#### Abstract

To answer the question, "Can a quartet be the ground state of heteroatom analogues of trimethylenemethane (TMM)?", B3LYP, CASSCF, and CASPT2 calculations have been performed on the lowest doublet and quartet states of the positive and negative radical ions of TMM and of several heteroatom-substituted analogues. Of the molecules on which calculations were performed, all those containing three $\pi$ electrons, including $\mathrm{AlO}_{3}{ }^{\bullet}$, were found to have doublet ground states. However, a quartet ground state was computed for $\mathrm{O}\left(\mathrm{SiH}_{2}\right)_{3}{ }^{\bullet+}$, a radical ion containing five $\pi$ electrons. Calculations on $\mathrm{H}_{3}{ }^{\bullet}$ and $\mathrm{HeH}_{3}{ }^{\bullet}$ models revealed a similar difference between the three- and five-electron cases. A doublet was computed to be the ground state of $\mathrm{H}_{3}{ }^{\bullet}$ at all $D_{3 h}$ geometries, but at some $\mathrm{He}-\mathrm{H}$ distances the quartet was computed to be the ground state of $D_{3 h} \mathrm{HeH}_{3}{ }^{\circ}$. The model calculations lead to an explanation of why radicals containing three $\pi$ electrons are all predicted to have doublet ground states; whereas, the quartet is computed to be the ground state of at least one radical containing five $\pi$ electrons.

Since its conception by Moffitt ${ }^{1}$ in 1948 and its synthesis and spectroscopic observation by Dowd ${ }^{2}$ in 1966, trimethylenemethane (TMM) and its derivatives have become the most thoroughly studied non-Kekulé hydrocarbon diradicals. ${ }^{3}$ The ground state of TMM has long been known to be a triplet, ${ }^{2,4}$ as expected from both qualitative molecular orbital (MO) ${ }^{5}$ and valence-bond $(\mathrm{VB})^{6}$ theories. The size of the singlet-triplet energy splitting has been measured ${ }^{7}$ and found to be in good agreement with the results of high-level ab initio calculations. ${ }^{8}$

TMM
Much less is known about the radical ions of TMM than about the neutral diradical. The parent radical cation (TMM ${ }^{+}$) has been generated by Shiotani and co-workers and studied by EPR. ${ }^{9}$ As predicted computationally, 10 years before the EPR study was performed, ${ }^{10}$ the doublet ground state was found to pseudorotate from one Jahn-Teller-distorted geometry to another with little or no barrier. Derivatives of $\mathrm{TMM}^{\bullet+}$ have been formed as reactive intermediates by one-electron oxidation of methylenecyclopropanes. ${ }^{11}$

Even less is known about the TMM radical anion (TMM ${ }^{-}$) than about the radical cation. $\mathrm{TMM}^{--}$was generated in the gasphase by Hu and Squires and used to obtain the negative ion photoelectron spectrum of TMM. ${ }^{7}$ In the same study, the results of CASSCF and UB3LYP calculations on the two, Jahn - Teller distorted, $C_{2 v}$ states of $\mathrm{TMM}^{{ }^{-}}$were reported. The ${ }^{2} \mathrm{~A}_{2}$ state was computed to be $0.1-0.6 \mathrm{kcal} / \mathrm{mol}$ lower in energy than the ${ }^{2} \mathrm{~B}_{1}$ state. ${ }^{7}$

Recently, Iwamura and co-workers have prepared derivatives of TMM radical ions in which the three methylene groups were

[^0]replaced by $p$-(tert-butylnitroxyl)phenyl groups and the central carbon was replaced by boron or by nitrogen. ${ }^{12} \mathrm{~B}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet}$ is isoelectronic with $\mathrm{TMM}^{\bullet+}$, and $\mathrm{N}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet}$ is isoelectronic with TMM ${ }^{-}$.

EPR magnetic susceptibility studies showed that the $\mathrm{B}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\circ}$ and $\mathrm{N}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet}$ derivatives prepared by Iwamura and co-workers had doublet ground states. However, the presence of a thermally populated, excited quartet state was detected in both compounds. UB3LYP calculations on a model for the aza compound, in which the tert-butyl substituents on the nitroxyl groups were replaced by methyls, gave a doublet-quartet energy separation that was in good agreement with that measured. ${ }^{12}$

Iwamura's study raises the question of whether it might be possible to prepare heteroatom analogues of TMM radical ions in which the ground state is a quartet, rather than a doublet. In this paper we address this question and report the results of $a b$ initio and density functional theory (DFT) calculations on the doublet-quartet energy differences $\left(\Delta E_{\mathrm{DQ}}\right)$ in planar $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3}$ radicals with three $\pi$ electrons ( $\mathrm{X}=\mathrm{Al}, \mathrm{B}$, and $\mathrm{C}^{+}$) and five $\pi$ electrons ( $\mathrm{X}=\mathrm{C}^{-}, \mathrm{N}$, and $\mathrm{O}^{+}$). We also describe how replacement of the three methylene groups in $\mathrm{Al}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\circ}$ by oxygen atoms and in $\mathrm{O}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet+}$ by $\mathrm{SiH}_{2}$ groups affects the calculated values of $\Delta E_{\mathrm{DQ}}$.

We have found that our computational results on molecules containing three and five $\pi$ electrons are mirrored by the results of calculations on $\mathrm{H}_{3}{ }^{\bullet}$ and $\mathrm{HeH}_{3}{ }^{\bullet}$ models. These models provide an explanation for why the quartet can fall below the doublet in properly designed heteroatom derivatives of $\mathrm{TMM}^{\bullet-}$ but not in heteroatom derivatives of $\mathrm{TMM}^{\bullet+}$.

## Computational Methodology

We were interested in comparing the relative energies of the doublet and quartet states of the $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3}$ radicals with fully conjugated $\pi$ systems, since at such geometries the quartet has the best chance of being competitive in energy with the lowest
doublet state. Therefore, most of our calculations were performed on molecules that were constrained to be planar. The geometries of the doublet and quartet states of molecules, thus constrained, were optimized in the $C_{2 v}$ and $D_{3 h}$ point groups, respectively.

Especially for the $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3}$ radicals containing five $\pi$ electrons, pyramidalization of X and/or the peripheral $\mathrm{CH}_{2}$ groups was computed to be energetically favorable. Consequently, for such molecules, the optimized $C_{2 v}$ and $D_{3 h}$ geometries are not energy minima but are, instead, stationary points of higher order, usually with several imaginary vibrational frequencies. Therefore, the relative energies of the doublet and quartet states of such molecules were not corrected for differences between their zero-point vibrational energies.

Unless otherwise specified, all calculations were performed with the $6-31+G(d)$ basis set. ${ }^{13}$ Unrestricted (U)DFT calculations were carried out utilizing Becke's three-parameter, hybrid functional ${ }^{14}$ and the nonlocal correlation functional of Lee, Yang, and Parr ${ }^{15}$ (B3LYP). The Gaussian 98 suite of programs ${ }^{16}$ was used to perform the UB3LYP calculations.

CASSCF calculations were carried out with the GAMESS package of ab initio programs. ${ }^{17}$ The active space for the CASSCF calculations consisted of the number of $\pi$ electrons in each species [e.g. three for $\mathrm{B}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet}$ and five $\mathrm{N}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\circ}$ ], distributed among the four $\pi \mathrm{MOs}$ of TMM. To include the effects of dynamic electron correlation ${ }^{18}$ in the (3/4)CASSCF and (5/4)CASSCF calculations, CASPT2 ${ }^{19}$ single point calculations were performed at the CASSCF optimized geometries, using the MOLCAS suite of programs. ${ }^{20}$ Absolute UB3LYP, CASSCF, and CASPT2 electronic energies and the optimized UB3LYP and CASSCF geometries for each of the low-lying electronic states of all the molecules discussed in this paper are available as Supporting Information.

