

pound If was identified by characterization of the 2,4-dinitrophenylhydrazones; Id was identified by infrared and n.m.r. spectra taken on the crude compound and characterization of the pure 2,4-dinitrophenylhydrazone.

**Preparation of Dialkyl Aroylphosphonate 2,4-Dinitrophenylhydrazones.**—The data in Table II were accumulated in experiments performed in essentially the following manner. A stock solution of 2,4-dinitrophenylhydrazine was prepared by placing 6 g. of the reagent (m.p. 198–199°) in 30 ml. of concentrated sulfuric acid and adding this mixture to 40 ml. of water and 140 ml. of 95% ethanol. To 25 ml. of this solution was added 0.5 g. of the dialkyl aroylphosphonate to give a precipitate of the corresponding highly colored 2,4-dinitrophenylhydrazone. Methanol was used to recrystallize all of the derivatives.

**Acid Hydrolysis of Dimethyl *p*-Anisoylphosphonate (Ib).**—A flask was charged with 2.44 g. (0.01 mole) of Ib and 10 ml. of 0.1 *N* hydrochloric acid. The reaction mixture was stirred for 4 hr. at room temperature without any noticeable change in composition. After stirring for 24 hr. the mixture deposited 1.50 g. (98.7%) of *p*-anisic acid.

**Basic Hydrolysis of Dimethyl *p*-Anisoylphosphonate (Ib).**—In a system identical with that used for acid hydrolysis was added 2.44 g. (0.01 mole) of Ib and 10 ml. of 0.1 *N* sodium hydroxide. Within 15 min. a heavy white precipitate was observed in the reaction mixture. The solid material was filtered off and the free *p*-anisic acid was regenerated from its sodium salt by treatment with 0.1 *N* hydrochloric acid. The acid (1.43 g., 94.1%) had m.p. 184° after recrystallization from ether.

### Tertiary Amine Oxide Rearrangements. III. The Mechanism of the Demethylation of Nicotine<sup>1</sup>

By J. CYMERMAN CRAIG, NOURI Y. MARY,<sup>2</sup> NORMAN L. GOLDMAN, AND LYNN WOLF

RECEIVED OCTOBER 19, 1963

The metal complex catalyzed rearrangement of nicotine N-oxide has been shown, by the combined use of thin layer and gas chromatography, to yield formaldehyde and nicotine, N-methylmyosmine, normicotine, myosmine, nicotyrine, and cotinine. A simple unified mechanism is capable of rationalizing the formation of these nicotine alkaloids, as well as of all other known metabolites of nicotine.

Nicotine (I) is metabolized in animals and plants to give a variety of products of which only normicotine (II) may be accounted for by a simple demethylation. Other metabolic products of nicotine include: nicotine 1'-oxide (III) ("oxynicotine"),<sup>3</sup> 3-methylaminopropyl 3'-pyridyl ketone (IV) ("pseudooxynicotine"),<sup>4</sup> 3-nicotinoylpropionic acid (V),<sup>4,5</sup> N-methylmyosmine (VI)<sup>6</sup> (which in aqueous solution is present, by a reversible dehydration-hydration, in equilibrium with IV in the form of its cyclic aminoketal IVa), nicotyrine (VII),<sup>3d,6c,7</sup>  $\gamma$ -3-pyridyl- $\gamma$ -methylaminobutyric acid (VIII)<sup>8-10</sup> (which cyclizes spontaneously at pH 7 into its lactam cotinine (IX)<sup>11,12</sup>), desmethylcotinine (X),<sup>9,11</sup>  $\gamma$ -3-pyridyl- $\gamma$ -oxo-N-methylbutyramide (XI),<sup>13</sup>  $\gamma$ -3-pyridyl- $\gamma$ -hydroxybutyric acid (XII),<sup>14</sup> and myosmine (XIII), a naturally occurring nicotine alkaloid<sup>15</sup> also formed by autoxidation of nicotine.<sup>3d</sup>

In the preceding paper<sup>16</sup> the rearrangement of N-benzylidimethylamine oxides was shown to proceed concurrently along two pathways giving formaldehyde and the appropriate benzaldehyde, in a ratio determined (in the absence of steric factors) by the available  $\alpha$ -protons (*i.e.*, adjacent to nitrogen) and by their relative acidities. In the case of nicotine 1' oxide (III), this rearrangement may occur in the following three possible ways, since three different types of  $\alpha$ -proton exist in III: A. Loss of the proton from the N-methyl group, leading to the methylolamine (XIV) known to give formaldehyde and normicotine (II). Since there are three such protons available, this reaction will have a high statistical probability and is the expected route for N-demethylation. Nicotine-methyl-<sup>14</sup>C has been found to give radioactive respiratory carbon dioxide *in vivo*,<sup>17</sup> in agreement with the expected conversion of formaldehyde to carbon dioxide *via* formic acid.

