b) is obtained. The allyl alcohol molecules keep in contact with the electrode surface and supply electrons for the complete reduction of the oxide layer in a single step.

¹We take the intercept as the value of $\log \tau$ at the critical potential point in which the oxygen coverage takes intermediate values ($E = 1.2 \text{ V}_{\text{SCE}}$).

Fig. 7. Plots of t_a vs. τ in $0.1 \text{ M H}_2\text{SO}_4$ at different allyl alcohol concentrations. $E_a = 1.20 \text{ V}$. $T = 25^\circ\text{C}$.

Fig. 8. Plots of $\log \tau$ vs. $1/T$ at different t_a values. $0.1 \text{ M H}_2\text{SO}_4 + 10^{-2} \text{ M allyl alcohol}$. $E_a = 1.20 \text{ V}_{\text{SCE}}$.

Fig. 9. Plots of E vs. t/τ in $0.1 \text{ M H}_2\text{SO}_4$ at different allyl alcohol concentrations. $t_a = 45\text{s}$. $E_a = 1.20 \text{ V}_{\text{SCE}}$.

Section A-B is hardly influenced by stirring. This suggests that the chemical process is not transport dependent. In this range, the rate-determining step should be the adsorption of the organic substance as predicted by the assumed mechanism.

Finally, an interpretation of the Au-electrode open-circuit potential decay in absence of alcohol can also be given.

Fig. 10. Influence of stirring on the $E-t$ curves taken after different t_a values. $E_a = 1.20 \text{ V}_{\text{SCE}}$. $0.1\text{M H}_2\text{SO}_4 + 10^{-2}\text{M}$ allyl alcohol. Dashed line: without stirring. Solid line: with stirring.

In basic medium the reaction mechanism would be initiated by the oxidation of OH^- species

and

The $\text{OH}\cdot$ radicals can then react with each other and produce H_2O_2 . In acidic medium, the H_2O molecules could play the role of the reduced species which can be oxidized and induce the reduction of the oxides

giving rise to $\text{OH}\cdot$ radicals which can produce H_2O_2 .

The fact that $\tau_{\text{basic medium}} < \tau_{\text{acid medium}}$ seems to predict a reaction [18] slower than reaction [16]. It can be said that the transition times in acid as well as in basic solutions are much longer without, than with, allyl alcohol present in the solution.

Conclusions

On the basis of the experimental data, a mixed mechanism (chemical-electrochemical) can be postulated for the reduction of gold oxide layers (23-26). The following equations give a summarized view of the process described in Fig. 1

On the surface, after reduction of Au^{3+} ions, the uncompensated charges of O^- make them to repel each other. If the proposed mechanism should take place, the rate of the third step would be dependent on the $(\text{H}^+)_{\text{aq}}$ according to

and

$$v = -\frac{d\theta_{\text{O}^-}}{dt} = K(\theta_{\text{O}^-})^a \cdot (\text{H}^+)_{\text{aq}}^b \cdot f(E)$$

where $K = (1/\tau)$, and $f(E)$ is a function of the potential

Fig. 11. Voltammograms of $0.1\text{M K}_2\text{SO}_4 + 10^{-2}\text{M}$ allyl alcohol solutions. a: Without stirring. b: With stirring.

value, decreasing from the first to the third step. Thus, at $(\text{H}^+)_{\text{aq}} = 10^{-7}\text{M}$, the third step could become rate determining. Both $E-t$ curves and $i-E$ potentiodynamic diagrams seem to agree with such supposition: The $E-t$ curves obtained in neutral electrolytes show three different plateaus (Fig. 3). The first one corresponds to the peak potential value obtained for the oxide reduction in voltammograms taken in acidic electrolytes. This process is then attributed to the reduction of Au_2O_3 . The second one appears at a potential value similar to the one of a second reduction peak obtained maintaining the electrode at oxide formation potentials values for a given time. This peak is attributed to the reduction of Au_2O , formed by reduction of Au_2O_3 . The third one is attributed to the reduction of a more stable form of Au_2O , directly formed during the gold oxidation, and after having undergone the so-called aging process (23-25). This process seems to stabilize such oxide species and that can explain why its reduction occurs only at more negative potentials. In summary, the following equations could describe the processes supposed to be taking place at the potentials of the different plateaus

Step 1:

Step 2:

Step 3:

Thus, the Au_2O coverage would be formed in the following way

$$(\theta_{\text{Au}_2\text{O}})_{\text{total}} = (\theta_{\text{Au}_2\text{O}})_{\text{initial}} + (\theta_{\text{Au}_2\text{O}})_{\text{(from step 1)}}$$

supposing

$$(\theta_{\text{Au}_2\text{O}})_{\text{initial}} \ll \theta_{\text{Au}_2\text{O}_3}, \text{ then } (\theta_{\text{Au}_2\text{O}})_{\text{step 1}} \approx \theta_{\text{Au}_2\text{O}_3}$$

The higher values of τ for the second and the third plateaus reflect not only the higher stability of both Au_2O species, but also the lower electro-oxidation rate of allyl alcohol with decreasingly positive potentials. The decrease of θ_{O^-} gives rise to a lower electrostatic repulsion between neighboring O^- , influencing in this way also, the rate of the third step. The influence of $(\text{H}^+)_{\text{aq}}$ is confirmed since in very acidic solutions, the second plateau almost disappears.

Likewise, the potentiodynamic $i-E$ curves in the same neutral solutions (Fig. 8) show two cathodic reduction peaks. Only the second one appears under stirring. Stirring carries away from the electrode the intermediates produced in the allyl alcohol oxidation before that process occurs completely. Thus, a partial reduction of Au^{3+} would take place, giving rise to Au_2O , which, in turn, reduces, giving a second peak. Without stirring the alcohol, oxidation continues and produces the e^- for the direct reduction from Au^{3+} to Au (one single peak).

In summary, it has been shown that an interaction between gold oxides and organic substances takes place and that the interaction follows a similar pattern to the process occurring between the same type of substances and Pt-oxides. The differences observed must be a consequence of the more complex oxidation processes occurring on gold electrodes.

ABSTRACT

A cyclic voltammetric study of the ferrocene redox reaction was used to evaluate the substituent effect in various *para*-substituted poly-*N*-phenylpyrrole films used as electrodes. To determine the film electrode substituent effect on the ferrocene couple reaction, the heterogeneous standard rate constant values were determined. The observed changes in the film electron-transport rate are the result of the structure monomer variation. Electronic interaction between the polypyrrole nucleus and the *para* substituents on the *N*-phenyl ring affects the electron-transfer rate of polymer electrodes.

A new class of organic electrodes has become available through the electropolymerization of aromatic compounds such as pyrrole (1). Electrochemically grown thin films of highly conductive polypyrrole, doped with BF_4^- , are insoluble and have long-term stability.

Conductive films of polypyrrole can be modified by introducing substituents into the cationic pyrrole polymer or varying the accompanying anion (2). The fact that the polypyrrole films are prepared electrochemically facilitates these modifications since the variations are made in the selection of the electrolyte or the monomer. We have now made a study of polypyrrole films modified by placing phenyl substituents in the *N* position of the pyrrole ring; the phenyl substituent assumes a particularly important role because it provides a means of introducing a wide selection of functional groups into the polymer structure as substituents on the phenyl ring.

In polymeric coatings on electrodes, the rate of charge and electron transport across the layer defines the usefulness of these films in devices. This paper deals with a cy-

clic voltammetric study of the quasi-reversible redox behavior of ferrocene on some poly-*N-para*-substituted phenylpyrrole films used as electrodes. We found that the electron transfer rate constant (k_s) of the ferrocene couple reaction depends on the film electrodes.

Experimental

The polymeric films of poly-*N-para*-substituted phenylpyrrole were prepared by electropolymerization of the corresponding *N-para*-substituted phenylpyrrole monomer with *p*-H, *p*-CH₃, *p*-OCH₃, *p*-Cl, *p*-Br, and *p*-NO₂.

All *N-para*-substituted phenylpyrroles were synthesized from 2,5-dimethoxytetrahydrofuran and the appropriate amine (3). The pure pyrrole monomers were identified by ¹H-NMR, IR, and MS and compared with reported data (4).

The film preparations were performed in a one-compartment cell using Pt as the working electrode, a similar counterelectrode, and a saturated calomel reference electrode (SCE). Each electrolytic solution contained 10⁻³M of the corresponding pyrrole monomer, plus 0.1M of tetra-

* Electrochemical Society Active Member.

ethylammonium tetrafluoroborate in distilled acetonitrile. The films were grown on 0.5 cm² Pt electrode surface, passing 20 mC·cm⁻² of charge to control the film thickness, estimated as *ca.* 50 nm considering the area of the electrode, density of the film, and the apparent *n* value for the reaction (5).

The electro-oxidation of the *N*-*para*-substituted phenylpyrroles conducted at a constant potential of 1.50V for *p*-H and *p*-NO₂, 1.12V for *p*-CH₃ and *p*-OCH₃, and 1.19V for *p*-Cl and *p*-Br, proceeds with the formation of insoluble polymer film on the electrode, as was previously reported (6). Films of these polymers, when mounted in acetonitrile/Et₄NBF₄ solution, can be electrochemically driven between the oxidized and the neutral forms. The films are stable to this reaction and can be cycled repeatedly without evidence of decomposition.

The cyclic voltammetric study of ferrocene (1 × 10⁻³M in acetonitrile/Et₄NBF₄ solution) was accomplished using thin films of *N*-phenyl-pyrroles on a Pt working electrode. All the measurements were prepared with IR compensation.

Electrochemical measurements were performed with a Princeton Applied Research Model 173 Potentiostat, a Model 175 Programmer, and a Hewlett-Packard 7004B X-Y recorder.

Results and Discussion

As can be seen in Table I, the formal potentials, E° , for the redox reaction of the dissolved ferrocene using [Pt] poly-*N*-*para*-substituted-phenylpyrrole-BF₄ electrodes are not significantly different from those measured with a Pt bare electrode. Peak heights vary linearly with the square root of the sweep rate, $\nu^{1/2}$, from 10 to 100 mV/s, as expected for a diffusion-limited process, and the ratio of the peak heights i_{pa}/i_{pc} is always close to unity. There is no evidence of absorption or adsorption on the polymer surface, indicated by the fact that $i/AC\nu^{1/2}$ values (A is the electrode area, C , mol/cm³) remains constant in the potential sweep range tested. The cyclic voltammograms produced using thicker films (70 nm) provide the same $i/AC\nu^{1/2}$ values, indicating that the signal amplitudes do not depend on film thickness. Moreover, the E° for ferrocene do not superimpose on the E° of the polymer films (6). Representative cyclic voltammograms are displayed in Fig. 1.

The potential difference between the peaks E_{pa} and E_{pc} (ΔE) is greater than 59 mV and increases with the sweep rate. Nicholson's treatment (7) for determining k_s values was used to evaluate the effect of the electrode on the redox reaction. Values for the Ψ parameter were obtained from the ΔE values. For a quasi-reversible reaction, Nicholson's empirical equation is

$$\Psi = k_s (RT/nF\pi D\nu)^{1/2}$$

where $n = 1$ electron/molecule for this reaction, D is the diffusion coefficient [$D = 2.76 \times 10^{-5}$ cm²/s, ferrocene in CH₃CN, measured chronocoulometrically (8)], F the Faraday, R gas constant, and T absolute temperature.

Fig. 1. Cyclic voltammograms of 1 × 10⁻³M ferrocene using 20 mC of [Pt]-coated electrodes with poly-*N*-*para*-methylpyrrole (dot-dash line) and poly-*N*-*para*-chlorophenylpyrrole (dotted line) at 100 mV/s in CH₃CN containing 0.1M Et₄NBF₄.

All these polypyrroles, PPy, polymers, are produced by an electrochemical oxidative coupling process which yields an acceptor-doped conducting complex directly, such as PPy⁺BF₄⁻ (9, 11). With acceptor doping, Hall coefficient measurements (12) clearly showed that the conduction is *p*-type, *i.e.*, positively charged carriers. It demonstrates that the majority of the carriers move through the organic material and not through the dopant array (13). Then the modification of the monomer should affect the charge transfer rate of the polymer, as can be observed in Table I.

In an earlier communication (14), it was proposed, on a qualitative basis, that a poor interaction between the pyrrole and the phenyl ring was produced by an orthogonal conformation through both rings. Further studies showed that in the *N*-*ortho*phenylpyrrole series electroactive substituents exhibit electronic and steric effects (15), whereas in the *N*-*para*-phenylpyrroles only electromeric effects were observed (6). Therefore, the electron-attractive or electron-repulsive induction of *para* groups involve interannular conjugation as well as inductive effects.

In the first study of this series (14), the electroactive behavior of the nitro phenyl group in the poly-*N*-*para*-nitrophenylpyrrole was analyzed by cyclic voltammetry. Although the nitrophenyl group is independently electroactive, the electron-transfer process between the platinum and the film for the reduction reaction involves an electron exchange between the unsaturated pyrrole matrix and the pendent nitrophenyl groups rather than a hopping process between the groups.

Consequently, the electronic interaction between the polypyrrole nucleus and *para*-substituents on the *N*-phenyl ring affects the electron-transfer rate of polymer electrodes (16). In effect, when the log of k_s are plotted against their respective Hammett-Brown substituent constants, a linear correlation is obtained (Fig. 2); the resonance and inductive interaction effects are undoubtedly

Fig. 2. Electron-transfer rate constant of the ferrocene couple reaction on the poly-N-*para*-substituted phenylpyrrole vs. their respective Hammett-Brown substituent constants.

the principal effects involved in the $\rho_{\pi}\sigma^+$ relationship. The positive sign for the substituent constant ρ_{π} reveals that as the substituents take on more electrophilic character the electron-transfer rate becomes faster.

We can conclude that changes in the electron-transfer rate of the series of polypyrroles is dependent on electronic interaction between the electroactive pyrrole ring of the polymer and the *para*-substituent through the phenyl ring. This electronic interaction has also been observed in the oxidation of the corresponding monomer, due to the fact that, as the substituent takes on more electrophilic character, the oxidation of the N-substituted phenylpyrrole proceeds with more difficulty (6). The mobility of the carriers will be determined by a variety of effects, including chain perfection, crystallinity, etc. (17); however, a delocalized π -system with relatively broad energy bands is certainly an advantage for effective electron transport.

Oxygen Reduction in Tetrafluoroethane-1,2-Disulfonic Acid

K. A. Striebel, P. C. Andricacos,^{*1} E. J. Cairns,* P. N. Ross,* and F. R. McLarnon*

Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720

ABSTRACT

The kinetics of oxygen reduction on platinum in tetrafluoroethane-1,2-disulfonic acid (TFEDSA) and trifluoromethane sulfonic acid (TFMSA) have been studied with the rotating disk electrode technique at pH 1. The resulting Tafel plots coincide within the error of the experiment, indicating similar kinetics in the two electrolytes. The reaction order with respect to oxygen concentration was studied by varying the partial pressure of oxygen above the electrolyte. The rotation-independent currents at 0.90V vs. DHE were used to calculate a reaction order equal to one. A first-order analysis of the rotation-dependent currents was then used to extract kinetic currents at lower potentials. These kinetic currents also exhibited first-order dependence on oxygen concentration.

Trifluoromethane sulfonic acid (TFMSA) has been considered for low temperature (< 110°C) fuel cell applications due to the favorable oxygen reduction rate observed in this electrolyte compared with phosphoric acid (1). The use of the less-volatile, higher homolog of TFMSA, tetrafluoroethane-1,2-disulfonic acid (TFEDSA), was suggested by Baker *et al.* (2) to overcome the problems of high acid vapor pressure and low contact angle with PTFE observed with concentrated TFMSA. Preliminary investigations with TFEDSA (3) show insignificant acid vapor pressure and acceptable water vapor pressure at

*Electrochemical Society Active Member.

60-70 weight percent acid, as well as high (nonwetting) contact angles with PTFE. In this work, the kinetics of oxygen reduction in TFEDSA and TFMSA on smooth Pt have been studied with the rotating disk electrode (RDE) technique. Kinetic measurements were made in each of the acids at pH = 1. The dependence of the reduction current on oxygen concentration was determined by varying the partial pressure of oxygen in contact with the electrolyte. This reaction order has been shown to be unity in perchloric, sulfuric, and phosphoric acid electrolytes (4-6). However, in "superacid" electrolytes (TFEDSA and TFMSA) the analysis of RDE data according to a first-order model has not been conclusive. Deviations from first-order analysis have previously been attributed to

impurity effects (7, 8) and a nonunity reaction order with respect to oxygen (9). We varied the bulk concentration of oxygen in the electrolyte in order to have an independent method for determining reaction order.

Experimental

Experiments were performed in a Pyrex cell with a surrounding water jacket. Circulation of thermostatically controlled water was used to maintain the cell temperature of $25^\circ \pm 0.5^\circ\text{C}$. The rotating disk platinum working electrode had an area of 0.458 cm^2 and was polished with a succession of alumina papers, followed by $6\text{ }\mu\text{m}$ and then $1\text{ }\mu\text{m}$ diamond paste. Rotation was achieved with a Pine Instruments analytical rotator. A dynamic hydrogen electrode (DHE) (10) was held in a separate compartment which was connected to the main cell through a Luggin capillary. The DHE held a constant potential of 3 mV negative of an RHE at the same pH. A 1 cm^2 Pt-foil counterelectrode was used directly in the cell, placed as shown in Fig. 1. Premixed cylinders of oxygen and nitrogen ($4.31\text{-}58.66\% \pm 0.01\%$ oxygen), pure oxygen, and pure nitrogen were further purified by passing through three molecular-sieve beds (9). All gases were humidified by bubbling through doubly distilled water at room temperature before entering the cell.

The potential of the working electrode was controlled with a PAR Model 173 potentiostat and a PAR Model 175 universal programmer. Current-potential data could be recorded simultaneously with a Nicolet digital oscilloscope and an HP7046B X-Y recorder.

All glassware and electrodes (except the DHE) were cleaned by soaking in a mixture of concentrated sulfuric and 70% nitric acids for two days. This was followed by rinsing and soaking in freshly distilled water at least four times.

TFMSA (from 3M Corporation) was purified by distillation and hydrogen peroxide treatment as reported earlier (8). Tetrafluoroethane-disulfonate was received as the potassium salt from KOR, and it was converted to the acid via ion exchange with prepurified resin (11). Complete conversion to the acid was checked by titration. Water was removed by vacuum distillation, leaving the acid dihydrate. The hygroscopic nature of this solid prevented exact knowledge of the water content. Solutions were prepared by dilution with ultrapure water² to pH 1. TFMSA solutions were prepared in a similar manner. Both solutions were pre-electrolyzed in the cell for at least 72h at a current of 1 mA .

Results and Discussion

Two single-sweep cyclic voltammograms recorded in TFEDSA at pH = 1 are shown in Fig. 2. Curve A was recorded for the stationary disk following the pretreatment potential profile shown in the inset of Fig. 2. For an indication of electrolyte purity, curve B was recorded following the same pretreatment profile with the addition of a

Fig. 2. First-sweep cyclic voltammetry in TFEDSA, pH = 1, 25°C , Ar atmosphere. A: Recorded after pretreatment. B: Recorded after pretreatment and holding 60s at 0.4 V while rotating at 1600 rpm .

min hold at 0.4 V vs. DHE while rotating the working electrode at 1600 rpm before recording the voltammogram on the stationary electrode.

Several voltammograms were recorded in both electrolytes without repolishing the working electrode. The charge associated with the hydrogen adsorption region of the curves increased chronologically. The relative increase in this charge was used to quantify the increase in active electrode area caused by repeated cycling (roughening). All kinetic currents were adjusted downward to an effective roughness factor of 1.5. However, current densities were computed using the projected electrode area.

Similar voltammograms were recorded at a sweep rate of 10 mV/s in order to quantify the anodic currents associated with platinum oxidation. These anodic currents were added to the reduction currents recorded with low pressures of oxygen to adjust for the nonzero base line observed in those experiments.

Current-potential sweeps at rotation speeds of $100\text{-}1600\text{ rpm}$ for TFEDSA in contact with pure oxygen are shown in Fig. 3. The potential profile used for electrode pretreatment is shown in the inset in Fig. 3. The reduction currents were found to depend somewhat on sweep rate and sweep direction because of the changing oxidation state of the electrode. Therefore, for the purpose of comparing TFEDSA and TFMSA, positive going sweeps at 10 mV/s were used in all cases. Uncompensated solution resistances of $15\text{-}20\Omega$ were accounted for by reading constant-potential data along lines of constant surface potential (with slopes of $1/R_s$), as is indicated in Fig. 3.

The current-potential relationship

$$I = nFAk_c (C_{\text{O}_2}^{\circ})^m \exp\left(\frac{-\alpha VF}{RT}\right) \quad [1]$$

where A is the electrode area, k_c is the reaction rate constant for the cathodic reaction and includes the pH dependence, $C_{\text{O}_2}^{\circ}$ is the concentration of oxygen at the electrode surface, m is the reaction order for oxygen, α is the fraction of the overvoltage aiding the reduction reaction, and V is the electrode potential, is expected to apply for oxygen reduction on platinum. Because of the large overpotentials in this reaction, the anodic term has been neglected.

During cathodic reduction, the concentration of oxygen at the electrode surface is lower than that in the bulk. For transport to the rotating disk, it can be shown that

$$C_{\text{O}_2}^{\circ} = \left(\frac{I_L - I}{I_L}\right) C_{\text{O}_2}^{\infty} \quad [2]$$

where I_L is the limiting current and $C_{\text{O}_2}^{\infty}$ is the bulk concentration of oxygen in the electrolyte. Since, in general,

Fig. 3. Current-potential sweeps in TFEDSA, pH = 1, 25°C

$C_{O_2}^\circ$ is not known, but $C_{O_2}^\infty$ can be known or controlled, a more useful expression is obtained by substitution of Eq. [2] into Eq. [1], dropping the last term of Eq. [1], with the result

$$I = nFAk_c (C_{O_2}^\infty)^m \left(\frac{I_L - I}{I_L} \right)^m \exp \left(\frac{-\alpha FV}{RT} \right) \quad [3]$$

When I is small compared to I_L , then the reaction order m can be determined from the slope of a plot of $\log I$ vs. $\log C_{O_2}^\infty$ for constant V . For other conditions, the determination of m is more complicated.

Before reaction order m can be determined, it is necessary to establish the relationship between p_{O_2} , the controlled variable, and $C_{O_2}^\infty$. This was done by use of the Levich equation

$$I_L = 0.62nFC_{O_2}^\infty D^{2/3} \nu^{-1/6} \omega^{1/2} \quad [4]$$

The slope of a plot of I_L vs. $\omega^{1/2}$ is therefore proportional to $C_{O_2}^\infty$. If Henry's law is obeyed

$$C_{O_2}^\infty = K_H p_{O_2} \quad [5]$$

the Levich slope $B = 0.62nFC_{O_2}^\infty D^{2/3} \nu^{-1/6}$ should be proportional to p_{O_2} .

The applicability of Eq. [4] to the results of Fig. 3 is shown in Fig. 4. All of the lines are straight and pass through the origin, as they should. Figure 5 shows a plot of $\log B$ vs. $\log p_{O_2}$, which has a slope of unity, demonstrating that Henry's law holds for O_2 in both TFMSA and TFEDSA at pH = 1 and 25°C.

Equation [5] now may be substituted into Eq. [3], yielding

$$I = nFAk_c K_H^m p_{O_2}^m \left(\frac{I_L - I}{I_L} \right)^m \exp \left(\frac{-\alpha FV}{RT} \right) \quad [6]$$

For potentials near 0.9V, the currents are insensitive to rotation speed above about 400 rpm, as shown in Fig. 3. Under these conditions $I \ll I_L$, so that $(I_L - I/I_L)$ approaches unity, and, according to Eq. [6], a plot of $\log I$ vs. $\log p_{O_2}$ for constant V should be a straight line of slope m . This plot for TFMSA and TFEDSA (see Fig. 6, part A) indicates that the reaction order m is 1.0 ± 0.05 .

Fig. 4. Levich plots for TFEDSA and TFMSA at various oxygen partial pressures. A: 1.0 atm. B: 0.5866 atm. C: 0.3503 atm. D: 0.2028 atm. E: 0.1258 atm. F: 0.0753 atm. G: 0.043 atm.

The result that m is unity (at 0.90V) allows a simplification of further analysis for higher currents and overvoltages. Even though Eq. [6] is difficult to apply when I is not very small relative to I_L , it can be rearranged as follows. First, define the kinetic current I_k (for $m = 1$)

Fig. 5. Levich slopes from Fig. 4

Fig. 6. Kinetic current dependence on oxygen pressure in TFEDSA and TFMSA. A: 0.90V vs. DHE. B: 0.80V vs. DHE. C: 0.70V vs. DHE.

$$I_k = nFAk_c C_{O_2}^m \exp\left(\frac{-\alpha FV}{RT}\right) \quad [7]$$

Substituting Eq. [7] into Eq. [6], setting $m = 1$, and rearranging yields the familiar relation (11)

$$\frac{1}{I} = \frac{1}{I_k} + \frac{1}{I_L} \quad [8]$$

Equation [8] shows that I_k may be obtained from a plot of I^{-1} vs. I_L^{-1} , or since $I_L = B\omega^{1/2}$, a plot of I^{-1} vs. $\omega^{-1/2}$ for constant V and p_{O_2} yields I_k from the intercept. The values of I_k may then be used with Eq. [5] and [7] to test the value of m , by plotting $\log I_k$ vs. $\log p_{O_2}$ for a given voltage. This is shown in Fig. 6 for 0.8 (lines B) and 0.7V (lines C), and m is seen to be unity within experimental error.

A direct comparison of the kinetic current densities for TFEDSA and TFMSA was made by first multiplying the currents in TFEDSA by the ratio of the roughness factors (calculated from the hydrogen oxidation peaks observed in the voltage-sweep experiments of the type shown in Fig. 2): $[(RF)_{TFMSA}]/[(RF)_{TFEDSA}] = 0.83$. These currents were then divided by the geometric area of the rotating disk electrode, 0.458 cm^2 . No correction for solubility or diffusivity differences was made, since $B = 0.46$ and $0.44 \text{ mA/cm}^2\text{-s}^{1/2}$ for TFMSA and TFEDSA, respectively, at $p_{O_2} = 1.0$. The potential-log current density curves for 1 atm oxygen pressure are shown in Fig. 7. Over the potential range 0.67-1.0V vs. DHE, the kinetic currents are very similar. The familiar change of slope is observed at 0.8V, as is the case in other acids. This change in Tafel slope occurs at the potential below which the electrode surface is oxide free. Exchange current densities calculated by extrapolation of the results obtained at higher potentials are 4×10^{-6} and $6 \times 10^{-6} \text{ mA/cm}^2$ for TFMSA and TFEDSA, respectively. These can be compared with the exchange current density of $9 \times 10^{-8} \text{ mA/cm}^2$ reported for 1.1N TFMSA, 25°C, by Appleby and Baker (7).

Fig. 7. Tafel plot for oxygen reduction in TFEDSA (squares) and TFMSA (circles) at 1 atm oxygen; pH = 1.0; 25°C.

Conclusions

From the experiments reported above and the analysis of the data, it is concluded that the reaction order of the electrochemical reduction of oxygen on platinum in TFEDSA and TFMSA with respect to oxygen concentration is unity, over the full potential range studied (1.0-0.65V vs. DHE). The kinetics of oxygen reduction on platinum in TFEDSA are very similar to those for TFMSA, the currents being very closely comparable at pH = 1 for identical overvoltages.

These results offer some promise for the use of fluorinated organic acids in high performance fuel cells, while avoiding the high vapor pressure of TFMSA and its undesirable wetting of PTFE. Furthermore, pressurization is expected to improve significantly the performance of cathodes in fuel cells using TFEDSA and TFMSA.

ABSTRACT

The electrochemical behavior of (100) IrO₂ single-crystal electrodes in 0.5 mol/dm³ H₂SO₄ has been studied using linear potential scan cyclic voltammetry. A highly irreversible behavior of the main electrochemical process of hydrogen or hydronium ion injection/ejection has been found in the potential range 360-580 mV (*vs.* Ag/AgCl reference). The obtained voltammograms have been compared with those for RuO₂ single crystals possessing similar electrocatalytic properties and the same crystallographic structure and also with the behavior of sputtered and anodic IrO₂ films. It has been found that the energy of major interaction of hydrogen species with the IrO₂ single-crystal structure is close to that observed for sputtered IrO₂ films but differs by *ca.* 29 kJ/mol (corresponding to 300 mV in the potential scale) from that for the anodic IrO₂ films. The penetration depth for hydrogen is highly minimized in the case of single-crystal IrO₂ electrodes and involves at most one or two monolayers. Thus, the coloration/bleaching process described for the IROX films cannot develop on nonhydrated single-crystal IrO₂ electrodes unless their crystallographic structure is damaged by cycling in a wide potential range.

Anodic films of iridium dioxide have recently been the subject of numerous studies on account of their interesting electrocatalytic and electrochromic behavior. Both the oxygen and chlorine evolution reaction proceed on the IrO₂ electrodes with extremely low overvoltages (1-5). In contrast to RuO₂ possessing similar electrocatalytic properties (6-10), the IrO₂ films undergo dissolution at higher positive potentials ($E > 1600$ mV *vs.* Ag/AgCl) and can be removed from the electrode surface (2, 11-13). The hydrous, amorphous IrO₂ films on Ir metal electrodes show electrochromic properties (13-22) sensitive to the change in the electrode potential. The mechanism proposed for the rapid coloration/bleaching process (about 40 ms) is based on the proton injection/ejection mechanism (13). It has been found that the electrochemical processes of anodic formation and cathodic reduction of a thick porous IrO₂ film are highly reversible (12-14).

The initial stages of IrO₂ film growth on Ir electrodes have recently been studied by Mozota and Conway (11), Capon and Parsons (23), and other authors (24-26). The mechanism of interaction of the IrO₂ surface with aqueous solutions has also been discussed from the point of view of the surface acid-base properties (27-31). The latter works have been done using thermal IrO₂ powders.

The behavior of the anodic oxide on Ir electrodes during oxygen evolution in acidic solutions has also been studied by *ex situ*, x-ray photoelectron spectroscopy (XPS) by Kotz *et al.* (32). These authors demonstrate conclusively that a thin oxide (or hydroxide) is formed on iridium surface during O₂ evolution and no higher than IV oxidation states of Ir are present in the film. The composition profiles within the amorphous anodic IrO₂ films have been determined by McIntyre and co-workers (13) using nuclear reactions. The thickness of the hydrated IrO₂ films has been measured by Kim *et al.* (33) using XPS technique.

As regards single crystals, the electrical-transport properties of IrO₂ have been reported by Ryden *et al.* (34) and conduction electron screening effects have been demon-

strated in IrO₂ by Wertheim and Guggenheim (35). The optical properties of a single-crystal IrO₂ have been described by Goel *et al.* (36). The latter authors, measuring a near-normal incidence reflectivity in the photon energy range 0.5-9.5 eV, have determined the spectral dependence of the complex dielectric function and refractive index. This in turn allowed making a direct comparison with recent band structure and density-of-states calculations performed by Mattheiss (37).

In this paper, the voltammetric characteristics of the IrO₂ single-crystal electrodes with the exposed (100) surface are presented and discussed in terms of the hydrogen and hydronium ion injection/ejection processes. The observed significant differences between the electrochemical behavior of the IrO₂ (100) electrodes and that of the anodic IrO₂ films on Ir substrates (IROX films) are discussed in detail. A comparison is also made with the RuO₂ and TiO₂ single-crystal electrodes having the same crystallographic structure.

Experimental

The electrochemical cell was of a conventional three electrode design. A coiled Pt wire counterelectrode was separated from the working electrode compartment by a sintered glass joint. A double-junction Ag/AgCl electrode with a saturated KCl internal solution was used as a reference electrode.

The working electrodes were prepared from the oriented IrO₂ single crystals using silver epoxy resin for low resistance contacts and Epoxide (Buehler) for body insulating. The IrO₂ single crystals were grown in this laboratory by a chemical vapor transport in a flowing gas system at 1300°C under 2 atm of the oxygen partial pressure. This procedure was similar to the growth of large RuO₂ single crystals (38, 39). The source materials were the Ir powder of the electronic-grade purity and oxygen. The exposed surface area of the IrO₂ (100) electrode was approximately 0.01 cm². The crystal was oriented by x-ray Laue backscattering to within 1°.

A PAR Model 173 potentiostat and PAR Model 175 universal programmer were used for cyclic voltammetry (CV) measurements. The experimental curves were recorded using a Hewlett-Packard 7044 X-Y recorder.

Results

Typical cyclic voltammetry characteristics for the IrO_2 single-crystal electrode with the exposed crystallographic face (100) are shown in Fig. 1 and 2. One major pair of anodic/cathodic peaks is observed in the potential range 360-600 mV vs. Ag/AgCl in 0.5 mol/dm³ H_2SO_4 at 298 K. Several other small features are clearly seen or can be inferred both on the anodic and cathodic half-cycles. They are labeled from A_1 to A_4 for anodic processes and C_2 to C_4 for cathodic ones. The sharp current increase A_5 at $E = 1300$ mV is due to the oxygen evolution reaction. The hydrogen evolution reaction C_0 starts at $E = -370$ mV.

It is informative to discuss the voltammetric behavior of the IrO_2 (100) electrodes comparing the obtained characteristics with published voltammograms for another transition metal dioxide RuO_2 [single crystals with several orientations (9)] and for iridium metal electrodes covered with anodic IrO_2 films (11, 13, 23-26). There are significant differences in CV characteristics for these electrodes in the whole accessible "structure" window from HER (hydrogen evolution reaction) to OER (oxygen evolution reaction). They are discussed separately for the hydrogen deposition/ionization region and the oxide rearrangement region, although, in case of the IrO_2 single-crystal electrodes, presumably all the processes are based on the injection/ejection of hydrogen or hydronium ions (13). The observed results are reported in the same order.

Hydrogen deposition/ionization region.—In the cathodic half-cycle of the voltammograms for the IrO_2 (100) electrodes, two small features C'_2 and C''_2 are resolvable on the expanded scale curves as illustrated in Fig. 3. The peak potentials are -70 and $+25$ mV, respectively. On the anodic side of the voltammograms a peak A_2 is observed at $E = +170$ mV and may be considered as a counterpart of one or both the cathodic peaks C'_2 and C''_2 . Another anodic peak A_1 appears at $E = -180$ mV (Fig. 2), when the cathodic inversion potential is well shifted into HER region.

The oxide rearrangement region.—The anodic IrO_2 films formed on Ir electrodes contain large amounts of water, and they are porous and amorphous (11-26). These properties result in a high degree of reversibility of the process involved in the oxide rearrangement region.

Fig. 1. Dependence of the CV characteristics for the IrO_2 (100) electrode in 0.5 mol/dm³ H_2SO_4 upon the anodic inversion potential $E_{i,a}$ [mV]: (1) 400, (2) 500, (3) 600, (4) 700, (5) 800, (6) 900, (7) 1000, (8) 1100, (9) 1200, (10) 1300. Potential scan rate $v = 200$ mV/s.

Fig. 2. Dependence of the CV characteristics for the IrO_2 (100) electrode in 0.5 mol/dm³ H_2SO_4 upon the cathodic inversion potential $E_{i,c}$ [mV]: (1) 650, (2) 550, (3) 450, (4) 350, (5) 250, (6) 150, (7) 50, (8) -50 , (9) -150 , (10) -250 , (11) -350 . Potential scan rate $v = 100$ mV/s.

However, the oxide rearrangement processes we observed on the well-defined, water-free IrO_2 (100) substrates exhibit significant retardation due to the compact structure of the electrode material. The appearance of the main pair of peaks A_3 - C_3 is illustrated in Fig. 1 and 2 and in a narrow potential scale in Fig. 4. The peak potentials at scan rate $v = 200$ mV/s are 580 and 350 mV for the peaks A_3 and C_3 , respectively. A small increase in the peak height is observed after prolonged cycling in the po-

Fig. 3. Part of a cyclic voltammogram for the IrO_2 (100) electrode in 0.5 mol/dm³ H_2SO_4 , showing cathodic features C'_2 and C''_2 . Cycling between -250 and $+1300$ mV. Scan rate $v = 100$ mV/s.

Fig. 4. Cyclic voltammograms for the IrO₂ (100) electrode in 0.5 mol/dm³ H₂SO₄ solution. Effect of the prolonged cycling between +50 and +950 mV at $v = 200$ mV/s. Cycle numbers are indicated in figure.

tential range 50-950 mV. In Fig. 4, curves are presented for cycles number 2, 70, and 155. The electrode was previously used in cycling experiments, so that some amount of disordered surface monolayers could eventually exist on the electrode surface. However, the pronounced observed irreversibility, as evidenced by the peak separation, remains all the time unchanged. At more positive potentials, there is seen a second pair of peaks labeled A₄-C₄ (the peak A₄ is seen in Fig. 1 when the anodic inversion potential does not exceed 1100 mV). The peak potentials are both equal to 715 mV and are independent of the scan rate v . In contrast to the process A₃-C₃, this is a reversible reaction. The broadness of the peak C₄ suggests repulsive interactions in the presumably hydrated monolayer of the rearranged oxide.

Another pair of peaks labeled A'₃-C'₃ in Fig. 5 appears rather unexpectedly during the long term experiments with changing scan rates from 1 up to 200 mV/s. The peak potentials of this irreversible process change with v and at $v = 110$ mV/s are 740 and 160 mV for A'₃ and C'₃, respectively. The peaks are situated on the falling branches of the main peaks, A₃ and C₃. The peaks A'₃ and C'₃ disappear after 15 min conditioning of the electrode at $E = 550$ mV, as shown in Fig. 6. Note that the peaks A'₃-C'₃ were not observed after prolonged cycling in the range 50-950 mV (Fig. 4). Therefore, the only possible reason for the observed change in voltammetric behavior of the IrO₂ electrode is a difference (300 mV) in the cathodic inver-

sion potential ($E_c^1 = -250$ mV in the reported slow scan rate experiments (see also Fig. 5). A possible explanation of this behavior and a comparison with the behavior of the anodic oxides on the Ir electrodes are given in the next section.

Fig. 6. The CV characteristics for the IrO_2 (100) electrode in $0.5 \text{ mol/dm}^3 \text{ H}_2\text{SO}_4$ solution obtained after prolonged experiments at very slow scan rates (dashed curves) and after additional stirring deoxygenation and conditioning at $+550 \text{ mV}$ (solid curves). v [mV/s]: (1) 10, (2) 20, (3,3') 50, (4,4') 100, (5,5') 200.

Discussion

Most of the 4d and 5d transition-metal dioxides crystallize with a distorted rutile-type structure with a monoclinic or orthorhombic symmetry (37). Among the almost undistorted materials are IrO_2 , RuO_2 , and OsO_2 . The lattice parameters, a , c , and c/a for IrO_2 are as follows: $a = 4.4983\text{\AA}$, $c = 3.1544\text{\AA}$, and $c/a = 0.701$, which can be compared with data for the RuO_2 single crystals whose voltammetric behavior for several crystallographic orientations we have presented elsewhere (9): $a = 4.4919\text{\AA}$, $c = 3.1066\text{\AA}$, and $c/a = 0.696$. The parameter c/a serves as a measure of the distortion from the ideal rutile structure, which has $(c/a)_{\text{ideal}} = 0.586$. We see that the lattice parameters for both the IrO_2 and RuO_2 crystals are almost identical. However, the Fermi surface cross sections as calculated (37) or derived from the experimental magneto-thermal-oscillation data obtained by Graebner *et al.* (40) are entirely different for IrO_2 and RuO_2 since the Ir atoms are in a $5d^5$ state while the Ru atoms are in $4d^5$ state. It is of a considerable interest to compare the electrochemical characteristics for these two oxides, and also for the n-TiO₂ semiconductor electrode, to gain our understanding of the electrocatalytic properties of these materials. The generalized electrode reaction which can be considered for the above materials is the reduction-oxidation process involving injection/ejection of hydrogen and change in the apparent oxidation state of the metal M

There are many possible ways for hydrogen to interact with MO_n structure. In the limiting case, the hydration water can be formed. However, hydrogen can also penetrate through the lattice channels and create intercalation structures. The apparent oxidation state of the metal changes, but charge is not localized at any particular metal atom because of the electron band structure, which in the case of IrO_2 and RuO_2 consists of a partially filled E_g band. The oxidation state of the trapped hydrogen may be different. In TiO_2 , hydrogen can be considered as a highly ionized neutral donor (41). In anodic IrO_2 films, hydrogen is mainly in the form of hydronium ions near the electrode/electrolyte interface (13), so the net reduction process can be expressed as follows

where $n = 2$. The energy of interaction between the hydrogen and the rutile-type oxide structure may also vary with the hydrogen uptake. This is observed, for example, in some lithium intercalation materials. The multiple peak structure in cyclic voltammetry characteristics for transition metal oxide electrodes is therefore not unexpected. At the present stage of our knowledge, we cannot derive any conclusive correlations between the voltammetric peak structure and the localization of the hydrogen interactions. However, it is interesting to compare voltammetric characteristics for different transition metal oxide single crystals having similar crystallographic structure but different electron-band structure and chemical activity. On the other hand, we would like to emphasize significant differences we observed in voltammetric behavior of the same basic compound (IrO_2) synthesized in a different way. Thus, we compare our data for IrO_2 (100) single-crystal electrodes with literature data for anodic IrO_2 films (11-27) and those for IrO_2 sputtered layers (42).

By analyzing voltammograms for the IrO_2 (100) electrode and those for the RuO_2 single crystals with exposed surfaces (110), (001), (111), (101), and (100), we find differences rather than similarities. The behavior of the RuO_2 electrodes is highly reversible in the oxide rearrangement region, and the suggested penetration depth for hydrogen does not exceed one monolayer. In the case of the IrO_2 single crystal, the irreversible character of the major pair of peaks (A_3 - C_3) for hydrogen injection/ejection processes [2] remains even at $v = 1 \text{ mV/s}$. Moreover, the penetration depth increases upon cycling, especially when cathodic limit is below 0 mV and anodic limit exceeds 1300 mV (OER region).

In the hydrogen region, the voltammetric behavior of the IrO_2 (100) electrode shows some similarities with that of the RuO_2 (100) surface and the n-TiO₂ (001) electrode [there are no electrochemical data for TiO₂ (100) surface]. For all the three crystals, IrO_2 (100), RuO_2 (100), and n-TiO₂ (001), there are seen two cathodic adsorption peaks and only one anodic desorption peak.

In comparison with other single-crystal electrodes, the overvoltage for hydrogen evolution is very low for the IrO_2 (100) electrodes. If the "bleaching" process as described for the hydrated anodic IrO_2 films on the Ir electrodes (13) would take place efficiently on our nonhydrated compact IrO_2 crystals, one would not expect as sharp a current increase at HER potential as we observed. Certainly, the decrease in conductivity and hydrogen diffusion into the crystal bulk is rather inefficient in the case of the IrO_2 (100) electrode. This observation may be compared with the effect of cathodization of the n-TiO₂ single-crystal electrodes (41) resulting in the modification of the doping level by the hydrogen injection into the crystal lattice. An increase in conductivity and the majority carrier concentration is observed in this latter case.

On the basis of the crystallographic structure of IrO_2 single crystals and the experimental observations, we propose a model of the ideal (100) surface being in contact with an aqueous solution. In this model illustrated in Fig. 7, we attempt to correlate the findings of previous authors (12-14) concerning changes in the composition of

Fig. 7. Schematic representation of the IrO₂ (100) ideal surface after hydration and hydrogenation in first monolayer.

the IROX films upon cathodization ("bleaching") and anodization ("coloration"). The iridium atoms present on the ideal (100) surface have broken bonds with oxygens caused by crystal termination. On contact with an aqueous electrolyte, the iridium atoms will form active centers for the adsorption of water molecules that take an orientation with hydrogens directed toward the electrolyte phase. A dissociation of the hydrogen-oxygen bonds is very probable. It has been found by Trasatti and co-workers (31) that the IrO₂ powders in aqueous solutions are highly negatively charged. The XPS studies revealed (43) that the dissociative adsorption of water molecules always takes place on the iridium metal samples. A negatively charged IrO₂ surface should lead immediately to the attraction of hydronium ions from the solution. The most stable arrangement of the H₃O⁺ ion, in the center of the unit cell, is shown in Fig. 7. The composition of the unit cell (two first plane plus surface water) is then HIrO₂ · 3H₂O, the same as found by McIntyre *et al.* (13, 14) for "bleached" IROX films. On anodization, this composition should change to IrO₂ · H₂O, what can be achieved by withdrawal of H₃O⁺ ion. We feel that it would be difficult for hydration and hydrogenation of the next monolayers of a nonhydrated IrO₂ single crystal to proceed without reconstruction of the unit cell. This in turn requires large energies due to the high activation barriers associated with reconstructing process. The single protons can eventually penetrate into the crystal bulk. Cycling in a wide potential range may result in a distortion of the surface lattice and a formation of the next monolayer of the hydrated form of IrO₂ with the expanded unit cell. This process could possibly be manifested by an additional pair of peaks like A₃-C₃ in Fig. 5b with a high degree of irreversibility.

Comparing the electrochemical behavior of the anodic hydrated IrO₂ films on the Ir electrodes described by previous workers (11-27) with that of the IrO₂ (100) electrodes presented in this paper, one observes good reversibility of the main, hydrogen injection/ejection process [2] represented by a couple of peaks at 720 mV in the former case and a high degree of irreversibility of this process (peaks A₃-C₃) in the latter case. Also, the reversible potential for this process is lower for single-crystal electrode ($E = 410$ mV). In the hydrogen region, CV characteristics for the anodic IrO₂ films become sluggish because of the re-

duced conductivity in the bleached material. This phenomenon is not observed in case of the IrO₂ (100) electrode as the hydrogen penetration depth is highly minimized in the single crystal and does not involve more than perhaps one or two monolayers.

It is characteristic that the sputtered IrO₂ films (42) exhibit a reversible voltammetric behavior similar to the IROX (anodic) films, but in contrast to them the reversible potential for the major process [2] is equal $E = 450$ mV, *i.e.*, very close to the value $E = 410$ mV we observed for our single-crystal IrO₂ (100) electrode. Note that the density of the sputtered films decreases on operating in aqueous electrolytes from 10 to 7.8 g/cm³ due to water uptake. These numbers can be compared with the density for crystalline IrO₂, which is equal to 11.68 g/cm³ and resembles compact structure of the latter material. On the other hand, the electric conductivity of the IROX films changes by four orders of magnitude during the bleaching/coloration process (from 100 to 0.01 Ω-cm), while that of the sputtered layers changes only by one order of magnitude (from 0.01 to 0.001 Ω-cm). The specific resistivity for crystalline IrO₂ is 10⁻⁴ Ω-cm, and we did not observe in voltammetric characteristics any significant changes in resistivity of our single-crystal IrO₂ electrodes. Thus, the interatomic distances and water content in IrO₂ samples which are determined by the method of synthesis and pretreatment procedure are directly responsible for both the energy of interaction of hydrogen with IrO₂ structure and the degree of reversibility of the hydrogen injection/ejection process [2]. Also, the electric conductivity and the penetration depth of hydrogen species into the electrode material are directly related to the structural changes caused by preparation conditions.

Conclusion

A highly irreversible behavior of the main electrochemical process of the hydrogen injection/ejection corresponding to Eq. [2] at single-crystal IrO₂ electrodes has been described for the (100) surface. It is manifested by a difference between the voltammetric peak-potentials for the anodic and cathodic half-reactions which approaches 220 mV at $v = 200$ mV/s. This behavior can be opposed to that of the sputtered and anodic IrO₂ films on the Ir substrates which is reversible. Also, we did not observe characteristic ceasing of the current in the hydrogen region caused in case of the IROX films by a decrease in electrical conductivity associated with the "bleaching" process. Instead, a low overvoltage for the hydrogen evolution reaction has been observed on the IrO₂ (100) electrodes. All these differences can be interpreted by a strong retardation of the hydration and hydrogenation of the compact IrO₂ single crystals in comparison with the favorable compositional changes of the amorphous anodic IrO₂ films. These changes can involve layers 100-200 nm thick in the latter case, while the hydrogen penetration depth for the IrO₂ single crystal electrodes does not exceed one or two monolayers.

Thus, the coloration/bleaching process as described for the IROX films cannot develop on nonhydrated single-crystal IrO₂ electrodes unless their crystallographic structure is damaged by cycling in a wide potential range.

The energy of major interaction of hydrogen species with the IrO₂ single-crystal structure is close to that observed for sputtered IrO₂ films but differs by *ca.* 29 kJ/mol (corresponding to 300 mV difference in the reversible potential for reaction [2]) from that for the anodic IrO₂ films.

Finite-Element Method Approach to the Problem of the IR-Potential Drop and Overpotential Measurements by Means of a Luggin-Haber Capillary

Department of Electronic Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227, Japan

ABSTRACT

A finite-element method is applied to the problem of potential distribution around a Luggin-Haber capillary placed perpendicularly to the planar working electrode for the cases when overpotential is absent and when there is overpotential which is linear to current density. Approximate equations are presented for the IR-potential drop between the working electrode and the Luggin-Haber capillary as functions of the outer and inner radii of the capillary tip, the distance from the capillary tip to the working electrode, conductivity of the solution, and average current density. Approximate equations which relate the measured overpotential to the true overpotential, the IR-potential drop, and the relevant parameters are also presented. In the presence of overpotential or polarization, it has been shown that the measured potential can be regarded as a sum of the true overpotential and the IR-potential drop, provided that the tip of the Luggin-Haber capillary is placed no closer from the electrode surface than a distance equal to the outer diameter of the capillary tip.

Measurement or control of the potential of a working electrode under current flow is of great importance not only in the studies on electrode kinetics, but also in practical electrolysis. For this purpose, a Luggin-Haber capillary connected to a reference electrode is usually employed. The cell voltage of a galvanic cell composed of

the working and reference electrodes is measured or controlled. Minimization of the ohmic potential drop included in the measured or controlled voltage will be achieved by placing the tip of the Luggin-Haber capillary as close to the surface of the working electrode as possible. When the capillary tip is placed very close to the electrode, however, it shields the latter, causing a decrease in current density and distortion of equipotential surfaces near the capillary tip, so that the potential measured or controlled by the capillary corresponds to a spot of the

*Electrochemical Society Active Member.

¹Present address: Sanyo Electric Company, Limited, Research Center, Hirakata, Osaka 573, Japan.

electrode at which the current density is much lower than that in the region of electrode surface sufficiently remote from the capillary tip.

Piontelli and co-workers (1, 2) and Barnartt (3, 4) performed potential mapping studies using rather large model electrolysis cells and obtained equipotential maps around the electrode and capillary tip. Barnartt (3, 4) concluded that the potential inside a capillary of diameter $2r_0$ placed $4r_0$ from one of a pair of parallel-plate electrodes is equal to that in the undistorted field a distance $2r_0/3$ closer than the capillary tip position.

From a theoretical viewpoint, the solution of the Laplace equation with appropriate boundary conditions is required in order to obtain the potential or primary and secondary current distributions in electrolytic cells. Since Kasper's work (5), there have been a number of papers on the potential and current distributions in electrolysis cells. Although it is highly desirable to have analytical solutions, they can be given only for simple geometries by the use of conformal or imaging transformations (6-12). The recent development of high speed computers has made it possible to apply various numerical methods to the problems for more complicated electrode geometries. A finite difference method was utilized by Klingert *et al.* (13) for the computation of the primary and secondary current distribution in an L-shaped region. Pierini and Newman (14) employed the superposition technique to calculate the potential distribution around a disk electrode in axisymmetric cylindrical cells. Fedkiw (15) applied a perturbation method to the calculation of the primary current distribution at an electrode with a sinusoidal profile. An orthogonal collocation technique (16) and a variational method (17) have also been applied to current distribution problems. In recent years, the finite-element method (FEM) has been used in various fields of engineering (18-20). It is a powerful numerical procedure for solving the differential equations of physics and engineering. To our knowledge, the first application of FEM to electrochemistry was done by Kawai and co-workers (21-23) for the solution of Fick's equation and that coupled with chemical reaction terms. One of the advantageous properties of FEM is that it allows us to treat boundary value problems for two- or three-dimensional regions with irregularly shaped boundaries to which an analytical approach is usually very difficult. From this viewpoint, the application of FEM to many problems in electrochemistry is expected. Recently, Alkire *et al.* (24) used FEM to predict the shape changes at a cathode during electrodeposition. Sautebin *et al.* (25) applied FEM to the simulation of the leveling of triangular surface during anodic dissolution in electrochemical machining. In our laboratory, FEM has been used for the calculation of primary current distribution in a two-dimensional model cell composed of an electrode with holes (26) and for the calculation of chronopotentiometric $i-t$ curves at the electrodes coated with polymer of uneven thickness (27).

The present paper describes the application of FEM to the calculation of the potential distribution around the Luggin-Haber capillary placed perpendicularly to the working electrode in the cases (i) where overpotential is absent and (ii) where there is overpotential which is assumed to be linear to current density. This assumption may be justified if the current densities do not deviate much from the average current density. Approximate equations with reasonable accuracies are presented for the IR-potential drop as functions of the outer and inner radii of the capillary tip, the distance between the capillary tip and the working electrode, conductivity of the solution, and average current density. Furthermore, approximate equations which relate the measured overpotential to the true overpotential, the IR-potential drop, and the relevant parameters are presented. It has been shown that in the presence of overpotential or polarization the measured potential can be regarded as a sum of true overpotential and the IR-potential drop when the distance between the capillary tip and the electrode surface is no closer than the outer diameter of the capillary tip. A part

of this work has been published as a preliminary note (28).

Formulation of the Problem

The electrochemical problem.—Consider an electrolysis cell composed of three electrodes: a working, an auxiliary, and a reference electrode. The variation of electrical potentials in the cell is schematically shown in Fig. 1. For convenience, we assume in what follows that the working electrode acts as a cathode and the auxiliary as an anode. Since the electrode potential is defined as the difference between the inner potential of the electrode phase and that of the solution adjacent to the electrode surface, we have

$$E^c = \psi^c - \phi^c \quad [1]$$

We can assume without any loss of generality that there is no polarization at the auxiliary electrode and the potential of the electrode is constant

$$E^a = \psi^a - \phi^a = \text{const.} \quad [2]$$

We can also assume that the potential of the reference electrode is constant since current passing through it is negligibly small and polarization at the electrode can be ignored. Thus we have

$$E^{\text{ref}} = \psi^{\text{ref}} - \phi^{\text{ref}} = \text{const.} \quad [3]$$

In Fig. 1, the variation of potentials is depicted in reference to the inner potential of the electrolyte solution adjacent to the auxiliary electrode, ϕ^a , which is also assumed to be constant. Under the equilibrium condition where no current flows through the cell, the inner potential of the electrolyte solution is uniform throughout the cell

$$\phi_{\text{eq}}^c = \phi_{\text{eq}}^{\text{ref}} = \phi^a \quad [4]$$

Since the cell voltage is defined as

$$V = \psi^a - \psi^c \quad [5]$$

the cell voltage under the equilibrium condition is given by

$$V_{\text{eq}} = \psi^a - \psi_{\text{eq}}^c = (\psi^a - \phi^a) - (\psi_{\text{eq}}^c - \phi_{\text{eq}}^c) = E^a - E_{\text{eq}}^c \quad [6]$$

When current flows without any overpotential at the working electrode (cathode), the electrode potential at the

Fig. 1. Schematic diagram of variation of electrical potentials in an electrolysis cell.

cathode is equal to that under the equilibrium condition $E_{\eta=0^c} = E_{\text{eq}}^c$, i.e.

$$\psi^c - \phi_{\eta=0^c} = \psi_{\text{eq}}^c - \phi_{\text{eq}}^c \quad [7]$$

If the electrode reaction occurs at the cathode with overpotential, η , then we have

$$\eta = E^c - E_{\eta=0^c} = E^c - E_{\text{eq}}^c = (\psi^c - \phi^c) - (\psi_{\text{eq}}^c - \phi_{\text{eq}}^c) = (\psi^c - \psi_{\text{eq}}^c) + (\phi_{\text{eq}}^c - \phi^c) \quad [8]$$

In terms of Eq. [4]-[6], Eq. [8] can be rewritten as

$$\eta = -(V - V_{\text{eq}}) + \phi^a - \phi^c \quad [9]$$

As stated above, the measured or controlled electrode potential is the potential difference between the terminals of a galvanic cell composed of the working and the reference electrodes; that is, the inner potential of the working electrode against that of the reference electrode

$$(E^c)_m = \psi^c - \psi^{\text{ref}} \quad [10]$$

Thus, the equilibrium potential of the working electrode is given by

$$(E_{\text{eq}}^c)_m = \psi_{\text{eq}}^c - \psi_{\text{eq}}^{\text{ref}} = E_{\text{eq}}^c - E^{\text{ref}} \quad [11]$$

The IR-potential drop, ΔV_{IR} , due to the solution resistance can be given as the difference between the measured potential of the working electrode when current flows without any overpotential and that at equilibrium

$$-\Delta V_{\text{IR}} = (E_{\eta=0^c})_m - (E_{\text{eq}}^c)_m \quad [12]$$

where ΔV_{IR} is taken to be positive. Equation [12] can be written as

$$\begin{aligned} -\Delta V_{\text{IR}} &= (\psi^c - \psi_{\eta=0^c}^{\text{ref}}) - (E_{\text{eq}}^c - E^{\text{ref}}) \\ &= \psi^c - \phi_{\eta=0^c} + \phi_{\eta=0^c}^{\text{ref}} - \psi_{\eta=0^c}^{\text{ref}} - (E_{\text{eq}}^c - E^{\text{ref}}) + \phi_{\eta=0^c} - \phi_{\eta=0^c}^{\text{ref}} \\ &= \phi_{\eta=0^c} - \phi_{\eta=0^c}^{\text{ref}} \quad [13] \end{aligned}$$

where the last expression is obvious from Fig. 1. On the other hand, the measurable overpotential is given by

$$\begin{aligned} (\eta)_m &= (E^c)_m - (E_{\text{eq}}^c)_m = \psi^c - \psi^{\text{ref}} - (\psi_{\text{eq}}^c - \psi_{\text{eq}}^{\text{ref}}) \\ &= (\psi^a - \psi_{\text{eq}}^c) - (\psi^a - \psi^c) + (\psi_{\text{eq}}^{\text{ref}} - \psi^{\text{ref}}) \\ &= -(V - V_{\text{eq}}) + (\phi^a - \phi^{\text{ref}}) \quad [14] \end{aligned}$$

The electrolytic cell model.—Figure 2 shows the schematic diagram of the axisymmetric cylindrical cell together with the cylindrical coordinates employed for the analysis. The cathode (working electrode) and the anode, facing each other, are located in the planes $z = 0$ and $z = 25r_0$, respectively, where r_0 denotes the outer radius of the Luggin capillary. The cell has a cylindrical insulator wall at $r = 15r_0$. The following two cases are treated: (i) the Luggin capillary is placed in front of the cathode, the tip of the capillary is at $z = d$, and (ii) the capillary is placed through the back of the cathode, its tip being flush with the front surface of the cathode. In either case, z -axis is taken as the center axis of the capillary. Although the choice of the distance between the cathode and the anode ($25r_0$) and the position of the insulator wall ($15r_0$) is arbitrary, these are chosen so that the presence of the capillary does not affect the potential or current distributions in the vicinities of the anode or the insulator wall. It has been confirmed that the use of the values larger than $25r_0$ and $15r_0$ has little effect on the calculated results.

The boundary value problem.—Inner potential in the solution satisfies the Laplace equation

$$\nabla^2\phi = \partial^2\phi/\partial r^2 + r^{-1}\partial\phi/\partial r + \partial^2\phi/\partial z^2 = 0 \quad [15]$$

The boundary conditions are as follows: at anode (Γ^a)

$$\phi = \phi^a \quad [16]$$

at cathode (Γ^c)

$$\phi = 0 \quad [17]$$

Fig. 2. Schematic diagram of axisymmetric cylindrical model cell and the cylindrical coordinates employed for the analysis. The Luggin-Haber capillary is placed along the center axis either in front of the cathode or through the back of the cathode.

when there is no overpotential, or

$$f(\phi_{\text{re}}, [\partial\phi/\partial n]_{\text{re}}) = 0 \quad [18]$$

when there is overpotential, and at insulator surface or symmetric axis (Γ^i)

$$\partial\phi/\partial n = 0 \quad [19]$$

where n is the outward normal and the function f defines the potential-current density relationship.

