

detection of synthetic coloring matters (*U. S. Dept. of Agriculture, Bureau of Chemistry, Bulletin 107*, page 136) and none were found that gave any color to the wool from the second bath. It was found preferable, however, to thoroughly wash the wool with a strong soap solution, when taken from the first bath, in order to remove all oil and resin. Samples colored with the ordinary oil-soluble synthetic dyes were readily detected by this test.

The results of the examinations made are tabulated below. It will be noted that paprika produced from the shells alone contains not to exceed 7.50 per cent. of ash, and not to exceed 8.00 per cent. total ether extract, having an iodine number of not less than 127, while paprika made from the whole pods contains not to exceed 7.50 per cent. ash, and not to exceed 13.00 per cent. of total ether extract, having an iodine number of not less than 130.

BUREAU OF CHEMISTRY,  
U. S. DEPARTMENT OF AGRICULTURE,  
WASHINGTON, D. C.

## THE NATURE OF THE VOLATILE MATTER OF COAL AS EVOLVED UNDER DIFFERENT CONDITIONS.<sup>1</sup>

BY HORACE C. PORTER AND F. K. OVITZ.

Received June 30, 1908.

The experiments described below have been a part of the fuel investigations conducted during the year 1907-1908 by the Technologic Branch, U. S. Geological Survey. The investigation is still in progress along the same and similar lines.

It is a familiar fact to retort coke oven and gas works operators that the volatile products of coal are largely affected both in quantity and character by the conditions of temperature and rapidity of the rise of temperature in the coal, and by the conditions to which the products are subjected after leaving the coal. The laboratory determination of volatile matter serves almost universally as a more or less valuable indication of the coal's adaptability to industrial uses either for combustion, destructive distillation or gasification. The method for this determination is, however, an arbitrary one and does not duplicate closely that of any industrial operation, nor is the character of the volatile matter produced by the laboratory method known with any degree of certainty.

<sup>1</sup> Presented with the permission of the Director, U. S. Geological Survey.

Furthermore, the results by the laboratory method are very sensitive to varying conditions and the influence of such variation on the character of the volatile products has not heretofore been the subject of extended study.

The importance of the rôle played by the volatile matter in all industrial applications of fuel is generally recognized. There are more heat units in the volatile matter in proportion to its weight than in the fixed residue. Pittsburg coal of 30.0 per cent. volatile matter and 7.0 per cent. ash has 36.0 per cent. of its heat value in its volatile matter, as shown by comparing the heat values of coal and coke. When coal is fired under a boiler either by hand or mechanically, it first undergoes a process of distillation, and both the quantity and quality of the volatile products and the relative ease of their liberation are concerned very largely in the boiler efficiency and the production of smoke.<sup>1</sup> It is reasonable to suppose that coals of different origin may yield volatile gases carrying different percentages of tarry vapors and heavy hydrocarbons and may on that account differ in smoke-producing tendencies. A knowledge of the chemical reasons why coals smoke in varying degree, and why high-volatile coals are hard to burn with maximum efficiency is a necessary preliminary to the taking of intelligent steps toward improvement in these respects.

The gas producer for bituminous and low-grade fuels is coming more and more into favor. Here also the volatile matter in the fuel plays a very important rôle, since at the top of the fuel bed a process of distillation is continually going on. A certain proposed new type of producer will utilize high volatile fuels, such as bituminous coal, lignite, peat and wood, by passing the hot gases from the producer through the raw fuel in a series of preliminary chambers, thus distilling the valuable hydrocarbon gases (as well as ammonia) out of the fuel before it is charged into the producer itself.

Attention need hardly be called to the preeminent importance of the volatile matter of coal in the illuminating gas and by-product coke oven industries. It is of interest, however, to note the increasing favor accorded by the gas industry to the vertical gas retort as most successfully operated by the Bueb system at Dessau, Germany,<sup>2</sup> and to explain that one advantage of this process lies in avoiding the decomposition of certain valuable gases in passing over heated surfaces, as occurs in the ordinary processes, although at the same time a higher gas yield is obtained by using higher temperatures in the retort itself.