B. Another pathway, on the basis of the rearrangement of the N-benzylidimethylamine oxides,<sup>16</sup> is by loss of a proton from the  $\alpha$ -position adjacent to the pyridine ring, giving a tertiary hydroxynicotine (IVa), the cyclic ketal of 3-methylaminopropyl 3'-pyridyl ketone (IV). The expected facile dehydration of the tertiary hydroxyl would give the conjugated N-methylmyosmine (VI).

C. Proton removal from the other  $\alpha$ -position of the pyrrolidine ring gives a new secondary hydroxynicotine (XV), the cyclic acetal of  $\alpha$ -3-pyridyl- $\gamma$ -methylaminobutyraldehyde (XVa). Ready dehydrogenation of this aldehyde to the acid yields the known  $\gamma$ -3-pyridyl- $\gamma$ -methylaminobutyric acid (VIII), easily ring closing to form its lactam, cotinine (IX), which may also arise directly from an oxidation or dehydrogenation of the cyclic acetal XV. Nicotine metabolism in rabbit<sup>18</sup> forms a hydroxynicotine with the properties of a cyclized

<sup>b</sup> Ref. 26a reports polyethyleneglycol 20,000 at 190°; nicotine = 5.2 min. <sup>c</sup> Ref. 27a reports polyethylene glycol 6000 at 220°; nicotine = 10.6 min.

**E. Quantitative Estimation of the Alkaloidal Products from the Reaction Mixtures.**—Generally symmetrical peaks were obtained, and the amount of each alkaloid identified in the benzene extract was calculated against its corresponding standard from the area of the peak. The amount of four unidentified substances was also determined in the same manner, using the nicotine peak as the standard. Table II provides the individual and total amount of the alkaloids in the reaction mixture (average of two determinations, each repeated in triplicate and reproducible to within 5%).

**Thin Layer Chromatography.**—It was found that myosmine and anabasine had the same retention time and were not separated by gas chromatography. To establish whether peak E in the benzene extract was myosmine or anabasine, thin layer chromatography was used. A plate coated with silica gel G at 250  $\mu$  was spotted with 5  $\mu$ l. of 1% solutions in benzene of nicotine, nornicotine, myosmine, and anabasine, and with 10  $\mu$ l. of the benzene solution (10%) of the reaction mixture. The plate was developed in a mixture of methanol and chloroform (15:85), and the alkaloids were identified with potassium iodoplatinate spray. In the benzene solution of the reaction mixture, no spot corre-

TABLE II

## AMOUNT OF INDIVIDUAL ALKALOIDS IN THE REACTION PRODUCT

Peak	Retention time ratio	Alkaloid	Weight, %	Amt. per ml. of reacc. prod. soln., <sup>a</sup> mg.
A	1.00	Nicotine	4.09	3.62
W	1.07	?	4.09	3.62
X	1.35	?	0.96	0.85
C	1.49	N-Methylmyosmine	2.87	2.54
D	2.30	Nornicotine	77.15	68.24
E	2.49	Myosmine	9.50	8.40
Y	3.09	?	0.17	0.15
G	3.42	Nicotyrine	.58	.52
Z	4.28	?	.16	.14
I	13.84	Cotinine	.40	.36

<sup>a</sup> Total amount = 88.44 per ml. of reaction product solution; 180 mg. of nicotine N-oxide gave 130 mg. of crude alkaloidal product from the benzene extract. This was dissolved to make 1.30 ml. of reaction product solution, which therefore contained 115 mg. of total alkaloids isolated.

myosmine were all present in the benzene reaction mixture solution. The  $R_f$  values were 0.17, 0.29, 0.67, and 0.79 for nornicotine, anabasine, nicotine, and myosmine, respectively. N-Methylmyosmine, nicotyrine, and cotinine were present in too small an amount in the benzene extract to be clearly seen with the Dragendorff spray.

## Results and Discussion

Gas chromatography of nicotine alkaloids has been carried out by Quin<sup>26</sup> and Kobashi,<sup>27</sup> both using polyethylene glycols as the stationary phase. We obtained good separation on 2-m. columns at a column temperature of 200°, as shown in Fig. 1. In the case of myosmine and anabasine, the retention times were so close that separation did not occur on the gas chromatograph. This pair

(27) (a) Y. Kobashi, *J. Chem. Soc. Japan, Pure Chem. Sect.*, **82**, 1262 (1961); (b) Y. Kobashi and M. Watanabe, *ibid.*, **82**, 1265 (1961).

of alkaloids was, however, readily separated by thin layer chromatography as described. The retention times of the nicotine alkaloids are shown in Table I, together with the values obtained by Quin<sup>26a</sup> and by Kobashi.<sup>27a</sup> Agreement is remarkably good.