In this paper, we assume that the overpotential is given as a linear function of current density (29)

$$\eta = \eta_0 + hj \quad [20]$$

where η_0 and h are constants. Although, in general, such a relation does not hold over a wide range of current densities, this approximation may be adequate so far as the current densities do not deviate too much from the average current density. Since the current density at the cathode is given by

$$j = -\kappa(\partial\phi/\partial z)_{z=0} \quad [21]$$

where the sign of cathodic current is taken to be negative and κ is conductivity of the solution, we have in place of Eq. [18]

$$\eta = \eta_0 - h\kappa(\partial\phi/\partial z)_{z=0} \quad [22]$$

or, by the use of Eq. [9]

$$\phi^a - \phi^c - (V - V_{\text{eq}}) = \eta_0 - h\kappa(\partial\phi/\partial z)_{z=0} \quad [23]$$

With the transformation of the variables

$$\Phi = \Phi^a[1 - (\phi^a - \phi)/(V - V_{\text{eq}} + \eta_0)] \quad [24]$$

$$R = r/r_0 \quad [25]$$

$$Z = z/r_0 \quad [26]$$

and

$$n^* = n/r_0 \quad [27]$$

our boundary value problem is given as

$$\partial^2\Phi/\partial R^2 + R^{-1}\partial\Phi/\partial R + \partial^2\Phi/\partial Z^2 = 0 \quad [28]$$

at Γ^a

$$\Phi = \Phi^a \quad [29]$$

at Γ^c

$$\Phi = 0 \text{ or } \Phi = (hk/r_0)(\partial\Phi/\partial Z) \quad [30]$$

at Γ^i

$$\partial\Phi/\partial n^* = 0 \quad [31]$$

The FEM representation of the problem.—Now divide the domain Ω to be analyzed into a number of finite elements and let the potential Φ at any point within a finite element (e) be approximated by

$$\Phi = [N^{(e)}]\{\Phi^{(e)}\} \quad [32]$$

where $[N^{(e)}]$ is a row vector of interpolation (or shape) function of element (e), and $\{\Phi^{(e)}\}$ is a column vector composed of nodal values. Using $[N^{(e)}]$ as weighting functions, applying the Galerkin method to Eq. [28], we have

$$\int_{\Omega} [N^{(e)T}] (\partial^2\Phi^{(e)}/\partial R^2 + R^{-1}\partial\Phi^{(e)}/\partial R + \partial^2\Phi^{(e)}/\partial Z^2) d\Omega = 0 \quad [33]$$

where superscript T denotes a transpose and $d\Omega = R d\theta dR dZ$ because of axisymmetry. Performing the integration in Eq. [33] by parts and using the Green Gauss theorem yields local finite-element equations

$$[k^{(e)}]\{\Phi^{(e)}\} = \{f^{(e)}\} \quad [34]$$

where

$$[k^{(e)}] = 2\pi \int_{\Omega^e} \{ (\partial[N^{(e)T}]/\partial R)(\partial[N^{(e)}]/\partial R) + (\partial[N^{(e)T}]/\partial Z)(\partial[N^{(e)}]/\partial Z) \} R dR dZ + 2\pi (r_0/hk) \int_{\Gamma^c} [N^{(e)T}][N^{(e)}] R dR \quad [35]$$

$$\{f^{(e)}\} = 2\pi \int_{(\Gamma^c+\Gamma^i)} [N^{(e)T}](\partial[N^{(e)}]/\partial Z) R dR \quad [36]$$

In the derivation of Eq. [35] and [36], boundary conditions [30] and [31] have been taken into account. The global finite-element equations are obtained by assembling the contributions of each element equation

$$[K]\{\Phi\} = \{F\} \quad [37]$$

where

Fig. 3. Example of quadrilateral element grid used in the analysis for the geometry $d/r_0 = 0.5$ and $r_1/r_0 = 0.75$. Shaded part for $Z \geq 0.5$ indicates the cross section of the capillary wall, and that for $Z \leq 0$ denotes the cathode.

$$\{\Phi\} = \sum_e \{\Phi^{(e)}\}; [K] = \sum_e [k^{(e)}]; \{F\} = \sum_e \{f^{(e)}\} \quad [38]$$

Procedure of computation.—Since our problem is axisymmetric, the region Ω was divided into a number of ring elements obtained by revolving quadrilaterals. Quadratic elements were employed. Division of Ω into isoparametric quadratic quadrilateral elements and numbering of nodes were carried out semiautomatically by use of a FORTRAN program which is a modified version of one proposed by Cohen (30). The region Ω was usually divided into ca. 200 elements and thus had 1000 ~ 1200 nodes. Automatic renumbering of nodes was employed to minimize the bandwidth of the global matrix $[K]$ (31). Examples of the parts of element grid thus divided are shown in Fig. 3 and 7. The region where sharp potential change is considered to occur was divided into smaller elements than other region. It is well known that the boundary between the electrode and the insulator wall (e.g., the point at $Z = 0$ and $R = 1$ in Fig. 7) is a mathematical singular boundary where the derivative of potential is discontinuous. For the elements including such a singular point, singular elements introduced by Henshell and Shaw were employed (32). The global matrix was assembled by the stiffness method and then altered according to the boundary conditions given by Eq. [29] and [30]. The set of simultaneous equations was solved by the Gauss elimination method.

Calculations were carried out for various values of parameters, r_1/r_0 (0.0 ~ 1.0), d/r_0 (0.1 ~ 4.0), and hk/r_0 (0.0 ~ 20.0). Φ^a was taken to be 25.0.

Results and Discussion

Primary potential distribution and the IR potential drop.—Figure 4 shows, as an example, the potential distribution around the Luggin-Haber capillary calculated for geometry $d/r_0 = 0.5$ and $r_1/r_0 = 0.75$ based on the element grid, part of which is shown in Fig. 3, and for $h = 0$ and $\eta_0 = 0$, i.e., when there is no overpotential. It can be seen that the presence of the capillary causes distortion of equipotential surfaces only in the vicinity of the capillary tip and that the potential distribution in the solution region farther than $2r_0$ from the capillary tip is almost equal to that in the absence of the capillary. The value of potential in the capillary becomes constant in the region about

Fig. 4. Primary potential distribution around the capillary tip for the electrode geometry shown in Fig. 3. Numerals on the curves indicate values of function Φ .

$2r_0$ inside from the tip. The difference between this potential and that of the working electrode surface corresponds to the IR-drop involved in the measured electrode potential. Although the equipotential surfaces in Fig. 4 are given not in ϕ but in Φ , it can be seen from Eq. [24] that the real potential distribution is similar to that in Fig. 4.

The current density at the cathode is given by Eq. [21]. By use of Eq. [21], [24], and [26] and condition $\eta_0 = 0$, we have

$$j = -(V - V_{eq})(\kappa/r_0\Phi^a)(\partial\Phi/\partial Z)_{Z=0} \quad [39]$$

Thus the current density at the place sufficiently remote from the capillary is given by

$$j^\infty = -(V - V_{eq})(\kappa/r_0\Phi^a)(\partial\Phi/\partial Z)_{Z=0, R \rightarrow \infty} \quad [40]$$

Then we have

$$j/j^\infty = (\partial\Phi/\partial Z)_{Z=0}/(\partial\Phi/\partial Z)_{Z=0, R \rightarrow \infty} \quad [41]$$

Variations of relative current distribution j/j^∞ near the capillary tip with the distance from the center axis are shown in Fig. 5 for $r_i/r_0 = 0.75$ when d/r_0 is changed. As a matter of fact, one can see that the more remotely the capillary tip is placed from the electrode surface, the less distortion of the current distribution there is. This figure also reveals that only the part of the electrode just below the capillary tip is shielded and that the current density becomes almost uniform in the region $r \geq 3r_0$. In addition, it has been found that the thinner the capillary wall, the less the distortion of the current distribution, although this is not shown in the figure.

Now we consider the IR-potential drop, ΔV_{IR} , due to the solution resistance under the effect of the presence of the capillary. This can be given by Eq. [13]. Eliminating ϕ from Eq. [13] and [24] and using the condition, $\Phi_{\eta=0} = 0$ yields

$$\Delta V_{IR} = (V - V_{eq})\Phi_{\eta=0}^{ref}/\Phi^a \quad [42]$$

Dividing Eq. [42] by Eq. [40] and rearranging the resulting equation gives

$$\Delta V_{IR} = (-j^\infty r_0/\kappa)\Phi_{\eta=0}^{ref}/(\partial\Phi/\partial Z)_{Z=0, R \rightarrow \infty} \quad [43]$$

Values of $(-j^\infty r_0/\kappa)\Delta V_{IR}$ are plotted in Fig. 6 against d/r_0 for several values of r_i/r_0 . The straight dot-dashed line corresponds to the uniform potential distribution when there is no capillary. It can be seen from Fig. 6 that the IR-potential drop measured with the capillary is a function of both d/r_0 and r_i/r_0 and that when d/r_0 is larger than 2, the measured value of ΔV_{IR} is smaller by a constant value than the value which would be observed in the absence of the capillary. We tried to express this dependence of ΔV_{IR}

Fig. 5. Effect of the distance between the capillary tip and the cathode on the relative primary current density distribution at the cathode near the capillary tip.

Fig. 6. Dependence of IR-potential drop measured with Luggin-Haber capillary on the distance between capillary tip and the cathode and on the thickness of capillary wall.

on d/r_0 and r_i/r_0 in terms of elementary functions and obtained the following approximate equation with reasonable accuracy

$$\Delta V_{IR} = (-j^\infty/\kappa)[d - r_0\sigma\{1 - 0.1898 \exp(-1.51d/r_0) - 0.8102 \exp(-1.757d/r_0)\}] \quad [44]$$

where σ is a function of r_i/r_0 given by

$$\sigma = 0.780\{1 - 0.01896(r_i/r_0) - 0.08812(r_i/r_0)^2 - 0.1739(r_i/r_0)^3\} \quad [45]$$

The curved lines in Fig. 6 are those calculated from Eq. [44] and [45]. Equation [45] indicates that the effect of the thickness of the capillary wall is rather small since the value of σ changes only from 0.78 to 0.56 when r_i is changed from 0 to r_0 . If the value of d/r_0 exceeds 2.8, then the exponential terms in Eq. [44] are negligible within an error of 1%, and hence Eq. [44] reduces to

$$\Delta V_{IR} = (-j^\infty/\kappa)(d - r_0\sigma) \quad [46]$$

Barnartt (3) proposed $2/3$ as a value of σ for $d/r_0 \geq 4$ from his experiment using a model capillary of $r_i/r_0 = 2/3$. Introducing this value into Eq. [45] yields $\sigma = 0.699$, which is 5% higher than the value $2/3$ proposed by Barnartt. It can be said that these values are in good agreement if we consider that the experimental value might have some contribution of polarization. Piontelli *et al.* (2) concluded from the experiment with capillaries of varied wall thickness from $r_i/r_0 = 0.08$ -1 that $\sigma = 0.6$ for $d/r_0 \geq 6$ and that the approximate equation can be used practically even for $d/r_0 \geq 2$. They also demonstrated that σ is dependent on the ratio r_i/r_0 and varies from 0.714 to 0.476 when r_i/r_0 changes from 0.08 to 1 for $d/r_0 \gg 1$. The discrepancy between these values and those calculated from Eq. [45] may result from their semicylindrical model cell, the diameter of which is 200 mm, being too small for the model capillary of 63 mm diam.

The primary potential and current distributions were also calculated for the electrode geometry where the capillary is placed through the back of the working electrode. Figure 7 shows an example of the element grid for the geometry $r_i/r_0 = 0.75$ employed in the FEM calculation. The primary potential distribution is depicted in Fig. 8, which reveals that the equipotential surfaces are almost parallel to the cathode surface if $r \leq 2r_0$ or $z \leq 2.5r_0$. The potential measured by the Luggin-Haber capillary depends on the inner radius of the capillary; the thinner the capillary wall, the higher the measured potential value. The relative primary current density distribution at such an elec-

Fig. 7. Part of the quadrilateral element grid used in the analysis for the electrode geometry where the capillary is placed through the back of the cathode. $r_1/r_0 = 0.75$. Shaded part for $0.5 \leq R \leq 1.0$ indicates the cross section of the capillary, and that for $R \geq 1.0$ does the cathode.

Fig. 8. Primary potential distribution around the capillary tip for the electrode geometry shown in Fig. 7. Numerals on the curves indicate values of function Φ .

trode geometry is shown in Fig. 9. It will be seen that the current density becomes infinity at the boundary between the cathode and the Luggin-Haber capillary wall. Variation of the IR-potential drop calculated from Eq. [41] with the ratio r_1/r_0 is depicted in Fig. 10. It was found that the potential drop ΔV_{IR} can be approximated as a function of r_1/r_0 by

$$\Delta V_{IR}(\kappa/r_0 | j^\infty) = 0.64 \exp[-0.018(r_1/r_0) - 0.159(r_1/r_0)^2 - 0.24(r_1/r_0)^3 - 0.082(r_1/r_0)^{10}] \quad [47]$$

This equation is valid within an error of 0.01 or a relative error of 2.2%.

Fig. 9. Relative primary and secondary current density distributions at the cathode for the geometry shown in Fig. 7.

Fig. 10. IR-potential drop measured with the capillary placed through the back of the electrode as a function of r_1/r_0 .

Secondary potential distribution and overpotential measured by Luggin-Haber capillary.—In the presence of overpotential, the electrode potential of the cathode is a function of position or $R = r/r_0$. On the assumption of the linear relation between the overpotential and the current density given by Eq. [22], we can use a quantity $h\kappa/r_0$ as a single parameter expressing the effect of overpotential on the potential distribution in the electrolytic cell as can be seen from the foregoing derivation in the Theoretical section. The parameter is known as the Wagner number (12), and is defined by

$$Wa = (d\eta/dj)(\kappa/L) = h\kappa/r_0 \quad [48]$$

where L is the characteristic length and is taken to be equal to r_0 . If the current density-overpotential relation is given by the Tafel equation and is approximated by the linear relation [20], then h is given by b/j^∞ , where b is the Tafel coefficient.

The potential distributions for the electrode geometries shown in Fig. 3 and 7 are depicted in Fig. 11 and 12, respectively, for $h\kappa/r_0 = 1.0$. Contrary to the case in the absence of overpotential shown in Fig. 4 and 8, the potential at the cathode surface is a function of position in the presence of overpotential, which is manifested in Fig. 11 and 12 by the equipotential surfaces intersecting with the cathode surface. One can see, however, that the distortion of equipotential surfaces are confined only to the region close to the capillary tip. Current density in the presence of overpotential is written in terms of Φ by

$$j = -(V - V_{eq} + \eta_0)(\kappa/r_0\Phi^a)(\partial\Phi/\partial Z)_{Z=0} \quad [49]$$

Fig. 11. Secondary potential distribution around the capillary tip for the electrode geometry shown in Fig. 3 for $h\kappa/r_0 = 1.0$. Numerals on the curves show values of function Φ .

Fig. 12. Secondary potential distribution around the capillary tip for the electrode geometry shown in Fig. 7 for $h\kappa/r_0 = 1.0$. Numerals on the curves show values of function Φ .

The relative current density distribution is calculated from Eq. [41] which is also obtained from Eq. [49] or directly from

$$j/j^\infty = \Phi_{Z=0}/\Phi_{Z=0, R \rightarrow \infty} \quad [50]$$

This equation is obtained from Eq. [41] and [30]. In Fig. 13, variations of the relative current density distribution with the distance from the center axis are shown for the geometry of $r_1/r_0 = 0.75$ and $d/r_0 = 1.0$ and for the various values of the Wagner number $h\kappa/r_0$. For the electrode geometry depicted in Fig. 7, the effect of $h\kappa/r_0$ on the current density distribution is shown in Fig. 9. Figures 13 and 9 indicate that the more uniform current density distribution is obtained as the $h\kappa/r_0$ value becomes higher, i.e., the higher the overpotential or the conductivity of the solution, and that the presence of the capillary has little effect on the current density distribution of the electrode region $r \geq 3r_0$.

Evaluation of true overpotential.—It is of interest to examine the significance of the measured overpotential, $(\eta)_m$. We have, from Eq. [14], [24], and [49]

$$(\eta)_m = \eta_0 + (j^\infty r_0 / \kappa) \Phi^{\text{ref}} (\partial\Phi/\partial Z)_{Z=0, R \rightarrow \infty} \quad [51]$$

From Eq. [51] and [43] it follows

$$\begin{aligned} (\kappa/j^\infty r_0) \{ (\eta)_m + \Delta V_{\text{IR}} - \eta_0 \} \\ = \Phi^{\text{ref}} (\partial\Phi/\partial Z)_{Z=0, R \rightarrow \infty} - \Phi_{\eta_0}^{\text{ref}} (\partial\Phi/\partial Z)_{Z=0, R \rightarrow \infty} \end{aligned} \quad [52]$$

Values of $(\kappa/j^\infty r_0) \{ (\eta)_m + \Delta V_{\text{IR}} - \eta_0 \}$ calculated from the right-hand side of Eq. [52] are plotted against $h\kappa/r_0$ in Fig. 14 for varied values of d/r_0 . One can see the plot is almost linear and has unity slope when $d/r_0 \geq 2$. We tried to find an approximate equation which expresses the term $\{ (\eta)_m - (\eta_0 + hj^\infty) + \Delta V_{\text{IR}} \}$ as a simple function of $h\kappa/r_0$ and obtained the following relation

$$(\eta)_m = (\eta_0 + hj^\infty) - \Delta V_{\text{IR}} - (j^\infty r_0 / \kappa) \{ c_1 (h\kappa/r_0) / (c_2 + h\kappa/r_0) \} \quad [53]$$

where c_1 and c_2 are coefficients which depend on d/r_0 and r_1/r_0 and can be expressed by

$$\begin{aligned} c_1 = 0.402 \exp[-0.709(d/r_0)] \\ + [2.5 - 1.3(r_1/r_0)] \exp[-2.8(d/r_0)] \end{aligned} \quad [54]$$

and

$$c_2 = -0.963 + 2.93(d/r_0)^{0.278} \quad [55]$$

Fig. 13. Dependence of relative current density distribution around the capillary tip upon the parameter $h\kappa/r_0$ for the electrode geometry of $r_1/r_0 = 0.75$ and $d/r_0 = 1.0$. Curve A is identical with curve D in Fig. 5.

respectively. Equations [53]-[55] are valid for $d/r_0 \geq 0.5$ and $0.5 \leq r_i/r_0 < 1.0$ within the relative error of 2%. Although the error involved in Eq. [53]-[55] becomes larger for values of d/r_0 less than 0.5 and these equations cannot be used, it is not recommended that one place the tip of the Luggin-Haber capillary closer than $0.5r_0$ from the electrode surface as will be seen from the discussion below. Figure 15 shows the plots of $(\kappa/r_0 j^\infty) \{(\eta)_m - (\eta_0 + hj^\infty) + \Delta V_{IR}\}$, which is equivalent to $-c_1(h\kappa/r_0)/(c_2 + h\kappa/r_0)$, against d/r_0 for three values of $h\kappa/r_0$. One can see from Eq. [54] that the values of c_1 are small when $d/r_0 \geq 2$, and also see from Fig. 15 that the values of $(\kappa/r_0 j^\infty) \{(\eta)_m - (\eta_0 + hj^\infty) + \Delta V_{IR}\}$ are very small irrespective of the value of $h\kappa/r_0$ when $d/r_0 \geq 2$. It has also been found that values of $(\kappa/r_0 j^\infty) \{(\eta)_m - (\eta_0 + hj^\infty) + \Delta V_{IR}\}$ scarcely depend on r_i/r_0 . These facts indicate that the last term on the right-hand side of Eq. [53] can be neglected and the following approximate equation

$$(\eta)_m = (\eta_0 + hj^\infty) - \Delta V_{IR} \quad [56]$$

is valid under the condition $d \geq 2r_0$. This means that as far as the distance between the capillary tip and the electrode surface is larger than the outer diameter of the capillary tip, the measured overpotential can be regarded as a sum of the true overpotential $(\eta_0 + hj^\infty)$ and the potential

drop due to the solution resistance, $(-\Delta V_{IR})$. In other words, if the capillary tip is located at a distance from the electrode surface closer than its diameter, the effect of the shielding of the electrode surface by the capillary can no more be neglected. One can see from Fig. 15 that the measured overpotential is always equal to or larger than the sum of the true overpotential and the IR-potential drop.

For the electrode geometry where the capillary is placed through the back of cathode, Fig. 16 shows plots similar to those in Fig. 14 and 15. It has been established that the following approximate equation holds

$$(\eta)_m = (\eta_0 + hj^\infty) - \Delta V_{IR} + (j^\infty r_0 / \kappa) [c_3 (h\kappa/r_0)^p / (c_4 + (h\kappa/r_0)^p)] \quad [57]$$

where c_3 , c_4 , and p are coefficients which are functions of r_i/r_0 . We obtained simple approximate equations for these coefficients

$$c_3 = 0.338 + 0.0691(r_i/r_0)^4 + 0.0377(r_i/r_0)^8 \quad [58]$$

$$c_4 = 1.138 + 0.229(r_i/r_0)^4 - 0.633(r_i/r_0)^8 \quad [59]$$

$$p = 0.719 - 0.0281(r_i/r_0) \quad [60]$$

Using Eq. [57]-[60], $(\eta)_m$ can be calculated within 3% relative error. Although there occurs no shielding of the electrode surface in this case, one can note that the absolute value of the measured potential is always larger than the sum of the values of true overpotential and the IR-potential drop. It can be said that although this electrode geometry looks sophisticated, it is not recommended for practical use in view of the above fact and the difficulty in fabrication except for the case where the disturbance of electrolyte solution flow due to the presence of the Luggin-Haber capillary should be avoided.

Conclusion

Potential and current distributions around the Luggin-Haber capillary placed perpendicularly to the plane electrode surface have been obtained by solving Laplace equation with a finite element method. Approximate equations with reasonable accuracy have been presented for the IR-potential drop as functions of the outer and inner radii of the capillary tip, distance between the capillary tip and the working electrode, conductivity of the solution, and average current density. Approximate equations which relate the measured overpotential to the true overpotential, the IR-potential drop, and the relevant parameters have also been presented. In the presence of overpotential, it has been confirmed that the measured potential can be regarded as a sum of the true overpoten-

Fig. 14. Variation of the difference between the measured overpotential and IR-potential drop with the value of the parameter $h\kappa/r_0$ for the electrode geometries of $r_i/r_0 = 0.75$ and varied values of d/r_0 .

Fig. 15. Dependence of the difference between the measured overpotential and the sum of true overpotential and IR-potential drop on the position of the capillary tip.

LIST OF SYMBOLS

c_1, c_2, c_3, c_4	coefficients in Eq. [53] and [57]
d	distance between the capillary tip and the cathode (m)
E	electrode potential (V)
$\{f^{(e)}\}$	element flux vector
$\{F\}$	global flux vector
h	constant (see Eq. [18]) ($\Omega\text{-m}^2$)
j	current density ($\text{A}\cdot\text{m}^{-2}$)
j^∞	current density at the place sufficiently distant from the capillary ($\text{A}\cdot\text{m}^{-2}$)
$[k^{(e)}]$	element coefficient matrix
$[K]$	global coefficient matrix
L	characteristic length (m)
n	normal boundary coordinate (m)
n^*	transformed normal boundary coordinate
$[N^{(e)}]$	row matrix of interpolation functions
p	coefficient in Eq. [57]
r	radial coordinate (m)
r_i	inner radius of the Luggin-Haber capillary (m)
r_o	outer radius of the Luggin-Haber capillary (m)
R	transformed radial coordinate
V	cell voltage (V)
ΔV_{IR}	IR-potential drop (V)
W_a	Wagner number
z	axial coordinate (m)
Z	transformed axial coordinate

Greek characters

Γ	boundary or surface of the region analyzed
η	overpotential (V)
η_0	constant (see Eq. [18]) (V)
θ	angular coordinate
κ	conductivity of solution ($\text{S}\cdot\text{m}^{-1}$)
ϕ	inner potential of solution (V)
Φ	transformed potential function
ψ	inner potential of electrode (V)
Ω	region to be analyzed

Superscripts

a	anode
c	cathode
(e)	element
i	insulator
ref	reference electrode
T	transpose of matrix

Subscripts

eq	at equilibrium
$\eta=0$	without overpotential
m	measured or measurable

Electrochemistry of Molten Calcium Nitrate Tetrahydrate

Keith E. Johnson* and F. Wayne Yerhoff

Department of Chemistry, University of Regina, Regina, Saskatchewan, Canada S4S 0A2

ABSTRACT

The electrochemical properties of calcium nitrate tetrahydrate were studied by voltammetry, coulometry, and chemical analysis. The electrolyte anode reaction was oxidation of water to oxygen on either gold or platinum. The major reaction at a gold cathode was reduction of nitrate to nitrite and a solid calcium hydroxide electrode film. Small amounts of oxygen and more than the theoretically predicted quantity of nitrite were detected, suggesting a secondary chemical reaction. The reduction reaction at platinum gave 50-75% of the theoretical yield of nitrite. The voltammetric behavior of OH^- , NO_2^- , and HNO_3 in this system were studied.

Molten calcium nitrate tetrahydrate and similar molten hydrates are of considerable interest as solvents with properties intermediate between those of aqueous solutions and ionic melts. Conductance measurements (1), additivity of molar volumes (2), PMR studies (3), entropies of solution (4), diffusion coefficients [(5, 6) but see Ref. (7)], acoustic velocity measurements (8), and x-ray diffraction measurements (9) all indicate that the water molecules in calcium nitrate tetrahydrate melts are strongly coordinated to the calcium ion. The result is a liquid with the properties of an ionic melt composed of bulky $(\text{Ca}(\text{H}_2\text{O})_4)^{+2}$ cations and nitrate anions. The low melting point of this compound (42.7°C), together with a metastable supercooled phase extending to room temperature, thus allows the direct comparison of an "ionic" solvent with dilute aqueous solutions.

Calcium nitrate tetrahydrate has been used as a supporting electrolyte in the electrochemical investigation of a number of cations (5-7, 10-15). Courgnaud and Tremillion (16) have investigated the electrochemistry of the molten hydrate itself at gold and platinum electrodes using bulk electrolysis followed by chemical analysis and single sweep voltammetry. The anode reaction was found to give oxygen and protons, as expected for water electrolysis, but at a potential almost 0.7V more negative for Au than for Pt. The authors concluded, on the basis of their finding no detectable concentration of nitrite ion after electrolysis with a platinum cathode, that the electrolytic reduction of this melt also involved only water. Like the anode reaction, reduction appeared to occur at a more negative potential (by 0.3V) at gold than at platinum.

These solvent electrolysis properties, as described, appeared useful for a coal electrogasification study we had undertaken, since only water was electrolyzed and some control over initial decomposition potentials appeared to be available simply by changing electrode materials. Our preliminary results, however, did not correspond to those reported, and we therefore reexamined in detail the electrochemical properties of calcium nitrate tetrahydrate.

Experimental

Calcium nitrate tetrahydrate (Fisher certified ACS or BDH analytical reagent) was used without further purification. Dehydration *in vacuo* at room temperature, then at 150°C, gave a hydration number of 4.00 ± 0.01 . Certified ACS sodium nitrite (Fisher), calcium hydroxide (Fisher), and nitric acid (CIL) were also used without purification. Electrodes were of 99.999% Pt or Au (Johnson, Matthey, and Mallory) sealed in soft glass. Microelectrodes were ground to a flat surface with a Bethlehem 7a7 CW12 glass grinding wheel; electrode areas, measured by optical micrometry, were 0.018 mm² for Pt and 0.066 mm² for Au.

Cyclic voltammograms were obtained using a Metrohm E626 Polarecord and E612 VA Scanner plus a Houston Instruments RE0074 X-Y recorder. All electrochemical measurements were made relative to a 0.05M Ag^+/Ag in $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ reference electrode consisting of a 0.8 mm

diam silver wire dipped in the silver ion solution contained in a narrow glass tube ending in a porous ceramic plug. This system has been shown to be well behaved in calcium nitrate tetrahydrate melts (4). The microelectrode, reference electrode, and a spiral Pt wire counterelectrode were mounted in a rubber stopper which was fitted tightly into the cell containing the solution in $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ to prevent loss of water. Voltammograms of electrolytes in this solvent were made first upon a weighed amount of the most concentrated solution. Weighed amounts of pure solvent were then added with thorough mixing to give the lower concentrations measured. Solutions were maintained at $70.0 \pm 0.1^\circ\text{C}$ using a Polyscience Polytemp bath thermostat. No inert gasses were passed through the solution once it had been confirmed that oxygen was too insoluble to be detected in this system (6, 16).

Bulk electrolysis was performed using a Fisher controlled potential electroanalyzer; current was measured using a Weston Instruments milliammeter, and total charge calculated by graphical analysis of the current-time curve. The cell was equipped with a cathode compartment, consisting of a 2.5 cm diam glass tube ending in a fine sintered glass frit, which was suspended from the rubber cell cover so as to be easily removed. After electrolysis, the cathode compartment plus the Au (16 cm²) or Pt (19 cm²) plate cathode was removed, rinsed off with water, dried, and weighed. The catholyte was thoroughly mixed, and then weighed samples taken for analysis. Finally, the cathode cell components were washed, dried, and weighed to give the total weight of catholyte (25-30g). After the longer electrolyses, nitrite was also detectable in the anolyte, presumably because of leakage through the fritted disk; this quantity was included in the nitrite total.

A weighed sample of electrolyzed material in aqueous solution was tested for nitrite by addition of sulfanilamide and N(1-naphthyl)-ethylenediamine dihydrochloride (Marshall's reagent), followed by comparison of the 550 nm absorption of the diazo compound thus formed with external standards. The total concentration of reducing agents formed by electrolysis was measured by adding a weighed sample of electrolyzed melt to water or cold saturated H_3BO_3 solution, adding a measured quantity of standard Ce(IV) solution sufficient to oxidize all reducing agents, and backtitrating with standard Fe(II) using "ferroin" indicator.

Gas analysis was run in cells with a sealed anode or cathode compartment connected to a "Tedlar" gas sampling bag and arranged to allow flushing of the system with purified nitrogen. Two plates were arranged to allow complete emptying of the gas bag by squeezing. The system was flushed with nitrogen, and the gas bag was emptied, after which the electrolysis was run. After electrolysis, gas was transferred from the sampling bag to a gas measuring apparatus to give the total quantity of gas produced. Gas analysis was performed using a Carle AGC-311 gas chromatograph, with a thermistor detector calibrated to allow quantitative determination of the gas composition.

Results

The products of oxidation of pure calcium nitrate tetrahydrate (90°-95°C, +1.3V vs. Ag/Ag⁺ reference) at a platinum anode were oxygen and nitric acid, as reported (16). The nitric acid concentration in the gases above the electrolyte was substantial, and resulted in chemical attack on the gas sampling bag used in the apparatus, as well as any rubber or tygon seals or connectors used. The measured quantity of oxygen produced in such cases was somewhat variable. In a glass apparatus plus sampling bag with relatively short contact times or in runs where the theoretical amount of Ca(OH)₂ had been added to neutralize HNO₃, oxygen production was 100 ± 5% of theoretical.

The major product of reduction at a gold cathode (90°-95°C, -1.2 to -1.3V) was nitrite, detected both by specific analysis for nitrite and by quantitative analysis for reducing agents (methods agreed within 1%). Figure 1 shows the total amount of NO₂⁻ as a percentage of the theoretical yield relative to the total number of coulombs passed. The amount of nitrite detected in excess of 100% (8% at 68C) was well above the total estimated error. The only significant gaseous cathode product was a small amount of oxygen observed after extensive electrolysis (100-350C), amounting to 5-10% of the theoretical nitrite value. After the most extensive electrolysis, traces of hydrogen and nitrous oxide were also detected by GC.

The major product of reduction of calcium nitrate tetrahydrate at a platinum cathode (90°-95°C, -1.2 to -1.3V) was again nitrite ion, although in considerably lower yield. Figure 1 shows nitrite produced at a Pt electrode, cleaned in concentrated nitric acid before each run, as a function of total coulombs passed. Electrodes not cleaned in a systematic manner before use gave less regular nitrite/coulomb relationships. A white, water-insoluble film was again formed on the electrode. Gas bubble formation on the electrode was sometimes observed to a slight extent. No measurable volume of gaseous products could be detected. Electrolysis under a propane atmosphere showed no significant production of nitrogen. The possibility that water was being reduced at the cath-

Fig. 1. Total amount of nitrite produced as a percentage of the theoretical yield by electrolysis of calcium nitrate tetrahydrate melt at 90°-95°C using a platinum (19 cm²) or a gold (16 cm²) plate cathode.

ode to hydrogen, which then reacted chemically with nitrate or nitrite, was tested: no sign of reaction between hydrogen gas and calcium nitrate tetrahydrate with or without added nitrite ion could be detected after contact with stirring at 95°C for 3 days. The possibility of further reduction of nitrite ion at the electrode was also considered: no significant quantities of the gaseous reduction products NO, N₂O, or N₂ were detected by GC, nor was any trace of the characteristic color of NO₂ or the characteristic smell of NH₃ observed at any time. In two cases the catholyte was analyzed both for reducing substances [by Ce(IV)/Fe(II) redox titration] and spectrophotometrically for nitrite. The reducing capacity of the catholyte was found to be equivalent to the quantity of nitrite present, indicating that no other soluble oxidizable products of NO₃⁻ reduction had been formed.

Calcium nitrate tetrahydrate electrochemistry was also examined by means of linear sweep and cyclic voltammetry. Figure 2 shows full range (+2.0 to -2.5V) and partial range (+1.4 to -1.2V) cyclic voltammograms obtained for this electrolyte using both gold and platinum electrodes relative to 0.05M Ag⁺/Ag in calcium nitrate tetrahydrate. Table I summarizes the peak current potentials observed, along with the reactions represented and the symbols identifying these peaks in Fig. 2. The electrolyte oxidation potentials were found to be similar (1.1-1.3V) for both Au and Pt, in contrast to the previously reported (16) difference of 0.7V. The major cathodic process was attributed, from the chemical evidence, to reduction of nitrate to nitrite with concomitant formation of an insulating film on the electrode. The apparent peak A in Fig. 2, which occurred consistently at -1.5V with both Au and Pt electrodes at 50 mV/s, was an artifact of film formation. If the reverse sweep potential was not taken above 0.7-0.8V, all current flow ceased. Increasing the sweep rate resulted in large cathodic shifts in the "peak" position as well as large increases in the maximum current.

The electrode film produced during reduction of nitrate was removed by the oxidative process giving rise to

Fig. 2. Cyclic voltammograms of calcium nitrate tetrahydrate at 70.0°C using a platinum or a gold microelectrode. a: +2.0 to -2.5V b: +1.5 to -1.1V.

anodic peak B of Fig. 2 in the area of 0.8-1.3V. This peak was not observed where the cathodic sweep did not go beyond -1.0V. The cyclic voltammogram of calcium hydroxide solution in calcium nitrate tetrahydrate between +0.5 and +1.3V showed a single broad anodic peak with no cathodic peak, rapidly decreasing on subsequent cycles. Peak voltages were similar for Au and Pt electrodes (Table II). The single sweep peak current varied linearly with concentration for both electrodes up to approximately 0.02*m*, giving lines with similar slopes. A linear relationship between peak current and the square root of scan rate was found for scan rates from 10 to 300 mV/s for both metals, with a similar slope and small negative current intercept for each. A corresponding peak (peak C, Fig. 2) is observed for pure solvent only in the limited range sweeps, where film formation is not extensive enough to block all current flow.

Voltammetry cycles between +1.3 and -1.3V in the pure melt gave rise to an additional anodic peak at approximately +0.5V on a gold electrode (peak D, Fig. 2). This was identified as the oxidation peak of nitrite ion by studies of dilute solutions of sodium nitrite. Cyclic voltammograms of such solutions showed a broad peak near +0.5V (Table II) with both Au and Pt electrodes; peak currents decreased rapidly on subsequent cycles. Both metals also gave a small shoulder about 0.2V less anodic, which disappeared on subsequent cycles. The gold electrode gave a small additional anodic peak near +0.75V. Single-sweep voltammetry anodic peak currents were shown to vary linearly with concentration for both metals (similar slopes, intercepts near 0) up to about 0.015*m* NaNO_2 . The peak current *vs.* (sweep rate)^{1/2} relationship was linear from 10 to 300 mV/s, with a small positive intercept and a slope slightly greater for Au than Pt. This relationship was also roughly linear for the small +0.75V peak on gold.

Cyclic voltammetry of NaNO_2 solutions with either Au or Pt gave, on the cathodic sweep, a broad cathodic peak at 0.1-0.3V, also seen in the voltammograms of pure calcium nitrate tetrahydrate (peak E, Fig. 2), and identified as characteristic of nitric acid (below). An additional sharp cathodic peak was also seen with a gold electrode (peak Z, Fig. 2), and was investigated further. Cyclic sweeps in 0.01*m* NaNO_2 at 100 mV/s were run from -0.2V to positive potentials beginning at +0.6V and incremented by +0.1V. The sharp cathodic peak Z was just detectable (at +0.66V) on the return from a sweep to +0.8V. The peak grew and shifted to +0.56V over the next three cycles (to +1.1V), after which it stayed approximately constant. A similar experiment run with pure calcium nitrate tetrahydrate, however, showed no trace of this peak until anodic sweeps to 1.3-1.4V were run, *i.e.*, until some nitric acid had been generated by solvent electrolysis. In addition, cycles run as far as +1.3V in circumstances where an oxidizable species (NO_2^- , OH^- , film) was present but nitric acid could not persist [*e.g.*, sat. $\text{Ca}(\text{OH})_2$] did not produce a +0.56V peak on the cathodic return, but rather led to a new cathodic peak at -0.2V. This indicated that the formation of the electroactive species responsible for the +0.56V peak required both a potential greater than +0.7V and the presence of nitric acid.

The electrochemistry of nitric acid in calcium nitrate tetrahydrate gave considerably different voltammograms with gold and platinum microelectrodes. With gold, a sweep from +1.0 to -0.5V gave two cathodic peaks (Fig. 3, Table II), one at about +0.2V and a sharp peak at about +0.6V. The first, at +0.2V, gave a peak current varying linearly with added HNO_3 concentrations up to 0.025*m* at a sweep rate of 50 mV/s (Fig. 4). The second, corresponding to peak Z in Fig. 2, showed an approximately constant current at all HNO_3 concentrations. The peak current *vs.* (sweep rate)^{1/2} relationship for the +0.2V peak due to 0.010*m* HNO_3 was composed of two linear portions with a distinct break between 100 and 150 mV/s, also observable in the peak potential values (Fig. 5). The anodic sweep of the cycle was consistent with nitrite oxidation.

The shape of the voltammetric curve due to nitric acid on a platinum electrode (Fig. 3) was dependent upon both the nitric acid concentration and the sweep rate. At low concentrations or high sweep rates the cathodic sweep gave a single peak near 0.0 V (Table II). The return anodic sweep gave a broad peak at +0.6V characteristic of nitrite oxidation. At low sweep rates or high concentrations the voltammograms had the complex form shown in Fig. 3. The anodic return sweep, starting from 0 current, produced a strong cathodic current. The relationship observed between cathodic peak currents and HNO_3 concentration at a 50 mV/s sweep rate is shown in Fig. 4; the transition between simple peaks and the type shown in Fig. 3 occurred between 0.005 and 0.010*m*. Figure 5 shows the dependence of cathodic peak currents on (sweep rate)^{1/2} for 0.010*m* HNO_3 . Voltammograms of the type shown in Fig. 3 occurred at sweep rates of 50 mV/s or less, simple voltammograms were observed at 200 mV/s or greater, and transitional shapes were observed at intermediate sweep rates. This transition was a function of both sweep rate and concentration.

Aside from nitric acid reduction, the most marked difference between calcium nitrate tetrahydrate voltammograms using Au and Pt microelectrodes was the appearance of a large cathodic peak at -1.25V (peak Y, Fig. 2) only with platinum. This peak, which partly overlapped the nitrate reduction "peak," was presumed to represent the process which did not lead to nitrite production during coulometric analysis using a Pt cathode at -1.2 to 1.3V. Cyclic voltammograms were run from various positive potentials to -1.35V. Those run from +0.7V or less deteriorated rapidly to 0 current flow. However, cycles from +1.25 to -1.35V gave a stable system which showed the -1.25V peak on the cathodic sweep. On the anodic sweep, a cathodic current peak appeared at approximately the same potential (Fig. 6). The only other current observed was an anodic peak at +1.0V, as expected for hydroxide film removal. Table III shows the results obtained from cyclic voltammetry at various sweep rates; as rate increased the cathodic peak current stayed almost constant, while the anodic sweep cathodic current increased until it was the greater of the two. Peak potentials were almost constant throughout. In order to determine if the reaction producing peak Y was responsible for film formation on Pt, 500 mV/s cyclic voltammograms were run from 0.0 V to negative potentials starting at -1.20V

Table II. Peak potential values of electroactive solutes in $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, 70°C

Solute	I variable concentration 50 mV/s				II variable scan rate, 0.010M			
	0.005M		0.025M		25 mV/s		300 mV/s

^a Leading peak.

and incremented by -0.05V. Runs to -1.20 and -1.25V showed no significant change in the maximum (edge) current after ten cycles. Runs to -1.30, -1.35, and -1.40V showed a drop in maximum current of 10, 20, and 40%, respectively, after ten cycles. Thus, film formation appeared much more closely related to the nitrate reduction "peak" A than to peak Y.

Full +2.0 to -2.5V cycles at 50 mV/s with a gold electrode and added water (1-10M) showed no additional peaks. A general increase in peak current beyond -1.5V was observed. The platinum electrode behaved similarly, but the unique peak Y appeared to decrease slightly in size and shift to a slightly more anodic value. Peak current values for Y obtained from 50 mV/s cyclic voltammetry between +1.4 and -1.4V are shown in Table IV as a function of added water concentration. The cathodic peak potential became slightly more positive with increasing water content, while the anodic sweep cathodic current increased. These peak current changes may be related to electrode film dissolution by water.

Attempts to detect a number of other species in calcium nitrate tetrahydrate solution by voltammetry were not successful. Bubbling of oxygen, hydrogen, or nitrous oxide for up to 1/2 h gave no detectable peaks in this solvent or in solvent saturated with $\text{Ca}(\text{OH})_2$. The lack of reactivity of oxygen had been observed previously (6, 16) and attributed to the low solubility of oxygen in the melt.

Discussion

The solvent oxidation reaction in calcium nitrate tetrahydrate appears to be a straightforward oxidation of water

We have not been able to reproduce the 0.7V difference in oxidation potential previously observed (16) between

Fig. 3. Cyclic voltammograms of 0.01M nitric acid in calcium nitrate tetrahydrate at 70.0°C using a platinum or a gold microelectrode.

gold and platinum electrodes in this electrolyte. Both voltammetry and the potentials observed during bulk electrolysis indicate similar oxidation potentials at both electrode materials.

The major solvent reaction at a gold cathode is clearly reduction of nitrate to nitrite ion

The excess of nitrite observed coupled with the observation of oxygen as a cathode product suggests the results observed in the reduction of alkali nitrate melts (17), where oxide dianions produced in the electrochemical reduction of nitrate react chemically with nitrate ion to give additional nitrite and peroxide ions

The existence of oxide ions in a hydrate melt appears unlikely, but in this system an insoluble basic film, as shown by cyclic voltammetry, forms rapidly on the cathode. Similar films occur at the cathode during the reduction of $\text{Ca}(\text{NO}_3)_2/\text{KNO}_3$ melts (18). Local depletion of water could occur near the electrode surface, allowing oxide ions to exist long enough to react with nitrate. The concentration of free water in this system is low, and the rate of diffusion of bulky $(\text{Ca}(\text{H}_2\text{O})_4)^{2+}$ into the film should be

Fig. 4. Cyclic voltammetric cathodic peak current as a function of concentration of nitric acid in calcium nitrate tetrahydrate at 70.0°C and 50 mV/s using a platinum or a gold microelectrode.

Fig. 5. Cyclic voltammetric cathodic peak current and peak potential as a function of the square root of scan rate for 0.01M nitric acid in calcium nitrate tetrahydrate at 70.0°C using a platinum or a gold microelectrode.

relatively slow. Peroxide ions produced by the oxide/nitrate reaction would diffuse out and produce oxygen after reaction with water. This evidence for the production of oxide dianion suggests that water is not involved in the initial electrochemical reduction reaction on gold.

The previously reported 0.3V difference in solvent reduction potential between Au and Pt appears to be due to the identification of the slope of peak Y (Fig. 2) as due to solvent reduction; a peak in this position was in fact observed in voltammetry of the 2.6 H₂O hydrate melt (16). The fact that the reaction represented by peak Y does not give nitrite as a reduction product explains why the authors concluded that water reduction was the major solvent reaction in this system.

The reaction represented by peak Y appears, both from the chemical evidence and from the absence of nitrite oxidation peaks in the anodic sweep (Fig. 2 and 6), to produce a product other than nitrite. This peak may represent reduction of water to hydrogen, but if so then all the

hydrogen must be adsorbed on the electrode, since none is detected by GC and hydrogen has been shown to be neither reactive nor soluble in the melt. A second possibility is reduction of a previously formed platinum oxide film. The possibility that peak Y represents a further reduction of nitrite cannot be excluded, although no plausible products of such a reaction could be detected.

We have observed that a cyclic voltammogram of Ca(NO₃)₂·4H₂O run using a freshly ground Pt microelectrode surface does not show peak Y, although it appears as soon as an electrochemical reaction occurs at the electrode or if the electrode is soaked in concentrated nitric acid. This result supports the "PtO" reduction hypothesis, since concentrated HNO₃ is known to produce such films (23-25). The observed reaction, however, represents a very large quantity of material. If one assumes that the roughly linear increase in bulk nitrite production represents a linear decrease in peak Y material, the percentage NO₂⁻/coulomb data in Fig. 1 can be used to estimate that 0.65 C/cm² are required for complete reduction of this material. The surface area of bright platinum has been estimated to be 1.5-2.5 times the theoretical value by hydrogen charging experiments, which imply that the total charge required to reduce one "monolayer" of "PtO" will be 400-650 μC/cm² (19-21). It has been demonstrated that more than one monolayer may be deposited on a Pt electrode, but, although the exact nature of this oxide/oxygen film was controversial, there was a general belief that it amounted to no more than two to five additional "monolayers," whether deposited by anodization (19-22) or chemically (23-25). This gives an estimated charge required for complete film removal of 1-3 mC/cm², or approximately 300 times less than the estimated charge consumed here. The large charge capacity of the reaction is confirmed by the peak current observed in voltammetry, where the estimated area of peak Y in Fig. 2 represents a value of about 0.7 C/cm².

The reaction represented by peak Y also exhibits unusual behavior during cyclic voltammetry, in that a cathodic peak is observed during the anodic sweep of the cycle (Fig. 6). This type of anomaly has been reported in a few other cases (11-13, 26-28) and attributed to adsorption or other surface phenomena. The observation of an adsorption/desorption phenomenon is more easily associated with the hypothesis that this peak is due to production of adsorbed hydrogen, since a similar result is reported for the neutral molecule N₂O in alkaline aqueous solution (26). There was, however, no detectable effect on the electrochemistry of this system resulting from hydrogen (or N₂O or O₂) being bubbled through the melt. Water did cause both a change in peak current and a small positive shift in peak potential, but this may be attributable to a solvent effect on the electrode film. An important difference in the *I* vs. (scan rate)^{1/2} relationship was also observed: with the N₂O reduction peak, these values were found to be directly proportional, while in this work such a relation was not found. The explanation involving trace organic impurities (28) may be relevant to this system: reagent-grade calcium nitrate tetrahydrate shipped in plastic bottles was used without further purification and may well have contained trace organics.

The overall cyclic voltammogram of calcium nitrate tetrahydrate indicates no reversible electrochemical reactions for any of the solvent oxidation or reduction products. Of the three major products, soluble hydroxide, presumably in the form (CaOH(H₂O)₃)⁺, behaves in the simplest manner on both gold and platinum electrodes

Linear relationships with near-zero intercepts are seen for both metals between peak current values and both the concentration up to 15-20 mM and the square root of scan rate up to 300 mV/s. Peak potentials show a small increase with increasing scan rate. The peak potential on Pt

Table III. Peak current and potential values, $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, 70°C, Pt electrode +1.25 to -1.35V, variable scan rate

Scan rate (mV/s)	Cathodic scan			Anodic scan

5	-1.20	-2.25	-1.19	-1.45	+0.95	1.05
7.5	-1.19	-2.15	-1.17	-1.70	+0.90	0.85
10	-1.19	-2.35	-1.19	-2.35	+0.86	1.15

is in reasonable agreement with a single-scan value derived previously (16).

The oxidation of nitrite also appears reasonably straightforward. Variations of peak current with concentration are again linear up to 15-20 *mM*, as is the relationship with (scan rate)^{1/2} up to 300 mV/s. The detection of HNO_3 on the reverse sweep indicates the overall reaction

An additional cathodic peak (peak Z) is seen only with a gold electrode, and appears to be a gold oxide film reduction peak. It is observed only in the presence of nitric acid and when the potential is more positive than +0.7V, but the peak current is independent of nitric acid concentration. The peak is narrow ($E_p - E_p/2 = 30$ mV) and symmetrical; there is no detectable diffusion current due to this peak. A small secondary peak on the nitrite diffusion current is also observed at +0.75V at high nitrite concentrations. In the absence of nitric acid but in the presence of oxidizable substances, this peak is not observed; rather, a peak with similar characteristics appears at -0.2V.

The reduction mechanism of nitric acid appears complex, with substantial differences between gold and platinum electrodes. The reduction peak shape on gold is simple (Fig. 3), and the relationship between peak height and concentration is linear at 50 mV/s to at least 25 *mM* (Fig. 4). The I vs. (scan rate)^{1/2} relationship, however, shows a sharp break to a lower slope at approximately 100 mV/s (Fig. 5). Changes in slope of this kind are characteristic of a change from reversible (fast electrode kinetics) to irreversible (slow electrode kinetics) systems, as is the simultaneous change from constant peak potential to decreasing peak potential observed here. In simple cases of this kind, however, there is a substantial, nonlinear, "quasi-reversible" zone not seen here. Additionally, the low slope and high slope linear portions of the relationship both extrapolate to the origin in the simple system (29), whereas in this case the low slope line extrapolates to a large positive current. Behavior of this type implies a more complex reduction mechanism. Switches from high to low slope roughly similar to that observed are predicted in systems where reversible or quasi-reversible electrode kinetics are followed by irreversible chemical reaction. The present system will be still more complex since reduction here will produce two molecules, one of which will be a basic anion which should react irreversibly with an additional molecule of the starting material, HNO_3

The situation at the platinum electrode appears even more complex. Two entirely different peak shapes are observed, depending upon both HNO_3 concentration and scan rate. The low sweep rate/high concentration form (Fig. 3) features, on the cathodic sweep, a leading peak which trails into a level plateau region terminating in a drop to near zero current over only 150 mV. This is accompanied on the reverse anodic sweep by a cathodic current peak, also of complex shape. Other instances of reverse current peaks have already been described with reference to peak Y. In this case, the observation that continuation of the sweep beyond -0.6V gives rise to a new peak with concomitant loss of the return cathodic current suggests that an adsorbed insulating film is responsible for the current drop at -0.2V in the anodic sweep. Presumably, the anodic sweep cathodic current results from desorption of the film allowing further reduction, while the -0.6V peak represents reductive destruction of the film and renewed reduction of HNO_3 . The correlation of this peak system with HNO_3 concentration suggests that the adsorbed material is a product of HNO_3 reduction (or chemical reaction). The shape of the cathodic peak/plateau is of a type predicted for either a reversible chemical reaction followed by reversible reduction or reversible reduction followed by irreversible catalytic chemical reaction (29). Neither of these simple situations is likely to describe the system fully.

At high sweep rates or low concentrations, the peak shapes simplify to a single cathodic peak on the cathodic sweep with no detectable cathodic peak on the anodic return sweep. The simple cathodic peak has, however, an exceptionally low trailing diffusion current relative to that observed with a gold electrode, while the I_p vs. (scan rate)^{1/2} relationship (Fig. 5), although apparently linear, has a large negative current intercept. Both observations suggest a continuing effect due to adsorbed material. The reason for the change in peak shape with scan rate, which is not of the type predicted for simple systems, is unclear. The disappearance of the cathodic peak on the anodic sweep shows that the role of adsorption has changed; the rate of formation of adsorbable material, the total quantity of adsorbable material, and the rate of desorption at potentials less than -0.2V may all be involved. A complex equilibrium network involving NO_3^- , NO_2^- , HNO_3 , HNO_2 , and H_2O is likely associated with reductions at both Pt and Au electrodes.

A Capacitance and Electrolyte Electroreflectance Study of the ZnSe/Electrolyte Interface

P. Lemasson,* C. Hinnen, N. R. de Tacconi,¹ and C. Nguyen Van Huong

Laboratoire d'Electrochimie Interfaciale du CNRS, 92195 Meudon Principal Cedex, France

ABSTRACT

The semiconductor-electrolyte junction is studied in the particular case of n-ZnSe/indifferent electrolytes by means of capacitance and electrolyte electroreflectance measurements. In comparing both kinds of results obtained for two extreme pH conditions (pH = 0 and 14), we need to define a reference state for the clean electrode in each medium. A basic solution acts as a more able etching solution than an acidic one creating fast acceptor interface states in the vicinity of the valence band maximum tending to fix the Fermi level. The evolution of these reference states with controlled perturbations of the interface confirm that the characteristics of the junction remains governed mainly by the presence of interface states at the semiconductor electrode. Such an analysis of combined electrical and spectroscopic data constitutes a promising way for a better understanding of the semiconductor/electrolyte junction in connection with the physical models developed for metal/semiconductor junctions.

During the last 30 years, the semiconductor-electrolyte junction has received much attention. This attraction was mainly due to the simple preparation procedure and the versatility of this junction as compared to the classical solid Schottky barriers, although such an important parameter as temperature cannot be easily varied in a large range.

The models used in the description of the semiconductor-electrolyte interface (1) are generally based on those already elaborated for solid-state junctions, especially metal-semiconductor junction (2). However, this analogy necessitates the definition of a proper Fermi level in the electrolyte. Such a requirement can be easily fulfilled in the case of a redox electrolyte, but it presents much more difficulty for an electrolyte without an explicit redox couple (3). Due to its fundamental interest as well as its use in physical measurements (electroreflectance) and semiconductor technology, the latter case necessitates more insight, and it is the aim of the present article to deal with some physical and electrochemical aspects of semiconductor-indifferent electrolyte junctions.

The semiconductor used as an electrode in such investigations must fulfill two requirements: (i) its physical properties are clearly established and can be accounted for unambiguously by a band model; (ii) its electrochemical behavior has already received attention and can be considered as simple. For this purpose, we selected n-ZnSe, a II-VI compound with wide energy gap (2.7 eV) whose electrochemical behavior (5, 6) and EER investigations have been previously described (6c).

By analyzing mainly two types of measurements, capacitance and electrolyte electroreflectance (EER), which bring complementary information, we attempt in this article to give more insight into the formation of the semiconductor-electrolyte (indifferent) junction. The description of such a junction necessitates the use of many different physical parameters. The various data obtained can then be accounted for by a model similar to that of metal-semiconductor junctions, provided that the existence of different types of interface states is taken into account.

Experimental

The zinc selenide single crystals were grown and donated by Professor Lozykowski.² They were In doped

with a free carrier density of $\sim 2 \times 10^{17} \text{ cm}^{-3}$ as determined by Hall effect measurement. Prior to their mounting as electrodes, an ohmic contact was realized with In-Hg amalgam by heating at $\sim 300^\circ\text{C}$ in argon atmosphere for 1-2 min. A gold wire was then soldered to these contacts. The back and sides of the crystals were insulated from the electrolyte by means of an epoxy resin (Scotch Cast, 3M Company) and then mounted on the electrode holder. The exposed face was carefully polished with diamond paste ($0.25 \mu\text{m}$) and, when necessary, etched in a 1% bromine in methanol solution at $\sim 5^\circ\text{C}$. The best etching time was found to be 20s (see Discussion section).

The cell was of the classical three-electrode type with quartz windows for light passage and a gold counterelectrode. The reference electrode was a mercury-mercurous sulfate immersed in saturated potassium sulfate aqueous solution (0 V vs. MSE = +0.65V vs. NHE).

Electrolytes were prepared by dissolving Merck-Suprapur grade chemicals in Millipore purified water. The following solutions were used: 1M HClO_4 , 1M NaOH, and 10^{-2}M $\text{K}_3\text{Fe}(\text{CN})_6$ + 1M HClO_4 , and 10^{-2}M $\text{K}_3\text{Fe}(\text{CN})_6$ + 1M NaOH. In order to saturate or to eliminate oxygen, either an oxygen or an argon bubbling of the electrolytes was undertaken prior to electrochemical experiments.

As a light source, a 400W tungsten-halogen lamp was used together with electrochemical and electroreflectance equipment which have been described previously (6a, 7).

The capacity measurements are achieved at 15 Hz and 100 kHz. The EER spectra are recorded at almost normal incidence for the light beam, and with an electrical perturbation whose characteristics are 15 Hz and $0.5V_{\text{eff}}$.

Results

Etched Electrode Surface and Definition of a Reference State

The changes in voltammograms, capacity curves, and EER spectra are studied simultaneously as a function of the semiconductor surface preparation. The characteristics are reported in Fig. 1 in the case of 1M NaOH electrolyte. During the electrochemical investigations, the potential range was limited negatively to hydrogen evolution and positively at +2.0V vs. MSE, *i.e.*, in a range where no anodic current is detectable within the limit of $10^{-9} \text{ A}\cdot\text{cm}^{-2}$. The EER spectra are reported for a dc potential of 0 V vs. MSE; thus, the possibility of anodic current even for large ac modulation ($1V_{\text{eff}}$) can be excluded.

In the case of a freshly polished electrode surface, without etching treatment (Fig. 1) the Mott-Schottky plot (C^{-2} vs. V, where C is capacity and V is potential) is far from linear and the EER signal is small and without distinct structure in the vicinity of the fundamental transition E_0 at about 2.72 eV.

The influence of a further chemical etching in bromine-methanol solution is clearly evidenced in Fig. 1 for two different etching times (10 and 20s). In both cases, the C^{-2} -V plots now present an acceptable linearity, but the flatband potential V_{FB} as well as the free carrier density N_D deduced from these plots differ noticeably ($V_{\text{FB}} = -2.6\text{V}$ vs. MSE and $N_D = 3.6 \times 10^{17} \text{ cm}^{-3}$ for 10s; $V_{\text{FB}} = -3.1\text{V}$ and $N_D = 8 \times 10^{17} \text{ cm}^{-3}$ for 20s). We have to emphasize that these values are deduced from measurements with a 15 Hz perturbation. At 100 kHz, in the second case (etching time 20s) we obtain $V_{\text{FB}} = -3.1\text{V}$ vs. MSE and $N_D = 2.7 \times 10^{17} \text{ cm}^{-3}$. The EER spectrum shows more clearly the influence of the etching (Fig. 1b), and it is only in the second case that it becomes acceptable, with a large signal enabling a precise determination of the peak energies. This typical spectrum and the corresponding capacity values being reproducible are proposed to characterize the reference state for this junction.

Equivalent observations are made in acidic medium (1M HClO_4 , pH 0) (Fig. 2). We notice, however, that the C^{-2} -V plots as well as the EER spectra differ in some aspects, when the so-called reference state is reached. Excluding the variation of V_{FB} with pH, the slopes of the C^{-2} -V plots are larger and lead to a unique value of $N_D \approx 2 \times 10^{17} \text{ cm}^{-3}$ at 15 Hz and 100 kHz; the EER spectrum pres-

ents oscillations of slightly lower amplitude. As will be discussed in the Discussion section, these observations may certainly be correlated with physical differences during the formation of the semiconductor-electrolyte interface.

