#### Abstract

The $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ Raman spectra of all-trans-spheroidene and its deuterio derivatives (10-d, 12-d, 14-d, $15-\mathrm{d}$, $15^{\prime}-\mathrm{d}, 14^{\prime}-\mathrm{d}$, and $15,15^{\prime}-\mathrm{d}_{2}$ ) were recorded in $n$-hexane solution. The $\mathrm{T}_{1}$ state was generated by the use of a sensitizer, anthracene. An empirical normal-coordinate analysis of the spectral data was performed by using Urey-Bradley-Shimanouchi force field; non-UBS cross terms were also introduced. By the use of each carbon-carbon stretching force constant as a scale of bond order, large changes in bond order upon triplet excitation were identified in the central part of the conjugated chain: decrease in bond order was in the order, $\mathrm{C} 13=\mathrm{C} 14>\mathrm{C} 11=\mathrm{C} 12>\mathrm{C} 9=\mathrm{C} 10>\mathrm{C} 15=15^{\prime}$, whereas increase in bond order was in the order, $\mathrm{C} 12-\mathrm{C} 13>\mathrm{C} 14-\mathrm{C} 15 \approx \mathrm{C} 14^{\prime}-\mathrm{C} 15^{\prime}$. In other words, the triplet-excited region where the largest changes in bond order take place was located, not at the center of the entire carbon skeleton, but at the center of the conjugated chain. The $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ Raman spectra of $15-\mathrm{cis}$-spheroidene and its deuterio derivatives (12-d, $14-\mathrm{d}, 15-\mathrm{d}, 15^{\prime}-\mathrm{d}, 14^{\prime}-\mathrm{d}$ and $15,15^{\prime}-\mathrm{d}_{2}$ ) incorporated into the photoreaction center from Rhodobacter sphaeroides R26 were also recorded. The $T_{1}$ state of spheroidene was generated by excitation of bacteriochlorophyll at the $\mathrm{Q}_{x}$ absorption and subsequent triplet-energy transfer to the carotenoid. The $\mathrm{S}_{0}-$ and $\mathrm{T}_{1}$-state carboncarbon stretching force constants showed changes in bond order similar to those of all-trans-spheroidene in solution. However, empirical and normal-coordinate analysis of the $T_{1}$ Raman spectra showed twistings around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}, \mathrm{C} 13=\mathrm{C} 14$ and $\mathrm{C} 11=\mathrm{C} 12$ bonds, the values of which were temporarily estimated to be $+45^{\circ}$, $-30^{\circ}$ and $+30^{\circ}$, respectively. A hypothetical mechanism of triplet-energy dissipation triggered by rotational motion around those double bonds has been proposed.

## Introduction

The carotenoid (Car), spheroidene, in the photoreaction center (RC) of Rhodobacter (Rb.) sphaeroides plays the photoprotective function (see refs 1 and 2 for reviews). When excessive light energy is supplied, the reducing conditions cause the reverse electron transfer along the L branch, and charge recombination at the special-pair $\mathrm{BChls}(\mathrm{P})$ to generate the triplet $\left(\mathrm{T}_{1}\right)$ state. To avoid sensitized generation of singlet oxygen, the triplet energy needs to be transferred to the Car, presumably via one of the accessory BChls $\left(\mathrm{B}_{\mathrm{M}}\right)$, to be dissipated. The detailed mechanisms of the triplet-energy dissipation, in which both the

[^0]Car and the apo-peptides are apparently involved, are still unknown.

The properties of the special-pair triplet $\left({ }^{3} \mathrm{P}\right)$ and the mechanisms of the triplet-energy transfer to the Car have been extensively studied (see ref 3 for a review) by means of time-resolved electronic-absorption ${ }^{4-9}$ and EPR ${ }^{10,11}$ spectroscopies: A unique property of the $\mathrm{P} \rightarrow$ Car triplet-energy transfer is its strong temperature dependence; at room temperature, its efficiency is very high and only ${ }^{3} \mathrm{Car}$ (triplet carotenoid) is practically seen, whereas below 20 K , its efficiency drastically goes down and only ${ }^{3} \mathrm{P}$ is seen. The crucial role of $\mathrm{B}_{\mathrm{M}}$ in mediating the $\mathrm{P} \rightarrow$ Car triplet-energy transfer has been established, ${ }^{7,8,11}$ and the activation energies of the triplet-energy transfer were determined for $\mathrm{BChl} \mathbf{a}$ and its derivatives bound at the $\mathrm{B}_{\mathrm{M}}$ site. ${ }^{9}$

A unique cis configuration of the Car was first identified in this organism by resonance-Raman spectroscopy. ${ }^{12}$ The configuration of spheroidene in the RC from $R b$. sphaeroides has
been determined to be 15 -cis by resonance-Raman, ${ }^{13,14} \mathrm{CD}^{15}$ and NMR ${ }^{16-18}$ spectroscopies, and by X-ray crystallography. ${ }^{19,20}$ The distortion of the conjugated backbone of those Cars upon binding to the RCs has been identified by Raman spectroscopy. ${ }^{16,21-23}$

The particular 15 -cis configuration has been ubiquitously found not only in the quinone-type RCs of other purple photosynthetic bacteria i.e., Rb. sphaeroides G1C ${ }^{21}$ and Rhodospirillum rubrum $\mathrm{S} 1,{ }^{24}$ and that of spinach PS II, ${ }^{25}$ but also in the ion sulfur-type RCs of a green bacterium, Chlorobium tepidum, ${ }^{26}$ an alga, Synechococcus vulcanus, ${ }^{26}$ and spinach PS I. ${ }^{27}$ Because the photoprotective function is expected to be most crucial in the RC, it is natural to correlate the natural selection of the 15 -cis configuration, during the history of the photosynthetic organism, to this particular function, and to address a question: Why has the 15 -cis configuration been selected by the RCs (see refs 2 and 28 for reviews)?

Comparison among a set of cis-trans isomers in solution may provide information concerning the unique $\mathrm{T}_{1}$-state properties of the 15 -cis configuration: A set of cis-trans isomers of $\beta$-carotene was examined by time-resolved Raman ${ }^{29}$ and absorption ${ }^{30}$ spectroscopies and by determination of tripletsensitized isomerization. ${ }^{31}$ The results indicated that the presence of extremely rapid 15 -cis to all-trans isomerization in the $\mathrm{T}_{1}$ state (the 15 -cis $\mathrm{T}_{1}$ is too short-lived to be detected) with a quantum yield of almost unity (see ref 32 for a review). Most recently, a set of cis-trans isomers of spheroidene was examined by time-resolved absorption spectroscopy and determination of the quantum yield of triplet-sensitized isomerization. ${ }^{33}$ All the cis isomers exhibited the $\mathrm{T}_{1} \rightarrow \mathrm{~S}_{0}$ intersystem crossing six times faster than the all-trans isomer, and the $\mathrm{T}_{1}$-state isomerization was the fastest in the 15 -cis isomer. The results strongly suggested that the 15 -cis isomer is most advantageous in dissipating the triplet energy.

The above pair of comparison of isomeric carotenoids has lead us to propose a hypothetical mechanism of triplet-energy dissipation, which includes rotation around the 15 -cis bond of the RC-bound spheroidene. ${ }^{23,34}$ The key idea behind this hypothetical mechanism is that the rotation around a carboncarbon double bond causes a change in the orbital angular momentum around the carbon atoms, and as a result, a change in the spin angular momentum to enhance the $\mathrm{T}_{1} \rightarrow \mathrm{~S}_{0}$ intersystem crossing (relaxation) accompanying the triplet-energy dissipation.

The structure of the RC-bound 15-cis-spheroidene in the $\mathrm{T}_{1}$ state should provide further insight into the mechanism of tripletenergy dissipation: Transient resonance-Raman spectroscopy showed that a cis configuration was retained in the $\mathrm{T}_{1}$ state, ${ }^{35}$ although enormous enhancement of some Raman lines strongly suggested the twisting of the conjugated backbone. ${ }^{23}$ The twisting around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ cis bond seemed to support the above hypothetical mechanism. Prolonged irradiation actually caused the generation of the all-trans isomer. ${ }^{23}$

This mechanism has been questioned by incorporating locked-$15,15^{\prime}$-cis-spheroidene (hereafter called "locked 15-cis-spheroidene") into the RC of Rb. sphaeroides: ${ }^{36}$ locking the 15 -cis configuration by introducing additional single bonds did not substantially change the decay time of the $\mathrm{T}_{1}$ Car. This question needs to be answered before establishing the above hypothetical mechanism. In the present investigation, we have tried to extract the structural information of (unlocked) 15-cis-spheroidene bound to the RC from Rb. sphaeroides, in both the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ states, by means of transient-Raman spectroscopy and normalcoordinate analysis of spheroidene and its deuterio derivatives
incorporated into the RC from the Rb. sphaeroides R 26. The results have provided us with deeper insight into the mechanisms of triplet-energy dissipation.

The $S_{0}$ Raman spectra of $d_{0}$ and deuterio spheroidenes in solution and bound to the RC have been presented and analyzed empirically in relation to the structure of spheroidene in the $\mathrm{S}_{0}$ state. ${ }^{37}$ The present investigation is based on the normalcoordinate analysis of the $S_{0}$ and $T_{1}$ Raman spectra, and focuses on the $\mathrm{T}_{1}$-state structures and the mechanisms of triplet-energy dissipation by the RC-bound Car.

