### ABSTRACT

Various groupings from eighty-two metal complexes of monothio-beta-diketones having different ligands, have been studied by normal and reversed phase thin-layer chromatography in single and binary solvent systems. The data is discussed in terms of keeping the ligand, RCSCHCOR', constant and varying the metal; keeping the metal constant and varying the R'-group of the ligand; keeping the metal constant and varying the R-group of the ligand.

Separation patterns are discussed in terms of choice of solvent systems and the magnitude of the  $R_f$  values are discussed with reference to the R and R'-groups of the ligand.

### INTRODUCTION

Monothio- $\beta$ -diketonate complexes are monomeric, anhydrous and soluble in organic solvents, whereas, metal complexes of  $\beta$ -diketones are solvated and insoluble in organic solvents (1). The thin-layer chromatographic behavior of some metal  $\beta$ -diketonates on silica gel and microcrystalline cellulose has been reported (2,3). Stable and extractable chelates of two monothio- $\beta$ -diketones,  $RCSCHCOR'$ , where R and R' are phenyl and R is 2'-thienyl and R' is trifluoromethyl has been done (4-6). Also a TLC separation of some dithio- $\beta$ -diketonate complexes has been reported (7). More recently we have used a silica gel adsorbent to separate some trifluoro- $\beta$ -diketonate complexes (8) and to separate three series of nickel, zinc and cobalt complexes with the ligands having R-2'-thienyl, R'-CHF<sub>2</sub>; R-2'-thienyl, R'-CF<sub>3</sub>; R-2'-naphthyl, R'-CF<sub>3</sub> (9).

We now report the thin-layer chromatographic behavior of eighty-two metal complexes of monothio- $\beta$ -diketones using normal and reversed phase TLC in single and binary solvent systems.

### EXPERIMENTAL

#### Plate Preparation

Normal phase TLC was done on silica gel (100 $\mu$ ) sheets (Eastman) on a flexible polyethylene terephthalate supporting surface with a polyacrylic acid as a binder. The TLC sheets were activated by heating at 100°C for 1 hr. Reverse phase TLC was done on KC<sub>18</sub> plates (Whatman).

Solvent Systems and Detection

Eleven single solvent (Table 1), fourteen binary solvent (Table 2) and six reversed phase solvent (Table 3) systems were used in the separation studies. The intense color of the complexes in most cases was used for detection. The Cu and some

Solvent System	Solvent	Solvent System	Solvent
1	95% ethanol	4	n-pentanol
2	n-propanol	5	3-methyl-1-butanol
3	n-butanol	6	t-butyl alcohol

Zn chelates were void of color but they were visible under UV light. For some of the Zn, Ni and Pd chelates the color faded and a dilute solution of dithizone in 6 M  $\text{NH}_3$  when sprayed on these chelates gave the following colors: pink (Zn), blue (Ni), orange (Pd). The developing time was for a 10 cm distance with  $R_f$  values held to a reproducibility of 0.03  $R_f$  units, with a good separation having the  $R_f$  values differ by at least 0.05  $R_f$  units.

#### RESULTS AND DISCUSSION

The various complexes studied are presented in Table 4. The four-coordinate Ni, Pd and Pt complexes are cis-square planar and the six-coordinate Co, Zn, Fe, Ru and Ru complexes are facial (cis) octahedral. The geometry of the four-coordinate Cu complex is not known. The four-coordinate Zn complex is tetrahedral. The  $R_f$  data was analyzed for three basic patterns: ligand constant-vary the metal; R of the ligand constant - vary  $R'$  of the ligand; keeping R of the ligand constant and vary  $R'$

of the ligand. R and R' refer to the ligand's substituents of RCOCHCSR'.