## Results and Discussion

Corrections for Artifactual Symmetry Breaking. In the lowest doublet state of a planar $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3}$ radical that contains either three or five $\pi$ electrons, an odd number of electrons must be placed in the pair of nonbonding $\pi$ MOs. At $D_{3 h}$ geometries these MOs belong to the degenerate $e^{\prime \prime}$ representation of the $D_{3} h$ point group. Since the $\mathrm{e}_{x}{ }^{\prime \prime}$ and $\mathrm{e}_{y}{ }^{\prime \prime}$ NBMOs are degenerate at $D_{3 h}$ geometries, at such geometries the energies of the ${ }^{2} \mathrm{E}_{x}{ }^{\prime \prime}$ and ${ }^{2} \mathrm{E}_{y}$ " states that result from singly occupying one or the other of these two NBMOs should be exactly the same.

However, in practice, the computed energies of the two states that result from singly occupying one or the other of the two NBMOs usually do not have exactly the same energy. As discussed in detail elsewhere, ${ }^{10,21}$ approximate wave functions usually show artifactual symmetry breaking, because at $D_{3 h}$ geometries the two lowest doublet wave functions for $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3}$ radicals do not really have pure $\mathrm{E}_{\mathrm{x}}{ }^{\prime \prime}$ and $\mathrm{E}_{\mathrm{y}}{ }^{\prime \prime}$ symmetry. Instead the wave functions belong to, respectively the $A_{2}$ and $B_{1}$ representations of the $C_{2 v}$ subgroup of $D_{3 h}$. Since $\mathrm{A}_{2}$ and $\mathrm{B}_{1}$ are not degenerate representations (the $C_{2 v}$ point group has none), at $D_{3 h}$ geometries the two lowest doublet wave functions generally do not have the same energy.

Like the pure ${ }^{2} \mathrm{E}_{x}{ }^{\prime \prime}$ and ${ }^{2} \mathrm{E}_{y}{ }^{\prime \prime}$ wave functions to which they correspond, the ${ }^{2} \mathrm{~A}_{2}$ and ${ }^{2} \mathrm{~B}_{1}$ states each undergo a first-order Jahn-Teller distortion ${ }^{22}$ to a $C_{2 v}$ geometry of lower symmetry. One of these states is expected to represent the maxima and the other the minima along the lowest energy pathway for pseudorotation of the lowest doublet state of an $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3}$ radical around a $D_{3 h}$ geometry. ${ }^{21}$ However, if the energies of these two states are spuriously computed to be different at $D_{3 h}$ geometries,

${ }^{a}$ Energy, which, when subtracted from that of ${ }^{2} \mathrm{~B}_{1}$, would make the energy of ${ }^{2} \mathrm{~B}_{1}$ the same as that of ${ }^{2} \mathrm{~A}_{2}$ at the $D_{3 h}$ equilibrium geometry of ${ }^{4} \mathrm{~A}_{1}$ ". ${ }^{b}$ Relative energies of ${ }^{2} \mathrm{~B}_{1}$ and ${ }^{2} \mathrm{~A}_{2}$ at their equilibrium geometries, after correction of the energy of ${ }^{2} B_{1}$ for the effect of artifactual symmetry breaking at the $D_{3 h}$ geometry of ${ }^{4} \mathrm{~A}_{1}{ }^{\prime \prime} .{ }^{c} \Delta E_{\mathrm{DQ}}$.
there is every reason to believe that this energetic advantage of one state over another will also be manifested in the relative energies of the states at the optimized $C_{2 v}$ geometry of each.

The simplest way to correct for this effect of artifactual symmetry breaking, due to the approximate nature of the electronic wave functions, is to subtract the energy difference between ${ }^{2} \mathrm{~A}_{2}$ and ${ }^{2} \mathrm{~B}_{1}$ at a $D_{3 h}$ geometry (e.g., at the optimized geometry of the quartet, ${ }^{4} \mathrm{~A}_{1}{ }^{\prime \prime}$ ) from the energy difference between these two doublet states at the optimized $C_{2 v}$ geometry of each. For example, our calculations almost invariably found that, at the $D_{3 h}$ geometry of ${ }^{4} \mathrm{~A}_{1}{ }^{\prime \prime},{ }^{2} \mathrm{~B}_{1}$ was higher in energy than ${ }^{2} \mathrm{~A}_{2}$. The energy that has to be subtracted from the energy of ${ }^{2} \mathrm{~B}_{1}$, to make it degenerate with ${ }^{2} \mathrm{~A}_{2}$ at the optimized $D_{3 h}$ geometry of ${ }^{4} \mathrm{~A}_{1}{ }^{\prime \prime}$ is shown in the first column of Tables 1 and 2. The second column shows the energy of ${ }^{2} \mathrm{~B}_{1}$, relative to ${ }^{2} \mathrm{~A}_{2}$, at the optimized $C_{2 v}$ geometry of each state, after this correction for artifactual symmetry breaking has been applied.

The results in Tables 1 and 2 show that artifactual symmetry breaking in ${ }^{2} \mathrm{~A}_{2}$ and ${ }^{2} \mathrm{~B}_{1}$ has a much larger effect on the relative UB3LYP energies of these two states than on their relative CASSCF or CASPT2 energies. The effect of artifactual symmetry breaking on theUB3LYP relative energies increases with

Figure 1. Schematic depiction of (a) the $\pi$ MOs for TMM and how they are occupied in the (b) ${ }^{2} \mathrm{E}_{y}{ }^{\prime \prime}$ and (c) ${ }^{4} \mathrm{~A}_{1}{ }^{\prime \prime}$ states of an $\mathrm{XY}_{3}$ radical containing three $\pi$ electrons. Only the top lobe of each 2 p AO is shown.
the difference between the electronegativities of the central and terminal atoms.

As the difference between the electronegativities of the central and terminal atoms in $\mathrm{XY}_{3}$ increases, configurations, other than the one of lowest energy, become increasingly important for both doublet states (vide infra). Since the UB3LYP calculations are based on wave functions that consist of a single configuration, it is not at all surprising that, as the difference between the electronegativities of the central and terminal atoms in $\mathrm{XY}_{3}$ increases, UB3LYP does a poorer job than CASSCF or CASPT2 of computing the relative energies of the two lowest doublet states.

Apparently, ${ }^{2} \mathrm{~B}_{1}$, in which the unpaired electron occupies an orbital of the same symmetry $\left(b_{1}\right)$ as the doubly occupied $\pi$ orbital(s), is less well-described by a single configuration at the UB3LYP level than is ${ }^{2} \mathrm{~A}_{2}$, in which the unpaired electron occupies an orbital of different symmetry $\left(\mathrm{a}_{2}\right)$ than the doubly occupied $\pi$ orbital(s). The poorer quality of the UB3LYP wave functions for ${ }^{2} \mathrm{~B}_{1}$, compared to those for ${ }^{2} \mathrm{~A}_{2}$, is reflected, not only in the higher UB3LYP energies of ${ }^{2} \mathrm{~B}_{1}$, relative to ${ }^{2} \mathrm{~A}_{2}$, but also in the larger deviations of the values of $\left\langle S^{2}\right\rangle$ for ${ }^{2} \mathrm{~B}_{1}$ from the value of $\left\langle S^{2}\right\rangle=3 / 4$ for a pure doublet wave function. Therefore, in discussing the UB3LYP results in Tables 1 and 2, we will use the ${ }^{2} \mathrm{~A}_{2}$, rather than the ${ }^{2} \mathrm{~B}_{1}$ energies.

