Received June 29, 1998. Revised Manuscript Received October 29, 1998

**Abstract:** Binding energies and entropies have been measured for the attachment of up to six  $\text{H}_2$  ligands to ground-state  $\text{Cu}^+$  ions ( $^1\text{S}$ ,  $\text{Ar}3\text{d}^{10}$ ), to electronically excited  $\text{Cu}^{+*}$  ions ( $^1^3\text{D}$ ,  $\text{Ar}4\text{s}^13\text{d}^9$ ), and to hydrated  $\text{H}_2\text{O}\cdot\text{Cu}^+$  ions. The ground-state  $\text{Cu}^+$  ion added four  $\text{H}_2$  ligands in the first solvation shell with bond dissociation energies (BDEs) of 15.4, 16.7, 8.8, and 5.1 kcal/mol. The fifth and sixth ligands begin a new solvation sphere and were very weakly bound. The BDEs for addition of  $\text{H}_2$  to electronically excited  $\text{Cu}^{+*}$  were also small (4.2, 2.5, and 1.4 kcal/mol for the first three ligands). The difference between ground- and excited-state association energies is almost entirely due to the repulsive nature of the 4s electron. Hydration of the  $\text{Cu}^+$  ion significantly increased the BDE of the first  $\text{H}_2$  ligand (to 19.6 kcal/mol) but greatly reduced that of the second (to 3.8 kcal/mol). Theoretical calculations with large basis sets at the DFT-B3LYP and MP2 levels were done on all species both to determine geometries and vibration frequencies and to examine the origin of the bonding and its variation with  $\text{Cu}^+$  coordination. The calculations show that covalent interactions are important in these  $\text{Cu}^+$  clusters and that the observed changes in BDE as different ligands are added are due to electronic rather than steric effects. These sources of bonding are discussed, and comparisons are made to the  $\text{Co}^+(\text{H}_2)_n$  and  $\text{Ni}^+(\text{H}_2)_n$  systems. It is also shown that the  $\text{M}^+$ –ligand interactions are similar for  $\text{H}_2$  and  $\text{CO}$  ligands. Special attention is paid to the origin of the highly symmetric  $D_{3h}$  planar structure found in  $\text{Ni}^+(\text{H}_2)_3$ ,  $\text{Cu}^+(\text{H}_2)_3$ , and  $\text{Cu}^+(\text{CO})_3$ .

## Introduction

In the past 10 years, our understanding of the bonding present in gas-phase transition metal ion clusters has evolved from a simple electrostatic view to an appreciation of the complex factors actually present. The experiments of Kubas et al.<sup>1</sup> first showed that  $\text{H}_2$  could be attached as an uninserted species to an oxidized transition metal center. Since then, systematic experiments have examined the role of the metal ion in a large number of gas-phase  $\text{M}^+\cdot\text{X}_n$  clusters. Relatively simple systems with  $\text{X} = \text{H}_2$ ,<sup>2–9</sup>  $\text{CO}$ ,<sup>10,11</sup> and the rare gases<sup>12</sup> have been examined, as well as saturated and unsaturated hydrocarbons and a variety of other species.<sup>13</sup> The strong influence of the

nature of the metal ion on both bonding energies and structures in these clusters clearly shows the presence of covalent forces in the bonding. This is reinforced by noting the large difference in  $\text{M}^+-\text{H}_2$  bond energies between the truly inert alkali ions and the transition metals.<sup>14</sup> Our efforts, in conjunction with many theoretical investigations<sup>13,15–18</sup> have identified a number of these covalent forces. First is the electron donation from the  $\text{H}_2$   $\sigma$  orbital to the metal which stabilizes the ion charge.<sup>13,16,18</sup> Most of this donation is to the metal 4s orbital with a minor amount to the 3d orbital of the proper symmetry. Second, in

the late metal ions with filled 3d orbitals, donation to the  $\text{H}_2$   $\sigma^*$  orbital occurs from the metal  $d\pi$  orbitals.<sup>13,17,18</sup> There are two benefits from this back-donation: greater  $\sigma$  donation occurs because electron density is returned to the  $\text{H}_2$  ligands, and 3d–3d exchange stabilization on the metal increases. Third, in ions with half-filled 3d orbitals, a hybridization between the  $3d_z^2$  and the 4s orbital occurs which reduces on-axis Pauli repulsion.<sup>13,15,17,18</sup> Fourth, the 4p orbitals, while significantly higher in energy, may still play a significant structural role.<sup>13,17</sup> Finally, the noncovalent electrostatic interactions (charge-induced dipole and charge quadrupole) are present but usually comprise a small fraction of the total bond strength.<sup>13,14,15</sup> The relative importance of these five factors depends strongly on the valence configuration of the metal ion. The 4s orbital is especially critical, and its occupation is always severely destabilizing.<sup>6,12,13</sup>

Among the late transition metals we have used both theory and experiment to examine  $\text{M}^+(\text{H}_2)_n$  clusters with  $\text{M} = \text{Fe}, \text{Co},$  and  $\text{Ni}$ ,<sup>7,8,9</sup> while Bauschlicher and Maître<sup>17a</sup> and Perry and Goddard<sup>17b</sup> have done very high level calculations on the  $\text{Co}^+(\text{H}_2)_n$  system. These metal ions all have relatively strong bond dissociation energies (BDEs) and similar structures for the first and second clusters. Very different structures are found for larger numbers of ligands, however. In the third cluster, both Fe and Co assume a “T” shape<sup>7,17</sup> while Ni has a planar  $D_{3h}$  geometry.<sup>9</sup> In the fifth cluster, Fe and Co both form distorted square pyramids while  $\text{Ni}^+(\text{H}_2)_5$  is a trigonal bipyramid. Both Fe and Co have six  $\text{H}_2$  ligands in their nearly octahedral first solvation spheres while Ni has only five.

The  $\text{Cu}^+$  ion differs from other late metals in having a filled 3d valence shell in its ground state.<sup>19</sup> It is of interest to see the effect of this filled 3d shell on the  $\text{M}^+-\text{H}_2$  interaction, especially the importance of electron holes in the 3d orbital (present in  $\text{Ni}^+$  and  $\text{Co}^+$ , absent in  $\text{Cu}^+$ ). In addition, the  $\text{Cu}^+(\text{H}_2)_n$  clusters can be compared with the analogous  $\text{Cu}^+(\text{CO})_n$  ions<sup>11</sup> to establish the extent to which the bonding forces present in  $\text{Cu}^+(\text{H}_2)_n$  apply to other systems. Toward these ends, we present here a combined experimental and theoretical study of  $\text{Cu}^+(\text{H}_2)_n$ .

In addition to the clusters with a ground-state  $\text{Cu}^+$  core ( $^1S, 3d^{10}$ ), we also describe the bonding of metastable excited ( $4s^1 3d^9$ )  $\text{Cu}^{+*}$  ions. Our aim here is a comparison with other 4s-containing metals, especially  $\text{Zn}^+$ , which has been examined previously.<sup>6</sup> Finally, bond strengths of  $\text{H}_2$  ligands in  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)_{1,2}$  ions were also measured to determine the differential effects on subsequent bonding caused by an  $\text{H}_2$  or  $\text{H}_2\text{O}$  first ligand.

