

# Liquid–Solid Phase Equilibria and Thermodynamic Modeling for Binary Organic Carbonates

Michael S. Ding\*

Army Research Laboratory, 2800 Powder Mill Road, Adelphi, Maryland 20783

Temperature–composition values of liquid–solid equilibrium were measured calorimetrically and tabulated for 10 binary solutions of these 5 organic carbonates: ethylene carbonate, propylene carbonate, dimethyl carbonate, ethyl methyl carbonate, and diethyl carbonate. Further, heat capacity ( $C_p$ ) and temperature ( $T_m$ ) and enthalpy ( $\Delta_{\text{fus}}H$ ) of fusion were measured for the five carbonates, with the  $C_p$  values fitted with polynomial functions. Based on these  $T_m$  and  $\Delta_{\text{fus}}H$  values and polynomial functions of  $C_p$ , the binary phase diagrams were fitted with thermodynamic nonideal solution models for an evaluation of the model parameters. The results of the evaluation were tabulated and discussed as an indication of the nature and strength of the molecular interactions between different carbonates. These interactions were shown to determine many of the important features of the binary phase diagrams.

## Introduction

Organic carbonates have long been considered as the most suitable solvents for electrolytes of lithium-ion batteries due to their exceptional chemical stability and other favorable physicochemical properties.<sup>1,2</sup> Of critical importance among the latter is the lower-temperature boundary of the liquid range of a carbonate, which places a limit on the low-temperature operation of the battery in which it serves as the electrolyte solvent. This boundary is the melting point for a pure carbonate and the liquidus temperature for a carbonate mixture. Owing to the significant lowering of the melting point of a carbonate when mixed with a second one, in addition to other favorable changes in properties, liquid–solid phase diagrams have been experimentally mapped and published in graphical form for all the binary combinations of these five common carbonates: ethylene carbonate (EC), propylene carbonate (PC), dimethyl carbonate (DMC), ethyl methyl carbonate (EMC), and diethyl carbonate (DEC), of which EC and PC are cyclic in molecular structure and DMC, EMC, and DEC are linear.<sup>3–5</sup> Subsequently, these measured phase diagrams have been thermodynamically modeled, first qualitatively with a regular solution model for the purpose of understanding the underlying molecular mechanisms,<sup>6</sup> and then quantitatively with a nonregular solution model for the purpose of predicting a ternary phase diagram of EC + PC + DMC.<sup>7</sup>

The aim of this work is first to tabulate the numerical values of temperature–composition for the phase diagrams of the 10 binary carbonates that have only been published graphically. These values comprise those measured anew and those measured in the previous studies.<sup>3,4</sup> It is second to list the temperature and enthalpy of fusion and the heat capacity in functional form for the five carbonate components. It is third to describe thermodynamic modeling of the binary phase diagrams in which parametrized nonideal solution models were optimized against the measured temperature–composition values, to tabulate the resulting parameter values, and to briefly discuss the molecular

mechanisms for some observed trends in the phase diagrams in terms of the evaluated model parameters.

## Experimental Section

### *Experimental Determination of Phase Diagrams.*

The 10 binary phase diagrams of the 5 carbonates EC, PC, DMC, EMC, and DEC have previously been determined using a differential scanning calorimeter (DSC 7 by Perkin-Elmer).<sup>3,4</sup> However, in light of a successful determination in a more recent work of the eutectic temperatures of PC + EC and PC + DEC binaries with very PC-rich samples,<sup>8,9</sup> the eutectic temperatures of PC + DMC and PC + EMC binaries and the solubility curves of EC, EMC, and DEC in PC were similarly determined in this work. These extended solubility curves, in combination with the accurately determined eutectic points, allow the eutectic compositions to be accurately determined. The addition of these solubility curves and eutectic points to the experimental data set for the thermodynamic fitting greatly improved the quality of the model parameters thus evaluated in this study.