## Experimental Section

Sample Preparation. (a) All-trans-Spheroidene and its Deuterio Derivatives. All-trans-spheroidene of natural-abundance isotopic composition (hereafter called " $\mathrm{d}_{0}$ spheroidene") was prepared as described previously. ${ }^{38}$ All-trans-deuterio spheroidenes including $10-\mathrm{d}, 12-\mathrm{d}, 14-\mathrm{d}, 14^{\prime}-\mathrm{d}, 15-\mathrm{d}, 15^{\prime}-\mathrm{d}$ and $15,15^{\prime}-\mathrm{d}_{2}$ spheroidenes were prepared by the methods described previously. ${ }^{39}$ (b) Preparation of the RCs from $R b$. sphaeroides Containing $d_{0}$ and Deuterio Spheroidenes. The RC containing $\mathrm{d}_{0}$ spheroidene was prepared by (i) solubilization of the chromatophores (25000-278000 $\times g$ fraction) from $R b$. sphaeroides 2.4.1 with LDAO in the presence of 150 mM NaCl , (ii) ammonium sulfate precipitation, and (iii) DE52 ion-exchange column chromatography using stepwise elution with 50-200 mM NaCl according to the method of Cogdell and Parson. ${ }^{4,40}$ The RCs containing deuterio spheroidenes were obtained by their incorporation ${ }^{41}$ into the RC from Rb. sphaeroides $\mathrm{R} 26,{ }^{42}$ the spheroidene: RC ratio being 15:1. We found that iodinesensitized photoisomerization ${ }^{38}$ of each all-trans-spheroidene in advance greatly enhanced the efficiency of incorporation. The amounts of incorporation of $12-\mathrm{d}, 14-\mathrm{d}, 14^{\prime}-\mathrm{d}, 15-\mathrm{d}, 15^{\prime}-\mathrm{d}$, and $15,15^{\prime}-\mathrm{d}_{2}$ spheroidenes into the RC for $\mathrm{S}_{0} / \mathrm{T}_{1}$ Raman measurements were $98 / 98,78 / 88,78 / 88,76 / 85,87 / 82$, and $80 / 86 \%$, respectively.

Raman Measurements. (a) $S_{0}$ Raman Measurements. The Raman spectra of $\mathrm{d}_{0}$ and deuterio all-trans-spheroidenes in the $\mathrm{S}_{0}$ state were recorded in $n$-hexane solution $\left(0.2-5.0 \times 10^{-4}\right.$ M) at liquid nitrogen temperature by the use of the CW 488.0 nm line $(7-14 \mathrm{~mW})$ of an $\mathrm{Ar}^{+}$laser (Lexel 95) and a Raman spectrometer (JASCO TRS-300) equipped with an imageintensified diode-array detector (Princeton Instruments IRY700). The Raman spectrum of $d_{0}$ and deuterio spheroidenes incorporated into the RC from $R b$. sphaeroides R26 was measured by the use of the CW 514.5 nm line, instead. No spectral smoothing was performed. The Raman frequencies were calibrated against those of acetone, benzene, ethyl acetate, $n$-hexane, and toluene.
(b) $T_{1}$ Raman Measurements. The Raman spectra of $\mathrm{d}_{0}$ and deuterio all-trans-spheroidenes in $n$-hexane solution (1.3-5.0 $\left.\times 10^{-5} \mathrm{M}\right)$ were recorded in the presence of a triplet sensitizer, anthracene $(60-100$ fold), by the use of a pump-probe technique described previously ${ }^{29}$ with the following modifications: The 355 nm pulses (power $5.0 \mathrm{~mJ} /$ pulse, duration 6 ns , and repetition 10 Hz ) from a Nd:YAG laser (Lumonics HY400) were used for pumping, whereas the 532 nm pulses ( 2 $\mathrm{mJ} / \mathrm{pulse}, 5 \mathrm{~ns}$ and 10 Hz ) from a Nd:YAG laser (Spectron SL284G) were used for probing. The pump and probe pulses coaxially irradiated a flat jet stream of the sample solution from an angle of $45^{\circ}$, and $90^{\circ}$ Raman scattering was collected. The delay time between the pump and probe pulses was set to be $1.0 \mu \mathrm{~s}$ by the use of a high-voltage pulse generator (Princeton Instruments, FG-100). The Raman scattering was detected by the above image-intensified diode-array detector, which was

Figure 1. Chemical structure and models of spheroidene: (a) Chemical structure and the numbering of skeletal carbon atoms of spheroidene, (b) the bond lengths and (c) the bond angles of the model used for the normal-coordinate analysis of all-trans-spheroidene in solution, and (d) the twistings of the conjugated backbone of the model used for the normal-coordinate analysis of $\mathrm{T}_{1} 15$-cis-spheroidene bound to the RC (the same bond lengths and bond angles as the model of all-trans-spheroidene were assumed). Twisting around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond by $30^{\circ}$ alone was assumed in the $\mathrm{S}_{0}$ state (not shown).
gated for $3.5 \mu$ s by the use of a delay-pulse generator (Stanford Research Systems DG-535). A T $T_{1}$ Raman spectrum was obtained as a difference spectrum of "with pump" minus "without pump" after subtracting the Raman lines of the solvent, $n$-hexane, from each spectrum. For the $T_{1}$ Raman spectra of $10-\mathrm{d}, 12-\mathrm{d}, 14-\mathrm{d}$, $15-\mathrm{d}, 15^{\prime}-\mathrm{d}$ spheroidenes, spectral smoothing was performed. The purity of each sample examined by HPLC using a detection wavelength of 450 nm , before/after the $\mathrm{T}_{1}$ Raman measurement, was as follows: $\mathrm{d}_{0}, 97 / 95$; 10-d, 100/-; 12-d, 100/91; $14-d, 88 / 75 ; 14^{\prime}-d, 62 / 54$; $15-\mathrm{d}, 80 / 74 ; 15^{\prime}-d, 75 / 60 ; 15,15^{\prime}-\mathrm{d}_{2}$, 99/87\%.

The Raman spectra of $d_{0}$ spheroidene in wild-type RC and deuterio spheroidenes incorporated into carotenoidless RC were recorded by the method of Ohashi et al. ${ }^{23}$ except for the following modifications due to the limited amounts of deuterio spheroidenes: the sample concentrations were reduced to $\mathrm{OD}_{800}$ $11-18 \mathrm{~cm}^{-1}$, and the power of pump pulses ( $600 \mathrm{~nm}, 5 \mathrm{~ns}$ and 10 Hz ) and that of probe pulses ( $532 \mathrm{~nm}, 6 \mathrm{~ns}$ and 10 Hz ) were increased to $3.0 \mathrm{~mJ} /$ pulse and $0.75-1.5 \mathrm{~mJ} /$ pulse, respectively.

Normal-Coordinate Analysis. Figure 1a shows the entire chemical structure of all-trans-spheroidene, and Figure 1b-d
shows the models of all-trans- and 15-cis-spheroidenes that were used for normal-coordinate analyses. One peripheral group beyond C 1 and the other peripheral group beyond $\mathrm{C} 7^{\prime}$ were truncated, and replaced by a pair of mass units of 15 . The bond lengths and the bond angles concerning the carbon skeleton were estimated based on the structure of $\beta$-carotene determined by X-ray crystallography; ${ }^{43}$ the methyl and olefinic $\mathrm{C}-\mathrm{H}$ bond lengths were set to be 1.095 and $1.08 \AA$, respectively. Completely planar conformations were assumed for the all-trans isomer in solution in both the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ states. For the 15 -cis isomer bound to the RC , the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond was twisted by $+30^{\circ}$ in the $\mathrm{S}_{0}$ state, whereas the $\mathrm{C} 15=\mathrm{C} 15^{\prime}, \mathrm{C} 13=\mathrm{C} 14$ and $\mathrm{C} 11=\mathrm{C} 12$ bonds were twisted by $+45^{\circ},-30^{\circ}$ and $+30^{\circ}$, respectively, in the $T_{1}$ state (vide infra).

In the present normal-coordinate analyses, we used Urey-Bradley-Shimanouchi (UBS) force field expressed by the force constants of stretching $(K)$, bending $(H)$, nonbonded repulsion $(F)$, intramolecular resistance force $(\kappa)$, wagging $(W)$, and torsion (T). Non-UBS cross terms including the stretching-stretching $(k)$, bending-bending ( $h$ ), and wagging-wagging ( $w$ ) cross terms were also introduced. In 15-cis-spheroidene, additional cross terms ( $k h$ ) between (1) the $\mathrm{C} 14-\mathrm{C} 15$ and $\mathrm{C} 14^{\prime}-\mathrm{C}^{\prime} 5^{\prime}$

Figure 2. $\mathrm{S}_{0}$ Raman spectra (488 nm probe) and the $\mathrm{T}_{1}$ Raman spectra ( 532 nm probe) of $\mathrm{d}_{0}$ and various deuterio all-trans-spheroidenes in $n$-hexane solution. The $\mathrm{T}_{1}$ state of spheroidene was generated by excitation of anthracene (sensitizer) at 355 nm and subsequent tripletenergy transfer to the Car.
stretchings and (2) the $\mathrm{C} 14-\mathrm{H}, \mathrm{C} 15-\mathrm{H}$ and $\mathrm{C}^{\prime} 5^{-}-\mathrm{H}$ bendings within the 15 -cis bend were introduced. The Normal vibrations were calculated by Wilson's GF-matrix method ${ }^{44}$ using programs BGLZ, LSMB, and LXZ originally written in Prof. Takehiko Shimanouchi's laboratory. ${ }^{45}$

## Results

Empirical Assignments of the $S_{0}$ and $T_{1}$ Raman Lines of $\mathbf{d}_{0}$ Spheroidenes Based on Deuteration Effects. (a) All-transSpheroidene in Solution. Figure 2 shows the Raman spectra of all-trans-spheroidene in $n$-hexane solution in both the $\mathrm{S}_{0}$ and the $\mathrm{T}_{1}$ states. Table 1a summarizes a set of empirical assignments for the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ Raman lines of $\mathrm{d}_{0}$ all-trans-spheroidene, the details of which will be described below according to the following order of appearance in the spectral region of 1600$900 \mathrm{~cm}^{-1}$ : (1) the $\mathrm{C}=\mathrm{C}$ stretchings ( $1600-1500 \mathrm{~cm}^{-1}$ ), (2) the methyl in-plane (ip) asymmetric and symmetric deformations ( $\sim 1450$ and $1390 \mathrm{~cm}^{-1}$, respectively), (3) the $\mathrm{C}-\mathrm{H}$ ip bendings $\left(1300-1250 \mathrm{~cm}^{-1}\right)$, (4) the $\mathrm{C}-\mathrm{C}$ stretchings (1250-1100 $\mathrm{cm}^{-1}$ ), (5) the methyl ip rockings ( $1010-1000 \mathrm{~cm}^{-1}$ ), and (6) the $\mathrm{C}-\mathrm{H}$ out-of-plane (op) waggings ( $960-940 \mathrm{~cm}^{-1}$ ). (Hereafter, we will omit "ip" and "op" except when they are

necessary.) Those vibrational modes in which the displacements of atoms are in accord with those upon the $1^{1} \mathrm{~B}_{\mathrm{u}}{ }^{+} \leftarrow 1^{1} \mathrm{~A}_{\mathrm{g}}{ }^{-}$ $(\sim 480 \mathrm{~nm})$ and the $n^{3} \mathrm{~A}_{\mathrm{g}}{ }^{+} \leftarrow 1^{3} \mathrm{~B}_{\mathrm{u}}{ }^{+}(\sim 505 \mathrm{~nm}) \pi-\pi^{*}$ transitions should give rise to strong or medium resonance-Raman lines in the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ states when probed at 488 and 532 nm , respectively. Thus, all the observed Raman lines are ascribable to the normal modes which are associated with the conjugated chain.