## Experimental Section

Experimental details have been given previously.<sup>2,5,20</sup> Briefly, the  $\text{Cu}^+$  ions are formed in a glow discharge ion source using an Ar bath gas. The isotope of interest (either  $^{63}\text{Cu}^+$  or  $^{65}\text{Cu}^+$ ) is mass selected in the first quadrupole and injected into a drift/reaction cell filled with typically 10 Torr of  $\text{H}_2$ . The ions' excess kinetic energy is rapidly thermalized by collisions. An equilibrium between the various  $\text{Cu}^+(\text{H}_2)_n$  cluster products ( $n = 0-6$ ) is quickly established as the ions are moved through the 4 cm long cell with a small electric field. The field is small enough that no measurable perturbation of the thermodynamic temperature occurs. The ions then exit the cell and are mass analyzed in a second quadrupole. The resulting mass peaks are recorded and integrated and together with the pressure of  $\text{H}_2$  ( $p_{\text{H}_2}$ ) are used to calculate the equilibrium constant ( $K_p$ ):

$$K_p^\circ = \frac{\text{Cu}^+(\text{H}_2)_n(760)}{\text{Cu}^+(\text{H}_2)_{n-1}p_{\text{H}_2}} \quad (1)$$

**Figure 1.** Plot of experimental  $\Delta G_T^0$  vs temperature for the association reaction  $\text{Cu}^+(\text{H}_2)_{n-1} + \text{H}_2\text{Cu}^+(\text{H}_2)_n$ . Data for ground-state  $\text{Cu}^+$  ( $3d^{10}$ ) reactants are shown. The  $n = 6$  data are the open circles below 100 K. The solid lines are statistical mechanical fits to the data which yield values of  $\Delta H_0^0$  at  $T = 0$  K (see text).

The standard free energy is then found using eq 2.

$$\Delta G_T^0 = -RT \ln K_p^\circ \quad (2)$$

Measurements are taken as a function of temperature from 77 to 780 K. The resulting plots of  $\Delta G_T^0$  vs  $T$  are linear over the experimental temperature range with  $\Delta H_0^0$  and  $\Delta S_0^0$  as the intercept and slope, respectively. The linearity of these plots shows that  $\Delta H_0^0$  and  $\Delta S_0^0$  are only very weak functions of temperature over the experimental temperature range. The experimentally determined  $\Delta H_0^0$  and  $\Delta S_0^0$  values for a particular association reaction are used, together with the theoretically determined structure and vibrational frequencies, to determine the heat of reaction at 0 K. The BDE is  $-\Delta H_0^0$ .

Electronic state chromatography experiments<sup>21</sup> showed that both ground-state ( $^1S, 3d^{10}$ ) and electronically excited  $\text{Cu}^{+*}$  ( $^1^3D, 4s^1 3d^9$ ) were present in our experiment. The excited state was extraordinarily resistant to collisional deactivation by  $\text{H}_2$ . The use of very high ion injection energies (800 eV) did minimize the amount of excited  $\text{Cu}^{+*}$  but could not eliminate it. Ordinarily, this would be a minor annoyance; however, in this case, the persistence of the  $\text{Cu}^{+*}$  ion allowed the association reactions of both ground-state and electronically excited copper ions to be examined separately. This was possible, despite the identical product masses, because of the large difference in BDEs in the two groups. At high temperatures, no measurable excited-state clustering occurred and the more strongly bound ground-state  $\text{Cu}^+(\text{H}_2)_n$  could be examined. At low temperatures the equilibria between the weakly bound  $\text{Cu}^{+*}(\text{H}_2)_{1,2,3}$  ions with  $\text{H}_2$  could be measured since all of the ground-state  $\text{Cu}^+$  had reacted to form the  $\text{Cu}^+(\text{H}_2)_4$  terminal ion. Plots of vs  $T$  for the ground- and excited-state association reactions are shown in Figures 1 and 2; data for the association of  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)_{n-1}$  with  $\text{H}_2$  are shown in Figure 3.

## Theory

The product ions discussed here were all examined theoretically both to determine the molecular parameters needed to analyze the experimental data and to identify factors important in the bonding. Calculations were carried out at the DFT level using the B3LYP functional<sup>22,23</sup> on both ground state and

<sup>a</sup> In kcal/mol. BDE  $\equiv -\Delta H_0^\circ$ . <sup>b</sup> In cal/(mol·K). <sup>c</sup> In Kelvin,  $\pm$  refers to temperature range, not uncertainty. <sup>d</sup> Fitting with theoretical frequencies and geometries. <sup>e</sup> DFT geometries. <sup>f</sup> MP2 geometries. <sup>g</sup> Fitting with  $\Delta C_p$  correction; error small at low temperature. <sup>h</sup> Fit by correspondence with fifth cluster; not enough data for  $\Delta S$  and  $\Delta H$  measurement. <sup>i</sup> Orientation of equatorial  $\text{H}_2$  ligands with respect to the equatorial ( $xy$ ) plane. The more stable planar structure has all six H atoms in the  $xy$  plane.

**Figure 2.** Plot of experimental  $\Delta G_T^\ddagger$  vs temperature for the association reaction  $\text{Cu}^{+*}(\text{H}_2)_{n-1} + \text{H}_2 \rightarrow \text{Cu}^{+*}(\text{H}_2)_n$  for electronically excited  $\text{Cu}^+$  ( $4s^1 3d^9$ ). The solid lines are statistical mechanical fits to the data which yield values of  $\Delta H_0^\circ$  at  $T = 0$  K (see text).

**Figure 3.** Plot of experimental  $\Delta G_T^\ddagger$  vs temperature for the association reactions of  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)_{n-1} + \text{H}_2 \rightarrow \text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)_n$ . The solid lines are statistical mechanical fits to the data which yield values of  $\Delta H_0^\circ$  at  $T = 0$  K (see text).

electronically excited clusters. For comparison, the ground-state clusters were also examined at the MP2 level.<sup>24</sup> The basis set used for the calculations is composed as follows. The hydrogen basis set is the scaled (4s)/[2s] set of Dunning,<sup>25</sup> augmented with a polarization p function ( $\zeta_p = 1.20$ ) and diffuse s ( $\zeta_s = 0.071$ ) and p functions ( $\zeta_p = 0.40$  and  $0.13$ ). The optimization of these exponents is described elsewhere.<sup>18</sup> The copper basis

set is an [8s4p3d] contraction of the (14s9p5d) primitive set proposed by Wachters<sup>26</sup> supplemented with two diffuse p functions (we used the Wachter's exponents<sup>26</sup> multiplied by 1.5), one diffuse d function,<sup>27</sup> and a polarization f function.<sup>28</sup> This leads to a (14s11p6d3f)/[8s6p4d1f] contraction.<sup>28</sup> In most cases no significant differences in the DFT and MP2 geometries were found. The DFT bond strengths were generally higher, however. Care must be taken here since DFT calculations of the BDEs of the late metal ions with  $\text{H}_2$  are unusually sensitive to the choice of basis set.<sup>9,17a</sup> Calculations by Maître and Bauschlicher have been previously reported on the  $\text{Cu}^+(\text{H}_2)_{1,2}$  and the  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)$  ions.<sup>18</sup>

## Results and Discussion

A summary of the experimental and theoretical enthalpies and experimental entropies for the ground- and excited-state association reactions is given in Table 1. Calculated vibrational frequencies are listed in Table 2. All of the cluster ions discussed here consist of an intact  $\text{Cu}^+$  core ion surrounded by largely unperturbed  $\text{H}_2$  ligands. No evidence of insertion was found.