<sup>2</sup> *Amer. Gas Light J.*, 86, 319; 86, 361; 86, 407; 88, 446; *J. Gas Light*, 96, 484.

In connection with the by-product coke oven industry there have been many experiments carried out on the industrial scale to determine the yield and quality of by-products from coal, and the composition of the gas at successive stages,<sup>1</sup> and many also of similar nature in connection with illuminating gas manufacture.<sup>2</sup> In very few of these experiments, however, has there been any comparison of the behavior of different types of coal under the same conditions or any study of the effect of varying conditions on the volatile products.

The purpose of the investigation described in this paper has been (1) to throw light on the nature of the volatile products from coal, and on the manner in which they are affected by the conditions prevailing during their formation or to which they are subjected after formation; (2) to contribute, in the interests of smoke abatement, some data on the comparative amount and character of the gases and vapors distilled from different coals at low temperatures, a subject intimately concerned in the production of smoke; (3) to prove experimentally that the volatile product of coal is to some extent incombustible, and that the proportion of inert volatile matter varies in different coals; and finally (4) to show that the oxygen of coal is in many cases evolved in the volatile matter very largely in combination with carbon as CO and CO<sub>2</sub>, as well as with hydrogen as water, thereby explaining in great degree the discrepancy found in these cases between the determined calorific value and that calculated by Dulong's formula.

*Volatile Matter at Ordinary Temperature.*—Parr and Wheeler<sup>3</sup> have noted the accumulation after ten months of combustible gas in tightly sealed glass jars containing samples of Illinois coal. They do not, however, report any determinations of the quantity or composition of these gases. Other investigators have extracted and analyzed gas from coal under reduced pressure at ordinary temperature.<sup>4</sup> But a study of the formation of gas and absorption of oxygen by coal during storage for a long period does not seem to have been attempted heretofore.

In connection with a series of experiments, not yet completed, on the deterioration in heat value of various coals during storage under different conditions, we have found in certain cases a liberation of gas in remarkably large quantities. About 25 lbs. of coal of buckwheat size were stored in a 20-liter glass bottle closed with a rubber stopper, which was provided with glass tubes for removing gas samples. The bottles stood in the

laboratory at a temperature ranging from 20° to 25°. In some of the bottles the coal was immersed in distilled water and the interstices well filled with water by attaching a partial vacuum for about one hour. About 400 cc. of air remained above the surface of the water. Some of the results on the examination of the gas are given below.

TABLE I.  
Composition of gas (taken at surface of coal, if not immersed).

The gas liberated in the above cases consists almost entirely of methane with a very slight amount of CO<sub>2</sub> and no more than doubtful traces of CO and heavy hydrocarbons. No hydrogen could be detected by the palladium fractional combustion method. Whether this gas may properly be considered as volatile matter due to decomposition of the coal or whether it is held in the coal as such by occlusion or adsorption cannot be decided without further study. The fact that the oxygen of the air surrounding the coal is rapidly absorbed without forming CO<sub>2</sub>, indicates a change of composition in the coal. By comparison of the analyses at the 10-day period from dry and immersed coal it may be seen that more methane has been formed by the dry coal, since the gas sample in this case represents a larger volume of gas. It is reasonable to sup-

<sup>1</sup> Hydrogen was determined separately only in the analysis at 104 days; hence the higher hydrocarbons of the paraffin series could not be calculated, except in that analysis and none was found there.

<sup>2</sup> Hydrogen tested for, by palladium method.

pose that a larger quantity of gas escaped between the mining of the coal and the starting of the experiments than was measured during the experiments. The measurement of the quantity of gas formed is therefore of little value. The gas pressure in case of No. 23, immersed, reached at one time 7 inches of mercury.

*Volatile Matter at 105°.*—A series of experiments conducted primarily for direct weighing of moisture driven off from coal at 105° yielded results incidentally which showed the extent of the loss of substances other than moisture. Ten grams of air-dried, powdered coal in a 20 cm. copper boat were heated at 105° in a current of dry air in a glass tube. The gaseous products passed out of the tube into a train consisting of two CaCl<sub>2</sub> U-tubes, a tube of soda lime and a U-tube containing platinized asbestos at 300°, preceded and followed by a bulb of clear lime water. A blank test in which 5 cc. of natural gas (94 per cent. CH<sub>4</sub>) mixed with 95 cc. of air were passed through the apparatus gave a very distinct precipitate in the second lime water bulb, while a blank with air alone showed none. The following results were obtained with three typical coals.