Spectral changes upon deuteration are useful in assigning the Raman lines of $\mathrm{d}_{0}$ spheroidene: In a planar conjugated chain, an ip $\mathrm{C}-\mathrm{H}$ bending vibration can couple with the $\mathrm{C}=\mathrm{C}$ stretching and the $\mathrm{C}-\mathrm{C}$ stretching vibrations appearing on the higher- and the lower-frequency-sides, and as a result, push (through the coupling) the former to the higher frequencies and the latter to the lower frequencies. Upon replacement of an olefinic proton by a deuterium, the above coupling is removed (the $\mathrm{C}-\mathrm{D}$ bending vibration shifts all the way down to below $950 \mathrm{~cm}^{-1}$ ), and the low-frequency-shift (high-frequency-shift) of the relevant $\mathrm{C}=\mathrm{C}(\mathrm{C}-\mathrm{C})$ stretching Raman line takes place. Therefore, the deuteration of each olefinic H facilitates assignments of the coupled $\mathrm{C}=\mathrm{C}$ and $\mathrm{C}-\mathrm{C}$ stretchings. It is to be noted that all the $\mathrm{C}=\mathrm{C}$ and $\mathrm{C}-\mathrm{C}$ stretchings and the $\mathrm{C}-\mathrm{H}$ bendings, which take place within a planar polyene skeleton terminated by a pair of methyl groups on both ends, can couple with one another. This type of coupling among ip modes is also useful to probe the planarity of the conjugated chain.

Assignments of the $S_{0}$ Raman Lines. (1) The strongest Raman line at $1529 \mathrm{~cm}^{-1}$ can be assigned to a set of $\mathrm{C}=\mathrm{C}$ stretchings coupled in-phase (the $\mathrm{a}_{\mathrm{g}}$-type mode). The low-frequency shifts upon the $10-\mathrm{d}, 12-\mathrm{d}, 14-\mathrm{d}, 15-\mathrm{d}, 14^{\prime}-\mathrm{d}$, and $15^{\prime}-\mathrm{d}$ substitutions
are $4,15,5,10,3$, and $8 \mathrm{~cm}^{-1}$, respectively. The results suggest that the stretchings of the double bonds in the central part of the conjugated chain are coupled with one another (see Figure $1)$. Similar shifts upon the $14-\mathrm{d}$ and $14^{\prime}$-d substitutions ( 5 and $3 \mathrm{~cm}^{-1}$ ) as well as those upon the $15-\mathrm{d}$ and $15^{\prime}-\mathrm{d}$ substitutions ( 10 and $8 \mathrm{~cm}^{-1}$ ) strongly suggest that the atomic displacements in this particular mode are symmetric with respect to the $\mathrm{C} 15=\mathrm{C}^{\prime} 5^{\prime}$ bond. (2) The 1445 and $1391 \mathrm{~cm}^{-1}$ Raman lines can be assigned to the methyl asymmetric and symmetric deformations, respectively, based on their frequency and intensity. (3) A pair of weak but distinct Raman lines at 1293 and $1281 \mathrm{~cm}^{-1}$ can be associated with the $\mathrm{C} 11-\mathrm{H}$ and $\mathrm{C} 11^{\prime}-\mathrm{H}$ bendings, because they change spectral patterns substantially upon the $10-\mathrm{d}$ and $12-\mathrm{d}$ substitutions, but very little upon other deuterations. (4) It was shown, in all-trans- $\beta$ carotene, that the stretching between the methylated and unmethylated carbon atoms in the conjugated chain is higher in frequency than that between a pair of unmethylated carbon atoms. ${ }^{46,47}$ The weak $1210 \mathrm{~cm}^{-1}$ Raman line splits into two components upon the 12-d substitution; one component upshifts to $1235 \mathrm{~cm}^{-1}$ and the other component stays at $1212 \mathrm{~cm}^{-1}$. Upon the $14-\mathrm{d}$ and $14^{\prime}$-d substitutions, it shifts to as high as to be overlapped with the $\mathrm{C} 11-\mathrm{H}$ bending Raman lines mentioned above ( $\sim 1280 \mathrm{~cm}^{-1}$ ). Therefore, the $1210 \mathrm{~cm}^{-1}$ Raman line can be assigned to an overlap of coupled vibrations, i.e., one, the $\mathrm{C} 12-\mathrm{C} 13$ stretching which is coupled with the $\mathrm{C} 12-\mathrm{H}$ and $\mathrm{C} 14-\mathrm{H}$ bendings and the other, the $\mathrm{C} 12^{\prime}-\mathrm{C} 13^{\prime}$ stretching which is coupled with the $\mathrm{C} 12^{\prime}-\mathrm{H}$ and $\mathrm{C} 14^{\prime}-\mathrm{H}$ ip bendings. The other weak $1191 \mathrm{~cm}^{-1}$ Raman line shifts to $1278 \mathrm{~cm}^{-1}$ upon the $10-\mathrm{d}$ substitution, but no clear spectral changes are seen upon other deuterations. Therefore, the Raman line can be assigned to the $\mathrm{C} 8-\mathrm{C} 9$ stretching coupled with the $\mathrm{C} 10-\mathrm{H}$ bending. It was also shown ${ }^{46,47}$ that the $\mathrm{C}-\mathrm{C}$ stretchings coupled in-phase taking place in the central part of a long conjugated chain give rise to strong resonance-Raman lines: The second strongest Raman line at $1161 \mathrm{~cm}^{-1}$ splits into a peak at $1169 \mathrm{~cm}^{-1}$ and a shoulder at $1160 \mathrm{~cm}^{-1}$ upon the $10-\mathrm{d}$ substitution, and widely splits into a pair of Raman lines at 1169 and $1159 \mathrm{~cm}^{-1}$ upon the $12-\mathrm{d}$ substitution. The results indicate a strong contribution of the C10-C11 stretching (which can couple with the C10-H and the C12-H bendings) to this Raman mode. Upon the $15-\mathrm{d}$ and $15^{\prime}$-d substitutions, a part of this $1161 \mathrm{~cm}^{-1}$ Raman line seems to upshift to 1233 and $1236 \mathrm{~cm}^{-1}$, respectively, and the remaining component splits into two components (1166 and $1154 \mathrm{~cm}^{-1}$ and 1168 and $1158 \mathrm{~cm}^{-1}$, respectively). This indicates the contribution of the $\mathrm{C} 14-\mathrm{C} 15$ and the $\mathrm{C} 14^{\prime}-\mathrm{C} 15^{\prime}$ stretchings as well; similar spectral changes upon the $15-\mathrm{d}$ and $15^{\prime}$-d substitutions indicate that the atomic displacements in this particular mode are symmetric with respect to the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond. (5) The strong $1004 \mathrm{~cm}^{-1}$ Raman line can be assigned to the methyl rocking vibration based on its frequency and intensity referring to the cases of all-trans- $\beta$-carotene ${ }^{46,47}$ and all-transretinal. ${ }^{48}$ (6) The $959 \mathrm{~cm}^{-1}$ Raman line can be assigned to a $\mathrm{C}-\mathrm{H}$ wagging vibrations coupled with the $\mathrm{C}=\mathrm{C}$ torsion.
Assignments of $T_{l}$ Raman Lines. (1) The strongest Raman line at $1500 \mathrm{~cm}^{-1}$ can be assigned to the $\mathrm{C}=\mathrm{C}$ stretchings localized on the $\mathrm{C} 11=\mathrm{C} 12$ and $\mathrm{C} 13=\mathrm{C} 14$ bonds. It shifts to $1491 \mathrm{~cm}^{-1}$ upon both the $10-\mathrm{d}$ and $12-\mathrm{d}$ substitutions, a fact which indicates the contribution of the $\mathrm{C} 11=\mathrm{C} 12$ stretching. The downshifts of this Raman line upon the 14-d and 15-d substitutions ( -8 and $-2 \mathrm{~cm}^{-1}$ ) are larger than those upon the $14^{\prime}-\mathrm{d}$ and $15^{\prime}-\mathrm{d}$ substitutions ( +4 and $-1 \mathrm{~cm}^{-1}$ ), a fact which indicates a contribution of the $\mathrm{C} 13=\mathrm{C} 14$ stretching rather than that of the $\mathrm{C} 13^{\prime}=\mathrm{C} 14^{\prime}$ stretching. (2) The $1450 \mathrm{~cm}^{-1}$ Raman