**Ground-State  $\text{Cu}^+(\text{H}_2)_n$  Clusters.  $\text{Cu}^+(\text{H}_2)$ .** The first  $\text{H}_2$  ligand adds side on to the  $\text{Cu}^+$  ion (in  $C_{2v}$  symmetry) and has a BDE of 15.4 kcal/mol. The cluster structure is nearly identical to that of other late metals such as  $\text{Co}^+(\text{H}_2)$  and  $\text{Ni}^+(\text{H}_2)$ . The  $\text{Cu}^+(\text{H}_2)$  BDE is similar to but about 15% smaller than that of  $\text{Co}^+(\text{H}_2)$  and  $\text{Ni}^+(\text{H}_2)$  (see Table 3 for a comparison). This is somewhat surprising since  $\text{Cu}^+$  has a slightly smaller ionic radius than either  $\text{Co}^+$  or  $\text{Ni}^+$ <sup>29</sup> and we might expect that both the electrostatic and covalent attractions would be larger due to a closer approach. Theory indicates that bonding in all three ions is largely covalent and should be very similar. These covalent interactions consist mainly of donation from the  $\text{H}_2$   $\sigma$  orbital to the empty  $M^+$  4s orbital and back-donation from the filled  $3d_{yz}$  ( $d\pi$ ) orbital to the  $\text{H}_2$   $\sigma^*$  orbital. Both interactions cause an increase in the H–H bond length and a decrease in the H–H stretching frequency relative to the free  $\text{H}_2$  (Figure 4 and Table 2). The origin of the lower bond strength in  $\text{Cu}^+(\text{H}_2)$

<sup>a</sup> In units of kcal/mol. <sup>b</sup> Binding energy with respect to lowest  $d^3$  configuration. <sup>c</sup> Binding energy with respect to lowest  $d^7$  configuration. <sup>d</sup> The increase in  $-\Delta H_0^\circ$  for  $n = 6$  is due to a spin change from quintet to triplet on the core  $\text{V}^+$  ion (see refs 5 and 18). <sup>e</sup> The sum of the binding energies divided by the total number of ligands (for the first solvation sphere). <sup>f</sup> Start of next solvation sphere.

**Figure 4.** Theoretical geometries of the  $\text{Cu}^+(\text{H}_2)_{1-4}$  ions calculated at the DFT B3LYP level (MP2 geometries are given in parentheses). All distances are in angstroms. Relative energies (in kcal/mol) for each isomer are given in parentheses.

is the filled  $3d_z^2$  ( $d\sigma$ ) orbital on  $\text{Cu}^+$  which destabilizes the complex. In both  $\text{Co}^+(\text{H}_2)$  and  $\text{Ni}^+(\text{H}_2)$  the  $\text{H}_2$  approaches a half-filled  $3d_z^2$  orbital. The filled  $3d_z^2$  orbital in  $\text{Cu}^+$  both reduces  $\sigma$  donation from  $\text{H}_2$  to  $\text{Cu}^+$  and increases the on-axis repulsion between  $\text{Cu}^+$  and  $\text{H}_2$ . Since most donation is into the empty

$\text{Cu}^+$  4s orbital, the decrease in donation is minor. The increase in repulsion is thus mainly responsible for the smaller BDE found for  $\text{Cu}^+(\text{H}_2)$  relative to  $\text{Co}^+(\text{H}_2)$  and  $\text{Ni}^+(\text{H}_2)$ . In  $\text{Co}^+(\text{H}_2)$  and  $\text{Ni}^+(\text{H}_2)$ , where the  $3d\sigma$  orbital is half-filled, calculations indicate  $3d\sigma/4s$  hybridization reduces the  $\text{M}^+-\text{H}_2$  repulsion by moving the  $z$  axis electron density to the  $xy$  plane.<sup>9,13,17</sup> This process requires a partial  $3d-4s$  promotion, with the energy cost being recovered from the increased bond strength. In the case of the  $\text{Cu}^+(\text{H}_2)$  ion, the filled  $3d_z^2$  ( $d\sigma$ ) orbital requires a promotion to a  $4s^23d^8$  configuration to reduce the on-axis repulsion by an equivalent amount. This is a much higher energy process,<sup>19</sup> and the smaller  $\text{Cu}^+(\text{H}_2)$  BDE reflects this. It seems clear, however, that this hybridization does occur to some extent in  $\text{Cu}^+(\text{H}_2)$ , since the second BDE is greater than the first (as in  $\text{Co}^+(\text{H}_2)$  and  $\text{Ni}^+(\text{H}_2)$ , see Table 3).

Very similar arguments have been advanced to explain the bonding present in the  $\text{Cu}^+(\text{CO})_n$  ions.<sup>11,30</sup> The filled carbon  $\sigma$  orbital donates into the  $\text{Cu}^+$  4s orbital while the filled  $\text{Cu}^+$   $d\pi$  orbitals ( $3d_{xz}$  and  $3d_{yz}$ ) donate into the CO  $p\pi^*$  orbitals which are largely localized on the carbon. Hybridization of the  $\text{Cu}^+$  4s and  $3d\sigma$  orbitals is used to reduce Pauli repulsion. Again, the  $\sigma$  and  $\pi$  dative interactions are synergistic: the  $\pi$  donation makes the CO more negative and thus better able to donate into the  $\text{M}^+$  4s orbital. The strength of the  $\text{M}^+-\text{CO}$  bond is much greater than that of  $\text{M}^+-\text{H}_2$  (35.5<sup>11</sup> vs 15.4 kcal/mol). This is probably at least partly due to the use of the nonbonding CO  $\sigma$  orbital for donation (i.e., the CO bond is not weakened by the donation) and to the presence of two  $\pi$  interactions instead of one. Both  $\text{M}^+(\text{CO})$  and  $\text{M}^+(\text{H}_2)$  show similar trends as the  $\text{M}^+$  ion is changed. Both ligands have similar BDEs with  $\text{Co}^+$ ,<sup>8,10a</sup>  $\text{Ni}^+$ ,<sup>9,10b</sup> and  $\text{Cu}^+$ ,<sup>11</sup> with the  $\text{Cu}^+$  BDE about 10–15% smaller for both CO and  $\text{H}_2$ . The principal difference between the  $\text{H}_2$  and CO ligands is that the  $\text{M}^+-\text{H}_2$  bond strengths are about 40–45% of the  $\text{M}^+-\text{CO}$  values.

**$\text{Cu}^+(\text{H}_2)_2$ .** The calculated structure of the  $\text{Cu}^+(\text{H}_2)_2$  ion is shown in Figure 4. The second  $\text{H}_2$  ligand binds opposite the first in  $D_{2d}$  symmetry with a measured BDE of 16.7 kcal/mol. This BDE is 1.3 kcal/mol larger than that of the first cluster. The similarity in the two bond strengths is also seen in the bond lengths and vibrational frequencies in the two clusters and is due to the similar interactions of the two  $\text{H}_2$  ligands with  $\text{Cu}^+$ . In both cases, donation from the  $\text{H}_2$   $\sigma$  orbitals into the  $\text{Cu}^+$  4s orbital occurs as well as back-donation from the  $d_{yz}$  and  $d_{xz}$  ( $d\pi$  orbitals) to the  $\text{H}_2$   $\sigma^*$  orbitals. The  $D_{2h}$  structure is 0.2 kcal/mol higher in energy than the  $D_{2d}$  because in  $D_{2h}$  symmetry back-donation to both ligands is from a single  $\pi$ -type orbital

( $d_{yz}$ ). A similar, small decrease in BDE with  $H_2$  orientation is found in the  $Co^+(H_2)_2$  case. Since the back-donation effect is estimated to add  $\sim 6$  kcal/mol to the BDE,<sup>18</sup> this rather minor decrease in bond strength with axial  $H_2$  rotation shows that a single  $d\pi$  orbital can back-donate to two  $H_2$  ligands almost as efficiently as two separate  $d\pi$  orbitals. It also indicates that little, if any, polarization of the  $Cu^+$   $d\pi$  orbital occurs (toward the  $H_2$   $\sigma^*$  orbital) since this would greatly favor the  $D_{2d}$  structure in the second cluster.