As the quality of the wave functions for the components of a degenerate state improves, the amount of artifactual symmetry breaking decreases; and the energies of the components become more nearly the same at the geometry of highest symmetry. This can be clearly seen by comparing the sizes of the CASSCF and CASPT2 corrections for artifactual symmetry breaking in Tables 1 and 2 with the UB3LYP corrections. Except in $\mathrm{C}\left(\mathrm{CH}_{2}\right)_{3^{--}}$, the largest CASSCF correction is $0.3 \mathrm{kcal} / \mathrm{mol}$, and the largest CASPT2 correction is $0.1 \mathrm{kcal} / \mathrm{mol}$.

Effect of Including Dynamic Electron Correlation. Our (3/4)- and (5/4)CASSCF calculations do not include the effects of dynamic electron correlation between the $\sigma$ and the $\pi$ electrons, ${ }^{18}$ but our CASPT2 calculations do. Therefore, there is every reason to expect the CASPT2 results for $E\left({ }^{4} \mathrm{~A}_{1}{ }^{\prime \prime}\right)$ $E\left({ }^{2} \mathrm{~A}_{2}\right)=\Delta E_{\mathrm{DQ}}$ in Tables 1 and 2 to be more accurate than the CASSCF results.

UB3LYP does not explicitly include any correlation between the $\sigma$ and the $\pi$ electrons in the Kohn-Sham orbitals from which the densities are computed. However, the effects of both dynamic and nondynamic electron correlation are included in the B3LYP functional, from which the energy is calculated.

Thus, perhaps it is not surprising that inspection of Tables 1 and 2 shows the energy differences between ${ }^{4} \mathrm{~A}_{1}$ " and ${ }^{2} \mathrm{~A}_{2}$, obtained by the CASPT2 and UB3LYP calculations, are generally in much better agreement with each other than with the CASSCF results. Consequently the following discussions of $\Delta E_{\mathrm{DQ}}$ for the molecules in Tables 1 and 2 is based on the CASPT2 and UB3LYP results for the energy differences between ${ }^{4} \mathrm{~A}_{1}$ " and ${ }^{2} \mathrm{~A}_{2}$ in Tables 1 and 2, rather than on the CASSCF results.

Effect of Heteroatom Substitution on $\Delta E_{\mathrm{DQ}}$ in $\mathbf{C}\left(\mathbf{C H}_{2}\right)^{++}$. The values of $\Delta E_{\mathrm{DQ}}$ in Table 1 for the $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3}$ radicals with three $\pi$ electrons decrease in the order, $\mathrm{X}=\mathrm{C}^{+}>\mathrm{X}=\mathrm{B}>\mathrm{X}$ $=\mathrm{Al}$. The reasons for this decrease are easy to understand from the $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3} \pi$ MOs and how they are occupied in the lowest doublet and quartet states. The MOs and their occupancies in ${ }^{2} \mathrm{~A}_{2}$ and ${ }^{4} \mathrm{~A}_{1}$ " are depicted schematically in Figure 1.

The formation of ${ }^{4} \mathrm{~A}_{1}$ " from either of the lowest doublet states requires the excitation of an electron from the bonding $1 \mathrm{a}_{2}{ }^{\prime \prime}$ MO to the $e^{\prime \prime}$ NBMO that is empty. Therefore, the difference between the $e^{\prime \prime}$ and $1 \mathrm{a}_{2}{ }^{\prime \prime}$ orbital energies plays a crucial role in determining the size of $\Delta E_{\mathrm{DQ}}$ for the radicals in Table 1. Since $1 \mathrm{a}_{2}{ }^{\prime \prime}$ is a bonding MO and $\mathrm{e}^{\prime \prime}$ is nonbonding, $\Delta E_{\mathrm{DQ}}$ should decrease with a decrease in the strength of the $\pi$ bonds between the central atom, X , and $\mathrm{CH}_{2}$. Thus, since $\pi$ bond strengths decrease in the order $\pi(\mathrm{C}-\mathrm{C})>\pi(\mathrm{B}-\mathrm{C})>\pi(\mathrm{Al}-\mathrm{C}),{ }^{23}$ the fact that $\Delta E_{\mathrm{DQ}}$ decreases in the same order is easily understandable.

However, this is not the only manner in which the identity of X in $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3}$ affects the difference between the $\mathrm{e}^{\prime \prime}$ and $1 \mathrm{a}_{2}{ }^{\prime \prime}$ orbital energies and, hence, the size of $\Delta E_{\mathrm{DQ}}$. As shown in Figure 1, the $\mathrm{e}^{\prime \prime}$ MOs have a node at the central atom, whereas $1 \mathrm{a}_{2}{ }^{\prime \prime}$ does not. Consequently, a $1 \mathrm{a}_{2}{ }^{\prime \prime} \rightarrow \mathrm{e}^{\prime \prime}$ excitation transfers electron density from X to the peripheral carbons. Thus, the less electronegative X is, relative to C , the smaller the $\mathrm{e}^{\prime \prime}-$ $1 \mathrm{a}_{2}{ }^{\prime \prime}$ orbital energy difference and the lower the calculated size of the $\Delta E_{\mathrm{DQ}}$ energy difference in Table 1.

Replacing $\mathrm{Y}=\mathrm{CH}_{2}$ in $\mathrm{XY}_{3}$ with a more electronegative group or atom should also decrease the size of the $e^{\prime \prime}-1 \mathrm{a}_{2}{ }^{\prime \prime}$ orbital energy difference and, hence, the size of $\Delta E_{\mathrm{DQ}}$. As shown in Table 1, going from $\mathrm{Al}\left(\mathrm{CH}_{2}\right)_{3}$ to $\mathrm{AlO}_{3}$ is computed to lower the CASPT2 value of $\Delta E_{\mathrm{DQ}}$ from $4.4 \mathrm{kcal} / \mathrm{mol}$ to only $1.0 \mathrm{kcal} /$ mol. Since an $\mathrm{Al}-\mathrm{O} \pi$ bond is stronger than an $\mathrm{Al}-\mathrm{C} \pi$ bond, ${ }^{23}$ this decrease in $\Delta E_{\mathrm{DQ}}$ is clearly not due to a decrease in $\pi$ bond strengths but to the greater electronegativity of O , relative to $\mathrm{CH}_{2}$.

A Simple Model for $\mathrm{XY}_{3}$ Radicals with Three $\boldsymbol{\pi}$ Electrons and $Y$ Much More Electronegative than $X$. In a hypothetical $\mathrm{XY}_{3}$ radical that is isoelectronic with $\mathrm{C}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet+}$, if Y were infinitely more electronegative than X , all three $\pi$ electrons would be localized in $\mathrm{p}-\pi \mathrm{AOs}$ on the electronegative Y atoms. If there really were no delocalization of electrons into the empty $\mathrm{p}-\pi \mathrm{AO}$ on X , this would be equivalent to not having a $\mathrm{p}-\pi$ AO on the central atom or to not having a central atom at all. Therefore, $\mathrm{H}_{3}{ }^{\bullet}$ with equal separations between all three hydrogens should provide an adequate model for the $\pi$ system of such an $\mathrm{XY}_{3}$ radical at $D_{3 h}$ geometries. ${ }^{24}$

