#### Abstract

The acid dissociation constants, $\mathrm{pK}_{\mathrm{a}}$, of twelve biol ogi cally active 6 -phenyl-4,5-dihydro-3(2H)-pyridazinone derivatives were determined using spectroscopic techniques. Elucidation of the structure-reactivity relationships was attempted from structural considerations based on the acid dissociation constants.

## Introduction

It is well-known that biological processes are based on chemical reactions. The main factors of life such as providing energy, transmission of pulses, metabolism, and transfer of genetic information are all chemical reactions in which heteroaromatic molecules take part. Therefore, knowledge about the structure of heteroaromatic molecules is invaluable in understanding their reactivity. The acid dissociation constants have been used in various areas of research, such as stereochemical and conformational structure determinations, ${ }^{1,2}$ the directions of nucleophilic and electrophilic attack, the stabilities of intermediates, the size of activation energies in organic reactions, ${ }^{3}$ and determination of the active centers of enzymes in biochemistry. ${ }^{4}$

In the present work we report on the acid-base behavior of some 6 -phenyl-4,5-dihydro-3(2H)-pyridazinone derivatives with potential antihypertensive effects. ${ }^{5-8}$ The acid dissociation constants, $\mathrm{pK}_{\mathrm{a}}$, were determined by means of the UV technique. The results were used to interpret the structure-reactivity relations.

## Experimental Section

Reagents. The studied compounds weresynthesized and reported elsewhere. ${ }^{9}$ Sulfuric acid, nitric acid, and sodium hydroxide were all Analar grade reagents and were not purified further. The weight percentage acidities were checked with a densitometer for sulfuric acid solutions lower than $90 \%$. For higher percentages, they were titrated with a 0.1 N sodium hydroxide solution using methyl orange/xylene cyanol as the indicator. The buffer solution was prepared using Analar hydrochloric, boric, and acetic acids, a standard 0.1 N sodium hydroxide solution, and potassium dihydrogen phosphate.

Determinations of Acidity Constants. Spectrometry is an ideal method when a substance is not soluble enough for potentiometry or when its $\mathrm{pK}_{\mathrm{a}}$ value is particularly low or high ${ }^{10,11}$ (e.g. less than 2 or more than 11). The method depends on the direct determination of the ratio of the molecular species, that is, the neutral molecules to the

[^0]corresponding ionized species in a series of nonabsorbing buffer solutions where pH values are either known or measured. To provide a series of solutions in highly acid and highly basic regions, the acidity functions $\mathrm{H}_{0}$ and $\mathrm{H}_{-}$ were used. ${ }^{12}$ In strong acid solutions in which the ionic strength is high, the proton-donating ability of the medium is no longer measured by the concentration of hydrogen ions, since the molar activity coefficients of the ions in the solution are not unity. As a measure of the acidity degree to which a weak organic base is protonated, Hammett and Deyrup established the $\mathrm{H}_{0}$ acidity scale. ${ }^{13}$ This scale was improved by J orgensen and Harterr ${ }^{14}$ and then J ohnson, Katritzky, and Shapiro. ${ }^{15}$ F or a weak base B which ionizes by simple proton addition, we have
$$
\mathrm{BH}^{+} \rightleftharpoons \mathrm{B}+\mathrm{H}^{+}
$$
that is
\[

$$
\begin{equation*}
\mathrm{K}_{\mathrm{a}}=\frac{[\mathrm{B}]\left[\mathrm{H}^{+}\right]}{\left[\mathrm{BH} \mathrm{H}^{+}\right]} \frac{\gamma_{\mathrm{B}} \gamma_{\mathrm{H}^{+}}}{\gamma_{\mathrm{BH}}+}=\frac{[\mathrm{B}]}{[\mathrm{BH}]} \frac{\gamma_{\mathrm{B}} \gamma_{\mathrm{H}^{+}}}{\gamma_{\mathrm{BH}}++} \tag{1}
\end{equation*}
$$

\]

Therefore,

$$
\begin{equation*}
\mathrm{pK}_{\mathrm{a}}=\frac{\left[\mathrm{BH}^{+}\right]}{[\mathrm{B}]}+\mathrm{H}_{\mathrm{x}} \tag{2}
\end{equation*}
$$