The linear ground-state structure found for  $Cu^+(H_2)_2$  is similar to that of the other late metal complexes ( $Fe^+(H_2)_2$ ,  $Co^+(H_2)_2$ , and  $Ni^+(H_2)_2$ ). This is in contrast to the early metals where bent structures are either favored (as in  $Sc^+(H_2)_2$  and  $Ti^+(H_2)_2$ )<sup>3</sup> or are low in energy ( $V^+(H_2)_2$ ).<sup>4</sup> This preference for bent structures with the early metals is due to the presence of two empty 3d orbitals which can accept both in-phase and out-of phase electron donation from the  $H_2$   $\sigma$  orbitals (or in the case of the first excited state of  $V^+(H_2)_2$  (which is bent), a single empty  $3d_{xy}$  and an  $sd$  hybrid orbital). On-axis repulsion is not an issue since the 3d orbitals are empty. In the late metals, however, all of the 3d orbitals are at least half-filled. Because of this, donation into the 3d orbital is small and repulsion becomes the determining factor. Now the linear geometry is preferred because  $s/d$  hybridization efficiently minimizes the on axis repulsion of both ligands. The increase in BDE from the first to second cluster is due to this  $s/d$  hybridization. The symmetric hybridization increases the second ligand bond strength as well as the first, but the associated energy cost is paid in the first addition.<sup>13</sup>

Again the carbonyl system mimics the dihydride due to the similar bonding mechanisms present. The  $Cu^+(CO)_2$  ion is linear with both CO ligands donating into the  $Cu^+$  4s orbital and both accepting electron density from the  $Cu^+$   $d\pi$  orbital into their  $p\pi^*$  orbitals.<sup>31</sup> The  $Cu^+$  back-donating orbitals are thus shared by the two CO ligands, unlike the  $Cu^+(H_2)_2$  case. The second CO BDE is about 15% greater than the first (35.5 vs 41 kcal/mol<sup>11</sup>), similar to the 8% increase seen with in the  $H_2$  clusters. The larger increase in BDE in the carbonyl system is presumably due to the greater amount of  $sd$  hybridization present, relative to the dihydrogen system.

**$Cu^+(H_2)_3$ .** The optimized DFT structure for the  $Cu^+(H_2)_3$  ion is of  $D_{3h}$  symmetry with all atoms in the  $xy$  plane (see Figure 4). The BDE of the third  $H_2$  ligand is much lower than that of the first two: 8.8 kcal/mol. This corresponds to an average BDE of 13.6 kcal/mol for three ligands vs 16.1 kcal/mol for the first two ligands. This decrease is not due to steric interference between the  $H_2$  ligands. This can be shown theoretically by fixing the  $H_2-Cu^+-H_2$  angle in  $Cu^+(H_2)_2$  and then calculating the system energy *without* the  $Cu^+$ . As the angle is systematically decreased from 180° to 90°, no significant increase in energy results, showing the lack of  $H_2-H_2$  interference (Figure 5). When the second cluster is constrained to a 120°  $H_2-Cu^+-H_2$  bond angle (as in the third cluster) and the system is optimized with the  $Cu^+$  ion present, a 3 kcal/mol per ligand destabilization is found relative to the 180° structure. This is similar to the experimental decrease in average BDE from the second to the third cluster and indicates that a reduction in the covalent interaction, rather than steric interference, is responsible for the decrease in BDE. In fact, the origin of both the highly symmetric structure and the marked decrease in bond strength lies primarily in the repulsive interaction of the  $H_2$   $\sigma$  orbitals with the filled 3d shell on  $Cu^+$ . In the planar  $D_{3h}$  structure, the three  $H_2$  ligands have a repulsive  $\sigma$  interaction with three of the  $Cu^+$  3d orbitals (the  $3d_{z^2}(a_1')$  and  $3d_{x^2-y^2}/3d_{xy}(e')$ , the  $z$  axis

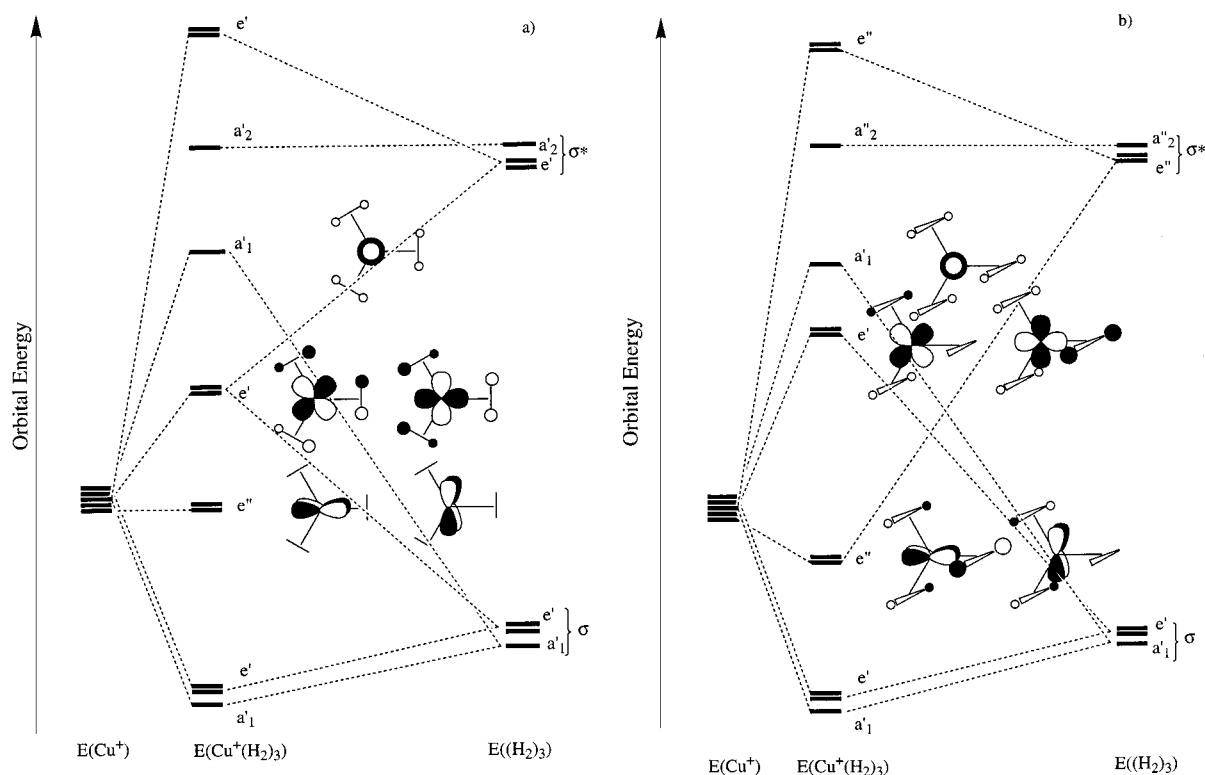

**Figure 5.** Relative energy of the  $Cu^+(H_2)_2$  ion (calculated at the DFT level) as a function of the  $H_2-Cu^+-H_2$  angle. All other geometrical parameters have been optimized for each fixed angle. The open squares correspond to the energy of the  $Cu^+(H_2)_2$  ion, and the filled diamonds correspond to the energy of  $(H_2)_2$  subsystem fixed at the optimized geometry of the  $Cu^+(H_2)_2$ . The lack of change in the  $(H_2)_2$  system with changing angle shows that ligand–ligand repulsion is unimportant in this system. See text.