At both pH values, there was no noticeable influence of the presence of oxygen in the electrolyte.

Modifications of the Reference State

Influence of a positive polarization.—The electrochemical treatment is achieved in order to induce a modification of the semiconductor-electrolyte interface when studied under the same conditions as described in the previous section, allowing a comparison with the reference state. The treatment is strictly dependent on the pH of the solution.

pH 0.—In this case, a positive polarization at a potential value where a detectable current crosses the junction induces a remanent effect only if the solution is saturated in oxygen and if the electrode is illuminated during the process. The particular conditions used here are (i) polarization value of +8.0V vs. MSE, (ii) electrolyte saturated in oxygen, and (iii) illumination with white light.

The main results obtained in capacity and EER measurements are reported in Fig. 3. During the whole treatment, the current density is small ($\sim 1.5 \mu\text{A}\cdot\text{cm}^{-2}$) and constant. We observe that at 15 Hz, the C^{-2} -V plot differs from that obtained in the reference state (the slope and the linear portion decrease), whereas at 100 kHz the C^{-2} -V plot remains identical to that of the reference state. The EER spectra at a dc voltage of 0 V diminish in amplitude, mainly for the negative part of the oscillation, and after 1h of such a treatment present the perturbed shape indicated in the lower part of Fig. 3b.

pH 14.—In that case, the perturbation of the junction is obtained with a positive polarization only (no noticeable influence of either oxygen or light). Our experimental conditions are then (i) polarization at +4.0V vs. MSE up to 15 min, and (ii) presence of oxygen and illumination or not.

We already noticed that a treatment lasting more than 15 min does not further influence the behavior of the semiconductor-electrolyte interface. The net result of the electrochemical treatment on both C^{-2} vs. V plot and EER spectra is presented in Fig. 4. Whereas an enhancement of the EER signal together with an improvement of the signal/noise ratio is noticeable, the C^{-2} -V plots at 15 Hz are strongly modified: the linearity range and the slope decrease together.

Influence of oxidizing species.—The Ox species is $\text{K}_3\text{Fe}(\text{CN})_6$. The treatment is achieved in an electrochemical cell devoted exclusively to this purpose; the characterization is then realized in a separate cell containing the supporting electrolyte.

pH 0.—The electrode treatment is achieved in a 1M HClO_4 solution containing 10^{-2}M $\text{K}_3\text{Fe}(\text{CN})_6$. The complete cycle is eight voltage sweeps between -2.0 and $+2.0\text{V}$ vs. MSE at a sweep rate of $50 \text{ mV}\cdot\text{s}^{-1}$.

The result of this treatment is presented in Fig. 5. We notice that the C^{-2} -V plot is slightly modified at high frequency as well as at low frequency, whereas the EER signal decreases progressively in a way analogous to that observed with an electrochemical treatment (see the positive polarization pH 0 section).

Furthermore, we mention that at the end of the treatment the electrode surface presents a slightly modified aspect (green-gray) easily detectable with naked eye.

pH 14.—During the treatment, which consists of six voltage sweeps between -2.0 and $+2.0\text{V}$ vs. MSE at a sweep rate of $50 \text{ mV}\cdot\text{s}^{-1}$, the electrolyte is 1M NaOH + 10^{-2}M $\text{K}_3\text{Fe}(\text{CN})_6$ solution.

Under further investigation in 1M NaOH electrolyte, the behavior of the ZnSe-electrolyte interface changes slightly for Mott-Schottky plots (at high and low frequency) but drastically for the EER spectra, which pres-

Fig. 1. Electrical and electro-optical characteristics of the n-ZnSe-1M NaOH junction for different semiconductor surface preparations. 1 and 1': Just polished with $0.25 \mu\text{m}$ diamond paste. 2: Etched 10s in 1% bromine-methanol solution. 3: Etched 20s in 1% bromine-methanol solution. a(above): Dark current and C^{-2} vs. V characteristics. In the latter case, the perturbation frequency is 15 Hz. For clarity's sake, the Schottky plot at 100 kHz is not represented. b(right): EER spectra.

ent a complete rotation of phase together with an important attenuation (Fig. 6).

The semiconductor surface becomes reddish as the treatment is completed. The red layer formed is dissolved easily in CS_2 , thus indicating that it is a selenium layer.

Discussion

Reference State: Electrical and Electro-optical Characterization

Prior to electrochemical investigations, the semiconductor electrode is mechanically polished and chemically etched. Such a preparation plays a major role in the subsequent electrode behavior. Results presented in the Results section allow a definition of quality for the semiconductor surface, based upon electrical (capacity) and electro-optical (electroreflectance) measurements. More precisely, the criteria are twofold.

First, the differential capacity *vs.* potential measurement must lead to linear Mott-Schottky plots (C^{-2} - V) for high as well as low frequency perturbation. Furthermore, in a large potential range ($\geq 1\text{V}$), a correct Mott-Schottky plot enables calculation of free carrier density analogous to that determined by physical techniques such as Hall effect measurement. This requirement is generally obeyed only at high frequency, but, in some cases, it can be verified even at low frequency (a few hertz).

Second, the electroreflectance signal must be sufficiently large in the vicinity of the fundamental E_0 transition ($\sim 10^{-3}$ in absolute value in our case).

Third, nevertheless, this latter criterion must be adequately adapted due to the influence of the free carrier density on the amplitude of the EER signal as outlined by Aspnes (8).

In addition to the large signal amplitude, the broadening parameter, Γ , must be sufficiently small ($\sim 50 \text{ meV}$ in the present case).

When the first two conditions are fulfilled, it becomes possible to (i) fix the energy position of the semiconductor Fermi level in an electrochemical scale by means of the flatband potential value V_{FB} and (ii) determine a precise value of the fundamental transition energy E_0 (and of the higher transition energies).

Results reported in Fig. 1 indicate that the damaged layer produced by the mechanical polishing must be removed by an adequate chemical etching which depends on the semiconductor. Thus, in the case of ZnSe, a satisfying surface preparation consists in a mechanical polishing with diamond paste $1/4 \mu\text{m}$ followed by a chemical etching in 1% bromine in methanol solution at $\sim 5^\circ\text{C}$ for $\sim 15\text{s}$.

The parameter values corresponding to the reference state are reported in Table I. We must notice first that an open-circuit barrier height or band bending, V_s , can be deduced from rest and flatband potentials. The rest potential is accurately determined using an electrometer. From one experiment to another, fluctuations are very small and V_R can be considered as really fixed. This band bending is pH dependent

$$V_s = 1.65\text{V at pH} = 0$$

$$V_s = 2.3\text{V at pH} = 14$$

Such values are large as compared to those obtained for ZnSe in the metal-semiconductor configuration (9). However, they seem to be fairly explained by the existence of acceptor interface states, located in the range 0.5-1.0 eV

Fig. 2. Comparison of electrical and electro-optical characteristics of the n-ZnSe-indifferent electrolyte junction in the reference states (see the text for the definition) at pH 0 and 14. a(above): C^{-2} vs. V . Filled squares: pH 0, 15 Hz, and 100 kHz. Open squares: pH 14, 15 Hz. Circles: pH 14, 100 kHz. b(right): EER spectra. Solid line: pH 14. Dashed line: pH 0.

higher than the valence-band maximum, which tend to fix the Fermi level. The existence of such acceptor states has already been demonstrated for semiconductor-vacuum interfaces by photoemission measurements, especially in the case of n-GaAs, which is isoelectronic to ZnSe (10), and also for ZnSe (11). They may be explained by the penetration in the gap of the empty surface-state band associated with Se atoms upon removal of the "clean" surface reconstruction. In contact with an electrolyte this removal is more pronounced when the solution is an etchant for ZnSe, which is the case for NaOH. The higher value of V_s at pH 14 agrees well with these considerations. Further discussion is possible together with an analysis of capacity and EER measurements in the reference state of the electrode.

Differential capacity.—At high frequency (100 kHz), the reference states are slightly different at pH 0 and 14 (N_D calculated from the Mott-Schottky slope changes from $2 \times 10^{17} \text{ cm}^{-3}$ to $2.7 \times 10^{17} \text{ cm}^{-3}$) and differ noticeably at low frequency (N_D changes from 2×10^{17} to $8 \times 10^{17} \text{ cm}^{-3}$). The flatband potential value is here insensitive to the perturbation frequency (Table I). These observations may likely be correlated with the above considerations on the existence of acceptor surface states in the vicinity of the valence-band maximum.

We attempt now to estimate the density of surface states analyzing the capacity measurements. This estimation is made assuming that the models established in the case of the metal-semiconductor junctions can be used for electrolyte-semiconductor junctions and the analysis is different according to the possibility or impossibility for the interface states to follow the perturbation (2a, 12).

At 100 kHz, we may assume that the interface states do not follow the perturbation. This hypothesis corresponds to a linear C^{-2} - V plot in a large potential range for band bendings greater than 2V. If the interface states followed the ac perturbation at 100 kHz, no such linear plots could exist. In that case and provided that the occupation of

these states is governed by the semiconductor Fermi level, the slope of the Mott-Schottky plot is no longer proportional to N_D^{-1} but to $[(1 + \alpha)N_D]^{-1}$ (12), where

$$\alpha = \frac{e\delta D_{sa}}{\epsilon_1} \quad [1]$$

and δ is the thickness of the interfacial layer, D_{sa} the density of states per surface unit, ϵ_1 the dielectric constant of the interfacial layer, and e the electron charge. Therefore, due to the similarity between $(N_D)_{\text{Hall}}$ and $(N_D)_{\text{Schottky}}$ at pH 0, we may assume that D_{sa} is smaller than that at pH 14, a statement which matches well the etching character of basic solutions. From the slope value at 100 kHz in the electrolyte of pH 14, we calculate

$$\alpha = 0.35 \quad [2]$$

It seems reasonable to assume δ of the order of some angstroms and ϵ_1 slightly lower than ϵ_s ($8.7\epsilon_0$). This leads to the estimation of D_{sa}

$$D_{sa} \sim 5 \times 10^{13} \text{ cm}^{-2} \quad [3]$$

a value which is compatible with the barrier height of 2.3 eV.

At low frequency, it is no longer valid to assume that the interface states do not follow the perturbation and the above analysis is no longer possible. However, Fonash (12) has recently proposed a detailed treatment of that case, and we applied it to our results. Without giving more details, it is sufficient to say that the amount of very slow surface states, as deduced from this treatment, is low, on the order of 10^{11} cm^{-2} .

The D_{sa} value, as computed from relation [1], seems to be in the limits for Fermi level pinning, as established re-

Fig. 3. Characteristics of the n-ZnSe-1M HClO₄ junction before and after electrochemical perturbation (positive polarization + 8V vs. MSE and illumination in the presence of oxygen). 1. Reference state. 2 and 3: After, respectively, 30 min and 1h of perturbation. a(above): C⁻² vs. V (15 Hz). b(right): EER spectra.

cently by Zur *et al.* (13), in the case of submonolayer metal coverage. The influence of the very slow surface states is therefore negligible on this phenomenon irrespective of their influence on the frequency dispersion of Mott-Schottky plots.

Electrolyte electroreflectance.—Provided that the low field approximation can be made, the EER spectra can be fairly analyzed using the three-point method (14). The validity of this method depends on the existence of a fully depleted layer at the surface of the semiconductor and on the assumption that the electro-optical energy $\hbar\Omega$ and the broadening parameter obey the relation

$$3\hbar\Omega < \Gamma \quad [4]$$

Consequences of relation [4] are (i) the proportionality between the EER signal amplitude and that of the alternating modulation and (ii) the constancy of the transition energy when the dc potential changes.

In the present case, we have

$$\hbar\Omega = 24 \text{ meV}$$

$$\Gamma = 50 \text{ meV}$$

and condition [4] is clearly not fulfilled. However, the two main consequences are verified and it seems reasonable to assume that the low field limit approximation is valid. The E_0 and Γ values deduced are reported in Table I

and we remark that they differ slightly between pH 0 and 14. The smaller value of Γ at pH = 0 seems to be consistent with the above remarks about the lower density of interface states at this pH than at pH 14. Another feature, not reported in Table I, consists in the larger signal amplitude at pH 14 than at pH 0. If we follow a treatment proposed recently by Tomkiewicz *et al.* (15), the general expression for $\Delta R/R$ (8)

$$\frac{\Delta R}{R} = - \frac{2eN_D V_{ac}}{\epsilon_s} L(\hbar\omega) \quad [5]$$

[where $L(\hbar\omega)$ is the spectral lineshape function] can be rewritten

$$\frac{\Delta R}{R} = A \left(1 - \frac{e}{C_H} \frac{dD_{sa}}{dV} \right) dV \quad [6]$$

with $A = - \frac{2eN_D}{\epsilon_s} L(\hbar\omega)$ and C_H the capacity of the

electrolyte Helmholtz layer. Changing expression [5] to expression [6] is possible assuming that the variations in potential are divided between the space-charge layer and the Helmholtz layer by means of interface states. If the dc potential is fixed, an interface which presents acceptor states must correspond to larger signals than an interface

Fig. 4. Characteristics of the n-ZnSe-1M NaOH junction before and after electrochemical perturbation (polarization + 4V vs. MSE). a(above): C^{-2} vs. V (15 Hz). Circles: Reference state. Open squares: 5 mn treatment. Triangles: 10 mn treatment. Closed squares: 15 mn treatment. The C vs. V (100 kHz) plots do not differ noticeably and are not represented. b(right): EER spectra. Solid line: Reference state. Dashed line: After 15 min electrochemical perturbation.

without states: in the first case dD_{sa}/dV is negative and in the second $dD_{sa}/dV = 0$. We have to notice that the treatment which leads to expression [6] is independent of the nature of the interface states, and will be used in the following when the existence of donor interface states can be assumed.

Expression [6] accounts for the difference observed in $\Delta R/R$ amplitude between pH 0 and 14 and is consistent with the existence of acceptor interface states in greater amount at pH 14.

A conclusion deduced from both capacity and EER data analysis concerning the reference state can already be pointed out: the interface ZnSe-electrolyte (and this is certainly not limited to ZnSe) behaves more ideally at pH 0 than at pH 14.

The Perturbed Reference State

Electrochemical perturbation.—This type of perturbation corresponds to that induced by the various treatments achieved in supporting electrolyte under positive polarization of the electrode. According to the remarks about the experimental results (Results section), we can ascertain that the charge transfer mechanism at pH 14 differs from that at pH 0. In the former case, there is no influence of both dissolved oxygen and illumination, whereas in the latter the situation is completely reversed. It appears that at pH 14 the transfer step must be associated with majority carriers (electrons) and at pH 0 with minority carriers generated by illumination. Such an analysis has already been proposed by one of us (6b), but, nevertheless, needs to be made more precise. The main results are reported in Table I.

pH 0.—At pH 0, the transfer step is associated with holes and induces a modification of the electrode behavior only in the presence of oxygen. Therefore, the complete

reaction is not specifically limited by the potential value, provided that the electric field in the space-charge layer is large enough to confine the holes in the immediate vicinity of the semiconductor surface. The exact reaction occurring is difficult to determine, but a comparison with results obtained about the oxidation of ZnSe exposed to oxygen and light (16) allows the assumptions of (i) the formation of both Zn excess and ZnO and (ii) the transformation of Se into soluble products (H_2SeO_3 , presumably).

After such a treatment, the differential capacity measured at 100 kHz remains unchanged, whereas at 15 Hz it leads to noticeably different apparent values of N_D ($8.6 \times 10^{17} \text{ cm}^{-3}$) and to a diminution of the potential range where a Mott-Schottky behavior is observed. This observation may be accounted for by the statement that the fast interface states remain unaffected, whereas new slow states are created in an amount of approximately 10^{11} cm^{-2} (this result is obtained by arguments similar to those developed in the Differential capacity section).

More striking are the variations with respect to the reference state observed in the EER oscillations in the vicinity of E_0 . In this energy range, the absorption coefficient, α , is $10^3 < \alpha < 10^4 \text{ cm}^{-1}$ (17) and the penetration depth of light is at least one order of magnitude larger than the space-charge layer thickness. We conclude from this observation that EER spectra would account mainly for the bulk properties of the semiconductor. Such a statement contradicts clearly our experimental results. We observe an important spectrum shape modification, a slight shift of E_0 towards lower values, and an important attenuation of the spectrum amplitude. By reference to Eq. [6], these results imply the formation of new interface states (already deduced from capacity measurements) and we can ascertain that these states are of the donor type ($dD_{sa}/dV > 0$). Such observations may be correlated with those made by photoemission during the formation of metal-semiconductor junctions where such donor states have been evidenced (18, 19).

Fig. 5. Behavior of the n-ZnSe-1M HClO₄ junction before and after chemical perturbation [cycling between -2.0 and +2.0V vs. MSE in 1M HClO₄ + 10⁻²M Fe(CN)₆³⁻ for eight cycles at a sweep rate of 50 mV·s⁻¹]. a(above): C⁻² vs. V plots. Closed squares: Reference state at 15 Hz and 100 kHz. Triangles: Perturbed state at 15 Hz. Open squares: Perturbed at 100 kHz. b(right): EER spectra. 1: Reference state. 2: After two cycles. 3: After four cycles. 4: After eight cycles.

pH 14.—The transfer step is associated with electrons, and the resulting modifications to the reference state are independent of both oxygen and light. It seems reasonable to assume that electrons are injected by OH⁻ adsorbed at the electrode surface into the semiconductor conduction band. The control of this process by the electrode potential indicates that the transfer occurs via a tunneling process. By analogy with the metal-semiconductor case, we can attempt to determine the present transfer mechanism more precisely.

Calculating the probability *P* of a triangular barrier being penetrated by an electron with energy ΔE less than the height of the barrier, it is found that

$$P = \exp \left[-\frac{2}{3} (\Delta E)^{3/2} / E_{00} V_s^{1/2} \right] \quad [7]$$

where the parameter

$$E_{00} = \frac{\hbar}{2} \left[\frac{N_D}{m_e^* \epsilon_s} \right]^{1/2} \quad [8]$$

(m_e^* is the effective mass of the electron in the semiconductor) plays a major role. In the present case ($m_e^* = 0.17 m_0$; $\epsilon_s = 8.7\epsilon_0$, and $N_D = 2 \times 10^{17} \text{ cm}^{-3}$), we have

$$E_{00} = 6.8 \times 10^{-3} \text{ eV}$$

Using the expression developed by Padovani and Stratton (20), we can define the band bending values delimiting the various charge transfer processes: thermionic, thermionic-field, and field emission (the two latter refer

to tunneling processes). Details of the calculations are beyond the scope of the present paper, and the results are

$$\begin{aligned} V_s \leq 0.6V & \quad \text{thermionic emission} \\ 0.6 < V_s \leq 29.4V & \quad \text{thermionic-field emission} \\ V_s > 29.4V & \quad \text{field emission} \end{aligned}$$

Obviously, the band bending value during the electrochemical treatment ($\sim 10 \text{ eV}$) implies that the transfer process we observe is analogous to thermionic-field emission. A consequence of these considerations is that ΔE must be rather small (ca. 0.1 eV), thus leading to the location of the OH⁻ adsorbed groups which donate their electrons in the vicinity of the conduction bandedge ($-3.1V$ vs. MSE) in an energy position very different from that they occupy in the electrolyte bulk.

The electrochemical treatment analyzed above induces some particular features in the differential capacity as well as the EER signal. The high frequency capacity remains unchanged, whereas the low frequency capacity is strongly modified and the "pseudo" Mott-Schottky slope increases up to 2×10^{19} (Table II). This variation can be interpreted in terms of slow interfacial energy states (cf. the Differential capacity section) and leads to a density of states of ca. $2 \times 10^{12} \text{ cm}^{-2}$. This density of states can be related to the increase of the EER signal, which, by means of relation [6], indicates that dD_{sa}/dV is more negative than in the reference state at pH 14.

The electrochemical treatment can then be considered as a strong etching process which, like the etching by

Fig. 6. Characteristics of the ZnSe-1M NaOH junction before and after chemical perturbation [cycling between -2.0 and $+2.0$ V vs. MSE in $1\text{M NaOH} + 10^{-2}\text{M Fe(CN)}_6^{3-}$ for six cycles at a sweep rate of $50\text{ mV}\cdot\text{s}^{-1}$]. a(above): C^{-2} vs. V plots. 1 and 1': Reference states at 100 kHz and 15 Hz , respectively. 2 and 2': Perturbed states at 100 kHz and 15 Hz , respectively, at the end of the six cycles. b(right): EER spectra. 1: Reference state. 2: After two cycles. 3: After three cycles. 4: After four cycles. 5: After five cycles. 6: After six cycles. Notice that the phase rotation appears to be complete after four cycles and after six cycles, and that the spectrum is restored in phase but strongly attenuated as compared to the reference state.

NaOH, preserves the surface stoichiometry (Zn and Se are involved in final soluble products) and increases the density of interfacial acceptor energy states.

Chemical perturbation.—By chemical perturbation, we mean that the chemical composition of the semiconductor surface is severely perturbed. The use of the oxidizing species Fe(CN)_6^{3-} seems especially adequate for this purpose (6b). The exact process by which this species produces the modified semiconductor surface is not yet clear and depends on the pH of the solution. At pH 0, the reaction seems to be chemical, whereas at pH 14 it seems to be a mixture of electrochemical and chemical processes. At each pH value, the resulting surface is different and behaves specifically when studied in supporting electrolyte of equivalent pH value.

pH 0.—The modified interface behaves like that produced by electrochemical perturbation at pH 0 both in capacity and EER.

It seems reasonable to assume that the semiconductor surface produced by the ferricyanide treatment is similar

to that produced by the former electrochemical treatment and, therefore, we do not emphasize it.

pH 14.—The final result of the treatment is to create a selenium layer on the top of the ZnSe electrode. This layer induces a specific behavior of the modified electrode when immersed further in an electrolyte of pH 14. The EER signal is strongly attenuated and rotates in phase. The slope of the Mott-Schottky plot changes at low frequency, but does not at high frequency. In the latter case, in addition, the flatband potential shifts towards a slightly more positive value. This observation seems in good agreement with that already made on CdSe electrodes upon deposition of a Se layer (21). By analogy with the observation made during the formation of Ge-GaAs interfaces (22), it seems appropriate to assume the creation of donor interface states with large relaxation time due to the interaction between Se atoms and the ZnSe surface. The strong attenuation of the EER signal is in part accounted for by the absorption of light in the Se layer, whose fundamental energy gap is ca. 2 eV, and the absorption coefficient larger than 10^5 cm^{-1} in the region

Table I. The reference state parameters at pH 0 and 14. The steady-state barrier height V_s (open circuit) can be deduced from V_R and V_{FB} determinations using the relation $V_s = |V_{FB} - V_R|$. The free carrier density as determined by Hall effect is $\sim 2 \times 10^{17}\text{ cm}^{-3}$ and serves as a reference value

Electrolyte	Rest potential V_R (V vs. MSE)	Capacity				N_D (cm^{-3}) Hall effect	Electroreflectance	
		V_{FB} (V vs. MSE)		N_D (cm^{-3})			E_0 (eV)	Γ (meV)
HClO_4 (pH = 0)	-0.65	15 Hz	100 kHz	15 Hz	100 kHz	2×10^{17}	2.724	43
		-2.2	-2.3	2×10^{17}	2×10^{17}			
NaOH (pH = 14)	-0.8	-3.2	-3.1	8×10^{17}	2.7×10^{17}	2×10^{17}	2.711	57

Table II. The question mark indicates that the experimental results cannot be interpreted using a simple model. The Schottky plots are not clearly linear in a large potential range, and the phase rotation of the EER signals excludes the use of the three-point method

Electrolyte	Treatment	Capacity				EER	
		V_{FB} (V)		N_D (cm ⁻³)		E_0 (eV)	(meV)
HClO ₄	Positive polarization + Oxygen } + Light }	15 Hz	100 kHz	15 Hz	100 kHz	2.714	35
		?	-2.3	8.6×10^{17}	2×10^{17}		
	Fe(CN) ₆ ³⁻	?	-2.2	2.4×10^{17}	2.1×10^{17}	2.728 (?)	43
NaOH	Positive polarization	-3.1	-3.1	2×10^{19}	3.0×10^{17}	2.732	61
		(?)					
	Fe(CN) ₆ ³⁻	-3.2	-3.0	1.5×10^{18}	2.8×10^{17}	?	?
		(?)			(?)		

of 2.7 eV (23). The phenomenon of phase rotation of the EER signal has already been described by other authors and has been accounted for similarly by the existence of interface energy states induced by an electrochemical treatment (15) and by the formation of a heterojunction (24).

Conclusion

By coupling electrochemical and *in situ* electroreflectance measurements and by applying controlled perturbations at the interface, we tried to infer a description of the ZnSe-electrolyte interface by analogy with the models used for the metal-semiconductor junctions.

The above discussion establishes that the ZnSe-supporting electrolyte junction behaves like a metal-semiconductor junction. However, the main interface properties are governed not by the bulk properties of the semiconductor-electrode, but by its surface states. These surface states can be either intrinsic to the semiconductor surface or resulting from a specific interaction with the electrolyte.

Summing up, we can say that an electrolyte with no etching properties (acidic medium) leads to the formation of an interface with a low density of interface states, whereas a basic electrolyte with etchant character leads to a pinning of the semiconductor Fermi level by acceptor surface states located ca. 0.5 eV above the valence band maximum.

Perturbing the reference state defined above induces particular effects which differ according to the nature and intensity of the perturbation. The simple model with acceptor interface states governing the junction properties must be made more sophisticated to incorporate a relatively large density of donor interface states located in the upper part of the semiconductor gap.

Provided that these considerations are taken into account, an electrolyte-semiconductor junction can be described, at least qualitatively, like a metal-semiconductor interface.

ABSTRACT

Photoelectrochromic properties of polypyrrole-coated Si electrodes in propylene carbonate solutions were investigated to obtain fundamental information on optical image formation. It took about 1 s or more for a coated film ca. 90 nm thick to complete its color change when the entire surface of the film was illuminated with a 500 W xenon lamp, an observation of which indicates diffusion limitation of electrolyte anions in the film. In contrast, different image forming behaviors were seen when the film was illuminated with a He-Ne laser. Illumination of the film on n-type Si substrates with the laser for 1 s gave an optical image of about ten times of the illuminated area, while an optical image comparable with the illuminated area was obtained for p-type Si substrates for the same illumination time. In either case, continuous irradiation caused peripheral growth of the optical image in the film.

One of recent interests in polymer-coated electrodes concerns their electrochromic properties (1-14). A polymer film is usually deposited on a metallic conductive substrate, such as a thin Pt film, and highly conducting SnO_2 and In_2O_3 . A color change of the coated film occurs when it is stimulated by a large current pulse that causes oxidation of a reduced film or reduction of an oxidized film. If a semiconductor is used in place of the metallic conductive substrates, different features in electrochromism will appear with the assistance of illumination. Since semiconductor electrodes have a photosensitized action, illumination of polymer-coated semiconductor electrodes should spontaneously cause the color change without a change in the applied bias if the electrodes are properly biased in advance. Several interesting features of photoelectrochromism have recently been reported by Inganaes and Lundström for polymethylpyrrole-coated n-type Si (15). In this paper, we wish to report detailed characteristic features concerned with optical image formation and its storage. The polymer chosen was electropolymerized polypyrrole, which was deposited onto n- and p-type single-crystal wafers. It will be shown that behavior of the color change caused by illumination shows little difference between the conductivity type of the semiconductor substrate.

Experimental

Silicon single-crystal wafers manufactured by Osaka Titanium Company were used. They were polished with 0.06 μm alumina to give a mirror finish, then etched in 46% HF for 15 min, and finally rinsed with methanol. Electrodeposition of polypyrrole was made at 0.3 $\text{mA}\cdot\text{cm}^{-2}$ in 0.1M pyrrole dissolved in propylene carbonate. The electrolysis charge usually employed was 36 $\text{mC}\cdot\text{cm}^{-2}$, which gave ca. 90 nm thickness (14).

The polymer deposition on n-type Si electrodes was carried out by illuminating the electrode with light of wavelengths longer than 390 nm, obtained from a 500 W xenon lamp in combination with a colored glass filter (Toshiba UV-390), while the deposition onto p-type Si was conducted without illumination. The illumination intensity was ca. 2.3 W, as determined by a power meter (Coherent Radiation, Model 201).

For *in situ* measurements of the color change associated with the redox reaction of the polymer film, the electrode was set in an electrolytic cell in such a way that the incident light path was ca. 45° with respect to the perpendicular from the surface. The illuminating light in this case was the same as that described above. The light reflected from the electrode surface was passed through a monochromator (JASCO, Model CT-25), a chopper (Nikon, Model M205), and introduced to a PbS detector (Hamamatsu Photonics, Model P397). The signal from the detector was measured by an electrophotometer (Nikon, Model SP 104). The monochromator was used to isolate

*Electrochemical Society Active Member.

the 400 nm light from the reflected light. According to the published optical properties of oxidized and neutral polypyrrole films (14, 16, 17), the latter film has large absorptivity at this wavelength, but this is not so for the oxidized film. In order to obtain optical image formation, a 1.3 mm diam area of the film on Si was illuminated with a He-Ne laser (NEC, Model GLG 5700). The intensity of the laser beam was 24.5 mW.

A potentiogalvanostat (Hokuto Denko, Model HA 101), a function generator (Hokuto Denko, Model HB 104), and a X-Y recorder (Yokogawa Electric, Model 3077) were used for conventional electrochemical measurements. A saturated calomel electrode (SCE) served as a reference electrode, and the counterelectrode was a Pt plate. The potential cited in this paper is referred to this reference electrode. Polypropylene carbonate was purified by distillation (18), and lithium perchlorate was dried *in vacuo* at 150°C overnight. Other chemicals were reagent grade.

Results and Discussion

Current-potential curves taken under illumination of polypyrrole-coated Si at 100 $\text{mV}\cdot\text{s}^{-1}$ are shown in Fig. 1 and 2 for the cases of n- and p-type Si substrates, respectively, together with the reflectance change associated with photoelectrochemical reactions of the coated elec-

trodes. Also given in the figures are the dark currents. In the case of using the n-type Si substrate, some reduction of the oxidized polymer occurred in the dark at 0.4V (not shown in the figure). This potential was chosen as the anodic limit of the potential sweep in Fig. 1, since the oxidized polymer on Pt is reduced a little at this potential. Appreciable reduction of the oxidized polymer in the dark occurred, however, at potentials where a large cathodic wave appeared under illumination. The polymer-coated p-type Si did not show appreciable reactivities in the dark unless the film was in a neutral state. The neutral film shows voltammograms similar to those shown in Fig. 2 during the anodic scan.

The color of polypyrrole in the neutral state is yellow. In the oxidized state it is dark brown. The film on Si electrodes was, however, green in the neutral state and dark brown in the oxidized state to the naked eye, owing to interference of the black Si substrate.

The oxidized film on p-type Si was not reduced in the dark, and, similarly, the neutral film on n-type Si was not oxidized in the dark at potentials similar to those shown in Fig. 1 and 2. Thus, the electrode potentials of -0.9V for p-type Si and 0.4V for n-type Si were chosen in the following experiments to cause photosensitized reactions of the coated polymer film. As Fig. 1 and 2 demonstrate, these potentials are sufficiently large to reduce the film on p-type Si and to oxidize the film on n-type Si electrodes, respectively.

The transient photocurrent behavior and reflectance change of the film-coated electrode are shown in Fig. 3 together with the imposed electrode potential profiles; in each case, the entire electrode surfaces were illuminated. Upon illumination of the neutral film-coated n-type Si electrode at 0.4V , anodic photocurrents flowed until the film was completely oxidized, as seen in the reflectance change (Fig. 3a). Additional illumination had no significant effect. When the electrode potential was switched to -1.2V , cathodic currents flowed, as shown in the figure, and simultaneously the film was reduced to give the original reflectance. The reduction behavior of the film at -1.2V was not greatly affected by the illumination. Similar results were obtained for the p-type Si substrate except that illumination was required to reduce the film. A long time was required to complete the color change of the films for both n- and p-type Si electrodes; it took about 1s or more. The diffusion of electrolyte anions in the polymer film seems to control the rate of the color change (6).

The film color at p-type Si produced by photosensitized reduction of the oxidized film was stable after interruption of illumination, provided that the electrode bias was not interrupted (Fig. 4a). Under open-circuit condition, however, the color of the reduced film gradually changed, indicating that oxidation occurred. Residual oxygen in the electrolyte solution must be responsible for

Fig. 3. Transient behavior of current and reflectance at 400 nm of polypyrrole-coated Si electrodes during an imposed potential step. a: n-Type Si electrode coated initially with neutral polypyrrole film. b: p-Type Si electrode coated initially with oxidized polypyrrole film. The entire surfaces of the electrodes were illuminated during the measurements.

the observed color change. In the case of the oxidized film on n-type Si, the interruption of illumination at 0.4V caused small instantaneous cathodic current flow, as described above. The initial value of this cathodic current was ca. $1/15$ of the initial current observed when the electrode potential was switched from 0.4 to -1.2V under illumination (Fig. 3a).

This current, however, soon decayed to zero. As a result, the cathodic charge due to this dark current did not result in any significant fading of the film color. The color produced by the photosensitized oxidation of the neutral film was stable irrespective of whether or not the electrode bias was interrupted, possibly because the residual oxygen has no effect on the oxidized state of the film.

The durability of the color change to repeated potential step pulses was investigated under illumination of the

Fig. 4. Stability of the film color produced by illumination during its interruption. a: Polymer-coated p-type Si polarized at -0.9V in the dark (solid line) and under open circuit (dashed line). b: Polymer-coated n-type Si in the dark with and without polarization at 0.4V .

coated film. The voltage pulse chosen had a 10s interval and ranged from 0.8 to -0.9 V for p-type Si and from -1.2 to 0.4 V for n-type Si. The response characteristics during the initial stage are those shown in Fig. 3. It was found that with repeated potential step cycles, reduction of the film decreased. If the ratio of the difference in reflectance of the film between the oxidized and the reduced state at extended potential pulse cycles (ΔR) to that at the first cycle ($\Delta R_{\text{initial}}$) is plotted as a function of the cycle number, Fig. 5 is obtained.

We speculated that the decrease of $\Delta R/\Delta R_{\text{initial}}$ with the cycles might have been brought about by oxidative decomposition of the coated film (19). The effect of the anodic potential on the durability of the film was then investigated. The results showed, however, that the decrease in the anodic potential from 0.4 to 0 V for the case of n-type Si and from 0.8 to 0.3 V for p-type Si did not make any appreciable improvements. Furthermore, the decrease in the anodic potential also produced a slow-down in the response of the color change. Additional studies are required to clarify detailed chemistry related to the decrease of $\Delta R/\Delta R_{\text{initial}}$ with the potential step cycles.

In order to obtain information on optical image formation, the film was irradiated with a laser beam to produce an image pattern in a spot on the coated film. The same anodic potential was used as that employed in obtaining Fig. 3: 0.4 V for n-type Si and -0.9 V for p-type Si. While an image could be formed, the area of the spot gradually increased on continuous irradiation of the film. The peripheral growth of the image occurred more rapidly at the n-type Si electrode than at the p-type one. Photographs of image patterns were taken at different illumination time, and the patterned area of the spot to the total filmed area was determined. This ratio was compared with the ratio of the charge consumed in the image formation to that required in the conversion of all the film to the same color as the image. The results are shown in Table I. The area of the laser beam was 0.013 cm², and the total area of the electrode surface was 0.95 cm².

As may be seen in Table I, the illumination for 1s of p-type Si coated with the oxidized polymer produced an image of the laser beam. In the case of the n-type material, the image pattern was ten times larger than the area of the laser beam. The charge consumed during the image formation was larger for all illumination times for the p-type electrode compared to that at the n-type one. As described below, such difference in the image formation behavior must be closely related to the mechanism by which the color change initially propagates.

When the image is formed in the film on the n-type Si electrodes, electrolyte anions are incorporated into the illuminated part of the film in its outermost part, to change there from a reduced state of high electrical resistivity to an oxidized state of low electrical resistivity.

Fig. 5. The ratio of the difference in reflectance between the oxidized and neutral states at extended potential pulse cycles to that at the first cycle vs. the cycle number of the potential pulse. a: n-Type Si substrate. b: p-Type substrate. Potential pulse: -0.9 to 0.8 V for a, and -1.2 to 0.4 V for b. The interval of the pulse: 10s.

Table I. Growth of the optical image pattern with continuous irradiation of a fixed area of the electrode surface^a

Illumination time (s)	n-Type Si		p-Type Si	
	Colored area ^b (%)	Fraction of charge consumed ^c (%)	Colored area (%)	Fraction of charge consumed (%)
1	15	0.92	1.2	4.2
2	22	1.8	4.9	16

4	42	3.5	15	27
5	68	4.3	31	31

^a The semiconductor electrodes coated with polypyrrole of ca. 90 nm thickness were illuminated with a He-Ne laser beam of 24.5 mW. The n-type Si coated initially with a neutral film was polarized at 0.4 V, and the p-type one with an oxidized film was polarized at -0.9 V.

^b The colored area to the entire electrode surface is given.

^c The ratio of charge consumed in the formation of the colored image to that required for the complete coloring of the entire surfaces.

Once the outermost part of the film becomes highly conductive, the peripheral growth of the optical image pattern will easily occur at the film/solution interface, as illustrated in Fig. 6a. However, the growth of the optical image in the p-type Si electrode is associated with exclusion of the incorporated anions to give an insulating polymer film. The image pattern formation in this case must occur initially from the film/semiconductor interface as a result of diffusion of the incorporated anions towards the solution side of the film, as illustrated in Fig. 6b.

As already reported (20-23), adhesion of the polymer to Si is rather poor, so that the existence of electrolyte solu-

Fig. 6. Schematic illustration of the growth of the domain where the color change of the coated film occurs. a: n-Type Si substrate. b: p-Type substrate. X⁻ denotes an electrolyte anion.

tions in the film as well as at the film/Si interface is highly probable. If so, the distance for photogenerated charge carriers to travel an insulating layer zone will be short compared with the apparent film thickness, and the real situations encountered in the image forming process will be more complicated than that discussed above. Nevertheless, the different behavior of the propagation of the image pattern with illumination time between the n-type and p-type S substrate (Table I) can be explained well by the above described discussion with use of Fig. 6.

Conclusion

In this study, we employed polypyrrole films as photoelectrochromic material. The durability of the coated film and its response behavior are unsatisfactory from the view point of practical application, but improvements in the properties might be made by suitable choice of another kind of electrically conductive polymer. The resolution of the optical image formed, however, will be controlled by similar manner, as shown in Table I and schematically illustrated in Fig. 6. In this sense, the exposure of patterned light for well-controlled time is said to be important for the formation of good optical images.

Technical Notes

Performance of Suspension-Impregnated Sintered Nickel Composite Electrodes

W. A. Ferrando*

Naval Surface Weapons Center, Materials Division, White Oak, Silver Spring, Maryland 20903-5000

Low cost, high performance nickel electrodes will be required for improved Ni-H₂, Ni-Zn, Ni-Fe cells. Several years of effort have been directed to the development of a porous sintered, nickel-plated graphite fiber plaque impregnated by the electrochemical method (1, 2). Plaques were successfully fabricated by compression sintering of electroless nickel-plated graphite mat (3). In the course of optimization, it was found that plaques produced using chopped electroplated graphite fiber exhibited more uniform porosity, durability, and other properties.

Concurrently, an effort was undertaken to find an alternative method of active material [Ni(OH)₂] impregnation suitable for these composite plaques. The electrochemical method had been observed to produce good results. Although simpler and quicker than the older chemical methods, the electrochemical method requires batch processing in tanks with temperature, pH, time, and current

control, as well as time-consuming rinsing. There is also some concern over bath concentration depletion and chemical attack on the plaque.

The Suspension Impregnation Method

It was found that the pore size (~50 μm) and open pore structure of the composite plaque allowed it to accept direct impregnation by fine particulate Ni(OH)₂. To accomplish this, commercial battery-grade Ni(OH)₂ was ground by ball milling to particle diameters (~1-20 μm). The powder was mixed with ethylene glycol (b.p. 198°C) to the consistency of a heavy cream (about 1:2 by weight). The inert semiviscous glycol fluid served to hold the fine active material particles in suspension and provided the lubrication necessary for direct infiltration into the pores.

The impregnation procedure consists of several simple steps. The plaque is placed on a level, nonporous surface. A quantity of the freshly mixed suspension fluid is ap-

*Electrochemical Society Active Member.

Fig. 1. SEM micrographs, composite plaque cross sections (as cut surfaces). Active material deposition by electrochemical impregnation (A), and by suspension impregnation (B).

plied on and gently rubbed into the plaque surface. The operation is repeated from the reverse side. The plaque is heated ($\sim 150^{\circ}\text{C}$) to evaporate the glycol carrier fluid. Finally, it is brushed lightly to remove surface material and weighed to determine electrode capacity. The operation is repeated, if necessary, to achieve the desired loading level. The entire process can be carried out in a few minutes. Figure 1 shows SEM photographs of the cut edges of suspension-impregnated (A) and electrochemically impregnated (B) composite plaques. Cut ends of the nickel-plated graphite fibers are visible. The pictures enable one to make a rough visual comparison of the initial active material distribution through the cross section by the two methods.

Cobalt Additive Addition

Cobalt additive has long been used to improve utilization and cycle life of nickel electrodes. Recent investigation (4) has revealed that cobalt additive is most efficiently utilized when it is applied to the active material surfaces within the pores, rather than as a volume constituent. The cobalt apparently facilitates proton charge transfer across the active material-electrolyte interface. This addition may be accomplished chemically by soaking the impregnated plaque in an aqueous cobalt compound solution followed by conversion to $\text{Co}(\text{OH})_2$. Cobalt may be added also by a very brief electrochemical deposition from a cobalt impregnation bath. Cobalt added by either method constitutes about 1-4 weight percent of the active mass. Surface deposition of the additive allows the suspension-impregnated electrode to achieve 90% utilization within five to ten discharge cycles.

Test cells were fabricated using a single composite nickel electrode sandwiched between two commercial negatives in 31% KOH with no electrolyte additives and under flooded conditions. Electrochemically impregnated electrode capacities were determined from the postformation weight gain of active material. Capacities of the suspension-impregnated electrodes were determined by the total weight increase measured after cobalt treatment.

Results

Continuous cycling tests were performed on the cells. The imposed regime included charging at the C rate (125%), 10 min rest, followed by discharge at the $C/2$ rate to 0.75V cutoff ($> 95\%$ DOD). Table I lists several important parameters for representative composite electrodes tested according to this regime. The reported utilizations were measured after the initial rise in capacity. Since an objective of this effort was to maximize the usable energy density, several electrodes (no. 83, 85, 95) were electrochemically reimpregnated after initial formation in order to augment loading levels. The high theoretical loadings achieved were of little advantage, however, since reduced utilizations were observed for these electrodes. Working energy densities of 150-170 Ah/kg ($0.27\text{-}0.35\text{ Ah/cm}^2$) were realized generally for the electrochemically impregnated electrodes. The inability to effect a usable increase in energy density by repeated electrochemical impregnation was due probably to the difficulty of maintaining proper conditions within the pores for compact deposition at high loading levels.

Suspension-impregnated electrodes did not suffer this drawback to high loading levels. Entries to Table I indicate that a combination of high active material loading and good utilization could be attained. Operating energy densities in the range of 175-192 Ah/kg ($0.24\text{-}0.325\text{ Ah/cm}^2$) were observed in the cycling tests. Utilization of active material rarely failed to achieve 90% and sometimes exceeded 100% of theoretical capacity. Table I includes several 2.5 mm thick electrodes, which were rapidly and efficiently impregnated by the suspension method. Thick plaques normally present a challenge for any impregnation method. Microgrinding or special precipitation techniques might be able to produce a finer $\text{Ni}(\text{OH})_2$ powder for use in the suspension. In such case, better filling of small pores might allow somewhat higher useful energy densities to be attained.

Several electrodes without current collector grids were fabricated and tested. These are represented by entry no. 44 of Table I and in the data of Fig. 2. The limited test (80 cycles) yielded good utilization and verified the inherent integrity and electrical conductivity of the composite structure. This result indicates that successful composite electrodes might be fabricated without a current collector grid.

Table I. Test electrode parameters

Electrode ^a	Plaque porosity (%)	Nominal thickness (mm)	Theoretical capacity (Ah/kg)	Theoretical capacity (Ah/cm ²)	Ultimate utilization (%)
83-A ^b	89	1.0	190	0.345	82

Fig. 2. Active material utilization and volumetric energy density vs. charge-discharge cycles for suspension-impregnated electrodes. No. 75 with current collection grid. No. 44 without current collection grid.

Figure 2 shows the excellent life-cycle durability results obtained with the suspension-impregnated composite electrode. Electrode no. 75 yielded very constant utilization in excess of 100% throughout its lifetime of 800 cycles under the aforementioned test regime. This performance level was typical of the test electrodes with cobalt surface treatment, although most tests were not carried beyond 80-100 cycles.

In order to provide a meaningful life-cycle base line, a commercial positive was tested under substantially identical conditions. Its capacity was determined from the manufacturer's specified cell rating. This capacity, however, apparently underestimated its true capacity somewhat from the observed extended discharge period. This, in turn, implied correspondingly lighter cycling conditions than the specified charge (C) and discharge (C/2). Figure 3 shows the test results. The utilization, normalized here to the maximum observed value, remained reasonably constant over most of the test period. A (gravimetric) energy density of about 115 Ah/kg was achieved. A useful life of about 900 cycles was observed. Cycle-life durability is a major consideration in any secondary battery system. Thus, the main intention in presenting Fig. 2 and 3 is to show the comparability of cycle life between the composite electrode and a powder sintered electrode under the same demanding cycling regime.

Fig. 3. Normalized active material utilization and volumetric energy density vs. charge-discharge cycles for commercial powder sintered electrode.

In conclusion, this work shows the potential for a successful high energy density, electrically durable, lightweight nickel composite electrode fabricated by a relatively simple suspension method of active material impregnation.

Electroless and Immersion Plating of Palladium on Zirconium

Cheazone Hsu and Robert E. Buxbaum

Department of Chemical Engineering, Michigan State University, East Lansing, Michigan 48824-1226

Zirconium is an important metal which is widely used in nuclear and chemical industries. In some applications, the zirconium surface is coated with a thin metal film to prevent corrosion or to change the surface properties. A thin coating of copper, nickel, or iron on zirconium is reported to prevent corrosion of cladding material in nuclear reactors (1, 2). Also, Dini *et al.* (3) studied plating nickel, silver, or chromium on zirconium in order to join zirconium to stainless steel.

Palladium is a particularly attractive coating for zirconium. Buxbaum (4) describes the advantages of using a coated palladium window of zirconium for separating tritium from the breeder blanket of a fusion reactor. Also, Stokes and Buxbaum (5) have suggested using a palladium coating to allow the removal of H isotopes from zirconium pressure tubes in CANDU-PHW reactors.

Currently, the following metals can be plated on zirconium: Ni, Fe, Cu, Sn, Cr, and Ag. Schicker *et al.* (6, 7) describe nickel and iron electrodeposition on zirconium following pretreatment by mechanical descaling, alkaline

cleaning, and chemical etching. After electrodeposition, the sample is baked at 200°C to prevent blistering. Kohan (8) describes immersion plating of nickel, copper, and tin on Zircaloy 2 using a pretreatment of vapor blasting, cathodic alkaline cleaning, and pickling. Thicknesses up to 7 μm are deposited by this method. Saubestre (9) describes nickel and copper electroplating on zirconium using a cathodic pretreatment in a suitable electrolyte. Wax *et al.* (10) describe the electroplating of copper, nickel, and chromium on zirconium using an activation solution of ammonium bifluoride and sulfuric acid; and Donaghy (1, 2) holds two patents on processes for electroplating and electroless plating of these same metals. Recently, Dini *et al.* (3) described electroplating nickel, silver, and chromium on zirconium, and showed that adhesion was improved by a postplating heat-treatment at 700°C in constrained geometry or by mechanical treatments such as surface threading or knurling.

At least two dozen formulations for palladium plating baths have been suggested or patented. However, no

technique has been published for either electroplating or nonelectrolytic plating palladium on zirconium.

Experiments

The following two palladium bath formulations were selected for this study. First, we used the immersion plating solution that Johnson (11) used to plate palladium on copper, brass, beryllium-copper, phosphor-bronze, and nickel-silver. The composition was PdCl₂, 5 g/liter; HCl (38%), 200 ml/liter. The temperature was 25°C. Second, we used the electroless palladium bath solution of Pearlstein and Weightman (12). The composition was PdCl₂, 2 g/liter; HCl (38%), 4 ml/liter; NH₄OH (28%), 160 ml/liter; NH₄Cl, 27 g/liter; NaH₂PO₄ · H₂O, 10 g/liter. The temperature was 50°C. The pH was 9.8.

The surface pretreatment was as follows.

1. The sample, zirconium disk with surface area of 10 cm², was machined from a zirconium bar of 99.8% purity.
2. Surface grinding and polishing were used to remove some surface scale and oxide.
3. Detergent washing and solvent cleaning with trichloroethylene were used to remove surface oil and grease.
4. The sample was given a cathodic alkaline cleaning. (Composition: NaOH, 35 g/liter; Na₃PO₄, 10 g/liter. pH: 12. Temperature: 90°C. Time: 3 min. Cathodic current density: 0.1 A/cm². Voltage: 4V.)
5. The sample was given a water rinse.
6. The sample was given an "acid pickling" (13). (Composition: HNO₃ 70%, 10 parts; HF 49%, 1 part; H₂O, 10 parts. Temperature: 25°C. Time: 0.5 min.)
7. Another water rinse was given.
8. The sample was given an activation etching. (Composition: NH₄HF₂, 15 g/liter; H₂SO₄, 1 g/liter. Temperature: 25°C. Time: 1, 2, 3, 6, or 10 min.)
9. A final water rinse was applied.
10. Then, the palladium plating was applied. Immersion plating was tried with and without activation etching step in the surface pretreatment.

Immersion Plating Results

Because the positive potential of zirconium is higher than that of palladium, the palladium ions can theoretically replace atoms of the zirconium substrate in solution by immersion plating. For this process, zirconium atoms must be simultaneously oxidized and dissolved as ions into the solution while palladium ions in solution deposit onto the zirconium substrate. We find, however, that immersion plating (using a PdCl₂-HCl solution) does not give good results: the palladium did not coat the zirconium surface. Without the activation etching prior to immersion plating, a possible explanation is that an oxide film stopped the replacement reaction. Zirconium, being a reactive metal, quickly forms a stable film of surface oxide when the pickled surface is exposed to air or water. Although the thickness of surface oxide is less than 0.0025 μm (14), it may be thick enough to stop atomic replacement. With activation etching in the surface pretreatment, a thin film of zirconium hydride was formed

on the surface and there was still no replacement reaction.

Electroless Plating Results

The surface was activated for electroless plating of palladium on zirconium by forming an adherent, electrically conducting film of black zirconium hydride using a solution containing 15 g/liter NH₄HF₂ and 1 g/liter H₂SO₄. Zirconium hydride provides an improved surface for palladium deposition because it, like palladium, is a face-centered cubic structure (15). Activation etching times of 1, 2, 3, 6, and 10 min were tested at 25°C, and it was found that at least 3 min is necessary to form an adherent palladium deposit. About 9 μm of zirconium was etched off after 3 min of activation at 25°C.

Adhesion was determined by scratching through the coating with a sharp blade; the surface showed no lifting or peeling when viewed under a microscope. Adhesion was also evaluated by a heat quenching test (16): the sample was heated in a vacuum oven to 200°C at a rate of 30°C/h, and was then immersed in room temperature water. No flaking, peeling, or blistering was observed. An adherent palladium coating 5 μm thick was achieved after 3h plating at 50°C.

Effect of Active Layer Composition on the Service Life of (SnO₂ and RuO₂)-Coated Ti Electrodes in Sulfuric Acid Solution

Chiaki Iwakura and Kenji Sakamoto

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka, Japan

Although RuO₂- and IrO₂-coated Ti electrodes (Ti/RuO₂ and Ti/IrO₂) have been known to possess high catalytic activity, not only for chlorine evolution, but also for oxygen evolution, they lack the stability required for practical

use as an oxygen anode, and therefore many researchers have been trying to prolong their service lives by different means (1). In general, the addition of ca. 70 mole percent (m/o) TiO₂ to the RuO₂ layer produces the bene-

ficial properties for chlorine evolution (2), but the service life as well as catalytic activity of the (TiO₂ and RuO₂)-coated Ti electrodes (Ti/TiO₂-RuO₂) for oxygen evolution decreases monotonously with increasing TiO₂ content (3). Recently, Burke and McCarthy (4) have reported that the addition of 20 m/o ZrO₂ to the RuO₂ layer increased the service life of the Ti/RuO₂ electrode for oxygen evolution in 6M KOH at 80°C by a factor of 5.3. Noguchi *et al.* (5) have also reported that the addition of ca. 33 m/o Co oxide to the IrO₂ layer increased the service life of the Ti/IrO₂ electrode for oxygen evolution in 4M H₂SO₄ at 60°C by a factor of 12.5. In both cases, however, it is not clear why such compositions are optimum for the active layers.

In this work, the effect of active layer composition on the service life of (SnO₂ and RuO₂)-coated Ti electrodes (Ti/SnO₂-RuO₂) in sulfuric acid solution was investigated in connection with the electrodes physicochemical properties from a fundamental viewpoint rather than a practical viewpoint. Both fundamental and practical investigations on the Ti/SnO₂-RuO₂ and related electrodes are still active, as can be seen from recent papers (6-9), although the idea of the use of SnO₂ in RuO₂-based anodes for industrial brine electrolysis goes back to earlier patents (10-12). The electrocatalysis of such electrodes for oxygen and chlorine has already been studied by Chertykovtseva *et al.* (13) and the present authors (14).

Experimental

The test electrodes (Ti/SnO₂-RuO₂) were prepared by a thermal decomposition method in the following way. First, a Ti plate (2.5 cm²) was mechanically polished with emery paper (~ no. 1000) and then chemically etched with a boiling aqueous solution of 0.2M oxalic acid for 10 min. Next, an appropriate amount of a mixture of 0.1M SnCl₄ and 0.1M RuCl₃-20 weight percent (w/o) HCl aqueous solution was applied to one side of the cleaned Ti plate. It was dried at 50°C and then placed in a preheated furnace at 350°C for 10 min. Such operations were repeated four times. Finally, the fifth coating was made and then the plate was dried at 50°C, followed by heating at 450°C for 1h to complete the thermal decomposition. The total loading amount of SnO₂ and RuO₂ was kept constant at 1×10^{-5} mol/cm². The amount of each metal oxide will be indicated in parentheses in mole percent.

All the electrochemical measurements were done in 0.5M H₂SO₄ at 30°C by conventional means. An all-Pyrex glass H-type cell with Teflon stoppers was used as an electrolytic cell and a Pt sheet as a counterelectrode. The reference electrode used was a mercury (I) sulfate electrode (Hg/Hg₂SO₄, 0.5M H₂SO₄).

The other experimental procedures and conditions will be given in the next section when necessary.

Fig. 1. Typical potential-time curves for Ti/RuO₂ (a) and Ti/SnO₂(70)-RuO₂(30) (b) electrodes under anodization at 500 mA/cm² in 0.5M H₂SO₄.

Fig. 2. Plot of service life against RuO₂ content for Ti/SnO₂-RuO₂ electrodes.

Results and Discussion

The accelerated life tests of the Ti/SnO₂-RuO₂ electrodes with different RuO₂ contents were carried out by anodization at 500 mA/cm². Typical potential-time curves are shown in Fig. 1. In any case, the potential remains almost unchanged for a certain time and then increases rapidly. Hereinafter, the service life will be defined as the time of operation before the anode potential increases significantly, say 5V vs. Hg/Hg₂SO₄ (iR included). Figure 2 shows the plot of service life against RuO₂ content. It is clear that the service life vs. RuO₂ content plot has a maximum at around 30 m/o RuO₂. This happened to coincide in Sn/Ru ratio with the reported Sn-Ru binary alloys, *i.e.*, Ru₃Sn₇, RuSn₃, and Ru₂Sn₅ (15). The service life of the Ti/SnO₂(70)-RuO₂(30) electrode is longer than that of the Ti/RuO₂ electrode by a factor of 4.5-5. This is in a marked contrast to the result obtained with a series of Ti/TiO₂-RuO₂ electrodes for oxygen evolution (3).

The anodic polarization curves of some Ti/SnO₂-RuO₂ electrodes are shown in Fig. 3. All the electrodes shown, except for the Ti/SnO₂(90)-RuO₂(10) electrode, have the dual Tafel slopes of 0.06 and 0.12 V/decade, suggesting that the mechanism of the oxygen evolution reaction is

Fig. 3. Galvanostatic polarization curves of Ti/SnO₂(90)-RuO₂(10) (a), Ti/SnO₂(70)-RuO₂(30) (b), Ti/SnO₂(50)-RuO₂(50) (c), Ti/SnO₂(30)-RuO₂(70) (d), and Ti/RuO₂ (e) electrodes.

unchanged. Furthermore, the current-potential curves of these electrodes can almost completely be superposed upon each other when they are replotted on the basis of the current density per given amount of RuO_2 (e.g., 1×10^{-5} mol/cm²). This indicates that the active center for the oxygen evolution reaction is on the Ru sites, which is in agreement with the view reported previously (14).

Figure 4 shows SEM microphotographs of the surfaces of the Ti/RuO_2 and $\text{Ti/SnO}_2(70)\text{-RuO}_2(30)$ electrodes. Evidently, the surface of the latter electrode is much more smooth and compact, with smaller cracks and pores than those of the former electrode. Thus, the result of Fig. 2 cannot be explained simply on the basis of an increase of effective surface area in the usual way (8). The increased smoothness and compactness of the electrode surface are considered to lead to the prolonged service life because they depress the penetration of electrolyte through cracks or pores in the active layer and thereby the formation of a resistive TiO_2 film on the Ti substrate (3).

The coloring of the solution straw-yellow during the life tests indicates clearly the occurrence of the anodic dissolution of the active layer, which can also lead to the formation of a resistive TiO_2 film on the Ti substrate (3). So, the dissolution rate of the active layer during anodization was determined by fluorescent x-ray analysis for both the Ti/RuO_2 and $\text{Ti/SnO}_2(70)\text{-RuO}_2(30)$ electrodes. Many test electrodes were used in the measurements, so that one electrode corresponds to each point in Fig. 5 as well as in Fig. 2. Figure 5 shows the variation of the normalized residual amounts of Ru and Sn species with the anodization time. In either case, the Ru species dissolve fast at the first stage, quite slowly in the middle period, and again rapidly at the final stage. From a detailed comparison of these data with the data shown in Fig. 1, one can notice that the potential change is almost paralleled by the dissolution of RuO_2 . In addition, the charges, de-

Fig. 7. Plot of x-ray diffraction angle against RuO_2 content for $\text{Ti/SnO}_2\text{-RuO}_2$ electrodes.

termined by cyclic voltammetry between 0.1 and 0.3V vs. $\text{Hg/Hg}_2\text{SO}_4$, was also found to change correspondingly with the anodization time; i.e., it increased and decreased at the first and final stages, respectively. Though the reason why a period of constancy in overpotential, as well as charges, with no dissolution exists is unclear at the present stage, it is evident from Fig. 5 that the RuO_2 dissolution is depressed to a great extent by the coexistence of SnO_2 and RuO_2 and that not only RuO_2 but also SnO_2 dissolve anodically, as was already confirmed by means of SIMS (14). Besides these facts, it is worth noting that both RuO_2 and SnO_2 dissolve almost in the same manner, suggesting the interaction between them.