TABLE II.

Coal No.	Time of drying.	Loss in weight.	Moisture weighed.	CO <sub>2</sub> weighed.	Hydrocarbons or CO.	Remarks.
16	2 hrs.	0.46	0.62	0.01	None

5	2 hrs.	9.23	9.13	0.27		In nitrogen

*Coal No. 16:* Pocohontas, W. Va. . . . . Official moisture. 0.47%

*Coal No. 23:* O'Gara, Saline Co., Ill. . . . . Official moisture. 2.30%

*Coal No. 5:* Sheridan, Wyo. (Sub-bituminous). Official moisture. 9.40%

It may be seen from the above results that a slight amount of carbon dioxide is produced by drying the Illinois and Wyoming coals at 105° for two hours (whether in air or in nitrogen), but only slight traces of hydrocarbons or carbon monoxide. The direct moisture weighings in air and in nitrogen show that oxidation of the coal has occurred to the extent of 0.4–0.5 per cent. (as increase in weight of coal). The direct moisture weighed is greater in almost every case than the official moisture (determined at about the same time).

*Volatile Matter at 500°–1100°.*—In studying the nature of the volatile matter at the medium and higher temperatures (500°–1100°) two sets

of experiments were run, using a different apparatus in each. In one (see Fig. 2) a small sample (10 grams) was heated in a platinum retort suspended in an electric resistance furnace maintained constant at the desired temperature, the gases evolved being collected by displacement of water in a bottle. No attempt was made in this set of experiments to duplicate the methods or results of industrial practice. The apparatus was designed with the idea of maintaining definite and controllable conditions which would yield results comparable with each other in experiments on different coals. The other set of experiments (see Fig. 1) was run on a somewhat larger scale, heating 400 grams of coal

FIG. 1. APPARATUS FOR COLLECTING BY-PRODUCTS FROM THE COKING OF COAL.

in a cast iron retort resting in a cylindrical electric resistance furnace, the tar, water, ammonia, carbon dioxide, hydrogen sulphide, and gas being collected in appropriate absorption apparatus and measured. Owing to the heavy nature of the retort and the large sample of coal the temperature in the coal could not be varied as easily in these experiments as in those using the platinum retort. Accordingly one set of conditions was adopted approximating as nearly as possible those of industrial by-product coke oven practice, and a number of typical coals compared under these conditions. The object was rather to compare the different coals with each other under this set of conditions, than to determine absolutely the industrial by-product yields; and further to determine the composition of the volatile matter from different coals under these conditions.

The coal, crushed to buckwheat size, was placed in the inner end of the retort, a 10 cm. layer of coke added and the retort made tight. The

furnace having been heated to 1050°, the retort was introduced and the by-product apparatus connected. The heating was continued until gas practically ceased to be formed, usually about one and one half hours. The temperature in the interior of the coal rose to 700° in 25–30 minutes.

The mixed tar and aqueous liquor after being weighed in the absorption vessels was washed out with a measured amount of water. The mixture was separated for determination of water first by decantation and then by distillation of the tar; the water was measured and the aqueous liquor then distilled for ammonia. The carbon dioxide, and hydrogen sulphide were absorbed in a strong solution of potassium hydroxide on which blank determinations had been run, the carbon dioxide was determined by evolution with acid and the hydrogen sulphide by titration with iodine. The gas after passing through a meter was collected over water and analyzed.

The following results were obtained on four typical coals:

<sup>4</sup> Difference between average coke yield and 100; therefore includes moisture.

<sup>5</sup> Total water minus moisture.

<sup>6</sup> Does not include moisture or free nitrogen of gas. Values obtained by difference between volatile (without moisture) and tar + gas + H<sub>2</sub>S.