#### SINGLE SOLVENT SYSTEMS

##### a. Ligand Constant/Vary the Metal

Table 5 displays mixtures of the monthio- $\beta$ -diketonates which are separable by 0.05  $R_f$  units. The data suggests that the nonpolar solvents of carbon disulfide and carbon tetrachloride are excellent solvent choices. In general these two solvents gave low  $R_f$  values. The polar solvents of acetonitrile, nitrobenzene and methylene chloride gave the expected high  $R_f$  values. Separations in most of these solvents proved to be poor choices as the chelate moved with the solvent front. Ethyl acetate gave varying  $R_f$  values and in some mixtures gave good separations. Benzene, with its low dielectric constant, was expected to give low  $R_f$  values; however, the reverse situation was found and therefore benzene has limited ability for separation. Toluene generally gave lower  $R_f$  values than benzene, but also proved to be of limited use in separations. Chloroform, mixed xylenes and chlorobenzene gave  $R_f$  values of intermediate value in the 10 cm. range and showed potential as developing solvents for certain mixtures. Acetonitrile resulted in the streaking of some chelates. Methylene chloride and toluene produced tailing in the nickel and cobalt chelates.

Several observations with regard to the metal can be made from Table 5. Nickel and palladium chelates are often not

separable as were the chelates of palladium and platinum. However, nickel can be separated from either palladium or platinum. Cobalt and zinc can be separated from each other as well as from all other metals containing various ligands. Cobalt, iron, ruthenium and rhodium are separable as a mixture. Copper can be separated from both square planar complexes as well as octahedral complexes. In general in a mixture containing a larger number of metals, separation and identification would be limited to approximately four to six metal chelates depending on the ligand used, due to production of similar  $R_f$  values with these single solvent systems.

The  $R_f$  values from single solvent development reflect certain trends between the transition metals investigated. Overall, the nickel and palladium complexes give  $R_f$  values greater than the corresponding cobalt and zinc complexes. For only nickel and palladium complexes, the latter yields larger  $R_f$  values. Ruthenium complexes yields greater  $R_f$  values than rhodium complexes while both gave greater  $R_f$  values than cobalt complexes. Iron, zinc and copper complexes yield very low  $R_f$  values. It is important to notice that the chelates of certain ligands do not yield specific trends. In these cases, the  $R_f$  values show much scatter.

**b. R Constant/Vary R'**

In analyzing the substituent effects of the monothio- $\beta$ -diketone metal chelates on the  $R_f$  values by holding the R sub-

stituent constant and varying the R' substituent, the data follows along two lines. First, the R substituent can be either electron rich or electron poor in nature. Second, the R' substituent can be changed from one which is electron rich to electron poor. Also when the electron withdrawing substituent is a perfluoroalkyl group, the  $R_f$  values can be studied by varying the length of the carbon chain.

Keeping the R substituent as methyl and varying the R' substituent methyl group to a phenyl group, the  $R_f$  values failed to show a consistent trend between the chelates on zinc, nickel and cobalt for single solvent systems. For the nickel and cobalt chelates only, the order of  $R_f$  values is  $C_6H_5 < CH_3$ , and the pattern for the zinc chelate is the reverse order.

In the case of the electron rich R-group, the R' substituent was varied as:  $OC_2H_5$ ,  $C_6H_5$ ,  $CF_3$ ,  $C_2F_5$  and  $C_3F_7$  for chelates of nickel, palladium and cobalt. In changing the R' substituent from  $OC_2H_5$  to  $C_6H_5$  or in changing from either  $OC_2H_5$ ,  $C_6H_5$  to  $CF_3$ , the metal chelates fail to show a trend in  $R_f$  values for these single solvent systems. However, when the R' substituent is a perfluoroalkyl group, a pronounced effect on the  $R_f$  values is seen as the length of the carbon chain is increased. With the nonpolar and nonaromatic solvents, carbon disulfide and carbon tetrachloride, the following trend is observed;  $CF_3 < C_2F_5 < C_3F_7$ .

This order of the  $R_f$  values remains the same when R is naphthyl for the aromatic solvents of xylene and chlorobenzene; however, the trend changes from  $CF_3 < C_3F_7 < C_2F_5$  in the previously mentioned solvents. When the electron rich substituent (R) is thienyl, the  $R_f$  values follow the first trend for the solvent carbon disulfide. This same trend is observed for the corresponding palladium series in a nitrobenzene or chlorobenzene solvent and the latter trend is observed in the solvent carbon disulfide. The ruthenium and rhodium series in which the R substituent is thienyl the order of  $R_f$  values for the complete range of single solvent systems  $CHF_2 < CF_3$ .