The x-ray diffraction measurement was carried out for different electrode samples under the following conditions: a counterelectrode of Cu; tube voltage of 30 kV; tube current of 10 mA, time constant of 4s, scan rate of $0.5^\circ(2\theta)/\text{min}$; and a slit width of 0.3 mm. Figure 6 shows the x-ray diffraction patterns of some $\text{Ti/SnO}_2\text{-RuO}_2$ electrodes together with the mixed powders of $\text{SnO}_2(70)$ and $\text{RuO}_2(30)$. In this figure, only the patterns for each main peak in a (110) plane are shown since the patterns for the subpeaks in the other planes such as (101) and (211) were quite similar to those for the main peaks. As shown typically for the $\text{Ti/SnO}_2(50)\text{-RuO}_2(50)$ electrode, the peaks of the electrodes with relatively high RuO_2 contents coin-

Fig. 8. Probable triple-rutile structure of RuSn_2O_6 . Small filled circles: Ru. Large filled circles: Sn. Open circles: O.

cided in diffraction angle with the peak of the Ti/RuO₂ electrode though they were somewhat broader, probably because of the replacement of Ru site by Sn species without change of the RuO₂ crystal structure. However, the Ti/SnO₂(70)-RuO₂(30) electrode exhibits a specific diffraction peak which lies between the two peaks of SnO₂ and RuO₂. The change of the diffraction angle of the main peak with the composition is more clearly shown in Fig. 7. No diffraction peak was observed for the Ti/SnO₂(95)-RuO₂(5) electrode, indicating the destruction of the SnO₂ crystal structure. The alternative broad diffraction peaks appeared at the Ti/SnO₂(90)-RuO₂(10) electrode, and they became sharp gradually with increasing RuO₂ content up to 30 m/o. These suggest strongly that a new, somewhat distorted, crystalline structure, probably RuSn_2O_6 , is formed at the electrode with the composition of around SnO₂(70)-RuO₂(30) during the electrode preparation. From the analogy to triple-rutile structure of mossaite FeNb_2O_6 (16), the new crystal may be represented by the structure shown in Fig. 8, though further detailed studies are necessary.

In conclusion, the service life of the Ti/RuO₂ electrode can be prolonged by the presence of SnO₂ in the active layer with the optimal composition of around 70 m/o SnO₂ and 30 m/o RuO₂. This is probably due to the formation of a new crystalline but somewhat disordered RuSn_2O_6 , which leads to the depression of the anodic dissolution of the active layer, in addition to the increased smoothness and compactness of the active layer.

Application of Electrochemical Fluorination to the Synthesis of Perfluoroalkane Sulfonic Acid Electrolytes

Preparation of $F_2C(SO_3H)_2$

E. J. M. O'Sullivan*,¹

Department of Chemistry, Case Center for Electrochemical Sciences, Case Western Reserve University, Cleveland, Ohio 44106

F. W. Klink,** C. C. Liu,* and E. B. Yeager*

Department of Chemical Engineering, Case Center for Electrochemical Sciences, Case Western Reserve University, Cleveland, Ohio 44106

Perfluorinated alkane sulfonic acids have been receiving attention in the last few years as potential fuel cell electrolytes (1, 2). However, except for trifluoromethane sulfonic acid, acids of this class are not widely available, particularly the multifunctional compounds. Consequently, progress in the evaluation of the electrolyte properties of these acids has been impeded. Effective methods for the synthesis of attractive perfluorinated sulfonic acids are therefore needed which can generate appreciable quantities of these acids in a highly pure form.

Synthetic routes based on electrochemical fluorination (ECF) (3-7) in anhydrous hydrogen fluoride (AHF) are attractive for the preparation of perfluoroalkane sulfonic acids. Although the fluorination of alkane sulfonic acids cannot be carried out directly by ECF (3), Brice and Trott (8) and Gramstad and Haszeldine (9) showed that alkane sulfonyl halides (chlorides and fluorides) could be successfully fluorinated by this method to give perfluoroalkane sulfonyl fluoride products in fairly high yields. The perfluorinated sulfonyl fluoride products were converted to the corresponding acid salt by alkaline hydrolysis, the free acid then being obtained either by distillation from a solution of concentrated sulfuric acid and sulfonic acid salt, or by ion exchanging solutions of the salt (10).

In this paper, the electrochemical fluorination of methanedisulfonyl fluoride, $H_2C(SO_2F)_2$, to produce difluoromethanedisulfonyl fluoride, $F_2C(SO_2F)_2$, in high yields is described, along with the conversion of the latter compound to the disulfonic acid form. The formation of $F_2C(SO_2F)_2$ from $H_2C(SO_2F)_2$ via ECF has been reported previously (11). Methanedisulfonyl fluoride was selected as a substrate for ECF rather than the corresponding disulfonyl chloride since it has been established (9) that substrates containing the $-SO_2F$ group rather than the $-SO_2Cl$ group give higher yields of the perfluoroalkane sulfonyl fluoride compounds. Also, in the case of substrates containing a high ratio of $-SO_2Cl$ groups to C-H bonds there is the possibility of formation of undesirable C-Cl bonds in the course of electrolysis.

Experimental

The methanedisulfonyl fluoride reactant used in the electrochemical fluorination reaction was synthesized via a two-step process. In the first step, methanedisulfonyl chloride, $H_2C(SO_2Cl)_2$, was synthesized by a reaction involving acetic acid (Fisher, Reagent), chlorosulfonic acid (Pfaltz and Bauer, 99%), and phosphorous oxychloride (Fisher, Purified) as described by Fild and Rieck (12). In the second step, the $H_2C(SO_2Cl)_2$ was converted to $H_2C(SO_2F)_2$ by the action of potassium bifluoride (Harshaw, 97%) in acetonitrile (Fisher, 99%). Following removal of the precipitated KCl product by filtration, the $H_2C(SO_2F)_2$ was recovered by vacuum distillation. Typically, chemical yields of 70-75% were obtained by each of

these two reactions. Elemental analysis and proton and fluorine NMR confirmed the identification of $H_2C(SO_2F)_2$. This material was purified by further vacuum distillation, and its purity was found to be in excess of 98% by gas chromatography. The major impurities in the $H_2C(SO_2F)_2$ were $H_2C(SO_2Cl)_2$ and $H_2C(SO_2Cl)SO_2F$.

The electrochemical fluorination reaction was conducted in a Simon-type reactor (3) with a volume of 500 ml. The details of the cell design and support system have been reported previously (13). In a typical experiment, the reactor temperature was maintained at $10^\circ \pm 1^\circ C$ with the condenser kept at -50° to $-60^\circ C$. A 20 ml/min flow rate of nitrogen was maintained throughout the experiment in order to sweep away hazardous gaseous products. Typically, 450 ml of anhydrous hydrogen fluoride (AHF) was added directly to the cell and purified by pre-electrolysis at a constant cell voltage at 5.5V until the current decayed to a constant base-line value of $\sim 0.2 A/dm^2$. The purpose of this pre-electrolysis step, which was typically conducted for 12-18h, was to form the anodic nickel fluoride film and remove any water present in the AHF.

After the pre-electrolysis of the AHF, approximately 30g of $H_2C(SO_2F)_2$ was added to the cell, bringing the reactant concentration to 5% by weight. The cell was operated at a constant cell voltage of 5.5V with an average current density of $\sim 0.5 A/dm^2$. The electrolysis current remained relatively constant as long as the reactant was present and rapidly decayed when the last amount of reactant was consumed. New reactant was then added when the current decayed to the base-line value. A typical run duration was 150h. The fluorination product formed a separate heavy phase, which could be observed along with some solid corrosion products, at the bottom of the reactor when the agitation was turned off. A greenish-white corrosion product, presumably nickel difluoride (9), could also be observed loosely coating the anodes.

One of the methods employed for carrying out salt-to-acid conversions in the present work was electrodiolysis. A three-compartment PTFE cell was employed which used Nafion 117 membranes as separators. The Nafion membranes (proton version, 1100 eq weight, 0.007 in. thick) were cleaned in hot water, which was frequently changed, for at least two weeks prior to use. A solution of the sulfonate salt, $F_2C(SO_3Li)_2$, rather than the Ba salt, was placed in the central compartment. Solutions of LiOH (0.5M) and trifluoromethane sulfonic acid (1.0M) were placed in the cathode and anode compartments, respectively. Platinum gauze was used for the anode and cathode. Current densities of $10 A/dm^2$ with respect to the Nafion membranes were employed. In view of the rather high electric fields present across the membrane at such high current densities, diffusion of the bulky $F_3CSO_3^-$ ion from the anode compartment should be negligible. Similarly, back-diffusion of Li^+ ion from the cathode compartment should also be minimal.

Results and Discussion

At the completion of the electrolysis experiment, the cell and cell condenser were warmed to room tempera-

ture. To facilitate recovery of volatile products from the cell, which included the $F_2C(SO_2F)_2$, a cold trap consisting of coiled Monel tubing immersed in a Dry Ice/isopropanol mixture (temperature $\sim -73^\circ C$) was incorporated in the outlet gas stream from the condenser. HF and product material were simultaneously carried over from the warmed cell and condenser in a stream of N_2 gas and were collected in a flask of ice water placed at the outlet of the cold trap. The HF dissolved in the water, while the $F_2C(SO_2F)_2$ product was insoluble, forming a second, transparent layer at the bottom of the flask. Only a trace quantity of organic material remained with the corrosion products in the cell. The product recovered in the ice water trap was separated from the aqueous phase and washed further with water to remove traces of HF. No traces of color were exhibited by this product at any time.

Fractional distillation of the ECF product initiated at $56.5^\circ C$ and rose rapidly to a steady temperature of $57.2^\circ C$. A 250 ml round-bottom glass distillation flask was employed and operated at ambient pressure. In order to avoid any introduction of contaminants, no stopcock grease was used for the glass joints. Thermometers with ground glass joints were placed in both the still flask and at the entrance of the condenser. Only the product recovered at $57.2^\circ C$ was employed for the conversion to $F_2C(SO_3H)_2$. Fluorine NMR confirmed the structure of $F_2C(SO_2F)_2$ showing two triplets, one centered at -36.6 ppm relative to $CFCl_3$ and the other at 96.8 ppm. Proton NMR confirmed the absence of C-H bonds in the product, indicating the maximum C-H material presented was less than 5%.

The chemical yield of the ECF step was approximately 70%, with a product-recovered-based current efficiency averaging 44%.

Preparation of $F_2C(SO_3H)_2$ from $F_2C(SO_2F)_2$.—Various methods were explored for converting $F_2C(SO_2F)_2$ to the acid form. In general, perfluorinated alkane sulfonyl fluorides are readily hydrolyzed under alkaline conditions only (9). The hydrolysis of $F_2C(SO_2F)_2$ was found to be most effectively carried out using concentrated aqueous solutions of either $Ba(OH)_2$ or $LiOH$ since the relatively insoluble fluoride salt by-products, BaF_2 and LiF , respectively, could be separated from the hydrolysis mixtures by filtration. The stoichiometric equation for the $Ba(OH)_2$ hydrolysis reaction, for example, may be written as follows

The hydrolysis reactions were conducted at room temperature over periods of 1-2 days. In this step, the $F_2C(SO_2F)_2$ was added in a batchwise manner to the alkali solutions in FEP bottles. The additions were carried out in such a manner that the reaction temperature did not exceed $35^\circ C$. A slight excess of alkali was employed in order to insure complete conversion of sulfonyl fluoride functional groups to sulfonate groups. At the completion of the reaction, the insoluble fluoride salts were removed by filtration. The Ba or Li disulfonic acid salts were recovered from the filtrate after removal of the water using an aspirator.

Sulfate anion was detected in the hydrolysis solutions utilizing $LiOH$ as the hydrolyzing base. The odor of sulfur dioxide from the hydrolysis solutions has also been detected at the completion of the hydrolysis reaction. The sulfate was removed as $BaSO_4$ by the addition of barium hydroxide. The amount of sulfate formed during the hydrolysis reaction has been found to be 0.001-0.002 mol per mole of $F_2C(SO_2F)_2$. Sulfate was not present in the original $F_2C(SO_2F)_2$ and only to a very minor extent as an impurity in the $LiOH$. The sulfate is evidently generated by hydrolysis of the $F_2C(SO_3^-)_2$ anion.

Fabes and Swaddl (14) have reported that $F_3CSO_3^-$ oxidatively hydrolyzes quantitatively in alkaline solutions at $297^\circ C$, and suggested the following equation for the process

Perhaps a process similar to reaction [2] leads to the instability of the difluoromethane disulfonate even though the temperature did not exceed $35^\circ C$. A more likely process, however, is the oxidation of the disulfonate in alkaline solution by O_2 from the air. The disulfonate may be more susceptible to oxidative hydrolysis than the monosulfonate because the presence of two $-SO_3^-$ groups on one carbon leads to lower stability.

Various methods were explored for converting the disulfonic acid salts to the acid form, principally ion exchange and electro dialysis. A disadvantage of the electro dialysis method is the relatively long periods required (several days) to reduce the Li^+ content to very low levels (e.g., 2-3%) in the disulfonic acid material. Furthermore, despite extensive cleaning of the Nafion 117 membranes employed in the cell, cyclic voltammograms of smooth Pt electrodes recorded in $F_2C(SO_3H)_2$ solutions (e.g., 1.0M) prepared by this method indicated the presence of impurities, particularly in the hydrogen adsorption/desorption region. These impurities were also found to interfere severely with rotating ring-disk electrode measurements of O_2 reduction in these electrolytes. These impurities were not removed by pre-electrolysis methods or by treatment with hydrogen peroxide. Since the $F_2C(SO_2F)_2$ was highly purified prior to hydrolysis by multiple fractional distillations, it seems likely that a major portion of these impurities were generated during the further hydrolysis of $F_2C(SO_3^-)_2$. The $F_2C(SO_3Li)_2$ salt cannot be purified readily by recrystallization from aqueous solutions prior to being submitted to electro dialysis owing to its extremely high solubility. In general, the most effective method for purifying the newly prepared $F_2C(SO_3H)_2$ was found to be distillation of its dihydrate under reduced pressure (~ 0.3 torr air). Distillation also served to remove traces of salt remaining after electro dialysis.

Ion exchange was also investigated as a convenient method for converting $F_2C(SO_3Li)_2$ to the acid form. Amberlite IR 120 resin was employed after being washed extensively with ultrapure water. The ion exchange resin did not appear to degrade while it was in contact with the disulfonic acid, and essentially quantitative conversion of the salt to the acid was achieved. The disulfonic acid prepared by ion exchange was also subsequently purified by vacuum distillation of its dihydrate, and its composition was confirmed by elemental analysis. In the case of perfluoroalkane sulfonic acid salts, which can be purified by recrystallization, e.g., the potassium salts of tetrafluoroethane-1,2- and hexafluoropropane-1,3-disulfonic acids, the method of electro dialysis would be one of the methods which should produce purer acid than ion exchange methods (15), since the resin is a potential source of organic impurities.

Voltammetry of platinum.—Linear potential sweep voltammetry of smooth Pt in a N_2 (Matheson, 99.9995%) saturated solution provides a convenient qualitative check of electrolyte purity. Cyclic voltammograms of 0.5M $F_2C(SO_3H)_2$ and 1.0M H_3PO_4 are shown in Fig. 1. The disulfonic acid was purified by twice distilling the dihydrate under reduced pressure, while the phosphoric acid was carefully purified as described elsewhere (16). The voltammogram of the $F_2C(SO_3H)_2$ exhibits reasonably well-defined hydrogen and oxide film regions. The minor peak present at $\sim 0.75V$ vs. RHE (1 atm) in the anodic sweep increases slightly with sweep rate and becomes less pronounced at lower concentrations. It is probably an impurity peak. Overall, however, the voltammogram of $F_2C(SO_3H)_2$ indicates that this acid is reasonably pure.

There are some differences between the hydrogen and oxide regions of the voltammetric profiles of Pt recorded in the 0.5M $F_2C(SO_3H)_2$ and H_3PO_4 electrolytes. The onset of oxide formation in the anodic sweep occurs at ~ 70 mV more negative in the case of the sulfonic acid electrolyte relative to phosphoric acid. This is an indication of weaker adsorption on Pt by the sulfonic acid electrolyte relative to phosphoric acid. Also, as observed in the case

Fig. 1. Voltammograms of platinum in purified 0.5M $F_2C(SO_3H)_2$ (solid line) 1.0M H_3PO_4 (dashed line) at 25°C, N_2 saturated, sweep rate = 25 mV/s.

of weakly adsorbing acids (17), e.g., $HClO_4$, the peak current for the strongly adsorbed form of hydrogen on Pt at ca. 0.25V is lower for the $F_2C(SO_3H)_2$ than for the H_3PO_4 . The absence of significant adsorption behavior on electrode surfaces such as platinum is a desirable property for acid fuel cell electrolytes.

Conclusions and Future Works

Electrochemical fluorination of methanedisulfonyl fluoride in AHF is a viable route for the production of difluoromethanedisulfonyl fluoride. High yields are obtained by this method, and it is anticipated that a variety of other perfluoroalkane sulfonyl fluorides may be prepared in this manner. We have recently constructed a new electrochemical reactor system with a three-electrode configuration, improved agitation, and a more uniform current density distribution. We believe these improvements will increase the yield and permit use of higher current densities.

The physicochemical properties of $F_2C(SO_3H)_2$, e.g., conductivity and vapor pressure, are being characterized. The dihydrate does not wet Teflon above its melting point ($\sim 70^\circ C$). Studies of O_2 electroreduction on platinum using rotating ring-disk and gas-diffusion electrode tech-

niques are also in progress and will be reported. The stability of $F_2C(SO_3H)_2$ will also be checked, particularly at elevated temperatures.

In Situ Spectra of Intermediate Species Recorded during Electrochemical Reduction of p-Benzoquinone

Chong-Hong Pyun* and Su-Moon Park**

Department of Chemistry, University of New Mexico, Albuquerque, NM 87131

p-Benzoquinone has been studied extensively photochemically and/or electrochemically due to its importance as an electron acceptor in many chemical as well as biological reactions. It is generally recognized to undergo an electrochemical-chemical-electrochemical (ECE) reaction when reduced in nonaqueous media (1-6), i.e.

where BQ represents p-benzoquinone. Rates of chemical steps, i.e., reactions [2] and [4] have not been reported in nonaqueous solutions, but are slow enough for a nearly complete reoxidation peak for the anion radical to be observed on cyclic voltammetric scales. The apparent decay rate of $BQ^{\bullet -}$ was reported by Fukuzumi *et al.* (7) to be $5.7 \times 10^{-3} \text{ min}^{-1}$ in neutral water at room temperature with first-order kinetics. The second-order disproportionation rate of $BQ^{\bullet -}$, i.e.

is, however, reported to be 1.7×10^8 and $1.1 \times 10^9 \text{ M}^{-1}\text{s}^{-1}$ at pH = 7.2 and 2, respectively, in water by Adams and Michael (8). This disparity indicates the complexity of the

chemistry of p-benzoquinone anion radicals. We believed that a half-life of about 2h for $BQ^{\bullet-}$ in water as reported by Fujuzumi *et al.* (7) was excessively long.

Spectra of intermediate species including $BQ^{\bullet-}$ and BQH^{\bullet} have been studied using either pulse radiolysis (8-12) or by oxidation of hydroquinone (BQH_2) with solid oxidants such as MnO_2 in water (7). The medium was either water (pure or buffered) or a water-isopropylalcohol (up to 3M) mixture. These media are often saturated with N_2O to scavenge radical species produced upon pulse radiolysis, which may lead to some unknown side reactions. Iso-propylalcohol was used to remove any intermediate radical species other than OH^{\bullet} . Attempts at recording transient spectra *in situ* in an electrochemical cell under well-controlled conditions have been made (5, 6), but to the best of our knowledge no such spectra have been recorded using spectroelectrochemical methods with controlled amounts of proton donors.

In this communication, we report the spectra of intermediate species electrogenerated in dimethylsulfoxide (DMSO) solution using near-normal incidence reflectance spectroelectrochemistry (NMIRS). We believe we recorded spectra for all the intermediate species, *i.e.*, $BQ^{\bullet-}$, BQH^{\bullet} , and BQH^- .

Eastman Organic's reagent-grade p-benzoquinone was used after recrystallization from water. Mallinckrodt's reagent-grade DMSO was used after fractional distillation with a reflux ratio of 5:1 under the reduced pressure. Tetra-n-butylammonium perchlorate (TBAP; Southwestern Analytical, Incorporated, Austin, Texas) was used as a supporting electrolyte after drying for 24h at about 100°C. The spectra were recorded at a reflective platinum disk electrode (Sargent Welch S-30101-20A) using a bifurcated optical fiber probe. The spectroelectrochemical system was controlled by an Apple II+ microcomputer. Details of the instrumentation are described elsewhere (13). Cyclic voltammograms were recorded with a Princeton Applied Research (PAR) Model 173 potentiostat-galvanostat along with a PAR Model 175 universal programmer.

Cyclic voltammograms (CV's) shown in Fig. 1 indicate that the anion radical produced upon negative potential sweep is very stable. When water is added to this electrochemical system, practically the same reversible CV is obtained with a prewave due to the enhanced adsorption at the electrode surface. The adsorbed species is stripped off with one scan, leaving the following electron transfer practically reversible (Fig. 1b). This illustrates that the electrogenerated anion radical is fairly stable, even at a reasonably high concentration of the proton donor. Similarly, one can conclude from the CV's shown that the rate of protonation is fairly slow even in solutions containing water.

The spectrum of the anion radical, $BQ^{\bullet-}$, recorded after 11 min of electrolysis in "dry" DMSO, is shown in Fig. 2a. This spectrum was recorded while electrolysis was proceeding. To compensate the amount of the $BQ^{\bullet-}$ building up in the probe path, the wavelengths were scanned up and down, and the average value of the two was used. The data acquisition time was approximately 5 min.

The spectrum shown in Fig. 2a has exactly the same features as in those recorded in water (7-12), except that the absorption bands are red shifted by about 30 nm in DMSO. We believe that the spectral blue shift observed in the aqueous medium is due to the hydrogen bonding to the benzoquinone carbonyl groups, as was observed in the 9,10-anthraquinone system (14). To confirm this, we ran an experiment in water with 0.20M $NaClO_4$ as a supporting electrolyte; exactly the same spectrum as shown in Fig. 2a was observed. The spectrum in water, however, showed about 32 nm of blue shifts. Furthermore, the anion radical was reasonably stable. To our surprise, the anion radical spectra were observed even after more than 30 min after its generation by controlled potential electrolysis. The absorption maxima are believed to arise from the $\pi-\pi^*$ transition, and spectral features are due to the C—O stretching vibration in the excited state (15).

Fig. 1a: Cyclic voltammogram (CV) recorded in a solution containing 1.87 mM p-benzoquinone and 0.10M TBAP in "dry" DMSO. b: CV recorded in a solution containing 1.21 mM p-benzoquinone, 0.10M TBAP, and 10.0% H_2O in DMSO. The reference electrode was a Ag wire, and the scan rate was 100 mV/s for both experiments.

When further electrolysis is performed under the same condition, the spectrum shown in Fig. 2b is obtained. One can notice in this spectrum that the absorption bands at 427 nm and at about 670 nm are growing. This effect is more pronounced when the electrolysis is carried out in DMSO containing 10.0% H_2O even at a much shorter electrolysis time. Note also that the spectral bands show 4 ~ 5

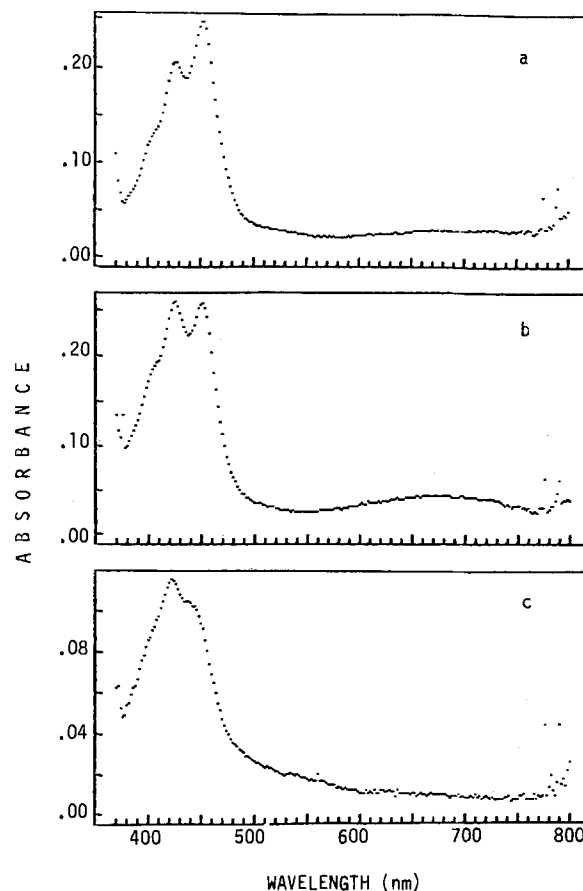

Fig. 2a: Absorption spectrum recorded after 11 min of electrolysis for the solution containing 1.87 mM p-benzoquinone at $-0.68V$ vs. Ag wire electrode. b: Absorption spectrum recorded after 36 min of electrolysis for the same solution as in a. c: Absorption spectrum recorded after 3 min of electrolysis for the solution containing 1.21 mM p-benzoquinone and 10.0% H_2O at $-0.62V$.

Fig. 3a: Difference spectrum obtained from those shown in Fig. 2b and 2a. b: Difference spectrum obtained from the solution containing 1.21 mM p-benzoquinone and 10.0% H₂O for electrolysis times of 8 and 19 min, respectively. c: Spectrum recorded with the circuit open after 30 min of electrolysis for the solution used in Fig. 3b.

nm blue shifts in Fig. 2c compared to those shown in Fig. 2a due to the addition of water. When the difference between the spectra shown in Fig. 2b and 2a is taken, a spectrum shown in Fig. 3a is obtained. The same spectra as in Fig. 3a are also obtained when differences are calculated from those shown in Fig. 2c and 2a. This indicates that the process producing a species responsible for the spectrum in Fig. 3a is facilitated by the presence of water. Note that this process is already occurring in "dry" DMSO but the rate is much slower. Thus, we attribute the spectrum in Fig. 3a to the free radical generated upon protonation of the anion radical, which is formed at the top of the diffusion layer. We believe that the broad band at about 670 nm is perhaps also from the free radical. For several spectra that we obtained, almost constant ratios of the absorbance at 410 nm to that at 670 nm were observed, indicating that both absorption peaks came from the same source. One may speculate, however, that the absorption band at 670 nm may have resulted from the intermediate dimer formed from the free radical. The presence of such a dimer was speculated by Eggins and Chambers from their cyclic voltammetric studies (5).

The absorption spectrum of the free radical, BQH•, was reported by Adams and Michael (8). They produced this species by generating anion radicals in water of pH = 2.0. The assumption was that anion radicals produced protonate quickly to produce free radicals at low pH's. The spectrum recorded at pH = 2.0 had similar spectral features to the one recorded at a neutral pH, but had its absorption maximum at about 410 nm. In our spectrum,

the blue shift of the free radical with respect to that of the anion radical is more extensive than in Adams and Michael's observation. This could perhaps be due to the solvent/supporting electrolyte effects. The transition of the benzoquinone anion radical should be affected by the solvent polarity more than that of the free radical, which does not carry any charges on it.

Also noticed in this spectrum (Fig. 3a) is the presence of an absorption band at about 500 nm. This band grows significantly enough to give a band broadening as shown in Fig. 3b, when the water content becomes high. When the electrical circuit is open, we notice that the absorption peak at about 500 nm grows at the expense of the one at 410 nm, as shown in Fig. 3c. Eventually, all the transient absorption peaks disappear, and the final solution is dominated by the absorption peaks attributable to the final product, hydroquinone (BQH₂). Of course, this happens only when the exhaustive electrolysis is performed. This series of spectroscopic observations indicate that there are no final products detectable other than hydroquinone. Thus, we believe that the absorption band observed at about 500 nm is due to the protonated anion (BQH⁻) in reaction [3]. An attempt to obtain the spectrum of BQH⁻ by deprotonating BQH₂ in strong alkaline medium was not successful; the deprotonation reaction was accompanied by the oxidation of BQH₂ as well. Although the spectra of intermediate species were assigned mostly from the sequence of reactions summarized by [1]-[4], they are in good agreement with those reported for BQ• and BQH• obtained under quite different experimental conditions. The spectrum for BQH⁻ has not been reported to the best of our knowledge.

We conclude from the current spectroelectrochemical study that we observed transient spectra corresponding to the anion radical (BQ•), protonated free radical (BQH•), and protonated anion (BQH⁻) species. Surprisingly, as already pointed out, the electrogenerated BQ• is reasonably stable even in neutral water as was originally observed by Fukuzumi *et al.* (7). Perhaps the benzoquinone anion radical generated by pulse radiolysis (8-12) may not be stable due to the host of other reactive intermediate species produced along with the desired product. Particles of very high energies are employed in pulse radiolysis. Further work on the solvent effect on the spectra, effect of water, and the rate of decay of each intermediate species is in progress in our laboratory.

Investigation of Photoelectrode Redox Polymer Junctions

Ronald L. Cook* and Anthony F. Sammells*

Eltron Research, Incorporated, Aurora, Illinois 60505

There are several incentives for the characterization of semiconductor junctions with redox containing solid polymer electrolytes (SPE). An understanding of such junctions can be expected to have important implications on the design of solid-state photoelectrochemically rechargeable galvanic devices possessing charge capacity. In addition, the presence of polymer-incorporated redox species in close proximity to the semiconductor surface may act as an antenna probe for measuring perturbations in interbandgap surface states when the junction is exposed to selected chemical species.

We have previously shown the viability of such junctions for the storage of photogenerated electrochemical energy (1, 2). Here, solid-state cells based upon both poly(ethylene oxide) and Nafion¹ as SPE's have been shown to be potentially attractive for energy storage. A recent example discussed by us is the two photoelectrode cell

$p/\text{InP}/\text{Fe}^{+3}$ porphine/Nafion 117/ Ru^{2+} (bpy)₃/ $n\text{-CdS}$

which has been shown to generate photopotentials in excess of 1V upon simultaneous AM1 illumination of both photoelectrodes, using the above electrochemically reversible redox couples (2). In addition, semiconductor films deposited onto appropriate substrates have been found promising, via the use of impedance techniques, for the detection of gases such as CO (3-5).

For electrochemical energy storage, the redox polymer phase should, in principal, possess the following properties: (i) the redox species must be fixed into a relatively immobile polymer site so that any self-diffusion resulting in spontaneous self-discharge would be eliminated; (ii) the immobilized redox species must retain some electrochemical reversibility; and (iii) an excess concentration of mobile conducting species should be present in the vicinity of the redox couple, over and above that normally necessary for ionic conduction, to preserve electroneutrality in the proximity of the immobilized redox species during redox electrochemistry. The perfluorinated cation exchange material Nafion was selected as a candidate SPE material whose properties may address these criteria (6-9).

Photoelectrochemical (PEC) cells using $n\text{-CdS}$ as a photoanode and Nafion 117 as the SPE were prepared and doped with a variety of transition metal complexes of varying redox potentials and overall molecular charge (+2, 0, -1). The role of such introduced redox species for perturbing photoelectrode properties was of interest both for understanding conditions which promote electron transfer for charge (or discharge) in solid-state PEC storage devices, and also for understanding their role in changing semiconductor properties which might facilitate the use of this junction for various detector applications.

Experimental

$n\text{-CdS}$ single crystals were obtained from Cleveland Crystals, Incorporated, and were initially polished with 600 grit emery paper, followed by 5 μm alumina on a Texmet polishing cloth and finally with 0.3 μm alumina on a Microcloth polishing cloth. The ohmic contact area was initially etched with a solution of $\text{HNO}_3:\text{H}_2\text{SO}_4:\text{HOAc}:\text{HCl}$ (30:20:10:0.1) for 20s. Ohmic contact was achieved by introduction of a gallium-indium eutectic onto the etched CdS face. Current collection was achieved via a Nichrome wire using a silver epoxy, which was cured at 150°C for 1h. Immediately prior to fabrica-

* Electrochemical Society Active Member.

¹ Nafion is the registered trademark for a family of perfluor-sulfonic acid ion-exchange membranes manufactured by E. I. du Pont de Nemours and Company.

tion of the cell, the front face was polished with 5 and 0.3 μm alumina, rinsed, and the face etched with $\text{HNO}_3:\text{H}_2\text{SO}_4:\text{HOAc}:\text{HCl}$ solution as above.

Electrochemical measurements were performed using potentiostatic control provided by either a Stonehart Associates BC 1200 or a Wenking LT 78 potentiostat. Differential capacitance measurements for Mott-Schottky plots were performed using a H-P 4276A digital LCZ meter at 1000 and 10,000 Hz. Thin film coatings of gold and silver were vacuum-deposited on glass slides with an Edwards 306A evaporator. Photoelectrode illumination was achieved via a Sylvania 300W ELH bulb. Light intensities were measured with an Eppley 8-48 pyranometer. Cyclic voltammograms on the redox couples were run in acetonitrile (Burdick and Jackson) with tetrabutylammonium hexafluorophosphate (Southwestern Analytical Chemicals, Incorporated) as supporting electrolyte. A three-electrode configuration consisting of a platinum working electrode, a platinum counterelectrode, and a Ag/Ag^+ reference electrode was used for the cyclic voltammetry scans.

Results and Discussion

Cell preparation.—Solid-state PEC cells were fabricated by introducing 0.05 ml of a solution containing 50 mg/ml of Nafion 117 and 0.5 mg/ml of the appropriate redox couple in a solution of lower aliphatic alcohols onto the surface of a $n\text{-CdS}$ photoanode and a glass slide possessing both an evaporated gold counterelectrode and silver quasi-reference electrode. The Nafion was allowed to dry partially for 15 min on each of these surfaces, after which the two half-cells were pressed together and allowed to dry for an additional 2h. The cell configuration used in this work is shown in Fig. 1. The transition metal complexes selected for introduction into the Nafion polymer included FeCp_2 , $\text{Ru}(\text{bpy})_3^{2+}$, $\text{Fe}(\text{bpy})_3^{2+}$, $\text{Fe}(\text{CN})_6^{4-}$, and $\text{Fe}(\text{acac})_3$. These complexes were selected to provide for both a variation in overall molecular charge and chemical potential at localized sites within the Nafion polymer. Several films were initially cast onto Teflon substrates and allowed to dry. Upon removal and visual examination of these films (40 \times magnification), the polymer con-

Fig. 1. Schematic diagram of cell configuration used in this work

taining $\text{Ru}(\text{bpy})_3^{2+}$ was yellow and homogeneous. For concentrations of $\text{Ru}(\text{bpy})_3^{2+}$ up to 20 mg/ml SPE, the polymer remained homogeneous in appearance. Similar observations were made when $\text{Fe}(\text{bpy})_3^{2+}$ was introduced into the polymer.

In comparison, ferrocene, was in fact insoluble at concentrations greater than 1 mg/ml of the SPE, as manifested by its appearance as microcrystalline needles upon solvent removal from the polymer. Similar observations were made when $\text{Fe}(\text{acac})_3$ was introduced into the polymer. The anionic complex $\text{Fe}(\text{CN})_6^{4-}$ remained homogeneous at concentrations up to 2 mg/ml SPE.

Photoelectrochemical measurements.—To gain some preliminary insight into the respective PEC characteristics of the SPE cell when the redox species FeCp_2 , $\text{Ru}(\text{bpy})_3^{2+}$, $\text{Fe}(\text{CN})_6^{4-}$, and $\text{Fe}(\text{acac})_3$ are present in the proximity of semiconductor/SPE junctions, cells possessing the general configuration n-CdS/SPE + redox species/Au were prepared using the procedures discussed above. The initial photopotentials realized from these cells under simulated AM1 illumination conditions are compared in Table I. As can be seen, these photopotentials (which are mainly around 200 mV) appear to be relatively invariant when compared to, for example, $E_{1/2}$ values for the same redox species in acetonitrile using a platinum electrode, e.g., FeCp_2 (0.285V vs. Ag/Ag^+), $\text{Ru}(\text{bpy})_3^{2+/3+}$ (1.25V vs. Ag/Ag^+).

Although this was initially thought explainable by the presence of Fermi level pinning by the n-CdS, it was later observed that photopotentials for $\text{Ru}(\text{bpy})_3^{2+}$ -modified SPE-PEC cells were in the -500 to -600 mV range when SnO_2 conducting glass was used as the counterelectrode. This result suggests that the photopotentials observed in the CdS/Nafion + redox couple/Au system may have been limited by inadequate interfacial contact between the Nafion polymer and the gold counterelectrode. Such interfacial contact limitations have previously been reported using Nafion/ WO_3 -based SPE electrochromic devices (10). SnO_2 , however, shows significant adhesive strength attributable to covalent bonding between the sulfonic acid groups in the SPE and receptive functional groups on the SnO_2 substrate electrode (11). Thus, the increased photopotentials observed for n-CdS/SPE cells using SnO_2 conducting glass counterelectrodes can, in part, be explained by improved interfacial contact with the Nafion polymer at the counterelectrode.

In order to determine the dependency of the SPE-incorporated redox species concentration on the photopotential of n-CdS/Nafion + $\text{Ru}(\text{bpy})_3^{2+}$ /conducting glass, SPE cells, $\text{Ru}(\text{bpy})_3^{2+}$ concentrations were varied between 0.0004g and 0.006 g/ml/SPE and their photopotentials under 100 mW/cm² illumination compared. As can be seen from Table II, the photopotentials for this system were not dependent on the concentration of the incorporated redox species over the concentration range studied, thereby indicating that the double layer present at the semiconductor/SPE junction was invariant under these experimental conditions. If significant perturbation of the double-layer region were to have occurred, however, this might have influenced the photopotential observed by changing the space charge region width and the corresponding barrier height.

For cells based upon the proton conducting SPE, generally low currents were observed which were attributed

to the poor conductivity of this polymer when used in solid-state cells. However, substitution of Na^+ for H^+ conductivity in the SPE/alcohol mixture before polymer formation on the semiconductor substrate was found to enhance overall ionic conductivity of the final solid-state cell. Figure 2 shows a current-voltage PEC curve for the cell n-CdS/SPE: FeCp_2 : NaCl/Au . Overall cell resistance was found to be 14 k Ω , and a current density of 25 $\mu\text{A}/\text{cm}^2$ could be obtained by applying a 300 mV anodic overpotential to the photoanode.

Capacitance measurements.—For cells prepared in this work, differential capacitance measurements were performed on n-CdS/redox SPE junctions, to determine if there was any sensitivity of the measured n-CdS flatband potential to the redox species introduced into the Nafion polymer. Figure 3 compares differential capacitance measurements performed on n-CdS junctions with the proton conducting SPE, (i.e., no introduced redox species) and the SPE's containing $\text{Ru}(\text{bpy})_3^{2+}$ and $\text{Ru}(\text{bpy})_3^{2+} + \text{FeCp}_2$, performed at 1000 Hz. These C_{sc}^{-2} vs. V plots show good linearity even though some of the cells possessed a relatively high resistance. Some frequency dispersion was noted at higher frequencies. Deviations from linearity for such plots might be expected if there is a high electrolyte resistance in series with the semiconductor space charge region or if a high population of surface states is present at the semiconductor/electrolyte interface (12). Results obtained from both current-voltage curves and the application of an ac signal to the cell suggested that some degree of rectification may be present at the semiconductor/SPE interface. Here, the ac signal from a signal generator was introduced through the cell and a measuring resistor. The output current as measured across the resistor was fed into an oscilloscope. The negative half of the sine wave was only two thirds the height of the positive half of the sine wave. This suggested that

Fig. 2. Current-voltage relationship for the cell n-CdS/Nafion: FeCp_2 : NaCl/Au

about 30% rectification was present in the cell. It should be noted that for semiconductor/metal oxide solid-state junctions where current rectification is seen, linear Mott-Schottky plots have been obtained (12).

Since good linearity and reproducibility were obtained from C_{sc}^{-2} vs. V plots in work reported here, it was of interest to compare measured n-CdS flatband potentials (V_{FB}) as a function of the introduced redox species. For the undoped proton, conducting SPE, V_{FB} was $-0.43V$ vs. the silver reference electrode. Upon the introduction of Ru(bpy)₃²⁺ or FeCp₂ into the SPE, the n-CdS flatband potential was shifted progressively in a cathodic direction [$V_{FB} = 0.151V$, Ru(bpy)₃²⁺, $V_{FB} = 0.097V$, (FeCp)₂]. This cathodic shift is consistent with that for the oxidation potentials seen for Ru(bpy)₃²⁺ ($E_{1/2} = 1.25V$ vs. SCE) and FeCp₂ ($0.285V$ vs. SCE) in acetonitrile. Similar cathodic shifts have also been observed in the cells n-TiO₂/Nafion + redox couple/SnO₂ conducting glass and n-TiO₂/polyamps² + redox couple/SnO₂ conducting glass.

Such changes in V_{FB} may be due to modifications at the electrode surface induced either by direct adsorption of the redox couple or to variations in the capacitance associated with the polymer itself upon changing the redox species. Currently experiments are being performed by us to identify the origin of such observed V_{FB} shifts upon varying the introduced redox couple. If, in fact, the shift in V_{FB} is directly dependent in part on the redox potential of the introduced redox couple, then such semiconductor/SPE junctions might form the basis of a detector technology. For example, an introduced gas or chemical species might be expected to modify the immediate chemical environment of the SPE-incorporated redox couple and thus give detectable parametric changes (e.g., V_{FB}) at the semiconductor surface.

For the n-CdS/redox SPE solid-state junctions considered here, changes occurring in the Helmholtz double-layer voltage V_H as a result of varying redox species can result in perturbation of the semiconductor bandedge en-

ergy. This can be expected by consideration of the relationship

$$V_{FB} = E_{sc}^0 - \mu + V_H$$

where μ is the difference in energy between the bulk conduction bandedge and the Fermi level, and V_H is the Helmholtz double-layer voltage. When a redox-containing surface is introduced onto a semiconductor, three possibilities can be envisioned for perturbing V_H : (i) the presence of interface states at the junction may induce a voltage drop across the polymer that may be indistinguishable from a Helmholtz voltage; (ii) if the polymer is insulating, the point of zero charge (PZC) will be different than that for the bare semiconductor resulting in perturbation of V_H ; and (iii) if electron exchange can occur between semiconductor surface states and polymer-incorporated redox species, then the former will define V_H and thus V_{FB} .

Donor surface states are expected near the valence band and acceptor states near the conduction band. If the E_{redox} for a redox species is below the donor state, or above the acceptor state, then the energetics will promote charging of surface states and thus change V_{FB} . Work is currently being performed directed towards clarifying which of these effects influences V_{FB} at n-CdS/SPE interface. It is not clear at this time, however, which of these mechanisms is responsible for the observed shift in the n-CdS flatband potential.

In conclusion, (i) it has been observed that the measured flatband potential in the described cells can be modified by introduction of selected redox species into the SPE, (ii) photopotentials in the range 500-600 mV can be obtained if good interfacial contact is maintained at both the working and counterelectrode, and (iii) the photopotentials obtained in the n-CdS/Nafion 117 + Ru(bpy)₃²⁺ conducting glass SPE cells are not dependent on the concentration of the incorporated redox species.

Rapid Isothermal Fusion of PSG Films

ABSTRACT

This paper presents results on rapid isothermal fusion (RIF) characteristics of phosphosilicate glass (PSG) obtained using an incoherent lamp annealer in a N_2 ambient. The effects of varying the temperature (1000°-1200°C), the cycle duration (10-60s), and the phosphorus concentration in the glass (2.5-8.0 w/o) were investigated. The out-diffusion of phosphorus from the PSG films during RIF cycles were also studied. In conjunction with these experiments, dopant redistribution induced by typical RIF cycles in a boron-implanted silicon substrate was measured to assess the practicality of the RIF technique for VLSI applications and to identify a process window. The results for the boron profile redistribution were used as a basis of comparison between RIF and conventional furnace treatments. Although restricted to VLSI applications where a relatively high phosphorus content of approximately 8 w/o is acceptable in PSG films, it is concluded that RIF in a N_2 ambient is nevertheless much more effective for the fusion of PSG films than conventional furnace processing and thus much more compatible with VLSI processing.

As a part of the fabrication sequence for integrated circuits, a layer of phosphosilicate glass (PSG) is deposited to provide passivation and electrical insulation between metal interconnects and underlying structures. Before the subsequent deposition of metal takes place, it is necessary to smooth the surface topography to ensure continuity of the overlying metallization. At present, this treatment is typically a furnace glass fusion cycle at 1000°C for 30 min or more (1-5) and is the last high temperature process step in the fabrication of LSIC's. This heavy thermal load will be unacceptable for processing new generations of VLSI circuits because it will induce appreciative lateral and vertical dopant redistribution in small geometry devices.

Thermal processing requirements can be eased by using different materials or ambients during the fusion cycle. Although increasing the phosphorus concentration does lead to a lower fusion temperature for PSG films, excessive concentrations eventually promote the formation of phosphoric acid in the presence of moisture (2, 4), thereby causing reliability problems due to corrosion of overlying aluminum interconnect lines. As an alternative solution, rapid isothermal fusion (RIF) has been shown in limited studies to improve PSG step coverage, while causing less junction diffusion than conventional furnace processing cycles because of its lower time-temperature product (6-9).

In this work, we have studied the effect of RIF on PSG films having a practical range of phosphorus concentrations, namely, 2.5, 4.0, 6.6, and 8.0 w/o. The RIF experiments were performed in a N_2 ambient using a tungsten halogen lamp system.³ In addition, the out-diffusion of phosphorus from the PSG films during RIF was examined.

The amount of dopant diffusion induced by RIF in underlying device junction areas will largely determine its range of usefulness for VLSI applications (6-12). There-

fore, boron-implanted silicon wafers were also processed separately and junction depths were measured after undergoing typical RIF cycles. Finally, fusion and dopant redistribution experiments were carried out in a conventional furnace and the results were compared with the RIF data to assess the relative applicability of each technique to VLSI processing.

Experimental Procedures

Sample preparation.—The test structure used to observe PSG fusion is illustrated in Fig. 1. A thermal SiO_2 layer was first grown on a Si(100) substrate to a thickness of 100 nm, at a temperature of 1000°C. A 1.0 μm LPCVD polysilicon film was deposited at 625°C and phosphorus-doped with a $POCl_3$ cycle at 900°C. The polysilicon was then patterned into sharp steps using a dry etching technique. Finally, 1.0 μm thick PSG films were deposited in a horizontal, hot-wall LPCVD system at a temperature of 410°C using the silane and phosphine oxidation process.

Samples for studying dopant redistribution in silicon were formed by first growing a 40 nm thermal oxide on (100) n-type Si substrates. Boron was then implanted through this oxide layer with a dose of $3 \times 10^{15} B/cm^2$ at an energy of 25 keV.

Rapid isothermal fusion.—The fusion cycles were carried out in a commercially available tungsten halogen lamp systems. Cycle durations were varied from 10 to 60s and temperatures from 1000° to 1200°C. The RIF experi-

Fig. 1. Test structure for RIF studies, showing the step coverage angle θ . The PSG film is 1.0 μm thick, the polysilicon step is 1.0 μm high, and the thermal oxide thickness is 100 nm.

ments were performed in a N_2 ambient. The temperature was controlled using feedback from a Chromel-Alumel thermocouple attached to a silicon test piece situated to the side of the wafer.

Junction dopant redistribution.—Boron-implanted silicon wafers were subjected separately to rapid isothermal annealing (RIA) cycles identical to some of those used in the RIF experiments. Other implanted samples were subjected to an 80 min, 900°C annealing cycle in 1 atm of N_2 , performed in a conventional furnace.

Analysis.—To quantify the extent of the fusion, SEM cross-sectional micrographs were used to measure the change in the PSG step coverage angle θ , with an accuracy of $\pm 5^\circ$. In order to measure the angle θ with the SEM, the samples were cleaved and given a decorative etch for 1 min in 50:1 buffered HF to delineate the underlying polysilicon/PSG interface. The phosphorus concentration of the PSG films was determined with energy dispersive x-ray (EDX) electron microprobe analysis to within ± 0.2 w/o.⁴ For an electron-beam energy of 6 keV, a value of 600 (± 60) nm was calculated for the probing depth.

The dopant redistribution in the implanted silicon samples was evaluated using secondary ion mass spectroscopy (SIMS) and a "bevel-and-etch" (B&E) technique. The B&E method relies on the larger etch rate of doped silicon relative to undoped silicon in certain etchants. By using this property on a beveled ($\sim 1^\circ$ - 2°) implanted silicon substrate, the junction area can be delineated interferometrically and related back to the actual junction depth. SIMS measures both active and inactive impurity concentrations, *i.e.*, the metallurgical junction depth, while the B&E technique yields a measure of the depth of active dopants, *i.e.*, the electrical junction depth.

Results and Discussions

Rapid isothermal fusion.—A summary of the complete RIF results is given in Table I. For all phosphorus concentrations investigated, the control (*i.e.*, as-deposited) PSG samples showed a typical step coverage angle θ of approximately 80° . Representative results obtained after RIF for a range of initial phosphorus concentrations $[P]_0$ are shown in the SEM micrographs of Fig. 2. For all but the 8.0 w/o PSG films, a temperature of 1200°C and/or a 60s cycle duration is needed to obtain substantial PSG fusion (*i.e.*, $\theta \geq 110^\circ$).

Results for 8.0 and 6.6 w/o PSG films are shown in Fig. 3 and 4, respectively. For these films, an 1100°C/10s RIF cycle is sufficient to obtain a value of 113° for θ (Fig. 3c). It would seem quite plausible that by increasing either the RIF cycle duration to 60s or the temperature to 1200°C, further fusion will be obtained. Unfortunately, the SEM micrograph of Fig. 3d shows that large voids form on each side of the step as a consequence of these extreme RIF treatments. For the 6.6 w/o films, the SEM micrographs of Fig. 4 show similar results, except under more severe RIF conditions.

The formation of voids has been observed previously, although their presence was largely attributed to the use

⁴ Calibration was obtained using colorimetric analysis performed at Balazs Laboratory, Mountain View, California.

of a H_2 ambient (13). In that study, it is argued that the presence of phosphorus in the glass, in the form of phosphorus pentoxide (P_2O_5), is also directly responsible for

the formation of voids. This conclusion is supported by our findings, since an enhancement in void formation was observed with an increase in the phosphorus content of the PSG films.

Because P_2O_5 sublimates at a temperature of about 300°C , a sufficient local concentration of P_2O_5 could, under the right conditions, lead to the formation of cavities in the glass. In the case of RIF, accelerated sublimation of the P_2O_5 may result from the rapid heat-treatment which would not allow sufficient time for the P_2O_5 to diffuse slowly out of the film without creating a permanent deformation of the softened PSG. The reasons for which the conditions favoring the formation of voids are found only on the sides of steps are not clear. To our knowledge, the only experimental evidence suggesting different glass properties in these regions comes from the faster etch rate observed on each side of steps for as-deposited oxide films, after the cross-sectional decorative etch of cleaved samples has been performed for the SEM examination. As a result, diagonal etch lines, visible in the SEM micrograph of Fig. 3a, are formed in the glass on each side of the polysilicon steps. RIF inhibit the occurrence of these etch lines, as seen in the micrographs of Fig. 3. Although the severity of these etch lines is observed to decrease proportionally with the nominal phosphorus content in the layer, they still remain for undoped glass films. Therefore, a localized structural property which does not depend entirely on the presence of phosphorus, such as a different glass density or stress level, could also be involved in the formation of voids. More work is needed to understand the mechanisms of such localized void formation.

Phosphorus out-diffusion.—Some loss of phosphorus from the PSG films occurs during RIF treatments, as can be inferred from the initial phosphorus concentrations $[P]_0$ and the final concentrations $[P]_t$ detailed in Fig. 2 and 3. Since only the top half of each PSG film was probed with EDX during the phosphorus analysis, it can be concluded that the observed changes in phosphorus concentration were likely caused by out-diffusion to the ambient. These results can be plotted to extract useful information on the diffusion of phosphorus in PSG during RIF.

If we assume that the probing depth d_p (600 ± 60 nm) for the EDX electron microprobe analysis of phosphorus in the PSG films is much larger than the diffusion length $(Dt)^{1/2}$, the reduction in phosphorus concentration $\Delta[P]$, lost to the ambient out of the original concentration $[P]_0$, is given by (14)

$$\Delta[P]/[P]_0 \approx (2/d_p)(Dt/\pi)^{1/2} \quad (1)$$

where D is the diffusion coefficient for phosphorus in SiO_2 and t is the time. In Fig. 5, we plot the expression $\Delta[P]/[P]_0 t^{1/2}$ against $1/T$, which should also vary with $D^{1/2}$, to find an Arrhenius relationship, described by $D = D_0 \exp(-E_D/kT)$. Only data for $[P]_0 = 6.6$ and 8.0 w/o were used, since for these cases alone was the loss $\Delta[P]$ sufficiently greater than the experimental error. An activation energy $E_D = 2.24 \pm 0.28$ eV, which is twice the slope of the line fit in the plot shown in Fig. 5, was determined. For example, a value of $D = 8.5 \pm 2.3 \times 10^{-13}$ cm^2/s is calculated at 1100°C . These values obtained for both E_D and D are comparable to results reported elsewhere (15, 16) for studies performed in a conventional furnace at similar phosphorus concentrations ($\sim 10^{21}$ cm^{-3}). Values for D which are several orders of magnitude lower than the above result have also been published, although lower phosphorus concentrations were involved (15, 17).

Dopant redistribution.—Figure 6 shows the effect of various RIA cycles on the diffusion of boron in implanted silicon test samples, as determined by SIMS (closed symbols) and by the B&E techniques (open symbols). The as-implanted values of junction depth measured with these two techniques were 0.35 and 0.20 μm , respectively. It must be noted that, although the absolute results obtained from the two measurement techniques

Fig. 5. Arrhenius plot for the out-diffusion of phosphorus during RIF treatments, for two concentrations and various RIF conditions. $\Delta[P] = [P]_t - [P]_0$ is the amount of phosphorus lost to the ambient during RIF. The slope of the linear fit yields $E_D/2$, where E_D is the activation energy for phosphorus diffusion in glass.

are different, the measurements of the junction depth increases Δx_j agree quite closely. The SIMS results from the 900°C , 80 min furnace annealing cycle in N_2 are also included in Fig. 6.

Example of VLSI process window for RIF.—In order to establish the upper bound of a process window for the application of RIF of PSG films to VLSI processing, the issue of dopant redistribution induced by rapid isothermal processing in underlying device shallow junctions must be addressed (7-12). For VLSI applications, a somewhat arbitrary upper limit of 0.1 μm could be placed on the acceptable junction depth increase resulting from a fusion cycle. This would correspond to, for example, a 50% displacement of a typical 0.2 μm shallow junction. As a consequence, the results from Fig. 6 indicate upper limits to RIF conditions of $1000^\circ\text{C}/60\text{s}$ or $1100^\circ\text{C}/10\text{s}$.

The dopant redistribution results also show that any 1200°C RIF cycle would be too extreme. Also, on the basis of the RIF results alone (Table I), a 1200°C cycle should be

Fig. 6. Graph showing the temperature dependence of the junction depth increase in a boron-implanted Si substrate induced by various heating cycles. The results shown were obtained with both the B&E method (open symbols) and SIMS (closed symbols). The implantation conditions are given in the text. The junction depth for the as-implanted Si samples was 0.20 μm , as measured with the B&E method, and 0.35 μm , as measured with SIMS. The result for the $60\text{s}/1200^\circ\text{C}$ was $\Delta x_j = 1.4$ μm (B&E) and thus was not included in the figure.

avoided in any case since undesirable fusion characteristics are observed, namely, void formation in high phosphorus content PSG and insufficient fusion in low phosphorus content PSG. In addition, the use of a long fusion period (> 20 s) could be economically impractical in a serial processing system.

It must be emphasized that the discussion for the given example applies to silicon substrates implanted with boron, which is one of the fastest diffusing species of the commonly used dopants in IC fabrication (18). If a slower diffusing species is used, such as arsenic, larger and/or hotter RIF cycles could be acceptable. However, if even shallower junctions are required, more stringent restrictions would be imposed on the RIF conditions.

The RIF results summarized in Table I can be used to determine the lower bound for the process window which is defined as the point when the reentrant profile is eliminated (i.e., $\theta > 90^\circ$). From Table I, it is clear that the 1100°C/10s RIF cycle can only induce acceptable fusion in 8.0 w/o PSG films. It has also been reported that an 1100°C/10s RIA cycle would be sufficient for the dopant activation of shallow junctions (10). Furthermore, experiments conducted in our laboratories and elsewhere (19) have shown that wafer warpage induced by RIA cycles of up to 1100°C is negligible; in some cases, wafer flatness is even improved. For the 1000°C/60s case, which is really too long for practical applications, as discussed above, satisfactory fusion was not obtained for any of the phosphorus concentrations investigated.

RIF vs. conventional furnace processing.—A comparison between RIF results and conventional furnace fusion (FF) results in a N_2 ambient is shown in Table II. In this experiment, the same boron implant used above to define a process window was the basis of comparison between RIF and FF. The results for the optimum 1100°C/10s RIF cycle ($\Delta x_j \approx 0.1 \mu\text{m}$ and $\theta \approx 113^\circ$) are compared with FF results obtained with the 900°C, 80 min furnace annealing cycle. The dopant redistribution result for the boron-implanted silicon substrate during the FF cycle ($\Delta x_j = 0.3 \mu\text{m}$) is much larger than for the RIF result ($\Delta x_j \approx 0.1 \mu\text{m}$), as also shown in Fig. 6. Nevertheless, absolutely no fusion was obtained during the FF cycle, for all phosphorus concentrations investigated. Similar fusion results were also obtained elsewhere (1). This comparison demonstrates quite convincingly that, for equivalent redistribution of a typical boron dopant profile in silicon, RIF is much more effective than FF for the fusion of PSG films.

Table II. Comparison of rapid isothermal processing and conventional furnace processing, giving the increase in junction depth Δx_j in an implanted silicon substrate, for a dose of $3 \times 10^{15} \text{ B}^+/\text{cm}^2$ implanted at 25 keV through a 40 nm thermal SiO_2 layer, and the change in step coverage angle θ (initially at 80°) of a reflowed PSG film

Process (N_2 ambient)	Heating cycle	Δx_j (μm)	Fusion for 8 w/o PSG
Furnace	80 min at 900°C	0.3	None
RIF	10s at 1100°C	0.1	$\theta = 113^\circ$

Conclusion

We have proved that, for equivalent dopant redistribution of junction profiles in silicon, rapid isothermal processing in a N_2 ambient is much more effective than conventional furnace processing for the fusion of PSG films.

A process window has been identified for typical VLSI applications. It consists of an 1100°C/10s RIF treatment of PSG films containing approximately 8 w/o phosphorus. These conditions increased an initial reentrant step coverage angle of 80° to a final value of more than 110° . A typical boron profile implanted in a silicon substrate and subjected to the same conditions underwent only a 0.1 μm increase in junction depth, making RIF compatible with VLSI applications where a relatively high phosphorus content is acceptable in PSG films.

Effects of Wet Cleaning on Si Contaminated with Heavy Metals during Reactive Ion Etching

Tetsuo Hosoya, Yoshiharu Ozaki, and Kazuo Hirata

Nippon Telegraph and Telephone Corporation, Atsugi Electrical Communication Laboratory, 1839, Ono, Atsugi-shi, Kanagawa Prefecture 243-01, Japan

ABSTRACT

Heavy metal removal from Si wafers contaminated during reactive ion etching (RIE) is studied using wet cleaning techniques. Si wafers are intentionally contaminated during RIE with Fe, Cr, or Ni, which are atomic components of stainless steel, the material used in dry etching apparatus. The Si wafers are washed with several reagents, and heavy metal removal results are estimated using secondary ion mass spectrometry and stacking fault observation. The results show that Fe and Cr are removed by wet etching the Si wafers to approximately a 30 nm depth but that Ni cannot be removed. The results indicate that to protect Si wafers against heavy metal contamination during RIE, Ni-free materials should be used for fixtures in the dry etching chamber.