Figure 3. $S_{0}$ Raman spectra ( 514.5 nm probe) and the $T_{1}$ Raman spectra ( 532 nm probe) of $\mathrm{d}_{0}$ and various deuterio 15-cis-spheroidenes bound to the RC. The $\mathrm{T}_{1}$ state of spheroidene was generated by excitation of bacteriochlorophyll at 600 nm and subsequent tripletenergy transfer to the Car.
line on the shoulder and the weak $1352 \mathrm{~cm}^{-1}$ Raman line can be assigned to the methyl asymmetric and symmetric deformations, respectively. (3) A Raman line at $1268 \mathrm{~cm}^{-1}$ can be associated with the $\mathrm{C}-\mathrm{H}$ ip bendings. Apparent changes in the Raman line upon the $10-\mathrm{d}$ and $12-\mathrm{d}$ substitutions suggest the contributions of the $\mathrm{C} 10-\mathrm{H}$ and $\mathrm{C} 12-\mathrm{H}$ bendings. (4) The strong $1165 \mathrm{~cm}^{-1}$ Raman line can be assigned to a vibration in which the $\mathrm{C} 10-\mathrm{C} 11$ and $\mathrm{C} 14-\mathrm{C} 15$ stretchings are coupled with each other, because it substantially upshifts upon the $10-\mathrm{d}$ ( 8 $\mathrm{cm}^{-1}$ ), 12-d ( $8 \mathrm{~cm}^{-1}$ ), 14-d ( $6 \mathrm{~cm}^{-1}$ ) and $15-\mathrm{d}\left(6 \mathrm{~cm}^{-1}\right)$ substitutions, but hardly affected by the $14^{\prime}$-d and $15^{\prime}$-d substitutions. The medium $1112 \mathrm{~cm}^{-1}$ Raman line on the shoulder that upshifts upon the $12-\mathrm{d}, 14-\mathrm{d}, 15-\mathrm{d}, 15^{\prime}-\mathrm{d}$, and $14^{\prime}$-d substitutions ( $6,24,7,10,3$, and $16 \mathrm{~cm}^{-1}$, respectively) can be assigned to a delocalized coupled mode extending the entire region from the $\mathrm{C} 10-\mathrm{C} 11$ to the $\mathrm{C} 14^{\prime}-\mathrm{C} 15^{\prime}$ bond. (5)(6) The $1006 \mathrm{~cm}^{-1}$ and the $944 \mathrm{~cm}^{-1}$ Raman lines can be assigned to the methyl ip rocking and the $\mathrm{C}-\mathrm{H}$ wagging vibrations, respectively, as in the case of the $S_{0}$ state.
(b) 15-cis-Spheroidene Bound to the RC. Figure 3 shows the Raman spectra of 15 -cis-spheroidene bound to the RC in both the $S_{0}$ and $T_{1}$ states. Table 1 b summarizes a set of empirical assignments, the details of which will be described below. Assignment of the $S_{0}$ Raman lines. (1) The strongest Raman profile above $1530 \mathrm{~cm}^{-1}$ can be regarded as an overlap of two components: One at $1534 \mathrm{~cm}^{-1}$ is a coupled mode of the $\mathrm{C} 11=\mathrm{C} 12, \mathrm{C} 13=\mathrm{C} 14$ and $\mathrm{C}_{1} 3^{\prime}=\mathrm{C} 14^{\prime}$ stretchings that
downshift upon the $12-\mathrm{d}, 14-\mathrm{d}$ and $14^{\prime}$-d substitutions to 1520 , 1528 and $1530 \mathrm{~cm}^{-1}$, respectively, because of decoupling from the $\mathrm{C} 12-\mathrm{H}, \mathrm{C} 14-\mathrm{H}$ and $\mathrm{C} 14^{\prime}-\mathrm{H}$ bendings. The other at 1532 $\mathrm{cm}^{-1}$ is the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ stretching that downshifts upon the 15d, $15^{\prime}-$ d and $15,15^{\prime}-\mathrm{d}_{2}$ substitutions to as low as 1517,1515 and $1500 \mathrm{~cm}^{-1}$ because of decoupling from the $\mathrm{C} 15-\mathrm{H}$ and C15' ${ }^{\prime}$ H bendings. (2) The $1445 \mathrm{~cm}^{-1}$ Raman line can be assigned to the methyl asymmetric deformation as in the case of $\mathrm{d}_{0}$ all-trans-spheroidene. (3) The weak $1288 \mathrm{~cm}^{-1}$ Raman line which is not so affected by all the present deuterium substitutions can be temporarily associated with the $\mathrm{C} 11-\mathrm{H}$ and $\mathrm{C} 11^{\prime}-\mathrm{H}$ bendings (no $11-\mathrm{d}$ or $11^{\prime}-\mathrm{d}$ spheroidenes are now available). The medium Raman line at $1239 \mathrm{~cm}^{-1}$ can be assigned to the key Raman line of the 15 -cis configuration that has been identified in $\beta$-carotene ${ }^{46,47}$ and other carotenoids. ${ }^{28}$ It is due to the $\mathrm{C} 15-\mathrm{H}$ and $\mathrm{C} 15^{\prime}-\mathrm{H}$ ip bendings coupled with the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ stretching in the 15 -cis configuration. It is almost unaffected by the $12-\mathrm{d}, 14-\mathrm{d}$ and $14^{\prime}$-d substitutions, but substantially decreased in intensity upon the $15-\mathrm{d}, 15^{\prime}$-d and $15,15^{\prime}-\mathrm{d}_{2}$ substitutions (the remaining component may be due to another normal mode). (4) A pair of weak Raman lines at 1212 and $1190 \mathrm{~cm}^{-1}$ can be assigned to the $\mathrm{C} 12-\mathrm{C} 13$ and the $\mathrm{C} 8-\mathrm{C} 9$ stretchings as in the case of $\mathrm{d}_{0}$ all-trans-spheroidene. One of the medium Raman lines at $1168 \mathrm{~cm}^{-1}$, which is unaffected by the $12-\mathrm{d}, 14-\mathrm{d}$, and $14^{\prime}-\mathrm{d}$ substitutions but disappears upon the $15-\mathrm{d}$ and $15,15^{\prime}-\mathrm{d}_{2}$ substitutions, can be assigned to the $\mathrm{C} 14-\mathrm{C} 15$ stretching coupled with the $\mathrm{C} 15-\mathrm{H}$ bending. The other medium Raman line at $1159 \mathrm{~cm}^{-1}$, which disappears upon the $12-$ d substitution and remains unaffected upon other deuterium substitutions, can be assigned to the C10-C11 stretching. (5)(6) The $1001 \mathrm{~cm}^{-1}$ Raman line can be assigned to the methyl ip rockings, whereas the 973 and 954 $\mathrm{cm}^{-1}$ Raman lines to the $\mathrm{C}-\mathrm{H}$ waggings.

Assignments of $T_{l}$ Raman lines. (1) A pair of strong Raman lines appear in the $\mathrm{C}=\mathrm{C}$ stretching region: The $1526 \mathrm{~cm}^{-1}$ Raman line, which disappears upon the 12 -d substitution but remains with reduced intensity in other deuterium substitutions, can be assigned to the $\mathrm{C} 11=\mathrm{C} 12$ stretching coupled with the C12-H deformation. The other $1505 \mathrm{~cm}^{-1}$ Raman line which downshifts by 13 and $8 \mathrm{~cm}^{-1}$ upon the 14 -d and $15-\mathrm{d}$ substitutions can be associated with the $\mathrm{C} 13=\mathrm{C} 14$ and $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ stretchings coupled with the relevant $\mathrm{C}-\mathrm{H}$ bendings. The contribution of the $\mathrm{C} 13=\mathrm{C} 14$ stretching and the $\mathrm{C} 14-\mathrm{H}$ bending may be the strongest. (2)(3) None of the methyl deformation and the $\mathrm{C}-\mathrm{H}$ bending modes appear in the spectrum. (4) Another pair of strong Raman lines appears in the $\mathrm{C}-\mathrm{C}$ stretching region: The $1182 \mathrm{~cm}^{-1}$ Raman line, which disappears upon the $12-\mathrm{d}$ substitution but remains in a similar frequency region upon other substitutions (as a higher-frequency component) can be assigned to the $\mathrm{C} 10-\mathrm{C} 11$ stretching. The 1156 $\mathrm{cm}^{-1}$ Raman line, which disappears upon the $15-\mathrm{d}$ and $15,15^{\prime}$ $\mathrm{d}_{2}$ substitutions but remains unaffected by other deuterations, can be assigned to the $\mathrm{C} 14-\mathrm{C} 15$ stretching.

Unique features of the $\mathrm{T}_{1}$ Raman spectrum of the RC-bound 15 -cis-spheroidene is the enormous intensity enhancement of the methyl rocking and the $\mathrm{C}-\mathrm{H}$ wagging Raman lines as well as the disappearance of the methyl deformation and the $\mathrm{C}-\mathrm{H}$ bending Raman lines. This strongly suggests a substantial twisting of the conjugated chain upon the $\mathrm{T}_{n} \leftarrow \mathrm{~T}_{1}$ transition. The disappearance of the key Raman line of the 15 -cis configuration at $1239 \mathrm{~cm}^{-1}$ and the appearance of a weak feature around $1335 \mathrm{~cm}^{-1}$ suggest the presence of substantial twisting around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond upon triplet excitation of the RCbound spheroidene (vide infra).

Sets of assignments for various deuterio spheroidenes of the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ Raman lines for the all-trans isomer in $n$-hexane solution and the 15 -cis isomer bound to the RC have also been obtained (data not shown).

Normal-Coordinate Analyses. (a) All-trans-Spheroidenes in Solution. Determination of Force Constants in the $S_{0}$ and $T_{1}$ States. The $\mathrm{S}_{0}$-state force constants were determined as follows: A set of force constants determined by Saito and Tasumi ${ }^{46}$ for all-trans- $\beta$-carotene was initially transferred (force constants in the peripheral parts were transferred from other molecules). Then, most of the UBS force constants and non-UBS cross terms were adjusted to fit the frequencies and the empirical assignments of the observed Raman lines of all the $\mathrm{d}_{0}$ and deuterio spheroidenes. The fixed and adjusted force constants are shown in Table 2 in Roman and italic, respectively. No attempts were made either to fit the frequencies of the methyl deformations and rockings or to fit those of the $\mathrm{C}-\mathrm{D}$ bendings. The $\mathrm{L}_{x}$ matrix showing the replacements of atoms was used to choose those normal modes which are supposed to give rise to resonanceRaman intensity; in particular, extended skeletal modes taking place in the central part of the conjugated chain were selected as strongly-Raman active modes. The number of observed Raman lines used for fitting was 71, whereas the number of force constants determined was 57 .

