### Summary

The Raman spectra of several dicyclopentadienyl complexes  $\text{Cp}_2\text{M}$  of transition metals (M = Mn, Cr, V, Ru, Os) are obtained in the solid and liquid states and are discussed together with the infrared data. The assignment of some Cp-vibrations is revised and a new assignment is proposed. The observed difference between the Raman spectra of the low temperature amber-brown form and the rose form of manganocene is considered as a manifestation of a possible equilibrium between two different isomers of the compound in its low-temperature form.

---

Due to its unusual magnetic properties, manganocene occupies a special place among dicyclopentadienyl complexes. While being isoelectronic with the ferricinium ion,  $\text{Cp}_2\text{Fe}^+$ , manganocene ( $\text{Cp}_2\text{Mn}$ ) exhibits paramagnetism in melt and solutions which corresponds to the presence of five unpaired electrons ( ${}^6A_{1g}$  ground state). The low-temperature amber-brown phase, existing up to 432 K, possesses antiferromagnetic properties (Neel temperature 134 K). However, the field dependence of magnetic susceptibility, although weak, is retained up to 432 K, the point of transition into the paramagnetic rose form which is a normal paramagnetic one and corresponds to the sextet ground state [1]. On the other hand, the existence of stable diamagnetic complexes of manganese enabled M.E. Dyatkina to suggest that the energy difference between the sextet  $\text{Cp}_2\text{Mn}$  state and the possible doublet state, similar to  $\text{Cp}_2\text{Fe}^+$  (ground state  ${}^2A_{1g}$  or  ${}^2E_{2g}$ ), is not very great [2]. This suggestion was recently confirmed by the study of the EPR spectra of  $\text{Cp}_2\text{Mn}$  and  $(\text{MeC}_5\text{H}_4)_2\text{Mn}$  [3]. Data obtained at 4.2 K were in agreement with a "doublet" ground state. It was proposed that the anomalous magnetic properties of the low-temperature form of  $\text{Cp}_2\text{Mn}$  may be due to an equilibrium between these two forms. We thought it promising to use vibrational spectroscopy for the study of this problem. For the brown form of

$\text{Cp}_2\text{Mn}$ , IR absorption spectra in the region of  $4000\text{--}400\text{ cm}^{-1}$  have been described [1,4], to our knowledge the Raman spectra have not previously been recorded.

In the present work we have recorded the Raman spectra of  $\text{Cp}_2\text{Mn}$  in two crystalline modifications and as a melt, and the IR spectra of the low-temperature form in the  $4000\text{--}250\text{ cm}^{-1}$  region. The data obtained are compared with the spectra of chromocene, vanadocene, ruthenocene, and osmocene. For  $\text{Cp}_2\text{Cr}$  and  $\text{Cp}_2\text{V}$  only the IR spectra have been described [4,5]. Analysis of available IR spectra of  $\text{Cp}_2\text{Cr}$  and  $\text{Cp}_2\text{V}$  shows that decomposition products (for example, cyclopentadiene) were present in the studied samples. Raman spectra of these compounds have not been previously recorded. For  $\text{Cp}_2\text{Ru}$  and  $\text{Cp}_2\text{Os}$ , Raman spectra have been obtained only for solid state and solutions, and the degree of Raman line depolarization, due to low solubility, has only been measured for the strongest lines [6–9]. We have recorded the Raman spectra of melts and determined the line polarization.

### Experimental

IR spectra were recorded on Perkin–Elmer 457 and UR-20 Zeiss spectrophotometers. Preparation of samples and recording of spectra were carried out in the absence of oxygen and moisture. Compounds were deposited in a vacuum glass cryostat onto a KRS-5 window cooled to 90 K. Before evacuating, a small capillary containing the substance to be studied was crushed in a side arm of the cryostat in an Ar atmosphere. During deposition the side arm was heated to  $60\text{--}100^\circ\text{C}$  in a heating jacket. Despite these precautions weak bands of cyclopentadiene were sometimes observed in the IR spectra.