where $H_{x}$ is an acidity function. The $H_{0}$ scale is defined such that, for the uncharged primary aniline indicators used, the plot of $\log \mathrm{I}$ (i.e. $\log \left(\left[\mathrm{BH}^{+}\right] /[\mathrm{B}]\right)$ ) against $\mathrm{H}_{0}$ has unit slope. It was observed from work on bases other than the Hammett type that the slopes of the plots of $\log$ I against $-\mathrm{H}_{0}$, donated by m , were not always unity. Thus, series of structually similar bases, like triarylmethanols, ${ }^{16}$ primary amides, ${ }^{17,18}$ and tertiary aromatic amines ${ }^{19}$ defined individual acidity functions, $\mathrm{H}_{\mathrm{R}}, \mathrm{H}_{\mathrm{A}}$, and $\mathrm{H}_{0}{ }^{\prime \prime}$, which have a linear relationship to $\mathrm{H}_{0}$ with m values of 2.0, 0.6 , and 1.3, respectively. Yates proposed that any acidity function $\mathrm{H}_{\mathrm{x}}$ would be proportional to $\mathrm{H}_{0}$ over the entire acidity range, that is $\mathrm{H}_{\mathrm{x}}=\mathrm{mH}_{0}$, with a common point $\mathrm{H}_{0}$ $=0 .{ }^{20}$
Therefore, an experimental plot of $\log \mathrm{I}$ against $\mathrm{H}_{0}$ does not yield the $\mathrm{pK}_{\mathrm{a}}$ at $\log \mathrm{I}=0$, unless it is a Hammett base, but rather the $\mathrm{H}_{0}$ at half protonation ( $\mathrm{H}_{0}{ }^{1 / 2}$ ). The general

Table 1. Nomenclature of the Studied Compounds (1-12)

| 12 | 2-methyl-6-(4-bromophenyl)- 4,5-di hydro-3(2H)-pyridazinone | $\mathrm{CH}_{3}$ | H | Br |

eq 3 may therefore be applied.

$$
\begin{equation*}
\log \mathrm{I}=\mathrm{m} \cdot\left(\mathrm{H}_{0}^{1 / 2}-\mathrm{H}_{0}\right) \tag{3}
\end{equation*}
$$

It follows that

$$
\begin{equation*}
\mathrm{pK}_{\mathrm{a}}=\mathrm{mH}_{0}^{1 / 2} \tag{4}
\end{equation*}
$$

Generally, those bases for which m lies roughly between 0.85 and 1.15 are called "Hammett Bases" and $m$ is taken as unity. Therefore, its important to measure $m$ as well as $\mathrm{H}_{0}{ }^{1 / 2}$ for each base studied.

It is evident that yet other acidity functions could exist at the extreme alkaline edge of the pH range, namely, above pH 14 , for measuring the $\mathrm{pK}_{\mathrm{a}}$ values of weak acids and strong bases, the former with an $\mathrm{H}_{-}$scale and the latter with an $\mathrm{H}_{0}$ scale. This is a more difficult region of pH than the acidic strength dealt with in the foregoing, insofar as the glass electrode becomes increasingly inaccurate and strong $\mathrm{OH}^{-}$absorption swamps the reading. It is well established that the basic properties of aqueous alkalies increase in nonlinear fashion, with concentration. ${ }^{21}$ The use of $\mathrm{H}_{-}$in highly alkaline solution was described in the literature. ${ }^{22,23}$ The sigmoid curve approach (see below) should be carried out carefully in this region to make sure that the function being used is a relevant one. Any discussion about the acid dissociation constants in this region should be done by taking the half protonation values rather than the $\mathrm{pK}_{\mathrm{a}}$ values.

The calculation of half protonation values (i.e. $\mathrm{H}^{1 / 2}$ ) was carried out as follows: the sigmoid curve of optical density against $\mathrm{pH}, \mathrm{H}_{0}$, and $\mathrm{H}_{-}$at the analytical wavel ength (OD, $\lambda$ ) was first obtained. The optical densities of the fully protonated $\left(O D_{\mathrm{ca}}\right)$ and nonprotonated compounds $\left(\mathrm{OD}_{\mathrm{fb}}\right)$ were then calculated by linear extrapolation of the arms of the curve. The ionization ratio was given by eq 5 , where the $\mathrm{OD}_{\text {obs }}$ is the measured optical density of the solution at the analytical wavelength

$$
\begin{array}{r}
\mathrm{I}=\left[\mathrm{BH}^{+}\right] /[\mathrm{B}]=\left(\mathrm{OD}_{\mathrm{obs}}-\mathrm{OD}_{\mathrm{fb}}\right) /\left(\mathrm{OD}_{\mathrm{ca}}-\mathrm{OD}_{\mathrm{obs}}\right)= \\
\left(\epsilon_{\mathrm{obs}}-\epsilon_{\mathrm{fb}}\right) /\left(\epsilon_{\mathrm{ca}}-\epsilon_{\mathrm{obs}}\right) \tag{5}
\end{array}
$$

The linear plot of log I against $\mathrm{pH}, \mathrm{H}_{0}$ or $\mathrm{H}_{-}$, using $-1.0<$ $\log \mathrm{l}$ < 1.0, had slope m , yielding half protonation values $H^{1 / 2}$ at $\log I=0$, as defined in eq 3 . The multiplication of the slope m with the half protonation value gives the $\mathrm{pK}_{\mathrm{a}}$ values, as show in eq 4. At high acidity $\left(-\mathrm{H}_{0}>3\right)$, the values of Shapiro ${ }^{15}$ were used; in the region $3>-\mathrm{H}_{0}<3$, the values of Bascombe and Bell ${ }^{24}$ were used. Typical determinations of $\mathrm{H}^{1 / 2}$ and $\mathrm{pK}_{a}$ values were given in Figures 1 and 2.