The additional determinations were carried out on samples of carbonates the source and the preparation of which were the same as in a previous work.<sup>8</sup> Measurement of liquidus and eutectic temperatures was carried out using a modulated differential scanning calorimeter (MDSC 2920 by TA Instruments). Liquid nitrogen was used for cooling the sample stage, and the sample was sealed in a pair of aluminum pan and lid (0219-0062 by Perkin-Elmer). For the actual determination of the characteristic temperatures, a sample was first made to crystallize by cooling it to a temperature well below its eutectic point and then heated at a rate of 2 K min<sup>-1</sup> without modulation through its eutectic and liquidus temperatures. For the pure solvents, the melting point was determined as the onset of the heat absorption due to the melting, and the enthalpy of fusion by integrating the absorption peak against baseline. For the solvent mixtures, the eutectic point was determined as the onset of the heat absorption at the solidus transition and the liquidus temperature at the peak point at the liquidus transition. The uncertainty was

estimated to be 0.5 K in the measurement of eutectic (or solidus) and melting temperatures and 1 K in the measurement of liquidus temperature.

#### Experimental Determination of Heat Capacities.

Heat capacities,  $C_p$ , of the carbonates were determined on the MDSC with samples crimp-sealed in a pair of aluminum pan and lid.<sup>8</sup> For a measurement, a sample was first equilibrated at 173 K and then heated at 1 K min<sup>-1</sup> to 323 K with a modulation of 0.5 K amplitude and 60 s period. The temperature range was such that the lower limit was below the lowest eutectic temperature of the binary phase diagrams and the upper limit was above the highest melting point of the carbonate components. For calibration, a piece of Al<sub>2</sub>O<sub>3</sub> crystal disk of 21.8 mg was measured in the same temperature range under the same conditions. This  $C_p$  curve, together with the standard values published,<sup>10</sup> was used to correct the  $C_p$  values of the carbonate samples at different temperatures. These corrected values were further fitted with polynomial functions for use in the thermodynamic fitting of binary phase diagrams.

#### Computational Optimization of Thermodynamic Models.

Programs for fitting the measured phase diagrams with thermodynamic nonideal solution models were written in Mathematica 4 (Wolfram Research) and run on a Pentium 4 personal computer. The models contained up to three fitting parameters in the expression for the excess Gibbs energy of mixing. The target function to be minimized was the sum of the squared differences between the measured solvent compositions and the modeled ones for different temperatures. Equal weight was given to each measured point except those lying on the solidus line for the PC-containing binaries, to which more weight was given due to the high consistency in the measurement of these points and to the difficulty of obtaining more points at less PC-rich compositions due to the strong resistance of PC to crystallization.<sup>3</sup>

## Results and Discussion

**Liquid–Solid Phase Equilibria for Binary Carbonates.** Temperature–composition values measured at liquid–solid equilibrium for the 10 binary carbonates are listed in Table 1 for those binaries with DMC as a component that exhibited a measurable solid–solid phase transition and in Table 2 for the rest of the binaries. They are also graphically plotted in Figure 1 together with the associated phase lines resulting from the thermodynamic modeling to show the general features of the phase diagrams and the closeness of the fit. It can be seen that although vastly different in detail, the phase diagrams of all the carbonates are of the simple eutectic type, showing them to be completely soluble in one another in the liquid state but insoluble in the solid state. It can also be seen, in a comparison of the phase diagrams containing EC as the common component as plotted in Figure 2a, that the lower-temperature liquid boundary shifts upward in the order of DMC, EMC, and DEC, contrary to the trend in the melting points of these linear carbonates. This observation was quite counterintuitive and thus significant in pointing out the right direction to the formulation of carbonate mixtures for low-temperature application.<sup>4</sup> It can also be observed, as exemplified by the phase diagrams of those binaries having DMC as the common component as plotted in Figure 2b, that a cyclic carbonate dissolves another cyclic more readily than another linear, and vice versa. These observations are manifestations of a higher degree of molecular compatibility between carbonates of the same cyclicity than of the opposite and, in the case of EC with the linear carbonates, of this molecular compatibility diminishing from DMC to EMC to DEC.<sup>6</sup>