is the symmetry axis, see Figure 6a). The ion uses two methods to reduce this repulsion. First, the 4s and  $3d_{z^2}$  orbitals are hybridized to move electron density from the  $xy$  plane to the  $\pm z$  lobes. This hybridization is similar to that found in the first two clusters, but with an opposite shift in electron density. Second, and more important, the  $Cu^+$  ion donates electron density from the repulsive  $3d_{x^2-y^2}/3d_{xy}(e')$  pair of orbitals to the  $H_2$   $\sigma^*$  orbitals. This pair of orbitals is symmetry adapted to produce both two repulsive  $\sigma$  interactions and two attractive  $\pi$  interactions with the three ligands. The resulting  $\pi$  back-donation is similar in nature to that in the first two clusters, but in the third cluster, the back-donation also reduces the  $\sigma$  repulsion. This “push–pull” mechanism has the effect of increasing the extent of back-donation while (at the same time) reducing  $\sigma$  repulsion and is the primary driving force for the  $D_{3h}$  structure. Despite this, there is an overall reduction in back-donation in going from the second to the third cluster due to the greatly increased  $\sigma$  repulsion.

The remaining metal–ligand interactions are similar to those found in the first two clusters. Ligand to metal donation in  $Cu^+(H_2)_3$  is again primarily from the  $H_2$   $\sigma$  orbital to the  $Cu^+$  4s orbital, although the natural bond order (NBO) population analysis indicates that a very small amount of  $4p_{xy}$  character may be present in the acceptor orbital (i.e., a minor amount of  $sp^2$  hybridization). This would provide some directionality to the acceptor orbital for better overlap with the  $H_2$   $\sigma$  orbitals. The reduction in average BDE from 16.1 kcal/mol in the second cluster to 13.6 kcal/mol in the third is mainly a consequence of the increased  $\sigma$  repulsion (three ligands interacting repulsively with three orbitals vs two ligands interacting with one repulsive orbital). Although the repulsion is reduced through the mechanisms discussed, the result is a lower average bond strength. A very similar reduction in BDE is found between  $Cu^+(CO)_2$  and  $Cu^+(CO)_3$ ,<sup>11</sup> although no calculations have been done on the tricarbonyl system and no detailed understanding of the decrease has been presented.

The second (vertical)  $D_{3h}$  structure, with the  $H_2$  ligands perpendicular to the  $xy$  plane, is 3.7 kcal/mol higher in energy and is actually a transition state (see Figure 4). The isomer spontaneously reverts to the planar form under an unconstrained

(31) Maître, P. Work in progress.

**Figure 6.** Relative energies of the molecular orbitals for the two lowest energy  $D_{3h}$  structures of  $\text{Cu}^+(\text{H}_2)_3$ : (a) planar geometry with all three  $\text{H}_2$  molecular ligands lying in the  $xy$  plane (lowest energy structure); (b) vertical geometry with all three  $\text{H}_2$  molecules perpendicular to the  $xy$  plane. In a, the lowest ( $a_1'$ ,  $e'$ ) and highest ( $a_2'$ ,  $e'^*$ ) pairs of orbitals are primarily symmetry-adapted sets of  $\text{H}_2$   $\sigma$  orbitals and  $\sigma^*$  orbitals while the center three MOs are primarily  $\text{Cu}^+$  3d orbitals. Similar assignments hold for the orbitals in b.

geometry optimization. This might seem surprising since the vertical and planar  $D_{3h}$  forms are superficially quite similar. They have nearly identical  $\sigma$  repulsion and the vertical isomer also has a degenerate pair of d orbitals available for back-bonding (the  $e''$  set,  $3d_{xz}/3d_{yz}$ , see Figure 6b). Further, the vertical isomer has lower ligand–ligand repulsion (although this is a negligible effect). The destabilization of the vertical  $D_{3h}$  cluster is due to the loss of the very beneficial “push–pull” mechanism present in the planar geometry. In the vertical geometry, the back-donation from the  $e''$  pair of orbitals does *not* lead to any reduction in  $\sigma$  repulsion. The result is a greatly reduced amount of back-donation, increased  $\sigma$  repulsion, and finally, a smaller bond energy. This can also be seen as a result of the splitting of the 3d orbital energies in the  $D_{3h}$   $\sigma$  ligand field (the energy ordering is  $3d_z^2(a_1') > 3d_{xy}/3d_{x^2-y^2}(e') > 3d_{xz}/3d_{yz}(e'')$ ) which reduces the  $3d(e'')\text{--H}_2$   $\sigma^*$  energy difference and thereby enhances the  $\pi$  back-donation in the planar ion. Comparisons of the NBO populations, bond lengths and vibrational frequencies found in the two structures all show increased back-donation in the planar ion.

The preference for either the planar  $D_{3h}$  structure (as in  $\text{Cu}^+(\text{H}_2)_3$  and  $\text{Ni}^+(\text{H}_2)_3$ ) or a “T” geometry (as in  $\text{Co}^+(\text{H}_2)_3$  and  $\text{Fe}^+(\text{H}_2)_3$ ) is worth examining. As detailed above, steric effects can be discounted. Rather, the preference for the  $D_{3h}$  over a “T” structure depends on a symmetric population of the  $3d_{xy}$  and  $3d_{x^2-y^2}$  orbitals (the  $e'$  set in  $D_{3h}$  symmetry). If these orbitals are both filled (as in  $\text{Cu}^+(\text{H}_2)_3$  and  $\text{Ni}^+(\text{H}_2)_3$ ), the  $D_{3h}$  geometry is favored for two reasons. First, the “push–pull” mechanism discussed above produces a large, synergistic back-donation which greatly enhances the bond strength and reduces  $\sigma$  repulsion. Second, the “T” structure is destabilized due to the extra metal–ligand repulsion in the  $x\text{--}y$  plane. If, on the other hand, one of these orbitals is only half-filled (as is required in  $\text{Fe}^+(\text{H}_2)_3$  and  $\text{Co}^+(\text{H}_2)_3$  to maintain a pure ground electronic

configuration), the “push–pull” effect in the  $D_{3h}$  geometry is greatly reduced and the third  $\text{H}_2$  will approach the  $\text{M}^+(\text{H}_2)_2$  in a “T” configuration. In this geometry, all three  $\text{H}_2$  ligands approach half-filled  $3d\sigma$  orbitals which both minimizes repulsion and maximizes donation onto the metal ion. Further, if both the  $e'$  and  $e''$  orbital sets are half-filled (as in  $\text{Cr}^+$ ), a  $D_{3h}$  geometry is also favored.<sup>5</sup> In this case, one-electron back-donation is used to reduce the  $\sigma$  repulsion, despite the fact that this is inherently less favorable than the two-electron process in  $\text{Cu}^+(\text{H}_2)_3$ .<sup>13</sup> Finally, the same conclusions about structural preference can be reached via a pure symmetry argument: the  $D_{3h}$  structure becomes unstable with respect to a Jahn–Teller distortion when the  $e'$  and  $e''$  sets of orbital are not equally occupied and a less symmetric “T” shape results.