Figure 1. Sigmoid curve of $\epsilon_{\max } \mathrm{Vs} \mathrm{pH}$ for the $\mathrm{pK}_{\mathrm{a}}$ determination of 6-(4-bromophenyl)- 4,5-dihydro-3(2H)-pyridazinone.

## Results and Discussion

The structures of studied molecules indi cate that thefirst six molecules (1-6) have one proton-loss and two protongain centers whereas the $\mathrm{N}-\mathrm{Me}$ derivatives ( $\mathbf{7 - 1 2 \text { ) nor- }}$ mally should have only two proton-gain centers and no deprotonation center (Table 1; Figure 3). The obtained results, however, indicated that the model compounds (712) also have deprotonation centers, most probably the hydrogen atoms to the carbonyl groups, which are acidic enough to be removed in basic media (Table 2; Scheme 1). Presumably the driving force to form structure caccording to the above suggested mechanism (Scheme 1) is to gain more conjugation. In the case of the parent compounds (16), however, there is a possibility of $\mathrm{N}-\mathrm{H}$ proton loss (Scheme2). The latter possibility is rather stronger because

## Scheme 1. Possible Mechanism for Deprotonation of the Studied Compounds (1-12)

$\mathrm{R}=\mathrm{H}$ (for parent compounds, 1-6) ; $\mathrm{CH}_{3}$ (for model molecules compounds, 7-12)
$\mathrm{X}=\mathrm{H}, \mathrm{CH}_{3}, \mathrm{OCH}_{3}, \mathrm{Cl}, \mathrm{Br} \quad \mathrm{Y}=\mathrm{Cl}$
the resultant molecule $\mathbf{f}$ has more conjugation than molecule c.

We can arrange the parent molecules (1-6) in order of increasing acidity or decreasing basicity strength by taking into account the proton-loss half protonation values as follows:

$$
\begin{aligned}
& \mathrm{H}^{1 / 2} \text { (deprot) } 15.23>14.35>14.20>13.79>13.67>13.29 \\
& \text { compd } \underset{-\mathrm{MeO}}{\mathbf{3}}>\underset{-\mathrm{H}}{\mathbf{1}}>\underset{-\mathrm{Me}}{\mathbf{2}}>\underset{-\mathrm{Br}}{\mathbf{6}}>{ }_{-\mathrm{Cl}, \mathrm{Cl}}^{\mathbf{5}}>{ }_{-\mathrm{Cl}}^{\mathbf{4}} \\
& \text { decreasing basicity or increasing acidity } \rightarrow \\
& \leftarrow \text { increasing basicity or decreasing acidity }
\end{aligned}
$$

Since the concept of slope (see Experimental Section) is rather unreliable in basic solutions, we have concentrated our discussion on the half protonation values for protonloss processes.

It seems that the MeO group in the para-position of the phenyl ring makes compound 3 the least acidic or the most basic one within the series by providing electrons to the pyridazine ring mesomerically and keeping the proton more firmly. However, p-Me cannot do the same because of the weak inductive effect in compound 2 whereas, in compounds 4-6, the halogens pull electrons from the ring inductively and keep the protons less firmly. Observation of a different trend of acidic and/or basic strengths for the model molecules 7-12 could indicate different deprotonation mechanisms between the parent molecules 1-6 and their $\mathrm{N}-\mathrm{CH}_{3}$ derivatives (i.e. fixed models) 7-12.

## Scheme 2. Possible Mechanism for Deprotonation of the Parent Compounds (1-6)

d

f
$\mathrm{R}=\mathrm{H}$ (for parent compounds, 1-6) ; $\mathrm{CH}_{3}$ (for model molecules compounds, 7-12)
$\mathrm{X}=\mathrm{H}, \mathrm{CH}_{3}, \mathrm{OCH}_{3}, \mathrm{Cl}, \mathrm{Br} \quad \mathrm{Y}=\mathrm{Cl}$
A dissimilar trend of acidic and/or basic strengths for the model molecules 7-12, however, was observed, as shown below:

$$
\begin{array}{ccccc}
\mathrm{H}^{1 / 2} \text { (deprot) } 16.67>14.24>14.08>14.05>13.73>13.60 \\
\text { compd } & \mathbf{8}>\mathbf{9}>\mathbf{7}>\mathbf{1 1}>12>1 \mathbf{1 0} \\
-\mathrm{H}-\mathrm{MeO}-\mathrm{Me}-\mathrm{Br}-\mathrm{Cl}, \mathrm{Cl} & -\mathrm{Cl} \\
& \text { decreasing basicity or increasing acidity } \rightarrow
\end{array}
$$