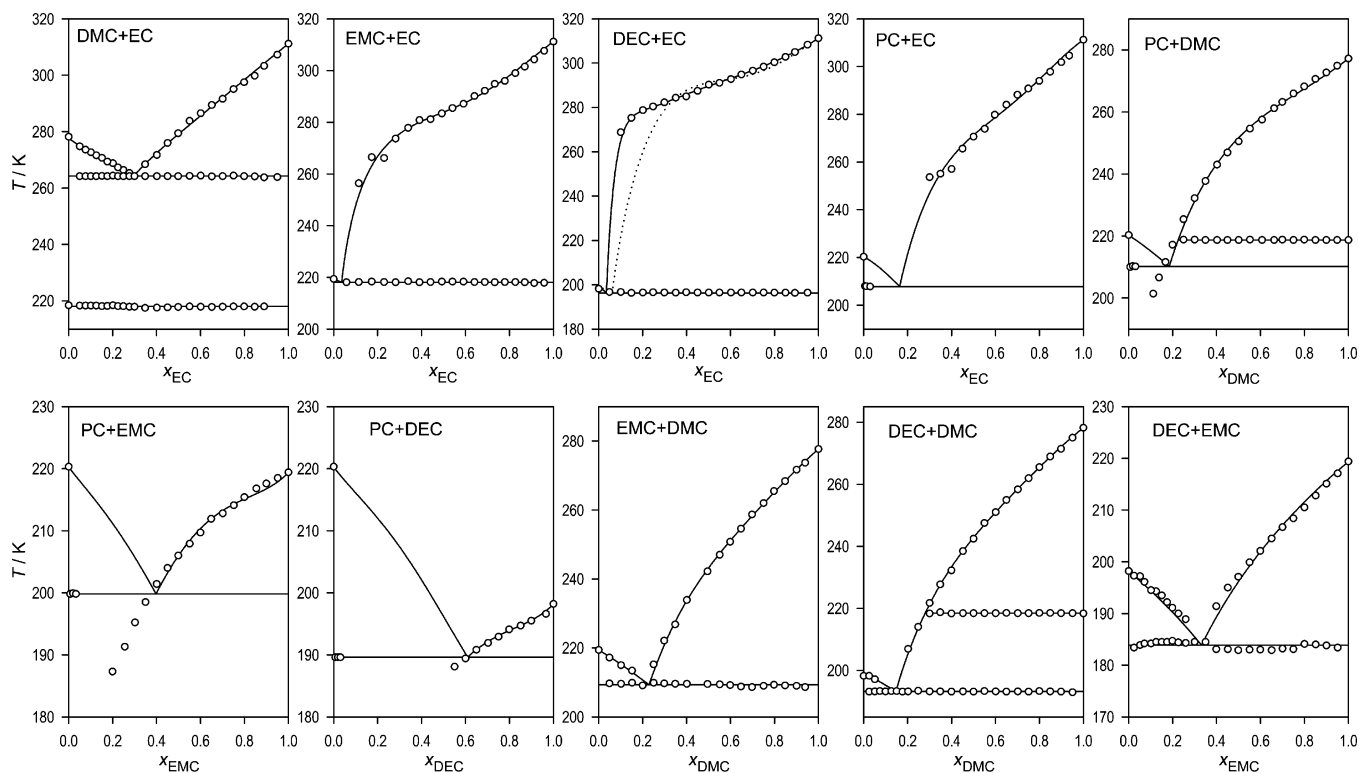

**Heat Capacity and Temperature and Enthalpy of Fusion of Carbonates.** Heat capacities of the carbonates were measured mainly for use in the thermodynamic

**Table 2. Experimental Values for the Temperature,  $T$ , of Liquidus and Solidus Phase Transitions at Different Values of Mole Fraction,  $x_1$ , for the Binary Organic Carbonates without a Measurable Solid–Solid Phase Transition**

modeling of the binary phase diagrams but not for providing accurate values for tabulation; the uncertainty in these measurements was estimated to be as high as 5% due to inherent limitations of the method and the procedures used. Therefore, the measured  $C_p$  values have not been tabulated here; instead, the constants in the polynomial functions that have been fitted to these measured values and used in the thermodynamic modeling are tabulated in Table 3 for an approximate representation of the heat capacities. In addition, the functions are plotted in Figure 3 to show the temperature dependence of and the relations among the heat capacities of the carbonates. For liquids below their melting points, the carbonates were supercooled as low as possible and measured for their  $C_p$  in subsequent

heating, and heat capacities at lower temperatures where the supercooling could not be achieved without crystallization were linearly extrapolated from the measured values at higher temperatures. For solids in their superheated state above their melting points, the heat capacities were represented with linear functions with the same values as those of the corresponding solids at the melting points and with the same slopes as those of the corresponding liquids.<sup>7,11</sup> These extrapolations were necessitated by and used in the thermodynamic modeling and are not intended as estimates for the actual  $C_p$  values. The measured  $C_p$  values, despite their significant uncertainty, should have a high degree of internal consistency since they were all determined under the same conditions against the same