In both  $\text{M}^+(\text{H}_2)_3$  geometries, there is a reduction in BDE in going from the second to the third cluster. In ions which form a “T” structure ( $\text{Co}^+(\text{H}_2)_3$ <sup>17</sup> and  $\text{Fe}^+(\text{H}_2)_3$ <sup>7,31</sup>), this reduction in bond strength is mainly due to a reduction in the amount of s/d hybridization present in the second cluster as well as  $\sigma$  repulsion from a second 3d orbital. The s/d hybridization present in the second cluster produces a region of high electron density in the  $xy$  plane which the third  $\text{H}_2$  must approach. As a result, the amount of s/d hybridization is reduced and the first two  $\text{H}_2$  ligands are destabilized. (The electron cloud may also be partly polarized away from the third ligand using the 4p orbital as well,<sup>7,17</sup> but these orbitals are high in energy and the process is not as efficient as the s/d hybridization in the first two clusters.) As discussed above, the reduction in BDE in the clusters with the  $D_{3h}$  structure is due mainly to greater  $\sigma$  repulsion from the  $e'$  and  $a_1'$  orbitals. To illustrate the importance of this repulsion in the  $D_{3h}$  geometry, note that the average BDE in the  $\text{Ni}^+$  third cluster (with a half-filled  $3d_z^2(a_1')$  orbital) is  $\sim 2$  kcal/mol greater than that in  $\text{Cu}^+(\text{H}_2)_3$  (where the orbital is filled). In fact,  $\text{Ni}^+(\text{H}_2)_3$ , which has the optimum electron occupation for a  $D_{3h}$

structure, has the highest average third BDE of all the transition metal ions (see Table 3).

**Cu<sup>+</sup>(H<sub>2</sub>)<sub>4</sub>.** The Cu<sup>+</sup>(H<sub>2</sub>)<sub>4</sub> cluster closes the first solvation sphere. The ion is quasi-tetrahedral (*D*<sub>2d</sub> symmetry, see Figure 4) with a BDE of 5.1 kcal/mol. This represents a 2.1 kcal/mol decrease in average BDE from the third cluster (from 13.6 to 11.5 kcal/mol), presumably due both to reduction in donation to Cu<sup>+</sup> from the H<sub>2</sub> ligands as well as increased  $\sigma$  repulsion. The BDE of Cu<sup>+</sup>(CO)<sub>4</sub> is also much lower than Cu<sup>+</sup>(CO)<sub>3</sub>.<sup>11</sup> The effect of the H<sub>2</sub>–Cu<sup>+</sup>–H<sub>2</sub> bond angle is shown in Figure 5. When this angle is constrained to 105° (as in Cu<sup>+</sup>(H<sub>2</sub>)<sub>4</sub>), there is a 1.3 kcal/mol reduction in average BDE relative to a 120° angle (as in Cu<sup>+</sup>(H<sub>2</sub>)<sub>3</sub>). Thus the increased repulsion and decreased  $\sigma$  donation at the 105° angle accounts for a majority of the 2.1 kcal/mol decrease found experimentally. The amount of donation into the Cu<sup>+</sup> 4s orbital per H<sub>2</sub> ligand also becomes smaller in the larger clusters due to the greater number of ligands, further reducing the BDE. The reduction in  $\sigma$  donation in Cu<sup>+</sup>(H<sub>2</sub>)<sub>4</sub> is reflected in higher H–H stretching frequencies and shorter H–H bond lengths (more like free H<sub>2</sub>). There is also a substantial increase in Cu<sup>+</sup>–H<sub>2</sub> bond length (from 1.72 Å in the third cluster to 1.80 Å in the fourth, at the B3LYP level of theory). Back-donation in the third and fourth clusters is surprisingly similar. In Cu<sup>+</sup>(H<sub>2</sub>)<sub>4</sub>, two of the three 3d orbitals which are symmetry adapted for back-donation are destabilized by  $\sigma$  repulsion, leading to the same “push–pull” effect found in Cu<sup>+</sup>(H<sub>2</sub>)<sub>3</sub>.

Both Cr<sup>+</sup>(H<sub>2</sub>)<sub>4</sub> and Ni<sup>+</sup>(H<sub>2</sub>)<sub>4</sub> have similar *D*<sub>2d</sub> quasi-tetrahedral structures. (The Cu<sup>+</sup>(CO)<sub>4</sub> ion is highly symmetric with *T*<sub>d</sub> symmetry.<sup>31</sup>) This may partly reflect the use of 4p acceptor orbitals (i.e., donation is partly into an sp<sup>3</sup> hybrid orbital on Cu<sup>+</sup>), although the orbital population analysis is uncertain. Use of the 4p orbitals would allow both in-phase and out-of-phase contributions from the four H<sub>2</sub> ligands, which was an important stability factor in the Ti<sup>+</sup>(H<sub>2</sub>)<sub>n</sub> system.<sup>3</sup> Both Fe<sup>+</sup>(H<sub>2</sub>)<sub>4</sub><sup>7</sup> and Co<sup>+</sup>(H<sub>2</sub>)<sub>4</sub><sup>17</sup> also have distorted tetrahedral geometries, but here, the structure is derived from a “T”-shaped third cluster and the bonds are not all equivalent. Orbital populations do indicate that the 4p orbitals are partly responsible for these geometries as well, however.<sup>17</sup>

**Cu<sup>+</sup>(H<sub>2</sub>)<sub>5,6</sub>.** Data for the Cu<sup>+</sup>(H<sub>2</sub>)<sub>5</sub> cluster could be obtained only at very low temperatures. Both the extremely weak BDE (1.0 kcal/mol) and, especially, the very small  $\Delta S^\ddagger$  show that this ligand is added in the second solvation shell. The very low vibrational frequencies, free H<sub>2</sub> rotations, and large rotational moments which result all give rise to more product entropy and make the  $\Delta S^\ddagger$  of association more positive (–12.5 cal/(mol·K) vs –20 to –24 cal/(mol·K) for the first four association reactions). Our DFT calculations are consistent with the observed increase in  $\Delta S^\ddagger$ . The lowest energy structure for Cu<sup>+</sup>(H<sub>2</sub>)<sub>5</sub> in the first solvation shell is a trigonal bipyramid (as in Ni<sup>+</sup>(H<sub>2</sub>)<sub>5</sub>); however, it is unbound with respect to the separated reactants (Cu<sup>+</sup>(H<sub>2</sub>)<sub>4</sub> + H<sub>2</sub>, see Table 1). Data for the Cu<sup>+</sup>(H<sub>2</sub>)<sub>6</sub> cluster could be taken only at 77 K but matched that of the fifth cluster.

The Co<sup>+</sup>(H<sub>2</sub>)<sub>n</sub> and Ni<sup>+</sup>(H<sub>2</sub>)<sub>n</sub> systems have first solvation shells of six and five H<sub>2</sub> ligands, respectively.<sup>8,9</sup> This is due to the presence of two and one half-filled 3d orbitals (respectively). In Co<sup>+</sup>(H<sub>2</sub>)<sub>n</sub> the e<sub>g</sub> (3d<sub>x<sup>2</sup>–y<sup>2</sup>}/3d<sub>z<sup>2</sup></sub>) orbital set is half-filled and an octahedral arrangement results.<sup>17</sup> In Ni<sup>+</sup>(H<sub>2</sub>)<sub>5</sub> the single half-filled orbital leads to a stable trigonal bipyramid structure in which two polar H<sub>2</sub> ligands are attached to the *D*<sub>3h</sub> core found in the third cluster.<sup>9</sup> Although this same *D*<sub>3h</sub> structure is found in Cu<sup>+</sup>(H<sub>2</sub>)<sub>3</sub>, the corresponding fifth cluster is not stable due to</sub>

**Figure 7.** Theoretical geometries of electronically excited Cu<sup>+</sup>\*(H<sub>2</sub>)<sub>1–3</sub> ions calculated at the DFT B3LYP level, assuming a <sup>3</sup>D, 4s<sup>1</sup>3d<sup>9</sup> copper ion core configuration. All distances are in angstroms. Relative energies (in kcal/mol) for each isomer are given in parentheses.

the filled 3d<sub>z<sup>2</sup></sub> orbital which strongly destabilizes the two polar ligands. The result is a Cu<sup>+</sup>(H<sub>2</sub>)<sub>n</sub> solvation shell of four H<sub>2</sub> ligands. From a general chemistry viewpoint, the progressive reduction in the number of ligands in the first solvation shell illustrates the balance between the attractive forces in the complex and the occupation of the antibonding orbitals. The stability of Co<sup>+</sup>(H<sub>2</sub>)<sub>6</sub> shows that the destabilization resulting from single occupancy of the e<sub>g</sub> orbitals is more than compensated for by the stabilization energy resulting from  $\sigma$  donation,  $\pi$  back-donation, and electrostatic attraction. It is not surprising, however, that adding one and two electrons to these antibonding orbitals results in the loss of one and two H<sub>2</sub> ligands from the hypothetical Ni<sup>+</sup>(H<sub>2</sub>)<sub>6</sub> and Cu<sup>+</sup>(H<sub>2</sub>)<sub>6</sub> octahedral clusters.