In fabrication processes for high density LSI's, dry etching techniques are essential in producing fine patterns with high accuracy. Reactive ion etching (RIE) is especially useful in etching fine patterns because of its anisotropic etching features. However, RIE results in more contamination and damage to etched Si wafers than plasma etching. This is due to the sputtering and bombardment action of energetic ions generated during RIE. Many studies have been done on relationships between RIE conditions and device characteristics (1-3). It has been found that heavy metal contamination in a reactor during RIE causes a decrease in Si wafer minority carrier lifetime in silicon wafers subsequently subjected to high temperature heat-treatment.

To avoid heavy metal contamination in Si wafers, RIE reactor design improvement is required to prevent stainless steel used in the etching chamber from coming into contact with the plasma, or materials containing heavy metals should not be used in the etching chamber. Another approach, to eliminate the influence of heavy metal contamination, is to develop effective methods for removing the contaminated layer in the LSI fabrication process. This paper concerns Si wafer heavy metal-contaminated layer removal by wet cleaning methods, focusing on the behavior of Fe, Cr, and Ni, stainless steel's constituent elements.

In this study, Si wafers were intentionally contaminated with heavy metals during RIE. Pure metals, Fe, Cr, and Ni, are used as contamination sources, and wet cleaning procedures are developed so as to be applicable to LSI processes. The Fe and Cr removal and Ni nonremoval results are obtained through examination using secondary ion mass spectrometry (SIMS) and stacking fault (SF) observation.

The following sections describe the experimental procedures and results, the reason for Ni nonremoval, and application of findings to RIE apparatus design.

Experimental

Si wafer heavy metal contamination was carried out using RIE. The RIE reactor used in this work is shown schematically in Fig. 1. The RF power (13.56 MHz) was applied to the cathode electrode. Si wafers, which were 3 Ω -cm boron-doped (100) slices with a diameter of 3 in., were loaded on a stainless steel cathode electrode (Fe 74%, Cr 18%, Ni 18%). CF_4 was used as the etching gas at a pressure of 2 Pa. The RF power density and the etching time were set to 0.18 W/cm² and 30 min, respectively. Etching rates for Si were 9 ~ 13 nm/min. The wafers were contaminated with heavy metals sputtered from the cathode electrode. When using pure metals as a source of contamination, metal plates with a high purity (99.9%), i.e., Fe, Cr, and Ni, were set on the cathode electrode. The wafers were then placed on the plates. A 50 μ m thick Teflon sheet was placed between the plates and the cathode electrode. This sheet was replaced with a new sheet after ev-

ery plate change to avoid Si wafer contamination from other plate metals which may have adhered to the sheet.

Cleaning procedures following the contamination step in RIE consisted of the following steps: (i) ashing in O_2 glow discharge, (ii) washing in $H_2SO_4 + H_2O_2$ solution and rinsing in deionized water, (iii) cleaning by RCA treatment (4) (washing in $NH_4OH + H_2O_2$ and $HCl + H_2O_2$ solution) followed by diluted HF washing after each step. The reagents used were IC-grade EL-class reagents. In this paper, the authors call these three treatment steps the basic cleaning procedure. Steps i and ii are for removal of the plasma polymerized film and resists after dry etching, and step iii is for final Si wafer cleaning. As a result, the Si surface was etched off to an 8 nm depth in the basic cleaning procedure. When heavy metal contamination was not sufficiently removed from the Si wafers by the basic cleaning procedure, additional cleaning treatments using various liquid reagents were tried between steps ii and iii.

SIMS and SF observation were used to evaluate the degree of heavy metal removal. SIMS analysis was carried out using both Hitachi IMA-2 for estimating the heavy metal amounts remaining on the Si surface and Cameca ims-3f for the depth profile analysis. Hitachi IMA-2 was used under 10 kV Ar^+ ion beam acceleration voltage conditions with a 1300 μ m spot diameter. Cameca ims-3 was used under 15 kV O_2^+ ion beam acceleration voltage conditions with a 150 μ m spot diameter. Evaluation was carried out using the peak height ratio of each secondary ion spectrum intensity to that of $^{28}Si^+$. It is desirable to detect isotopes with the highest existence ratio for each metal in order to detect the secondary ions in high sensitivities. In this work, $^{54}Fe^+$, $^{52}Cr^+$, and $^{60}Ni^+$ were picked to detect each heavy metal. This was done to avoid an S/N ratio reduction due to the secondary ion settling on Si. The SF occurrence was observed as follows. Contaminated Si wafers were treated using the above-mentioned cleaning procedure. Next, they were oxidized at 1100°C in a wet O_2 atmosphere for 2h. After the SiO_2 was etched off with an HF solution, SF was visualized by etching the wafers to a

1 μm depth by Wright etching (5) and observed with a microscope.

Results

Removal of heavy metal contamination originating from stainless steel.—SIMS analysis was carried out on stainless steel-contaminated samples and cleaned using the basic cleaning procedure. Fe, Cr, and Ni, which compose stainless steel, were detected on the Si surface, as shown in Fig. 2. Heavy metal mass peak intensities on the Si surface after the basic cleaning procedure were high for Ni, Fe, and Cr in descending order. Cr was removed to the SIMS detection limit level after cleaning. These results indicate that Ni is the most difficult material to remove from Si.

Removal of heavy metal contamination originating from pure metals.—Si wafers contaminated with Fe, Cr, or Ni pure metals were prepared using RIE and SF observation. After applying the basic cleaning procedure, SF's were not observed on the Cr-contaminated Si wafers but were observed on those contaminated with Fe and Ni, as shown in Fig. 3. No SF's were observed on the Fe-contaminated Si wafers when the wafers were etched to a 20 nm depth with an $\text{HNO}_3 + \text{HF} + \text{CH}_3\text{COOH}$ solution before RCA treatment as shown in Fig. 4A. However, on the Ni-contaminated wafers, SF's were observed, as shown in Fig. 4B. In the wet etching process, used in Fig. 4, Si was etched off to an 8 nm depth using the basic cleaning procedure and to 20 nm depth with the mixed solution. Consequently, the Si etched depth was estimated to be about 30 nm.

The relation between remaining Fe, Cr, or Ni amounts and the cleaning steps was investigated by SIMS, using the ratio of mass intensities to ${}^{28}\text{Si}^+$. Remaining amounts of the three elements decreased with each step in the cleaning procedure, as shown in Fig. 5. The amount of Cr was below the SIMS detection limit level after the basic cleaning steps with no Si wet etching. For Fe, the amount was the same as for Cr if the Si wet etch procedure was employed before RCA treatment. However, Ni remained

Fig. 3. SF observation results after basic cleaning procedure. SF's were made visible by Wright etching method.

Fig. 4. SF observation results after adding 20 nm Si wet etching to basic cleaning procedure. SF's were made visible by Wright etching method.

Fig. 5. Relation between remaining Fe, Cr, and Ni amounts and cleaning steps, using pure metals as the contamination source, expressed by SIMS spectrum intensity ratios, $M^{+}/^{28}\text{Si}^{+}$. SIMS measurement was done at A, B, C, and D steps.

high even after all cleaning steps were carried out. These results support the SF observation.

Metal plate wet etching rates were investigated using the solutions employed in the basic cleaning procedure. Ni was etched in considerable quantity, as much as Fe, with the HCl + H₂O₂ solution, as shown in Table I.

Thus, the etching of metals in Si is different from that of metal itself. The chemical state of the Ni atom added to Si wafers during RIE was of concern and was investigated by XPS analysis.

XPS analysis of the Ni-contaminated wafer.—Possible Ni atom chemical states were considered to be either of a metallic state, a compound with Si, or a compound with the etching gas element. The compound with Si, nickel silicide, is known to be formed at 200° ~ 300°C (6) and to be insoluble in acids except for hydrofluoric acid (7). XPS analysis was carried out on the Si surface immediately after Ni contamination. A Ni and a nickel oxide were detected, while nickel silicide was not, as shown in Fig. 6. Nickel oxide formation is considered to be caused by the Ni oxidation during ashing treatment.

On the basis of XPS analysis results mentioned above, nickel removal investigations were carried out using wet cleaning methods.

Ni-contaminated layer removal.—Several kinds of wet etching solutions were applied before the RCA treatment in the basic cleaning procedure. These are summarized in Table II. The treatments were aimed at accomplishing the following: treatments a, b, and c were for Ni removal. Treatment d was to remove nickel oxide with HCl and nickel with HNO₃. Treatment e was for Ni removal and was carried out in diluted HCl using a 5 mA dc current between the Ni-contaminated sample and a Si cathode

Table I. Etching rates for heavy metals by the solutions used in the basic cleaning procedure

Solutions	Etching rates for metals (at./cm ² -min)	
	Ni	Fe
H ₂ SO ₄ + H ₂ O ₂	2 × 10 ¹⁸	1 × 10 ¹⁸
Diluted HF	2 × 10 ¹⁷	2 × 10 ¹⁶
NH ₄ OH + H ₂ O ₂	1 × 10 ¹⁶	1 × 10 ¹⁶
HCl + H ₂ O ₂	5 × 10 ²⁰	5 × 10 ²¹

electrode. The results obtained indicate SF occurrence in all the samples and that Ni was impossible to remove from the Si surface.

Discussion

The experimental results are summarized as follows: (i) Cr is removed using the basic cleaning procedure; (ii) Fe is removed by adding 20 nm Si wet etching to the cleaning procedure; and (iii) Ni is not removed despite the application of several cleaning procedures. The reason Ni cannot be removed is discussed below.

Consider a simple model in which metal atoms sputtered from metal plates are ionized in glow discharge and impinge on the Si wafer surface with an acceleration energy equivalent to the cathode fall potential. Metal ions such as Fe⁺, Cr⁺, and Ni⁺ are implanted at a finite depth from the Si surface. Here, the metal atom depth profiles become important in interpreting wet cleaning characteristics.

The Ni depth profile in Si wafers was measured using SIMS profile analysis. It is found that Fe and Ni were introduced to 50 and 60 nm depths, respectively, as shown in Fig. 7. The SIMS profile analysis generally presents a deeper profile due to a tailing phenomenon in highly concentrated impurity analysis (8). Thus, the impurity profile depth shown in Fig. 7 must be slightly exaggerated. For example, as already mentioned, Fe was removed by etching the Si to approximately a 30 nm depth, while Fig. 7 shows that Fe exists to 50 nm. The Fe depth in the wafer is shown to be 20 nm larger using SIMS profile analysis than that found in actual wet etching. Considering the Fe case, Ni is inferred to etch at most 40 nm in the Si wafer. This inference also comes from Ni ion's small acceleration energy of 700 eV for the 0.2 W/cm² power condition. It thus follows that Ni could be removed by etching the Si to approximately 40 nm.

Fe and Ni profiles were estimated using the "step etch" method. Namely, metal-contaminated Si wafers were

etched to a certain depth using a $\text{HNO}_3 + \text{HF} + \text{CH}_3\text{COOH}$ solution after ashing followed by diluted HF etching. SIMS analysis was performed after these steps. Results are the same as if Ni is penetrated to a depth of 150 nm, while they show that Fe was below the SIMS detection limit level at 30 nm. This is shown in Fig. 8. Etching of the Ni-contaminated Si wafer using the mixed solution stopped at 150 nm depth. It was necessary to dip the Ni-contaminated wafer into an HF solution to restart etching. Some layer seemed to prevent the etching.

Thus, the fact that Ni in Ni-contaminated Si wafers, contaminated during RIE, cannot be removed is believed to be caused by Ni redeposition onto the Si wafers in the wet cleaning procedure. High Ni metal etching rates, and discrepancy in Ni depth profiles between the SIMS profile analysis and step etching, would be explained by this readhesion concept.

These results indicate that one means of protecting Si wafers against heavy metal contamination during RIE is to select Ni-free materials for the fixtures in the dry etching chamber.

Conclusion

Wet cleaning effects on Si wafers have been investigated for removing heavy metal-contaminated layers introduced during RIE. Si wafers were intentionally contaminated with stainless steel constituent elements, *i.e.*, Fe, Cr, and Ni, during RIE. Wet cleaning procedures were designed to combine washing in $\text{NH}_4\text{OH} + \text{H}_2\text{O}_2$ solution and $\text{HCl} + \text{H}_2\text{O}_2$ solution with etching employing a $\text{HNO}_3 + \text{HF} + \text{CH}_3\text{COOH}$ solution. The amount of heavy metal removed was estimated by SIMS and SF observation in the Si wafers after wet cleaning. The results show that Fe and Cr are removed by etching the Si wafers to approxi-

Fig. 8. Heavy metal depth profile in Si wafers estimated by step etch method, expressed by SIMS spectrum intensity ratios, $M^+/^{28}\text{Si}^+$.

mately 30 nm using wet cleaning procedures. However, Ni cannot be removed, even though Ni-contaminated Si wafers were etched to 150 nm. This failure to remove Ni is probably due to Ni redeposition to the Si surface during wet etching. Usage of Ni-free materials for fixtures in the dry etching chamber will be one way to avoid heavy metals contamination in Si wafers.

Acknowledgment

The authors wish to thank Toyoki Kitayama for his valuable suggestions and encouragement and Izumi Kawashima for carrying out the SIMS analysis.

Deep-UV Contact Lithography Using a Trilevel Resist System for Magnetic Bubble Devices with Submicron Minimum Feature

H. Umezaki, N. Koyama, Y. Maruyama, Y. Sugita, and R. Suzuki

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

Deep UV lithography using a trilevel resist system has been developed to delineate submicron patterns for magnetic bubble memory devices. The trilevel resist system consists of PIQ[®] as a bottom polymer layer, spin-coated TiO_x as an intermediate layer, and MRS as a top imaging resist. All these layers can be spun and baked sequentially. MRS resist patterns are defined by deep-UV contact printing and transferred to TiO_x layer and PIQ layer sequentially using reactive ion etching with CF₄ gas for TiO_x and O₂ gas for PIQ. Using this trilevel resist process, 0.4 μm lines and spaces were fabricated and contiguous disk patterns of 2 μm bit period for bubble memory devices of 16 Mb/cm² were also fabricated successfully.

Magnetic bubble memory devices with the bit capacity of 1 and 4 Mb are now in volume production(1). These devices are all Permalloy devices in which track patterns for bubbles consist of Permalloy patterns. These patterns have gaps between neighboring bits. The minimum feature of these patterns is 1 μm, and the patterns are fabricated using contact printer or 10× projection printer with conventional UV light. High density ion-implanted bubble memory devices of 4-16 Mb in memory capacity are now under development (2, 3). Bubble propagation tracks of these devices are fabricated by implanting H₂ or Ne ions into bubble garnet through mask patterns. Since the mask patterns, named contiguous disks, have no gaps between neighboring bits, the requirement for lithography can be relaxed compared with Permalloy devices. However, for higher density devices of 4-16 Mb/cm², the delineation of patterns with the minimum feature of 0.5-1.0 μm is required even using this approach to fabricate 4-16 Mb/cm² devices.

Conventional UV lithography, however, is insufficient for this purpose because of its lack of practical resolution. Deep-UV lithography is known to be superior to UV lithography and has the high resolution capability in submicron range (4). Deep-UV contact lithography uses the same technique as the conventional UV lithography, except for light source and resist. A Xe-Hg lamp is well known to be the deep UV-light source. As deep-UV resist, we employ the negative-type MRS¹ resist, which is composed of poly(p-vinylphenol) and 3,3'-diazidodiphenyl sulfone (5, 6, 7). The MRS resist has properties of high sensitivity to 200-300 nm radiation, high resolution, and good resistance to dry etching.

The mask patterns for ion-implanted bubble devices should satisfy the following requirements: (i) the thickness is large enough to stop incident ions; (ii) the material is highly heat resistant not to be deformed during implantation; and (iii) the edge profile is steep and smooth to obtain a clearly defined propagation track. To satisfy these requirements, we employ the polyimide resin PIQ(8)² with the thickness of 1.5 μm as a mask material and transfer MRS patterns to PIQ layer using trilevel resist technique (9).

In this paper, the characteristics of MRS resist such as resolution capability and process latitude in resist profile control and linewidth control are reported. The trilevel resist process using the MRS resist as top imaging resist, the spin-coated TiO_x as an intermediate layer, and the PIQ as a bottom polymer layer is presented. Experimental results demonstrating the performance of the process are also included.

Experimental

The MRS resist films were spin-coated on substrates to thickness of 0.3-0.6 μm and prebaked at 80°C for 20 min.

¹MRS stands for micro resist for shorter wavelength, and is commercially available from Hitachi Chemical Company Limited under the trade name RD2000N.

²PIQ stands for Polyimide Iso-indroquinazolinedione, and is a trade name of Hitachi Chemical Company Limited.

The thickness was changed for the purpose of the experiment and adjusted by diluting the resist solution with cyclohexanone. Exposure was carried out using the contact aligner Cobilt CA800 equipped with a 500W Xe-Hg lamp (Ushio Electric, Incorporated) and an aluminum mirror. Since the spectral photosensitivity of the MRS resist is restricted to 200-300 nm wavelength, a cold mirror is not necessary to expose the MRS resist. The photomask used in the experiment consisted of a quartz substrate and a thin layer of chromium patterns which were delineated by electron-beam writing. The thickness of the quartz substrate was 2.4 mm. After exposure, the MRS resist was developed in MF312 developer (Shipley) diluted with water at 1:4 and rinsed in deionized water.

In order to compare the resolution capability of MRS with conventional UV resist, the resolution of AZ1350J (Shipley) was also investigated. To perform the experiment under the same condition, the same photomask and the same aligner were used, except for a light source, *i.e.*, a Xe-Hg lamp for MRS and a Hg lamp for AZ1350J. The AZ1350J resist was developed in the AZ developer (Shipley), diluted with water at 1:1, and rinsed in deionized water.

The trilevel resist system studied here consists of MRS/TiO_x/PIQ. A schematic diagram of the process is shown in Fig. 1. A substrate was coated successively with the thick polymer layer of PIQ (1.5 μm), the thin layer of spin-coated TiO_x (0.1 μm), and the thin MRS resist layer (0.3 μm). The TiO_x film was obtained by spin-coating and baking an organotitanium solution which will be described in detail later. The top imaging resist MRS was defined by the deep-UV contact printing. Transfer of the resist patterns to TiO_x layer was performed by reactive ion etching (RIE) in CF₄ plasma. The patterns in TiO_x layer were then replicated in thick PIQ layer by RIE in pure O₂ plasma.

Results and Discussion

Characteristics of MRS.—The resolution of MRS was compared with the conventional UV resist AZ1350J. The results are shown in Fig. 2. Both resist patterns were defined by the same contact aligner using the same photomask patterns of lines and spaces. The thicknesses of these two types of resist were both 0.6 μm. It can be seen from the figure that the resolution of AZ1350J is about 0.5 μm and that of MRS is less than 0.4 μm. The resolution of MRS is thus superior to that of AZ1350J. As for AZ-type resist, Smith *et al.* demonstrated the linewidth of 0.4 μm using a contact printer and conformable photomask (10). In our experiment, however, the resolution is about 0.5 μm. This is presumably due to the difference of photomask structures. In our experiment, a hard mask plate was used and this should cause the degradation of resolution.

The MRS resist thus exhibits a high resolution. But this resist is also known to have such a property that the cross-sectional profile varies sensitively according to de-

Fig. 1. Schematic diagram of the trilevel resist process

velopment conditions (5). Examples of this phenomenon are shown in Fig. 3. The resist thickness is $0.6 \mu\text{m}$ for the left-hand samples and $0.25 \mu\text{m}$ for the right-hand samples. A development time was changed by 15s from the minimum time required to delineate a pattern. In the case of $0.6 \mu\text{m}$ thick resist, the profile changes with increasing a development time and results in the undercut profile. On the other hand, for the resist with the thickness of $0.25 \mu\text{m}$, the profile does not change and is always steep in all development conditions.

The undercut profile shown here is caused by a strong absorption of deep-UV light by MRS resist (5). In the case of $0.6 \mu\text{m}$ thick resist, the deep-UV light cannot reach at the lower layer, owing to a strong absorption, and the resists at the lower part are removed by prolonged development. In the case of $0.25 \mu\text{m}$ thick resist, however, the thickness is so small that the deep-UV light can penetrate all through the resist. Therefore, the resist profile is always steep at every development condition. This property is desirable, since the steep profile ensures that the good linewidth control and the restriction on development condition can be relaxed compared with the case of thick MRS resist.

Fig. 2. Comparison of the resolution of MRS resist (deep UV) and AZ1350J resist (UV) delineated by contact printing.

Fig. 3. MRS resist profiles as a function of development time. The thicknesses are $0.6 \mu\text{m}$ for the left-hand samples and $0.25 \mu\text{m}$ for the right-hand samples.

Figure 4 shows the linewidth variation of thin MRS resist patterns as functions of exposure and development time. The results of UV resist AZ1350J are also shown in the figure. The thicknesses of MRS and AZ1350J are $0.27 \mu\text{m}$ and $0.26 \mu\text{m}$, respectively. The test patterns used in the experiment were lines and spaces with the widths of 1.0 , 0.75 , and $0.5 \mu\text{m}$, respectively. The patterns on the photomask were transferred to the resists with each exposure and development condition. The exposure time was changed from the minimum time to delineate a pattern to about eight times the minimum time. The development time was changed from 5 to 160s. Under these exposure and development conditions, linewidth for MRS resist and spacewidth for AZ1350J resist were measured by scanning electron microscope (SEM) observation.³

The contour lines shown in the figure were obtained from the values of measurement points and indicate the same linewidth is obtained. Therefore, as the density of contour lines is small, the latitude of exposure and development condition becomes large. It can be seen that the density of contour lines for MRS resist is smaller than that for AZ1350J resist. That is, the linewidth variation of MRS caused by a fluctuation of exposure or development condition is smaller than that of AZ1350J resist. The rectangular regions in the figure correspond to the latitude of linewidth control $\pm 20\%$, that is, 1 ± 0.2 , 0.75 ± 0.15 , and $0.5 \pm 0.1 \mu\text{m}$, respectively. As shown in the figure, the rectangular region of MRS resist is larger than that of AZ1350J resist for each linewidth. The rectangular region of $0.75 \mu\text{m}$ patterns for MRS resist is almost the same as that of $1.0 \mu\text{m}$ patterns for AZ1350J resist. This indicates that the $0.75 \mu\text{m}$ pattern can be fabricated with the same

³Since the types of these two resists are different, i.e., MRS is the negative-type resist and AZ1350J is the positive-type resist, the line pattern for MRS resist corresponds to the space pattern for AZ resist when the same photomask pattern is used.

Fig. 4. Linewidth variations of MRS resist and AZ1350J resist patterns as functions of exposure and development times.

Fig. 5. Fourier transform infrared spectra for Atolon NTi films which were baked at temperatures from 100° to 300°C.

tolerance as that for 1 μm pattern of AZ1350J resist. As for 0.5 μm pattern, the MRS pattern can be obtained at every exposure and development condition. The condition for AZ1350J resist is restricted, as can be seen in the figure.

Here it should be noticed that the thin resist cannot be used in itself as a mask pattern for etching or ion implantation. Therefore, we introduced the trilevel resist process where thin MRS resist was used as the top imaging resist.

Trilevel resist process.—The present trilevel resist system is composed of PIQ, TiO_x , and MRS as already indicated in Fig. 1. An intermediate layer TiO_x was obtained from the organometal solution of tetra(acetyl-isopropenato)titanium (Atolon NTi®; Nippon Soda Company Limited). Figure 5 shows the Fourier transform infrared spectra for Atolon NTi films which were baked at temperatures from 100° to 300°C. The baking treatment was performed in the air atmosphere for 30 min in all cases. The strong absorptions due to organic compounds are observed for the samples baked at less than 250°C, but they disappear when the baking temperature is greater than 280°C. From these results, it can be said that the inorganic TiO_x is obtained by baking Atolon NTi at temperature higher than 280°C.

The TiO_x films thus obtained have some advantages compared with spin-on glass (SOG) (11) or SiO_2 films deposited by plasma enhanced chemical vapor deposition (PECVD) (9). These materials are widely used as an intermediate layer for trilevel resist process. Table I shows the comparison of these materials. A deposition process of TiO_x and SOG is simple because there is no need of evacuation process, which is necessary for PECVD. The adhesion of MRS or AZ resist to the TiO_x film is excellent, and the adhesion promoter such as hexamethyl disilazane (HMDS) is not needed here. On the other hand, the adhesion promoter is necessary for SOG and SiO_2 . The stability of Atolon NTi solution is good compared with the SOG solution. In the case of SOG solution, proper storage is required since the silicate material can easily be hydrolyzed by moisture in the air to form SiO_2 -like crystals. These crystals cause defects in a spin-on film. The TiO_x films obtained from Atolon NTi solution pose no such problem, because the hydrolysis in this case hardly occurs and defects in the films are few. The defects in PECVD SiO_2 film are usually caused by particles which eventually flake off from the surrounding wall of PECVD chamber. Therefore, careful cleaning procedures are required to decrease defects in a film.

Table I. Comparison of intermediate layers for trilevel resist process.

Material	TiO_x (Spin-On)	SOG (Spin-On)	SiO_2 (PlasmaCVD)
Process Simplicity	○	○	X
Adhesion of MRS or AZ	○	X	X
Defect	○	△	△

Linewidth control.—Linewidth control of the patterns delineated by the trilevel resist process depends on three factors, i.e., image transfers of photomask patterns to resist layer, resist patterns to intermediate layer, and intermediate patterns to bottom layer. As described previously, the accuracy of image transfer to MRS resist is superior to that of AZ resist. In the present case, the MRS patterns are transferred to TiO_x and PIQ layer successively. Therefore, these etching processes must be controlled precisely. The TiO_x etching process is especially critical since the thin (0.3 μm thick) MRS resist must be used to etch TiO_x layer using reactive ion etching. To control a linewidth precisely in TiO_x etching, therefore, the sufficient etching selectivity is required. For this purpose, we investigated etching conditions, that is, an etching gas and RF power. The results are shown in Fig. 6. The etching gases studied here were CF_4 , CF_4/O_2 , CHF_3 , and CHF_3/Ar , and the RF power was changed from 100 to 400W. The vacuum pressure was 5 Pa in every case. It can be seen that the etching rate of TiO_x in CF_4 plasma is relatively high and the etching rate ratio of TiO_x to MRS is also high. When O_2 gas is mixed in CF_4 gas, the etching rate of TiO_x increases. However, the etching rate of MRS also increases and the ratio becomes smaller. In the case of CHF_3 plasma, a deposition process occurs when an RF power is small (100-200W). At high RF power (400W), the etching becomes possible and the etching rate ratio is high. CHF_3/Ar plasma etching behavior is almost the same as the case of CHF_3 plasma.

In order to obtain the high etching rate ratio, the CHF_3 or CHF_3/Ar plasma with 400W RF power is most favora-

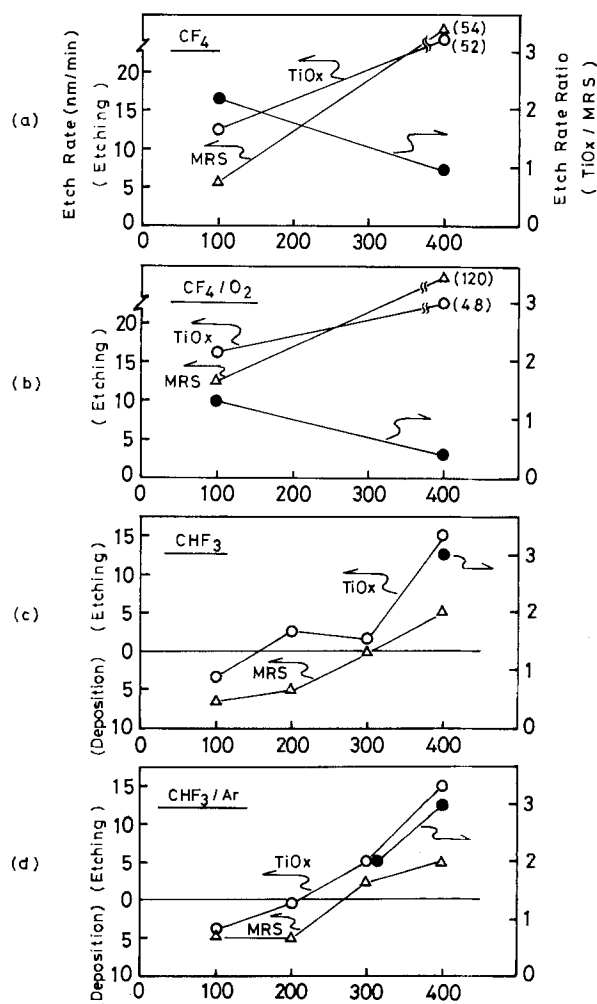

Fig. 6. Etching rate of TiO_x and MRS resist and etching rate ratio of TiO_x/MRS as a function of RF power. a: CF_4 50 sccm. b: CF_4 50 sccm + O_2 5 sccm. c: CHF_3 50 sccm. d: CHF_3 50 sccm + Ar 15 sccm. Vacuum pressure was 5 Pa in every case. The substrate on which wafers were placed was SiO_2 for CF_4 and $\text{CF}_4 + \text{O}_2$ gases and Teflon for CHF_3 and $\text{CHF}_3 + \text{Ar}$ gases.

Fig. 7. Linewidth variations of TiO_x patterns as a function of etching time. Etching gas was CF_4 with the flow rate of 50 sccm. Vacuum pressure was 5 Pa, and RF power was 100W.

ble. However, the plasma discharge is unstable at that condition and the reproducibility of etching becomes poor. The stability of plasma discharge was improved when the vacuum pressure was increased (to 10 Pa). But, at the high vacuum pressure, the deposition process again occurred.

From these results, we selected the CF_4 as an etching gas and the RF power to be 100W. Under these conditions, the linewidth variation was measured as a function of etching time. The results are shown in Fig. 7. The linewidth decreases linearly with increasing the etching time, and the decreasing rate is $0.005 \mu\text{m}/\text{min}$. The rate is so small that the linewidth can be controlled precisely. The linewidth variation is only $\pm 0.025 \mu\text{m}$ when the etching time was changed from the standard time (for example at 15 min) by ± 5 min.

Figure 8 shows the etching rates of PIQ, MRS, and Atolon NTi films in O_2 RIE. The Atolon NTi film was baked at 200° or 300°C . The RF power was 100W, and the vacuum pressure was 0.27 Pa. It can be seen that the etching rates of PIQ and MRS are almost the same: 23 nm/min. The Atolon NTi baked at 200°C is etched slightly, and the etching rate is 0.7 nm/min. However, the Atolon NTi baked at 300°C is not etched in this measurement time. As mentioned previously, the Atolon NTi baked at 200°C still contains organic contents and is, therefore, slightly etched by O_2 RIE. On the other hand, the Atolon NTi baked at 300°C changes to the inorganic material TiO_x and remains intact during O_2 RIE. From these results, it can be concluded that the Atolon NTi film baked at 300°C serves as a good mask material for an etching of PIQ by O_2 RIE.

Fig. 8. Etching rates of PIQ, MRS, and Atolon NTi by O_2 reactive ion etching. Atolon NTi films were baked at 200° and 300°C . RF power was 100W, and vacuum pressure was 0.27 Pa.

Fig. 9. Amounts of undercut as a function of etching time. Vacuum pressure was changed from 0.27 to 1.3 Pa. RF power was 100W.

The vacuum pressure in O_2 RIE is a key parameter for linewidth control (12). When the vacuum pressure is too high, an undercut profile occurs. On the other hand, the plasma discharge becomes unstable as the vacuum pressure is too low. To obtain the practical condition, we investigated the amount of undercut of the PIQ pattern under the protective TiO_x layer as a function of vacuum pressure. The results are shown in Fig. 9. The vacuum pressure was changed from 0.27 to 1.3 Pa. The amounts of undercut were measured by an SEM observation. When the pressure is 1.3 Pa, the amount of undercut increases rapidly with increasing the etching time and reaches $0.2 \mu\text{m}$ at the etching time of 90 min, which is about twice the time required to eliminate $1.5 \mu\text{m}$ thick PIQ layer. The amount of undercut decreases when the vacuum pressure is low. At the pressure of 0.27 Pa, the undercut becomes very small and the amount is $0.06 \mu\text{m}$ even at the etching time of 90 min, which is about 50% greater than the time required to eliminate PIQ layer. With our RIE apparatus, the lowest pressure above which the plasma discharge is stable is about 0.13 Pa. Therefore, the vacuum pressure of 0.27 Pa was selected.

Applications.—Figure 10 is an SEM photograph of lines and spaces patterns delineated by the trilevel resist process with a deep-UV contact printing. Linewidths are 0.75 and $0.4 \mu\text{m}$, respectively. The patterns consist of 1.5 mm thick PIQ with $0.1 \mu\text{m}$ thick TiO_x on the top surface.

Fig. 10. SEM photographs of lines and spaces patterns delineated by the trilevel resist process with a deep-UV contact printing. Linewidths are 0.75 (a) and $0.4 \mu\text{m}$ (b).

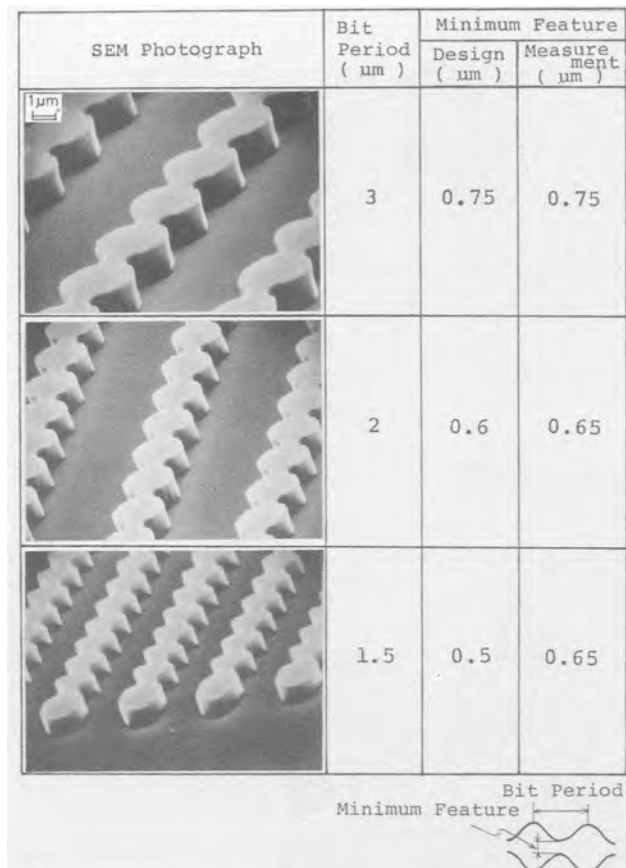

Fig. 11. Contiguous disk patterns for ion-implanted bubble memory devices delineated by the trilevel resist process with deep-UV contact printing.

As can be seen in the figure, the undercut of PIQ layer is very small and submicron patterns of 0.75 and 0.4 μm are delineated successfully.

Figure 11 shows the contiguous disk patterns for ion-implanted bubble memory devices. Bit periods of these patterns are 3, 2, and 1.5 μm and the minimum features are designed to be 0.75, 0.6, and 0.5 μm , respectively. The thicknesses of PIQ are 1.5 μm thick for 3 and 2 μm period patterns and 1.0 μm thick for a 1.5 μm period pattern. These thicknesses are necessary to stop accelerated ions used in each ion implantation. It can be seen that the edge profiles of these patterns are steep and smooth, which are the characteristics necessary for the mask pattern against an ion implantation, as mentioned previously. Patterns of 0.75 μm minimum feature for 3 μm period pattern are defined precisely, and that for 2 μm period pattern is also allowable. However, the discrepancy between a design and measurement value becomes large in the case of 1.5 μm bit period pattern. Therefore, the practical resolution limit of deep-UV contact printing is seen to be about 0.6 μm , and the minimum bit period is about 2 μm . The result is different from that for lines and spaces test patterns. The difference is caused by a diffraction effect. Since a contiguous disk pattern contains a cusp shape at the minimum feature part, the corner of the cusp is rounded by a diffraction effect and the width of the neck, which is the minimum feature, becomes large. That is, a diffraction in practical pattern is not so simple as in lines and spaces pattern and causes a degradation of resolution limit.

From the results obtained here, it can be said that deep-UV contact lithography can be applicable to 2 μm period ion-implanted bubble devices of 16 Mb/cm² in storage density.

Conclusion

Deep-UV contact lithography using trilevel resist system has been developed for magnetic bubble devices with submicron minimum feature. The trilevel resist system consists of MRS resist, TiO_x, and PIQ. The MRS resist patterns were delineated by deep-UV contact printing and the patterns were then transferred into TiO_x and PIQ sequentially using reactive ion etching in CF₄ plasma and in O₂ plasma, respectively. The thickness of MRS is 0.3 μm . The thin MRS resist like this can provide a submicron pattern with a greater process latitude than that of UV printing with AZ resist. The TiO_x film was obtained by spin coating and baking an organotitanium solution. Therefore, the three layers of the present process can all be formed by spin coating method. The adhesion of MRS resist to TiO_x film is good and etching selectivities of TiO_x to MRS (CF₄ RIE) and PIQ to TiO_x (O₂ RIE) are also good. Using the present trilevel resist process, 0.4 μm lines and spaces were delineated and the 2 μm period contiguous disk patterns with the minimum feature of 0.6 μm for bubble memory devices of 16 Mb/cm² were also fabricated successfully.

Lateral Growth Process of GaAs over Tungsten Gratings by Metalorganic Chemical Vapor Deposition

Hiroimitsu Asai and Seigo Ando

Nippon Telegraph and Telephone Corporation, Musashino Electrical Communication Laboratory, Musashino-shi, Tokyo 180, Japan

ABSTRACT

Lateral epitaxial growth of GaAs over tungsten gratings with 5 μm wide lines and spaces on (001) GaAs substrates is performed using metalorganic chemical vapor deposition. A study is made of the dependence of facet shapes and growth rates of the overgrown layers on grating direction, growth temperature, and arsine (AsH_3) and trimethylgallium (TMG) flow rates. From the perspective of crystallography, all the facets observed in the overgrown layers were found to be classified into four individual groups: $\{110\}$, $\{111\}\text{As}$, $\{112\}\text{As}$, and $\{113\}\text{Ga}$ faces. The GaAs opening direction on the (001) substrate surface is found to be the most essential parameter for determining the crystallographic planes of the facets. Other important controlling parameters for the facet formation are the growth temperature and partial pressure of AsH_3 . The partial pressure of TMG has no influence on the faceting growth. On the other hand, the overall growth rate of the overgrown layer is limited only by the TMG flow rate. These results can be qualitatively explained by the Langmuir-Rideal model.

Lateral epitaxial growth over oxide or metal mask films formed on crystal substrates has recently developed into an attractive technique for fabricating such new devices as permeable base transistors (PBT's) (1-3) and optical wave guides (4). To date, many reports on the lateral growth of GaAs (1-9), Si (10, 11), and InP (12) over metal or oxide mask films have been published.

Halide vapor phase epitaxy (VPE) has been employed as the most general method for overgrowth purposes, because it has several advantages for successfully accomplishing the overgrowth as will be mentioned below. In the VPE growth, there is a thermal equilibrium between the solid and vapor phases. The dependence of surface kinetics on substrate orientation makes an important contribution to the large ratio of lateral to vertical growth rates. In addition, polycrystalline solids, which prevent the lateral overgrowth, do not deposit over large areas of the mask films, because of the desorption or etching processes of source species. In this case, HCl, which is produced or introduced intentionally during the VPE growth, plays an important role in the etching process. In fact, Jastrzebski *et al.* (11) added HCl vapor etching steps intentionally to the Si overgrowth procedure using SiH_2Cl_2 , reporting that the nucleation of poly-Si over SiO_2 was eliminated. However, there are serious problems with the HCl introduction. For example, some kinds of chloride reactants generated during the deposition process react with a quartz reactor or substrates, and, consequently, cause unintentional doping, the so-called "autodoping." Additionally, abrupt interfaces in composition and doping or epitaxial layers containing Al cannot be readily obtained by this method.

For metalorganic chemical vapor deposition (MOCVD), on the other hand, such problems do not exist because of the growth system, which excludes HCl. Moreover, MOCVD is well known to have such advantages as allowing precise control of composition and doping in multicomponent structures. However, lateral overgrowth has been difficult to successfully accomplish using MOCVD, because polycrystalline GaAs can be readily deposited over mask films (13) due to the lack of etching process in this growth mechanism.

Recently, Gale *et al.* (14) and Asai *et al.* (3) demonstrated that the MOCVD lateral GaAs growth can be accomplished without polycrystalline deposits over mask films by optimizing the growth conditions. Lateral overgrowth using MOCVD has developed into an applicable technique for fabricating PBT's. However, the details regarding the GaAs overgrowth process in MOCVD have not yet been made clear.

In this paper, we report on the lateral GaAs growth over a tungsten grating with 5 μm wide lines and spaces on a (001) GaAs substrate using MOCVD. To study the over-

growth process, our attention has been focused on the facet shapes formed at GaAs overgrown film edges and the vertical growth rates of the overgrown films. The dependencies of geometrical shapes of the facets and growth rates on the tungsten grating direction, growth temperature, and source gas flow rates are examined. The tungsten grating direction on the (001) substrate surface is found to be the most essential parameter to determine the geometrical shape of the overgrowth layer. The other controlling parameters are the growth temperature and the partial pressure of arsine (AsH_3). However, the partial pressure of trimethylgallium (TMG) has no influence on the facet formation, though an overall growth rate of the overgrown layer is controlled by mass transport. On the basis of the obtained results, the MOCVD overgrowth mechanism is discussed.

Experimental Procedure

The MOCVD system used for GaAs overgrowth in this work was a conventional horizontal quartz reactor with an RF induction heater. The upper surface of a graphite susceptor was tilted about 7° from the gas flow. The growth temperature was monitored by a thermocouple inserted into the susceptor. An electronic-grade, 10% mixture of AsH_3 in hydrogen was used as an arsenic source. TMG vapor was provided by bubbling hydrogen through this liquid, which was held at 0°C in a stainless steel bubbler. A main impurity in the TMG was Si, whose concentration was nominally 1 ppm. A purified H_2 carrier gas having a 4 liter/min flow rate was introduced with the TMG and AsH_3 into the reactor. The overgrowth was performed under atmospheric pressure.

In order to examine the overgrowth processes, we used the patterned substrates having tungsten gratings, as shown in Fig. 1. After etching Si-doped ($2 \times 10^{18} \text{ cm}^{-3}$), GaAs (001) $\pm 0.5^\circ$ wafers with a $3\text{H}_2\text{SO}_4\text{-1H}_2\text{O}_2\text{-1H}_2\text{O}$ solution, a 400 \AA sputter tungsten grating of 5 μm wide lines and spaces was made as a masking pattern on the wafer with a conventional lift-off technique. A stripe direction of the tungsten grating oriented on the substrate is a very important factor for affecting facet shapes of the overgrown layers, as will be described later.

In this paper, the grating direction is defined as an angle from the $\langle 110 \rangle$ direction on the (001) GaAs surface called the "grating angle." The grating angle was varied from 0° to 90° to examine the dependence of the overgrowth on the grating direction. Taking the crystallographic symmetry of a zinc blende structure into account, this angle region can cover all grating directions on the (001) surface. The determination of the $\langle 110 \rangle$ and $\langle 110 \rangle$ directions on the (001) GaAs wafer was made by means of the etching profile test with a $1\text{H}_2\text{SO}_4\text{-1H}_2\text{O}_2\text{-1H}_2\text{O}$ solution (15).

Fig. 1. Schematic picture of a substrate used for overgrowth.

The growth procedure began with substrates having tungsten gratings being loaded into the reactor, after being washed sequentially in trichloroethylene, acetone, and methanol. To compare layer thicknesses, substrates having no grating were also used. The reactor was purged with a purified H_2 gas for about 2h. An AsH_3 gas was introduced when the susceptor temperature reached $400^\circ C$ to protect the substrate from thermal damage. Typical growth time was 2h. Growth conditions were varied widely, as summarized in Table I. When one condition was varied, the others were fixed at standard conditions in order to clarify the effects of the varied condition. This is indicated by the parentheses in Table I.

Our attention in this work focuses specifically on the facet shapes and layer thicknesses formed during overgrowth. In order to determine the crystallographic planes of the facets, $(\bar{1}10)$ and (110) cleavage planes of the overgrown layers were observed for 0° - 45° and 45° - 90° grating directions, respectively, with an optical microscope. All grown layers were stain etched with a $10H_2O$ - $1H_2O_2$ - $1HF$ solution for 15s. Consequently, buried tungsten stripes could be clearly seen as dark lines in the cross-sectional views. The thickness of a selectively grown layer was measured from the step height between the top surface of the layer and the tungsten grating in the cross-sectional view of the sample.

Overgrowth on Various Directional Gratings

In this section, we describe the effects of grating direction on lateral overgrowth from three perspectives. First, for typical grating directions, the relationship between surface morphology and facet formation of overgrown layers is examined. Second, the inclination of the facet with respect to a (001) substrate surface is studied as a function of the grating angle from $\langle \bar{1}10 \rangle$. Third, on the basis of the results, a model for the overgrowth process is discussed.

Cleaved cross sections of the GaAs layers simultaneously grown over tungsten gratings with various directions were observed by an optical microscope. Figures 2a, 2b, and 2c present the cross-sectional photographs of the grown layers over the tungsten gratings oriented at 0° , 30° , and 90° directions from the $\langle \bar{1}10 \rangle$, respectively. These samples were grown under the conditions of $630^\circ C$ and $[TMG]$ and $[AsH_3]$ mole fractions of 3.2×10^{-5} and 1.7×10^{-3} , respectively. Note that Fig. 2a and 2b indicate $(\bar{1}10)$ cleavage planes, while Fig. 2c represents a (110) cleavage plane. It is clear from this figure that the lateral overgrowth strongly depends on the grating direction.

Table I. Growth conditions

Growth temperature ($^\circ C$)	400-800	(630) ^a
[TMG] (mole fraction)	2.3 - 12.8×10^{-5}	(3.2×10^{-5})
$[AsH_3]$ (mole fraction)	0.2 - 7×10^{-3}	(1.7×10^{-3})
$[AsH_3]/[TMG]$	6-220	(53)
Total flow rate (liter/min)	4	
Grating direction from the $\langle \bar{1}10 \rangle$ ($^\circ$)	0-90	

^a Parentheses mean standard growth conditions (see text).

Fig. 2. Photomicrographs of cleaved cross sections of grown layers over tungsten gratings oriented at 0° (a), 30° (b), and 90° (c) from the $\langle \bar{1}10 \rangle$ direction. Note that the a and b show the $(\bar{1}10)$ cleavage planes and that the c represents the (110) plane.

For the 0° grating direction, which corresponds to the $\langle \bar{1}10 \rangle$ direction, the lateral overgrowth facets exhibited planes shaped perpendicularly to the (001) surface (Fig. 2a). For the 30° gratings, the facets had reverse-mesa-shaped planes at the initial overgrowth stage. As the overgrowth continued, the reverse-mesa-shaped GaAs stripes laterally developed and finally joined at the reverse-mesa top to form continuous, flat, specular layers. In the top view of such a sample, one could not observe any disturbance due to the presence of the $5 \mu m$ width-and-space tungsten grating. In the cross-sectional view, however, triangular voids were seen near the centers of the tungsten stripes as a result of reverse-mesa formation during initial overgrowth (see Fig. 2b).

For the 90° grating direction, which corresponds to the $\langle 110 \rangle$ direction, the overgrowth profile indicated ordinary mesa-shaped planes (Fig. 2c). When the overgrowth exhibiting this facet type continued, the top surface of the ordinary mesa became narrower as growth proceeded until the overgrown layer was finally composed of only inclined surfaces. The inclined plane was identified with $\{112\}As$ faces from the facet angle of 37° with respect to the (001) surface. The overgrowth continued further, and if the V-shaped grooves left on the layer surface were filled up one could then expect to obtain an overgrown layer free of voids near the center of the tungsten stripes. In contrast to this expectation, anomalous faceting growth took place actually as shown in Fig. 3. The facets could not be characterized by specific planes.

Fig. 3. Photomicrograph of a (110) cleaved plane of an overgrown layer for the 90° tungsten stripe direction which corresponds to $\langle 110 \rangle$.

Surface morphology of MOCVD layers is well known to depend strongly on substrate orientation (16). The layer surface on the $(\bar{1}\bar{1}\bar{1})$ As substrate indicated very defective morphology, including many poly-like hillocks (17). Since $(\bar{1}12)$ As and $(\bar{1}\bar{1}\bar{1})$ As surfaces are composed of a relatively large number of As atoms, the defective growth is considered to take place on the $(\bar{1}12)$ As, similarly to that on the $(\bar{1}\bar{1}\bar{1})$ As. Since the growing surface for the 90° grating direction is only the inclined $(\bar{1}12)$ As face, anomalous faceting growth such as is shown in Fig. 3 is believed to occur.

The overgrown layers are characterized by the facet shapes, as shown in Fig. 2. To determine the crystallographic plane for the facet, the angle of the facet with respect to the (001) surface was measured from cross-sectional photographs of the layers. The facet angle for the tungsten grating direction from 0° to 90° is presented in Fig. 4. All the samples were simultaneously grown under the conditions of 630°C and [TMG] and [AsH₃] of 3.2×10^{-5} and 1.7×10^{-3} mole fraction, respectively. From this figure, the facet angle can be clearly classified into three regions.

In the 0°-10° grating direction region, the facet angle was perpendicular to the substrate surface, which corre-

Fig. 4. Facet angle (see inset) with respect to the (001) surface plane as a function of the tungsten grating angle from $\langle 110 \rangle$.

sponds to the {110} crystallographic plane. For the substrates with 10°-45° grating orientations, the sidewalls of the overgrowth layers had an angle of 130° with respect to the (001) surface. This angle coincided with the one of the $\{\bar{1}\bar{1}\bar{1}\}$ As plane with respect to the (001) surface. For the 45°-90° GaAs opening directions from $\langle \bar{1}10 \rangle$, the overgrowth profile observed on a (110) cleavage plane indicated the inclined plane forming an angle of 37°. The angle coincided with the one of the {112}As face with respect to the (001) surface.

In each region of the grating angle, the sidewalls of the overgrown layers were found to retain the same angle with respect to the (001) surface planes as mentioned above. This suggests the following overgrowth process. Lateral overgrowth is seeded from the edges of the masking tungsten stripes by selective epitaxial deposits initially formed only on the exposed regions. However, the lateral growth fronts do not proceed perpendicularly toward the stripe direction.

Microscopically, the lateral growth fronts are composed of two small specific planes formed perpendicularly to the cleavage planes, as shown in Fig. 5. The specific plane can be determined by observation of the cleavage plane. For example, for the 30° grating directions, a small plane observed on the $(\bar{1}10)$ cleavage plane corresponds to the $\{\bar{1}\bar{1}\bar{1}\}$ As crystallographic plane forming an angle of 125.3°, in principle, with respect to (001) surface plane.

This overgrowth process is also supported by the observation of the overgrowth layer surface shown in Fig. 6. In this figure, although almost all growth fronts are parallel to the tungsten stripe, anomalous growth is observed in some areas. The anomalous growth areas are very similar to the zigzag growth process portrayed in Fig. 5. The areas of the films with parallel growth fronts are also believed to be composed of a number of facets, as previously reported by Vohl *et al.* (11). This overgrowth process, therefore, generally occurs in growth over the misoriented masking stripes, whose direction is not parallel to low indexes such as the $\langle \bar{1}10 \rangle$ and $\langle 110 \rangle$ directions.

Dependency of Overgrowth on Growth Parameters

Growth parameters in MOCVD control facet formation as well as layer quality, such as surface morphology and electron mobility. In this section, we describe the dependence of the overgrowth on growth temperature and AsH₃ and TMG mole fractions. Since a smooth surface of an overgrown film was found to be obtainable for the 30° grating direction, as mentioned in the preceding section, the main focus is on the dependency of the lateral growth over the 30° tungsten grating.

Growth temperature.—Growth temperature affects facet formation in overgrowth in conjunction with surface morphology. For typical growth temperatures, we have conducted a study on the relationship between the surface morphology and the facet formation of the overgrown layers. Figures 7a, 7b, 7c, and 7d present the overgrowth layers obtained at 710°, 630°, 600°, and 510°C, respectively, with all other growth conditions being the same, that is, [TMG] = 3.2×10^{-5} mole fraction and [AsH₃] = 1.7×10^{-3} mole fraction. All the specimens shown in

Fig. 5. Schematic picture of overgrowth process onto 30° GaAs stripe openings.

Fig. 6. Photomicrograph of the surface of the overgrown layer just before joining lateral growth fronts seeded from the edges of tungsten stripes.

these figures were grown over 30° gratings from the $\langle \bar{1}10 \rangle$ direction. Note that the cross-sectional views were observed on the $(\bar{1}10)$ cleavage planes.

The sidewall of an overgrown layer at the high temperature of 710°C consists of reverse-mesa- and ordinary mesa-shaped planes as shown in Fig. 7a. At a growth temperature above this value, only the ordinary mesa-shaped planes formed on the exposed GaAs stripes. The cross-sectional views of the samples at 630° and 600°C indicate the same reverse-mesa-shaped planes (see Fig. 7b and 7c). Though the triangular voids are also seen in the layer at 630°C , they were slightly smaller in size than those at 600°C . Therefore, the ratio of lateral to vertical growth rates tends to slightly increase with a decrease in the growth temperature. This tendency demonstrated qualitative agreement with the results using (011) GaAs substrates (12).

The surface of the films obtained at 630°C is flat and smooth (Fig. 7b) On the other hand, the surface of the

Fig. 7. Photomicrographs of surfaces and $\bar{1}10$ cleavage planes of layers grown over 30° tungsten gratings at 710°C (a), 630°C (b), 600°C (c), and 510°C (d).

film grown at 600°C represents defective morphology, which exhibits a rough-patterned structure reflecting the underlying tungsten grating, as shown in Fig. 7c.

At a growth temperature lower than 530°C , GaAs deposition occurred not only on the exposed GaAs surface but also on the masking tungsten stripes. The deposition of polycrystalline GaAs on the tungsten stripes prevented the lateral epitaxial growth from the edges of the tungsten stripes (see Fig. 7d). Consequently, the well-defined facets cannot be observed for the overgrown layers at the lower growth temperature.

The formation of polycrystalline GaAs over the mask surface, as shown in Fig. 7d, is the major problem encountered during lateral overgrowth. In MOCVD growth in particular, the poly-GaAs deposits readily over the tungsten mask, because the sticking coefficient for Ga is unity. For a growth temperature above 530°C , however, GaAs growth is initiated only on the exposed area. This suggests that Ga adatoms on the tungsten are transferred to the growing GaAs surface. The driving force behind transferring the Ga adatoms is produced by atomic surface diffusion and by the difference between the nucleation probabilities for the GaAs and the tungsten. The atomic surface diffusion length decreases with a decrease in the growth temperature. Nucleation of polycrystalline GaAs, therefore, takes place on the tungsten stripes at low growth temperature.

In addition to the growth temperature, the polycrystalline deposit onto the tungsten surface is very sensitive to the tungsten mask characteristics. For example, the poly-GaAs nuclei form around the defects present on the tungsten surface such as pinholes, topological irregularities, and contaminated regions. These defects considerably increase the nucleation probability on the tungsten surface. Furthermore, the intrinsic properties of a mask surface, such as its surface free energy and number of free surface sites where source species are incorporated (18, 19), also have influence on the nucleation probability for the mask.

The facets of films grown over 30° gratings are affected by the growth temperature, as shown in Fig. 7. To examine the facet shapes in detail, the angle of the facet was measured with respect to the (001) substrate surface. The facet angle for the growth temperature from 550° to 810°C is presented in Fig. 8. Other growth parameters remain the same, that is, $[\text{TMG}] = 3.2 \times 10^{-3}$ mole fraction and $[\text{AsH}_3] = 1.7 \times 10^{-3}$ mole fraction. It is remarkable that the growth temperature of 710°C represents the critical point in change from the reverse mesa to the ordinary mesa geometric shape of the overgrowth layers. The sidewalls of these geometric shapes indicate the facet forming angles of 130° and 27° , respectively. From these angles, the faces constituting the sidewalls of the overgrown layer are identified with the $\{\bar{1}\bar{1}\}\text{As}$ and the $\{11\}\text{Ga}$ crystallographic planes.

On the other hand, with the decrease in the growth temperature, the sidewall inclination of the overgrowth layer changed gradually from 130° to 105° with respect to the (001) substrates. The gradual change is attributed to the reduction in the surface diffusion length of source species with the decrease in the growth temperature. A well-defined facet is not formed due to the reduction of atomic diffusion along the top and side surfaces of the growing layers.

The temperature dependence of the facet formation mentioned above was not observed for all of the grating directions. For example, for the tungsten grating directions of 0° and 90° , which correspond to $\langle \bar{1}10 \rangle$ and $\langle 110 \rangle$, respectively, the facet angle with respect to the (001) surface plane is independent of the growth temperature, as shown in Fig. 9. For the 0° grating direction, the sidewall of the layer observed on the (110) cleavage plane indicates a plane perpendicular to the (001) surface, which corresponds to the $\{110\}$ crystallographic plane. For the 90° grating direction, the overgrowth profile on the (110) cleavage planes exhibits the inclined plane forming an angle of 37° with respect to the (001) surface plane. This

Fig. 8. Facet angle with respect to the (001) surface plane as a function of the growth temperature. Grating direction was 30° from $\langle\bar{1}10\rangle$. Other growth parameters: $[TMG] = 3.2 \times 10^{-5}$ mole fraction, and $[AsH_3] = 1.7 \times 10^{-3}$ mole fraction.

angle coincides with that of the $\{112\}As$ crystallographic plane. With respect to the facet formation, the relationship between the grating angle and the growth temperature is more complex. The details of this will be described below.

AsH₃ and TMG mole fractions.— AsH_3 and TMG mole fractions ($[AsH_3]$ and $[TMG]$) are key parameters in controlling the MOCVD film characteristics, such as p-n conversion. One can expect that the faceting growth onto the GaAs stripe openings is also affected by the $[AsH_3]$ and $[TMG]$ conditions. This represents our final experi-

Fig. 9. Facet angle with respect to the (001) surface plane as a function of the growth temperature. Grating directions were 0° and 90° , corresponding to the $\langle\bar{1}10\rangle$ and $\langle 110\rangle$ directions, respectively.

ment on facet dependence. In order to properly separate the $[AsH_3]$ and $[TMG]$ effects, the $[AsH_3]$ condition was varied under a constant $[TMG]$ and vice versa.

Figures 10a, 10b, and 10c are photomicrographs of the (110) cleaved planes of films grown at 6.8×10^{-3} , 1.7×10^{-3} , and 0.4×10^{-3} AsH_3 mole fractions, respectively. For all of the specimens, the tungsten grating directions were 30° from the $\langle\bar{1}10\rangle$, $[TMG]$ was 3.2×10^{-5} mole fraction, and the growth temperature was $630^\circ C$. The geometrical shape of the layer grown at $[AsH_3] = 1.7 \times 10^{-3}$ mole fraction was the reverse mesa, as shown in Fig. 10b. This condition of $[AsH_3]$ was optimal for obtaining the smooth surface of the layer. Even though the AsH_3 mole fraction was increased, the films exhibited the same reverse-mesa-shaped planes. The layer surface, however, became wavy and defective (see Fig. 10a). On the other hand, when the AsH_3 mole fraction was decreased, the ordinary mesa-shaped planes were formed in addition to the reverse-mesa-shaped planes as the sidewalls of the overgrown layer (Fig. 10c). This geometrical shape is very similar to that of the $710^\circ C$ growth temperature (cf. Fig. 7a).