**Figure 1.** Experimentally determined phase diagrams (the open dots) for the 10 binary combinations of EC, PC, DMC, EMC, and DEC and their thermodynamic fit (the curves) with the nonideal solution models of eqs 1–5, with the parameter values listed in Table 4. The dotted curves in the DEC + EC phase diagram would result with a nonregular solution model (polynomial) instead of the nonideal solution model (exponential) actually used.

**Figure 2.** Comparison of phase diagrams for the binary carbonates containing as the common component EC (a) and DMC (b).

reference. These functions also yield reasonable values when compared to the published data;<sup>12</sup> for example, they give for liquid PC at 298.2 K a value of  $153.6 \text{ J mol}^{-1} \text{ K}^{-1}$  against a published value of  $167.6 \text{ J mol}^{-1} \text{ K}^{-1}$ ;<sup>13</sup> for liquid EC at 323.2 K,  $136.2 \text{ J mol}^{-1} \text{ K}^{-1}$  against  $133.9 \text{ J mol}^{-1} \text{ K}^{-1}$ ;<sup>14</sup> for solid EC at 298.2 K,  $117.1 \text{ J mol}^{-1} \text{ K}^{-1}$  against  $117.4 \text{ J mol}^{-1} \text{ K}^{-1}$ ;<sup>13</sup> and for liquid DEC at 294.2 K,  $227.8 \text{ J mol}^{-1} \text{ K}^{-1}$  against  $210.9 \text{ J mol}^{-1} \text{ K}^{-1}$ .<sup>15</sup>

<sup>a</sup>  $C_p/\text{J mol}^{-1} \text{ K}^{-1} = a_0 + a_1(T/10^3 \text{ K}) + a_2(T/10^3 \text{ K})^2 + a_3(T/10^3 \text{ K})^3$ . <sup>b</sup> For  $C_p$  of DMC below its solid–solid phase transition at 220.1 K, the values for  $a_0$ ,  $a_1$ ,  $a_2$ ,  $a_3$ , and  $a_4$  are 271.76, -5638.2, 43952, -152041, and 197217, respectively. <sup>c</sup> s.h. solid stands for superheated solid, i.e., the solid phase of a carbonate above its melting point  $T_m$ .

As shown in Figure 3, the heat capacity of a carbonate in its solid state is always below that in its liquid state, as would normally be expected. However, an exception can be seen in DMC, which is the only one that displays two different phases in the solid state. As shown in the figure, the heat capacity is actually higher for the solid phase of lower temperature than of higher temperature and almost reaches the value of the liquid DMC at the solid–solid phase transition. Meanwhile, the enthalpy of the phase transition was quite low, which, in combination with the strong change in  $C_p$ , makes it reasonable to treat the transition as a second-order phase transition.

**Figure 3.** Heat capacity curves for the carbonates in liquid–solid pairs in the range of (–173 to 323) K, obtained by fitting polynomial functions to the measured  $C_p$  data where available, by linearly extrapolating the measured data to where data could not be measured, or, for solids in their superheated state, by linearly extending their  $C_p$  curves from their measured values at the melting points with the same slopes as those of their liquids. For each pair of curves, the upper one is for the liquid and the lower one for the solid.

Also listed in Table 3 are the measured values of temperature ( $T_m$ ) and enthalpy ( $\Delta_{\text{fus}}H$ ) of fusion that were used in the thermodynamic calculation. The  $T_m$  value agrees with the published ones within experimental error for EC<sup>13,16</sup> and DEC,<sup>4</sup> is about halfway in a 4 K span between the high and the low of the published values for PC,<sup>16–18</sup> and agrees closely with the generally accepted values for DMC and EMC.<sup>4</sup> The  $\Delta_{\text{fus}}H$  value agrees well with the published ones for EC but is about 7% smaller than the published ones for PC.<sup>13,16</sup> The evaluation results for the model parameters in the thermodynamic fitting of a binary phase diagram were not very sensitive to the  $C_p$ ,  $T_m$ , and  $\Delta_{\text{fus}}H$  of the binary components but were affected strongly by the diagram pattern.