Raman spectra were obtained on Coderg PHO and T-800 spectrophotometers with a He–Ne laser (6328 Å line). Samples were placed in capillaries which were vacuum sealed. To measure the spectra at elevated temperatures the capillaries were heated in a special copper holder connected to a furnace. The temperature was automatically controlled and was maintained within several degrees. Despite strong absorption satisfactory spectra of the amber-brown form of  $\text{Cp}_2\text{Mn}$  were obtained. We were not able to record several weak lines of  $\text{Cp}_2\text{Cr}$  and  $\text{Cp}_2\text{V}$ . No difficulties were encountered while measuring the spectra of  $\text{Cp}_2\text{Mn}$  melts, the rose form and the spectra of  $\text{Cp}_2\text{Ru}$  and  $\text{Cp}_2\text{Os}$  melts. The data obtained are presented in Table 1.

### Discussion

Vibrational spectra and assignments of the compounds studied are given in Table 1. Raman spectra of  $\text{Cp}_2\text{Mn}$ ,  $\text{Cp}_2\text{Cr}$  and  $\text{Cp}_2\text{V}$  have not been previously recorded. IR spectra obtained at  $-196^\circ\text{C}$  differ noticeably from those previously reported. The recorded Raman spectra of the  $\text{Cp}_2\text{Ru}$  and  $\text{Cp}_2\text{Os}$  melts made it possible to perform polarization measurements on several weak lines. Comparison of the spectra shows that in the region of cyclopentadienyl ring vibrations (above  $600\text{ cm}^{-1}$ ), regardless of the significant differences in the nature of metal–ligand bonds, spectra of all the compounds studied are very similar. Assignment was performed on the basis of  $D_{5d}$  molecular symmetry. The

eclipsed conformation with  $D_{5h}$  symmetry possible for these compounds does not change the selection rules and only leads to changes in the designations of the corresponding vibrations. Numeration of frequencies is the same as in [5]. Assignment of most of the frequencies is not discussed here since it corresponds to the accepted assignment for  $h^5$ -Cp compounds. Only new assignments and specific features of spectra are discussed below.

1. Frequencies of the out-of-plane CH ring vibrations in the 700–850  $\text{cm}^{-1}$  region are significantly affected by the metal atom. It is usually accepted [5] that these frequencies decrease with an increase in the ionic character of the M–Cp bond. This is confirmed by the position of the  $\rho(\text{CH})$  frequencies in spectra of melt and the rose form of  $\text{Cp}_2\text{Mn}$  and other ionic Cp complexes [10,11]. However, the dependence is apparently of a more complex nature. Thus, the  $\rho(\text{CH})$  frequencies of  $\text{Cp}_2\text{Fe}^+$  are higher than for ferrocene. For  $\text{Cp}_2\text{V}$  and  $\text{Cp}_2\text{Cr}$  a band near 840  $\text{cm}^{-1}$  is observed along with very intensive IR bands at 765–780  $\text{cm}^{-1}$ . It is of interest that the spectra of the low temperature manganocene form is more complex than the spectra of the rose form and of the melt; in addition to lines in the 750–780  $\text{cm}^{-1}$  region, bands appear near 830 and 860  $\text{cm}^{-1}$ . Their appearance can hardly be explained by the crystalline effects and their position is similar to that of the  $\rho(\text{CH})$  frequencies in the ferricinium ion spectrum. It may be assumed, in accordance with [3], that in the brown form of  $\text{Cp}_2\text{Mn}$  along with “sextet” molecules, “doublet”  $\text{Cp}_2\text{Mn}$  is present, an electron analogue of the ferricinium ion. This may be the cause of anomalous magnetic properties of the low-temperature form.

Results of polarization measurement of  $\rho(\text{CH})$  lines in the melt made it necessary to reverse the symmetry assignment of the 816 and 831  $\text{cm}^{-1}$  lines of osmocene. Unlike ferrocene [12], the line with higher frequency corresponds to the symmetrical vibration. It should be noted that in both cases the more intensive line in the IR spectra corresponds to  $\nu(9)$  vibration.