Correlation between the three electrons in the three 1 s orbitals of $\mathrm{H}_{3}{ }^{\bullet}$ can be handled by (3/3)CASSCF calculations. The results of $(3 / 3)$ CASSCF/6-311G(p) calculations on $\mathrm{H}_{3}{ }^{\bullet}$ at $D_{3 h}$ geometries are given in Table 3. The Table shows that, as the distance, $R$, between the three hydrogen atoms and their collective center of mass decreases, the energy of the ${ }^{4} \mathrm{~A}_{2}{ }^{\prime}$ state rises monotonically, while that of the ${ }^{2} \mathrm{E}^{\prime}$ state decreases by $20.9 \mathrm{kcal} / \mathrm{mol}$ between $R=4.00 \AA$ and the $D_{3 h}$ minimum at $R=0.65 \AA$. Consequently, although the energies of ${ }^{4} \mathrm{~A}_{2}$ ' and ${ }^{2} \mathrm{E}^{\prime}$ are essentially the same at $R=4.0 \AA$, the energy of ${ }^{4} \mathrm{~A}_{2}{ }^{\prime}$ never falls below that of ${ }^{2} \mathrm{E}^{\prime}$. Jahn-Teller distortions of ${ }^{2} \mathrm{E}^{\prime}$ from $D_{3 h}$ geometries would, of course, further stabilize the doublet state. ${ }^{24}$

The results in Table 3 of the CASSCF calculations on the $\mathrm{H}_{3}{ }^{\bullet}$ model indicate that a doublet should also be the ground state of an $\mathrm{XY}_{3}$ radical, containing three $\pi$ electrons, even if Y were infinitely more electronegative than X . To understand why a doublet is expected to be the ground state, even under those circumstances most likely to provide the smallest values of $\Delta E_{\mathrm{DQ}}$, it is instructive to continue to exploit the simple $\mathrm{H}_{3}{ }^{\circ}$ model.

Placing one electron in each 1s $\mathrm{AO}(\phi)$ of $\mathrm{H}_{3}{ }^{\bullet}$ minimizes the Coulombic repulsion energy between electrons. For the ${ }^{4} \mathrm{~A}_{2}{ }^{\prime}$ state this distribution of the three electrons is, of course, the only one allowed by the Pauli exclusion principle. Equation 1 gives the wave function for the component of the quartet in which the electron in each AO has spin $\alpha$.

$$
\begin{equation*}
{ }^{4} \Psi=\left|\phi_{1}^{\alpha} \phi_{2}^{\alpha} \phi_{3}^{\alpha}\right\rangle \tag{1}
\end{equation*}
$$

However, the quartet is not the only state in which one electron can be localized in each 1 s AO of $\mathrm{H}_{3}{ }^{\circ}$. There is a ${ }^{2} \mathrm{E}^{\prime}$ state in which this is also possible. The wave functions for its two components, ${ }^{2} \mathrm{E}_{x}{ }^{\prime}$ and ${ }^{2} \mathrm{E}_{y}^{\prime}$ (respectively, ${ }^{2} \mathrm{~A}_{1}$ and ${ }^{2} \mathrm{~B}_{1}$ in $C_{2 v}$ symmetry), are given in eqs 2 and 3 .

$$
\begin{gather*}
{ }^{2} \Psi_{x}=\frac{1}{\sqrt{6}}\left[2\left|\phi_{1}^{\beta} \phi_{2}^{\alpha} \phi_{3}^{\alpha}\right\rangle-\left|\phi_{1}^{\alpha} \phi_{2}^{\beta} \phi_{3}^{\alpha}\right\rangle-\left|\phi_{1}^{\alpha} \phi_{2}^{\alpha} \phi_{3}^{\beta}\right\rangle\right]  \tag{2}\\
{ }^{2} \Psi_{y}=\frac{1}{\sqrt{2}}\left[\left|\phi_{1}^{\alpha} \phi_{2}^{\beta} \phi_{3}^{\alpha}\right\rangle-\left|\phi_{1}^{\alpha} \phi_{2}^{\alpha} \phi_{3}^{\beta}\right\rangle\right] \tag{3}
\end{gather*}
$$

It is possible to rewrite the valence-bond wave functions in eqs $1-3$ in terms of MOs. The normalized MOs, $\psi$, of $D_{3 h} \mathrm{H}_{3}{ }^{\circ}$ can be expressed as linear combinations of the 1s AOs. Equation 4 gives the wave function for the $a_{1} \mathrm{MO}\left(\psi_{1}\right)$; and eqs 5 and 6 give, respectively, the wave functions for the degenerate pair of $\mathrm{e}_{x}\left(\psi_{2}\right)$ and $\mathrm{e}_{y}\left(\psi_{3}\right)$ MOs. The normalizations assume that the overlap between AOs is either negligible or is small enough to be neglected.

$$
\begin{gather*}
\psi_{1}=\frac{1}{\sqrt{3}}\left(\phi_{1}+\phi_{2}+\phi_{3}\right)  \tag{4}\\
\psi_{2}=\frac{1}{\sqrt{2}}\left(\phi_{2}-\phi_{3}\right)  \tag{5}\\
\psi_{3}=\frac{1}{\sqrt{6}}\left(2 \phi_{1}-\phi_{2}-\phi_{3}\right) \tag{6}
\end{gather*}
$$

Using eqs 4-6, each of the AOs can each be written as a linear combination of the MOs. Solving eqs 4-6 for each of the AOs affords

$$
\begin{gather*}
\phi_{1}=\frac{\sqrt{3}}{3} \psi_{1}+\frac{\sqrt{6}}{3} \psi_{3}  \tag{7}\\
\phi_{2}=\frac{\sqrt{3}}{3} \psi_{1}+\frac{\sqrt{2}}{2} \psi_{2}-\frac{\sqrt{6}}{6} \psi_{3}  \tag{8}\\
\phi_{3}=\frac{\sqrt{3}}{3} \psi_{1}-\frac{\sqrt{2}}{2} \psi_{2}-\frac{\sqrt{6}}{6} \psi_{3} \tag{9}
\end{gather*}
$$

Substituting eqs $7-9$ into eq 1 gives the ${ }^{4} \mathrm{~A}_{2}{ }^{\prime}$ wave function, expressed in terms of MOs. Not surprisingly, it reduces to the wave function in eq 10 , which places one $\alpha$ electron in each MO.

$$
\begin{equation*}
{ }^{4} \Psi=\left|\psi_{1}^{\alpha} \psi_{2}^{\alpha} \psi_{3}^{\alpha}\right\rangle \tag{10}
\end{equation*}
$$

Using eqs $7-9$, the ${ }^{2} E^{\prime}$ wave functions in eqs 2 and 3 can also be expressed in terms of the MOs in eqs 4-6. However, unlike the ${ }^{4} \mathrm{~A}_{2}$ ' wave function in eq 10 , the ${ }^{2} \mathrm{E}^{\prime}$ wave functions turn out to be linear combinations of configurations, each of which assigns the three electrons to a different set of MOs. The ${ }^{2} \mathrm{E}_{x}^{\prime}$ wave function is given in eq 11 , and the ${ }^{2} \mathrm{E}_{y}{ }^{\prime}$ wave function is given in eq 12.