<sup>7</sup> THIS JOURNAL, 29, 585, and Bull. No. 3, Illinois State Geol. Survey, 1906.

Dulong's calculation of available hydrogen from analytical data. Parr's values for inert volatile are in most cases considerably higher than those shown by the above experimental results. But the fact remains that the inert constituent of the volatile matter is a considerable quantity, varying in different coals and of importance in the differentiation of coal types.

No definite conclusions as to comparative by-product yields should be drawn from the above tests. They serve rather as indications of differences in behavior which require corroboration by a considerable number of parallel experiments. It may, however, be said that apparently the ammonia yield by this laboratory method is even larger from the low grade coals of the interior and western fields than from the high grade eastern coals. The high yield of gas of thin quality from Pocahontas coal, and its low ammonia and water yields accord with the results of commercial practice. In general the yield of tar is greater and that of gas less in the laboratory tests than in commercial practice, which is due

most probably to the slower distillation in the laboratory method and the unavoidable cooling of the furnace at the start by the cold iron retort.

Particular attention should be drawn to the wide variation in carbon dioxide, carbon monoxide, and water of constitution produced by the destructive distillation of the different coals.

*Experiments on 10 Grams of Coal.*—The series of tests in a platinum retort on 10 grams of coal at various temperatures is not yet completed but has yielded sufficient results to show their approximate agreement with those obtained on 400 grams of coal and also to indicate the composition of the gas produced from different coals in the early stages of heating at low temperatures. A thermo-couple was inserted in the retort so as to determine the temperature under the surface of the coal itself. The tests were run in an atmosphere of nitrogen which was passed through the retort until the exit gases contained less than 1 per cent. of

<sup>1</sup> Includes all higher paraffin hydrocarbons calculated as C<sub>2</sub>H<sub>6</sub>.

<sup>2</sup> Special test, heating neck of retort to redness.

<sup>3</sup> Special test on 10 grams running in air instead of in nitrogen. Gas contains 1.0 per cent. oxygen and very little more CO<sub>2</sub> than in corresponding test run in nitrogen.

<sup>4</sup> Special test, heating gradually during 50 minutes.

<sup>5</sup> Approximation of official volatile determination, heating 1 g for 7 minutes.

oxygen. The tar was collected in two 6-inch tubes of absorbent cotton heated to 100° and also weighed on the neck of the retort. The water was collected in a 5-inch calcium chloride U-tube, and always contained a slight amount of light oil driven over from the tar, causing an error of 1 per cent. or less.

The results given above in Tables VI and VII are in most cases averages of two or more parallel tests at each temperature. The following tabular statements show the detailed results of separate tests, and from these the averages given above were compiled:

obtained by distilling German bituminous and brown coals at low temperatures (up to 450°). The gas he finds high in carbon dioxide and in the *homologues of methane*; the tar carries no solid aromatic hydrocarbons.

From our results given in Table VI and in different form in Table XIV it may be seen that the low temperature gases are high in illuminants and the higher homologues of methane, and low in hydrogen. Comparing the four coals at 700° (565° in the coal) where the gas begins to be formed in considerable amount, the Connellsville is the richest of the four coals in illuminants and heavy hydrocarbons and the Pocahontas the highest in hydrogen. The high carbon dioxide and carbon monoxide from the Illinois and Wyoming coals accords with other experiments on these coals. The tar at 700° is greater also in the Connells-

<sup>1</sup> Calculated to undiluted gas. Oxygen assumed to be due to air.

<sup>2</sup> Includes all higher paraffin hydrocarbons.

<sup>3</sup> Separate tests from above gas tests.

ville coal. The smokeless character of the Pocahontas coal may be connected more or less with the presence of considerable hydrogen in its gas at low temperatures, since the low ignition point of hydrogen tends to assist in the burning of other gases present.

From Table XIV and the curves in Fig. 3 the bearing of these results on smoke formation may be seen. The smoke-producing constituents of the volatile matter are here considered as including tar, and the heavier hydrocarbon gases: benzene, ethylene and homologues of methane (calculated as C<sub>2</sub>H<sub>6</sub>). While at 440° (in the coal) the Illinois coal (and probably also the Wyoming) has produced more smoky gases than the Eastern coals, at 565° and higher the Connellsville produces much more. This accords with the finding in practice of greater difficulty in burning coals of the Connellsville type without smoke.

