A scale of solute hydrogen-bond acidity has been constructed using equilibrium constants (as log *K* values) for complexation of series of acids (i) against a given base in dilute solution in tetrachloromethane, equation (A). Forty-five such equations have been solved to yield  $L_B$  and  $D_B$

$$\log K^i = L_B \log K_A^H + D_B \quad (\text{A})$$

values characterising the base, and log  $K_A^H$  values that characterise the acid. In this analysis, use has been made of the novel observation that all the lines in equation (A) intersect at a given point where  $\log K = \log K_A^H = -1.1$  with *K* on the molar scale. Some 190 log  $K_A^H$  values that constitute a reasonably general scale of solute hydrogen-bond acidity have been obtained. It is shown that there is no general connection between log  $K_A^H$  and any proton-transfer quantities, although certain family dependences are obtained. A number of acid-base combinations are excluded from equation (A), and alternative log  $K_A^{HE}$  values have been determined for such cases. The general log  $K_A^H$  values may be transformed into  $\alpha_2^H$  values suitable for use in multiple linear-regression analysis through the equation  $\alpha_2^H = (\log K_A^H + 1.1)/4.636$ .

There is voluminous literature on hydrogen-bonding. Earlier reviews on hydrogen-bond complexation in solution listed 615 references (in 1968),<sup>1</sup> and 2 703 references (in 1974),<sup>2</sup> whilst Green<sup>3</sup> gave no fewer than 409 references to hydrogen-bonding by C-H groups, again in 1974. Since, then, much additional work on complexation constants and on enthalpies of complexation has been reported, notably by Abboud *et al.*,<sup>4,5</sup> Hadzi *et al.*,<sup>6,7</sup> Huyskens *et al.*,<sup>8,9</sup> Jarva,<sup>10</sup> Kivinen and Kuopio,<sup>11,12</sup> Luck *et al.*,<sup>13</sup> Taniewska-Osinska *et al.*,<sup>14</sup> Roussel *et al.*,<sup>15-19</sup> Ruostesuo *et al.*,<sup>20-26</sup> Spencer *et al.*,<sup>27,28</sup> Virtanen *et al.*,<sup>29</sup> Buchet and Sandorfy,<sup>30</sup> and Zeegers-Huyskens *et al.*,<sup>31-35</sup> as well as our own previous work,<sup>36-38</sup> Drago *et al.*,<sup>39</sup> and also Purcell *et al.*<sup>40</sup> have analysed enthalpies of complexation, but there are important reasons why analyses of complexation constants, as log  $K^\circ$  values or the equivalent  $\Delta G^\circ$  values, are more useful. First of all, it has been shown that numerous processes can be rationalised in terms of solute hydrogen-bond acidity and basicity.<sup>41,42</sup> Examples are octanol-water partition coefficients,<sup>43</sup> solubilities of non-electrolytes in water<sup>44</sup> and in blood,<sup>45</sup> the adsorption of solutes from water onto carbon,<sup>46</sup> h.p.l.c. retention indexes,<sup>47</sup> the toxicity of aqueous solutes to *Photobacterium phosphoreum*,<sup>48</sup> and the solubility of gases and vapours in polymers.<sup>49</sup> All these examples are equilibrium or free-energy-related processes, and hence it is the Gibbs energy of hydrogen-bond formation (or log  $K^\circ$ ) and not the enthalpy of hydrogen-bond formation that is the relevant thermodynamic parameter to use. Secondly, we have already shown<sup>38</sup> that in cases where enthalpies of complexation are perturbed through involvement of the solvent, the corresponding  $\Delta G^\circ$  or log  $K^\circ$  values are quite normal.

In the event, there have been very few discussions on general hydrogen-bond acidity and basicity in terms of  $\Delta G^\circ$  or log  $K^\circ$ ,<sup>50-53</sup> and only one realistic attempt to account for such properties over a wide range of solutes. Zeegers-Huyskens<sup>53</sup> was able to relate  $\Delta G^\circ$  values for hydrogen-bond complexation in solution to gas-phase proton-transfer acidities and basicities,

but only by considering various classes of bases separately, *cf.* also her work on enthalpies of complexation.<sup>54</sup> The only scales of solute hydrogen-bond acidity that have been used generally are those of Karger, Snyder, and Eon,<sup>55,56</sup> and of Kamlet and co-workers.<sup>41-49</sup> The former is based on enthalpy measurements and, for reasons already set out, is not directly relevant to the present work. The latter, denoted as  $\alpha_m$ , will be discussed when we set out our own scale, see later. Indeed, the main purpose of the present work is to establish a scale of solute hydrogen-bond acidity, based on log *K* values for hydrogen-bond complexation.