From the cross-sectional photographs shown in Fig. 10, the $[AsH_3]$ dependence of a facet angle with respect to the (001) surface was examined. The facet-angle variation for $[AsH_3]$ of $0.2-7 \times 10^{-3}$ mole fractions is represented in Fig. 11. The observed geometrical shapes of the overgrown layers are shown in the two insets. Up to a mole fraction of $[AsH_3] = 0.8 \times 10^{-3}$, which corresponds to $[AsH_3]/[TMG] = 25$, the sidewalls consisting of ordinary mesa- and reverse-mesa-shaped planes were formed,

Fig. 10. Photomicrographs of $\langle\bar{1}10\rangle$ cleavage planes of layers grown at $[AsH_3]$ of 6.8×10^{-3} (a), 1.7×10^{-3} (b), and 0.4×10^{-3} (c) mole fractions. All the layers were grown on the tungsten gratings oriented 30° from $\langle\bar{1}10\rangle$.

Fig. 11. Facet angle with respect to the (001) surface plane as a function of $[\text{AsH}_3]$. Growth temperature was 630°C .

whose angles with respect to the (001) surface were 130° and 27° , respectively (see the left inset of Fig. 11). From these angles, the facets were found to correspond to the $\{\bar{1}\bar{1}\bar{1}\}\text{As}$ and $\{113\}\text{Ga}$ faces. Above a mole fraction of $[\text{AsH}_3] = 0.8 \times 10^{-3}$, the sidewall indicated only the $\{\bar{1}\bar{1}\bar{1}\}\text{As}$.

From this result only, however, one cannot know whether the growth parameter causing the facet variation is $[\text{AsH}_3]$ or $[\text{AsH}_3]/[\text{TMG}]$. Therefore, we studied the effects of the $[\text{TMG}]$ variation on the overgrowth under $[\text{AsH}_3] = 1.7 \times 10^{-3}$ mole fraction. The facet angle with respect to the (001) surface as a function of $[\text{TMG}]$ is presented in Fig. 12. Under the conditions of $[\text{TMG}] = 2.3\text{--}12.8 \times 10^{-5}$ mole fraction corresponding to

Fig. 12. Facet angle with respect to the (001) surface plane as a function of $[\text{TMG}]$. Growth temperature was 630°C .

$[\text{AsH}_3]/[\text{TMG}] = 13\text{--}74$, the sidewall of the overgrown layer indicates only the facet forming an angle of 130° with respect to the (001) surface. Even below $[\text{AsH}_3]/[\text{TMG}] = 25$, no plane other than the $\{\bar{1}\bar{1}\bar{1}\}\text{As}$ face was formed regarding the sidewalls of the overgrown layers. On the other hand, when $[\text{AsH}_3]/[\text{TMG}]$ was reduced below 25 through a decrease in $[\text{AsH}_3]$ with a constant $[\text{TMG}]$, the $\{113\}\text{Ga}$ face was formed in addition to the $\{\bar{1}\bar{1}\bar{1}\}\text{As}$ face (see Fig. 11). Therefore, the facet formed during the selective growth on the tungsten gratings is concluded to depend on $[\text{AsH}_3]$ rather than $[\text{AsH}_3]/[\text{TMG}]$.

Vertical Growth Rate of Overgrown Layer

Studies of growth rate provide us with basic information on growth mechanisms. For selective growth without poly-GaAs deposition over a tungsten surface, reacting species which arrived from the gas phase to the tungsten surface should be (i) released again into the gas phase, or (ii) transferred to a growing GaAs surface. In case (i), the vertical growth rate on the limited area can be predicted as being essentially the same as the growth rate on the substrate without the tungsten grating. On the other hand, in case (ii), the vertical growth rate in the limited region is apparently enhanced compared to that on the surface without the tungsten grating.

The vertical growth rate was determined from the height of a top side of the overgrown layer on the limited GaAs area. The vertical growth thickness, t , vs. the grating angle is given as the closed circles in Fig. 13, where the growth time was 2h. The layer thickness on the substrate without the tungsten grating is also shown as an open triangle. From this figure, the thickness of the overgrown layer is found to strongly depend on the grating direction. Moreover, the vertical growth rates of the overgrown layers shown in Fig. 13 were larger than the layer thickness on a substrate without the tungsten grating. The vertical growth rate on a limited area is only apparently enhanced. Therefore, the arrival species at the tungsten surface are not released again into the gas phase but are transferred to the growing GaAs surface.

To clarify this situation further, let us consider an average layer thickness, \bar{t} , which is calibrated by filling up the V grooves or the triangular voids as shown in the inset of Fig. 13. The calibrated layer thicknesses are represented as open circles in the figure. The average layer thickness was found to coincide with the layer thickness on the substrate without the tungsten pattern in all the grating directions. Therefore, an amount of the reacting species which lead to the GaAs growth is basically the same. The difference in the heights of the top sides of the layers on the limited areas is only apparent.

Fig. 13. Layer thicknesses for 2h growth time as a function of grating direction.

Fig. 14. Layer thicknesses for 2h growth time as functions of growth temperature (a) and $[AsH_3]$ (b). The layers were grown over the 30° tungsten gratings at $630^\circ C$.

Vertical growth rates on the limited area are also studied with respect to growth temperature and $[AsH_3]$. Figures 14a and 14b plot film thickness at a growth time of 2h as functions of the growth temperature and $[AsH_3]$, respectively. All of the films were grown over the 30° tungsten gratings. The apparent and average thicknesses of the selectively grown layers are indicated as the closed and open circles, respectively. The layer thickness on the substrate without the grating is also represented as open triangles. Though the apparent thickness on the GaAs opening varied with the growth temperature and $[AsH_3]$, the average thickness was independent of the growth conditions. This was similar to the layer thickness on the substrate without the grating.

Moreover, the average thickness coincided with the thickness on the substrate without the grating. From the results of the average thickness, it can be concluded that the overall growth rate under this range of growth conditions is essentially limited by mass transport through the stagnant layer in the gas phase. However, surface kinetics cannot be ruled out as an MOCVD growth mechanism, because the various crystallographic faces form with a dependence on the tungsten stripe direction, the growth temperature, and $[AsH_3]$.

Crystallographic Aspect and Overgrowth Mechanism

In this section, we discuss the facets of the overgrown layers on the tungsten gratings demonstrated in Fig. 2, 7, and 10 from a crystallographic aspect. With respect to the crystallographic planes of the formed facets, the relationship between the grating direction and growth condition is studied. On the basis of these discussions, the overgrowth mechanism is examined.

Facet identification.—The facets of the overgrown layers on the tungsten gratings are studied from the crystallographic point of view. From the facet angle of the overgrown layers, the geometric shapes of the layers can be classified into four individual groups, as shown in Fig. 15.

The overgrown facet forming an angle of 90° with respect to the (001) surface plane was observed on $(\bar{1}10)$ cleavage planes for the near $\langle \bar{1}10 \rangle$ grating directions. This result was independent of the growth conditions. From this facet angle, these formed planes correspond to the $\{110\}$ crystallographic planes (see Fig. 15I). In the region of 10° – 45° tungsten opening directions, two types of facet shapes were observed on the $(\bar{1}10)$ cleavage planes. One is represented by the inclined planes forming an angle of 130° with respect to the (001) surface, which corresponds to the $\{\bar{1}\bar{1}\}$ As planes (Fig. 15II). The other is represented by the planes forming an angle of 27° with respect to the (001) surface planes, which corresponds to the $\{113\}$ Ga (Fig. 15III).

The $\{\bar{1}\bar{1}\}$ As and $\{113\}$ Ga planes, in principle, form angles of 125.3° and 25.2° , respectively, with respect to the (001) surface planes. One of these types was changed into the other by the growth temperature or $[AsH_3]$ conditions. For the 45° – 90° tungsten grating directions from $\langle \bar{1}10 \rangle$, only the plane forming an angle of 37° with respect to the (001) surface was observed on the (110) cleavage plane independent of the growth conditions (Fig. 15IV). From the angle of the inclined plane observed on the (110) cleaved plane, the facet corresponds to the $\{\bar{1}12\}$ As, which, in principle, forms an angle of 35.3° with respect to the (001) surface plane.

These facet types shown in Fig. 15 are summarized with respect to the grating direction and growth conditions. The classification of these facet types is plotted out for the growth temperature and grating angle in Fig. 16. Below the growth temperature of $440^\circ C$, no GaAs nuclei are deposited on the exposed GaAs regions nor on the tungsten surface. In the 530° – $440^\circ C$ region, poly-GaAs is deposited on the tungsten surface. Though monocrystalline GaAs was grown onto the exposed GaAs area, the facets could not be observed, owing to the deposition of poly-GaAs on the tungsten surface. Therefore, the temperature range above $530^\circ C$ is a subject of some discussion concerning the facet types.

Fig. 15. Schematic diagrams of the overgrowth profiles produced on the (001) GaAs plane under the various growth conditions (see text).

Fig. 16. Classification of facet types for growth temperatures and grating angles.

A similar classification is also mapped for $[\text{AsH}_3]$ and the grating angle in Fig. 17. Regions I, II, III, and IV in Fig. 16 and 17 mean the extent of growth parameters and grating direction, where the overgrowth profiles indicate types I, II, III, and IV as presented in Fig. 15. In these plots, for example, the region II+III means a conditional extent which produces the side wall consisting of the $\{\bar{1}\bar{1}\}\text{As}$ and $\{113\}\text{Ga}$ planes, as shown in Fig. 10c.

It is clear from these figures that the GaAs opening direction on the (001) substrate surface is the most essential parameter for the overgrowth. This is because the facet shape is controlled by the grating direction, except in the

Fig. 17. Classification of face types for $[\text{AsH}_3]$ and grating angle. Growth temperature was 630°C .

$10^\circ\text{--}45^\circ$ region. This reason is not well understood at present, but it is considered to relate to the atomic arrangements, atomic bond directions, and crystallographic polarity on the defined stripe opening of the (001)GaAs substrate surface. The other limitations for the faceting growth are growth temperature and $[\text{AsH}_3]$.

It is noteworthy that the $\{\bar{1}\bar{1}\}\text{As}$ sidewall plane of the selectively grown layer changes to the $\{113\}\text{Ga}$ at the growth temperature of more than 710°C . Additionally important is the fact that the $\{113\}\text{Ga}$ side plane is formed together with the $\{\bar{1}\bar{1}\}\text{As}$ plane at less than a 0.8×10^{-3} mole fraction of $[\text{AsH}_3]$. In short, an increase in the growth temperature and a decrease in $[\text{AsH}_3]$ have a similar influence on facet formation.

Overgrowth mechanism.—We will now discuss our experimental results in terms of the Langmuir-Rideal mechanism, where gas phase gallium species react with surface-adsorbed arsenic (20). Although the reacting species are written as Ga and As for the sake of simplicity, the actual surface species which lead to GaAs growth are considerably more complex in MOCVD (21).

In the Langmuir-Rideal model, the growth rate, R , is given by

$$R = K\Theta_{\text{As}}P_{\text{Ga}} \quad [1]$$

where K is a rate constant, P_{Ga} is the initial partial pressure of the Ga species in the gas phase, and Θ_{As} is the surface coverage of the As species. The Θ_{As} is written as

$$\Theta_{\text{As}} = \frac{\beta_{\text{As}}P_{\text{As}}}{1 + \beta_{\text{As}}P_{\text{As}}} \quad [2]$$

where P_{As} is the partial pressure of the As species in the gas phase and β_{As} is the Langmuir adsorption constant for the As species, that is, the ratio of the rate constant for the adsorption of the As species to the rate constant for desorption.

Assuming that TMG is completely decomposed by the homogenous reaction in the gas phase (22), $P_{\text{Ga}} \approx P_{\text{TMG}}$, where P_{TMG} is the inlet partial pressure of TMG in the gas phase, such that Eq. [1] can be rewritten into

$$R = K\Theta_{\text{As}}P_{\text{TMG}} \quad [3]$$

From this equation, one can expect that the slight difference in growth rate is caused by the Θ_{As} dependence on the surface orientation. However, the dependence of the growth rate on the orientation is not measurable by an experiment using individual substrates with various orientations because $\Theta_{\text{As}} \approx 1$, i.e., $\beta_{\text{As}}P_{\text{As}} \gg 1$, in almost all cases (20). Consequently, Eq. [3] is reduced to

$$R = KP_{\text{TMG}} \quad [4]$$

Therefore, the predicted growth rate demonstrates a linear dependence on the partial pressure of TMG, and is independent of the AsH_3 overpressure.

Let us consider the case where various crystallographic faces are arranged within the surface diffusion length of the reacting species. The growth rate dependence on the orientation predicted from Eq. [3] is enhanced by the diffusion of the reacting species from the face where the growth rate is relatively low to the face with the relatively high growth rate. As a consequence, the growth rate is considered to depend significantly on the surface orientation. The faceting growth is also dominated by this mechanism.

The planes where the growth rate is relatively small are believed to be formed as facets of the overgrowth layer. The Θ_{As} is dependent on the growth temperature and the AsH_3 partial pressure while being independent of the TMG partial pressure. Therefore, the faceting growth is strongly dependent on the temperature and the partial pressure of AsH_3 , while being independent of the partial pressure of TMG. However, the overall average growth rate of the overgrown layer depends only on the partial pressure of TMG.

Conclusion

Lateral epitaxial growth of GaAs over tungsten gratings with 5 μm wide lines and spaces on (001) GaAs substrates was performed using MOCVD. Lateral overgrowth was seeded from the edges of the masking tungsten stripes by selective epitaxial deposits initially formed only on the exposed regions. The facets were formed at the GaAs-overgrown film edges. From crystallographic aspect, all the facets observed in the overgrown layers were found to be classified into four individual groups of {110}, $\{\bar{1}\bar{1}\bar{1}\}$ As, $\{112\}$ As, and $\{113\}$ Ga faces. The GaAs opening direction on the (001) substrate surface was found to be the most essential parameter for determining the geometric shape of the overgrowth layer. The other controlling parameters were the growth temperature and the partial pressure of AsH₃. The partial pressure of TMG had no influence on the facet formation, although the average growth rate of the overgrown layer was controlled by the mass transport of the reacting species including Ga atoms. These results could be qualitatively explained by the Langmuir-Rideal model.

An Alternative Approach to the Calculation of Four-Probe Resistances on Nonuniform Structures

ABSTRACT

An alternative approach to the calculation of the four-probe resistance of nonuniform resistivity structures is presented. This approach is based upon two simplifications in the form of the four-probe resistance integral. The first arises from the integral's being independent of the probe current density as well as the probe radius. The second simplification involves the rewriting of the integral as one involving only the kernel (without any Bessel functions) and with finite limits which depend only upon the probe spacing. The form of these limits is determined by the analytic calculation of the four-probe resistance for the case of a semi-infinite slab. For the case of a uniform layer over an insulating or conducting boundary, the simplified integral leads to analytic expressions for the four-probe resistance which are compared with the more extensive technique and are also investigated as a function of the probe spacing. For nonuniform resistivity structures, the simplified integral can be easily evaluated by means of the Newton-Cotes numerical procedure. For general multilayer cases, the results obtained from the Newton-Cotes method are compared with those obtained from more extensive numerical techniques and are shown to be in excellent agreement. This allows for a vastly simplified implementation of the previously proposed spreading resistance calibration technique.

Recently, a multilayer expression for the in-line four-probe resistance, $Z(x, S)$, has been derived in the form (1)

$$Z(x, S) = 2\rho(x) \int_0^\infty A(x, \lambda) \{J_0(\lambda S) - J_0(2\lambda S)\} I_\nu(\lambda a) d\lambda \quad [1]$$

where $\rho(x)$ is the resistivity, $J_0(\lambda S)$ is the first-order Bessel function, $A(x, \lambda)$ is the kernel of the integral and is

related to the resistivity structure, $I_\nu(\lambda a)$ is the Hankel transform of the generalized probe-current density normalized to unit current (2), ν is an index which refers to the specific form of the current density, a is the probe radius, and λ is the integration variable. It was shown that the four-probe resistance could always be obtained from the two-probe spreading resistance, $R(x, S)$, from the general expression

*Electrochemical Society Active Member.

$$Z(x, S) = R(x, 2S) - R(x, S) \quad [2]$$

The four-probe resistance was also numerically shown to be (i) independent of the probe radius and the probe-current density, and (ii) simply related to the sheet resistance, $\mathfrak{R}(x)$, when the distance to an insulating boundary is small compared with the probe spacing. The former observation provided the basis for a calibration procedure for determining the value of the probe radius to be used in spreading resistance profile analysis. The use of the four-probe resistance in the calibration procedure requires the evaluation of the integral in Eq. [1]. This evaluation can be greatly simplified, and it is the purpose of the present work to derive a simplified expression for $Z(x, S)$ and hence greatly facilitate the use of the calibration procedure.

Derivation

As the four-probe resistance is independent of the probe current density and the probe radius, Eq. [1] may be rewritten as

$$Z(x, S) = \frac{\rho(x)}{\pi} \int_0^{\infty} A(x, \lambda) \{J_0(\lambda S) - J_0(2\lambda S)\} d\lambda \quad [3]$$

This particular simplification of the integral has been numerically verified for a range of structures. The thrust of the present work is to further simplify the integral by finding a function, $f(1/S)$, such that Eq. [3] can be written as

$$Z(x, S) = \frac{\rho(x)}{\pi} \int_{f(1/2S)}^{f(1/S)} A(x, \lambda) d\lambda \quad [4]$$

In going from Eq. [3] to Eq. [4], the Bessel functions have been removed from the integrand and their effect on the integral has been preserved by the replacement of the limits in Eq. [3] by finite limits which depend only upon S . This particular choice for the limits of the integral is not arbitrary but was motivated by the substitution of the Berkowitz-Lux (3) form of the spreading resistance in both terms in the right-hand side of Eq. [2]. The resulting expression contains the integral of $A(x, \lambda)$ where the lower limit depends upon $1/2S$ and the upper limit depends upon $1/S$. The particular form obtained from this substitution does not adequately represent the results for a wide class of structures. However, this observation provided the insight into the general form which the simplification of the integral would take.

The search for the function, $f(1/S)$, is aided by the calculation of Eq. [3] and [4] for the case of a semi-infinite slab. In this case, $A(x, \lambda) = 1$, and the integral in Eq. [3] can be evaluated analytically (4) to give

$$Z(x, S) = \frac{\rho}{\pi} \int_0^{\infty} \{J_0(\lambda S) - J_0(2\lambda S)\} d\lambda = \frac{\rho}{2\pi S} \quad [5]$$

This indicates that $f(1/S) = 1/S$, as can be verified by direct substitution into Eq. [4]. If this choice is generally correct, then the four-probe resistance will be represented by the equation

$$Z(x, S) = \frac{\rho(x)}{\pi} \int_{1/2S}^{1/S} A(x, \lambda) d\lambda \quad [6]$$

which is far simpler to evaluate and analyze than Eq. [1]. The validity of Eq. [6] was investigated for uniform layers over insulating or conducting boundaries, for a wide class of two-layer structures, and for general nonuniform multilayer structures. The results of these investigations are contained in the next three sections.

Uniform Resistivity Layers over Perfectly Insulating or Conducting Boundaries

The kernel for a uniform resistivity layer over an insulating or a conducting boundary, *i.e.*, $\coth(\lambda x)$, $\tanh(\lambda x)$, may be used to analytically evaluate the integral in Eq. [6] for these cases. Specifically

$$\begin{aligned} Z(x, S) &= \frac{\rho(x)}{\pi} \int_{1/2S}^{1/S} \coth(\lambda x) d\lambda \\ &= \frac{\rho}{\pi x} \ln \left\{ \frac{\sinh(x/S)}{\sinh(x/2S)} \right\} \end{aligned} \quad [7]$$

for an insulating boundary and

$$\begin{aligned} Z(x, S) &= \frac{\rho(x)}{\pi} \int_{1/2S}^{1/S} \tanh(\lambda x) d\lambda \\ &= \frac{\rho}{\pi x} \ln \left\{ \frac{\cosh(x/S)}{\cosh(x/2S)} \right\} \end{aligned} \quad [8]$$

for a conducting boundary. It is important to note in both cases that the probe spacing and the distance to the boundary appear as the ratio x/S . It is this ratio which determines the behavior of the functions.

For the situation where the distance to the boundary is small compared to the probe spacing, *i.e.*, $x/S < 1$, the \sinh function may be replaced by its argument whereas the \cosh function approaches unity. By making use of these limiting values for small x/S , it is straightforward to show that

$$\lim_{x/S < 1} Z(x, S) = \frac{\rho \ln(2)}{\pi x} \quad [9]$$

for an insulating boundary and

$$\lim_{x/S < 1} Z(x, S) = 0 \quad [10]$$

for a conducting boundary. From Eq. [9], it is clear that the idea of a "thin" isolated layer must be phrased in terms of the ratio of the thickness of the layer and the probe spacing. As the probe spacing becomes large compared to the distance to the boundary, the uniform layer may be considered to be "thin." This is important as it places an objective criterion on the use of the idea of thin layers. Equation [10] states for the case of a uniform layer over a conducting boundary that the four-probe resistance approaches zero as the probe separation becomes large compared to the distance to the conducting boundary.

For the situation where $x/S > 1$, the hyperbolic functions contained in Eq. [7] and [8] may be replaced by exponentials of the same argument. Then

$$\lim_{x/S > 1} Z(x, S) = \frac{\rho}{2\pi S} \quad [11]$$

for both the insulating and conducting boundary conditions. Hence, for $x/S > 1$, the results for both the insulating and conducting boundaries approach the semi-infinite slab result given by Eq. [5]. These results are summarized in Fig. 1, where the scaled four-probe function, $(\pi x/\rho)Z(x, S)$, is plotted for a wide range of x/S for each of the three boundary conditions. For $x/S < 1$, the three functions appear as three separate curves. The conducting boundary result decreases rapidly to zero, while the semi-infinite slab result decreases slowly to zero. In this same region, the insulating boundary result has reached its asymptotic value of $\ln(2)$. When x/S is approximately 0.5, the insulating boundary and conducting boundary results begin curving toward the semi-infinite slab results. This curving and merging is finally complete once x/S is approximately 2-3. Beyond this point, all three curves lie on top of each other, as indicated by Eq. [11]. These indicate, once x/S is approximately 2 or greater, that the effects of any boundary (especially an insulating boundary) have been completely removed. This would mean that four-probe resistance measurements made on thick layers, $x/S > 1$, should not be associated with a sheet resistance interpreted in terms of a parallel conduction model, *i.e.*, in terms of a sheet resistance $\mathfrak{R}(x)$, defined by

Fig. 1. The four-probe resistance scaled by $(\pi x/\rho)$, i.e., $(\pi x/\rho)Z(x, S)$, is presented for a large range of x/S for several boundary conditions. The curve denoted by A represents the result for an insulating boundary, while the curves denoted by B and C represent the results for a conducting boundary and no boundary (semi-infinite slab), respectively.

$$\Re(x) = \frac{1}{\int_0^x \sigma(x') dx'} \quad [12]$$

Having established the analytical results from the cases of semi-infinite slabs, uniform layers over insulating, or conducting, boundary conditions, what remains to be shown in this section is how well these results agree with the “exact” results obtained from Eq. [1]. Figure 2 contains the results of this comparison for a uniform layer over an insulator. In general, the agreement is very good. In the middle region of x/S values (from about 0.5 up to about 2.0), the maximum difference between the two results is about 10%.

A Two-Layer Structure

A particular example where the equations can be worked out exactly is the two-layer case where the top layer has a larger resistivity than the bottom layer. The resistivities of the bottom and top layers are ρ_1 and ρ_2 , respectively. The form of the kernel of the integral is given by

$$A_2(x, \lambda) = \frac{\rho_1 A_1 + \rho_2 \tanh(\lambda x)}{\rho_2 + \rho_1 A_1 \tanh(\lambda x)} \quad [13]$$

where x is the position of the surface of the top layer and A_1 is the kernel evaluated at the surface of the bottom layer. Introducing the variable q defined as $q = \rho_1/\rho_2$ and expanding the right-hand side of Eq. [13] to terms of order q , leads to the expression

$$\begin{aligned} A_2(x, \lambda) &= (qA_1 + \tanh(\lambda x))(1 - qA_1 \tanh(\lambda x)) \\ A_2(x, \lambda) &= \tanh(\lambda x) + qA_1(1 - \tanh(\lambda x)) + \dots \end{aligned} \quad [14]$$

Substituting this form for the kernel into Eq. [6] and evaluating the integral leads to the following expression of the four-probe resistance for this particular two-layer structure

$$Z(x, S) = \frac{\rho_2}{\pi x} \ln \left\{ \frac{\cosh(x/S)}{\cosh(x/2S)} \right\} + \frac{\rho_1}{\pi x} \ln \{ \tanh(x/S) - \tanh(x/2S) \} \quad [15]$$

Equation [15] represents the four-probe resistance of a

Fig. 2. The four-probe resistance scaled by (π/ρ) , $(\pi/\rho)Z(x, S)$, calculated from Eq. [1] and [7], are presented for the case of a uniform resistivity layer over an insulating boundary condition.

two-layer structure and reduces to Eq. [9] and [11] under the appropriate conditions.

Numerical Evaluation of $Z(x, S)$

A numerical integration scheme is required for the evaluation of the $Z(x, S)$ integral in Eq. [6] for the case of a general nonuniform resistivity structure. Two general techniques were used in the evaluation of the integral in Eq. [6]. The first makes use of the trapezoidal-Romberg technique with a 0.005% convergence criterion on the evaluation of the integral. This integration technique was the one which was used previously (5) to evaluate the spreading resistance correction factor integral. The second technique makes use of the nine-point Newton-Cotes method (6) in the evaluation of the integral. In particular, the logarithmic spacing used in Eq. [12] of Ref. (3) was employed. The purpose of using the first technique was to provide for an “exact” evaluation of the $Z(x, S)$ integral in Eq. [6]. The Newton-Cotes technique was investigated as a faster, more efficient, method. For the Newton-Cotes method of evaluation, the four-probe resistance was calculated using the expression

$$Z(x, S) = \frac{\rho(x)}{\pi} \ln(2) \sum_{i=0}^8 w_{9,i} \lambda_i A(x, \lambda_i) \quad [16]$$

where

$$\lambda_i = \frac{2^{i/8}}{2S} \quad (0 \leq i \leq 8) \quad [17]$$

$w_{9,i} = C_i/8$, and where C_i are the Newton-Cotes weighting factors (6). A comparison of the results of the integration performed with the trapezoidal-Romberg technique and with the nine-point Newton-Cotes method indicates that the latter method gives an excellent representation of the integral of Eq. [6]. Hence, for all subsequent analysis, the Newton-Cotes method will be used. The remaining item to be considered focuses upon the comparison of the four-probe resistances as calculated by Eq. [1] and by Eq. [6] (using the Newton-Cotes method).

The purpose of this section is to present the salient features of the calculation of the function $Z(x, S)$ for both “thin” and “thick” layers. As indicated previously, the concepts of “thin” and “thick” do not refer to the absolute layer thicknesses, but depend rather upon the ratio of the layer thickness (or distance to the insulating boundary) to the probe separation. Obviously, for almost all

practical applications, an isolated layer of up to approximately $10\ \mu\text{m}$ may always be considered to be thin. However, the distinction between thin and thick becomes important for the case of a nonuniformly doped layer over a substrate of the same conductivity type. Here, the total thickness of the wafer must be considered to be the depth to the insulating boundary, *i.e.*, the back of the wafer. Typically, this thickness can be several hundred microns and here the ratio x/S may be on the order of or greater than unity.

A number of implant-type resistivity structures were used with an insulating boundary placed up to several microns below the implanted region. This situation was used to simulate the implant into a junction isolating substrate. In these cases, x/S is always much less than unity and the junction-isolated layer formed by the implant is clearly thin in the sense described above. These structures were used to calculate $Z(x, S)$ using Eq. [1] and [6]. The probe spacings used ranged from 25 up to $1000\ \mu\text{m}$. In all cases, the results of the two techniques were found to be in agreement to within less than 1%. Also, direct evaluation of the sheet resistance showed that the relation between $Z(x, S)$ and the sheet resistance, $\mathfrak{R}(x)$, *i.e.*

$$Z(x, S) = \frac{\ln(2)}{\pi} \mathfrak{R}(x) \quad [18]$$

was satisfied. This would indicate that the Newton-Cotes technique for the evaluation of $Z(x, S)$ as given by Eq. [6] yields the correct result for a thin, *i.e.*, $x/S < 1$, layer.

The same gaussian-type implant structures were used with the insulating boundary placed at $350\ \mu\text{m}$ below the end of the implant structure. This was meant to simulate the situation which would arise from an implant structure into a substrate of the same conductivity type. As discussed above, the back surface of the wafer is now the insulating boundary condition. For the total thicknesses involved, the calculation should probe the results from the region where $x/S > 1$ down to the region where $x/S < 1$. In addition, the substrate resistivity was changed to emulate the approach to junction-type isolation at the end of the implant distribution. When the Newton-Cotes evaluation of $Z(x, S)$ was used and compared with the results of Ref. (1), the maximum deviation was found to be on the order of 10%. However, deviations of this magnitude were not typical of all structures, nor were they typical of any one structure. In general, deviations of about 1-2% were typical. In particular, deviations of this size were found in the surface region of nearly all the structures considered. Typical comparisons of the four-probe resistance integrals are contained in Fig. 3 for illustrative purposes. The overall quality of the Newton-Cotes results indicates that this computationally simpler form of $Z(x, S)$ presented in Eq. [16] and [17] can be used with confidence and at a substantial reduction in computation time. To illustrate the reduction in computation time, the calculations performed in Ref. (1) (using Eq. [1]) usually took several CPU minutes on a minicomputer (equivalent to at least an hour on a microcomputer). The same calculations using the Newton-Cotes method (Eq. [16] and [17]) take several CPU seconds on a minicomputer and on the order of 15-30s on a microcomputer. In addition, the calibration procedure proposed in Ref. (1) is now accessible as a simple add-on to any spreading resistance correction factor algorithm. This calibration procedure is described in detail in Ref. (1) and is implemented exactly as described there. The important difference resulting from the present work is that the calculation of the four-probe resistance for each value of the probe radius (used in the multilayer analysis of the spreading resistance data) can be performed very quickly even on a microcomputer system.

Fig. 3. The four-probe resistance integral as evaluated by the trapezoidal-Romberg method (Eq. [1]) and as evaluated by means of the Newton-Cotes evaluation (Eq. [16]) are plotted against each other in this figure. The data represent a wide range of structures. The data at the lower end represent deviations due to shorting substrates where the four-probe resistance does not provide any useful information.

A listing of the Newton-Cotes evaluation of $Z(x, S)$, written in FORTRAN (but easily translated to other languages), may be obtained from the authors upon request.

Results and Conclusions

A simplified method for evaluating the four-probe resistance has been presented and discussed. The resulting equation for the four-probe resistance involves an integral of $A(x, \lambda)$ over a small interval dictated by the probe spacing. In particular, the larger the value of the probe spacing, the closer the interval is to the origin. In a sense, this signals the importance of the substrate resistivity and the boundary condition as the small λ behavior of the kernel function is dominated by the ratio of the substrate resistivity and the resistivity of the point in question. Analytic expressions have been derived for the cases of a uniform layer over an insulating boundary or a conducting boundary. These expressions have been investigated as a function of x/S . For small values of x/S , the sheet resistance of a uniform layer has been shown to arise for the case of an insulating boundary. For large values of x/S , all three cases have been shown to merge together and provide a caveat in the interpretation of four-probe resistance measurements in terms of a sheet resistance obtained from a laminar conduction model.

A nine-point Newton-Cotes integration scheme has been presented and discussed for the evaluation of the simplified four-probe resistance integral and have been compared with the more complicated methods presented in Ref. (1). Typical differences between the two methods are in the 1-2% range with maximum values on the order of 10%. However, the Newton-Cotes method produces a reduction in computation time down into the region of seconds for both minicomputers and microcomputers. Consequently, the Newton-Cotes technique for evaluating the four-probe resistance can now be readily used in the calibration procedure which was proposed in Ref. (1).

Complete Process Modeling for VLSI Multilayer Structures

Kouichi Sakamoto, Kenji Nishi, Tetsuo Yamaji, Tatsuro Miyoshi, and Shintaro Ushio

Oki Electric Industry Company, Limited, 550-1 Higashiasakawa, Hachioji, Tokyo 193, Japan

ABSTRACT

A new one-dimensional process simulator, ASPREM or advanced SUPREM, has been developed. ASPREM features the capability for multilayer structures and the incorporation of many up-to-date models. In this paper, general features of ASPREM are first described. Then details of many up-to-date models, such as oxidation-enhanced diffusion with or without polysilicon, impurity diffusion in polysilicon and SiO_2 , and stress effects to phosphorus diffusion after high dose ion implantation are reported with experimental results. Finally, applications to base-emitter self-aligned technology (BEST) transistors are described, followed by brief concluding remarks.

More than half a decade has already passed since the first process simulators, SUPREM and its extended version, SUPREM-II, were introduced from Stanford University (1, 2). Several process simulators have since been developed from different organizations (3-6). Most of them are designed for simulating two-dimensional impurity profiles, since the lateral diffusion is becoming more important with shrinking minimum pattern size. However, because of mathematical complexities of moving boundary problems, major efforts have been made to solve efficiently the diffusion equation for simplified structures. No great efforts have been made to develop more accurate physical models for multilayer structures. We currently need process simulators for multilayer structures which always appear in VLSI devices.

The authors introduced the prototype of multilayer process simulator as early as 1981 (7). Many process models have since been developed and incorporated in this simulator which is currently called advanced SUPREM or ASPREM. Some of the newly developed models are oxidation-enhanced diffusion models of impurities under high concentration or with polysilicon on top of the substrate, diffusion models within silicon dioxide and polysilicon, and stress effects to phosphorus diffusion under various ambients.

Recently, SUPREM-III has been developed by Stanford University as a one-dimensional process simulator to handle multilayer structures (8). Though basic features of ASPREM are similar to those of SUPREM-III, ASPREM excels in such models as impurity diffusion within polysilicon and SiO_2 .

In this article, general features of ASPREM are first described. Then, some of the up-to-date process models are reported in detail. Finally, applications to base-emitter self-aligned technology (BEST) transistors (9) are described.

Process Models in ASPREM

General features.—ASPREM can handle multilayer structures including SiO_2 , Si_3N_4 , and polysilicon. Thickness, dopant profiles, and, in the case of the silicon substrate and polysilicon, sheet resistances can be calculated after each process step. In the case of MOS transistors, threshold voltage can also be calculated with varying back bias voltages.

Basic models for impurity diffusion are based on a vacancy mechanism formulation (10), except that impurities can diffuse by interstitialcy mechanism during oxidation. According to this model, increased charged vacancies account for enhanced diffusion under high concentration of impurities. In the case of phosphorus diffusion, the model developed by Fair *et al.* (11) is used with some modification on the evaluation of stress, which is described later. Recent developments on high concentration diffusion of phosphorus have shown that not vacancies, but self-interstitials or both, account for enhanced diffusion (12, 13). At this stage, however, Fair and co-workers' model is still the only quantitative model which can handle high concentration diffusion of phosphorus.

The oxidation process uses the Deal-Grove model (14). For the heavily doped silicon substrate, the model devel-

oped by Ho *et al.* (15, 16) has been implemented in ASPREM to account for the enhanced oxidation rate. Ho and co-workers' model is also used for the oxidation of heavily doped polysilicon, where carrier concentration is replaced by impurity concentration within grains. The ambient-pressure dependence of the oxidation rate is also included. The parabolic growth rate depends linearly on the ambient pressure, whereas the linear growth rate depends on the power of ambient pressure, with the power being less than unity (17). The possible explanation for the nonlinear relationship of the linear growth rate on ambient pressure may exist in atomic-level reaction of oxidants with silicon atoms in the substrate. Details can be found elsewhere (17).

As-implanted impurity profiles are assumed to be a joint-half gaussian distribution for arsenic, phosphorus, and antimony, and a modified Pearson IV distribution for boron in all materials including SiO_2 and Si_3N_4 (10). An exponentially decaying tail is assumed only within the silicon substrate because channeling could occur only within the single crystal. In addition to basic elements, ASPREM can handle implantation of compounds such as BF and BF_2 , which have gained increasing importance in applications to the formation of a shallow junction in CMOS devices. Here, we assumed that a resulting boron profile is the same as the one in which boron ions are implanted with the artificial energy calculated by multiplying the mass ratio of boron in the compound to the original implant energy (18). This is reasonable when we assume that, upon entering the substrate, the implanted compound immediately decomposes into its constituting elements, while conserving kinetic energy and momentum.

In the following, some of the process models including oxidation-enhanced diffusion, and impurity diffusion in polysilicon and SiO_2 , are described in detail.

Oxidation-enhanced diffusion.—The impurities such as boron and phosphorus diffuse faster in the silicon substrate during oxidation. This phenomenon, called oxidation-enhanced diffusion (OED), has been explained by the excess silicon self-interstitials generated at the oxidizing silicon surface, and depends on generation, recombination, and diffusion of interstitials. Taniguchi *et al.* (19) already reported the practical model of OED in which the increment of the diffusivity due to oxidation, ΔD , is proportional to the power of oxidation rate and decreases exponentially with the depth from the silicon surface. Some of the authors also reached the similar equation for ΔD , except that ΔD depends on the impurity concentration at the oxidizing silicon surface (20), as seen in Fig. 1. Thus, ΔD is expressed as follows

$$\Delta D = \frac{D_0}{1 + a \cdot C_s/n_i} V_{ox}^{0.3} \exp\left(-\frac{E_0}{kT}\right) \exp\left(-\frac{x}{L_1}\right) \quad [1]$$

where V_{ox} is the oxidation rate, C_s is the surface impurity concentration, n_i is the intrinsic carrier concentration, E_0 is the activation energy, T is the temperature, k is the Boltzmann constant, x is the depth from the silicon sur-

Fig. 1. D vs. surface impurity concentration for boron and phosphorus at 900°C .

face, L_1 is the characteristic length, D_0 is the fitting parameter which depends on impurity species, and a is also a fitting parameter which is fixed to 1.8. When C_s is much lower than n_i , Eq. [1] reduces to the one in Taniguchi's model. On the other hand, when C_s is much higher than n_i , ΔD in Eq. [1] becomes zero, indicating that no oxidation-enhanced diffusion occurs.

Oxidation-enhanced diffusion with polysilicon.—When there is a polysilicon layer on top of the silicon substrate, we must take the effects characteristic of polysilicon into account. Since the oxidation rate of polysilicon is similar to that of the silicon substrate, except for the difference in crystal orientation, we can expect that the amount of silicon self-interstitials generated by oxidation at the polysilicon surface is also similar to the one at the single-crystalline silicon surface. However, when silicon self-interstitials diffuse into the substrate through a polysilicon film, they may be easily trapped at polysilicon grain boundaries.

Some of the authors already reported (20) that ΔD of boron and phosphorus in the silicon substrate during oxidation of a polysilicon film on top of substrate is exponentially dependent on the polysilicon thickness, as shown in Fig. 2. Similar results were also obtained by Swaminathan (21). Hence, the complete expression for the impurity diffusion in the substrate during oxidation of polysilicon on top of it can be written as

$$\Delta D = \frac{D_0}{1 + a \cdot C_s/n_i} V_{\text{ox}}^{0.3} \exp\left(-\frac{E_0}{kT}\right) \exp\left(-\frac{x}{L_1}\right) \exp\left(-\frac{z}{L_2}\right) \quad [2]$$

where z is the polysilicon thickness and L_2 is the characteristic absorption length of interstitials in polysilicon.

Since the parameter, L_2 , depends on the annihilation of silicon self-interstitials at grain boundaries, it depends on the area of grain boundaries and, thus, on the grain size. From Fig. 2, in which the grain size is about $0.1 \mu\text{m}$, the obtained length for L_2 is 1100\AA , independent of impurity species. We note that this value is similar to Swaminathan's results (1000\AA). As for the L_2 dependence on the grain size, g , the following equation is used

$$L_2 = (g'/g \cdot (1/L'^2 - 1/L_1^2) + 1/L_1^2)^{-1/2} \quad [3]$$

where g' is $0.1 \mu\text{m}$ and L' is the absorption length when $g = g'$ and is 1100\AA as already stated. Usually, g is smaller than $10 \mu\text{m}$. In that case, it is easy to check whether or not L_2 is linearly dependent on g . Since g is linearly dependent on the reciprocal of grain boundary area and L_2 is expressed as $\sqrt{D_{\text{int}}\tau}$ where D_{int} is interstitial diffusivity and τ is a lifetime, linear dependence of L_2 on \sqrt{g} implies that τ is linearly dependent on the reciprocal of grain boundary area. When g approaches infinity, *i.e.*, the polysilicon approaches single-crystalline silicon, L_2 reduces to L_1 .

Fig. 2. D vs. polysilicon thickness for boron and phosphorus at 1000°C . The data are taken from Ref. (20).

This model has been implemented in ASPREM and has contributed to accurately simulate impurity profiles for polysilicon-source such as a base and an emitter region with doped polysilicon in conventional bipolar devices and BEST.

Stress effects on phosphorus diffusion.—Phosphorus diffusivity usually increases with increasing phosphorus concentration. However, when the phosphorus concentration exceeds several 10^{20}cm^{-3} , the enhancement factor decreases. Fair attributed this to the decrease of vacancy concentration caused by reduced bandgap, ΔE_g , due to the strain (22). However, he did not try to measure the values of strain experimentally, but rather obtained the relationship between ΔE_g and phosphorus concentration by fitting the calculated results to the experimental junction depths.

Using his relationship for the simulation of implanted phosphorus diffusion, we became aware that his estimates of E_g are too large. Sakamoto, one of the authors, and Sasaki tried x-ray double-crystal diffractometry in order to obtain the actual strain values in the phosphorus-implanted wafers after annealing in nitrogen or oxygen ambient (23). Figure 3 shows the actual maximum strain, s_m , vs. peak concentration of unprecipitated phosphorus. Also shown is the strain calculated from Fair's relationship by using Wortmann and co-workers' equation between ΔE_g and stress (24) and also the well-established relation of stress and strain. The strain calculated from Fair is larger than actual strain, as expected. It should be noted that the maximum strain depends on annealing ambients. As a best fit equation for s_m in the substrate and peak concentration of unprecipitated phosphorus, C_p , after annealing in nitrogen, the following equation is obtained

$$s_m = 1.9 \times 10^{-24} C_p + 4.2 \times 10^{-14} \sqrt{C_p - 1.3 \times 10^{20}} \quad (\text{cm}^{-3}) \quad [4]$$

The first term of the right-hand side alone is the strain after annealing in oxygen. The second term is added when the samples are annealed in nitrogen. More detailed experiments have revealed that the second term decreases inversely proportional to oxygen partial pressure when the samples are annealed in a mixture of nitrogen and oxygen (23). It is beyond the scope of this paper to discuss the difference in the strain after annealing in various ambients. We only note that this could be due to the difference in the type of residual lattice defects in implanted layers after annealing (25).

Equation [4] is used in ASPREM to calculate ΔE_g , which is used to obtain the reduced vacancy concentration and, thus, phosphorus diffusivity. In Fig. 4, we show examples of phosphorus diffusion in nitrogen or oxygen ambients.

Fig. 3. Maximum strain vs. phosphorus peak concentration after ion implantation and subsequent annealing in nitrogen or oxygen.

Si(100) wafers were implanted with phosphorus at 40 keV with a dose of $1 \times 10^{16} \text{ cm}^{-2}$ and were annealed at 900°C for 20 min in nitrogen. After these wafers were subsequently annealed at 900°C for 100 min in nitrogen or oxygen, phosphorus profiles were obtained by secondary ion mass spectroscopy (SIMS). Phosphorus tails extend deeper when annealed in oxygen, showing enhanced diffusion. Oxidation-enhanced diffusion expressed by Eq. [1] alone cannot account for this large enhancement, since ΔD in Eq. [1] is much smaller than phosphorus diffusivity in nitrogen when surface concentration is as high as that shown in Fig. 4. On the other hand, simulation results using ASPREM, which includes strain effects from phosphorus diffusion, are in good agreement with SIMS profiles. Thus, it is concluded that enhanced diffusivity

Fig. 4. Experimental and simulated phosphorus profiles after ion implantation and subsequent annealing in nitrogen or oxygen.

of high concentration phosphorus in oxygen is mainly due to the smaller strain compared with that in nitrogen.

Diffusion model in polysilicon.—The polysilicon layer has been found increasingly important in the fabrication of VLSI. The polysilicon layer is used for interconnects, gate electrodes, high valued resistance, and as a diffusion source for shallow junctions. Although several papers have been published for impurity diffusion in polysilicon, there has not been an effective diffusion model (8, 26, 27).

Difficulties in dealing with impurity diffusion in polysilicon arise from the fact that impurities can exist in two regions: within grains and at grain boundaries (21, 26). Another multilayer simulator, SUPREM-III, does not distinguish these two regions for diffusion analysis, although it includes segregation effects for the calculation of carrier concentration. In order to understand the diffusion mechanism in polysilicon, however, it is essential to include the effects of impurity segregation at grain boundaries. We have tried to model impurity diffusion in polysilicon including these effects.

Figure 5 shows a schematic cross section and impurity concentration in polysilicon. In the proposed model, we specify impurity concentration within grains and at grain boundaries independently. The sum of these concentrations gives the total impurity concentration. Impurities in each region can diffuse independently along the X-axis (depth direction). Diffusion along the Y-axis is also taken into account for impurities within grain boundaries by estimating the diffusion length within grains. Impurities in the two regions transport to each other through the interface of grains and their boundaries.

The model is summarized in the equations

$$C = C_i + C_b \quad [5]$$

$$\frac{\partial C_i}{\partial t} = \frac{\partial}{\partial x} \left(D_i \frac{\partial C_i}{\partial x} \right) - h' (mC_{is} - C_b) \quad [6]$$

$$\frac{\partial C_b}{\partial t} = \frac{\partial}{\partial x} \left(D_b \frac{\partial C_b}{\partial x} \right) + h' (mC_{is} - C_b) \quad [7]$$

where t is time, C is total impurity concentration, C_i (C_b) is impurity concentration within grains (at grain boundaries), D_i (D_b) is impurity diffusivity within grains (at grain boundaries), C_{is} is impurity concentration within grains near boundaries, h' is the coefficient for impurity transport through the interface of grains and their boundaries, and m is the segregation coefficient in thermal equilibrium. The value for m is taken from Mei and co-workers model (28) by taking the grain size into account. Equations [6] and [7] show impurity diffusion within grains and at their boundaries, respectively. The impurities at each region can diffuse independently except that they transport each other at the interface of grains and their boundaries. The amount of impurity transport is expressed by the second term of the right-hand side in Eq. [6] and [7]. Since the magnitude of m , which depends on the grain size, affects which of the impurities within

Fig. 5. Schematic model for impurity diffusion in polysilicon. F_i (F_b) and C_i (C_b) are impurity flow and impurity concentration within grains (at grain boundaries), respectively.

Table I. Impurity diffusivities at polysilicon grain boundaries

	Pre-exponential factor (cm ² /s)	Activation energy (eV)
Boron	0.82	2.74
Phosphorus	5.1	2.91
Arsenic	1100	3.53

grains or at grain boundaries is dominant in polysilicon, it is necessary to analyze impurity diffusion independently at each region.

Because of slower diffusion within grains, C_{is} may be different from C_i , which is the average impurity concentration within grains. We use $d \cdot C_i$ for C_{is} where d is $g/\text{minimum}(g, \sqrt{4D_i t})$. d reflects the effects of impurity diffusion within grains along the Y-axis and approaches unity for longer annealing. As the value for h' , we usually use a transport coefficient, h , which depends on temperature and impurity species. However, when C_{is} exceeds solid solubility of impurities within grains, impurity flow from grain boundaries into grain insides can be neglected. This is accomplished by equating $h' = 0$ when C_{is} is greater than solid solubility.

D_i is taken as impurity diffusivity within the silicon substrate, since grain insides are single crystalline. On the other hand, we have obtained D_b by fitting the simulated results to the experimental profiles by SIMS. D_b for boron, phosphorus, and arsenic through the temperature range 800°-900°C is shown in Table I, and is three orders of magnitude higher than D_i .

Figure 6 shows simulated and experimental profiles of boron and phosphorus. The samples are ion implanted with a dose of 10^{16} cm^{-2} to the 0.5 μm thick polysilicon with grain size of 0.1 μm , grown on (100) silicon. They are subsequently annealed at 800°C in nitrogen for 46 and 10 min for boron and phosphorus, respectively. In these profiles, we can distinguish surface and tail regions. In the surface region, impurities retain as-implanted profiles, indicating that no significant diffusion occurred. This slower diffusion is limited by impurity diffusion within grains. In the tail region, the profiles show a gentle slope indicating faster diffusion. This is due to very fast impurity diffusion through grain boundaries. It is

Fig. 6. Boron and phosphorus profiles in polysilicon after ion implantation and subsequent annealing in nitrogen.

noted that impurities at grain boundaries cannot be transported into grain insides, since C_{is} in the tail region exceeds solid solubility. On the other hand, at the diffusion front, the profile shows a relatively steep slope indicating slower diffusion. This is caused by a significant amount of impurities at grain boundaries transported into grain insides. Good agreements between simulated profiles and SIMS profiles show that the proposed model works effectively for impurity diffusion in polysilicon.

It should be pointed out here that simulation of oxidation of heavily doped polysilicon is also significantly improved by employing the proposed model for impurity diffusion in polysilicon. We use Ho and co-workers' oxidation model (15, 16) for polysilicon as well as for the silicon substrate. In their model, the oxidation rate depends on the surface carrier concentration. By assuming that surface carrier concentration is equal to surface impurity concentration within grains, simulated SiO_2 thickness after oxidation of polysilicon agrees well with the experimental result, which also confirms the effectiveness of the proposed model in polysilicon.

Phosphorus diffusion in SiO_2 .—While phosphorus diffusion in SiO_2 is important for MOS gate region, its mechanism has remained one of the least-known fields in VLSI processes. There have been a few reports on phosphorus diffusivity in SiO_2 (29, 30), but their values spread by several orders of magnitude. We have extensively studied phosphorus diffusion in SiO_2 , and obtained the diffusivity in relation to local phosphorus concentration.

Phosphorus with different doses was implanted to a thick oxide film thermally grown on (100) silicon. The wafers were subsequently annealed in dry oxygen at various temperatures. Figure 7 shows examples of phosphorus profiles measured by SIMS. A flat profile where phosphorus concentration is higher than 10^{20} cm^{-3} indicates that very fast diffusion occurred in this region. On the other hand, a steep slope in the lower phosphorus concentration region indicates slower diffusion. An assumption that phosphorus diffusivity, D_{ox} , depends only on the local phosphorus concentration has led to the following expression for the phosphorus diffusivity

$$D_{ox} = D_{i,ox} + bC_{ox}^n \quad [8]$$

where $D_{i,ox}$ is phosphorus diffusivity in low concentra-

Fig. 7. Experimental and simulated phosphorus profiles in SiO_2 after ion implantation and subsequent annealing in nitrogen.

tion, C_{OX} is phosphorus concentration, and both b and n are fitting parameters. Best fit values for $D_{1,OX}$, b , and n are

$$D_{1,OX} = 3.22 \times 10^{-2} \exp[-4.1 \text{ (eV)/}kT] \text{ cm}^2/\text{s} \quad [9]$$

$$b = 1.13 \times 10^{-20} \exp[-7.1 \text{ (eV)/}kT] \text{ cm}^{6.5}/\text{s} \quad [10]$$

$$n = 1.5 \quad [11]$$

In Fig. 7, simulated results are also shown with experimental profiles. We can see good agreement between simulations and experiments.

The tendency of increasing phosphorus diffusivity with phosphorus concentration in the high concentration region is similar to Ghoshtagore's experiments (30) in which phosphorus was diffused from PSG. The obtained phosphorus diffusivity in thermal SiO_2 in our experiments is also similar to his results. This may indicate that Eq. [8] is generally applicable to phosphorus diffusion in SiO_2 .

Examples

In order to demonstrate the capabilities of ASPREM, we show here an example of simulated impurity profiles from a bipolar process called BEST, which was first introduced from OKI as a high performance bipolar technology with extensive use of polysilicon (9).

The schematic cross section of BEST transistors is shown in Fig. 8. The simulated region is at a cross section through emitter and active base region, which constitutes an essential part of BEST transistors. Two different fabrication processes, named A and B, were simulated. A detailed description of process sequence A is as follows: epitaxy, oxidation in oxygen at 900°C for 20 min, BF_2 ion implantation with dose of $1 \times 10^{14} \text{ cm}^{-2}$ at 40 keV for base formation, annealing in nitrogen at 900°C for 30 min, SiO_2 etching, polysilicon deposition with thickness of 3000\AA , polysilicon oxidation in oxygen at 900°C for 30 min, Si_3N_4 deposition with thickness of 2000\AA , annealing in nitrogen at 900°C for 30 min and at 950°C for 50 min, Si_3N_4 and SiO_2 etching, oxidation in dry O_2 at 900°C for 30 min, arsenic implantation for emitter with dose of $1.2 \times 10^{16} \text{ cm}^{-2}$ at 60 keV, oxidation in steam at 950°C for 40 min at 0.67 atm, and annealing in nitrogen at 1000°C for 35 min.

Process B is intended to form shallower emitter and base regions, and boron was implanted after polysilicon was deposited. The process sequence is as follows: epitaxy, polysilicon deposition with thickness of 3000\AA , oxidation in oxygen at 900°C for 30 min, Si_3N_4 deposition with thickness of 2000\AA , annealing in nitrogen at 900°C for 30 min and at 950°C for 50 min, Si_3N_4 and SiO_2 removal,

Fig. 8. Schematic cross section of a BEST transistor. Base/emitter region (indicated by a vertical line) is simulated by ASPREM as an example.

polysilicon oxidation in steam at 950°C for 40 min at 0.67 atm, annealing in nitrogen at 1000°C for 15 min, boron implantation with dose of $4.5 \times 10^{14} \text{ cm}^{-2}$ at 70 keV, SiO_2 removal, oxidation in oxygen at 900°C for 30 min, annealing in nitrogen at 950°C for 30 min, arsenic implantation with dose of $1.2 \times 10^{16} \text{ cm}^{-2}$ at 60 keV, followed by annealing in nitrogen at 950°C for 60 min.

Figures 9a and b show simulated and experimental impurity profiles for processes A and B, respectively. First of all, it should be pointed out that overall agreement between simulated and measured impurity profiles are satisfactory for both the processes. A kink in the boron profile around a base/emitter junction can be attributed to the retarded diffusivity by the electric field generated from a steep profile of high concentration arsenic and is also simulated well. The electric field also affects the diffusion of phosphorus, which piles up around the base/emitter junction. This is caused by electric-field-driven phosphorus flow against the gradient of phosphorus concentration. Although it is not clear from Fig. 9, we note that the simulated SiO_2 thickness after oxidation of heavily arsenic-doped polysilicon agrees well with the actual thickness, which is a by-product of distinguishing impurities within grains from those at grain boundaries in the polysilicon diffusion model as discussed.

Measured profiles show a pile-up of arsenic at the polysilicon/Si interface. Although this phenomenon needs more study, the effect on the overall arsenic profile can be negligible. We can see a discontinuity of phosphorus profile at the polysilicon/Si interface. This is due to the use of a relatively large segregation coefficient, which

Fig. 9. Experimental and simulated impurity profiles at base/emitter region of a BEST transistor for (a) process A and (b) process B.

has been determined from another experiment on diffusion from a heavily phosphorus-doped polysilicon. Since, in ASPREM, the segregation coefficient is defined as the ratio of impurity concentration in Si to that within grains in polysilicon, interface discontinuity could appear for different process conditions. Further study is necessary for interface phenomena.

Conclusions

A multilayer simulator, ASPREM, has been developed. ASPREM features many up-to-date process models, which include an oxidation-enhanced model with or without polysilicon, strain effects to high concentration phosphorus diffusion, a diffusion model in polysilicon, and a phosphorus diffusion model in SiO₂. The details of these models have been discussed. As a multilayer simulator, ASPREM can be applied to the complete VLSI processes including bipolar and MOS transistors. The effectiveness of ASPREM has been demonstrated by BEST transistors. Especially, accurate simulation of diffusion and oxidation for polysilicon source emitter is worth noting, since similar processes are important for MOS transistors as well.

In addition to being applicable to current processes, ASPREM will serve as an effective tool in developing new multilayer models. This is significant, since multilayer structures are becoming more important, while few established models for multilayers exist.

Acknowledgment

We acknowledge Mr. Kawakatsu for sample preparation of BEST transistors and Mr. Ichikawa for SIMS measurements. We also acknowledge Mr. Higashi and Mr. Mizokami for their encouragement to complete this work.

Degradation Mechanism of Lightly Doped Drain (LDD) n-Channel MOSFET's Studied by Ultraviolet Light Irradiation

M. Saitoh, H. Shibata, H. Momose, and J. Matsunaga

Toshiba Corporation, Semiconductor Device Engineering Laboratory, 1, Komukai Toshiba-cho, Saiwai-ku, Kawasaki 210, Japan

ABSTRACT

The degradation of lightly doped drain (LDD) n-channel MOSFET's has been investigated in detail making use of ultraviolet light irradiation, and the following results have been obtained. The degradation of the parasitic MOSFET consisting of the gate, the LDD region, and the insulator in between, which dominates the deterioration of the total performance, can be divided into two phases. In the initial phase, the degradation is rapid compared to that in the succeeding phase. The initial phase degradation is due not to surface-state generation, but to electron capturing of the oxide covering the LDD region which has a large number of traps. The quality of the insulator above the LDD region should be carefully controlled in order to make highly reliable LDD MOSFET's.

As the device dimensions are reduced in VLSI's, hot carrier-induced MOSFET degradation becomes a problem of more importance, and many efforts have been made to solve it. Along with the studies on the degradation mechanism (1-15), explorations of highly reliable MOSFET's have also been made (16-22). Consequently, lightly doped drain (LDD) MOSFET has been proposed and widely believed to have high reliability.

Hsu *et al.* (21, 22), however, reported recently that when the LDD MOSFET's and the conventional MOSFET are compared under the same substrate current during the stress, the former shows two orders of magnitude faster deterioration in transconductance (G_m) than the latter. This fact seems to suggest that the LDD MOSFET's have their own degradation mechanism which makes them of little advantage to the conventional MOSFET.

Thus, in order to make highly reliable LDD MOSFET's, the degradation mechanism of the LDD structure should be made clear. For this purpose, we tried to make use of ultraviolet (UV) light irradiation, in which the energy distribution of generated hot carriers is almost independent of the impurity concentration of the LDD region. This fact makes experimental results easy to interpret.

Experimental

The MOSFET's examined were fabricated in a conventional poly-Si gate N MOS process with and without LDD (N^-) region (conventional MOSFET's were cofabricated as a reference).

After gate patterning, gate oxide over source/drain area was etched off by wet chemical etchant. Phosphorus ions were implanted to form N^- diffusion, while no ion implantation was made for the wafers of conventional MOSFET's. Then, so-called postoxidation was done.

A new type sidewall, self-defined polysilicon sidewall (SEPOS), was used at the sidewall making step for LDD Tr's. The process flow for the SEPOS is shown in Fig. 1. Onto the postoxide, LPCVD polysilicon was uniformly deposited, and then the surface was slightly oxidized. SiO_2 reactive ion etching (RIE) followed to leave oxide frame only at the vertical sides of the polysilicon steps. After subsequent polysilicon RIE, the oxide-framed polysilicon sidewall was completed. Then, arsenic ions were implanted to make N^+ regions. The polysilicon sidewall was removed by plasma etching, and CVD SiO_2 was deposited on it. Passivation was made by depositing BPSG (boro-phosphosilicate glass) onto the CVD SiO_2 film.

Surface impurity concentration of channel (boron) and N^+ (arsenic) regions were 1.5×10^{16} and 2×10^{20} cm^{-3} , respectively. That of N^- (phosphorus) regions was varied from 3.8×10^{17} to 3.2×10^{18} cm^{-2} (ion dose from 5×10^{12} to 4×10^{13} cm^{-2}). The effective channel length was 0.5-0.7 μm , and gate oxide thickness 25 nm. The N^- region length ranged from 0.24 to 0.36 μm , depending upon phosphorus concentration.

Samples were irradiated with UV light of 4.63 eV, as shown in Fig. 2, using a commercial EPROM eraser

which can erase EPROM data within 10 min. During the irradiation, all the electrodes were connected to the ground potential. All measurements were carried out at room temperature (21°-25°C).