<sup>1</sup> Calculated to undiluted gas; oxygen assumed to be present entirely as air.

<sup>2</sup> Includes all higher paraffin hydrocarbons calculated as C<sub>2</sub>H<sub>6</sub>.

### Methods of Gas Analysis.

For the determination of CO<sub>2</sub>, C<sub>6</sub>H<sub>6</sub>, C<sub>2</sub>H<sub>4</sub>, O<sub>2</sub> and CO the well-known apparatus of Hempel was used. For benzene, sulphuric acid (specific gravity 1.84) was the reagent used, as recommended by Morton.<sup>2</sup> For ethylene (or total illuminants) fuming sulphuric acid (specific gravity

<sup>1</sup> Compiled from results given in Table VI.

<sup>2</sup> THIS JOURNAL, 28, 1728 (1906).

1.53) was used in a double pipette provided with glass beads; and for carbon monoxide, an ammoniacal solution of cuprous chloride (according to Winkler's formula<sup>1</sup>) for which three double pipettes were used successively on each sample.

Hydrogen was determined in most cases separately by fractional combustion over palladium asbestos as recommended by F. C. Phillips.<sup>2</sup> Palladium black was precipitated upon acid-washed, ignited asbestos, by the action of alkaline sodium formate upon palladium chloride solution, and the product then washed, dried and ignited at a moderate red heat. A mixture of the gas residue and air, equivalent to a hydrogen-oxygen ratio of not more than 1:2 by volume, was passed slowly over the palladium in a small U-tube maintained at about 50° by a water bath, and the contraction measured. According to Prof. Phillips, hydrogen is completely burned under these conditions and hydrocarbons are not affected. We have verified this statement by tests with pure electrolytic hydrogen and with natural gas (testing for CO<sub>2</sub> formation).

Methane and its higher homologues were determined by the slow combustion method of Winkler as modified by Dennis and Hopkins.<sup>3</sup> The combustion pipette was of glass, the platinum spiral was heated by a direct current of 120 v. 6-8 amp. and in order to assist in the combustion and reduce the necessary temperature a few threads of platinized asbestos were inserted in the platinum spiral. The contraction and carbon dioxide formed were measured.

Hydrogen having been separately determined, the contraction due to its combustion is known and may be subtracted from the total contraction obtained by the complete burning in the Winkler pipette. The remainder is contraction due to the burning of hydrocarbons. If we assume only two hydrocarbons present, *viz.*, methane and ethane, and know the contraction and carbon dioxide formed from their combustion we can calculate their amount as follows:

1 volume CH<sub>4</sub> gives, on burning, 1 volume CO<sub>2</sub> and 2 volumes contraction.

1 volume C<sub>2</sub>H<sub>6</sub> gives 2 volumes CO<sub>2</sub> and 2½ volumes contraction.

Therefore,

$$\text{contraction found} = 2\text{CH}_4 + 2\frac{1}{2}\text{C}_2\text{H}_6.$$

$$\text{CO}_2 \text{ found} = \text{CH}_4 + 2\text{C}_2\text{H}_6.$$

Solving for CH<sub>4</sub> and C<sub>2</sub>H<sub>6</sub>:

$$\text{CH}_4 = \frac{1}{3} (4 \text{ contraction} - 5\text{CO}_2).$$

$$\text{C}_2\text{H}_6 = \frac{1}{3} (4\text{CO}_2 - 2 \text{ contraction}).$$

<sup>2</sup> Amer. Chem. J., 16, 164-168.

<sup>3</sup> Hempel, Gas Analysis (Transl. of 3rd German Ed.), p. 138.

Values thus obtained for the higher homologues of methane must be considered as merely approximate since several compounds are probably present whose average composition is uncertain. In case the higher homologues include others beside ethane ( $C_2H_6$ ) their total percentage will be less than the above calculation shows:

*Composition of Gas Formed in the Official Volatile Determination.*—By means of a thermocouple inserted through the lid of the crucible until it rested under the surface of the coal, a measurement of temperature in the coal was obtained during the official volatile determination in a platinum crucible.