**Electronically Excited Cu<sup>+</sup>\*(H<sub>2</sub>)<sub>n</sub> Clusters.** Electronic state chromatography<sup>21</sup> showed that metastable excited copper ions are formed about a Cu<sup>+</sup> core with a 4s<sup>1</sup>3d<sup>9</sup> valence configuration. Presumably this is the <sup>3</sup>D state (~65 kcal/mol excitation<sup>19</sup>), but the <sup>1</sup>D state (75.1 kcal/mol<sup>19</sup>) may also be present since both states are metastable. In both excited states the large 4s orbital controls the interaction with H<sub>2</sub>; hence, no significant difference between the bonding of these two states with H<sub>2</sub> is expected. Bond strengths are much weaker in these excited clusters, relative to the ground-state ions, due to the repulsive nature of the 4s electron.<sup>13,32</sup> The experimental  $\Delta H^\ddagger$  and  $\Delta S^\ddagger$  results are listed in Table 1, along with the derived BDEs and theoretical results for the triplet state. The calculated DFT structures for the triplet state clusters are shown in Figure 7.

Data were taken for the first three Cu<sup>+</sup>\*(H<sub>2</sub>)<sub>n</sub> clusters. The BDEs are ~20% of those found in the ground-state clusters (Table 1). There is a corresponding increase in Cu<sup>+</sup>–H<sub>2</sub> bond length (from 1.70 to 2.09–2.26 Å, see Figures 4 and 7) and a decrease in the Cu<sup>+</sup>–H<sub>2</sub> vibrational frequencies (Table 2). This is expected from the presence of the 4s electron which destabilizes the clusters in three ways: first, by greatly increasing the on-axis Pauli repulsion; second, by decreasing donation from the H<sub>2</sub> ligands to Cu<sup>+</sup> (normally into the 4s orbital); and third, by decreasing back-donation from the Cu<sup>+</sup> because of the much longer bond lengths.<sup>13,32</sup> These changes in the Cu<sup>+</sup>\*(H<sub>2</sub>)<sub>n</sub> ions are also reflected in the more positive association entropies for the excited Cu<sup>+</sup>\* reactions (Table 1). The larger rotational moments and lower vibrational frequencies produce greater product entropy than the more tightly bound ground-state Cu<sup>+</sup>(H<sub>2</sub>)<sub>n</sub> ions.

**Table 4.**  $\text{M}^+(4s^1 3d^{n-1})$ : Comparison of Binding Energies<sup>a</sup> for  $\text{M}^+(\text{H}_2)_{n-1} + \text{H}_2 \rightarrow \text{M}^+(\text{H}_2)_n$ 

$n$	$\text{Mn}^+$	$\text{Cu}^{+*}$	$\text{Zn}^+$
1	1.9	4.2	3.8
2	1.7	2.5	2.8
3	1.3	1.4	2.4

<sup>a</sup> In units of kcal/mol.**Figure 8.** Theoretical geometries of the  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)_{1,2}$  ions calculated at the DFT B3LYP level. All distances are in angstroms. Relative energies (in kcal/mol) for each isomer are given in parentheses.

The  $\text{Cu}^{+*}(\text{H}_2)_n$  ions can best be compared with the  $\text{Mn}^+(\text{H}_2)_n$  and  $\text{Zn}^+(\text{H}_2)_n$  systems which also have  $4s^1 3d^{n-1}$  valence configurations with no low-energy  $3d^n$  configurations available.<sup>19</sup> In all three cases, the  $\text{H}_2$  ligands add at  $90^\circ$  to each other (i.e., along the  $x$ ,  $y$ , and  $z$  axes).<sup>6</sup> This is due to the use of the  $4p$  orbitals to polarize the  $4s$  electron density away from the  $\text{H}_2$  ligand. Three separate  $4p$  orbitals are used for the first three ligands and bond angles of approximately  $90^\circ$  result. Table 4 shows that the  $\text{Cu}^{+*}(\text{H}_2)_n$  and  $\text{Zn}^+(\text{H}_2)_n$  systems have very similar BDEs while the  $\text{Mn}^+(\text{H}_2)_n$  ions have a considerably lower bond strengths. The  $\text{M}^+-\text{H}_2$  bond lengths are also similar in the  $\text{Cu}^{+*}(\text{H}_2)_n$  and  $\text{Zn}^+(\text{H}_2)_n$  systems and longer in the  $\text{Mn}^+(\text{H}_2)_n$  ions. Both effects are consistent with the larger size of the  $4s$  orbital in  $\text{Mn}^+$ .<sup>29</sup>

Finally we note that the  $\text{Cu}^{+*}(\text{H}_2)$  BDE appears to be somewhat greater than the corresponding  $\text{Zn}^+(\text{H}_2)$  value (Table 4). This must be due to the presence of a half-filled  $3d_z^2$  orbital in  $\text{Cu}^{+*}(\text{H}_2)$  which results in a smaller screening of the  $\text{Cu}^+$  nuclear charge. We found that the lowest triplet state ( $^3A_1'$ ) results from the  $\text{Cu}^{+*}$  electronic configuration in which the half-filled  $3d_z^2$  orbital is oriented toward the  $\text{H}_2$  ligands. The DFT calculations find that the  $^3A_2$  state, where the  $3d_{xy}$  is half-filled, has only about one-fourth of the ground-state binding energy and has a significantly longer  $\text{Cu}^+-\text{H}_2$  bond length (2.28 vs 2.09 Å).