$$
\begin{align*}
&{ }^{2} \Psi_{x}= \frac{1}{\sqrt{3}}\left[\left|\psi_{1}^{2} \psi_{2}^{\alpha}\right\rangle-\left|\psi_{1}^{\alpha} \psi_{3}^{2}\right\rangle-\right. \\
&\left.\frac{1}{\sqrt{2}}\left(\left|\psi_{1}^{\alpha} \psi_{2}^{\alpha} \psi_{3}^{\beta}\right\rangle-\left|\psi_{1}^{\alpha} \psi_{2}^{\beta} \psi_{3}^{\alpha}\right\rangle\right)\right]  \tag{11}\\
&{ }^{2} \Psi_{y}= \frac{1}{\sqrt{3}}\left[\left|\psi_{1}^{2} \psi_{3}^{\alpha}\right\rangle-\left|\psi_{2}^{2} \psi_{3}^{\alpha}\right\rangle-\right. \\
&\left.\frac{1}{\sqrt{2}}\left(\left|\psi_{1}^{\alpha} \psi_{2}^{2}\right\rangle-\left|\psi_{1}^{\alpha} \psi_{2}^{3}\right\rangle\right)\right] \tag{12}
\end{align*}
$$

At sufficiently large $\mathrm{H}-\mathrm{H}$ distances, the quartet wave function in eq 10 has exactly the same energy as the degenerate doublet wave functions in eqs 11 and 12 . However, as the hydrogen 1s AOs begin to overlap, two effects alter the relative energies of ${ }^{4} \mathrm{~A}_{2}^{\prime}$ and ${ }^{2} \mathrm{E}^{\prime}$. One involves electron repulsion in the overlap regions between the hydrogen atoms, which selectively stabilizes the quartet. The other involves bonding between the hydrogens, which selectively stabilizes the doublet.

Figure 2. Schematic depiction of (a) the $\pi$ MOs for TMM and how they are occupied in the (b) ${ }^{2} \mathrm{E}_{y}{ }^{\prime \prime}$ and (c) ${ }^{4} \mathrm{~A}_{1}{ }^{\prime \prime}$ states of an $\mathrm{XY}_{3}$ radical containing five $\pi$ electrons. Only the top lobe of each 2 p AO is shown.

The quartet wave function not only keeps the electrons from appearing in the same AO , but ${ }^{4} \Psi$ also prevents the electrons from appearing simultaneously in the regions where two of the 1s AOs overlap. The doublet wave functions, ${ }^{2} \Psi_{x}$ and ${ }^{2} \Psi_{y}$, contain one electron that has opposite spin from the other two, and there is no prohibition against having a pair of electrons of opposite spin simultaneously in the same overlap region. ${ }^{25}$ Consequently, the doublet wave functions each have a slightly higher Coulombic repulsion energy than the quartet, when the hydrogen 1 s AOs begin to overlap.

On the other hand, in the quartet the interactions between the hydrogen atoms are all antibonding; but in the doublets some are bonding and some are antibonding. For example, using eq 2 , it is easy to show that in ${ }^{2} \Psi_{x}$ the interactions between $\phi_{1}$ and both $\phi_{2}$ and $\phi_{3}$ are weakly bonding, but the interaction between $\phi_{2}$ and $\phi_{3}$ is antibonding. Similarly, using eq 3 it can be shown that just the reverse is true in ${ }^{2} \Psi_{y}$; the interactions between $\phi_{1}$ and both $\phi_{2}$ and $\phi_{3}$ are weakly antibonding, but the interaction between $\phi_{2}$ and $\phi_{3}$ is bonding. Overall, the doublet wave functions are each nonbonding. However, the quartet wave function is antibonding between all the hydrogens, and this confers an energetic advantage on the doublet.

Our CASSCF calculations find that, as the AOs of $\mathrm{H}_{3}{ }^{\bullet}$ begin to overlap, if the weights of the three types of configurations in each of the doublet wave functions in eqs 11 and 12 are kept equal, the quartet falls below the doublets in energy. ${ }^{26}$ However, as the AOs begin to overlap, and $\psi_{1}$ is stabilized, relative to $\psi_{2}$ and $\psi_{3}$, the coefficients of the three types of configurations in eqs 11 and 12 do not remain equal. For example, in eq 13 for the ${ }^{2} \mathrm{E}_{x}^{\prime}$ wave function, $c_{1}$, the coefficient of the configuration in which $\psi_{1}$ is doubly occupied, increases; and $c_{2}$, the coefficient of the configuration in which $\psi_{1}$ is empty decreases, as does the coefficient of the pair of configurations in which $\psi_{1}$ is singly occupied. The resulting increase in bonding between the hydrogens is what causes the doublets to be stabilized as the 1 s AOs of the hydrogens begin to overlap.

$$
\begin{array}{r}
{ }^{2} \Psi_{x}=c_{1}\left|\psi_{1}^{2} \psi_{2}^{\alpha}\right\rangle-c_{2}\left|\psi_{2}^{\alpha} \psi_{3}^{2}\right\rangle-\frac{c_{3}}{\sqrt{2}}\left(\left|\psi_{1}^{\alpha} \psi_{2}^{\alpha} \psi_{3}^{\beta}\right\rangle-\right. \\
\left.\left|\psi_{1}^{\alpha} \psi_{2}^{\beta} \psi_{2}^{\alpha}\right\rangle\right) \tag{13}
\end{array}
$$

Table 3 gives the coefficients of the three configurations in the ${ }^{2} \Psi_{\mathrm{x}}$ wave function for $\mathrm{H}_{3}{ }^{\bullet}$ at several distances, $R$, between each of the hydrogens and their center of mass. The degeneracy of ${ }^{2} \mathrm{E}_{x}^{\prime}$ and ${ }^{2} \mathrm{E}_{y}^{\prime}$ at $D_{3 h}$ geometries ensures that, as the hydrogens
begin to overlap, the changes in the coefficients of the configurations in ${ }^{2} \Psi_{y}$ are the same as those in the coefficients of the corresponding configurations in eq 13 for ${ }^{2} \Psi_{x}$. Table 3 shows the changes in the coefficients of the configurations in the ${ }^{2} E^{\prime}$ wave functions are accompanied by a decrease in energy of this state by $20.9 \mathrm{kcal} / \mathrm{mol}$ on going from $R=4.00 \AA$ to the $D_{3 h}$ geometry of minimum energy at $R=0.65 \AA$.

Bonding between the hydrogen 1 s AOs favors the doublet state over the quartet in our $\mathrm{H}_{3}{ }^{\bullet}$ model for an $\mathrm{XY}_{3}$ radical that contains three $\pi$ electrons and in which Y is much more electronegative than X. Similarly, even if $\pi$ bonding between X and Y does not provide any stabilization for the doublet state in such an $\mathrm{XY}_{3}$ radical, bonding between the $2 \mathrm{p}-\pi \mathrm{AOs}$ on Y will result in a doublet ground state. Consequently, we predict it is highly unlikely that an $\mathrm{XY}_{3}$ radical, containing three $\pi$ electrons, will ever be found in which the quartet is the ground state.

Effect of Heteroatom Substitution on $\Delta E_{\mathrm{DQ}}$ in $\mathbf{C}\left(\mathbf{C H}_{2}\right) 3^{-{ }^{-}}$. For $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3}$ molecules with five $\pi$ electrons, $\Delta E_{\mathrm{DQ}}$ in Table 2 shows exactly the opposite trend from $\Delta E_{\mathrm{DQ}}$ in Table 1 for $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3}$ molecules with three $\pi$ electrons. The value of $\Delta E_{\mathrm{DQ}}$ in Table 2 decreases with increasing electronegativity of X in the order $\mathrm{X}=\mathrm{C}^{-}>\mathrm{X}=\mathrm{N}>\mathrm{X}=\mathrm{O}^{+}$. Figure 2 shows that this decrease cannot be due to the fact that $\pi$ bond strengths increase in the order $\pi(\mathrm{C}=\mathrm{C})<\pi(\mathrm{N}=\mathrm{C})<\pi(\mathrm{O}=\mathrm{C}),{ }^{23}$ since formation of ${ }^{4} \mathrm{~A}_{1}{ }^{\prime \prime}$ from either of the lowest doublet states requires the excitation of an electron from the doubly occupied $e^{\prime \prime}$ NBMOs to the antibonding $2 \mathrm{a}_{2}{ }^{\prime \prime}$ MO. This excitation energy, and, hence, the size of $\Delta E_{\mathrm{DQ}}$, should increase with the strength of a $\pi$ bond between X and $\mathrm{CH}_{2}$; but the trend in Table 2 is just the opposite.