**Thermodynamic Modeling.** Thermodynamic nonideal solution models were fitted to the 10 measured binary phase diagrams for an evaluation of the model parameters<sup>19</sup> for a better understanding of the molecular mechanisms underlying the behavior of the carbonates in their liquid–solid phase equilibria<sup>20</sup> and for a greater ability to accurately predict ternary phase diagrams of carbonates.<sup>7,19</sup> The models assume a total absence of solubility of the carbonates in one another in their solid state, which, as evidenced by their measured phase diagrams shown in Figure 1,<sup>3,4</sup> should be a good approximation. They also assume that the part in Gibbs free energy of mixing in the liquid state due to change of entropy can be exclusively represented by the expression<sup>19,20</sup>

$$\Delta_{\text{mix}}G^{\text{id}} = RT(x_B \ln x_B + x_A \ln x_A) \quad (1)$$

where  $R$  is the gas constant,  $T$  is the temperature in Kelvin, and  $x_A$  and  $x_B$  are the mole fractions of the two components A and B. Thus, the Gibbs energy of mixing for a binary A + B in the liquid state can be written as

$$\Delta_{\text{mix}}G = \Delta_{\text{mix}}G^{\text{id}} + G^{\text{E}} + x_A\Delta_{\text{fus}}G_A + x_B\Delta_{\text{fus}}G_B \quad (2)$$

with the Gibbs energies of pure crystalline A and B as its reference. The Gibbs energy of fusion of A at temperature  $T$  is

$$\Delta_{\text{fus}}G_A = \Delta_{\text{fus}}H_A(1 - T/T_{m,A}) + \int_{T_{m,A}}^T (C_{p,A}^{\text{l}} - C_{p,A}^{\text{s}}) dT - T \int_{T_{m,A}}^T (C_{p,A}^{\text{l}} - C_{p,A}^{\text{s}}) d \ln T \quad (3)$$

where  $\Delta_{\text{fus}}H$  is the enthalpy of fusion at the melting point  $T_m$ , and  $C_p^{\text{l}}$  and  $C_p^{\text{s}}$  are the heat capacities of A in its liquid and solid states at the temperature. The same equation serves to describe the Gibbs energy of fusion for B when all its A's are replaced by B's. The excess Gibbs free energy of mixing,  $G^{\text{E}}$ , renders the model of eq 2 nonideal and is expressed as<sup>19</sup>

$$G^{\text{E}} = x_A x_B (a_0 + a_1 x_B + a_2 x_B^2) \quad (4)$$

for all but one of the binary carbonates. Not all the parameters  $a_0$ ,  $a_1$ , and  $a_2$  are always needed for eq 2 to produce a good fit to a measured phase diagram; therefore, according to whether one uses a zero, constant, linear, or quadratic term in eq 4, the resulting model is termed an ideal, regular, subregular, or nonregular solution model.<sup>19,20</sup> Despite its flexibility in fitting various phase diagrams,<sup>19</sup> the nonregular solution model was found inadequate in fitting a particular binary carbonate, EC + DEC, due to the unusual shape of the solubility curve of EC in DEC. Instead, the following expression was found to be far more suitable:

$$G^{\text{E}} = x_{\text{DEC}} x_{\text{EC}} [a_0 + a_1 (1 - e^{a_2 x_{\text{EC}}})] \quad (5)$$

As this nonpolynomial term makes unfit the use of *non-regular* solution for the description of the model utilizing the term, *nonideal* solution is used instead to cover all the thermodynamic models of this work.