2. We have proposed a new assignment of the line in the 1050  $\text{cm}^{-1}$  region to the in-plane bending vibration  $\beta(\text{CH})\nu(24)$  of  $E_{2g}$  class. This line is usually assigned to out-of-plane bending vibration  $\rho(\text{CH})\nu(25)$  of  $E_{2g}$  class. This assignment was first proposed by Lippincott and Nelson [13] while comparing spectra of metallocene compounds with benzene and tropylium ion spectra. The  $\rho(\text{CH})$  ( $E_2''$ ) vibration in the free  $\text{C}_5\text{H}_5^-$  ion ( $D_{5h}$  symmetry) is not active in the IR spectrum or in the Raman spectrum. It can be expected that, in the case of ionic Cp complexes, this line should be weak in the Raman spectra, however, for metallocenes, in which the ionic character of the bond is beyond all question ( $\text{Cp}_2\text{Mn}$  in the present work, tricyclopentadienyl complexes of lanthanides [11],  $\text{Cp}_2\text{Mg}$  [10]), this line is sufficiently intense and consequently, should be assigned to one of the allowed vibrations of the  $\text{C}_5\text{H}_5^-$  ion. The only suitable candidate seems to be the in-plane bending vibration  $\beta(\text{CH})$  ( $E_2'$ ) which in the  $\text{Cp}_2\text{M}$  model corresponds to  $\nu(24)$  and  $\nu(30)$  vibrations ( $E_{2g}$  and  $E_{2u}$ ). Other arguments in favour of this assignment will be discussed in a paper devoted to the analysis of vibrational spectra of the Cp-ligand in various cyclopentadienyl compounds [14].

3. The line in the 1230  $\text{cm}^{-1}$  region for  $\text{Cp}_2\text{Mn}$  and in the 1180  $\text{cm}^{-1}$  region for  $\text{Cp}_2\text{Os}$  is polarized. Previously we established that the corresponding line in the Raman spectra of  $\text{Co}_2\text{Fe}$  [12] and  $\text{CoMn}(\text{CO})_4$  is polarized [15]. This line is

usually assigned to an in-plane bending  $\beta(\text{CH})$  vibration ( $\nu(24)$ ,  $E_{2g}$ ). In [12] we suggested that this line corresponds to the overtone of the out-of-plane bending vibration of the ring  $\nu(28)$  strengthened by Fermi resonance with the  $\nu(3)$  vibration ( $A_{1g}$ ). Another important argument in favour of this assignment is the parallelism of frequency variation in the 600 and 1200  $\text{cm}^{-1}$  regions of  $\text{Cp}_2\text{Ru}$ ,  $\text{Cp}_2\text{Os}$  and  $\text{Cp}_2\text{Mn}$  spectra depending on the metal, the frequency of the latter taking into account the anharmonicity is equal to the doubled frequency of the  $\nu(28)$  vibration. This line was not observed in the Raman spectra of  $\text{Cp}_2\text{Cr}$  and  $\text{Cp}_2\text{V}$ , apparently owing to its very low intensity. In the solid state IR spectra of these compounds rather strong bands are observed in the 1250–1260  $\text{cm}^{-1}$  range. Their frequencies exceed  $2\nu(28)$  and, therefore they can not be assigned to the corresponding overtone. By analogy with  $\text{Cp}_2\text{Fe}$  [16] they probably correspond to the forbidden in-plane bending  $\beta(\text{CH})$  vibration ( $\nu(5)$ ,  $A_{1u}$ ,  $\nu(7)$ ,  $A_{2g}$ ) which appears in the spectrum as a result of crystalline effects.

4. The relative intensity of the degenerate in-plane ring vibrations  $\nu(26)$  ( $E_{2g}$ ) and  $\nu(15)$  ( $E_{1g}$ ) in the Raman spectra are strongly affected by the metal. This fact is of special interest since for corresponding vibrations of the  $\text{C}_5\text{H}_5^-$  anion ( $E'_2$  and  $E'_1$ ), the first is allowed in the Raman spectra, whereas the second is forbidden and may appear in the spectrum only as a result of the perturbation effect of the metal. In the spectra of covalent  $\text{Cp}_2\text{Ru}$  and  $\text{Cp}_2\text{Os}$  the intensity of the  $\nu(15)$  line is considerably higher than that of the  $\nu(26)$  line. For  $\text{Cp}_2\text{Mn}$  and  $\text{Cp}_2\text{V}$  the  $\nu(26)$  line intensity by far exceeds that of  $\nu(15)$ , indicating strong ionic character of the  $\text{M}-\text{Cp}$  bond in these compounds. In  $\text{Cp}_2\text{Cr}$  spectra these lines have approximately the same intensity. It has been noted that the IR band frequency of the  $\nu(20)$  vibration ( $E_{1u}$ ) increases with the ionic character of the metal–ring bond [5]. The corresponding  $\nu(15)$  vibration has a lower frequency (1400–1410  $\text{cm}^{-1}$ ) in the  $\text{Cp}_2\text{Ru}$ ,  $\text{Cp}_2\text{Os}$  and  $\text{Cp}_2\text{Cr}$  Raman spectra than in the spectra of  $\text{Cp}_2\text{V}$  and  $\text{Cp}_2\text{Mn}$  (rose form and melt) which is in agreement with this conclusion. For the low-temperature form of  $\text{Cp}_2\text{Mn}$ , 1405 and 1425  $\text{cm}^{-1}$  frequencies are present in the vibrational spectra. This may also serve as an argument in favour of the presence of two “electron isomers” in the crystal of this compound.