Instead, the decrease in $\Delta E_{\mathrm{DQ}}$ with the electronegativity of X is due the fact that an $\mathrm{e}^{\prime \prime} \rightarrow 2 \mathrm{a}_{2}{ }^{\prime \prime}$ excitation transfers electron density from $\mathrm{CH}_{2}$ to X . As already noted, $\mathrm{e}^{\prime \prime}$ has a node at the central atom, X ; whereas $2 \mathrm{a}_{2}{ }^{\prime \prime}$, like $1 \mathrm{a}_{2}{ }^{\prime \prime}$, does not. Therefore, the $\mathrm{e}^{\prime \prime} \rightarrow 2 \mathrm{a}_{2}^{\prime \prime}$ excitation energy behaves exactly opposite to the $1 \mathrm{a}_{2}{ }^{\prime \prime} \rightarrow \mathrm{e}^{\prime \prime}$ excitation energy and decreases with increasing electronegativity of X , relative to $\mathrm{CH}_{2}$.

On going from $\mathrm{X}=\mathrm{C}^{-}$to $\mathrm{X}=\mathrm{N}$ in $\mathrm{X}\left(\mathrm{CH}_{2}\right)_{3}$, the decrease in $\Delta E_{\mathrm{DQ}}$ is rather small. The decrease is calculated to be only $4.9 \mathrm{kcal} / \mathrm{mol}$ by CASPT2 and $1.8 \mathrm{kcal} / \mathrm{mol}$ by UB3LYP. We note, however, that the extra electron in ${ }^{2} \mathrm{~A}_{2} \mathrm{C}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\circ-}$ is computed to be unbound $(\mathrm{EA}=-6.7 \mathrm{kcal} / \mathrm{mol})$ by CASPT2 and barely bound $(E A=5.3 \mathrm{kcal} / \mathrm{mol})$ by UB3LYP. ${ }^{27}$ Since $\Delta E_{\mathrm{DQ}}>40 \mathrm{kcal} / \mathrm{mol}$ at both levels of theory, in the ${ }^{4} \mathrm{~A}_{1}{ }^{\prime \prime}$ state

TABLE 4: (3/3)CASSCF/6-311G(p) Energies (kcal/mol) and Coefficients of the Configurations in the Wave Function (eq 14) for the ${ }^{2} \mathrm{E}^{\prime}$ state of $D_{3 h} \mathrm{HeH}_{3}{ }^{\circ}$ as a Function of the $\mathrm{He}^{-} \mathbf{H}$ Distance, $R$ (Energies Relative to That of ${ }^{2} \mathrm{E}^{\prime}$ at $\mathrm{R}=4.0 \AA$

| $R(\AA)$ | $c_{1}$ | $c_{2}$ | $c_{3}$ | $\left({ }^{2} \mathrm{E}^{\prime}\right)$ | $E\left({ }^{4} \mathrm{~A}_{2}{ }^{\prime}\right)$ | $\Delta E_{\mathrm{DQ}}$ |
| :---: | :---: | :---: | :---: | ---: | ---: | ---: |

| 4.0 | 0.577 | 0.577 | 0.577 | $0^{b}$ | 0.00 | 0.00 |

${ }^{a}$ The maximum value of $\Delta E_{\mathrm{DQ}}=0.23 \mathrm{kcal} / \mathrm{mol}$ was found to occur around $R=1.6 \AA$. ${ }^{b} E=-4.359325$ hartrees.
of the radical anion the electron in the $2 \mathrm{a}_{2}{ }^{\prime \prime} \mathrm{MO}$ is unbound, by ca. $50 \mathrm{kcal} / \mathrm{mol}$ at the CASPT2 level and by ca. $35 \mathrm{kcal} / \mathrm{mol}$ at UB3LYP.

Hence, in the ${ }^{4} \mathrm{~A}_{1}$ " state of $\mathrm{C}\left(\mathrm{CH}_{2}\right)_{3}{ }^{0-}$ the electron in the $2 \mathrm{a}_{2}{ }^{\prime \prime}$ MO occupies a very diffuse, Rydberg-like, orbital, rather than a valence orbital, as in $\mathrm{N}\left(\mathrm{CH}_{2}\right)_{3} \cdot$. Therefore, the difference between the values of $\Delta E_{\mathrm{DQ}}$ in $\mathrm{C}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet-}$ and $\mathrm{N}\left(\mathrm{CH}_{2}\right)_{3}$ does not really reflect the difference between the energies of the $2 \mathrm{a}_{2}{ }^{\prime \prime}$ valence orbitals in these two radicals.

In the ${ }^{4} \mathrm{~A}_{1}{ }^{\prime \prime}$ states of both $\mathrm{N}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\circ}$ and $\mathrm{O}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet+}, 2 \mathrm{a}_{2}{ }^{\prime \prime}$ is a valence orbital. As a result, comparison of the $\Delta E_{\mathrm{DQ}}$, values in $\mathrm{N}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet}$ and $\mathrm{O}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet+}$ does reflect the effect of the difference between the electronegativities of N and O on the relative energies of the $2 \mathrm{a}_{2}{ }^{\prime \prime}$ MOs. It is for this reason that $\Delta E_{\mathrm{DQ}}$ decreases by ca. $30 \mathrm{kcal} / \mathrm{mol}$ on going from $\mathrm{N}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet}$ to $\mathrm{O}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet+}$.

Replacing X by a more electronegative atom is one way to decrease the $\mathrm{e}^{\prime \prime} \rightarrow 2 \mathrm{a}_{2}{ }^{\prime \prime}$ excitation energy and, hence, the size of $\Delta E_{\mathrm{DQ}}$. Another way is to replace carbon in $\mathrm{CH}_{2}$ by a more electropositive element, such as Si . The substitution of $\mathrm{SiH}_{2}$ for $\mathrm{CH}_{2}$ lowers the $\mathrm{e}^{\prime \prime} \rightarrow 2 \mathrm{a}_{2}{ }^{\prime \prime}$ excitation energy not only because Si is less electronegative than C , but also by virtue of the fact that a $\pi$ bond to Si is weaker than a $\pi$ bond to $\mathrm{C} .{ }^{23}$

As shown in Table 2, the CASPT2 value of $\Delta E_{\mathrm{DQ}}=9.0 \mathrm{kcal} /$ mol for $\mathrm{O}\left(\mathrm{CH}_{2}\right)_{3}{ }^{\bullet+}$ decreases to $-0.8 \mathrm{kcal} / \mathrm{mol}$ for $\mathrm{O}\left(\mathrm{SiH}_{2}\right)_{3}{ }^{\bullet+}$. Thus, in planar $\mathrm{O}\left(\mathrm{SiH}_{2}\right)_{3}{ }^{\circ+}$ the quartet is actually predicted to fall slightly below the doublet in energy. ${ }^{28}$

A Simple Model for $\mathbf{X Y}_{3}$ Radicals with Five $\pi$ Electrons and X Much More Electronegative than Y. Why is it possible to find a planar $\mathrm{XY}_{3}$ radical with a quartet ground state when there are five $\pi$ electrons, but not when there are three $\pi$ electrons? As already discussed, an $\mathrm{H}_{3}{ }^{\bullet}$ model predicts that the doublet will always remain the ground state of $\mathrm{XY}_{3}{ }^{\bullet}$ when there are three $\pi$ electrons, no matter how much more electronegative Y is than X . Therefore, it is reasonable to ask if a similarly simple model predicts that the quartet can become the ground state of $\mathrm{XY}_{3}{ }^{\bullet}$ when there are five $\pi$ electrons and X is much more electronegative than Y.