For a simple eutectic binary A + B, eq 2 with a given set of numerical values for the parameters  $a_1$ ,  $a_2$ , and  $a_3$  of eq 4 or 5, together with the assumption of mutual insolubility in the solid state, uniquely determines a pair of composition values for the solubilities of A in B and of B in A at a certain temperature, that is,

$$x = f(T, a_0, a_1, a_2) \quad (6)$$

**Table 4. Parameter Values<sup>a</sup> of  $a_1$ ,  $a_2$ , and  $a_3$  in the Nonideal Solution Models, Evaluated by Fitting the Models to the Measured Binary Phase Diagrams, and the Integral Gibbs Energy of Mixing,  $g$ ,<sup>b</sup> for the Binary Organic Carbonates**

| $g$   | 492.4    | 414.4    | 275.7    | 249.0    | 214.8    | 142.8    | -6.163    | -17.46    | -32.98    | -193.3  |

<sup>a</sup>  $G^E/\text{J mol}^{-1} = (1-x)x[a_0 + a_1(1 - \exp a_2x)]$  for DEC + EC and  $=(1-x)x(a_0 + a_1x + a_2x^2)$  for the rest, with  $x$  as the mole fraction of the second component as listed. <sup>b</sup>  $g^E(\text{J mol}^{-1}) = \int_0^1 G^E dx$ .

These two relations when plotted in the  $x$ - $T$  coordinates trace out the two solubility curves which meet at the eutectic point ( $x_e$ ,  $T_e$ ), in the process generating a complete solid-liquid phase diagram for the A + B binary.<sup>6</sup>

By reversing this process of building a phase diagram from a set of parameter values, a nonideal solution model can be optimized against a measured phase diagram for an evaluation of the parameters. This optimization has been achieved in this work by minimizing a target function consisting of sums of the squared differences between the measured values ( $T_i$ ,  $x_i$ ) and the model values [ $T_i$ ,  $f(T_i, a_0, a_1, a_2)$ ] and between the  $x$ -values of the two solubility curves at the measured eutectic point  $T_e$ :

$$S(a_0, a_1, a_2) = \left( \sum_i^A + \sum_i^B \right) [f(T_i, a_0, a_1, a_2) - x_i]^2 + n(f^A - f^B)^2(T_e, a_0, a_1, a_2) \quad (7)$$

where A and B denote the solubility curves of A in B and B in A, respectively, and  $n$  is the number of times by which the eutectic point has been measured at different compositions. Results of such optimization for the 10 measured phase diagrams of binary carbonates are plotted in Figure 1 against the measured phase points, the close fits of the models to the experimental data indicating a high degree of reliability in the model parameters thus evaluated. These parameter values are listed in Table 4 for  $a_1$ ,  $a_2$ , and  $a_3$ , together with the values of integral excess Gibbs energy of mixing  $g$  obtained by integrating the Gibbs energy in the whole composition range using the corresponding parameter values. This integral property can be seen as an indication of the nature and the strength of the intermolecular forces between the two component molecules in the liquid state; a high positive value reflects a much weaker attraction between the two different molecules than the average attractive forces between the molecules of the same kind, and a high negative value, a much stronger attraction.<sup>20</sup> Thus, a comparison of the first three  $g$ -values in Table 4 with their corresponding phase diagrams in Figure 2a shows that the upward shift of the solubility curve of EC in the linear carbonates in the order of DMC, EMC, and DEC is a result of the increasingly weaker attraction between the molecules of EC and the linear carbonates. Clearly, it is the molecular compatibility between the two components that determines the solubility of one in the other, not their melting points.<sup>6</sup> For the same reason, the higher solubility of DMC in EMC and DEC than in EC and PC shown in Figure 2b is a result of the higher molecular compatibility between two linear carbonates than between a linear and a cyclic carbonate, the  $g$ -values being both negative for the former and positive for the latter as seen in Table 4.

## Conclusions

Temperature-composition values of liquid-solid equilibrium were measured calorimetrically and tabulated for

10 binary solutions of these 5 organic carbonates: EC, PC, DMC, EMC, and DEC. Further, these binary phase diagrams were closely fitted with thermodynamic nonideal solution models, based on the measured values of heat capacity and temperature and enthalpy of fusion of the five carbonate components, for an evaluation of the model parameters. The evaluation results, combined with the phase diagrams, indicated that many of the important features of the phase diagrams are determined mainly by the molecular compatibility between the component carbonates. More specifically, a cyclic carbonate dissolved another cyclic more readily than another linear, and vice versa. Of particular interest and importance is the series of DMC, EMC, and DEC with EC, where these linear carbonates dissolved EC with increasing difficulty resulting in decreasing expansions of the liquid regions of the phase diagrams into low temperature, manifesting a diminishing molecular compatibility of EC with the linear carbonates from DMC to EMC to DEC.