In the $\mathrm{T}_{1}$ state, only the $\mathrm{C} 9=\mathrm{C} 10, \mathrm{C} 10-\mathrm{C} 11, \mathrm{C} 11=\mathrm{C} 12$, $\mathrm{C} 12-\mathrm{C} 13, \mathrm{C} 13=\mathrm{C} 14, \mathrm{C} 14-\mathrm{C} 15, \mathrm{C} 15=\mathrm{C}_{15}{ }^{\prime}$, and $\mathrm{C} 14^{\prime}-\mathrm{C} 15^{\prime}$ stretching force constants and the relevant stretching-stretching and bending-bending cross terms were adjusted because of the limited number of deuterio species and observed Raman lines. The rest of the force constants was assumed to be the same as those in the $S_{0}$ state. Here again, the adjustment of those force constants was performed to fit the calculated frequencies and Raman-active normal modes to the observed frequencies and the empirical assignments for all the $\mathrm{d}_{0}$ and deuterio spheroidenes.

Table 2 lists the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ force constants which have been determined as the results of the above normal-coordinate analysis (shown in italic). Figure 4 compares the observed and the calculated frequencies for $\mathrm{d}_{0}$ and various deuterio all-transspheroidenes. Agreement between the observed and the calculated frequencies are satisfactory in both the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ states with the exception of those of the $\mathrm{C}-\mathrm{D}$ bendings whose frequencies were not adjusted at all (below around $950 \mathrm{~cm}^{-1}$ ). Thus, the $\mathrm{C}=\mathrm{C}$ and the $\mathrm{C}-\mathrm{C}$ stretching force constants determined are considered to be reliable enough to use as a scale of the carbon-carbon bond orders (vide infra).

Normal Modes in the $S_{0}$ and $T_{1}$ States. Table 3a lists the calculated frequencies and the normal modes of $\mathrm{d}_{0}$ all-transspheroidene in solution in both the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ states. (Those of various deuterio all-trans-spheroidenes are shown in Table 1S of "Supporting Information available".) Each normal mode has been characterized in the table by referring to both the potential energy distribution (p.e.d.) and the $\mathrm{L}_{x}$ matrix. The empirical assignments based on the apparent changes in the spectral pattern upon various deuterations (Table 1a) are now confirmed, in general, and the normal modes have been more specifically determined by the present normal-coordinate analysis.

Close examination of Table 3a reveals that the normal modes in the $\mathrm{S}_{0}$ state tend to be symmetric with respect to the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond, whereas those in the $\mathrm{T}_{1}$ state tend to be localized on the left-hand-side of the molecule shown in Figure 1a: In the $\mathrm{S}_{0}$ state, the $1445 \mathrm{~cm}^{-1}$ Raman line is assigned to the 13 Me and $13^{\prime} \mathrm{Me}$ asymmetric deformations, and the 1004 $\mathrm{cm}^{-1}$ Raman line to the 13 Me and $13^{\prime} \mathrm{Me}$ rockings; each pair

#### Abstract

${ }^{a}$ UBS force constants are abbreviated as follows: $K$, stretching; $H$, bending; $F$, nonbonded repulsion; $W$, out-of-plane wagging; $T$, torsion; and $\kappa$, intramolecular resistant force. The units of force constants are $\mathrm{md} \cdot \AA^{-1}$ for $K, H, F$, and $\kappa$, and $\mathrm{md} \cdot \AA$ for $W$ and $T$. ${ }^{b}$ Non-UBS cross terms include $k$, stretching-stretching; $h$, bending-bending; and $w$, wagging-wagging. The units are md $\bullet \AA^{-1}$ for $k$, and md $\bullet \AA$ for $h$ and $w$. ${ }^{c, d, e}$ Subscript " $o$ " stands for the olefinic part, whereas subscripts "me" and "met" stand for the methyl and methylene parts, respectively. ${ }^{f}$ Subscript "long" indicate long-range interaction with the next neighbor. Force constants shown in Roman were transferred or assumed, and those shown in italic were determined in the present investigation. Each blank in the column of the $\mathrm{T}_{1}$ force constants indicates that the particular $\mathrm{T}_{1}$ force constant was assumed to be the same as the $\mathrm{S}_{0}$ force constant.

of modes taking place on both the left-hand-side and the right-hand-side is coupled in-phase with each other. In the $\mathrm{T}_{1}$ state, on the other hand, the $1450 \mathrm{~cm}^{-1}$ Raman line is assigned to the 13Me asymmetric deformation and the $1006 \mathrm{~cm}^{-1}$ Raman line to the 9 Me and 13 Me rockings, both taking place on the left-hand-side.

Figure 5a shows the displacements of atoms in the $\mathrm{C}=\mathrm{C}$ and $\mathrm{C}-\mathrm{C}$ stretching modes giving rise to high Raman intensities; it supports the above idea. In the $\mathrm{S}_{0}$ state, the $1529 \mathrm{~cm}^{-1}$ Raman line is due to the $\mathrm{C} 11=\mathrm{C} 12, \mathrm{C} 13=\mathrm{C} 14, \mathrm{C} 13^{\prime}=\mathrm{C} 14^{\prime}$ and $\mathrm{C} 11^{\prime}=\mathrm{C} 12^{\prime}$ stretchings coupled in-phase. Almost complete $C_{i}$ symmetry is seen even for the coupled $\mathrm{C}-\mathrm{H}$ ip bendings. The $1161 \mathrm{~cm}^{-1}$ Raman line is due to the $\mathrm{C} 14-\mathrm{C} 15$ and the $\mathrm{C} 14^{\prime}-\mathrm{C} 15^{\prime}$ stretchings that are coupled with the $\mathrm{C} 15-\mathrm{H}$ and
the $\mathrm{C} 15^{\prime}-\mathrm{H}$ ip bendings. Here again, $C_{i}$ symmetry is clearly seen. In the $\mathrm{T}_{1}$ state, on the other hand, the $1500 \mathrm{~cm}^{-1}$ Raman line is mainly due to the $\mathrm{C} 13=\mathrm{C} 14$ stretching and the 1165 $\mathrm{cm}^{-1}$ Raman line is due to the $\mathrm{C} 10-\mathrm{C} 11$ and the $\mathrm{C} 14-\mathrm{C} 15$ stretchings. Both normal modes are taking place on the left-hand-side of the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond. This type of difference in normal modes reflect changes in the stretching force constants (bond orders) upon triplet excitation, the details of which will be discussed later.
(b) 15-cis-Spheroidene Bound to the RC. Twisting of the Conjugated Backbone in the $S_{0}$ and $T_{1}$ States. In a previous investigation, we compared the $S_{0}$ Raman spectrum of the RC-bound 15 -cis-spheroidene to that of 15 -cis-spheroidene free in $n$-hexane solution (see Figure 1 of ref 23). The weak

Figure 4. Comparison of observed and calculated frequencies for the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ Raman lines of $\mathrm{d}_{0}$ and various deuterio all-trans-spheroidenes in $n$-hexane solution. The observed Raman lines are roughly classified into four groups in intensity (very strong, strong, medium, and weak), and the observed and the calculated frequencies are shown in solid and broken Raman lines, respectively.
$958 \mathrm{~cm}^{-1}$ Raman line in solution downshifted slightly and strongly enhanced upon binding to the RC to form the medium $954 \mathrm{~cm}^{-1}$ Raman line. The intensity enhancement was regarded as an indication of twisting around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond. ${ }^{23}$ Because the assignment of the Raman line to the $\mathrm{C} 15-\mathrm{H}$ and $\mathrm{C} 15^{\prime}-\mathrm{H}$ waggings coupled with the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ torsion is now established in the present normal-coordinate analysis, and because test calculations showed that twisting causes the downshift of the particular Raman line, we temporarily estimated the twisting angle around the $\mathrm{C} 15=15^{\prime}$ bond to be $30^{\circ}$.