### c. Vary R/R' Constant

The R' substituents used for this study are  $C_6H_5$ ,  $CF_3$ ,  $C_2F_5$  and  $C_3F_7$ . As in the previous section, the variable substituent is changed from one which is electron rich to one which is electron poor. For electron poor substituents, the effect of increasing the length and substitution of the alkyl chain on the  $R_f$  values was done. If the R substituent is a phenyl group, the effect of substituting the phenyl ring on the  $R_f$  values was also studied.

For the nickel and palladium series and in which the R' substituent is phenyl the R substituent is changed from  $CH_3$  to  $C_6H_5$ , the pattern of  $R_f$  values is such that  $C_6H_5 < CH_3$  when carbon disulfide is the developing solvent. The reverse trend is found for the corresponding zinc and cobalt series and these

trends are also followed for some chlorinated and aromatic solvents.

When the R' substituent is a perfluoromethyl group and the R substituent is an alkyl group, a consistent trend is observed in each series of the nickel, palladium and zinc chelates. As the length and substitution of the alkyl chain is increased, the  $R_f$  values increase. In the case of the nickel and palladium chelates on changing from a alkyl substituent to a phenyl substituent, there is a corresponding decrease in  $R_f$  values. No consistent trend in this regard is seen for the zinc chelates. In aromatic solvents, chlorobenzene and xylene, as the substitution of the phenyl (R) substituent is varied and R' is  $CF_3$  the  $R_f$  values increase for  $FC_6H_4 < CH_3C_6H_4 < C_6H_5$ . The trend observed is reversed for the nonpolar solvents of carbon disulfide and carbon tetrachloride.

For the substituents,  $C_6H_5$ ,  $2'-C_{10}H_7$  and  $2'-C_4H_3S$ , the following pattern is observed for the palladium series in both carbon disulfide and carbon tetrachloride and also the platinum series in carbon disulfide,  $C_{10}H_7 < C_4H_3S < C_6H_5$ . However, this order changes for the platinum series when the developing solvent is carbon tetrachloride. The observed trend is,  $C_4H_3S < C_{10}H_7 < C_6H_5$ . This new pattern also follows for the corresponding ruthenium and rhodium series when the developing solvent is either carbon disulfide or carbon tetrachloride. The rhodium

series expands the pattern as follows,  $\text{CH}_3\text{C}_4\text{H}_3\text{S} < \text{C}_4\text{H}_3\text{S} < \text{C}_{10}\text{H}_7 < \text{C}_6\text{H}_5$ .

Using copper chelates, two substituents,  $\text{C}_6\text{H}_5$  and  $\text{C}_4\text{H}_3\text{S}$  were compared and the results correspond to the other metals when the developing solvents are carbon disulfide and carbon tetrachloride. For these chelates, the  $R_f$  values are,  $\text{C}_4\text{H}_3\text{S} < \text{C}_6\text{H}_5$ .

The pattern in  $R_f$  values just described is reversed when the  $R'$  substituent is changed to a perfluoroethyl group. For the nickel, palladium and cobalt series, the pattern changes to,  $\text{C}_6\text{H}_5 < \text{C}_{10}\text{H}_7$ . The  $R_f$  values of the thienyl substituted chelates fluctuates and thus does not fit into a consistent trend. The expected trend was the opposite of that which was observed.

Two different patterns exist when the  $R'$  substituent is a perfluoropropyl group as the  $R$  substituent is varied from  $\text{C}_6\text{H}_5$ , to  $\text{C}_{10}\text{H}_7$  to  $\text{C}_4\text{H}_3\text{S}$ . The nickel series follows the trend seen when the  $R'$  substituent is  $\text{CF}_3$ . However, the trend breaks down to  $\text{C}_{10}\text{H}_7$ ,  $\text{C}_4\text{H}_3\text{S} < \text{C}_6\text{H}_5$ , for cobalt and palladium chelates.