TABLE XV.—TEMPERATURE DURING OFFICIAL VOLATILE DETERMINATION.

No. 1	200	530	720	800	825	830	832	832	832	830	830
No. 3	180	420	570	750	820	835	...	837	839	840	839

In order to determine the composition of the gas formed during the official volatile determination, two tests were run in the platinum retort on 1 g. of coal for 7 minutes at temperatures corresponding as nearly as practicable with the above. The retort was filled with nitrogen. The results are given at the end of Table VII.

An attempt was made also to measure the tar and water formed in the official volatile determination, but on account of the analytical difficulties in collecting these products from so small a sample of coal (1 gram) concordant results have not as yet been obtained.

There are given also in Table VII the results of a special test on Wyoming sub-bituminous coal (No. 5) in which the heating was very gradual. A smaller gas yield by 25 per cent. was obtained and a gas of higher carbon dioxide but lower illuminants than in case of rapid heating to the same temperature.

#### Calculation of the Heat Value of Coal from its Ultimate Analysis.

The experimental results given in the preceding pages show conclusively that in the process of breaking down under the influence of heat the coal substance gives up its oxygen partly in the form of carbon-oxygen compounds and partly as the hydrogen-oxygen compound water. Some recent work by Vignon in Europe supports this conclusion.<sup>1</sup> The figures demonstrating this point are given again below in more compact form.

Dulong's calculation of heat value from ultimate analysis assumes that all of the oxygen of the coal combines with hydrogen of the coal during combustion, thereby neutralizing, so to speak, the calorific value of hydrogen equal to O/8. Dulong's calculation, as is well known, gives

<sup>1</sup> *Bull. soc. chim.* [4], 3, 109.

in many cases less calories than are shown by experimental determination. These cases of discrepancy are usually medium and low grade coals, high in oxygen, which we have shown above give up their oxygen in large part combined with carbon instead of with hydrogen.

By combining with carbon instead of with hydrogen in the coal the oxygen exercises less of an anti-calorific influence on the efficiency of the coal since one gram of oxygen in combining with carbon to CO<sub>2</sub> neutralizes  $\frac{3}{8}$  gram of carbon or 3030 potential calories; with carbon to CO it partly neutralizes  $\frac{3}{4}$  gram of carbon thus neutralizing  $\frac{3}{4}$  (2490) = 1870 calories; while one gram of oxygen in combining with hydrogen to H<sub>2</sub>O neutralizes  $\frac{1}{8}$  gram of hydrogen or  $\frac{1}{8}$  (34460) = 4313 calories. The anti-calorific influence of a unit of oxygen in forming CO<sub>2</sub> or CO is therefore approximately either 70 per cent. or 43 per cent., respectively, of its influence when forming water.

In a paper before the Geological Society of Washington (*Science*, 27, 537, Apr. 3, 1908) David White has recently called attention to the uniform anti-calorific value of oxygen in coal and has based partly on this factor a scheme for the classification of coals. He states that the negative value of 1 per cent. of oxygen in "ordinary bituminous coals" is probably 70–80 calories, or "about twice as great as has been supposed." It is not clear to what supposition he refers, for Dulong's calculation assigns a negative value to 1 per cent. oxygen of  $\frac{1}{8} \times 1$  per cent. of 34460

<sup>1</sup> There is a possibility of the formation of CO<sub>2</sub> in slight amount from the oxygen of air in contact with the coal at the beginning of a test; assuming 500 cc. of air in contact with the coal, there could be formed, if all its oxygen entered into CO<sub>2</sub>, only 0.28 gram CO<sub>2</sub> or 0.07 per cent. on 400 grams of coal.

<sup>2</sup> From analysis of Ill. 34 (U. S. Fuel Testing Plant), a similar coal.

or 43 calories plus the diluent effect of 1 per cent. of the coal or approximately 65 calories, making a total of 108 calories, 50 per cent. greater than the value which White finds from experimental results. This excessive anticalorific value for oxygen in Dulong's method we propose to explain in some degree by the distribution of oxygen between carbon and hydrogen as set forth above.