As mentioned in a previous section, the $\mathrm{T}_{1}$ Raman spectrum of the RC-bound 15 -cis-spheroidene has suggested substantial twistings of the conjugated chain. The empirical and normalcoordinate analysis of the Raman spectrum shown in Figure 3 as well as test calculations to elucidate the effects of twisting around each $\mathrm{C}=\mathrm{C}$ bond on the normal frequencies lead us to the following conclusions: (1) Twisting around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond: (i) The key Raman line of the 15 -cis configuration at $1239 \mathrm{~cm}^{-1}$ in the $\mathrm{S}_{0}$ state disappeared from this spectral region and shifted to as high as $1335 \mathrm{~cm}^{-1}$ in the $\mathrm{T}_{1}$ state (the latter Raman line is more clearly seen in Figure 2 of ref 23). A set of
normal-coordinate calculations showed that the twisting around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond causes decoupling of a pair of the $\mathrm{C} 15-\mathrm{H}$ and the $\mathrm{C} 15^{\prime}-\mathrm{H}$ ip bendings from the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ stretching, which naturally causes increase in frequency and decrease in intensity. (ii) The $\mathrm{S}_{0}$ Raman line at $954 \mathrm{~cm}^{-1}$ with medium Raman intensity, which has been assigned to the $\mathrm{C} 15-\mathrm{H}$ and $\mathrm{C} 15^{\prime}-\mathrm{H}$ waggings coupled with the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ torsion, transforms into the $T_{1}$ Raman line at $935 \mathrm{~cm}^{-1}$ showing enormously high Raman intensity. This enhancement of the particular mode was ascribed to substantial twisting around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond. ${ }^{23}$ Test normal-coordinate calculations showed that the twisting of the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond $\left(\sim 45^{\circ}\right)$ causes substantial decrease in the above coupling, and as a result, low-frequencyshift of the particular mode. Further, the test calculations showed that the twisting around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond caused coupling of those "op" wagging mode with the "ip" type modes (the $\mathrm{C} 13-\mathrm{Me}$ and the $\mathrm{C} 13^{\prime}-\mathrm{Me}$ stretching and the $\mathrm{C} 14-\mathrm{C} 15=\mathrm{C} 15^{\prime}$ and the $\mathrm{C} 15=\mathrm{C} 15^{\prime}-\mathrm{C} 14^{\prime}$ bendings) to enhance the Raman intensity. (2) Twisting around the $\mathrm{C} 11=\mathrm{C} 12$ bond: (i) In the $\mathrm{S}_{0}$ state, the $\mathrm{C} 14-\mathrm{C} 15$ and the $\mathrm{C} 10-\mathrm{C} 11$ stretchings appear at 1168 and $1159 \mathrm{~cm}^{-1}$, whereas in the $\mathrm{T}_{1}$ state, they appear at 1156 and $1182 \mathrm{~cm}^{-1}$, respectively, with reversed order in frequency. Test normal-coordinate calculations indicated that the twisting around the $\mathrm{C} 11=\mathrm{C} 12$ bond $\left(\sim 30^{\circ}\right)$ causes decoupling among the ip vibrations including the $\mathrm{C} 10-\mathrm{C} 11$ stretching and the $\mathrm{C} 11-\mathrm{H}$ and $\mathrm{C} 12-\mathrm{H}$ bendings, and as a result, the high-frequency-shift of the particular stretching vibration. (ii) Upon the 15 -d substitution of the RC-bound 15 -cis-spheroidene in the $\mathrm{T}_{1}$ state, the $935 \mathrm{~cm}^{-1}$ Raman line due to the $\mathrm{C} 15-\mathrm{H}$ and $\mathrm{C} 15^{\prime}-\mathrm{H}$ waggings coupled with the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ torsion disappears from this region. Then, two Raman lines appears in this region; one at $949 \mathrm{~cm}^{-1}$, the $\mathrm{C} 11-\mathrm{H}$ and $\mathrm{C} 12-\mathrm{H}$ waggings coupled with the $\mathrm{C} 11=\mathrm{C} 12$ torsion, and the other at $921 \mathrm{~cm}^{-1}$, the C15-D bending. The considerably high intensity of the former Raman line supports the twisting around the $\mathrm{C} 11=\mathrm{C} 12$ bond. (3) Twisting around the $\mathrm{C} 13=\mathrm{C} 14$ bond: (i) A pair of clearly-split Raman lines in the $\mathrm{C}=\mathrm{C}$ stretching region is seen in the $\mathrm{T}_{1}$ spectrum of the RC -bound spheroidene; one at 1526 $\mathrm{cm}^{-1}$ which has been assigned to the $\mathrm{C} 11=\mathrm{C} 12$ and the $\mathrm{C} 11^{\prime}=\mathrm{C} 12^{\prime}$ stretchings and the other at $1505 \mathrm{~cm}^{-1}$ which has been assigned to the $\mathrm{C} 13=\mathrm{C} 14$ stretching. Test calculations showed that the frequency of the latter mode downshifts when the $\mathrm{C} 13=\mathrm{C} 14$ bond is twisted $\left(\sim 30^{\circ}\right)$. Therefore, the widely split $\mathrm{C}=\mathrm{C}$ stretching Raman lines indicate the twisting around the $\mathrm{C} 13=\mathrm{C} 14$ bond. It is also to be emphasized that such low frequency of the $\mathrm{C} 13=\mathrm{C} 14$ stretching mode could never be explained in terms of a stretching force constant when the value was similar to that determined for all-trans-spheroidene.

Taking into account all the results of the above test calculations, we estimated the twisting angles around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$, $\mathrm{C} 13=\mathrm{C} 14$, and $\mathrm{C} 11=\mathrm{C} 12$ bonds to be $+45^{\circ},-30^{\circ},+30^{\circ}$, respectively, in the case of the RC-bound 15 -cis-spheroidene in the $\mathrm{T}_{1}$ state. [We found that a model with the rotational angles $\left(+45^{\circ},+30^{\circ},+30^{\circ}\right)$ also explains the observed Raman data, a fact which indicates that decoupling of local vibrations on both sides of a particular twisted double bond is relevant to the spectral changes.] Those signs were chosen to minimize the change in the overall structure of the conjugated backbone and to fit the spheroidene molecule to the binding pocket (vide infra). The frequencies, the intensities and the normal modes of the relevant Raman lines do indicate the twisting around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}, \mathrm{C} 13=\mathrm{C} 14$, and $\mathrm{C} 11=\mathrm{C} 12$ bonds, but the twisting angles themselves are just a rough estimation that should not be taken too seriously.

TABLE 3: Frequencies of $S_{0}$ and $T_{1}$ Raman Lines and Frequencies and Normal Modes Calculated by Normal-Coordinate Analysis for (a) $\mathbf{d}_{0}$ All-trans-Spheroidene in $\boldsymbol{n}$-Hexane Solution and (b) $\mathbf{d}_{\mathbf{0}} \mathbf{1 5}$-cis-Spheroidene Bound to the RC

Determination of Force Constants and Normal Modes. The $\mathrm{S}_{0}$-state force constants for the RC-bound 15-cis-spheroidene were determined by the use of a model whose $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ cis bond is twisted by $30^{\circ}$. Then, normal-coordinate analysis was started by the use of force constants determined by Saito and Tasumi for 15 -cis- $\beta$-carotene (for the central part) ${ }^{46}$ and those determined for all-trans-spheroidene (the peripheral part). The number of independent force constants adjusted and the number of observed Raman lines used for fitting were 37 and 55, respectively.

In the $\mathrm{T}_{1}$ state, the $\mathrm{C} 10-\mathrm{C} 11, \mathrm{C} 11=\mathrm{C} 12, \mathrm{C} 12-\mathrm{C} 13$, $\mathrm{C} 13=\mathrm{C} 14, \mathrm{C} 14-\mathrm{C} 15, \mathrm{C} 15=\mathrm{C} 15^{\prime}$, and $\mathrm{C} 13^{\prime}=\mathrm{C} 14^{\prime}$ stretching force constants and the relevant cross terms alone were adjusted, assuming the twisting angles of $+45^{\circ},-30^{\circ}$, and $+30^{\circ}$ around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}, \mathrm{C} 13=\mathrm{C} 14$, and $\mathrm{C} 11=\mathrm{C} 12$ bonds. The rest of the force constants were assumed to be the same as those determined in the $\mathrm{S}_{0}$ state. As an initial guess, the above stretching force constants that were determined in $\mathrm{T}_{1}$ all-transspheroidene in solution were transferred. Then, those force constants were adjusted to realize the observed Raman frequencies and the empirical assignments for all the RC-bound $\mathrm{d}_{0}$ and deuterio 15 -cis-spheroidenes in the $\mathrm{T}_{1}$ state.

The results of normal-coordinate analysis for the $S_{0}$ and $T_{1}$ states of 15 -cis-spheroidene bound to the RC can be summarized as follows: Table 4 lists the $S_{0}$ and $T_{1}$ force constants determined in the above normal-coordinate analysis (shown in italic). Table 3b lists the calculated frequencies and the normal modes for the $\mathrm{d}_{0}$ species, which compare well to the observed Raman frequencies and the empirical assignments listed in Table 1b. (The calculated frequencies and the normal modes of various deuterio 15 -cis-spheroidenes are given in Table 2 S of "Supporting Information available".) Figure 6 depicts a comparison between the observed and the calculated frequencies for all the

RC-bound $\mathrm{d}_{0}$ and deuterio 15-cis-spheroidenes in both the $\mathrm{S}_{0}$ and $T_{1}$ states, which proves the reliability of the set of force constants determined in the present normal-coordinate analysis. The $\mathrm{C}=\mathrm{C}$ and the $\mathrm{C}-\mathrm{C}$ stretching force constants will be used as a scale in the discussion of changes in bond orders upon triplet excitation.

Figure 5 b characterizes the $\mathrm{C}=\mathrm{C}$ and the $\mathrm{C}-\mathrm{C}$ stretchings in the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ states of 15-cis-spheroidene. In addition to the low-frequency-shift of the former and the high-frequency-shift of the latter in general, the following changes are seen upon triplet excitation. The $\mathrm{C} 11=\mathrm{C} 12, \mathrm{C} 13=\mathrm{C} 14, \mathrm{C} 13^{\prime}=\mathrm{C} 14^{\prime}$, and $\mathrm{C} 11^{\prime}=\mathrm{C} 12^{\prime}$ stretchings ( $1534 \mathrm{~cm}^{-1}$ ) is overlapped with the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ stretching $\left(1532 \mathrm{~cm}^{-1}\right)$ to form a closely overlapped Raman line in the $\mathrm{S}_{0}$ state, whereas the low-frequency-shift of the $\mathrm{C} 13=\mathrm{C} 14$ stretching (due to twisting around the $\mathrm{C} 13=\mathrm{C} 14$ bond) results in a pair of widely split Raman lines in the $\mathrm{T}_{1}$ state ( 1526 and $1505 \mathrm{~cm}^{-1}$ ). On the other hand, the C14-C15 stretching ( $1168 \mathrm{~cm}^{-1}$ ) and the $\mathrm{C} 10-\mathrm{C} 11$ stretching (1159 $\mathrm{cm}^{-1}$ ) form slightly split lines in the $\mathrm{S}_{0}$ state, whereas a drastic high-frequency-shift of the latter (due to the twisting around the $\mathrm{C} 11=\mathrm{C} 12$ bond) causes a pair of widely split lines in the reversed order, i.e., the $\mathrm{C} 10-\mathrm{C} 11$ stretching $\left(1182 \mathrm{~cm}^{-1}\right)$ and the $\mathrm{C} 14-\mathrm{C} 15$ stretching $\left(1156 \mathrm{~cm}^{-1}\right)$ in the $\mathrm{T}_{1}$ state. Those calculated frequencies and normal modes nicely reflect the twistings of the conjugated backbone around the $\mathrm{C} 13=\mathrm{C} 14$ and $\mathrm{C} 11=\mathrm{C} 12$ bonds.

## Discussion

$\mathrm{S}_{0^{-}}$and $\mathrm{T}_{1}$-State Bond Orders in the Conjugated Chain As Probed by Stretching Force Constants. (a) All-transSpheroidene in Solution. Figure 7a depicts the $\mathrm{C}=\mathrm{C}$ and $\mathrm{C}-\mathrm{C}$ stretching force constants in the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ states which have
(a)

(b)

Figure 5. Comparison of normal modes among the prominent $\mathrm{C}=\mathrm{C}$ and $\mathrm{C}-\mathrm{C}$ stretching Raman lines in the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ states for (a) $\mathrm{d}_{0}$ all-trans-spheroidene in $n$-hexane solution and (b) $\mathrm{d}_{0} 15$-cis-spheroidene bound to the RC.
been determined for all-trans-spheroidene free in $n$-hexane solution. Open circles indicate force constants in the $\mathrm{S}_{0}$ state, whereas closed circles indicate those in the $\mathrm{T}_{1}$ state. Now, we are going to discuss the carbon-carbon bond orders in the central part by the use of the set of stretching force constants as a scale. Before starting discussion, the unique chemical structure of the spheroidene molecule should be pointed out (see Figure 1a); the center of the entire carbon skeleton is located on the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond, whereas the center of the conjugated chain on the $\mathrm{C} 12-\mathrm{C} 13$ bond.