**$\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)_{1,2}$  Clusters.** A summary of experimental and theoretical results for the  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)_{1,2}$  clusters is given in Table 5. Our calculated structures are shown in Figure 8, and the calculated vibrational frequencies are listed in Table 6. The  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)$  ion has been examined previously by Maître and Bauschlicher.<sup>18</sup> It is clear that addition of an  $\text{H}_2\text{O}$  ligand to  $\text{Cu}^+$  has a rather dramatic effect on the subsequent  $\text{H}_2$  binding energies. The experimental BDE of the second ligand increases from 16.7 to 19.6 kcal/mol when the first ligand is  $\text{H}_2\text{O}$  rather than  $\text{H}_2$ , while that of the third decreases from 8.8 to 3.8 kcal/mol. These changes in bond strength are also reflected in the

$\text{Cu}^+-\text{H}_2$  bond lengths and frequencies. A similar increase in BDE for the addition of the first  $\text{H}_2$  ligand was found both experimentally and theoretically in the  $\text{H}_2\text{O}\cdot\text{Co}^+(\text{H}_2)$  ion.<sup>8b,18</sup>

In its lowest energy structure,  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)$  has  $C_{2v}$  symmetry with the H-H bond perpendicular to the H-O-H plane (Figure 8). The structure with the H-H bond coplanar is only 0.4 kcal/mol higher in energy and corresponds to a transition state in the rotation of the  $\text{H}_2$  ligand about the  $\text{Cu}^+-\text{H}_2$  bond. Bond lengths and cluster frequencies show little change between the two forms. Since this rotation should cause no change in  $\sigma$  repulsion, this result indicates that back-donation into the  $\text{H}_2$   $\sigma^*$  orbital is only very slightly enhanced when the  $\text{Cu}^+$  back-donating orbital ( $3d_{yz}$ ) is destabilized by the oxygen lone pair (a  $\pi$  donor). It has been proposed that a significant amount of "pass through" back-donation might occur in this molecule, with the oxygen lone pair effectively donating to the  $\text{H}_2$  ligand via the  $\text{Cu}^+ 3d\pi$  orbital,<sup>33</sup> thereby increasing the  $\text{H}_2$  BDE in  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)$ . Apparently, however, this is a minor effect, although it is probably the origin of the weak preference for the nonplanar  $C_{2v}$  ground-state structure. Instead, we think the origin of the increased BDE when water is attached lies in increased  $s/d$  hybridization. The  $\text{Cu}^+-\text{H}_2\text{O}$  bond is over twice as strong as the  $\text{Cu}^+-\text{H}_2$  bond (37.6<sup>34,35</sup> vs 15.4 kcal/mol), and more  $s/d$  hybridization occurs (relative to the  $\text{H}_2$  clusters) because there is a larger payback. This is shown experimentally by the large increase in BDE between the  $\text{Cu}^+(\text{H}_2\text{O})$  and  $\text{Cu}^+(\text{H}_2\text{O})_2$  ions (37.6 to 40.6 kcal/mol<sup>34,35</sup>) due to hybridization which has occurred in the first cluster. This increased  $s/d$  hybridization in  $\text{Cu}^+(\text{H}_2\text{O})$  increases the bond energy when an  $\text{H}_2$  ligand is now added. As discussed above, this occurs in the pure  $\text{M}^+-\text{H}_2$  cluster, but the increase in the second  $\text{H}_2$  BDE is greater when the first ligand is  $\text{H}_2\text{O}$  because more hybridization has occurred with  $\text{H}_2\text{O}$ .

It is also interesting to look at the relative stabilities of the two-coordinate species and to observe that the reaction

is about 4.1 kcal/mol exothermic. Not only does the  $\text{H}_2\text{O}$  ligand enhance the BDE of the subsequent  $\text{H}_2$  ligand, but an  $\text{H}_2$  first ligand similarly enhances the binding of a subsequent  $\text{H}_2\text{O}$  ligand. Such a thermodynamic effect has been observed in saturated species and is referred to as a "cis influence" or "static cis influence".<sup>36</sup>

This enhancement of the  $\text{Cu}^+-\text{H}_2$  bond in  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)_n$  ends with the first  $\text{H}_2$ . The second  $\text{H}_2$  is bound far more weakly than in the pure  $\text{Cu}^+(\text{H}_2)_3$  clusters (3.8 vs 8.8 kcal/mol). This can be seen as a direct result of the enhancement of the first  $\text{H}_2$  bond. The simultaneous  $s/d$  hybridization of the empty  $4s$  acceptor orbital toward the  $\text{H}_2$  and of the filled  $3d_z^2$  away from the ligand yields a strong enhancement of the first  $\text{H}_2$  ligand but is unfavorable to the approach of the second. The consequential reduction in hybridization directly reduces the second  $\text{H}_2$  BDE. A similar loss occurs in the pure  $\text{Cu}^+(\text{H}_2)_n$  clusters, but the enhancement of the first BDE is greater in the first  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)$  ion and consequently the reduction in BDE with the next addition is greater.

The structure of the  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)_2$  ion is planar with  $C_{2v}$  symmetry (Figure 8). This is analogous to the planar  $D_{3h}$

<sup>a</sup> Harmonic vibrational frequencies for the different  $\text{M}^+(\text{H}_2)_n$  clusters as obtained by analytical differentiation of the SCF energy at the SCF geometry. The distinction between the different types of low-frequency modes is increasingly artificial for the larger clusters. <sup>b</sup> All numbers in  $\text{cm}^{-1}$ .

structure found with  $\text{Cu}^+(\text{H}_2)_3$  and a similar “push–pull” effect where  $\sigma$  repulsion drives the  $\pi$  donation operates here as well. A second  $C_{2v}$  structure exists for the  $\text{H}_2\text{O}\cdot\text{Cu}^+(\text{H}_2)_2$  ion with the  $\text{H}_2$  ligands parallel with the oxygen lone pairs (Figure 8). This is analogous to the vertical  $D_{3h}$  isomer of  $\text{Cu}^+(\text{H}_2)_3$ . As in  $\text{Cu}^+(\text{H}_2)_3$ , however, the planar orientation of the  $\text{H}_2$  is significantly more stable. This shows again that the in-plane 3d orbitals, destabilized by the  $\sigma$  orbitals of the ligands, are best suited for back-donation.

## Conclusions

(1) Bond dissociation energies and association entropies were determined for  $\text{Cu}^+(\text{H}_2)_{1-6}$ , indicating that the first four  $\text{H}_2$  ligands form the first solvation shell while the fifth and sixth  $\text{H}_2$  ligands begin the second solvation shell.

(2) Molecular geometries and vibrational frequencies were determined from extensive calculation at the DFT and MP2 levels.

(3) Bonding in the clusters consists mainly of donation to  $\text{Cu}^+$  from the  $\text{H}_2$   $\sigma$  orbital, back-donation from the  $\text{Cu}^+$  3d $\pi$  orbitals to the  $\text{H}_2$   $\sigma^*$  orbital, and the charge-induced dipole and charge quadrupole electrostatic attractions. These interactions in  $\text{Cu}^+(\text{H}_2)_n$  are similar to those found in  $\text{Co}^+(\text{H}_2)_n$  and  $\text{Ni}^+(\text{H}_2)_n$  but slightly weaker due to the increase in Pauli repulsion caused by the filled 3d shell in  $\text{Cu}^+(\text{H}_2)_n$ .

(4) Electronically excited  $\text{Cu}^{+*}(\text{H}_2)_{1-3}$  clusters (with a  $\text{Cu}^+$ , 4s<sup>1</sup>3d<sup>9</sup> configuration) were also examined and found to have much weaker bond energies, similar to  $\text{Zn}^+(\text{H}_2)_n$  and  $\text{Mn}^+(\text{H}_2)_n$ . The large repulsive 4s orbital was responsible.

(5) Addition of an  $\text{H}_2\text{O}$  ligand increased the bond strength of the first  $\text{H}_2$  ligand but dramatically reduced the BDE for the second  $\text{H}_2$ . These effects were explained in terms of increased s/d hybridization between the  $\text{Cu}^+$  and  $\text{H}_2\text{O}$  relative to the pure  $\text{H}_2$  clusters.

(6) Remarkably similar trends were found in the  $\text{Cu}^+(\text{H}_2)_n$  and in the  $\text{Cu}^+(\text{CO})_n$  systems with the  $\text{Cu}^+-\text{H}_2$  BDEs  $\sim 45\%$  of the  $\text{Cu}^+-\text{CO}$  values. This is due to the very similar  $\text{M}^+$ –ligand interactions in both systems. This same correspondence is also present in the corresponding  $\text{Ni}^+$  and  $\text{Co}^+$  systems.
