# Simultaneous Determination of Phase Equilibria Compositions and Phase Molar Densities of Hydrocarbon + CO<sub>2</sub> Systems

## Maria A. Barrufet\* and Saifur Rahman

Department of Petroleum Engineering, Texas A&M University, College Station, Texas 77843-3116

This paper presents new phase equilibria compositions and density data for (1) a quaternary mixture of propane + pentane + octane +  $CO_2$  at temperatures from 310 K to 394 K and pressures from 3 MPa to 6.374 MPa. Additionally, liquid densities for a ternary mixture of propane + pentane + octane at four temperatures and gas  $CO_2$  densities are included for comparison with literature values. A single mixture load can be used to measure simultaneously phase equilibria compositions and densities at various pressures and temperatures. This can be accomplished using a uniquely designed pressure/volume/ temperature-vapor/liquid /liquid equilibrium apparatus (*PVT*-VLLE) connected to a uniquely designed system for infinitesimal sampling to a gas cromatograph (GC) at high pressures and temperatures. Carbon dioxide density compares well with the published data of Vargaftik and the predicted densities by DDMIX. Saturated liquid hydrocarbon densities are within 0.5% of the densities predicted by the modified Rackett equation. For liquid mixtures containing  $CO_2$ , the deviations from the Rackett equation are within  $\pm 1\%$ . Therefore we conclude that this methodology is suitable for determining volumetric and phase equilibria properties of multiphase systems with sufficient accuracy for most engineering applications.

## Introduction

Carbon dioxide—hydrocarbon systems frequently occur in the petroleum industry either in  $CO_2$  flooding for enhanced oil recovery or in downstream separation processes. Phase equilibria in these systems are complex and may involve three or more equilibrium phases (Reid and Robinson, 1981). In  $CO_2$  flooding processes,  $CO_2$  is injected through an injector well to displace oil within the reservoir to a producer well. In this process, mass transfer mechanisms cause multiphase separations including a vapor phase, a hydrocarbon-rich liquid phase, and occasionally a  $CO_2$ —rich liquid phase.

Numerous papers have investigated the phase behavior of  $CO_2$ /hydrocarbon systems. Among these are Orr and Silva (1983), Leu and Robinson (1987), Cheng *et al.* (1989), Weng and Lee (1992), and Barrufet *et al.* (1995, 1996a). Because the equipment needed to measure high-pressure, high-temperature phase equilibria is complex, experimental data are expensive and scarce.

## Materials

The *PVT*-VLLE system was charged with the propane + pentane + octane + carbon dioxide mixture prepared gravimetrically using a Mettler PM No. 600 Delta range electronic balance (accuracy  $\pm 0.01$  g). All hydrocarbons used were from Aldrich Chemical Co. with 99+% purity. The water content was less than 0.0005% and the evaporation residue less than 0.0003%. The CO<sub>2</sub> used was +99.99% purity.

#### **PVT-VLLE** Apparatus and Sampling System

A mercury-free Ruska *PVT* Model 2370 is connected to a Hewlett Packard 5880 gas chromatograph (GC) using a specially designed sampling system capable of measuring the compositions of all equilibrium phases on-line at pressures up to 27 MPa and temperatures up to 500 K. Digitally-operated valves are used for injection of very small fluid volumes  $(0.1-0.5 \ \mu L)$ ; each of these valves is

connected to a switching valve for back-flushing to eliminate column contamination and to separate columns for various phase composition analyses. Since the volumes used for analysis represent less than  $10^{-5}$ % of the sample volume, the mass withdrawn for analysis is negligible as well and does not disturb the equilibrium of the system. Thus, systematic errors are minimized. Figure 1 sketches the connection between the GC and the *PVT* system. The volume of the two *PVT* cells can be changed separately by computer-controlled stepping motors, and sample mobility within the system can be achieved at constant temperature and pressure. This allows the measurement of phase volumes by positioning the interface at a specific location in the sapphire, see-through window located at the top of cell. This setup has been explained in greater detail in our previous publications (Rahman and Barrufet, 1995; Barrufet et al., 1996b).

Measured volumes depend upon the dimensions of the cylinders, piston position, temperature, pressure, reference points, and magnet volume. The internal volumes for both cells and interconnecting tubing have been calibrated, including pressure and temperature correction coefficients (Ruska M2370, 1990). These volumes are entered into a computer code and accurate phase volumes can be measured by placing the phase boundary at a reference point in the sapphire window. The sample mixing in both cells is accomplished by stirring a magnetic coupling.

This system has been calibrated and validated by reproducing experimental three-phase equilibrium pressures and compositions for hexane + water systems (Tsnonopolous and Wilson, 1983), and for octane + water systems (Heidman *et al.*, 1985; Rahman and Barrufet, 1995; Rahman, 1996; Barrufet *et al.*, 1996b).