If we calculate the heat value of an Illinois coal (Ill. No. 19)<sup>1</sup> and of a Wyoming coal No. 11<sup>2</sup> by Dulong's formula and by formulas based on the distribution of oxygen between H<sub>2</sub>O, CO and CO<sub>2</sub> according to our experimental results, the following values are found:

<i>Composition (Water Free):</i>	Ill. No. 19.	Wyo. No. 11.
Ash.....	6.16	5.56
Carbon.....	76.96	68.90
Hydrogen.....	4.49	4.56
Nitrogen.....	1.52	1.51
Sulphur.....	0.52	0.51
Oxygen.....	10.35	18.96
 <i>Calorific Value:</i>		
Dulong's calculation....	7322	6333 cal.
Modified calculation....	7453	6524 cal.
Determined.....	7536	6582 cal.

The formulas used for the modified calculation are the following:

*Illinois Type:*  $W$  (calor. value) = 8080 (C — 0.1200 × O) + 34460 (H — 0.063 × O) + 2250 S.

*Wyoming Type:*  $W$  (calor. value) = 8080 (C — 0.182 × O) + 34460 (H — 0.050 × O) + 2250 S.

### Summary.

1. It is shown that some coals liberate gas during storage, of a composition similar to that of natural gas, and that some coals rapidly absorb oxygen from the air during storage without forming carbon dioxide.

2. During drying in air at 105° C. some coals lose appreciable amounts of carbon dioxide, and most coals take up oxygen to a considerable extent, but none of those tested showed any considerable formation of combustible gases.

3. The nature of the volatile products distilled from several coals at low temperatures in the early stages of heating is shown to vary in different coals in accordance with their smoke-producing tendencies.

4. It is shown experimentally that the volatile matter of coal comprises a considerable proportion of non-combustible matter, varying with the type of coal.

<sup>1</sup> From Ziegler, Franklin Co., Illinois.

<sup>2</sup> From Dietz, near Sheridan, Wyoming (sub-bituminous).

5. The temperature in the coal during an official volatile determination was measured and the composition of the official volatile matter determined.

6. A modification is suggested of Dulong's heat value calculation for coal based on experimental results showing the distribution of oxygen between hydrogen and carbon.

### NOTES.

*A Characteristic Test for Hippuric Acid.*—Hitherto no easily-applied, characteristic test for hippuric acid in urine has been at hand. For the reason that its detection in urine is of little or no clinical value, the lack of a convenient practical method for its detection has not been felt. On the other hand, for purely scientific purposes, the methods now in use involve inconveniences that are surprisingly great when compared with the methods available for the detection of other constituents of urine. As a matter of fact, the detection of hippuric acid has necessitated the concentration of the urine, the extraction with organic solvents and either a melting point determination of the residue or its transformation into more easily recognized nitro or benzaldehyde derivative.<sup>1</sup>

The following test for hippuric acid can not only be applied directly to urine but it yields definite results in solutions so dilute even as hundredth-normal. A few cubic centimeters of the urine in a test tube are first treated with a quantity of sodium hypobromite solution, just sufficient to decompose the urea and to impart to the mixture a permanent yellow color. The solution is then heated to boiling; an orange or brown-red precipitate is formed, if hippuric acid is present. When present only as a trace the solution appears smoky and faintly red in color; when present in larger quantities the solution is rendered opaque and orange or brown-red in color. In either case after standing for some time the solution clears up and a light, finely divided precipitate settles. It consists of white "earthy phosphates" intermixed with the amorphous orange or brown-red solid<sup>2</sup> about to be described.

When a 0.1 N solution of hippuric acid is boiled with the sodium hypobromite solution, a deep brown-red color is formed at once and on standing settles to the bottom of the tube as an opaque, red, closely-adhering

<sup>2</sup> Application of the hypobromite test to aqueous solutions of other constituents of urine gave no color effects. The following were tested: uric, benzoic, oxalic and fatty acids, creatinine, acetone, acetic ester, glucose, glycogen and leucine.