Results

The changes in the linear region of drain current *vs.* gate voltage characteristics after 4h UV light irradiation are shown in Fig. 3 for low (3.8×10^{17} cm^{-3}) and high (1.7×10^{18} cm^{-3}) N^- LDD samples and, for comparison, for a conventional sample. The low N^- one reveals a drastic increase in threshold voltage and a certain amount of decrease in transconductance G_m , while the high N^- one shows only a small decrease in G_m . No change can be observed for the conventional one. Figure 4 compares their subthreshold characteristics. It is found that the low N^- one shows smaller subthreshold slope than the others, and the curve shows parallel shift in the positive direction after irradiation, while no change is observed for the high N^- and the conventional samples.

Figure 5 shows the time dependencies of (i) the increase in V_{th} which is defined as V_G giving rise to I_D of 10^{-7} A for $V_D = 0.1$ V and (ii) the decrease in I_{th} which is defined as I_D for $V_G = V_{th}(\text{initial}) + 3.5$ V, for the low N^- sample. Here, errors coming from temperature fluctuation are corrected. Two curves drawn in the same frame are the data

Fig. 1. Process flow for self-defined polysilicon sidewall (SEPOS).

Fig. 2. Ultraviolet (UV) light irradiation using an EPROM eraser

Fig. 3. Changes in the linear region of I_D vs. V_G characteristics caused by 4h UV light irradiation for a 3.8×10^{17} and a $1.7 \times 10^{18} \text{ cm}^{-3}$ N^- concentration LDD MOSFET, and a conventional MOSFET.

Fig. 4. Replots of the I_D - V_G curves in Fig. 3. Changes in sub-threshold characteristics are compared.

for different samples under the same experimental condition. The threshold voltage V_{th} shows rapid increase within 0.5h and comes to clear saturation thereafter, although the saturation values are largely different from sample to sample. On the other hand, I_{to} does not show such clear saturation. Figure 6 shows the results corresponding to Fig. 5 in the case of high N^- sample. The similar behavior is observed, though the V_{th} shift is very small.

Electrical stress was also studied, where the stress condition was $V_D = V_G = 6V$. Transconductance change ΔG_m and threshold voltage shift ΔV_{th} were measured in this case as a function of stress time. Source and drain were reversed during measurements. Samples of 6.9×10^{17} , 1.7×10^{18} , and $3.2 \times 10^{18} \text{ cm}^{-3}$ N^- concentrations showed a

Fig. 5. Increase in V_{th} and decrease in I_{to} as a function of UV exposure time. Here V_{th} is defined as V_G giving rise to 10^{-7} A of I_D for $V_D = 0.1V$, and I_{to} as I_D for $V_G = V_{th}(\text{initial}) + 3.5V$. Concentration of N^- region is $6.9 \times 10^{17} \text{ cm}^{-3}$.

decrease in G_m (which is revealed in Fig. 7) but a negligibly small ($< 10 \text{ mV}$) V_{th} shift. In contrast, in the case of $3.8 \times 10^{17} \text{ cm}^{-3}$ N^- concentration samples, G_m shows a negligibly small decrease ($< 1\%$) and V_{th} a fairly large increase, as shown in Fig. 8.

In Fig. 9, ΔG_m (ΔI_{to} for UV irradiation case) corresponds to the phase 1; initial rapid degradation stages (see Discussion section) are shown as a function of N^- concentration for both UV irradiation and electrical stress cases. In the former case, ΔG_m decreases with N^- concentration, while in the latter case it seems almost independent of the concentration.

Discussion

From the results shown in Fig. 3 and 4, we can derive a model for the LDD MOSFET's and the effect of UV light irradiation (Fig. 10). The features of the model are (i) LDD MOSFET's consist of a main Tr (A in Fig. 10a) and para-

Fig. 6. The same data as in Fig. 5, except for N^- concentration of $3.2 \times 10^{18} \text{ cm}^{-3}$.

Fig. 7. Decrease in G_m as a function of electrical stress time. Here G_m is defined as $(\partial I_D / \partial V_G)_{max}$. Concentration of N^- region is from 6.9×10^{17} to $3.2 \times 10^{18} \text{ cm}^{-3}$. Threshold voltage shift V_{th} is negligibly small (10 mV) for all cases. Definition of V_{th} is the same as in Fig. 5.

sitic Tr's (B in Fig. 10a) connected in series and (ii) UV irradiation brings change only to the parasitic Tr's. This is known from the fact that the conventional sample does not change. It is considered that in the low N^- concentration region ($3.8 \times 10^{17} \text{ cm}^{-3}$, for example) the threshold voltage of the parasitic Tr's is higher than that of the main Tr and they dominate the total I_D - V_G characteristics. Therefore, a drastic change including subthreshold curve shift occurs for low N^- sample. In the high N^- concentration region ($1.7 \times 10^{18} \text{ cm}^{-3}$, for example), the threshold voltage of the parasitic Tr's is lower than that of the main Tr. So, the expected threshold voltage shift in the parasitic Tr's results only in the transconductance decrease.

The relatively gentle subthreshold slope of the parasitic Tr comes from its depletion-type operation, the process-induced gate oxide thickening there, and/or the relatively large amount of surface states (although the amount does not increase by UV irradiation as shown by the parallel shift of the subthreshold curve). The fact that the para-

Fig. 8. Threshold voltage shift V_{th} and decrease in G_m as a function of electrical stress time. Concentration of N^- region is $3.8 \times 10^{17} \text{ cm}^{-3}$.

Fig. 9. G_m (for electrical stress) and I_{D0} (for UV irradiation) corresponding to phase 1 charge (see text).

sitic Tr of low N^- concentration before UV irradiation has a threshold voltage higher than that of the main Tr suggests that a certain amount of negative charge (or interface states) exists above the N^- regions when the fabrication process is finished.

As can be seen in Fig. 5, the change in the characteristics of the parasitic Tr can be divided into two phases: phase 1 is the part until the saturation in the V_{th} shift vs. UV exposure time curve, and phase 2 is the one after the saturation. Consequently, the total I_D - V_G characteristics of

(a)

(b)

Fig. 10. A model for the LDD MOSFET's and their own degradation mechanism. LDD MOSFET's consist of a main Tr (A) and parasitic Tr's (B). Degradation characteristics of LDD Tr arise from threshold voltage shift of the parasitic Tr's.

Fig. 11. A model for the location of fixed negative charge which changes the characteristics of parasitic Tr's.

the LDD Tr in triode operation can be expressed by

$$V_D/I_D = \frac{1}{G_{m1}(V_G - V_{th1})} + \frac{1}{G_{m2}(V_G - V_{th2})} + \frac{1}{G_{m3}(V_G - V_{th3})}$$

where V_{th1} , V_{th2} , and V_{th3} are the threshold voltages of the main Tr, of the parasitic Tr which corresponds to the phase 1 change, and of the parasitic Tr which corresponds to the phase 2 change. By UV light irradiation, V_{th1} does not shift, V_{th2} shifts rapidly and then becomes saturated, and V_{th3} shows relatively slow and long lasting shift. The picture derived from the above discussion is illustrated in Fig. 11. The phase 1 charge may be due to built-in traps in both the oxide grown from Si of N^- region and that grown from phosphorus-doped gate polysilicon during the postoxidation step. On the other hand, the phase 2 charge may be due to those in the LPCVD SiO_2 .

Because of the parallel shift of the subthreshold curve (Fig. 4), it is concluded that the V_{th2} shift comes not from surface-states generation, but from increase of trapped negative charges. This is also true for the V_{th3} shift if the barrier height for hot holes is not lowered by the trapped electrons, because the energy of UV light-generated hot holes, 3.51 eV, (4.63 eV photon energy - 1.12 eV bandgap of Si) is smaller than the potential barrier of Si- SiO_2 interface for holes (~3.7 eV) (2).

The dependence of ΔG_m on N^- concentration in the UV irradiation case (Fig. 9) is explained by the higher N^- sample's having lower sensitivity to the fixed charge above the N^- region. Here, the amount of the fixed charge is assumed to be the same for all the N^- concentrations, which is reasonable, as the UV light-induced hot carrier injection phenomenon does occur almost equally for all the N^- concentrations. In the electrical stress case, however, the saturation amount of the phase 1 charge seems to increase with the N^- concentration. In other words, it increases with the energy and population of hot carriers injected; higher N^- must lead to higher energy and population (23). This is why ΔG_m for the phase 1 (Fig. 9) seems to have little dependence on N^- concentration. Anyway, essentially the same mechanism seems to dominate the degradation both in the UV irradiation case and the electrical stress case.

Here it should be noted that the $6.9 \times 10^{17} \text{ cm}^{-3}$ N^- concentration sample reveals the behavior of low N^- sample (i.e., large V_{th} shift) in UV irradiation case (Fig. 5), while it reveals that of high N^- sample (i.e., negligibly small V_{th} shift) in electrical stress case (Fig. 7). It may come from the difference in the spacial and energetic distribution of

hot carriers from UV irradiation to electrical stress. However, we cannot make further comment on this, because the difference from sample to sample is too large, as can be seen in Fig. 5-8.

Finally, we would like to note that the quality of the insulator above the N^- region should be carefully controlled, as well as the impurity profile of the region, in order to make highly reliable LDD MOSFET's.

Conclusions

From a study making use of ultraviolet light irradiation, the following conclusions have been derived.

The LDD n-channel MOSFET has its own degradation mechanism as follows. The oxide covering the LDD (N^-) region, which is grown from the N^- region and the phosphorus-doped gate polysilicon, has a large number of electron traps. Electrons injected into the oxide are captured by these traps and shift the threshold voltage of the parasitic, depletion-type MOSFET in the positive direction. CVD SiO_2 by the side of the gate also has electron traps which play the similar role. The former shift is rapid compared to the latter one and becomes saturated in a certain amount. In contrast, the latter shift is slow and long lasting. This mechanism dominates the degradation of the LDD MOSFET's as far as the energy of hot-carriers is too low to activate another mechanism such as surface-state generation.

ABSTRACT

The redistribution and electrical characteristics of ion-implanted S in GaAs have been investigated using secondary ion mass spectrometry (SIMS) and Hall profiling in the dose range of 7×10^{12} to 1×10^{15} cm⁻². A significant dose dependence of the redistribution has been observed, with the light dose implants exhibiting the most severe diffusion during annealing. In the presence of a sufficiently high level of Si doping, the redistribution of implanted S is reduced for annealing temperatures up to 800°C, possibly due to the formation of a S-Si complex. Suitably chosen S + Si dual implants show a similar effect and result in a higher activation efficiency than is achievable by Si-only implants of the same total dose. Implantation damage produced by Ar and S dual implants also causes significant redistribution changes. Low levels of damage enhance the S redistribution during annealing, while a high level of damage strongly inhibits it for temperatures up to 900°C. Where the S redistribution is inhibited by damage, however, electrical activity is reduced or lost.

The redistribution of ion-implanted impurities during annealing is often nonfickian, owing to the presence of defects (1-5), self-interstitials (6), or another chemical species which interacts with the implanted impurity (7, 8). Both enhanced and retarded diffusion have been observed as a result. Data from early work show that implanted S in GaAs undergoes considerable redistribution upon annealing, with only fair to poor electrical activation (9-14). More recent studies using capless annealing in an H₂-As₄ atmosphere indicate less redistribution (15, 16), while other reports using dielectric encapsulation (17, 18) continue to describe severe S migration.

The redistribution characteristics of S-only implants for a variety of doses annealed at 900°C with Si₃N₄ encapsulation have been reported by Yeo *et al.* (17). The dose dependence of such redistribution has also been investigated by Wilson *et al.* (19) for a much larger dose range, using SiO₂ encapsulation and a melt-ambient capless technique (20). Some evidence of a possible S-Si interaction which retards the redistribution of S has been pointed out by Yoder (21) in the data of Oakes and Degenford (22). Wilson and Jamba (23) also showed that S redistribution during annealing is much reduced if the GaAs substrate has been preamorphized by equal doses of Ga and As ions before S implantation.

In this work, we examine the possibility of modifying the redistribution of implanted S in the presence of Si and/or excess implantation damage. To that end, the redistribution of implanted S is examined along with its electrical properties as a function of implantation dose and annealing temperature, and Si doping. We study S implants in the presence of implanted Si and Si introduced during crystal growth. An effort is made to isolate the effects of implantation damage by examining Ar coimplants with S which approximate the damage of the corresponding S + Si dual implants.

This study is performed using Si₃N₄ encapsulation, which is the most common encapsulant capable of preventing both Ga and As loss from the sample surface (24, 25).

Experimental Procedures

Redistribution characteristics of S-only implants were studied by performing 250 keV implants into Cr-doped semi-insulating GaAs substrates. Possible S-Si interactions were studied by dual implants of S and Si into Cr-

doped GaAs and also by implanting S into Si-doped MBE-grown layers. For studies of the effects of implantation damage on S diffusion, S and Ar dual implants were employed.

The energies of dual implants were chosen such that the projected ranges of the different ion species were approximately the same. All implantations were performed at room temperature with the substrates tilted 7° from the surface normal to avoid channeling effects. Annealing was performed in flowing forming gas using an oxygen-free RF plasma-deposited Si₃N₄ cap (24, 25). The resulting impurity distributions were measured with secondary ion mass spectrometry (SIMS), using a Cs⁺ primary beam for S or Si studies, and an O₂⁺ beam to detect Cr. Absolute concentrations for implanted species in unannealed samples were obtained by measuring the depths of the sputtered SIMS craters with a Sloan Dektak mechanical stylus and setting the integrated areas of uncalibrated SIMS profiles equal to the implantation doses. These were then used as standards for calibrating the SIMS profiles in annealed samples by comparing matrix and impurity secondary ion counts. Cr concentrations in the GaAs substrates were obtained by comparing with a GaAs sample having a known Cr implant. The accuracies of the depth scales are estimated to be 5-10%, and are limited by the Dektak accuracy, the uniformity of the sputtering rate, and the flatness of the bottom of the craters created. The uncertainties and reproducibility of the impurity concentrations obtained are estimated to be 10-20%, limited by the stability and reproducibility of the impurity ion yields relative to the matrix ion yield, both during a run and between runs. To enhance SIMS sensitivity, S implants were performed in most cases using the ³⁴S isotope to avoid mass interference from O₂ during SIMS analysis, achieving a detection limit of $\sim 10^{15}$ cm⁻³.

Carrier concentration and mobility profiles were obtained by double ac Hall measurements combined with chemical layer removal (26) using a 1:1:200 mixture of 30% H₂O₂, conc sulfuric acid, and deionized water. The Cr-doped GaAs substrates were first tested for possible type conversion during annealing by implanting with Ar ions and checking for electrical conductivity after a high temperature anneal. No type conversion has been found for these samples after annealing at temperatures up to 800°C. Such conversion does occur at 900°C, however, rendering electrical data for samples annealed at this temperature invalid.

Results and Discussion

S-only implants.—The redistribution of S-only implants was investigated first as a function of dose and annealing temperature to form a basis for comparison with later dual implants. Shown in Fig. 1 and 2 are the SIMS profiles of S implanted at 250 keV before and after annealing at 700°, 800°, and 900°C for doses of 7×10^{12} and 10^{15} cm^{-2} . The higher dose is above the amorphization threshold of $1.4 \times 10^{14} \text{ cm}^{-2}$ as estimated using the critical energy dep-

Fig. 2. SIMS profiles of ^{32}S due to a 10^{15} cm^{-2} implant and after annealing.

osition model (27) and Winterbon's energy deposition tables (28). In addition to these doses, data from an intermediate dose ($7 \times 10^{13} \text{ cm}^{-2}$) will be discussed.

Two artifacts of SIMS measurements should be noted here and distinguished from the rest of the data. Thin native oxides on the sample surfaces (inevitably formed as a result of atmospheric exposure) usually cause enhancement of secondary ion yields which are quite unrelated to the actual concentrations of the chemical species being monitored (29). Also, a short time is required before the sputtering rate and the rate of primary ion incorporation into the surface reach their steady state. As a result, the matrix and impurity counts have a period of instability corresponding to the first few hundred angstroms of sputtering, and the impurity profiles are discounted in this region.

The unannealed S profiles are skewed for both doses, with peaks occurring at $0.21 \pm 0.02 \mu\text{m}$. LSS statistics (30, 31) predict a projected range of $0.19 \mu\text{m}$ and a straggle of $0.07 \mu\text{m}$.

In the vicinity of their peaks, the unannealed distributions are approximately gaussian with a straggle $\Delta R_p \approx 0.11 \mu\text{m}$. The tail of the distribution is close to gaussian for the high dose case (Fig. 2), but is considerably deeper than gaussian for implants below the amorphization threshold (Fig. 1). Similar observations have been reported for implanted Se in GaAs and have been attributed to interstitial migration in crystalline GaAs during implantation when the total dose does not exceed the amorphization threshold (23).

Upon annealing, dose-dependent redistribution occurs similar to that reported by Wilson *et al* (19). For the low dose implant (Fig. 1), S diffuses significantly at temperatures as low as 700°C. At 800° and 900°C, the as-implanted peak is entirely lost. The tail regions of the profiles (*i.e.*, $> 0.9 \mu\text{m}$) for all three annealing temperatures are approximately gaussian locally. The diffusion coefficients in these regions are estimated to be 9×10^{-13} , 1×10^{-12} , and $8 \times 10^{-12} \text{ cm}^2/\text{s}$ for 700°, 800°, and 900°C, respectively. These values are consistent with those reported by Sansbury and Gibbons (10) for implanted S, but are almost an order of magnitude higher than the results of Kendall (32) and two to three orders of magnitude higher than those reported by Young and Pearson (33) for S indiffusion experiments into GaAs substrates. Some S outdiffusion into the Si_3N_4 cap also seems to take place, as evidenced by decreasing integrated areas under the S profiles with increasing annealing temperature. The high dose implant behaves differently (Fig. 2). The as-implanted peak is retained with only minor distortions even after a 900°C anneal. However, penetrating tails are still formed after 800° and 900°C annealing.

Implanted S in the presence of implanted Si.—Possible impurity interactions between S and Si (21, 22) were investigated by using dual implants in which various doses of Si were coimplanted at 220 keV with medium ($7 \times 10^{13} \text{ cm}^{-2}$) doses of S at 250 keV. At these ion energies, the range statistics of the two species are approximately the same, and the ratio of S to Si concentrations remains almost constant throughout the as-implanted layer.

Shown in Fig. 3 and 4 are the SIMS profiles of a $7 \times 10^{13} \text{ cm}^{-2}$ S implant in the presence of a $3 \times 10^{14} \text{ cm}^{-2}$ Si coimplant after annealing at 800° and 900°C, respectively. Shown also for comparison are the corresponding S distributions due to S-only implants and the Cr profiles in the dual implants. It is apparent that the Si coimplant substantially reduces the redistribution of S upon annealing at both temperatures and roughly preserves the as-implanted shape of the S profiles. However, at 900°C a secondary peak appears in the S profile when Si is coimplanted. Little outdiffusion into the cap occurs at either temperature, and SIMS analysis shows that the Si distribution is essentially unchanged by annealing.

Increasing the Si dose in the coimplant experiment to $5 \times 10^{14} \text{ cm}^{-2}$ or decreasing it to $1 \times 10^{14} \text{ cm}^{-2}$ gives the same general results shown in Fig. 3 and 4. However, further reducing the Si dose to $3.5 \times 10^{13} \text{ cm}^{-2}$ brings about

Fig. 3. SIMS profiles of ^{34}S due to a $7 \times 10^{13} \text{cm}^{-2}$, 250 keV ^{34}S implant in the presence of a $3 \times 10^{14} \text{cm}^{-2}$, 220 keV ^{28}Si coimplant and annealed at 800°C ("with Si"). Shown also for comparison are the SIMS profile of ^{34}S if the ^{28}Si coimplant is absent ("without Si") and the Cr distribution in the dual implants.

an entirely different behavior. With 800°C annealing (not shown), there is somewhat more S redistribution with the Si coimplant than in the case of the S-only implant. At 900°C, however, the Si coimplant causes the implanted S to be largely swept out of the implanted region (Fig. 5).

Fig. 4. SIMS profile of ^{34}S due to a $7 \times 10^{13} \text{cm}^{-2}$, 250 keV ^{34}S implant in the presence of a $3 \times 10^{14} \text{cm}^{-2}$, 220 keV ^{28}Si coimplant and annealed at 900°C ("with Si"). Shown also for comparison are the SIMS profiles of ^{34}S if the ^{28}Si coimplant is absent ("without Si") and the Cr distribution in the dual implants.

Fig. 5. SIMS profile of ^{34}S due to a $7 \times 10^{13} \text{cm}^{-2}$, 250 keV ^{34}S implant in the presence of a $3.5 \times 10^{13} \text{cm}^{-2}$, 220 keV ^{28}Si coimplant and annealed at 900°C ("with Si"). Shown also for comparison are the SIMS profiles of ^{34}S if the ^{28}Si coimplant is absent ("without Si") and the Cr distribution in the dual implants.

This appears to be a case of very pronounced defect-enhanced redistribution. The Si profile is again found to be little changed by annealing. The as-implanted S profile in Fig. 5 is somewhat narrower and has a peak closer to the surface than the corresponding profile in Fig. 4. The only difference in the implantation conditions is the dose of the Si coimplant, with the lower Si dose (which is not amorphizing) associated with the shallower and narrower as-implanted S profile. We believe that the discrepancy is mostly due to the uncertainties in the depth scale.

The behavior of the Cr originally present in the substrates is found to be quite independent of the dose of the Si coimplant. Annealing at 800°C results in the formation of a local Cr accumulation within a region characterized by extensive Cr depletion (Fig. 3). The local Cr accumulation can be attributed to gettering by residual damage (5), or Cr precipitation at nucleation sites provided by residual damage (4). At 900°C, the local Cr accumulation virtually disappears (Fig. 4 and 5), leaving a broad ($\sim 3 \mu\text{m}$) Cr depletion region.

S implantation into Si-doped MBE layers.—The above experiments suggest a possible S-Si interaction which slows down the redistribution of S when the Si concentration is sufficiently high. However, to discriminate between the effects of the implanted Si and the additional damage associated with the Si implant, S implants at 250 keV and $7 \times 10^{13} \text{cm}^{-2}$ have been performed into GaAs layers doped with Si ($N_A \approx 2.2 \times 10^{18} \text{cm}^{-3}$) during MBE growth. Upon annealing at 800°C (Fig. 6), the S redistribution is clearly less severe than if there is no Si doping, but is still considerable. There is also little outdiffusion of S into the cap (the integrated S concentration is $6 \times 10^{13} \text{cm}^{-2}$). The diffusion tail in this case is almost exponential, which is consistent with the view that fast diffusing S is slowed by trapping (34, 35) in the presence of Si doping. However, when the annealing temperature is raised to 900°C, the S redistribution is not inhibited by the Si doping.

Influence of Si on the S profile is not observed when the Si doping in the MBE layer is reduced to 1×10^{18}

Fig. 6. SIMS profiles of ^{34}S due to a $7 \times 10^{13} \text{ cm}^{-2}$ ^{34}S implant into heavily Si-doped ($N_d \approx 2.2 \times 10^{18} \text{ cm}^{-3}$) MBE GaAs annealed at 800°C ("with Si"). Shown also for comparison is the SIMS profile of ^{34}S if the Si doping is absent ("without Si").

Fig. 7. SIMS profile of ^{34}S due to a $7 \times 10^{13} \text{ cm}^{-2}$, 250 keV ^{34}S implant in the presence of a $3 \times 10^{14} \text{ cm}^{-2}$, 250 keV ^{40}Ar coimplant and annealed at 900°C ("with Ar"). Shown also for comparison is the SIMS profile of ^{34}S due to the same implant in the presence of a $3 \times 10^{14} \text{ cm}^{-2}$, 220 keV ^{28}Si implant annealed at the same temperature ("with Si").

cm^{-3} . This supports the view that the S-Si interaction is a short-ranged one, such as the formation of a nearest neighbor complex as suggested by Yoder (21). Such a S-Si complex may be a slower diffuser than S because of a large physical size or because Si itself has a very low diffusivity in GaAs. At sufficiently high temperatures, such complexes are expected to break up. This is apparently the case for the 900°C anneals observed here, in which S redistribution is not strongly slowed by the presence of Si.

S and Ar dual implants.—The results on S-implanted MBE layers suggest that the reduced redistribution of implanted S at 900°C observed in the case of Si coimplants (Fig. 4) must involve factors other than Si doping. It is therefore useful to investigate the role of implantation damage in such redistribution. To simulate the damage due to the Si implants, Ar was coimplanted with S at 250 keV to the same doses as the Si coimplants discussed above. In the case of a $7 \times 10^{13} \text{ cm}^{-2}$ S implant and a $3 \times 10^{14} \text{ cm}^{-2}$ Ar coimplant, the extent of S redistribution after 800°C annealing is observed to be somewhat less than if a Si coimplant had been used. When the annealing temperature is raised to 900°C , an approximately gaussian tail appears (Fig. 7) which largely coincides with the Si coimplant case, but without the secondary peak observed in Fig. 4.

For the same S dose ($7 \times 10^{13} \text{ cm}^{-2}$), when the dose of the Ar coimplant is raised to $5 \times 10^{14} \text{ cm}^{-2}$, very little S redistribution is observed for 800°C annealing. At 900°C , somewhat more redistribution is observed, but it is much less than in S-only implants and somewhat less than in S + Si dual implants. Again, the secondary peak observed for Si coimplants does not occur. When the dose of the Ar coimplant is lowered to $3.5 \times 10^{13} \text{ cm}^{-2}$, defect-enhanced redistribution is observed, similar to the corresponding low dose Si coimplant (Fig. 5).

Electrical properties.—Unlike Column IV dopants such as Si, S is not amphoteric and may therefore be capable of yielding heavier n-type doping in high dose implantations. Of particular interest are the electrical properties of S-only implants and the combinations of S + Si and S +

Ar dual implants where the redistribution of S is inhibited.

Figure 8 shows carrier concentration and mobility profiles due to a $7 \times 10^{13} \text{ cm}^{-2}$ (medium dose) S implant at 250 keV into Cr-doped GaAs, annealed at 800°C . Shown also for comparison is the atomic S distribution as measured by SIMS. It is apparent that activation efficiencies and carrier mobilities ($\sim 4000 \text{ cm}^2/\text{V-s}$) are high in the tail

Fig. 8. Carrier concentration and mobility profiles due to a $7 \times 10^{13} \text{ cm}^{-2}$ ^{34}S implant at 250 keV, annealed at 800°C . The SIMS profile is also shown for comparison.

of the atomic distribution. However, in the vicinity of the SIMS peak, a substantial fraction of the implanted S is electrically inactive and the carrier mobilities are also low relative to the active electron concentration. While little published data are available concerning the solid solubility of S in GaAs at 800°C, electron concentrations as high as $3 \times 10^{18} \text{ cm}^{-3}$ have been obtained by H_2S doping during VPE growth at 750°C (36). Group VIA elements (S, Se, Te) are known to form electrically inactive complexes or precipitates at high concentrations, but this does not happen until the active electron concentration exceeds $\sim 1 \times 10^{18} \text{ cm}^{-3}$ (37, 38). Apparently, the low activation in the vicinity of the SIMS peak is due to residual damage remaining after the 800°C anneal. The overall doping efficiency after correcting for outdiffusion into the cap is 36%.

When the S dose is lowered to $7 \times 10^{13} \text{ cm}^{-2}$, the carrier concentration profile after an 800°C anneal assumes a shape similar to the corresponding SIMS profile (shown in Fig. 1), and carrier mobilities are relatively high ($\sim 3700 \text{ cm}^2/\text{V-s}$) throughout. In contrast, raising the S dose to 10^{15} cm^{-2} results in electrical activity only in the tail region of the atomic profile, with a maximum electron concentration of $\sim 4 \times 10^{17} \text{ cm}^{-3}$. The overall activation is only 2.3%. This is consistent with an increasing amount of residual damage in the vicinity of the SIMS peak as the dose is increased. However, other factors may also be involved as discussed below.

Shown in Fig. 9 are the carrier concentration and mobility profiles due to a dual implant of $7 \times 10^{13} \text{ cm}^{-2}$ S at 250 keV and $3 \times 10^{14} \text{ cm}^{-2}$ Si at 220 keV, annealed at 800°C. Shown also for comparison (dashed line) is the carrier concentration profile due to a $3.7 \times 10^{14} \text{ cm}^{-2}$ Si-only implant at 220 keV annealed at the same temperature. SIMS profiles presented in Fig. 3 indicate that the redistribution of S in this case is reduced in the presence of the Si coimplant. Figure 9 shows also that the activation efficiency of the dual implant is higher than that of a Si-only implant of an equivalent dose. The peak electron concentration due to the dual implant is also 45% higher ($1.6 \times 10^{18} \text{ cm}^{-3}$ vs $1.1 \times 10^{18} \text{ cm}^{-3}$). A surface inactive layer of $0.25 \mu\text{m}$ exists in both cases and is presumably due to incomplete lattice recovery from implantation damage. This dual implant can be used to achieve a higher peak electron concentration and lower sheet resistivity than is obtainable by Si implantation alone, without encounter-

ing the problems caused by the high diffusivity of S-only implants. The improved n-type activation may result from S preferentially occupying As sites, thus forcing more of the Si to occupy Ga sites where they act as donors.

While SIMS profiles indicate that S + Ar dual implants in which the Ar dose in amorphizing are very effective in inhibiting S redistribution, no measurable electrical activity is detected for these dual implants after an 800°C anneal. The redistribution of Cr in these cases is very similar to those shown in Fig. 3 and 4, and is therefore quite insufficient to result in complete compensation of the implanted S. While the degree of recovery of the GaAs lattice achievable after high dose Ar implants is also in question, the following experiment showed that additional factors are involved. The experiment consisted of amorphizing a Cr-doped GaAs substrate with a $5 \times 10^{14} \text{ cm}^{-2}$ Ar implant and then annealing it for 15 min (instead of the usual 30 min) with Si_3N_4 encapsulation. The cap was removed and the partially annealed sample implanted with $7 \times 10^{13} \text{ cm}^{-2}$ S at 250 keV. Annealing was again performed with a second nitride cap at 800°C for an additional 15 min. The implantation damage associated with the amorphizing Ar implant was therefore annealed for a total time of 30 min, while the damage associated with the S implant was annealed for only 15 min. Electrical profiling showed that in this case the implanted layer recovered sufficiently to give a significant peak carrier concentration ($\sim 5 \times 10^{16} \text{ cm}^{-3}$) with a relatively high mobility (2000-4000 $\text{cm}^2/\text{V-s}$). It appears, therefore, that the total lack of electrical activity is only associated with annealing implanted S in the presence of a very large density of defects (as found in an amorphized substrate). This may occur through the formation of thermally stable but electrically inactive complexes which are too large to diffuse rapidly. This is also consistent with the observation that, in the case of high dose ($1 \times 10^{15} \text{ cm}^{-2}$) S-only implants, very low concentrations of carriers are found in the vicinity of the peak of the S distribution, where a similar mechanism may occur due to the presence of a high density of implantation damage.

Summary and Conclusions

The redistribution characteristics of ion-implanted S in GaAs have been investigated and found to be strongly affected by implantation damage and Si doping. In general, a high density of implantation damage inhibits the redistribution, while a low level of damage enhances it. As a result, implanted S profiles after annealing are characterized by relatively little change in the vicinity of the implant peak (for sufficiently high doses) and the formation of penetrating tails away from the peak due to defect-enhanced redistribution. The presence of Si doping in a sufficiently high concentration slows the redistribution of S for temperatures up to 800°C, possibly by the formation of a S-Si complex. Above 800°C, the complexing effect of Si is no longer sufficient to inhibit S redistribution.

In S + Si dual implants using a medium dose ($7 \times 10^{13} \text{ cm}^{-2}$) of S and a larger dose of Si, both the Si and the additional implantation damage due to the Si coimplant have a part in inhibiting redistribution of S during annealing. The secondary peak in the S profile after a 900°C anneal in this case (Fig. 4) is possibly due to a complex interaction between Si trapping, inhibited S redistribution in regions of heavy implantation damage, and enhanced redistribution in regions of lower level damage. Christel and Gibbons (39) have presented calculations which show that local stoichiometric disturbances due to unequal recoil of Ga and As can result in regions of excess As, followed by a deeper region of excess Ga, with a transition region in between. It is clear that Ga and As vacancies affect impurity diffusion; there is also experimental evidence that the Ga divacancy plays a significant role in aiding the diffusion of S in crystalline GaAs (33). Hence, the anomalous redistribution evident in Fig. 4 and 7 may involve such local stoichiometric imbalances. It is conceivable that locally enhanced out-diffusion of S from

Fig. 9. Carrier concentration and mobility profiles due to a dual implant of $7 \times 10^{13} \text{ cm}^{-2}$ ^{34}S at 250 keV and $3 \times 10^{14} \text{ cm}^{-2}$ ^{28}Si at 220 keV annealed at 800°C. The dashed line is the carrier concentration profile due to a $3.7 \times 10^{14} \text{ cm}^{-2}$ single ^{28}Si implant at 220 keV annealed at the same temperature.

a particular region (due to stoichiometric imbalances or otherwise) may result in a local minimum in the S profile and an apparent S buildup in adjacent regions, as is indicated in these figures.

The electrical activation of single S implants after 800°C annealing is fair for low and medium dose implants and poor for high dose implants. Activation is especially low near the peaks of medium and high dose implants where implantation damage is considerable. The level of damage required to prevent significant S redistribution during annealing will also prevent it from becoming electrically active. Apparently, annealing under these conditions produces thermally stable but electrically inactive S-defect complexes which do not diffuse significantly. In contrast, suitably chosen S + Si dual implants both inhibit the redistribution of S (up to 800°C) and result in a higher activation efficiency than is achievable by high dose Si-only implants of the same total dose. In this case, S implantation can be advantageously applied to achieve high donor concentrations without significant S migration. However, the results presented here indicate that such improvements exist in a rather narrow range of coimplant conditions and that residual defects in the surface layer remain after annealing.

ABSTRACT

Shallow p-n diodes with junction depths between 0.15 and 0.3 μm have been fabricated by rapid thermal and furnace annealing of boron fluoride implants made into single-crystal wafers. The implants were performed at 30 keV with a dose of 1×10^{15} or 3×10^{15} ion-cm⁻². For very shallow junctions, the residual implant damage is found to degrade the reverse bias diode leakage characteristics. The residual damage can be nearly eliminated and shallow junction characteristics can be improved by preamorphizing the wafers with a single 50 keV silicon implant at a dose of 1×10^{15} ion-cm⁻².

This report examines methods of obtaining shallow source-drain regions for p-channel devices used in complementary-metal-oxide-semiconductor (CMOS) structures. Shallow junctions (< 0.3 μm) will be required with the scaling down of device dimensions to increase component density. Ion implantation of boron into crystalline silicon, which is used to introduce the dopant into source-drain regions, is accompanied by a channeling effect which leads to increased penetration of the implanted profile. Because of the relatively high diffusion coefficient of boron in silicon, dopant redistribution occurs during furnace annealing.

In this study, boron is replaced by boron fluoride (BF₂) as the implanted species in order to obtain a shallow implanted profile in monocrystalline silicon (1). Rapid thermal annealing is utilized to minimize boron diffusion during dopant activation (2). The electrical carrier profiles and residual implantation damage are compared for rapid thermal and furnace annealing. In this way, the effect of the proximity of residual damage to the p-n junction is investigated by measurement of the p-n diode characteristics. These measurements are also performed on wafers with a surface layer amorphitized by a silicon implant, followed by a boron fluoride implant and a rapid thermal or furnace anneal. Other workers have used multiple silicon (3) or germanium (4) implants to displace the implantation damage from the device regions. It will be shown that a single, low energy silicon implant can be used to eliminate channeling of boron in a subsequent low energy, boron fluoride implantation and that the residual damage is greatly reduced compared to boron fluoride implanted into monocrystalline silicon.

Experimental

Boron fluoride was implanted at 30 keV with a dose of 1×10^{15} or 3×10^{15} ion-cm⁻² into 10 cm diam, (100) silicon wafers doped with phosphorus to a resistivity of 4-6 $\Omega\text{-cm}$. The 30 keV boron fluoride implant is equivalent to a boron implant at 6.7 keV. In some cases the silicon wafers had been preamorphized with a silicon implant at an energy of 50 keV and with a dose of 1×10^{15} ion-cm⁻². The silicon and boron fluoride implants were made with the ion beam tilted at an angle of 7° to the wafer normal in a random direction to minimize channeling. The substrates were held at approximately room temperature.

The implanted wafers were annealed either in a standard furnace or an AG210T HeatpulseTM system using a nitrogen ambient. The temperature control system in the Heatpulse system has a temperature feedback mechanism which enables the wafer to be held at a constant annealing temperature. The duration of the anneal is defined here as the time spent at the constant annealing temperature.

The boron and fluorine concentration profiles were obtained by secondary ion mass spectrometry (SIMS) using O₂⁺ primaries and positive secondary ions. The sheet resistance was measured by contour mapping with a four-point probe (5). The electrical carrier concentrations and the p-n junction depths were determined from spreading resistance profiles.¹ The junction depth measurements were reproducible to within $\pm 0.02 \mu\text{m}$. The implantation damage, before and after annealing, was examined by transmission electron microscopy (TEM).

Diode structures were fabricated using the implant and anneal conditions described above to evaluate the electrical characteristics of the p-n junctions. Current-voltage measurements were performed on oxide isolated, circular diodes of 1 mm diam.

Results and Discussion

Figure 1 shows the boron concentration profiles after implantation of boron fluoride into crystalline or into

¹ Measurements made by Solelec Laboratories, Incorporated, Sunnyvale, California 94089-2221.

amorphous silicon and illustrates the channeling effect observed with implantation into crystalline silicon. Figure 2 shows the boron and fluorine dopant concentration profiles, together with the boron electrical carrier concentration profile, after rapid thermal annealing of the implant made into crystalline material. The fluorine outdiffuses during the anneal, leaving a broad fluorine peak close to the wafer surface, together with a sharp peak at a depth of 50 nm. It will be shown below that this is the location of the residual implantation damage. However, the retained fluorine does not affect the boron electrical activation because only the tail region of the implanted boron remains inactive. Similar spreading resistance profiles were obtained after each of the implant and anneal conditions described in Table I. The junction depths shown in Table I were measured from the spreading resistance profiles at a carrier concentration of 10^{15} cm^{-3} , which corresponds to the background doping concentration.

The depth of the residual ion implantation damage was measured from TEM cross sections. Figure 3a depicts the initial implantation damage caused by a 30 keV boron fluoride implant with a dose of $3 \times 10^{15} \text{ ion-cm}^{-2}$. An amorphous layer is formed with a heavily damaged crystalline region just below the amorphous-crystalline interface. After rapid thermal annealing, a band of implantation damage remains at this depth (Fig. 3b). The TEM planar section (Fig. 3c) shows this damage to consist of irregularly shaped dislocation loops. The depth from the

wafer surface to the lower edge of the band of dislocation loops is listed in Table I. A similar defect structure occurs after furnace rather than rapid thermal annealing.

Shown in Fig. 4a is the amorphous layer formed after a silicon implant at 50 keV and a dose of $1 \times 10^{15} \text{ ion-cm}^{-2}$ followed by a boron fluoride implant at 30 keV and a dose of $1 \times 10^{15} \text{ ion-cm}^{-2}$. In this case, the silicon implant energy and dose was chosen to produce an amorphous layer (110 nm deep) which would contain the entire boron distribution from the subsequent boron fluoride implant. After the furnace anneal described in Table I, implantation damage is located at a depth of 80 nm but only small dislocation loops remain with an average loop diameter of 200 nm (Fig. 4b). A similar defect structure is observed if the boron fluoride implant is omitted, indicating that the damage is characteristic of the silicon implant. Almost complete elimination of implant damage has been reported for multiple silicon implants followed by a boron implant and furnace annealing (6). It has been shown here that this can be achieved by furnace annealing of dual silicon and boron fluoride implants.

There are several comparisons which can be made from Table I that illustrate the interdependence of residual implant damage, junction depth, diode leakage characteristics, and sheet resistance. First, the values listed in Table I for rapid thermal anneals are compared with those after furnace annealing for boron fluoride implanted into crys-

Table I. Structural and electrical properties of the p⁺/n junctions. The annealing conditions are: A, furnace anneal at 600°C for 30 min and at 950°C for 10 min; B, rapid thermal anneal for 5s at 1100°C

Implant	Si (50 keV)		BF ₂ (30 keV)		1×10^{15}	1×10^{15}
	1×10^{15}	3×10^{15}	A	B

talline silicon with a dose of 1×10^{15} or 3×10^{15} ion-cm⁻². It can be seen that a lower sheet resistance combined with a shallower junction depth can be achieved with rapid thermal annealing. This is consistent with the ability of rapid thermal annealing to thermally activate the implanted dopant while minimizing dopant diffusion. The higher annealing temperature of the rapid thermal anneal may account for the relatively low values of the sheet resistances. Although low sheet resistance values

and shallower junction are obtained, rapid thermally annealed diodes have relatively high leakage current densities. There is a correlation between increased leakage and a smaller separation between the residual damage and the p/n junction depth. This finding is now compared with the equivalent results for the dual silicon and boron fluoride implants. After furnace annealing, a low leakage current density (1 nA-cm^{-2} at -5V) combined with a small separation ($0.12 \mu\text{m}$) between the implant damage and the p/n junction is found. This suggests that the reverse bias characteristics are improved by a reduction of the residual defect density through use of the dual implant.

Conclusions

Shallow p-n diodes with good leakage characteristics are obtained by rapid thermal annealing or furnace annealing of boron fluoride-implanted, single-crystal silicon wafers. Generally, rapid thermally annealed diodes have shallower junction depths with lower sheet resistances but higher leakage current densities than furnace-annealed diodes. The high leakage current density is attributed to the close proximity of residual implant damage to the p-n junction.

The residual damage can be greatly reduced by pre-amorphization of the silicon wafers using a single silicon implant at 50 keV with a dose of 1×10^{15} ion-cm⁻². In this way, shallow junctions with good leakage characteristics can be obtained.

Two-Dimensional Ion Implantation Profiles from One-Dimensional Projections

M. D. Giles

J. F. Gibbons

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

ABSTRACT

Two-dimensional ion implantation profiles can be constructed from one-dimensional projections more quickly than by direct calculation. This method can be applied to many common target structures that can be reduced to an equivalent nonplanar single-layer target. This paper shows how the Boltzmann transport equation method can be extended to calculate two-dimensional effects for the implanted ion, damage distributions, and stoichiometry disturbances. The same approach can also be used with Monte Carlo methods.

The Boltzmann transport equation (BTE) approach (1) has been successfully applied to many ion implantation problems, predicting range and damage distributions, recoil distributions (2), and stoichiometry disturbances in compound semiconductors (3). The effects of ion backscattering can also be included if a multiple-pass scheme is used (4). All of this work has been restricted to one dimension. As device dimensions shrink, the lateral spread of implanted ions can no longer be neglected because of their effect on device behavior, providing the motivation to extend the method to two dimensions. Direct two-dimensional calculation is possible (5), but the computation time can be considerable. This paper describes a simpler method based on construction of two-dimensional information from one-dimensional projections.

Calculation of a two-dimensional profile by any method begins with the calculation of the results of implantation at a single point, yielding the point response function. There are then two levels of complexity possible. The simplest approach is to use the same response function at each point along the surface. A more general solution recomputes the response function at each point across the target. The simpler solution requires that the target have the same structure at each point along the surface, apart from the presence or absence of an opaque mask. This is satisfied exactly by a planar target even if it contains many planar layers. It is also approximately satisfied by a nonplanar single-layer target. The general solution can be used for any target shape and composition at the cost of an extra order in computation. These possibilities are illustrated in Fig. 1. Most cases of practical interest, such as silicon-silicon dioxide-polysilicon structures, are nonplanar multilayer (see Fig. 1f) and so require a general calculation scheme. We would like to treat these cases as a nonplanar single layer (see Fig. 1e) to speed up the calculations. This is made possible by a small scaling of the layers to form an equivalent silicon structure, as has been done previously for one-dimensional calculations. We will therefore concentrate on the single-layer case.

There are several approaches to the calculation of a point response in a single-layer target. The most common is to revert to a moments approach (6, 7) which allows the construction of a two-dimensional gaussian profile or a hybrid Pearson-Gaussian profile, and this has been used in several early two-dimensional simulation programs (8-10). At the other end of the spectrum in complexity, a full two-dimensional Monte Carlo (11) or Boltzmann (5) calculation can be performed. As will be seen, this can represent an unnecessarily large amount of work for this problem. As an intermediate approach, one-dimensional projections of the profile can be calculated and used to reconstruct the two-dimensional response function. It is found that two projections, one vertical and one lateral,

are sufficient to do an accurate reconstruction. This method can be applied to both the Monte Carlo and Boltzmann schemes.

Method

Monte Carlo.—The initial result from a program such as TRIM (12) is a three-dimensional histogram of the final ion positions in the target. In a one-dimensional calculation, the histogram is flattened onto one vertical dimension to describe the final profile. The number of ion tracks that is necessary to describe the distribution is governed by the desired statistical error in the distribution; if a histogram box contains N ions, then the error is approximately \sqrt{N} . This dictates the use of at least 10^4 ions to maintain roughly 10% accuracy over the first decade of the profile. For a two-dimensional direct calcula-

tion, the ions are spread over a plane rather than a line, so more ions must be followed to maintain statistical accuracy—between 10^5 and 10^6 ions are necessary, with a corresponding increase in calculation time.

In the alternative method proposed here, lateral information is obtained by flattening the histogram into one dimension laterally. The point response is then taken to be the product of the vertical and lateral projections. Because one-dimensional information is used throughout, 10^4 ion tracks are sufficient to define the result. The statistical error in the lateral projection is actually less than for the vertical profile because the lateral case is symmetric and the half-width is less than the total profile depth, so the histogram is spread over fewer bins. Figure 2 compares direct calculation using 10^5 ions with a reconstruction from 10^4 ions for 20 keV boron implanted into silicon. This comparison shows that the direct calculation is satisfactorily reproduced over the first two decades and justifies reconstruction from only two projections.

Boltzmann.—A one-dimensional Boltzmann vertical calculation does not contain lateral information because projection of the ion motion onto an axis is an integral part of the calculation. However, by changing the initial and boundary conditions, a lateral projected profile may be

Fig. 3. Comparison of Boltzmann calculation method for vertical and lateral profiles.

Fig. 4. Comparison of Monte Carlo and Boltzmann methods for lateral profile of 20 keV boron in silicon. Dose: 10^{15} cm^{-2} .

obtained. In a vertical calculation, the direction of integration is parallel to the initial beam direction. At each integration step, the ion motion is projected onto the integration direction so that the final result is a vertical projected profile. The surface is considered as an open boundary so that ions may be ejected out of the target. For a lateral calculation, the direction of integration is perpendicular to the initial beam direction. The same projection operation therefore produces a lateral projected profile. The surface is considered as a reflecting boundary so that only one half of the symmetric lateral distribution need be calculated. The two calculation conditions are compared in Fig. 3. For the lateral calculation, multiple passes (4) are essential because the beam angle causes many ions to be considered as backscattered. The multiple pass approach allows the motion of backscattered ions to be fully considered. Typical calculations require five passes, each of which is much shorter than a vertical calculation, leading to an overall calculation time of roughly twice the vertical time. The time to construct a point response for VLSI applications is in the range of

Fig. 5. Comparison of Monte Carlo and Boltzmann methods for lateral profile of 50 keV arsenic in silicon. Dose: 10^{15} cm^{-2} .

Fig. 6. Comparison of calculations for peak concentration for implantation of 50 keV arsenic through a narrow slit into silicon. Dose: $5 \times 10^{15} \text{ cm}^{-2}$.

5-50s on a Cray-1 computer, compared with 50-500s for the same calculations using a vectorized Monte Carlo code.

Figures 4 and 5 compare lateral profiles calculated by the Monte Carlo and Boltzmann methods, showing very good agreement, and also confirming the accuracy of the calculations because the methods are independent. Comparison is also possible with the two-dimensional Boltzmann work of Takeda *et al.* (5). Figure 6 shows the change in peak concentration with slit width for implantation of 50 keV arsenic through a narrow window on a silicon substrate. All three methods show the same trends, but the data from Takeda *et al.* indicate a wider spread in the point response for their work.

Direct measurement (13) of true lateral profiles has not yet been achieved to sufficient accuracy for a useful com-

Fig. 8. Damage point response function for 20 keV boron implanted into silicon. Dose: 10^{15} cm^{-2} .

parison to be made. The closest thing possible to an experimental comparison at this time is to compare with profiles from tilted-beam experiments (14-17). In the BTE approach, this corresponds to tilting the initial beam direction and leaving the surface boundary open. Figure 7 compares calculation with experiment (17) for 60 keV arsenic implanted at various angles, showing the same movement of the peak position with tilt angle. The poor fit to the deeper profiles is believed to be in part due to inaccuracy in the measured profiles. For example, the experimental data for normal incidence seem truncated in comparison with the calculated curve and also in comparison with the other experimental curves and published data (18).

In one dimension, the BTE approach has also been used to calculate damage distributions (1), stoichiometry disturbances (3), and recoils in multilayer targets (2). In

Fig. 9. Recoil atom point response function for 50 keV silicon implanted into gallium arsenide. Dose: 10^{15} cm^{-2} .

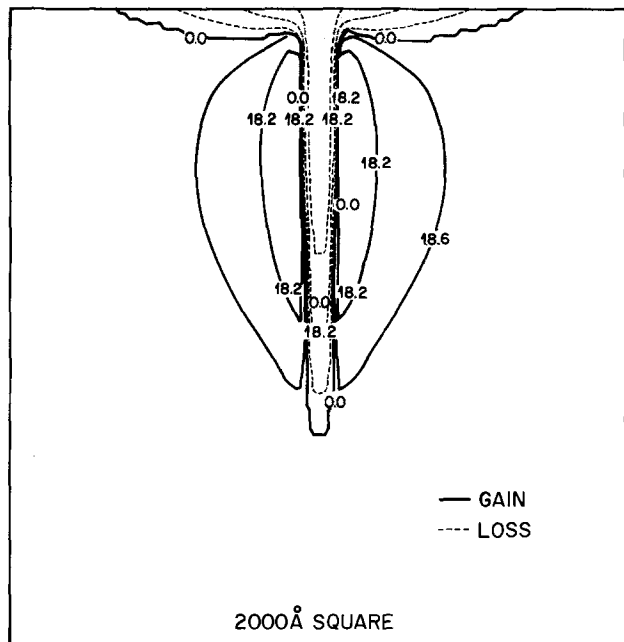

Fig. 10. Net substrate displacement from 50 keV silicon implanted into gallium arsenide. Dose: 10^{15} cm^{-2} .

Fig. 12. Concentration profile for 20 keV boron into silicon at a 45° mask edge.

two dimensions, we have restricted ourselves to single-layer targets, but calculation of damage and stoichiometry is still possible by constructing point response functions for the appropriate quantities. Figure 8 shows a calculation for damage from a 20 keV boron implant into silicon. The general shape is similar to that of the concentration profile, although the dynamic range is less. For displacement and stoichiometry calculations, it is necessary to construct responses for displaced atoms and the corresponding vacancies separately. The net disturbance is then the difference in the two response functions. Figure 9 shows the concentration response for recoils from 50 keV silicon implanted into gallium arsenide, considering the substrate atoms together because their masses are so similar. The corresponding profile for vacancies is almost identical. The difference in these two correlated

quantities gives the net imbalance, as shown in Fig. 10. This shows some surface loss of recoiled atoms and net displacement of atoms from the beam axis outward.

Example Profiles

Once the point response function has been calculated, it is easy to obtain two-dimensional profiles at various mask edges by convolution. Figures 11 and 12 illustrate calculations for 20 keV boron at an abrupt and a 45° mask edge, respectively. The construction time for each profile, given the one-dimensional sections, is much less than 1s on a Cray-1. Figure 13 shows a similar calculation for a damage distribution at a 45° mask edge. Finally, Fig. 14 shows net substrate atom displacement for a 50 keV silicon implant through a narrow window with abrupt edges into GaAs, which can be compared with the point response of Fig. 11.

Fig. 11. Concentration profile for 20 keV boron into silicon at an abrupt mask edge.

Fig. 13. Damage distribution from 20 keV boron into silicon at a 45° mask edge.

Fig. 14. Net substrate displacement from 50 keV silicon into gallium arsenide at an abrupt mask window.

Conclusions

The method of construction from projections allows two-dimensional implantation profiles to be calculated in the same order of magnitude of time as one-dimensional results, at the loss of some generality. Through scaling, the method can be used for practical useful structures, and it can be applied to both Monte Carlo and Boltzmann schemes. Through appropriate choice of point-response function, damage and stoichiometry effects can also be calculated. There is little advantage in using a more complex method unless a full, general solution is required and the increased computing resources are available.

ABSTRACT

Si-MBE is a low temperature deposition method for epitaxial silicon layers with thickness and doping profile control on a submicron level. The MBE equipment described in detail is designed for high throughput of round wafers (ten 3 in. wafers per day). The apparatus consists of six subsystems, the reliable and simple operation of which has been proved during a 2 yr test period. For the first time we report on fabrication of high performance integrated circuits using Si-MBE material. Frequency dividers were fabricated using, apart from MBE, a commercial process line. Clock frequencies of up to 2.8 GHz were realized by these dividers with integrated transistors with transit frequencies up to 7 GHz.

Si-MBE promises several advantages which should make it a powerful instrument for future material and device fabrication. Remarkable properties are low process temperature, precise control of thickness and doping profile on a submicron scale, and high flexibility concerning the choice of material combinations and layer numbers.

Up to now, much effort has been directed toward the technological development of the Si-MBE system and toward the fabrication of materials (1, 2) and of basic devices (3) demonstrating the capability of the method; see also, for instance, recent reviews (4, 5) and the excellent bibliography (6). Several groups now are intensively thinking about industrial application of the method, and they are bearing in mind that facts like cost, throughput, and yield are of the same importance as technical feasibility (7, 8).

Si-MBE may influence the fabrication of integrated circuits in an evolutionary or revolutionary way. For near-future applications, the evolutionary way accepting the well-established IC-process sequence has to be chosen. Our experience with this evolutionary way is described in the following report, which covers (i) layer growth in high throughput Si-MBE equipment with a ten-wafer cassette within a load-lock chamber; (ii) influence of surface treatment, buried layer structures, and postepitaxial processes on crystal perfection and dopant profiles of the MBE-layers; and (iii) fabrication of a GHz frequency divider. Apart from MBE all other process steps were taken from a process sequence routinely used for manufacturing these frequency dividers.

Si-MBE apparatus.—Si-MBE systems provide inside of a clean UHV chamber several individually regulated molecular beams (silicon, dopants, alloy materials, metals) which are directed onto the cleaned surface of a heated substrate. Our homemade apparatus (9) has been designed for high throughput fabrication of electronic-grade material. A wafer cassette positioned in a separate UHV-storage chamber which is connected to the growth chamber by a gate valve enhances the throughput. Crystal quality is improved by an extremely clean environment provided by low residual gas content (process pressure) and by the use of silicon as material for components which are in line of sight with the substrate. For simple operation, effusion cells emitting neutral molecular beams are used as dopant sources. Handling of round wafers without contaminating the back side is ensured by a special transport mechanism and by radiation heating of the substrates positioned in an annular holder made from silicon. This equipment, reliably working for two years, consists of the following six subsystems.

1. An ultrahigh vacuum system which allows a clean environment during the total process time. A proper choice

of pumps, vacuum parts, materials and their pretreatments, and of the procedure is necessary to obtain a process vacuum not substantially worse than the base vacuum. Our system (see Fig. 1) is pumped down by a turbo-molecular pump getting the gas molecules out of the vacuum chamber and by a high speed titanium-sublimation pump gettering the gas molecules inside the vacuum chamber (9). Materials used for components are copper and stainless steel for cold parts and molybdenum, titanium, boron nitride, graphite, and silicon itself as often as possible for hot parts. All components are preheated 50 K above their operation temperature and scrubbed by electrons. All hot components are heat shielded to reduce thermal load. The heat shieldings of the material sources are water cooled to avoid thermal coupling. Intentionally, we do not use liquid nitrogen-cooled "cold walls" in the line of sight of the substrate, because methane (CH_4) adsorbed on the cold wall can easily be desorbed by electrons. Typical process pressure is 10^{-10} mbar. The main residual gas is hydrogen.

2. The substrate heater should be able to uniformly heat large diameter wafers up to temperatures necessary for thermal cleaning and growth. The most promising type is a radiant heater positioned near the back side of the wafer, where care is taken to reduce thermal stresses on the wafer below the stress level activating slip line generation (10). This is successfully done with our substrate heater by using a graphite meander radiation source and a substrate holder made from silicon avoiding temperature differences at the rim of the wafer by providing equal absorption properties of substrate and ring holder. Crystal

Fig. 1. Sketch of our Si-MBE apparatus. Growth chamber on the right side. Load-lock with cassette on the left side. Both UHV chambers are connected by a gate valve with 150 mm aperture.

Fig. 2. X-ray topograph of a wafer with a $3 \mu\text{m}$ film grown on patterned oxide ($0.2 \mu\text{m}$ thick). Slip lines and dislocations were avoided by uniformly heating the substrate. Contrast arises from the strain field of the patterned oxide.

perfection and absence of slip lines are routinely checked by x-ray topography (see Fig. 2). Power consumption for heating a $75 \text{ mm } \varnothing$ wafer at a growth temperature of 750°C amounts to 700W .

3. The silicon molecular beam is generated by E-gun evaporation from pure silicon source material in the central portion melted and heated up to approximately 2000 K . Molten silicon is so reactive as to attack all other known crucible materials. The purity of the Si beam is enhanced by protecting the commercial E-gun from bombardment of backscattered electrons and ions by a silicon shielding. On a 30 cm distant substrate, typical growth rates are in the range of several micrometers per hour. Whereas E-gun evaporation is considered to be a reliable, clean, well-controlled process, it should be mentioned that it is also a source of particle beams (backscattered electrons, secondary electrons, silicon ions) and of electromagnetic radiation (light, x-rays, bremsstrahlung) influencing surface physics (adsorption, desorption, dissociation).

4. Dopant beams are generated by evaporation from effusion cells. For dopant materials we use Sb (for n-doping) and Ga (for p-doping). With Sb as a dopant material, concentrations up to the saturation limit of $2 \times 10^{19}/\text{cm}^3$ (at a growth temperature of 750°C) can be obtained (10, 11). But, near the saturation limit, incomplete electrical activation and degradation of the crystal perfection occurs. Well below the saturation limit, resistivity, Hall mobility of the layers, and their temperature dependence are similar to P- or As-doped bulk material (10-14). Thermodynamical calculations (15) predict a molecular beam that mainly consists of Sb_4 molecules. We found, by mass spectrometric analysis of the antimony beam, Sb atoms as well as Sb_2 and Sb_4 molecules. Up to now, a quantitative comparison with the calculations (15) has not been performed, because molecules are partly dissociated within the ionization chamber of the mass spectrometer and the sensitivity of the quadrupole mass spectrometer varies with atomic mass.

With Ga as a dopant material, carrier levels up to $2 \times 10^{18}/\text{cm}^3$ were achieved (16-18). The relatively high ionization energy of the Ga acceptor (70 meV) results in a dependence of resistivity on dopant concentration, quite different from B-doped bulk material. Already at Ga dopant levels above $1 \times 10^{17}/\text{cm}^3$ the acceptors start to be only partially ionized as proved by Hall effect measurements.

The upper Ga-dopant concentration amounts to approximately $1 \times 10^{19}/\text{cm}^3$ (growth temperature: 550°C). The carrier concentration belonging to this saturation limit amounts to $2 \times 10^{18}/\text{cm}^3$ at room temperature ($2.3 \times 10^{16}/\text{cm}^3$ at 77 K). With hole levels above $1 \times 10^{17}/\text{cm}^3$, device designers have to bear in mind the properties of the Ga acceptor.

