

ALGORITHMS FOR MODELING THE RANDOM WAVELENGTH  
OF COMPTON  $\gamma$ -PARTICLE SCATTERING

O. S. Marenkov

The solution of  $\gamma$ -transport problems in matter by the Monte Carlo method involves multiple modeling of Compton scattering. As the energy characteristic of the quantum it is advisable to use the wavelength in Compton units  $\lambda$ , since all the formulas for the Compton process have the simplest and therefore the most economical form from the viewpoint of computer time expenditure.

As is known, the random wavelength  $\lambda_n$  of the  $n$ -fold scattered  $\gamma$ -particle is defined on the basis of the Klein-Nishina distribution. To calculate  $\lambda_n$  from given  $\lambda_{n-1}$  and  $\xi$  (random number) it is necessary to solve a transcendental equation, which is a very uneconomical operation even with the use of high speed computers. The approximation of the functional relation  $\lambda_n = f(\lambda_{n-1}, \xi)$  in bounded intervals of  $\lambda$  variation by certain uncomplicated formulas of the polynomial approximation type in  $\lambda_{n-1}$  and  $\xi$  is possible. However, it is clear that use of the exact techniques for calculating  $\lambda_n$  is advisable in order to improve the quality of the statistical simulation.

The exact economical algorithms of modeling  $\lambda_n$  are based on the use of the so-called random "rejection" or exclusion technique. The Kahn algorithm [1] and the algorithm based on the use of the very simple random exclusion technique (see, for example [1]) and realized in  $\alpha = \lambda^{-1}$  units in [2] are known.

We shall realize the second algorithm in  $\lambda$  units. To this end we must determine the absolute maximum of the probability density function on the argument variation interval. It can be shown that the maximal value of the Klein-Nishina probability density function

$$k(\lambda_{n-1}, \lambda_n) = \left(\frac{\lambda_{n-1}}{\lambda_n}\right)^2 \left[ \frac{\lambda_{n-1}}{\lambda_n} + \frac{\lambda_n}{\lambda_{n-1}} + 2(\lambda_{n-1} - \lambda_n) + (\lambda_{n-1} - \lambda_n)^2 \right]$$

on the interval  $\lambda_{n-1} \leq \lambda_n \leq \lambda_{n-1} + 2$  equals 2 and is reached for  $\lambda_n = \lambda_{n-1}$ . In this case the algorithm for modeling  $\lambda_n$  is:

a) we select two random numbers  $\xi_1$  and  $\xi_2$  and calculate

$$\Lambda_n = \lambda_{n-1} + 2\xi_1;$$

b) we check the inequality

$$2\xi_2 \leq k(\lambda_{n-1}, \Lambda_n)$$

If the inequality is satisfied, then  $\lambda_n = \Lambda_n$ . Otherwise  $\xi_1$  and  $\xi_2$  are rejected and the procedure is repeated with a new pair of random numbers.

It is of practical interest to compare the effectiveness of the Kahn algorithm (denoted I hereafter) and the above algorithm (denoted II hereafter) over a broad energy interval. This was accomplished directly on the computer with determination in the multiple Compton scattering process of the mean time  $t$  for degradation of the particle energy from the initial  $\xi_0$  to the final  $\varepsilon_{\min} = \varepsilon_m$ , i.e., we modeled only the "retardation" process and not the particle trajectory as a whole. We followed no less than 1000 such retardations for each set of  $\varepsilon_0$  and  $\varepsilon_m$ .

Following are the results of determination of the ratio  $\tau = t_I/t_{II}$  for the values  $\varepsilon_m = 0.02, 0.05, 0.13$  MeV as a function of the values of  $\varepsilon_0$ , MeV.

$\varepsilon_0 =$	10	8	6	4	3	2.6	2	1	( $\varepsilon_m = 0.02$ )
$\tau =$	0.79	0.93	0.95	0.96	0.97	1	1.05	1.12	
$\varepsilon_0 =$	0.8	0.6	0.4	0.2	0.1	0.03	0.06	0.94	( $\varepsilon_m = 0.02$ )
$\tau =$	1.17	1.19	1.22	1.32	1.35	1.37	1.33	1.40	
$\varepsilon_0 =$	10	8	6	4	3	2	1	0.8	( $\varepsilon_m = 0.05$ )
$\tau =$	0.61	0.62	0.64	0.66	0.72	0.75	0.83	0.90	
$\varepsilon_0 =$	0.6	0.5	0.4	0.32	0.2	0.1	0.08	0.06	( $\varepsilon_m = 0.05$ )
$\tau =$	0.92	0.95	0.97	1	1.07	1.17	1.30	1.37	
$\varepsilon_0 =$	10	8	6	4	3	2			( $\varepsilon_m = 0.13$ )
$\tau =$	0.34	0.61	0.45	0.47	0.52	0.57			
$\varepsilon_0 =$	1	0.8	0.6	0.4	0.3	0.2			( $\varepsilon_m = 0.13$ )
$\tau =$	0.62	0.69	0.75	0.86	0.89	0.93			

The economy of the algorithms I and II depends significantly on  $\varepsilon_0$  and  $\varepsilon_m$ . If  $\varepsilon_m \geq 13$  MeV, then for any  $\varepsilon_0$  algorithm I is more favorable than algorithm II ( $\tau \leq 1$ ). For each value  $\varepsilon_m < 0.13$  MeV there exists a value  $\varepsilon_0 = \varepsilon_{0e}$  for which both algorithms are equally economical ( $\tau = 1$ ). With increase of  $\varepsilon_m$  the value of  $\varepsilon_{0e}$  shifts in the direction of lower energies. In the case  $\varepsilon_0 \leq \varepsilon_{0e}$  it is necessary to use the algorithm II ( $\tau > 1$ ).

The data shown in the figure make it possible to find the value of  $\varepsilon_{0e}$  as a function of  $\varepsilon_m < 0.13$  MeV. It is obvious that in the case  $\varepsilon_0 > \varepsilon_{0e}$  sequential use of algorithms I and II respectively is advantageous, particularly for  $\varepsilon_0 \gg \varepsilon_{0e}$  and relatively smaller  $\varepsilon_m$ .