## **Measurement of Phase Compositions**

During this portion of the experiment, the valve at the top of the piston cell is opened. The oven is heated to the desired temperature and the fluids are allowed to expand and vaporize until equilibrium is achieved. The liquid phase is at the bottom of the pump cell and the rest of the

**Figure 1.** Schematics of the *PVT*-VLLE integrated experimental setup.

volume is occupied by the vapor phase. The fluid within the sampling loop is vapor and is analyzed for composition. After the vapor phase analysis, the piston of the pump cell is moved upward and the float piston cell is moved up simultaneously by removing hydraulic oil. Both pistons are moved with identical volumetric speed so that the overall volume of the system is constant and equilibrium is maintained. The process of fluid movement continues until the liquid phase reaches the sampling loop and can be sampled for compositional analysis. For this procedure to be successful, one must optimize the total amount of mixture charged in the cell to ensure that the volumes of the equilibrium phases are larger than the dead volume of the blind tubes (35 cm<sup>3</sup>) and small enough to cover a wide range of pressures and temperatures. This blind volume is indicated between points A and A' in Figure 1. This blind volume was obtained from previous calibrations (Rahman, 1996), and it is kept at the same temperature and pressure of main the PVT cell.

The variable volume cell and sampling features of our experimental setup make this methodology 4-7 times faster than the current methods for phase equilibria and density determinations.

The temperatures in these experiments are considered accurate to  $\pm 0.2$  K, whereas the pressures are accurate to  $\pm 0.005$  MPa. This uncertainty was obtained from earlier tests by comparing three-phase equilibrium pressures of binary systems of water + *n*-alkanes from the literature (Rahman, 1996). The compositions reported are the average of three measurements and the reproducibility of these is better than 0.03%. The estimated maximum uncertainty on the equilibrium ratios (*K* values) calculated from these compositions is  $\pm 1\%$ . The chromatographic techniques used were the ASTM (1989) simulation distillation (SIMDIS) procedures.

#### **Evaluation of Phase Fractions and Densities**

The material balance equations relating overall (or feed) compositions with phase compositions and molar phase fractions (i.e. vapor and liquid) are

$$z_i = x_i f_1 + y_i f_v$$
  $i = 1, n$  (1)

$$f_{\rm l} + f_{\rm v} = 1 \tag{2}$$

where  $z_i$ ,  $x_i$ , and  $y_i$ , are the experimentally measured feed, hydrocarbon liquid, and vapor molar phase compositions

respectively, *n* is the number of components and  $f_1$  and  $f_v$  are the liquid and vapor phase fractions, respectively.

Placing eq 2 into eq 1, a four-component mixture exhibiting two-phase equilibria provides four different equations that could be used to determine the phase fractions. Due to experimental errors, these will likely provide different values for the phase fractions even with carefully prepared experiments. If the experiments were error free, one could select any equation to solve for the phase fraction. We used a least squares procedure and a self-correcting algorithm to provide consistent phase fractions.

Phase densities are evaluated from the measured phase volumes, overall mass charged into the system, and the

Figure 2. Carbon dioxide percent relative density differences from DDMIX (Ely, 1989).

phase fractions obtained from material balance as follows.

$$\rho_{\rm v}/{\rm g}\cdot{\rm cm}^{-3} = \frac{f_{\rm v}n_{\rm t}/{\rm mol}\sum_{i=1}^{n}y_iM_{\rm w}/{\rm g}\cdot{\rm mol}^{-1}}{V_{\rm v}/{\rm cm}^3} \tag{3}$$

Densities of pure  $CO_2$  were measured from the mass charged into the system and the volumetric measurements. Table 1 reports the measured densities for  $CO_2$  in this work. Figure 2 shows a percent relative difference plot of these densities from the values estimated by DDMIX (Ely, 1989). It can be observed that all were within  $\pm 0.8\%$  in the average. If Vargaftik (1975) values are used as a comparison, these deviations are about  $\pm 0.5\%$ .

To further test the procedure, we measured liquid densities for a ternary hydrocarbon mixture slightly above its bubble-point pressures. Saturated hydrocarbon liquid densities are well predicted from the modified Rackett equation (Spencer and Adler 1978), so we compared our measurements with those predicted from this equation. Table 2 shows the composition used for this mixture, the liquid densities measured and predicted from the Rackett equation, and the percent deviation from this equation, which were all within  $\pm 0.5\%$ .

Preliminary calibrations of this system with propane indicated that measured liquid densities were within  $\pm 0.5\%$  of those obtained by Thomas and Harrison (1982). Additionally, DDMIX (Ely, 1989) was used to verify these densities. We did not use DDMIX in this work because our mixtures contained octane, and the highest hydrocarbon component number in DDMIX data base is heptane.

Phase equilibrium compositions measured for the quaternary system are listed in Table 3. The estimated uncertainty in the measurements is considered better than

Table 4. Experimental Vapor and Liquid Densities for a Carbon Dioxide (1) + Propane (2) + Pentane (3) + Octane (4) System (Liquid and Vapor Compositions from Table 3; Predicted Liquid Density ( $\rho_{1p}$ ) from the Rackett Equation)

1% in compositions, and Table 4 shows the densities calculated for this system from material balance and volumetric measurements, as indicated in eq 3. Since liquid and gas compositions are measured simultaneously, equilibrium ratios can be calculated as the ratio of vapor and liquid mole fractions of component.

#### Conclusions

We measured simultaneously volumetric and phase equilibria data using a uniquely designed apparatus. We provide new phase equilibria compositions and phase density data for (1) a quaternary mixture of  $CO_2$  + propane + pentane + octane, (2) liquid densities for a mixture of propane + pentane + octane, and (3) gas  $CO_2$  densities as calibration data. These and previous calibration tests compare well with literature values. Because of the online infinitesimal and variable volume cell features, more and faster measurements can be made, using a single charge, than using conventional *PVT*-VLLE measurements. The data obtained are considered of enough accuracy for most engineering applications.