In the model for the five-electron case we again used three hydrogen atoms, arranged in the geometry of an equilateral triangle, as Y in $\mathrm{XY}_{3}{ }^{\bullet}$. As a very electronegative central atom with two valence electrons we chose He . We then carried out (5/4)CASSCF/6-311G(p) calculations on $\mathrm{HeH}_{3}{ }^{\bullet}$ at $D_{3 h}$ geometries with different values of the $\mathrm{He}-\mathrm{H}$ distance, $R$. The results are summarized in Table 4.

As shown in this Table, as $R$ is decreased, the energies of both the ${ }^{2} \mathrm{E}^{\prime}$ and ${ }^{4} \mathrm{~A}_{2}{ }^{\prime}$ states of $\mathrm{HeH}_{3}{ }^{\bullet}$ increase monotonically. At small $R^{2} \mathrm{E}^{\prime}$ is the ground state. However, at intermediate values of $R$, the quartet falls below the doublet. Thus, at these values of $R$, the $\mathrm{HeH}_{3} \cdot{ }^{\bullet}$ model successfully reproduces what our CASSCF and CASPT2 calculations predict to occur in planar $\mathrm{O}\left(\mathrm{SiH}_{2}\right)_{3}{ }^{+}$: the quartet becomes the ground state.

In understanding why the quartet falls below the doublet in both $\mathrm{O}\left(\mathrm{SiH}_{2}\right)_{3}{ }^{\bullet+}$ and in our $\mathrm{HeH}_{3}{ }^{\bullet}$ model for it, eq 14 is useful. It gives the wave function for the ${ }^{2} \mathrm{E}_{x}^{\prime}$ component of ${ }^{2} \mathrm{E}^{\prime}$ in $\mathrm{HeH}_{3}{ }^{\circ}$. Equation 14 differs from eq 13 by the fact that each configuration in eq 14 contains a term, $\mathrm{He}^{2}$, for the two electrons that occupy the 1 s AO on helium. However, as in eq 13, $\psi_{1}$, $\psi_{2}$, and $\psi_{3}$ are the combinations of hydrogen defined by eqs 4-6.

$$
\begin{align*}
& { }^{2} \Psi_{x}=c_{1}\left|\mathrm{He}^{2} \psi_{1}^{2} \psi_{2}^{\alpha}\right\rangle-c_{2}\left|\operatorname{He}^{2} \psi_{2}^{\alpha} \psi_{3}^{2}\right\rangle- \\
& \frac{c_{3}}{\sqrt{2}}\left(\left|\operatorname{He}^{2} \psi_{1}^{\alpha} \psi_{2}^{\alpha} \psi_{3}^{\beta}\right\rangle-\left|\operatorname{He}^{2} \psi_{1}^{\alpha} \psi_{2}^{\beta} \psi_{3}^{\alpha}\right\rangle\right) \tag{14}
\end{align*}
$$

In $\mathrm{HeH}_{3}{ }^{\bullet}, \psi_{2}$ and $\psi_{3}$ each have a node at the He atom, but $\psi_{1}$ has the correct symmetry to interact with the He 1s AO. Since $\psi_{1}$ interacts with this doubly occupied orbital of much lower energy, $\psi_{1}$ is destabilized by this interaction.

Table 4 shows how the coefficients of the configurations in the ${ }^{2} \mathrm{E}^{\prime}$ wave functions change as the $\mathrm{He}-\mathrm{H}$ distance, $R$, decreases and the interaction between $\psi_{1}$ and the He 1 s AO increases. Since $\psi_{1}$ is destabilized by its interaction with the He 1 s AO , at values of $R<2.5 \AA$ the coefficient, $c_{2}$, of the configuration in which $\psi_{1}$ is empty increases at the expense of $c_{1}$, the coefficient of the configuration in which $\psi_{1}$ is doubly occupied. As $R$ decreases, $c_{3}$, the coefficient of the configurations in which $\psi_{1}$ is singly occupied also decreases, but to a much lesser extent than does $c_{1}$.

Nevertheless, at $\mathrm{He}-\mathrm{H}$ distances, where the increases in the energies of both ${ }^{2} \mathrm{E}^{\prime}$ and ${ }^{4} \mathrm{~A}_{2}^{\prime}$ show that there is a nonnegligible interaction between the 1 s orbitals of these atoms (e.g., at $R=$ $2.0 \AA$ ), the coefficients $c_{1}, c_{2}$, and $c_{3}$ remain nearly equal. The reason is that, as the $\mathrm{He}-\mathrm{H}$ distance decreases, the $\mathrm{H}-\mathrm{H}$ distances also decrease. Although the $\mathrm{He}-\mathrm{H}$ interactions in $\psi_{1}$ are antibonding in $\mathrm{HeH}_{3}{ }^{\circ}$, the $\mathrm{H}-\mathrm{H}$ interactions in $\psi_{1}$ are bonding in $\mathrm{HeH}_{3}{ }^{\bullet}$, as they are in $\mathrm{H}_{3}{ }^{\circ}$. These two opposing effects on the energy of $\psi_{1}$ are what tend to keep the coefficients $c_{1}$, $c_{2}$, and $c_{3}$ nearly equal, until values of $R$ are reached at which $\mathrm{He}-\mathrm{H}$ antibonding dominates $\mathrm{H}-\mathrm{H}$ bonding (e.g., at $R=1.0$ A).

As already discussed, when these coefficients are equal or nearly so, the quartet has the advantage of having a slightly lower Coulombic repulsion energy than the doublet, because the Pauli principle prevents electrons of the same spin from simultaneously appearing in the overlap regions between atoms. Thus, at geometries of $\mathrm{HeH}_{3}{ }^{\bullet}$ where an appreciable fraction of the $\mathrm{He}-\mathrm{H}$ antibonding interactions in the doublet are canceled by $\mathrm{H}-\mathrm{H}$ bonding interactions, the lower Coulombic repulsion in the quartet can become the dominant energetic effect and cause ${ }^{4} \mathrm{~A}_{2}$ ' to fall below ${ }^{2} \mathrm{E}^{\prime}$.

Comparison of the CASSCF coefficients for the configurations in the ${ }^{2} E^{\prime}$ wave functions in Tables 3 and 4 shows that, at the same values of $R$ (e.g., $R=1.5 \AA$ ), $c_{1}$ and $c_{2}$ are more nearly equal in $\mathrm{HeH}_{3}{ }^{\bullet}$ than in $\mathrm{H}_{3}{ }^{\bullet}$. Similarly, one would expect the CASSCF coefficients for the configurations in the ${ }^{2} \mathrm{~A}_{2}$ wave functions that correspond to the first two configurations in eqs 13 and 14 to be more nearly equal in $\mathrm{O}\left(\mathrm{SiH}_{2}\right)_{3}{ }^{\circ+}$ than in $\mathrm{AlO}_{3}{ }^{\circ}$. In fact, at the equilibrium geometries of the doublet states of these two radicals, $\left(c_{2} / c_{1}\right)^{2}=1.12$ in $\mathrm{O}\left(\mathrm{SiH}_{2}\right)_{3}{ }^{\bullet+}$, but $\left(c_{1} / c_{2}\right)^{2}=$ 1.23 in $\mathrm{AlO}_{3}{ }^{\circ}{ }^{29}$

## Conclusions

Our CASSCF, CASPT2, and UB3LYP calculations all predict $\mathrm{AlO}_{3}{ }^{\bullet}$ to have a doublet ground state; whereas, the same types of calculations all predict the ground state of $\mathrm{O}\left(\mathrm{SiH}_{2}\right)_{3}{ }^{\bullet+}$ to be
a quartet. Model calculations on $\mathrm{H}_{3}{ }^{\bullet}$ and $\mathrm{HeH}_{3}{ }^{\bullet}$ support the following explanation for this difference between $\mathrm{AlO}_{3}{ }^{\circ}$ and $\mathrm{O}\left(\mathrm{SiH}_{2}\right)_{3}{ }^{++}$.

