Received October 5, 2002

Open-framework materials with ordered cavities of nanometer size are possible hosts for synthesis of nanocomposite materials in addition to their established importance in other areas such as ion exchange and catalysis.^{1,2} The aluminosilicates (zeolites), the traditional examples of such materials, are particularly suitable because of their high thermal stability and good optical transparency.^{3,4} Many attempts have been made to modify the physical and catalytic properties of zeolite frameworks by the incorporation of transition-metal ions.^{5,6} These efforts have led to the discovery of a number of porous structures formed from both silicate tetrahedra and transition-metal-centered polyhedra.^{7–15} Recently we reported a series of porous vanadosilicate compounds that are based on silicate sheets cross-linked by VO₅ square pyramids.^{16,17} By substituting UO₆ tetragonal bipyramids for the VO₅ pyramids we obtained also a number of open-framework uranium silicates.^{18,19} These new compounds were synthesized by using alkali metal cations as templating agents. We are investigating similar syntheses by using organic templates. In the development of zeolite synthesis, introduction of organic templates greatly increased the topology and composition spectrum of zeolite structures because of the huge variability of available template shapes and charge densities.⁴ Here we report the first example of an open-framework uranium fluorosilicate [(CH₃)₄N][(C₅H₅NH)_{0.8}((CH₃)₃NH)_{0.2}]U₂Si₉O₂₃F₄ (USH-8) that has been synthesized by using organic templates.

In a typical synthesis, fumed silica was dissolved in a mixture of water, tetramethylammonium (TMA) hydroxide, HF, and pyridine. Uranium acetate was subsequently added. The final mixture with the molar ratios TMAOH:SiO₂:UO₂(CH₃COO)₂:HF:pyridine:H₂O = 5:2:1:4:32:200, was sealed in a Teflon-lined autoclave in air and heated at 180 °C for 10 days. After cooling to room temperature, the product was vacuum-filtered and washed with water. Yellow-brown needlelike crystals of USH-8 were recovered as a single phase with high yield (65.9% based on U). Chemical analysis showed that the compound has a framework of composition U₂Si₉O₂₃F₄ consistent with the single-crystal X-ray diffraction data which indicates silicate double layers interlinked by chains of UO₃F₄ pentagonal bipyramids (Figure 1).²⁰

The silicate double layer consists of two single layers that are related by a glide plane. The single layer can be described as formed from fundamental chains that run along [100] and are built by linking double five rings with single tetrahedra (Figure 2).²¹ Interconnection of the chains results in large 10-ring voids in the single layer, but the voids are blocked by the other single layer because of the glide plane symmetry of the double layer. Two-ninths of the tetrahedra in the double layer are three-connected with their fourth terminal oxygen atom corners pointing to the outside of the double layer. These terminal oxygen atoms are further bonded to interlayer uranium atoms that have pentagonal bipyramidal

Figure 1. View of the structure of USH-8. Silicate tetrahedra are yellow and uranate pentagonal bipyramids green. Blue and gray circles represent nitrogen and carbon atoms, respectively.

coordination. The same silicate double layer is found in the structure of the zeolite ferrierite.²² In ferrierite, the silicate oxygen atoms that form part of the UO₃F₄ pentagonal bipyramids in USH-8 are shared to form 8-ring channels parallel to the layers. The UO₃F₄ pentagonal bipyramid has two apical uranyl oxygen atom corners and one equatorial oxygen atom corner that is shared with a silicate tetrahedron. Neighboring UO₃F₄ pentagonal bipyramids share an equatorial fluorine atom edge to form infinite chains along the [010] direction (Figure 2). The framework formed by connection of the uranate chains and the silicate double layers has 12-ring channels along [010] and 7-ring channels along [100]. The [010] 12-ring channels have a calabash-shaped cross-section with the middle part partially blocked by the uranyl oxygen atoms (Figure 1). The narrow side of the 12-ring channels is occupied by well-ordered TMA cations while the wide side is occupied by disordered pyridinium and trimethylammonium cations. The latter presumably were formed by decomposition of TMA during the synthesis reaction. Incorporation of the organic species was confirmed by infrared and ¹³C NMR data and chemical analysis.²³

The observed Si–O bond lengths (1.542–1.617 Å, average 1.594 Å) are somewhat shorter than typical values but are still within the normal range.²¹ We noted that the thermal parameters of the framework atoms are larger than expected under the low-temperature (–50 °C) conditions used for the X-ray measurement (for oxygen atoms, U_{iso}: 0.020(4)–0.045(4), average 0.033 Å²). These thermal parameters suggest some local static disorder at the

framework atom sites, which may cause the observed atom distances to appear shorter than their real values.²¹ The terminal Si–O bonds have the shortest bond length. The observed O–Si–O bond angles of 106.7–111.9° are well within the expected range. The two apical uranyl U=O bonds have bond lengths 1.744–1.760 Å and an O–U–O angle 178.8°. The equatorial U–O and U–F bond lengths are 2.23 and 2.354–2.363 Å, respectively.

Thermogravimetric analysis combined with X-ray powder diffraction indicates that the structure collapses after loss of the organic species between 300 and 600 °C in air. The openings in the channel systems of the framework are apparently too narrow for free removal of the bulky organic cations by oxidative decomposition.

In contrast to the *VSH-n* and some of other *USH-n* phases which are based on silicate single layers containing 4- and 6-ring channels, *USH-8* is based on silicate double layers containing 5-ring channels.^{17,18} The structural difference is related to the different synthesis conditions. The *VSH-n* phases are synthesized with high concentrations of alkali metal cations that were replaced by organic cations in the synthesis of *USH-8*. A similar correlation between structure and synthesis conditions has also been observed in zeolite synthesis.⁴ The uranate chains of *USH-8* are commonly found in uranium-rich minerals such as uranophane Ca(UO₂)(SiO₃OH)(H₂O)₅²⁴ but are rare in compounds with high Si/U ratios that usually contain isolated uranium centered polyhedra.²⁵ The condensation of the uranate bipyramids, which is facilitated by F[−] ions in *USH-8*, favors the high proportion of 4-connected silicate tetrahedra and, therefore, lowers the framework charge density to accommodate the organic templates.

In summary, we have synthesized a new open-framework uranosilicate *USH-8*. The framework is characterized by silicate double layers with high density of 5-ring channels and single chains of fluorouranate pentagonal bipyramids. The successful use of organic templates suggests further opportunities for synthesizing microporous uranium silicates in a systematic way.