Dopant atom incorporation can be enhanced and sharpness of interfaces can be improved by a technique we have called doping by secondary implantation during molecular beam epitaxy (DSI-MBE) (19). With this technique, silicon ions which are always produced by E-gun evaporation are accelerated by an electric field (typical potential difference between substrate and E-gun amounts to several hundred volts) toward the substrate. We believe that a main part of the low energy silicon ions implants atoms of the adsorbed dopant layer by impact (secondary implantation) into the growing MBE layer. The effect itself has been confirmed by another group (20), but the mechanism is a subject of controversial opinions.

5. *In situ* measurements of fundamental growth parameters are possible in the UHV environment of the growth chamber. Usually, analysis of the surface, the residual gas composition, the molecular beam intensities, and the temperatures of the substrate and effusion cells is employed. More than usual effort is directed by us toward mass spectrometry of dopant fluxes, absolute calibration of temperatures, and analysis of backscattered electrons.

Mass spectrometry of dopant fluxes is performed by a separate mass spectrometer sensitive to the range of atomic mass numbers 1-500 and by using a multiplier for ion counting. A shielding with properly positioned apertures protects the parts of the crossed-beam ion source of the spectrometer from being contaminated with dopant material or silicon. During operation of the effusion cells the mass numbers of Ga, Sb, Sb_2 , and Sb_4 isotopes can be detected. Using this mass spectrometer, we investigated the relation between effusion cell temperature and dopant flux density, the response of flux intensity on power variations of the cell heater, and the thermal cleaning of freshly loaded dopant materials from oxide layers.

Crystal perfection and dopant incorporation are influenced by the substrate temperature and the temperature of the evaporating surface of the dopant material. These temperatures differ from the reference temperatures measured by thermocouples mounted into the substrate heater and the effusion cells. The temperature differences between surface and reference thermocouple depend on design of substrate heater and effusion cell, on substrate doping (different absorption of radiation), on volume of cell load, and in some cases on thermal coupling from E-gun to substrate (significant only at very low growth temperatures) or from substrate heater to effusion cell (significant for wafer diameters greater than 50 mm and antimony effusion cell).

Intensity and energy spectrum of backscattered electrons, secondary electrons, and ions are measured by a Faraday probe with variable grid voltage. The primary source of electrons is the E-gun itself. Because of the magnetic field of the E-gun, the electron path is curved and only fast backscattered electrons can escape from the E-gun. The slow (several electronvolts) secondary electrons are generated by the impact of backscattered electrons onto the chamber wall. One can understand that the intensity and energy spectrum of the electrons scattered to the substrate sensitively depend on the design of the growth chamber. Near the substrate, the flux density of scattered electrons is in the order of $10^{12} \text{ electron}/\text{cm}^2\text{s}$.

6. The wafers are put into the growth chamber and removed through a load-lock chamber also pumped down to ultrahigh vacuum (see Fig. 1). Thereby the clean UHV environment within the growth chamber is maintained during several weeks until material must be reloaded or parts must be replaced. We have installed within the load-lock chamber a wafer cassette, the use of which further reduces the mean time for insertion of a wafer. On a nor-

mal working day, with this equipment, a 1 μm epitaxial layer can be deposited on ten 75 mm diam wafers.

Growth of device quality material.—The procedure consists of chemical cleaning of the substrate surface, insertion of the cassette into the load-lock chamber, pump down of the load-lock during the night, and epitaxy during the following day. One wafer after another is taken up from the cassette and transported by a transfer system to the growth chamber and put back after epitaxy. In the growth chamber, the wafer is inserted into the substrate heater. After a short heat cleaning step (900°C, 5 min), process parameters are adjusted to their proper values and growth is started by opening the main shutter and the cell shutters. Growth temperatures are between 550° and 800°C. The growth process is monitored by the *in-situ* control instruments and finished at the desired layer thickness by closing the shutters.

For establishing the growth of high quality layers one has to consider the importance of a clean environment, the role of surface diffusion of adatoms, the time dependence of dopant incorporation, and the existence of radiation (light, x-rays) and charged particles (electrons, ions) inside the growth chamber.

Models of ideal growth assume a clean surface on which pure beams of silicon and dopant material are impinging. Under real growth conditions, there will be undesired contaminating atoms, radiation, and charged particles. Actually, essential characteristics of Si-MBE are the attempt to suppress the contamination to a level as low as possible and the toleration of the level of electromagnetic and particle radiation inherently connected with the use of an E-gun. There are two principal sources of contamination, namely, the substrate surface itself mainly chemisorbed with oxygen and carbon, and residual gas. The chemisorbed substrate surface must be cleaned *in situ*, otherwise the deposited layer grows as a polycrystal. We use a short (5 min) thermal cleaning step at 900°C to remove the oxide layer. Strongly chemisorbed carbon cannot be removed by this moderate heating step. It is essential, therefore, to use a chemical pretreatment resulting in low carbon chemisorption (12, 21). It seems to us that careful handling, pure materials, and rapid transfer into the UHV chamber are more important than the choice between the different etching procedures. Carbon contaminants in the rising water not detected by electrical resistivity measurement may cause a nonreproducible carbon coverage. Remaining 5h in usual laboratory atmosphere increases the carbon coverage by a tenth of a monolayer as proved by ESCA measurements.

For perfect growth, the pressure and composition of the residual gas must also fulfill severe requirements during the cleaning and growth process. Heavy hydrocarbons must not be detected by a sensitive quadrupole-mass spectrometer. Partial pressures of oxygen, water, and also nitrogen should be well below the 10^{-11} mbar range. Only hydrogen as main component is allowed to be present at a partial pressure of several 10^{-10} mbar (22).

Fast surface diffusion of silicon adatoms was claimed (23) to play a dominant role for low temperature epitaxial growth under MBE conditions. Smooth surface, temperature-independent growth rate, and negligible desorption were explained by vertical growth via lateral motion of monatomic steps generated by the unintentional misorientation of commercial substrates (typically 1/4°). BCF (Burton, Cabrera, Frank) theory (24), assuming steps to be a capture site for diffusing adatoms, predicts negligible desorption only for an adatom diffusion length much higher than the step distance. A low energy barrier of surface diffusion (<1 eV) is compatible with the experimentally observed desorption and growth rates (23). These experiments should be compared with the strongly temperature-dependent growth rate, the desorption, and the moderate surface diffusion (energy of surface diffusion \approx 1.6 eV) observed with vapor phase epitaxy (25). Possibly, the difference in the energy barrier of surface diffusion is caused by hydrogen adsorption (26) during VPE or by radiation-enhanced motion during MBE.

Surface segregation, low sticking coefficients, and large time constants for incorporation of the dopants Sb and Ga (10, 12, 13, 17) rule out monatomic steps also to be an effective capture site for adsorbed dopant atoms, because during growth a step passes a point on the surface roughly every second. Therefore, BCF theory cannot describe dopant material incorporation during MBE. Other models (27, 28) describe the time dependence of dopant incorporation at least qualitatively.

There are considerable differences about the sticking coefficients of dopant material given in literature. Uncertainty of temperature was believed to be the cause of these differences (27). We have built three MBE equipments with different design but with the same careful calibration of cell and substrate temperatures. The sticking coefficient in every Si-MBE apparatus differs from the other. This experimental fact leads us to consider radiation and charged particle beams influencing the desorption, dissociation, and incorporation of dopant atoms. After every redesign of the apparatus, dopant level adjustment should take place. Electromagnetic and particle radiation also influence adsorption/desorption (29), contamination, and possibly silicon adatom migration as described above.

GHz-frequency divider.—A simple application of Si-MBE is to replace the epitaxial layer on an integrated circuit usually made by conventional vapor phase epitaxy by an MBE layer without changing pre- or postepitaxial processes or circuit layout. Clearly, in doing so the full potential of MBE will not be utilized, but this is an effective way to analyze the compatibility of the MBE process with the other IC manufacturing process steps. Improvements should be based on low growth temperature, reduced autodoping, and precise thickness control.

As a test vehicle, we selected a frequency divider used for television tuners. Initially, this commercial device was developed for an operating frequency up to 900 MHz (ultrahigh-frequency band of European television). Meanwhile, one needs frequency dividers up to X-band frequencies (12 GHz). Of late, Si bipolar IC's entered the lower microwave regime (30). Whereas in 1980 the fastest bipolar LSI circuits were considered to be based on integrated transistors with a transit frequency of $f_T = 4$ GHz (31), now the frequency limit of integrated bipolar transistors is shifted with laboratory examples toward $f_T = 14$ GHz (32) using a sidewall base contact structure (SICOS) technology. The highest reported clock frequency of a GHz-frequency divider is 5.5 GHz (33). These authors used a half-micron bipolar technology with advanced super self-aligned processes (SST-1A). Propagation delays for nonthreshold logic (NTL) of 42 ps/gate, power-delay products of 20 fJ/gate, and transit frequencies of 12.4 GHz were obtained with this technique. The highest operation frequency of the divider has been obtained at a high power dissipation of 884 mW. Encouraging results were also obtained with other special laboratory techniques. Using the direct nitride passivated base surface (DNP-II) process (34) resulted in a f_T value of 10 GHz and a clock frequency for the divider of 3.9 GHz at a power dissipation of 316 mW. Using vertically isolated self-aligned transistors (VIST) (35) resulted in a low power consumption of 84 mW at 2.5 GHz ($f_T = 6$ GHz) for a four-stage frequency divider (1:16).

We used, apart from Si-MBE, a 2 μm linewidth process sequence, which was developed for manufacturing of commercially available frequency dividers (36). Process sequence and circuit design were chosen to allow for the high yield production of a GHz-frequency divider with power dissipation below 100 mW. One layout of the test circuits is shown as a chip photograph (Fig. 3). This test chip contains a preamplifier, a master-slave flip-flop in ECL technique as binary divider, and test devices.

Prior to epitaxy, an As buried layer ($R_S = 8 \Omega/\square$) was diffused and a B-channel stopper was implanted to avoid inversion layers below the isolation oxide. Thermal processes after epitaxy were diffusion of the collector contact, oxidation of the isolation oxide, and annealing of

Fig. 3. Chip photo of a frequency divider with test devices. Layout-set number 7051.

base, base contact, and emitter implantation (Table I). The vertical structure of the integrated transistors is shown in Fig. 4. The effective thickness d_{eff} of the collector is lower than the epitaxial thickness d due to out-diffusion of the buried layer and due to the depth penetration of the base contact. Typical emitter depth amounts to $0.25 \mu\text{m}$, typical base width is $0.1 \mu\text{m}$, and base contact penetrates $0.55 \mu\text{m}$. In this experiment, the thickness d was reduced from 2.5 to $0.9 \mu\text{m}$, thereby reducing the effective thickness d_{eff} (see Fig. 4) from 1.6 to $0.2 \mu\text{m}$. The differences between d and d_{eff} are larger for thicker layers because of the prolonged time for oxidation of the isolation oxide. Alternatively, another test circuit was used (layout-set number 852) with diffused isolation and diffused emitter. The frequency limit of transistors with oxide isolation is roughly 2 GHz higher than the frequency limit (5 GHz) of transistors with diffused isolation (7).

With these test circuits we investigated yield as a function of the surface treatment, influence of pre- and post-epitaxial process steps on the quality of the MBE film, and transit frequency of the frequency divider and of integrated transistors as a function of the epitaxial layer thickness.

All fundamental growth experiments were performed on homogeneous substrates with flat, well-defined surfaces. Epitaxy for IC fabrication, however, starts on the surface of a heat-treated substrate, parts of which are oxidized, diffused, and ion implanted. These processes generate surface steps which are large compared with the monatomic misorientation steps present at flat surfaces. Surface contamination, defect propagation from substrate to layer, and growth mode can be influenced by these varied start conditions. Yield measurements can give general information about the significance of such varied start conditions. We obtained detailed information about causes of yield reduction by several methods for analysis of surfaces and defect structure (ESCA, TEM, x-ray topography, interference microscopy, defect etching). Initially, yield was considerably reduced when we replaced VPE layers by MBE layers. This was caused by residual

Fig. 4. Frequency divider. Vertical structure of integrated transistors with oxide isolation.

contamination at surface steps when applying the usual chemical cleaning treatment immediately before insertion into the magazine of the load-lock chamber. High device yield (up to 90%) was obtained by applying the following cleaning procedure. A modified cleaning solution based on hydrogen peroxide [known as RCA-etch (37)] yields low stacking fault and dislocation densities ($1 \times 10^3/\text{cm}^2$). This etching sequence is preceded by a centrifugal wafer spray. High purity water wets the spinning wafer; N_2 finally dries it for removal.

The buried layer zones themselves with their high As-dopant concentration do not degrade the high crystalline quality of the overlying film. Transmission electron micrographs clearly show that the epilayer grown onto buried layers exhibits the same lattice perfection as the part grown directly on the p-type substrate.

Autodoping is a well-known problem of epitaxy on substrates with buried layers. In order to investigate autodoping we grew layers on p-substrates, half of which were doped with arsenic in the same way as buried layer zones. Then we profiled doping level and junction abruptness on several spots on both halves of the wafer by C-V and spreading resistance measurements (see Fig. 5). We found that (i) junctions are abrupt within measurement accuracy (38) and carrier diffusion length (approximately a Debye length) and (ii) doping level is not influenced by the underlying substrate doping. That means practically that autodoping should not be considered when layer growth is performed by Si-MBE.

Postepitaxial processes may be influenced by the content of carbon, oxygen, or hydrogen, or by the concentration of interstitials or vacancies. Using the same process sequence as for the fabrication of the commercial devices, we did not find any hint that MBE material behaves other than VPE material with respect to postepitaxial processes.

The frequency limit depends on the thickness of the epilayer. Figure 6 exhibits the frequency limit, f_T , as a function of the emitter current, I_E , for several epitaxial thicknesses. Epitaxial dopant density is $1 \times 10^{19}/\text{cm}^3$. The emitter area is a single stripe $2.5 \mu\text{m}$ wide and $25 \mu\text{m}$ long. Collector-base voltage, U_{CB} , was fixed at 2 V . Frequency limit increases with increasing current up to a saturation value obtained at current densities of 1×10^8 – $2.5 \times 10^8 \text{ A/m}^2$. Frequency limits in excess of 4 GHz are obtained already at current densities above $3 \times 10^7 \text{ A/m}^2$ with epilayers 0.9 – $2.5 \mu\text{m}$ thick. The upper frequency limit of 7 GHz is obtained with epilayers about $1.2 \mu\text{m}$ thick. With thinner epilayers (see no. 192 in Fig. 6) the collector-base capacity increased, due to the reduced effective thickness decreasing the frequency limit (6 GHz for $d = 0.9 \mu\text{m}$). With thicker layers the collector resistance increases with increased effective thickness, reducing the frequency limit (5.8 GHz for $d = 2 \mu\text{m}$). The latter effect is more pronounced with lower epidoping level. With a doping level of $3 \times 10^{15}/\text{cm}^3$ (Sb), we obtained a frequency limit f_T of 6 GHz with $d = 1.2 \mu\text{m}$, $f_T = 4 \text{ GHz}$ with $d = 2 \mu\text{m}$, and $f_T = 2.5 \text{ GHz}$ with $d = 2.5 \mu\text{m}$. For low power consumption,

Table I. Postepitaxial processes. Heat cycles above 500°C

Aim	Process
Contact to buried collector	P diffusion, diffusion temperature dependent on epitaxial thickness (900° – 1000°C)
Oxide isolation	High pressure oxidation (20 bar) at 800°C , duration dependent on epitaxial thickness
Base, base contact, emitter	Room temperature implantation (B and As), furnace annealing at temperatures between 900° and 950°C

Fig. 5. Spreading resistance measurement of carrier profile of the epilayer on p-substrate with and without buried layer.

high frequency limits should be obtained at low collector-base voltage (U_{CB}) levels. An example is given in Table II. With integrated transistors of these frequency limits, frequency dividers with clock frequencies up to 2.8 GHz could be fabricated.

Fig. 6. Transit frequency f_T as a function of emitter current I_E for transistors with different epilayer thickness d .

U_{CB} (V)	0.5	1	2	4	5	6
f_T (GHz)	5.45	5.75	6.1	6.35	6.45	6.6

Conclusions

We have proved for the first time that use of Si-MBE material enables the fabrication of high speed integrated circuits with excellent performance. Apart from Si-MBE, the process sequence of a commercial frequency divider has been used. High crystal perfection on buried layer substrates, absence of autodoping, and compatibility with postepitaxial processing are offered by this conventional use of an epitaxial layer.

Further improvement should be expected by using the full capability of Si-MBE, including, in addition low process temperatures and precise control of submicron layers, the high flexibility of materials, profiles, and structures.

The layers have been grown in an Si-MBE apparatus which was designed for industrial application. Simple handling, high throughput, and reliable operation were demonstrated since the installation of this equipment in 1982. Based on the principles of this equipment (storage chamber with a cassette, excellent vacuum conditions, low process temperatures, large area wafer heater, high precision *in situ* process control), development of the next generation equipment should also fulfill high requirements with respect to low cost and high throughput production of Si-MBE layers.

Diffusion of Oxygen in Silicon Thermal Oxides

E. A. Taft*

General Electric Company, Schenectady, New York 12301

ABSTRACT

A method for comparing the oxidation rates of silicon under an initial 1000Å of thermal oxides is described. Ellipsometry is used to measure the thicknesses of a pair of samples before and after a relatively short time of additional oxide growth in dry oxygen. Excluding the known orientation effect, a large variation in growth rate at a given temperature is noted. The rate is directly related to the index of refraction of the initial oxide. As this index is known to depend upon the initial growth temperature, the apparent oxygen diffusion "activation energy" must include this newly documented temperature factor. Parabolic and linear rate constants are presented and are compared with literature values. This study gives further evidence that silicon thermal oxides are metastable structures.

The linear-parabolic model of Deal and Grove (1) is still the generally accepted interpretation of thermal oxide growth on silicon. Though recognized early by, e.g., Hopper *et al.* (2) and Irene and van der Meulen (3, 4) as not an exact model, careful experimental work did not result in much improved interpretation. Additions to the linear-parabolic approach continue to appear (5-9), and new physical possibilities are advanced (10-12), but the basic model remains. (Only a few of many papers are referenced here.)

This paper will present new oxygen diffusion data which should be considered within the linear-parabolic model framework. The experimental approach follows the lead of Taft (13) and of Irene *et al.* (14), who show density differences in silicon thermal oxides. The effect of this oxide structure variation on the diffusion rate of oxygen is examined.

The diffusion of gas through a network is strongly dependent on the relative size of the interstices of the network and diameter of the diffusant molecule (15). If the density of vitreous silicon oxides varies by several percent, the interstitial volume also varies. The diffusion of the oxidant through a silicon thermal oxide might be expected to strongly depend upon changes in this interstitial volume. Hence, as the index of refraction and density does vary with the oxide formation temperature (13), the diffusion constant of the oxidant should not be expected to be the same for all thermal oxides. Rate growth variations have been reported in other multiple oxidation studies (10, 16).

* Electrochemical Society Active Member.

It has been observed that the oxides are metastable in that they can be reheated up to the formation temperature without appreciable change in the index of refraction. Heating to a higher temperature will cause the film structure to relax to the index appropriate to that for a film grown at this higher temperature. Irene *et al.*, (14) have documented this oxide stability. This fact is a necessary part of the diffusion study.

This paper will also present data on the linear and parabolic rate constants of oxide growth in dry oxygen on <111> and <100> silicon wafers. The purpose here is not so much to give new data but to provide an informed starting place for comments on the rate constants and to show that the oxides reported are typical. The effective activation energy of the parabolic rate constant especially is discussed.

Experimental

Oxides were grown in dry oxygen on <100> and <111> single-crystal silicon at various temperatures to about 1000Å thick. The wafers were cleaned in hot H₂SO₄-H₂O₂ and given an HF acid dip to remove native or previously grown oxide. They were then hydrogen fired to 1200°C for 10 min. This high temperature cleaning (2, 17) gave initial ellipsometer readings of about 3Å as found by Claussen and Flower (17). The index of refraction and thickness was carefully checked with a Gaertner L119 ellipsometer. A second measurement was made the following day to test oxide stability. Pairs of wafers of the same orientation from different temperature runs were chosen to be of the same thickness to < 1%. Dilute HF

etching was used on one wafer, when necessary, to obtain a close thickness match. These pairs of wafers were then placed in an oxidation furnace at the lower of the original growth temperatures of the pair. A growth time for adding 5-10% to the original thickness was chosen. This new oxide is now considered as an incremental growth over a small part of the growth curve near 1000Å. The thickness and index of the incremented oxides were carefully remeasured. Again, a second measurement was made the following day to check reproducibility of measurements.

Also, oxide growth-time curves for 700°-1170°C temperature in dry oxygen were developed. <100> and <111> wafers of 1 1/2 in. diam were employed for this work also. The thickness data were taken in the 100-1500Å range with the Gaertner L119 ellipsometer.

Results

The matched thickness wafer pairs did not have matched growth rates. The oxide grown originally at the higher temperature always had a greater incremental growth thickness. The ratio of these new growth thicknesses was at first plotted against the initial growth temperature differences of the pairs. Only a trend was observed. As noted before (13), the index is a better measure of the state of the oxide film than growth temperature. Furnace contamination, generally water vapor, which might occur in our small tube furnace will give an effectively higher temperature to a sample. The incremental thickness ratio was then plotted against the difference in initial index for each pair of samples. This curve is shown in Fig. 1.

A point on this graph is found from the example of the following wafer pair. One wafer had an oxide thickness of 973Å with an index of 1.4686. The oxide was grown at 1000°C. A second wafer oxide grown at about 1170°C was chosen at nearly the same thickness at 975Å. Its index was 1.4623. After 20 min in the oxidation furnace at 1000°C, the first oxide was 57Å thicker at 1030Å with the index unchanged at 1.4685. The second oxide increased slightly in index to 1.4636 and was 107Å thicker at 1082Å. The initial indexes were different by 0.0063 and the ratio of incremental growths was 107/57, or 1.88. This point appears in Fig. 1.

The thickness of the oxide was measured immediately if a dilute HF etch was used. When checked the following day, it was noticed that, invariably, the thickness had increased by several angstroms. Subsequent measurements

were unchanged. Wafers from the oxidation furnace which were not etched appeared to have stable thicknesses. (Wafer pairs included samples with neither oxide etched and samples where either the high or the low temperature oxide was adjusted in thickness. No correlation was observed during subsequent measurements.) The thickness chosen for etched oxides was from the later stabilized value; repeatability was closer than $\pm 1\text{Å}$. The reproducibility of the index measurement was $< \pm 0.0005$. The thickness and index of refraction of the oxide readings taken on subsequent days were generally within these values. Additional readings were sometimes taken to verify the stability of the films, or to check for errors in this manually operated two-zone ellipsometer arrangement. The angle of incidence is the most critical setting. The observed reproducibility is well within the resetability of this angle.

After the short extended growth of the oxide pairs, it was typically found that the index of the lowest temperature film had not changed. This result might be expected, as the new growth was but a continuation at the temperature of the initial growth. The index of the higher temperature film was typically found to be higher than initially. In this case, the oxide added at the lower temperature would be expected to have a high index. The initial high temperature oxide remains unchanged with the lower temperature exposure. The averaged index of the composite film is then greater than the original index. A calculation from ellipsometer readings using a two film case shows that the agreement of thickness and indexes of refraction is good. One further note—Fig. 1 contains points from both <100> and <111> silicon oxidation pairs.

The thickness-time growth curves of <111> and <100> silicon oxide were analyzed by hand fitting to an equation of the form $t = A(X - 20) + B(X^2 - 20^2)$ (3). Minutes of growth is t ; A and B are the reciprocal rate constants; and X is the oxide thickness in angstroms. The rate constants are plotted in Fig. 2 and 3. The points for the lowest temperatures are not reliable, as large corrections were made for initial growth (18). The growth curves of Hopper *et al.* (2) and of Irene and van der Meulen (3), which were carefully analyzed, are not in particularly good agreement with each other. For this reason and the fact that there was some scatter in the 15-30 points making up our growth curves, the hand fitting of the equations seemed adequate.

Discussion

Diffusion.—Figure 1 shows that there are large readily measurable variations in the incremental growth rate of oxide films in the same environment. The variations appear to correlate to the sensitivity of the oxygen diffusion constant to the packing (in amorphous material) of the solid oxides. This conclusion is a restatement of commentary from the introduction. The sequence of the argument goes from our measured index of refraction change to the measured (14) and calculated density change through the Lorenz-Lorentz relation to an inferred interstitial volume change. The 0.43% decrease in index of refraction leads, in our example, to the 88% increase in the diffusion rate of oxygen through a thermal oxide on silicon.

This result indicates that another source for a temperature coefficient for diffusion in silicon thermal oxides has been identified. In the usual linear-parabolic analysis of oxidation, the coefficient for the parabolic rate contains the diffusion term. The temperature variation of this parabolic rate is often compared to the variation of molecular oxygen diffusion found for fused quartz (1). The possible constraint imposed by this comparison has now been removed, and a larger temperature variation may be considered more favorably.

If the incremental thickness differences in the oxide films described were attributed to only the parabolic term in the growth rate, these differences would also apply directly to the diffusion constant change. When the index changes of Fig. 1 are converted to inverse tempera-

Fig. 1. Incremental growth ratio for pairs of oxidized wafers relative to the initial index of refraction difference in the low and the high temperature oxides.

Fig. 2. Linear rate constants for dry oxides on $\langle 111 \rangle$ and $\langle 100 \rangle$ silicon.

ture through Ref. (13) and plotted against the logarithm of incremental thickness, a curve corresponding to an energy of ~ 0.3 eV is found for $\langle 111 \rangle$ silicon.

This structurally dependent diffusion rate of oxygen in silicon oxide is decreasing with decreasing temperature as does the normal temperature dependent diffusion rate for, e.g., fused quartz. In a series of grown oxide films, the net result is a steeper diffusion *vs.* inverse temperature curve or a higher apparent activation energy for diffusion. The activation energy for molecular oxygen in fused quartz according to Norton (19) is 1.17 eV. Adding the temperature effect found here, the net activation energy should be $1.17 + 0.3$ or 1.47 eV. This is for oxide formed on $\langle 111 \rangle$ silicon in dry oxygen. Taft (13) shows that oxides on $\langle 100 \rangle$ silicon have a slightly steeper index-temperature variation than those on $\langle 111 \rangle$ material. As the data of Fig. 1 also apply to $\langle 100 \rangle$ silicon, the apparent activation energy for diffusion in these oxides could be about 1.6 eV. It should be mentioned that these are minimum corrections. Consideration of the linear rate contribution or of the small effect of the two-layer oxide after regrowth will make for somewhat larger corrections.

The numbers are, of course, approximations, as the added factor is determined from data on a series of structurally different oxides. The data also indicate a T rather than $1/T$ relation with diffusion. It might be expected that the observed Arrhenius plot of the parabolic rate constant for oxide films would be nonlinear over an extended temperature range (8, 20, 21).

Rate constants.—As the major point of this paper is to present the oxygen diffusion effect, the rate constants determined in Fig. 2 and 3 are meant to serve in a corroborative role. The oxides grown here will be shown to be similar to those generally accepted in the literature. In the temperature range 900°–1200°C used for the diffusion measurements, the literature is fairly consistent.

Our activation energy for the linear rate constants is about 1.88 eV. This value is similar to that found by Hopper *et al.* (2), Kamigaki (6), and Lie *et al.* (8). Slightly greater values at ~ 2.0 eV are found by Deal and Grove (1) and Deal *et al.* (7). Slightly lower values are found by

Fig. 3. Parabolic rate constants for dry oxides on $\langle 111 \rangle$ and $\langle 100 \rangle$ silicon.

Irene (22, 23), Irene and van der Meulen (3), and Irene and Dong (20). The latter group finds the activation energy for $\langle 100 \rangle$ to be slightly higher than for $\langle 111 \rangle$ silicon. Also they find that the activation energy is not constant with temperature. Our rate constants for oxide on $\langle 111 \rangle$ silicon are slightly higher than those of Lie *et al.* (8) and Hopper *et al.* (2), and considerably higher than those of Deal and Grove (1) and Irene and van der Meulen (3). At 1000°C, the constant agrees with Revesz and Evans (24). The rate constant for oxide grown on $\langle 111 \rangle$ silicon appears to be about twice that grown on $\langle 100 \rangle$ silicon at the same temperature. This observation has been previously reported by van der Meulen (4), Irene (22), and Kamagaki (6). It appears that the linear rate constants for oxides grown in this experiment compare favorably to those reported in the literature.

Our activation energy for the parabolic rate constants is dependent upon the orientation of the silicon. For $\langle 111 \rangle$ silicon, it is ~ 1.45 eV, and for $\langle 100 \rangle$ silicon it is ~ 1.85 eV. For $\langle 111 \rangle$ silicon, our value is close to that of Lie *et al.* (8) and Hopper *et al.* (2), as was also noted for the linear term. Values nearer to 1.2 eV were found by Deal and Grove (1), Deal *et al.* (7), and by Revesz and Evans (24). Irene (22) and Irene and van der Meulen (3) found higher values. A larger activation energy for the $\langle 100 \rangle$ orientation is noted by Irene (22). Irene and Dong (20), Lie *et al.* (8), and Han and Helms (21) do not find a constant activation energy. The rate constants for $\langle 111 \rangle$ silicon are near those obtained by Lie *et al.* (8) and Hopper *et al.* (2) and smaller than the Deal and Grove (1) values. As with the linear term, our rate constants for the parabolic term are in reasonable agreement with reported values.

The actual oxide growth time for, e.g., a 1000Å oxide on $\langle 111 \rangle$ silicon at 1000°C, is found to be in better agreement among the several references given than are the derived rate constants. While our rate constants do not agree as well with those of Deal and Grove (1) as they do with others, the calculated growth times for this oxide are within a few percent of each other. It appears that the dry oxides grown for this diffusion experiment are much like other oxides reported.

Summary

Incremental growth rates in dry oxygen of oxides on silicon in the same furnace are found to differ by more than two. These rates are directly related to the index of refraction of the initial oxide film and thus to the original growth temperature. Therefore, there seems to be a change in diffusion rate because of a change in the oxide structure with growth temperature. This structure factor when added to the activation energy for the diffusion of oxygen through fused quartz could account for the higher effective activation energy of the parabolic rate constants usually observed. The activation energy for growth of oxide on <100> silicon should be higher than that on <111> silicon.

Acknowledgment

I should like to express my thanks to H. R. Philipp for his encouragement in the course of this work.

Oxidation Properties of Nickel in the Temperature Range 1073-1500 K

F. A. Elrefaie,¹ A. Manolescu,² and W. W. Smeltzer*

Institute for Materials Research and Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

Oxidation of nickel after preoxidation at 1473 K was investigated during isothermal stages in oxygen atmospheres, $10^3 \leq P_{O_2} \leq 10^5$ Pa, at temperatures in the range 1073-1500 K. The reaction kinetics were parabolic; the parabolic oxidation rate constant was proportional to $P_{O_2}^{1/n}$ with the value of n varying from 5.5 ± 0.2 at 1073 K to 6.2 ± 0.2 at 1473 K. The activation energy of oxidation was 225 ± 4 kJ/mol NiO. Marker measurements indicated that the polycrystalline columnar NiO scales, which exhibited a preferred (100) texture, grew by predominant outward nickel diffusion. The measured values of the parabolic oxidation rate constants were higher by a factor of ≤ 3 than values calculated using nickel self-diffusion coefficients of single-crystal NiO, due probably to a component of nickel migration along easy diffusion paths developed in the polycrystalline scales.

Oxidation of nickel is expected to follow parabolic kinetics when the kinetics are controlled by lattice diffusion of nickel via cation vacancies in the NiO scale. Application of Wagner's theory for parabolic oxidation (1) to the high temperature scaling of nickel has been examined by several investigators as reviewed in Ref. (2-5). The agreement between experimental and calculated values of the parabolic oxidation rate constant is satisfactory to a first approximation at temperatures higher than 1273 K; at lower temperatures, this agreement breaks down and can attain a discrepancy as high as 5-7 orders of magnitude at 773 K. This discrepancy arises because nickel migration along easy diffusion paths in the polycrystalline NiO layer such as dislocations and subgrain and grain boundaries plays a predominant role in the reaction mechanism. The purpose of this research, accordingly, was to investigate the influence of a preformed thin NiO layer, which was relatively free of easy diffusion paths, on the subsequent morphological development and oxida-

tion mechanism of scales grown during isothermal stages at 1073-1473 K.

Experimental

Nickel plate specimens, $2 \times 1 \times 0.05$ cm, were prepared from 99.995 atom percent (a/o) purity sheet containing impurity contents as listed in Table I. These specimens after abrasion on 600 and 800 SiC grit paper and ultrasonic cleaning in methanol were annealed in flowing ultrahigh purity argon at 1473 K. An annealed specimen, average grain size ~ 0.1 μ m, was polished on napless cloths to 1 μ m diamond paste using kerosene and cleaned as above prior to placement in the oxidation apparatus.

Oxidation kinetics were measured gravimetrically using a recording semimicrobalance assembly as described elsewhere (6). The oxidizing atmospheres maintained at 10^5 Pa were static air, flowing oxygen, or oxygen-argon mixtures of oxygen partial pressures ranging from 1×10^3 to 2×10^4 Pa. A specimen was oxidized initially at 1473 K for 120-300s, then the furnace temperature was altered to a lower value, whereupon the specimen was oxidized isothermally and subsequently at several other temperatures in the same atmosphere.

Table I. Impurity contents of nickel, 99.995 a/o pure

Element	B	C	N	O	F	Na	Mg	Al	Si	S	Cl
ppma	0.3	7	0.6	4	0.5	0.04	1	1	10	0.8	0.01
Element	K	Ca	Ti	Cr	Mn	Fe	Cu	Ag	Ba	Pb	
ppma	0.02	0.3	0.05	0.03	0.2	20	3	0.02	0.2	0.02	

Marker studies were carried out by placing platinum wire, 25 μm diam, around a nickel specimen which was sandwiched between two $\alpha\text{-Al}_2\text{O}_3$ disks and heated at 1273 K in argon for 10.8 ks to assure the absence of a gap between the wire and specimen surface.

Optical and electron microscopy was used to investigate the morphology of the NiO layers. Preferred orientations of the oxide grains within the polycrystalline scales were determined using an inverse pole figure method (7) whereby the texture coefficient of an (hkl) plane, P_{hkl} , of oxide is given by

$$P_{\text{hkl}} = \frac{I_{\text{hkl}}/I_{\text{r,hkl}}}{\frac{1}{n} \sum I_{\text{hkl}}/I_{\text{r,hkl}}} \quad [1]$$

In this expression, I_{hkl} and $I_{\text{r,hkl}}$ are integrated intensities from the (hkl) peak of oxide within the scale and of randomly oriented powder, and n is the number of peaks examined.

Results

Oxidation kinetics.—Typical oxidation curves are illustrated by the parabolic-type plots in Fig. 1. In this case, a nickel specimen was initially oxidized in air at 1473 K for 300s before altering the furnace temperature to 1098 K. Although this latter temperature was attained after 5.4 ks, the slope of the kinetic curve plotted in parabolic form continued to decrease and eventually reached a constant value after 30 ks from which the parabolic rate constant was determined. When the temperature was then changed over ~ 50 K ranges, parabolic oxidation behavior was established after 600–1800s from temperature stabilization.

Values of the parabolic oxidation rate constant obtained at specified temperatures are plotted vs. oxygen pressure in Fig. 2. This rate constant was proportional to $P_{\text{O}_2}^{1/n}$ where $n = 5.5, 5.8, 5.4, 6.3,$ and 6.2 at 1073, 1173, 1273, 1373, and 1473 K, respectively, within an estimated error of ± 0.2 .

Fig. 1. The parabolic oxidation of nickel in air at temperatures in the range 1098–1448 K. The specimen was preoxidized at 300s at 1498 K before altering temperature to 1098 K, followed by subsequent oxidation at 1098 K (a), 1148, 1198, 1248, and 1298 K (b), 1348 and 1398 K (c), and 1448 K (d).

Fig. 2. The dependence of the parabolic oxidation rate constants on oxygen pressure according to the relationship $k_p = k_p^0 (P_{\text{O}_2})^{1/n}$.

Arrhenius plots of the parabolic rate constants for oxidation of nickel in the various atmospheres are shown in Fig. 3. The activation energies calculated from the slopes of the least squares linear fits are given in Table II; an average value of 225 ± 4 kJ/mol NiO is estimated at constant oxygen pressure within $10^3 \leq P_{\text{O}_2} \leq 10^5$ Pa.

Oxide microstructure.—As illustrated in Fig. 4, a uniformly thick NiO layer was formed at 1473 K upon oxidizing nickel for 300s. One or two oxide grains extended

Table II. Activation energies for parabolic oxidation of nickel in various atmospheres

Atmosphere total pressure: 1 atm (1×10^5 Pa)	Temperature range (K)	Activation energy (J/mol NiO)
Oxygen	1073-1473	221,750
Air	1098-1500	223,840
O ₂ -Ar: $P_{O_2} = 2 \times 10^4$ Pa	1073-1473	228,030
O ₂ -Ar: $P_{O_2} = 4.6 \times 10^3$ Pa	1073-1473	223,840
O ₂ -Ar: $P_{O_2} = 10^3$ Pa	1073-1473	228,030

across this layer, and it exhibited a relatively flat outer surface. This scale morphology can be contrasted to that of the NiO layer formed when nickel was directly oxidized at the lower temperature of 1098 K for a long period of 155 ks as shown in Fig. 5. In this latter case, the small grains of $\sim 3 \mu\text{m}$ diam within the NiO layer were encased by oxide ridges, and they exhibited little preferred texture, as indicated by the values of P_{hkl} calculated for (111), (200), (220), and (311) planes, $0.9 < P_{hkl} < 1.1$, using Eq. [1].

A typical morphology of the oxide layers obtained after complete cycles of oxidation over several temperatures is shown in Fig. 6. The photomicrograph shown in Fig. 6a manifests the formation of a compact oxide layer having good adherence to the metal. The fracture cross section, Fig. 6a, illustrates formation of columnar NiO grains extending completely across the scale which are of smaller lateral dimension adjacent to the metal. The external surfaces of these grains, Fig. 6b, are flat even though the intersections of grain boundaries with the external surface were severely faceted. These fully developed scales exhibited a (100) preferred orientation texture as illustrated by the values of P_{hkl} recorded in Table III. The columnar grains in the scales exhibited little lateral growth during the oxidation cycles, as their average lateral diameter was $\sim 3 \mu\text{m}$ as measured along the midpoint line in the scale.

Marker measurements.—The oxidation run on the nickel specimen with markers was carried out in air according to the reaction sequence illustrated in Fig. 1, followed by a prolonged final oxidation state of 252 ks at 1448 K. Figure 7 illustrates the positions of two markers. The marker in Fig. 7a is located directly on the metal/oxide interface, and NiO internal precipitates exist beneath the marker. A thin layer of NiO was formed beneath the marker shown in Fig. 7b, but such markers re-

mained at positions tangent to the main metal/oxide interface. These markers were oxidized with indication of oxide precipitation within the marker matrix. Scale void population was high in the region around a marker and the scale tended to jut out from the marker.

Discussion and Conclusions

Values of the parabolic oxidation rate constant in oxygen atmospheres, $10^3 \leq P_{O_2} \leq 10^5$ Pa, were obtained at temperatures in the range 1073-1500 K by oxidizing nickel specimens isothermally in stages at several temperatures after brief preoxidation at 1473 K. This rate constant was proportional to $P_{O_2}^{1/n}$ where $5.5 \leq n \leq 6.2$, which is in agreement with the hypothesis that nickel migration

through NiO predominately by doubly charged cation vacancies determined the growth rate of this oxide layer (2-5). An average value of 22 kJ/mol for the activation energy of parabolic oxidation is of approximately the same magnitude, but 225 kJ/mol less than the most recent determination for the activation energy of nickel self-diffusion in single-crystal NiO (8).

The values obtained at different temperatures for the parabolic rate constant at $P_{O_2} = 10^5$ Pa are compared to those from the literature in Fig. 8. Fair agreement exists for all evaluations above 1273 K. The previously reported values at temperatures less than 1273 K are of larger mag-

Fig. 8. Arrhenius plots of parabolic oxidation constants at $P_{O_2} = 10^5$ Pa for NiO layer growth on polycrystalline, crystal faces, and pre-oxidized polycrystalline nickel. The numbers on plots are the references. The experimental determinations from Ref. (9) at 973 K are from direct observations of thickening of the NiO grain matrix.

nitude than those reported in this investigation and they yield Arrhenius plots of smaller slopes. In this lower temperature range extending down to 773 K, oxide growth has been interpreted as being controlled by nickel short-circuit diffusion involving easy diffusion paths in the polycrystalline NiO scales formed on nickel polycrystalline sheet or nickel single-crystal faces (2-5). These easy diffusion paths have been assumed to be largely associated with the oxide grain boundaries since these are decorated by a network of outward extending ridges at the external oxide surface when the metal is directly oxidized as illustrated in Fig. 5.

Arrhenius plots of the parabolic rate constants obtained under the condition of preoxidation were linear over the entire temperature range from 1073 to 1500 K, as shown in Fig. 3 and 8. This behavior arose because preoxidation at 1473 K led to formation of a thin oxide layer relatively free of easy diffusion paths. This layer thickened upon subsequent stages of oxidation at lower temperatures into scales containing large columnar oxide grains mainly by nickel lattice diffusion. These conclusions are also consistent with earlier optical measurements on the growth of individual large oxide grains in scales grown at 973 K (9) on polycrystalline nickel as illustrated in Fig. 8.

One can utilize the Wagner theory for parabolic oxidation based upon lattice ambipolar diffusion to quantitatively assess diffusional processes during nickel oxide layer growth. The parabolic rational rate constant (1) is

$$k_p \text{ (eq/cm}^2\text{-s)} = \bar{c} \int_{a'_0}^{a''_0} D \, d \ln a_0 \quad [2]$$

where \bar{c} is the average equivalent nickel concentration in NiO, D is the self-diffusion coefficient of nickel in NiO, and $a_0 = (P_{O_2})^{1/2} = \{P_{O_2} \text{ (Pa)} / 1.013 \times 10^5 \text{ (Pa)}\}^{1/2}$ is the oxygen activity integrated over the limits from the metal/oxide to oxide/oxygen interface. Since D conforms to a $P_{O_2}^{1/n}$ relationship where $4 \leq n \leq 6$ (15), Eq. [2] becomes

$$k_p \text{ (g O}^2\text{/cm}^4\text{-s)} = nD^0(P''_{O_2})^{1/n} \left(\frac{M_0 \rho_{NiO}}{M_{NiO}} \right)^2 [1 - (P'_{O_2}/P''_{O_2})^{1/n}] \quad [3]$$

Here, D^0 is the nickel self-diffusion coefficient at $P_{O_2} = 10^5$ Pa, M_0 and M_{NiO} are the atomic weight and formula weight of oxygen and NiO, respectively, and $\rho = 6.85$ g/cm³ is the density of NiO.

The tracer diffusion coefficient of nickel in NiO, D^* , was determined (14) recently at $P_{O_2} = 10^5$ Pa and at temperatures in the range 795-1673 K

$$D^* \text{ (cm}^2\text{/s)} = 2.2 \times 10^{-2} \exp - 246.9 \text{ kJ/RT} \quad [4]$$

Since the diffusion process is controlled by a vacancy mechanism, D^* is related to D by a correlation factor $D^* = fD$, where $f = 0.78$. At $P''_{O_2} = 1$, Eq. [3] becomes

$$k_p \text{ (g O}^2\text{/cm}^4\text{-s)} = 2.76nD^*[1 - (P'_{O_2})^{1/n}] \quad [5]$$

Based on Eq. [5], k_p values were calculated utilizing values of D^* (Eq. [4]) and $n = 6$ for doubly charged nickel vacancies, since $5.5 \leq n \leq 6.2$ from this investigation, and P'_{O_2} for equilibration of NiO with nickel (17). These calculated values are compared to the experimentally obtained values in Table IV and Fig. 8. These values are in fair

Table IV. A comparison of the measured and calculated values, Eq. [5], of the parabolic oxidation rate constants of preoxidized nickel in oxygen, $P_{O_2} = 10^5$ Pa, and over the temperature range 1073-1473 K

T (K)	Measured k_p (g ² /cm ⁴ -s)	Calculated k_p (g ² /cm ⁴ -s)	$\frac{k_p(\text{meas})}{k_p(\text{calc})}$
1473	$9.2 \pm 0.2 \times 10^{-10}$	5.7×10^{-10}	1.6
1373	2.3×10^{-10}	1.3×10^{-10}	1.8
1273	$5.0 \pm 0.3 \times 10^{-11}$	2.5×10^{-11}	2.0
1173	$8.2 \pm 0.2 \times 10^{-12}$	3.4×10^{-12}	2.4
1073	1.0×10^{-12}	3.2×10^{-13}	3.2

agreement, the measured values being two to three times larger than the theoretical values.

It would appear that the difference between the experimental and calculated values of the parabolic rate constant was not associated with oxide formation by inward diffusion of oxygen because its diffusion is at least two orders of magnitude less than that for nickel diffusion in NiO (18). Marker measurements, moreover, wherein the marker remains at the metal/oxide interface, indicate that the NiO layer grew predominantly by outward diffusion of nickel. Nickel and platinum are completely miscible and the platinum marker did not remain completely inert. Consequently, formation of internal oxide and a concaved oxide beneath the main metal/oxide interface and the markers, Fig. 7, was brought about by dissociation of NiO and inward oxygen migration through the marker. In similar reported marker experiments (11), NiO formed beneath a porous platinum film marker, but fine relatively inert Al_2O_3 powder markers remained at the Ni/NiO interface.

Since the NiO layer during growth was not completely free from easy diffusion paths such as dislocations, subgrain boundaries (sgb), and grain boundaries (gb), the nickel flux should be given in terms of an effective diffusion coefficient

$$D_{\text{eff}} = D + \sum D_i f_i \quad [6]$$

where D_i is a diffusion coefficient for an easy diffusion path and f_i is the fraction of diffusion sites in this path such that $\sum f_i \ll 1$. The comparison between experimental and calculated values of the parabolic oxidation rate constant, Table IV, demonstrates that $D_{\text{eff}}/D \sim 1.5$ -3.

One can readily demonstrate that preferential nickel diffusion via high angle boundaries characteristic of polycrystalline NiO did not play a role in growth of the columnar grained and textured scales. At 1073 K, $D = 2.8 \times 10^{-14}$ cm²/s (14) and $D_{\text{gb}} = 2 \times 10^{-9}$ cm²/s in polycrystalline NiO (16) where the width of the boundaries may be taken as 7×10^{-8} cm (16). The average diameter of the columnar NiO grains was ~ 3 μm . Thus, $D_{\text{gb}} f_{\text{gb}} = 2(2 \times 10^{-9})(7 \times 10^{-8})/(3 \times 10^{-4}) = 9 \times 10^{-13}$ cm²/s, which is 30 times larger, rather than two to three times larger, than D . Metallography, as shown in Fig. 4 and 6, also illustrated that the boundaries of the columnar grains in the preferentially (100)-textured scales did not exhibit evidence of ridges by enhanced oxide growth as did boundaries of grains in untextured oxide scales formed at 1098 K as shown in Fig. 5.

One therefore concludes that the grain boundaries in the textured columnar grained scale did not permit a rapid rate of nickel diffusion as exhibited by high angle boundaries in polycrystalline NiO. It would appear that any enhanced nickel diffusion by boundaries in the columnar scale is of the same magnitude as to be expected by dislocation arrays throughout the scale acting as

subgrain boundaries. Since $D_{\text{sgb}} = 6 \times 10^{-11}$ cm²/s at 1073 K (3, 14), $D_{\text{sgb}} f_{\text{sgb}} = 6 \times 10^{-14}$ cm²/s, yielding $D_{\text{eff}}/D = 2$ if each grain of ~ 3 μm diam is assumed to contain two subgrains. This latter consideration involving a small degree of short-circuit nickel diffusion by dislocation arrays at grain and subgrain boundaries is consistent with the findings that uniformly thick columnar grained (100)-textured scales grew on the preoxidized metal specimens.

Growth Mechanism of Silicon Plasma Anodic Nitridation

M. Hirayama, T. Matsukawa, H. Arima, Y. Ohno, and H. Nakata

Mitsubishi Electric Corporation, LSI Research and Development Laboratory, 4-1 Mizuhara, Itami, Hyogo 664, Japan

ABSTRACT

Nitridation of silicon was performed in a temperature range of 680°-920°C by 13.56 MHz RF oscillation in nitrogen-hydrogen plasma. Growth kinetics and activation energy of nitridation were investigated. The relationship between nitridation time (t) and nitrided film thickness (x_n) was found to be $x_n(2 - 0.00695V_{dc}) = 0.86 \times 10^{-6}t$. External dc voltage (V_{dc}) on plasma nitridation was effective in obtaining a high growth rate of nitrided film on silicon. Activation energy for the plasma anodic nitridation of silicon (0.25 eV) was twice as large as the value of plasma nitridation without an external dc voltage. The role of hydrogen in plasma nitridation was also studied with quadrupole mass spectroscopy.

Progress in MOS VLSI densification requires a large capacitance in a small capacitor area (1). Therefore, the direct nitridation of silicon may be one of the most attractive techniques for the device fabrication process. Compared with the widely used silicon dioxide film, silicon nitride film has a higher dielectric constant. The silicon nitride film is chemically stable and is also much better as a diffusion barrier for impurities and metals. In spite of these advantages, the silicon nitride film deposited on silicon wafers by LPCVD cannot be used for the gate dielectric film of MOSFET because it was interfacial instabilities between the silicon nitride and the silicon substrate. Many attempts at achieving direct nitridation and forming the silicon nitride film have already been made (2, 3). Ito *et al.* reported that uniform amorphous silicon nitride films could be obtained from the reaction of silicon in an ammonia ambient and applied to the LSI device fabrication (4). However, these films were very thin because of the slow diffusion of nitridant species through the nitrided film. To improve the low growth rate, plasma nitridation and plasma anodic nitridation were attempted. A high reaction rate was given by the plasma-excited reactive species compared with the thermal reaction. Plasma anodic nitridation was expected to give an enhanced growth rate, similar to that in the case of the anodic oxidation of silicon (5). Also, the reaction temperature could be decreased below the temperature of the thermodynamical limit because the plasma reaction forms reactive species.

In this paper, the growth mechanism of plasma anodic nitridation will be investigated. To prevent the contamination of oxygen and hydro-oxygen, we used highly purified hydrogen and nitrogen for our experiment.

Experimental

The vacuum system, gas sources, and experimental arrangements for achieving the plasma anodic nitridation of silicon are shown in Fig. 1. They are the same as those used in the earlier study (6). Nitrogen plasma was generated at a pressure range from 0.5 to 2.0 torr by an RF oscillator whose frequency was 13.56 MHz. Anodization voltage applied between the anode and the ground level was supplied by an external dc supply. The nitridation experiments were performed in a temperature range from 680° to 920°C. Boron-doped n-type (100)-oriented CZ silicon wafers, whose resistivity was about 10 Ω -cm, were used for the nitridation. To remove the native oxide on the silicon surface, hydrogen plasma was generated prior to the nitridation process under a pressure below 0.2 torr. The reaction chamber was first pumped down to less than 4×10^{-5} torr with a turbo molecular pump to minimize the residual gases. Then research-grade nitrogen and hydrogen were admitted to the reaction chamber. After the pressure became stable, glow discharge was initiated by applying RF power. The anodizing voltage applied to the sample was typically 150V. The nitridation time was varied between 10 min and 400 min.

In order to study the nitridation mechanism, quadrupole mass analysis of the reacting plasma in the chamber was performed. Transmission electron microscopy (TEM)

was carried out to examine the interface structure of silicon nitride and silicon. Also, characterization of the nitrided film was studied using Auger electron spectroscopy and infrared absorption.

Results and Discussion

Film composition.—The infrared absorption spectrum of Fig. 2 shows the characteristic absorption peak of nitride film at wave number of 865, 895 cm^{-1} . The wafer was nitrided at 920°C for 400 min with an external dc voltage of 150V. A peak at 610 cm^{-1} identified as the phonon absorption of the silicon substrate was observed, but no absorption interpreted as Si-O bonds was found in this spectrum. The 865 and 895 cm^{-1} peaks are due to the stretching vibration of Si-N bonds and seem to be almost the same as the peak described by Frieser (2). However, a peak at 920 cm^{-1} , higher than our measurement, results for Si-N bonds was reported by Ito *et al.* (4).

The chemical composition of films formed by plasma anodic nitridation was examined by Auger electron spectroscopy (AES). The AES analysis revealed the presence of nitrogen and oxygen at the surface of the nitrided samples. Since hydrogen is not detectable with Auger spectroscopy, the hydrogen content of these samples is not known. Carbon peaks were not observed from any AES spectra, so carbon atoms at the sample surface did not exist. Sputter etching was accomplished with a 1.0 keV argon ion to obtain in-depth profiles. A typical Auger spectrum of the plasma anodic nitridation film is shown in Fig. 3. The film was grown for 300 min in a nitrogen-hydrogen mixture with an external dc voltage of 150V. The N_{KLL} and O_{KLL} lines are clearly observed on this spectrum obtained from the surface of the nitrided film. From the results of infrared absorption and the Auger spectrum, it is concluded that the silicon surface was changed to silicon nitride by this plasma anodic nitridation.

Nitridation.—Figure 4 is a cross-sectional view of plasma-anodized silicon and the silicon dioxide boundary using a high resolution transmission electron microscope (TEM). It is observed that the thickness of the nitrided films on the silicon surface is almost the same as it is on the silicon dioxide surface. On the sidewall of the silicon dioxide, the film thickness is small. This nitridation behavior shows anisotropical growth resulting from plasma

Fig. 1. Schematic diagram of experimental apparatus for plasma anodic nitridation.

Fig. 2. Infrared transmission curve of nitrided silicon

Fig. 4. TEM micrograph of the nitrided film

reaction. The most remarkable point of this TEM photograph is the difference in the interface levels between the silicon-nitrided film and the original silicon-silicon dioxide film. This phenomenon is generally observed on the thermal oxidation of silicon. With the oxidation of silicon, the interface between silicon and silicon dioxide drops down into the bulk silicon, and the thickness ratio of the upper and lower parts of the oxidized film divided by the original silicon surface is generally about half and half. Therefore, in this nitridation experiment, it is supposed that the nitridant species also diffused into silicon and that the silicon surface is actually nitrided like the oxidation of silicon surface.

Growth kinetics.—Figure 5 illustrates the variation of growth rate with the dc power applied to the wafers. The RF power and the temperature were fixed at 500W and 900°C, respectively. The enhancement of the growth rate by the externally applied voltage (V_{dc}) is shown in this figure. It is obvious that the growth rate is remarkably enhanced by the application of the dc bias. The uniformity of the films grown in this system is quite good except in the upper area. For example, with a typical film about 17 nm thick, the standard deviation of the thickness was about 0.8 nm thick within the 4 in. wafer areas.

The dependence of the film thickness on the growth temperature is plotted against the inverse of nitridation temperature in Fig. 6. These lines were obtained from the samples under nitridation conditions listed in the insert.

The nitridation temperature dependences are indicated by the two pairs of parallel curves. From the straight lines shown as solid and dotted, one can obtain apparent activation energies of 0.12 and 0.25 eV, respectively.

Activation energies of the plasma nitridation with or without the external dc voltage indicate only a very weak temperature dependence in the range of 680°-920°C. The gradient difference of the curves is considered to be caused by the application of the external dc voltage on the nitridation. However, these activation energies are somewhat smaller than those reported by Murarka *et al.* for the thermal nitridation of silicon (7).

Next, we will discuss the kinetics of the plasma anodic nitridation of silicon and propose a theory for the anodization mechanisms of silicon. For this purpose, at first, we referred to the model of thermal oxidation of silicon.

In thermal oxidation, there are three basic steps theoretically established by Deal and Grove (8). These three steps are the transportation of oxidant gases, the diffusion of oxidant species in oxide film, and the reaction with the silicon surface. The theory consists of the flux correspondence to each step at each boundary and well explains the experimental results of thermal oxidation. The same analysis based on the solution of the continuity equation has been applied to thermal nitridation (9). It was concluded that the experimental results were adequately explained by the three step model.

Fig. 3. Typical Auger electron spectrum of plasma anodic nitrided film.

Fig. 5. Dependence of the film thickness on nitridation time

Fig. 6. Dependence of the film thickness on nitridation temperature

In the plasma anodic nitridation of a silicon surface, the growth rate constants and characteristic parameters of nitridation were deduced. When the nitridation time is long, the growth rate has an exact parabolic relationship for the plasma nitridation without the external dc voltage supply. The relationship between the nitridation time and the thickness of the growth film shown with open circles in Fig. 5 can be expressed in functional form as $x_n^2 = Bt$, where x_n and t are the silicon nitride thickness and nitridation time, respectively, and B is the temperature-dependent constant. In this relationship, the constant B is calculated as $0.86 \times 10^{-6} \mu\text{m}^2/\text{s}$.

The significant effect of an external dc voltage on nitridation growth kinetics was suggested by the experimental data. It is clear that the gradient of these curves increases as the external dc voltage increases, as shown in Fig. 5. The growth rate of nitride film on the silicon surface was accelerated with the positive dc voltage supplied on the silicon substrate. Therefore, the relationship between the nitridation time and the nitride film thickness is empirically described as $x_n(2 - mV_{dc}) = Bt$, where the constant m was given as 0.00695 V^{-1} .

The effect of the external dc voltage was investigated from the in-depth Auger profile of the nitrided film. Figure 7 shows a typical profile of the plasma anodic nitrided film. The film was grown for 400 min in a nitrogen-hydrogen mixture at an external dc voltage of +80V. The peak-to-peak heights of the N_{KLL} and O_{KLL} lines were plotted as a function of the sputtering time. The nitrogen and oxygen profiles are described with filled and open

Fig. 7. In-depth Auger profile of the nitrided silicon in nitrogen-hydrogen plasma with positive external voltage.

Fig. 8. In-depth Auger profile of the nitrided silicon in nitrogen-hydrogen plasma with negative external voltage.

circles, respectively, for both the samples loaded on the anode and the ground side of silicon carbide rods. The thickness of the films of the anodized sample loaded on the anode was almost twice that of the ground sample. The most interesting feature in Fig. 7 is that the tail of the nitrogen profile reaches deeply into the silicon substrate compared with that of the oxygen profile. Nitrogen apparently diffused into silicon more easily than oxygen, even though the nitridant species seems to diffuse slower through the nitride film in comparison to oxygen through the oxide. The nitrogen fraction is highest near the film surface and decreases toward the interface. It is also shown that the nitridant species has difficulty diffusing through the film and that the surface region is preferentially nitrided.

The effects of the anodization by the application of the external negative dc voltage were studied. The in-depth Auger profiles of nitrided films grown for 400 min in a nitrogen-hydrogen mixture plasma at an external dc voltage of -80V is shown in Fig. 8. Nitrogen profiles for both samples loaded on the cathode (the supplied voltage po-

larity was changed) and the ground show almost the same curve. Beside the oxygen profiles were drawn almost the same curve one above another for the external dc positive and negative voltages. There exists no difference of film thickness between the samples loaded on the cathode and the ground level.

Role of hydrogen content.—Nitridation using plasma anodization is considerably more complex, and, at present, we can only present a tentative description of the anodization mechanism. It has been previously suggested that the nitridation of silicon is generally subject to parabolic growth behavior. Analysis of growth behavior in plasma anodization indicates that nitridation is essentially a diffusion-limited process and, presumably, the nitridant species migrate to react with silicon at the interface. Figure 9 illustrates in-depth Auger profile of the film grown for 400 min in nitrogen only. The nitrogen profiles were shrunk abruptly for both samples loaded on the anode and the ground. However, the oxygen profiles fully broadened in the direction of the depth of the films. It is quite different from the former profiles of the nitrided film obtained in the hydrogen-nitrogen mixture plasma. The tail of the nitrogen profiles disappeared before the decline and fall of the oxygen profile for both samples loaded on the anode and the ground.