## 2. BINARY SOLVENT SYSTEMS

### a. Ligand Constant/Vary the Metal

The use of binary solvent systems allows the separation of certain mixtures that were not possible in single solvent systems. In general, nonaromatic solvent systems provided the best separations. Solvent system No. 23 proved to be one of the best

combinations. This was not unexpected as the major component is carbon disulfide. For most successful solvent systems at least one of the components was chlorinated. Table 6 lists the separation trends that were observed using binary solvent systems having  $R_f$  values that differ at least by 0.05 units.

Using binary solvent systems, palladium and nickel could be easily separated. However, as in the single solvent systems, the platinum and palladium complexes could not be separated. Zinc chelates again can be separated from any other metal. Ruthenium and rhodium are also separable. Unlike the single solvent systems, cobalt, ruthenium, rhodium and iron complexes are not always separable. The copper chelates of certain ligands gave  $R_f$  values of similar magnitude to the corresponding cobalt and iron chelates.

The zinc, copper and iron chelates again yield the lowest  $R_f$  values in the separation of most mixtures. From Table 6 the difference in trends between single and binary solvent systems occurs in ligands in which the R substituent is electron rich in nature. For example the ligand,  $C_{10}H_7CSCH_2COC_2F_5$ , the following pattern is observed for three metal chelates using carbon disulfide as the developing solvent;  $Co < Ni < Pd$ . However, when the developing solvent is changed to  $CHCl_3:CS_2$  (1:1), the pattern is rearranged to  $Ni < Co < Pd$ . Within mixtures of four or more complexes trends are not obvious. The nickel chelates in binary solvents generally have lower  $R_f$  values than the corresponding

cobalt chelates. This also is the opposite of what was observed with single solvent systems.

#### b. $R$ Constant/Vary $R'$

The use of binary solvent systems yields several trends in the  $R_f$  values as the  $R$  substituent is held constant and the  $R'$  substituent is varied. The  $R$  substituent in each case is elec-

tron releasing, while the R' substituent varies from electron releasing to electron withdrawing. A series of zinc chelates having the electron releasing R as CH<sub>3</sub> gave a pattern of R<sub>f</sub> values which was the reverse order for the corresponding nickel and cobalt chelates when the R' substituent was changed from a phenyl group to a trifluoromethyl group. This R<sub>f</sub> pattern of C<sub>6</sub>H<sub>5</sub> < CF<sub>3</sub> suggests that as you increase the electron withdrawing capabilities of the R' substituent, the R<sub>f</sub> values also increase. This pattern was not observed in single solvent systems.

Other R electron rich substituents of C<sub>6</sub>H<sub>5</sub> and C<sub>4</sub>H<sub>3</sub>S show a definite pattern in R<sub>f</sub> values as R' is varied for nickel, palladium and cobalt. However, if the R substituent is the larger 2'-C<sub>10</sub>H<sub>7</sub>, only a scatter of R<sub>f</sub> values can be recorded for the corresponding series. When the R substituent is a phenyl group and the R' substituent is changed from C<sub>6</sub>H<sub>5</sub> to CF<sub>3</sub>, opposite effects on the R<sub>f</sub> values are noticed for the zinc and cobalt series. The cobalt and palladium series show the R<sub>f</sub> values to decrease when the R' substituent is changed from CF<sub>3</sub> to C<sub>6</sub>H<sub>5</sub>. The zinc and nickel series show the R<sub>f</sub> values to increase as the electron releasing strength of the substituent is increased. However in the zinc series, the R<sub>f</sub> values decrease when the electron releasing strength of the R' substituent is changed to an alkyl group. Therefore, in these systems, the R<sub>f</sub> values fail to yield a trend of order as the electron releasing or electron

withdrawing power of the substituent is varied. Further with the zinc chelates, the opposite trend in  $R_f$  values for the  $R'$  substituents of  $CF_3$  and  $C_6H_5$  occur when the R substituent is changed from electron releasing to electron withdrawing.