In the $\mathrm{S}_{0}$ state, the bond order of the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond is the lowest among all the $\mathrm{C}=\mathrm{C}$ bonds, and the bond order of neighboring bond increases toward both ends symmetrically with respect to the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond. On the other hand, the bond
order of the $\mathrm{C}-\mathrm{C}$ bond exhibits a maximum around the $\mathrm{C} 14-\mathrm{C} 15$ and $\mathrm{C} 14^{\prime}-\mathrm{C} 15^{\prime}$ bonds. The symmetric changes in both carbon-carbon bond orders, with respect not to the center of the conjugated chain but to the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond, obviously reflect the electronic structure influenced by the pair of methyl groups attached to the C 13 and $\mathrm{C} 13^{\prime}$ positions. Figure 8 compares, between all-trans-spheroidene and all-trans- $\beta$ carotene, the dependence of the ${ }^{13} \mathrm{C}$ chemical shift on the position of each carbon atom in the $\mathrm{C} 11 \cdots \cdots \mathrm{C} 11^{\prime}$ region. If we simply assume that those chemical-shift values reflect the electron densities on those carbon atoms, it can be concluded that the electronic structure in the particular region still reflects the symmetric influence of the pair of the 13 and 13' methyl groups even in the case of the asymmetric carotenoid, all-transspheroidene, although it is not as perfect as the case of the symmetric carotenoid, all-trans- $\beta$-carotene. The shift of the center of the conjugated chain to the C12 and C13 atoms is also reflected as the asymmetry of the chemical-shift pattern with respect to the C 15 and $\mathrm{C} 15^{\prime}$ atoms.

In the $\mathrm{T}_{1}$ state, on the other hand, the bond order of the $\mathrm{C} 13=\mathrm{C} 14$ bond is the lowest among all the $\mathrm{C}=\mathrm{C}$ bonds, whereas that of the $\mathrm{C} 12-\mathrm{C} 13$ bond is the highest among the $\mathrm{C}-\mathrm{C}$ bonds. Both the $\mathrm{C}=\mathrm{C}$ and $\mathrm{C}-\mathrm{C}$ bond orders tend to systematically change toward both terminals with respect to the center of the conjugated chain, i.e., the $\mathrm{C} 12-\mathrm{C} 13$ bond. If we focus our attention to changes in bond order upon triplet excitation, decrease in the $\mathrm{C}=\mathrm{C}$ bond order is in the order, $\mathrm{C} 13=\mathrm{C} 14>\mathrm{C} 11=\mathrm{C} 12>\mathrm{C} 9=\mathrm{C} 10>\mathrm{C} 15=\mathrm{C} 15^{\prime}$, and increase in the $\mathrm{C}-\mathrm{C}$ bond order is the largest in the $\mathrm{C} 12-\mathrm{C} 13$ bond. Those changes in bond orders are in good accord with the idea of "the triplet-excited region" we proposed previously (see refs 28,31 , and 49 for reviews). The triplet-excited region has been defined as a region where largest changes in bond order take place upon triplet excitation, i.e., double bonds become single bond-like, whereas single bonds become double bond-like. It has a span of approximately six conjugated double bonds, it is localized in the central part of a conjugated chain, and it triggers cis-to-trans isomerization in the $\mathrm{T}_{1}$ state. It has been shown, in the present investigation, that the triplet-excited region is located in the center of the conjugated chain even in an asymmetric carotenoid, all-trans-spheroidene.
(b) 15-cis-Spheroidene Bound to the RC. Figure 7b shows the $\mathrm{C}=\mathrm{C}$ and $\mathrm{C}-\mathrm{C}$ stretching force constants in the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ states that have been determined for the RC-bound 15 -cisspheroidene. Again, we are going to use the stretching force constants as a scale of bond orders. In the $\mathrm{S}_{0}$ state, the bond order of the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond is the lowest among all the $\mathrm{C}=\mathrm{C}$ bonds, whereas the bond orders of the C14-C15 and the $\mathrm{C} 14^{\prime}-\mathrm{C} 15^{\prime}$ bonds are highest among all the $\mathrm{C}-\mathrm{C}$ bonds. Approximately symmetric changes with respect to the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond toward both ends of the conjugated chain are seen as in the case of all-trans-spheroidene in solution. In the $\mathrm{T}_{1}$ state, on the other hand, the lowest bond order is seen for the $\mathrm{C} 13=\mathrm{C} 14$ bond among all the $\mathrm{C}=\mathrm{C}$ bonds, and the highest bond order is seen for the $\mathrm{C} 12-\mathrm{C} 13$ bond among the $\mathrm{C}-\mathrm{C}$ bonds. Upon triplet excitation, decrease in the $\mathrm{C}=\mathrm{C}$ bond order is in the order, $\mathrm{C} 13=\mathrm{C} 14>\mathrm{C} 11=\mathrm{C} 12>\mathrm{C} 15=\mathrm{C} 15$ (the $\mathrm{C} 9=\mathrm{C} 10$ stretching force constant could not be determined in this case), whereas increase in the $\mathrm{C}-\mathrm{C}$ bond order is in the order, $\mathrm{C} 12-\mathrm{C} 13>\mathrm{C} 10-\mathrm{C} 11>\mathrm{C} 14-\mathrm{C} 15$. The magnitudes of changes in bond order upon triplet excitation in the RC-bound 15 -cis-spheroidene tend to be larger than those in all-transspheroidene in solution, although the patterns of changes are very similar to each other.

${ }^{a}$ See the foot notes of Table 2.

If one assumes a linear relation between the carbon-carbon bond length and the stretching force constant, a change of 1 $\mathrm{md} \cdot \AA^{-1}$ in force constant corresponds to a change of $0.064 \AA$ in bond length. Then, increase in the bond length of the $\mathrm{C} 13=\mathrm{C} 14$ bond upon triplet excitation, for example, can be estimated to be 0.04 and $0.05 \AA$ in all-trans-spheroidene in $n$ hexane solution and 15 -cis-spheroidene in the RC , respectively.

Rotational Motions around the $\mathbf{C 1 5}=\mathrm{C15}^{\prime}, \mathrm{C} 13=\mathrm{C} 14$, and $\mathbf{C 1 1}=\mathbf{C 1 2}$ Bonds As a Mechanism of Triplet-Energy Dissipation. Resonance-Raman spectroscopy and normal-coordinate analysis of the RC-bound $\mathrm{d}_{0}$ and various deuterio spheroidenes have provided us with structural information concerning the $\mathrm{T}_{1-}$ state spheroidene in the RC: (1) Large changes in bond order upon triplet excitation have been identified in the central part of the conjugated chain. The lengthenings of the $\mathrm{C} 13=\mathrm{C} 14$, $\mathrm{C} 11=\mathrm{C} 12$, and $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bonds have been estimated to be $0.05,0.04$, and $0.02 \AA$, respectively. (2) Twisting of the conjugated chain around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}, \mathrm{C} 13=\mathrm{C} 14$, and $\mathrm{C} 11=\mathrm{C} 12$ bonds, by approximately $+45^{\circ},-30^{\circ}$, and $+30^{\circ}$,
have been identified in the $\mathrm{T}_{1}$ state, whereas twisting around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond alone by $30^{\circ}$ has been found in the $\mathrm{S}_{0}$ state. The above structural changes in the RC upon triplet excitation must originate from the binding pocket of the apo-protein and the intrinsic $\mathrm{T}_{1}$-state properties of the chromophore, spheroidene. Actually, close examination of the X-ray structures of the RCbound 15 -cis-spheroidene (in the $\mathrm{S}_{0}$ state) and the binding pocket revealed that the left-hand-side of the spheroidene molecule shown in Figure 1a is in close contact with the M subunit, the macrocycle of one of the accessory bacteriochlorophylls and the phytyl chain of one of the special-pair bacteriochlorophylls. ${ }^{50}$ Therefore, the alternate signs of rotational angles around the cis- $\mathrm{C} 15=\mathrm{C} 15^{\prime}$, trans- $\mathrm{C} 13=\mathrm{C} 14$ and trans $\mathrm{C} 11=\mathrm{C} 12$ bonds $\left(+45^{\circ},-30^{\circ},+30^{\circ}\right)$ must become necessary even after triplet excitation. On the other hand, the right-hand-side of the molecule is in weak contact with the M subunit, allowing the rotational degree of freedom of this branch.

As an intrinsic property, 15-cis-spheroidene in solution rapidly isomerizes into all-trans-spheroidene upon triplet excitation, and

Figure 6. Comparison of observed and calculated frequencies for the $\mathrm{S}_{0}$ and $\mathrm{T}_{1}$ Raman lines of $\mathrm{d}_{0}$ and various deuterio 15 -cis-spheroidenes bound to the RC. The observed Raman lines are roughly classified into four groups in intensity (very strong, strong, medium and weak), and the observed and the calculated frequencies are shown in solid and broken lines, respectively.
therefore, it is not straightforward to apply resonance-Raman spectroscopy to the former to elucidate its $\mathrm{T}_{1}$-state structure. However, changes in bond order, basically the same as all-transspheroidene, are expected to take place upon triplet excitation to trigger the isomerization reaction, which is presumably caused by the steric hindrance on the concave side of the 15 -cis-bent structure.