In $\mathrm{AlO}_{3}{ }^{\circ}$ the $\mathrm{Al}-\mathrm{O}$ and the $\mathrm{O}-\mathrm{O} \pi$ interactions both selectively stabilize the $1 a_{2}{ }^{\prime \prime}$ bonding MO and, hence, favor the doublet state over the quartet. In contrast, in $\mathrm{O}\left(\mathrm{SiH}_{2}\right)_{3}{ }^{\bullet+}$ destabilization by $\mathrm{O}-\mathrm{Si} \pi$ antibonding of the $2 \mathrm{a}_{2}{ }^{\prime \prime} \mathrm{MO}$ that is largely localized on the silicons is partially offset by $\mathrm{Si}-\mathrm{Si} \pi$ bonding. As a result, occupancy of this $\pi \mathrm{MO}$ is not strongly disfavored, relative to occupancy of an $\mathrm{e}^{\prime}$ nonbonding MO. Consequently, in $\mathrm{O}\left(\mathrm{SiH}_{2}\right) 3^{\bullet+}$ the lower electron repulsion in the quartet can overcome the only slightly larger amount of $\pi$ bonding in the doublet.

More generally, the results described in this paper predict that the ground state of an $\mathrm{XY}_{3}$ radical with three $\pi$ electrons will always be a doublet, even if Y is much more electronegative than X . In contrast, in an $\mathrm{XY}_{3}$ radical with five $\pi$ electrons, if X is much more electronegative than Y , there is at least a possibility that the ground state will be a quartet.

We hope that our predictions of how $\Delta E_{\mathrm{DQ}}$ depends on the electronegativities of X and Y in $\mathrm{XY}_{3}$ radicals with three and with five $\pi$ electrons will be useful in designing $\mathrm{XY}_{3}$ radicals with very low-lying excited quartet states. We also hope our predictions-that the doublet will be the ground state of every $\mathrm{XY}_{3}$ radical with three $\pi$ electrons, but that the quartet can become the ground state of a planar $\mathrm{XY}_{3}$ radical with five $\pi$ electrons, when X is much more electronegative than Y -will stimulate experimental tests.

Acknowledgment. We thank the National Science Foundation for their generous support of this research. We also thank Professor Hiizu Iwamura for piquing our interest in $\Delta E_{\mathrm{DQ}}$ in $\mathrm{XY}_{3}$ radicals containing three and five $\pi$ electrons. Drs. William T. G. Johnson and David A. Hrovat are acknowledged for their assistance during the course of this research.

(24) This $\mathrm{H}_{3}{ }^{\bullet}$ model breaks down if distortions from $D_{3 \mathrm{~h}}$ geometries are allowed; since the Jahn-Teller-active vibrational modes in ${ }^{2} \mathrm{E}^{\prime}$ lead to stationary points with highly distorted geometries. One stationary point corresponds to a hydrogen molecule plus a distant hydrogen atom at a $C_{2 v}$ geometry, and another stationary point corresponds to a linear geometry, with equal $H-H$ bond lengths, that is the transition structure for the $\mathrm{H}_{2}+$ $\mathrm{H}^{\bullet}$ reaction.
(25) It is easy to use eqs 2 and 3 to show that electrons of opposite spin can appear simultaneously in the overlap regions between $\phi_{1}$ and $\phi_{2}$ and between $\phi_{1}$ and $\phi_{3}$ in ${ }^{2} \Psi_{x}$ and between $\phi_{2}$ and $\phi_{3}$ in ${ }^{2} \Psi_{y}$.
(26) If overlap were included in normalizing the MOs in eqs $4-6$, in eqs 7-9 the coefficients of $\psi_{1}$ would increase, and those of $\psi_{2}$ and $\psi_{3}$ would decrease. Therefore, with inclusion of overlap in the normalization, the weight of the first configuration in eqs 11 and 12 would be larger than the weight of the second configuration; and the combined weights of the last two configurations would have an intermediate value. Consequently, when overlap is significant, constraining the weights of the configurations in eqs 11 and 12 to be equal disadvantages these doublet wave functions, relative to the quartet, by making the doublets overall slightly antibonding, rather than nonbonding.
(27) Squires, et al. have measured $\mathrm{EA}=9.9 \mathrm{kcal} / \mathrm{mol}$ for $\mathrm{C}\left(\mathrm{CH}_{2}\right)_{3^{-}}{ }^{-7}$, in fair agreement with the value of $\mathrm{EA}=5.3 \mathrm{kcal} / \mathrm{mol}$, computed by UB3LYP. The agreement between the calculated and experimental EAs is further improved if the $\mathrm{CH}_{2}$ groups in $\mathrm{C}\left(\mathrm{CH}_{2}\right)_{3^{\bullet-}}$ are allowed to pyramidalize, which lowers the energy of the radical anion by $0.4 \mathrm{kcal} / \mathrm{mol}$, and gives EA $=5.7 \mathrm{kcal} / \mathrm{mol}$.
(28) Unconstrained reoptimization of the geometry of the quartet led to a $C_{1}$ structure, with all the silyl centers pyramidalized, which was 46.4 $\mathrm{kcal} / \mathrm{mol}$ lower in energy than planar ${ }^{4} \mathrm{~A}_{2}{ }^{\prime \prime}$. Attempts to reoptimize the geometry of the lowest planar doublet led, unfortunately, to pyramidalization accompanied by $\mathrm{Si}-\mathrm{Si}$ bond formation. However, constrained optimization of a ${ }^{2} \mathrm{~A}^{\prime \prime}$ wave function, with a plane of symmetry perpendicular to the molecular plane, led to a $C_{s}$ geometry with the two equivalent silyls pyramidalized in the opposite direction than the third. The energy of this doublet was computed to be $0.2 \mathrm{kcal} / \mathrm{mol}$ lower than that of the fully optimized quartet.
(29) In $\mathrm{O}\left(\mathrm{SiH}_{2}\right)^{\cdot+}$, the two unique bond lengths at the CASSCFoptimized $C_{2 v}$ geometry of the ${ }^{2} \mathrm{~A}_{2}$ state $(R=1.788$ and $1.789 \AA)$ are computed to be only slightly longer than those in the same state of $\mathrm{AlO}_{3}{ }^{\circ}$ $(R=1.741 \AA$ and $1.742 \AA)$. When the CASSCF calculation on $\mathrm{O}\left(\mathrm{SiH}_{2}\right)^{\bullet+}$ was repeated at the CASSCF-optimized geometry of $\mathrm{AlO}_{3}{ }^{\circ}$, the ratio ( $c_{2}$ / $\left.c_{1}\right)^{2}$ at the equilibrium geometry of $\mathrm{O}\left(\mathrm{SiH}_{2}\right)^{\bullet+}$ was essentially unchanged.