For the nickel, palladium and cobalt series in which the R substituent is a phenyl group, a common pattern in the  $R_f$  values occurs for binary solvent systems as the  $R'$  substituent is changed from  $OC_2H_5$  to  $C_6H_5$ . The trend being;  $C_6H_5 < OC_2H_5$ . This trend is consistent for a wide range of polarity and chemical composition of the solvent. This trend again indicates that the  $R_f$  values increase as the electron withdrawing capability is increased.

For perfluoroalkyl substituents, the trend in  $R_f$  values is similar to that seen with single solvent systems when the R substituent is  $C_6H_5$  or  $C_4H_3S$ . In these cases, the trend in  $R_f$  values for most binary solvent systems is such that;  $CF_3 < C_2F_5 < C_3F_7$ . However, when the R substituent is the larger  $2'-C_{10}H_7$  group, no trend is observed.

This trend is expanded to  $CHF_2 < CF_3 < C_2F_5 < C_3F_7$  for ruthenium and rhodium chelates when the R substituent is thienyl and the  $R'$  substituent is varied from  $CF_3$  to  $CHF_2$ . Therefore when the R substituent is electron rich, the  $R_f$  values increase as the  $R'$  substituent's electron withdrawing ability is also increased.

c. Vary R/R' Constant

A consistent pattern for the metal chelate series of nickel, cobalt, ruthenium, rhodium, copper and palladium is observed when the R' substituent is maintained as a fluorinated alkyl group and the R substituent is varied as C<sub>4</sub>H<sub>9</sub>S, CH<sub>3</sub>C<sub>6</sub>H<sub>4</sub>, C<sub>6</sub>H<sub>5</sub> and C<sub>10</sub>H<sub>7</sub>. The pattern in R<sub>f</sub> values is C<sub>4</sub>H<sub>9</sub>S < CH<sub>3</sub>C<sub>6</sub>H<sub>4</sub>, C<sub>6</sub>H<sub>5</sub>, C<sub>10</sub>H<sub>7</sub> when the R' substituent is CF<sub>3</sub>. This pattern again suggests that as the electron withdrawing ability is increased, the R<sub>f</sub> values likewise increase. The order, C<sub>10</sub>H<sub>7</sub> < C<sub>6</sub>H<sub>5</sub>, is followed for the platinum, ruthenium and rhodium series. The reverse order is found for the corresponding palladium series. The former trend is also observed for the nickel, palladium and cobalt series when the R' substituent is either C<sub>2</sub>F<sub>5</sub> or C<sub>3</sub>F<sub>7</sub>. The zinc series does not support the correlation between the magnitude of R<sub>f</sub> values and the electron withdrawing ability of the substituent as is evident by the following trend, C<sub>6</sub>H<sub>5</sub> < CH<sub>3</sub>C<sub>6</sub>H<sub>4</sub> < CH<sub>3</sub>.

In several series, the effect of placing a substituent on the phenyl R group was observed. According to the order of substituent ability, the R<sub>f</sub> values should increase as follows, CH<sub>3</sub>C<sub>6</sub>H<sub>4</sub> < C<sub>10</sub>H<sub>7</sub> < C<sub>6</sub>H<sub>5</sub> < FC<sub>6</sub>H<sub>4</sub>. This order is not strictly followed in any series. In most series, the phenyl substituted chelate has the largest R<sub>f</sub> value.

The results do not reveal any definite patterns in the R<sub>f</sub> values of the different chelate series investigated for the

effects of alkyl substituents in the R position. For example, in the nickel and cobalt series as the length and substitution of the alkyl substituent is increased, the  $R_f$  values should also increase. Instead they show much scatter in these binary solvent systems. Also, in the zinc series, the opposite trend from the expected one is found. In this series, the  $R_f$  values decrease as the electron withdrawing ability is increased when the R substituent is changed from  $\text{CH}_3$  to  $\text{C}_2\text{H}_5$ .

In considering the effect of changing the R substituent from an alkyl to a phenyl group when the R' substituent is a fluorinated alkyl group, the  $R_f$  values show that for the majority of the binary solvent systems,  $\text{C}_6\text{H}_5 < \text{CH}_3$ . This was observed in all nickel, cobalt, palladium and zinc series and also with single solvent systems. However when the R' substituent is phenyl, the  $R_f$  values show much scatter for these series of metal chelates.