It seems that the MeO group in the para-position of the phenyl ring cannot make compound 9 the least acidic or the most basic one within this. This phenomenon led us to conclude that there are two different deprotonation pathways for the parent molecule 3 (i.e. most probably $\mathrm{N}-\mathrm{H}$ deprotonation) and its model molecule 9 (i.e. have to be removal of the $\alpha$-carbonyl proton) and that the mesomeric electron donating effect of the MeO group is not effective here. The $\mathrm{N}-\mathrm{Me}$ group in compound 9 is also partly responsible for this basicity increase. The $\mathrm{N}-\mathrm{Me}$ group in compound 8 makes this compound less acidic than compound 2, as expected. In compounds 10-12 the halogens pull electrons inductively and decrease the basicity, as expected.

The data of acid dissociation constants for the studied compounds 1-12 for the first and second proton-gain processes are presented in Table 3. The slopes of the log I versus $\mathrm{pH}\left(\mathrm{H}_{0}\right)$ graphs for the first proton-gain of compound $\mathbf{1}$ and its model compound $\mathbf{7}$, in which the proton migration

[^1] for $\log \mathrm{I}$ versus pH (or $\mathrm{H}_{0}$ ) graphs.
is eliminated by replacing the mobile N -hydrogen atom with the N -methyl group, were found to be 1.03 and 1.86, respectively (Table 3). Since the values of the slopes of log I versus $\mathrm{pH}\left(\mathrm{H}_{0}\right)$ graphs are indicative of the protonation mechanism, it seems that compounds $\mathbf{1}$ and $\mathbf{7}$ are protonating by different mechanisms; in another words, originally they were not in the same tautomeric form, since the tautomeric form of compound $\mathbf{7}$ is fixed as the keto form 7a while compound $\mathbf{1}$ is most probably in the enol form 1b. The slope of 1.03 , indicating pyridine type protonation, favors tautomeric form b. F urthermore, we can claim that the first protonation in molecule $\mathbf{1}$ takes place at the 2 N position because of the mesomeric effect of the hydroxy group located at 3C of the pyridazine ring (Figure 2). For compound 7, however, we can suggest a proton attack on the carbonyl oxygen with a subsequent rearrangement into tautomeric form 7c by a positive charge transfer to 1 N , as suggested in in the literature, vide infra. ${ }^{25}$ In fact, the slope
of the log I versus pH $\left(\mathrm{H}_{0}\right)$ graph for the second protonation of compound $\mathbf{7}$ to $\mathbf{7 d}$ was found to be 0.79 , and this value, within experimental error, falls into the carbonyl (oxo) protonation range, whereas the value of 1.86 for the first pronation indicates amide type protonation. This point is also supported by theoretical studies. ${ }^{9}$ On the other hand, the slope of the $\log \mathrm{I}$ versus $\mathrm{H}_{0}$ graph (i.e. 0.99 ) for the second protonation for compound 1 suggests the 1 N protonation is in a fashion to keep the two positive charges away from each other, and that point has also been confirmed theoretically. ${ }^{9}$
The very same trend of the first protonation seems to be applicable for the parent molecules $\mathbf{2}$ and $\mathbf{4}$ and for the model molecules 7, 8, 9, and 11. For the rest of the molecules, protonation seems to take place at a pyridine type of nitrogen via tautomeric rearrangements (i.e. slopes of around 2), as indicated in the literature as unusual protonation behaviors of pyridazin-3-ones. ${ }^{25}$ The trend of

substituent effects seems better displayed for the second protonation rather than the first protonation of the parent molecules. Compound $\mathbf{3}$ was found to be the most basic one within the series because of the mesomeric electron donating effect of the $\mathrm{p}-\mathrm{OCH}_{3}$ group, but compound 5 was found to be the least basic, as expected, because of the inductive electron withdrawing effects of $\mathrm{p}-\mathrm{Cl}$ and $\mathrm{m}-\mathrm{Cl}$ atoms. The weaker inductive electron donor $\mathrm{p}-\mathrm{CH}_{3}$ group makes molecule $\mathbf{2}$ less basic than molecule $\mathbf{3}$ whereas it makes it more basic than molecules $\mathbf{1 , 6}, \mathbf{4}$, and $\mathbf{5}$, as expected. All these points explain that the second protonations occur in a way that the substituents are included in the conjugation of the whole system and that the mechanism of protonation is different from that of the first protonation, which takes place probably at a center which is not included in the conjugation.