*Data Analysis.*—The data we use refer to log *K* values for the 1:1 hydrogen-bond complexation reaction, equation (1), in

which a series of hydrogen-bond acids complex with a given reference base in an inert solvent. Both the acid and the base must be present at low concentration in order for both to be in solution as monomeric, unassociated solutes, otherwise some suitable correction for association must be applied.<sup>35</sup> Although several rather inert solvents have been used in studies of complexation, by far the largest number of investigations have used tetrachloromethane as the solvent. In order to simplify the analysis, we restrict the present work to this particular solvent (with one or two exceptions, as explained); we hope to extend our studies to other solvents later. We used both review,<sup>1-3</sup> and more recent papers<sup>4-38,40</sup> as sources of data, but invariably checked the original papers cited in reviews. The data is assembled as a series of log *K* values for acids against a given reference base in CCl<sub>4</sub> at a constant temperature with equilibrium constants expressed on the usual molar concentration scale. We refer to such a series of log *K* values as a 'set'. There were 45 such sets collected—i.e. series of log *K* values against 45 reference bases. In order for a general scale of

**Table 1.** Known combinations of acid and base excluded from the general scheme.<sup>a</sup>

<sup>a</sup> That is combinations of any of the acids listed with any of the bases listed. Results from ref. 57 and this work.

**Figure 1.** Plots of log *K* for series of acids against given reference bases *vs.* plots against any other reference base.

**Figure 2.** Plot of the standard deviation of 589 observed and calculated log *K* values against the chosen magic point.

hydrogen-bond acidity to be set up, it is necessary for a plot of log *K* (against reference base *x*) *vs.* log *K* (against reference base *y*) to yield a single straight line. That is, the various log *K* plots must show family-independent behaviour. Should such plots yield a number of lines for different families of acid (family-dependent behaviour) no completely general acidity scale can be constructed.

We have investigated family-independent or -dependent behaviour in hydrogen bonding in some detail,<sup>57</sup> using the methodology of Maria and Gal *et al.*<sup>58</sup> These workers defined an angle  $\theta$ , experimentally obtainable, characteristic of the electrostatic:covalent ratio in complexes between a given acid and a series of bases. Family-independent behaviour will only be exhibited between log *K* values for acids with the same, or nearly the same  $\theta$  value. It turns out that, for a large number of acids, including alcohols, phenols, and strong nitrogen acids, the variation in the characteristic  $\theta$  value is in the range 64–73 degrees. Hence for these acids, a 'reasonably general' acidity scale can be constructed. However, for a number of rather weak acids the characteristic  $\theta$  value rises to around  $82 \pm 5$  and such acids will then show family-dependent behaviour in conjunction with certain classes of base. We therefore have to exclude a number of acid–base combinations, so that our scale is not completely general, but is 'reasonably general.' In Table 1 are given the acids and bases that in combination must be excluded: the list of acids contains those that we have previously identified,<sup>57</sup> together with a few that we have identified during preliminary calculations. It must be stressed that the acids in Table 1 are excluded only when in combination with the bases in Table 1, but are included in our general scheme in combination with any other base.

Having excluded the combinations shown in Table 1, we selected the first 28 sets given in Table 2 for analysis. These particular sets were chosen because they contained a large number of data points or because the data points spanned a large range of log *K* values. Having plotted log *K* for one set *vs.* log *K* for another set, it became clear that a series of lines could be generated that all intersected at some given 'magic point,' as shown in Figure 1. We then forced the first 28 sets through various intersection points, and determined the standard deviation (s.d.) of the 589 observed and calculated log *K* values. Results are shown in Figure 2 as a plot of s.d. *vs.* the magic point chosen. It is quite clear that the best point of intersection is *ca.* –1.1 on the log *K* scale: for the total of 589 data points the standard deviation, when restricted in this way is 0.093 log units, as compared with an s.d. of 0.085 for the completely unrestricted plots. Furthermore, Figure 2 shows unambiguously that the first 28 sets in Table 2 do not define a series of parallel lines, since the standard deviation rises considerably as the lines are forced to be parallel. We shall discuss the significance of the magic point later, but refer now to work in progress on the construction of a hydrogen-bond basicity scale,<sup>59</sup> where we have found that sets of bases against reference acids in CCl<sub>4</sub> also intersect at exactly the same point, –1.1 on the log *K* scale.

We felt, beyond any doubt, that a magic point certainly exists for hydrogen-bond acid–base complexation in CCl<sub>4</sub>, and we then analysed the entire 45 sets in Table 2 as follows. A system of 45 linear equations (2) was constructed: log *K*<sup>*i*</sup> refers to log *K* values for a series of acids against a given reference base. The

$$\log K^i (\text{series of acids against base } 1) = L_1 \log K_A^H + D_1 \quad (2)$$

$$\log K^i (\text{series of acids against base } B) = L_B \log K_A^H + D_B$$

constants  $L_1$  to  $L_B$  and  $D_1$  to  $D_B$  characterise the reference bases (1 to *B*, where *B* = 45). The log  $K_A^H$  values then serve to characterise the hydrogen-bond acids, and hence represent the hydrogen-bond acidity of the acids over all the equations (1 to

**Table 2.** Bases in tetrachloromethane used in the correlations through equations (2).<sup>a</sup>

<sup>a</sup> The constants in equation (2) are  $L_B$  and  $D_B$ . S.d. and  $r$  are the standard deviation and correlation constant, and  $n$  is the number of data points. <sup>b</sup> All values at 298 K except for set 20 (302), 29 (300), 31 (300), 32 (295), 37 (302), and 40 (293).