### 3. REVERSED PHASE TLC

The cobalt nickel, copper and zinc chelate of series 7 (Table 4), the cobalt, nickel and palladium chelates of series 13 and the cobalt, nickel and palladium chelates of series 14 are separable in  $(\text{CH}_3)_3\text{COH}$ ,  $\text{C}_2\text{H}_5\text{OH}$  (also  $\text{C}_5\text{H}_{11}\text{OH}$ ) and  $\text{C}_2\text{H}_5\text{OH}$ , respectively. In most alcohols, the platinum and palladium chelates gave nearly identical  $R_f$  values. Also these  $d^8$ -metal chelates gave lower  $R_f$  values than the octahedral chelates, except for the six-coordinate iron complex in series 7 where the

$R_f$  values are  $Fe < Ni, Pd < Co < Zn$  in  $C_2H_5OH$ . Octahedral chelates can be separated from each other in more alcohol solvent systems than can the corresponding square planar complexes. A tetrahedral complex can always be separated from either a square planar or octahedral complex. For the eight chelates having  $R-C_6H_5$  and  $R'-CF_3$  of the ligand, the following trend of  $R_f$  values was observed:  $Pd, Pt < Ni < Ru, Rh < Co < Cu < Zn$ . Thus, there appears to be a dependence on geometry and  $R_f$  values for a mixture of chelates when using alcohol solvent systems in reversed phase thin-layer chromatography.

#### CONCLUSIONS

It is difficult to separate large mixtures of four or more metal ions with substituted monothio- $\beta$ -diketones by 0.05  $R_f$  units either single or binary solvent systems with normal phase thin-layer chromatography. Separation of 0.03  $R_f$  units or less are easily achieved in either solvent system. For single solvent systems, the nonpolar solvents of carbon disulfide and carbon tetrachloride offer the most potential as developing solvent. Chloroform, xylenes and chlorobenzene also offer some potential. In binary solvent systems, those systems in which the major component is carbon disulfide are excellent solvents for separation. The magnitude of the  $R_f$  values is not dependent on the polarity of the solvent systems.

The ability to separate two metals is mainly dependent on the choice of ligand. Therefore, it is possible to separate any

two metals by choosing the proper ligand. For some ligands, it is difficult to separate those metals which form chelates of like geometry, whereas, using these same ligands, metals from the same period in the periodic table can be separated and identified. The trends in  $R_f$  values do not show a dependence in geometry in either single or binary solvent systems. Binary systems do not necessarily offer better separations. Reversed phase thin-layer chromatography offers more sensitivity and therefore a greater ability to separate these mixtures.

Two important patterns in the magnitude of the  $R_f$  values are found as one substituent is held constant while the electron releasing and electron withdrawing ability of the other substituent is varied. First, when the R substituent is an electron releasing group, the  $R_f$  values increase as the electron withdrawing power of the R' substituent is increased. The second pattern involve holding the R' substituent constant as a perfluoroalkyl group and changing the R substituent. In the second pattern, a trend of increasing  $R_f$  values as the electron withdrawing ability of the R substituent is increased is followed for thienyl and phenyl substituents. This trend is broken when considering a group of large substituents:  $C_6H_5$ ,  $CH_3C_6H_4$  and  $FC_6H_4$ . The trend of the first pattern implies that with increasing the electron withdrawing ability of the R' substituent, the chelate become a more polar complex. Due to the lack of consistency when the R substituent is varied, it is implied that

the more significant changes occur when the R' substituent is varied. Changing of the R' substituent offers more potential for the manipulation of the R<sub>f</sub> values.

Reversed phase thin-layer chromatography is more sensitive in its ability to separate the transition metal chelates of substituted monothio- $\beta$ -diketones. In general, as the length of a straight chain primary alcohol increases (Table 3), the R<sub>f</sub> value increases then decreases as the solvent is changed to a branched alcohol.