When nicotine N-oxide was submitted to the metal complex catalyzed rearrangement<sup>28</sup> at 80° for 40 min., using the iron(III)-tartaric acid system at pH 6.3, the occurrence of the rearrangement was first shown by the isolation of formaldehyde (as the dimedone derivative). When the reaction mixture was made alkaline and extracted, gas chromatography of the alkaloidal residue revealed the presence of ten peaks, shown in Fig. 2. By comparing the retention times of these peaks with those of the standard alkaloids (Fig. 1), six of the peaks were identified as nicotine, N-methylmyosmine, nor-nicotine, myosmine, nicotyrine, and cotinine. Peaks W, X, Y, and Z remain unidentified; their retention times are 18.40, 22.88, 53.28, and 73.76 min., respectively. Thin layer chromatography confirmed the identification of nicotine, nor-nicotine, and myosmine, and the absence of anabasine.

Alkaloids were further identified by supplementing a portion of the reaction mixture extract with the known alkaloid in approximately equal amount, and submitting this to gas chromatography, when only the peak corresponding to that alkaloid would approximately double in height without any change in the retention time. By this means, the following alkaloids were identified in the quantities given in Table II: nicotine, N-methylmyosmine, nor-nicotine, nicotyrine, and cotinine. No 3-pyridyl ethyl ketone, 3-pyridyl *n*-propyl ketone, metanicotine,<sup>29</sup> anabasine, or anatabine were present. The identification of six nicotine alkaloids from the iron(III)-tartaric acid catalyzed rearrangement of nicotine N-oxide offers strong support for the unified demethylation mechanism outlined above.

It is seen from Table II that 77% by weight of the reaction product was found to be nor-nicotine. This finding is supported by the isolation of 72% of formaldehyde. Approximately 3% by weight only was identified as N-methylmyosmine. At first sight the preponderance of simple N-demethylation is unexpected, in view of the enhanced acidity of the  $\alpha$ -proton adjacent to the pyridine ring, and in view also of the results obtained using *N*-*p*-nitrobenzyl-dimethylamine oxide.<sup>13</sup>

However, the explanation may be found in the stereochemistry of the N-oxide III, which can exist in two possible conformations. From Dreiding models, and drawn in Newman projection, viewed along the axis joining the quaternary (tetrahedral) nitrogen atom to the  $\alpha$ -carbon atom adjacent to the pyridine nucleus, form III B has the pyridyl and methyl groups *cis* (eclipsed) to each other, while in form III A it is the N-oxide oxygen which is *cis* (eclipsed) to the pyridine ring.

Stuart-Briegleb models show that in form B the methyl group offers considerable steric hindrance to the *o*-hydrogen atoms of the pyridine ring, so that free rotation is severely restricted. In the other (A) form

of the N-oxide, the methyl group and the pyridine nucleus offer the minimum of mutual steric hindrance, and the compound may be expected to exist wholly or predominantly in this form.

The relative positions (distances and angles) of the methyl hydrogens and the N-oxide oxygen toward each other being unchanged in both isomers, any one of the three methyl hydrogens is available (with free rotation of the methyl group) to form the six-membered ring hydrogen-bonded metal-complex chelate intermediate<sup>28</sup> for the rearrangement by taking up a position *cis* to the oxygen. The formation of the methylolamine, and thence of nor-nicotine, will therefore not be affected.

In the  $\alpha$ -methylene group situated in the pyrrolidine ring, however, only one hydrogen is in a *cis* position to the oxygen in either form A or B, and able to form the chelate ring. Moreover, its acidity will be less than that of the methyl hydrogens because of the adjacent methylene chain.

Finally, the single benzylic hydrogen in form B is *cis* (eclipsed) to the oxygen, and therefore able to give the six-membered metal-complex chelate ring readily, whereas in form A this hydrogen is at a dihedral angle of approximately 120° to oxygen, and is unlikely to be able to form the chelate ring because of the rigidity of the pyrrolidine ring and steric interference by the adjacent pyridyl and methyl groups. As the benzylic hydrogen is by far the most acidic  $\alpha$ -hydrogen present, the conclusion would seem that the percentage of N-oxide existing in form B is very small compared with that in form A. Since the N-methyl group in natural (–)-nicotine is likely to be on the opposite, rather than on the same, side of the pyrrolidine ring as the bulky pyridine moiety for steric reasons, it is likely that in the formation of the N-oxide, the oxygen (presumably as OH<sup>+</sup> ion) would attack from below, *i.e.*, at the site of the lone electron pair of the nitrogen, to give form A of the N-oxide. This stereochemical problem is receiving further attention.