Time-resolved absorption spectroscopy has been applied to isomeric spheroidenes in solution to elucidate the unique $\mathrm{T}_{1^{-}}$ state properties of the 15 -cis-isomer. ${ }^{33}$ (1) The $\mathrm{T}_{1} \rightarrow \mathrm{~S}_{0}$ intersystem crossing takes place much faster in "cis- $\mathrm{T}_{1}$ " $(0.83$ $\mu \mathrm{s})$ than in "all-trans- $\mathrm{T}_{1}$ " $(4.76 \mu \mathrm{~s})$. (2) The $\mathrm{T}_{1}$-state isomerization from "cis- $\mathrm{T}_{1}$ " to "all-trans $-\mathrm{T}_{1}$ " takes place with efficiency in the order, " $15-$ cis- $\mathrm{T}_{1} "(0.56 \mu \mathrm{~s})>$ "13-cis- $\mathrm{T}_{1} "(0.77 \mu \mathrm{~s})>$ $" 9-c i s-\mathrm{T}_{1} "(0.83 \mu \mathrm{~s})>" 13^{\prime}-$ cis $-\mathrm{T}_{1} "(0.91 \mu \mathrm{~s})$. (3) The quantum yield of triplet-sensitized isomerization (per triplet species generated) was determined to be 15 -cis $(0.60)>13$-cis $(0.52)$ $>9$-cis $(0.50)>13^{\prime}$-cis $(0.48)$. The above results show that 15-cis-spheroidene is most advantageous over all the other cistrans spheroidenes in dissipating the triplet energy through rotation around the cis bond (see the Introduction section). The following excited-state dynamics is expected to take place upon triplet excitation of 15 -cis-spheroidene free in solution. First, decrease in the bond order of the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond should take place to reduce the barrier against isomerization. Then, "15-cis- $\mathrm{T}_{1}$ " is supposed to have two routes for relaxation down to

(b) $\quad 3=4 \quad 5=6 \quad 7=8 \quad 9=10 \quad 11=12 \quad 13=14 \quad 15=15^{\prime} \quad 13^{\prime}=14^{\prime} \quad 11^{\prime}=12^{\prime} \quad 9^{\prime}=10^{\prime}$

Figure 7. Comparison of the carbon-carbon stretching force constants determined in the $\mathrm{S}_{0}$ state (open circles) and the $\mathrm{T}_{1}$ state (closed circles) for (a) all-trans-spheroidene in $n$-hexane solution and (b) 15-cisspheroidene bound to the RC. Double open circles indicate those stretching force constants which were assumed and could not be determined because of the limited number of deuterio species and/or the lack of observed Raman lines due to the normal modes in the peripheral parts. Lined open circles indicate complete overlap of the open and double open circles.

Figure 8. Dependence of ${ }^{13} \mathrm{C}$ chemical shift on the position of skeletal carbon atom in the central part. Open circles indicate the ${ }^{13} \mathrm{C}$ chemical shifts for all-trans-spheroidene and closed circles those for all-trans-$\beta$-carotene.
the $\mathrm{S}_{0}$ state. Route A : to directly intersystem cross down to 15 -cis- $\mathrm{S}_{0}$ in submicroseconds ( $0.83 \mu \mathrm{~s}$ ). Route B : to isomerize into "all-trans- $\mathrm{T}_{1}$ " in submicroseconds ( $0.56 \mu \mathrm{~s}$ ), and then, to intersystem cross from "the resultant all-trans $-\mathrm{T}_{1}$ " to all-trans$\mathrm{S}_{0}$ in the microsecond time scale $(4.76 \mu \mathrm{~s})$. It is worthy of note that the time scale of $\mathrm{T}_{1} \rightarrow \mathrm{~S}_{0}$ intersystem crossing for the cis$\mathrm{T}_{1}$ species $(0.83 \mu \mathrm{~s})$ is in the same order as that of the $\mathrm{T}_{1}$-state isomerization of cis-spheroidenes ( $0.56-0.91 \mu \mathrm{~s}$ ). The result strongly supports the idea that the rotational motion around the $\mathrm{C}=\mathrm{C}$ bond strongly enhances the $\mathrm{T}_{1} \rightarrow \mathrm{~S}_{0}$ intersystem crossing. This relation can be easily understood because the rotational motion causes a change in the orbital angular momentum (the electronic structure of the relevant carbon atoms changes from the $\mathrm{sp}^{2}$ to the $\mathrm{sp}^{3}$ type), and as a result, it causes change in the
spin angular momentum conserving the total angular momentum ${ }^{51}$ (see the Introduction section).

The above considerations lead us to call Route A "a fast process of intersystem crossing through rotational motion", which is an intrinsic property of the $\mathrm{T}_{1}$-state 15 -cis-spheroidene. On the other hand, we call the latter part of Route B "a slow process of intersystem crossing in a fixed conformation", because "all-trans $-\mathrm{T}_{1}$ " has no further momentum of rotational motion to isomerize. [Fluctuation around the most stable rotational angle(s) may facilitate the intersystem crossing through the spin-orbit coupling mentioned above.] Now, we are going to apply the idea of the slow and fast processes of intersystem crossing to the case of the RC-bound spheroidene.

In the case of 15 -cis-spheroidene in the RC, the first part of Route B, i.e., complete isomerization to "all-trans- $\mathrm{T}_{1}$ ", is prohibited. Raman spectroscopy has shown that the twistings around the conjugated double bonds take place not only around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond but also around the $\mathrm{C} 13=\mathrm{C} 14$ and the $\mathrm{C} 11=\mathrm{C} 12$ bonds in "the triplet-excited region". Here, the rotational angles of $+45^{\circ},-30^{\circ},+30^{\circ}$ must be determined as the above-mentioned balance between the rotational momentum around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond (toward all-trans) vs the steric hindrance originating from the binding pocket of the apo-protein. After reaching this stationary-state twisted conformation in the $\mathrm{T}_{1}$ state, only "the slow process of intersystem crossing in a fixed conformation" can take place, because no rotational degrees of freedom to enhance the intersystem crossing are left in this equilibrium configuration. The situation is similar to the case of "all-trans- $\mathrm{T}_{1}$ " free in solution.

On the other hand, the rotational motions around the $15=15^{\prime}$ double bonds which is supposed to take place immediately after triplet excitation (before reaching the above stationary-state $\mathrm{T}_{1}$ structure) must strongly enhance the intersystem crossing down to the $\mathrm{S}_{0}$-state, the mechanism of which should be similar to the case of 15 -cis-spheroidene in solution. This corresponds to "the fast process of intersystem crossing through rotational motion" defined above. This type of rotational motion around the $\mathrm{C} 15=\mathrm{C} 15^{\prime}$ bond within the 15 -cis potential minimum has already been proposed as a mechanism of tripletenergy dissipation (see Figure 5 of ref 23). The present results show that this mechanism may need to be revised by adding the rotational motions around the $\mathrm{C} 13=\mathrm{C} 14$ and $\mathrm{C} 11=\mathrm{C} 12$ bonds as well, both under the influence of the trans potential minima.

Our hypothetical mechanism of triplet-energy dissipation initiated by the rotational motion around the cis- $\mathrm{C} 15=\mathrm{C}^{\prime} 5^{\prime}$ bond has been questioned by some investigators: Specifically, (1) Bautista et al. ${ }^{36}$ incorporated locked 15-cis-spheroidene, the configuration of which was chemically locked into 15 -cis, into the RC of a carotenoidless mutant of $R b$. sphaeroides R26.1, and determined the $\mathrm{T}_{1}$ decay time constant to be $7 \pm 1 \mu \mathrm{~s}$. This value was not substantially larger than that of unlocked 15-cisspheroidene in the RC, i.e., $4-5 \mu \mathrm{~s}^{4}$ or $5 \pm 2 \approx 7.2 \pm 1 \mu \mathrm{~s}$ (presented in the abstract and Table 1 of ref 9). Bautista et al. ${ }^{36}$ took the result as evidence for that locked 15-cis-spheroidene is as capable of quenching the primary donor triplet as the unlocked spheroidene. (2) The observation that the $\mathrm{T}_{1}$ lifetime of the LH2-bound all-trans-spheroidene, i.e., $7 \mu \mathrm{~s},{ }^{52}$ is not very different from that of the RC-bound spheroidene, i.e., $4-5 \mu \mathrm{~s}$, has also been taken as evidence against the hypothetical mechanism. ${ }^{53}$

Those observations can be nicely explained when one regards all the above decay time constants as representing "the slow process of intersystem crossing in a fixed conformation". When
the rotational motion (toward "all-trans- $\mathrm{T}_{1}$ ") is prohibited either by being buried in the binding pocket ( $4-5 \mu \mathrm{~s}$ ) or by locking by the use of chemical bonds ( $7 \mu \mathrm{~s}$ ), the decay time constant of such $\mathrm{T}_{1} 15$-cis-spheroidene is in a similar order of magnitude to that of $\mathrm{T}_{1}$ all-trans-spheroidene in solution $(4.76 \mu \mathrm{~s})$ or bound to the LH2 complex ( $7 \mu \mathrm{~s}$ ). It is worthy of note that the chemically locked 15 -cis-spheroidene tends to decay more slowly ( $7 \mu \mathrm{~s}$ ) than unlocked 15 -cis-spheroidene ( $4-5 \mu \mathrm{~s}$ ), and that all-trans-spheroidene bound to the LH2 complex ( $7 \mu \mathrm{~s}$ ) decays more slowly than that free in solution $(4.76 \mu \mathrm{~s})$. Those trends suggest that the rotational degree of freedom causing the fluctuation of rotational angles "in a fixed conformation" is an important factor even in "the slow process of intersystem crossing".

To fully understand the reason for the natural selection of the 15 -cis configuration by the RC , and to establish the mechanism of triplet-energy dissipation, it is absolutely necessary to experimentally identify the fast process of intersystem crossing and the rotational motion in the submicrosecond (or even shorter) time range in the RC-bound 15-cis-spheroidene. A quantitative analysis of time-dependent changes in the triplet population in this time scale by EPR spectroscopy as well as the detection of the initial rotational motions by time-resolved absorption or Raman spectroscopy may provide us with a strong support for the present, more specific hypothetical mechanism of triplet-energy dissipation.

Acknowledgment. The authors are indebted to Prof. Harry Frank for transferring to them the technique of incorporating spheroidene into the carotenoidless RC. Financial supports from the Science Research Promotion Fund and from the Japan Society for the Promotion of Science are gratefully acknowledged.