5. The frequencies of the CH stretching vibrations in all compounds studied are above 3000  $\text{cm}^{-1}$ . Bands in the 2900–3000  $\text{cm}^{-1}$  region reported in [4,5] for the same compounds have not been observed in the IR or Raman spectra, and therefore, should be attributed to the decomposition products or to impurities.

We shall restrict ourselves to these comments on the vibrations of the Cp–ring. Assignment of these vibrations and the effect of the metal–ring bond on them will be discussed in a separate paper.

The low-frequency region which includes metal–ligand vibrations is of considerable interest for comparing various dicyclopentadienyl compounds. For the  $D_{5d}$  model only two vibrations are allowed in the Raman spectra:  $\nu_4$  ( $A_{1g}$ ) and  $\nu_{16}$  ( $E_{1g}$ ). Assignment of low-frequency vibrations of  $\text{Cp}_2\text{Ru}$  and  $\text{Cp}_2\text{Os}$  has been carried out in [12]. In the Raman spectra of liquid  $\text{Cp}_2\text{Mn}$  we observed lines at 212 and 141  $\text{cm}^{-1}$ , the frequencies of which are lower than those for ionic  $\text{Cp}_2\text{Mg}$  (218 and 189  $\text{cm}^{-1}$ ). Two features of the  $\text{Cp}_2\text{Mn}$  spectrum in this region should be noted:

(a) Although the ionic character of Mn—Cp in the rose and melt forms of Cp<sub>2</sub>Mn is beyond doubt and is in good agreement with the existence of five unpaired electrons [1], the Mn—Cp line intensities are very high in relation to breathing ring  $\nu(3)$  vibrations and are close to line intensities in Cp<sub>2</sub>Ru and Cp<sub>2</sub>Os.

(b) The  $\nu(4)$  line has unexpectedly a higher frequency than  $\nu(16)$ . Such frequency inversion in relation to most metallocenes is also observed for dicyclopentadienyilmagnesium [10] and nickelocene [17], but unlike the latter, in Cp<sub>2</sub>Mn and Cp<sub>2</sub>Mg the intensity of the  $\nu(4)$  line is higher, not lower, than  $\nu(16)$ . Frequency inversion can be considered as another argument in favour of the ionic structure of Cp<sub>2</sub>Mn. If the contribution of the electrostatic interaction to the metal—ring bond is considerable, it can be expected that the force constant determining the frequencies of symmetrical vibrations ( $A_{1g}$ ) should be higher than the force constant for tilting vibrations ( $E_{1g}$ ).

Mn—Cp frequencies of the brown (153 and 203 cm<sup>-1</sup>) and the rose (155 cm<sup>-1</sup>) forms are quite close to the frequencies in the melt spectra. We were unable to observe new lines in the low frequency region of the Raman spectrum, corresponding to vibrations of the "doublet" form of Cp<sub>2</sub>Mn (for Cp<sub>2</sub>Fe<sup>+</sup> the  $\nu(4)$  and  $\nu(16)$  lines are near 300 and 400 cm<sup>-1</sup> respectively). In view of the absence of such lines in the spectra studied no final conclusion can be made about this problem. Another interesting feature of the brown form of Cp<sub>2</sub>Mn as well as of Cp<sub>2</sub>Fe<sup>+</sup> is the absence, in the IR low-frequency region, of bands that could be assigned to antisymmetrical metal—ligand vibrations ( $\nu(11)$  and  $\nu(21)$ ). This fact so far has no adequate explanation.

Assignment of the low-frequency of Cp<sub>2</sub>V and Cp<sub>2</sub>Cr does not present any difficulties; strong lines of symmetrical M—Cp vibrations are observed in the Raman spectrum, and bands of antisymmetrical vibrations in the IR spectra. Low frequency shift in relation to ferrocene frequencies is in agreement with the weaker metal—ring bond in these compounds.