$B$ , where  $B = 45$ ). These  $\log K_A^H$  values thus constitute a scale of solute hydrogen-bond acidity.\* A computer program was devised to carry out the computations. It is necessary to input not only all the  $\log K^i$  values, but also arbitrary  $\log K_A^H$  values for any two acids in order to define the  $\log K_A^H$  scale. However, the goodness-of-fit, and the relative  $\log K_A^H$  values are quite independent of the two input  $\log K_A^H$  values. The system of 45 equations contained 738 data points, as  $\log K^i$  values, and reproduced these data points with a standard deviation of 0.089 log units. The system of equations is given in Table 2 in terms of  $L_B$  and  $D_B$ , and the resulting  $\log K_A^H$  for the 89 acids included in the system are given in Table 3. Only acids that occurred in two or more equations were allowed in this primary list. As mentioned above, the combinations in Table 1 were excluded,

and a few other acids were also left out. For example, we chose not to include carboxylic acids, which have less certain  $\log K_A^H$  values, in order not to weight some of the equations unduly. Given the  $L_B$  and  $D_B$  values in Table 2, it is then possible to calculate by hand numerous secondary  $\log K_A^H$  values for acids excluded from the primary set: these secondary values are in Table 4, giving a total of 186  $\log K_A^H$  values in Tables 3 and 4. Some of these secondary values were obtained from results by Buchet and Sandorfy<sup>30</sup> who used *N*-ethylacetamide in  $\text{CCl}_4$  as the reference base, although this set was too restricted to be included in the system, equation (2). Similarly, values for a number of alkynes were calculated from results of Paugam and Lauransan,<sup>60</sup> not included in the general system.

A very interesting set of heterocyclic compounds has been studied by Roussel *et al.*,<sup>15-19</sup> who used the reference bases dimethyl sulphoxide (DMSO) and hexamethylphosphoric triamide (HMPT) in tetrachloromethane. From the recorded log  $K$  values and the constants in Table 2, it is possible to

\* These  $K_A^H$  values are formally equivalent to equilibrium constants for the series of acids against a particular base with  $L_B = 1$  and  $D_B = 0$ .

calculate  $\log K_A^H$  values in the usual way. Unfortunately, for the hydrogen-bond acids studied against each of the reference bases, there are systematic differences in the calculated  $\log K_A^H$  values. The latter are given separately in Table 5, but clearly further work is needed on these systems.

Although our analysis is based on  $\log K$  values in  $\text{CCl}_4$ , we have used otherwise unavailable results obtained by us against *N*-methylpyrrolidone (NMP) with 1,1,1-trichloroethane (TCE) as the solvent.<sup>36,37</sup> For acids, excluding those in Table 1, we find a reasonable correlation:

<sup>a</sup> These values generate the  $L_B$  and  $D_B$  values for the sets given in Table 2. <sup>b</sup> From a number of standard sources, chiefly E. P. Serjeant and B. Dempsey, 'Ionisation Constants of Organic Acids in Aqueous Solution,' Pergamon, Oxford, 1979; for alkanols: J. Murto in 'The Chemistry of the Hydroxyl Group,' ed. S. Patai, Interscience, New York, 1971, Part 2, p. 1087; for phenols, especially: A. I. Biggs and R. A. Robinson, *J. Chem. Soc.*, 1961, 388; and in general, from what appear to the authors to be the best-attested sources. <sup>c</sup> A. J. Kresge, *Acc. Chem. Res.*, 1975, **8**, 354. <sup>d</sup>  $pK_a$  of dinitromethane; A. T. Nielsen in 'The Chemistry of the Nitro and Nitroso Groups,' ed. H. Feuer, Interscience, New York, 1969. <sup>e</sup> Extrapolated from 4-nitrophenyl(phenyl)amine,  $pK_a$  15.90; bis(4-nitrophenyl)amine,  $pK_a$  14.08 (R. Stewart and J. P. O'Donnell, *Can. J. Chem.*, 1964, **42**, 1681).

$$\log K \text{ (against NMP in TCE)} = 0.883 \log K_A^H + 0.636 \quad (3)$$

$$r = 0.983 \quad \text{s.d.} = 0.129 \quad n = 24$$

where  $r$  is the correlation constant and  $n$  is the number of data points. From the above correlation, we were able to deduce  $\log K_A^H$  values for a number of carboxylic acids as shown in Table 6. For the overlapping acid, trichloroacetic acid, there is excellent agreement between the NMP/TCE value, and values obtained from results of Hadzi and Rajnvajn<sup>6</sup> using the equations in Table 2. We can therefore, include  $\log K_A^H$  values for ten carboxylic acids in Table 4.

Combinations of acid and base shown in Table 1 were excluded when the equations given in Table 2 were set up. Specifically,  $\log K$  values for the acids listed were not used in set 1 (pyridine), set 2 (triethylamine), set 16 (dioxane), set 17 (THF), and set 18 (ether). Of course, there are other sets that actually contained no  $\log K$  values for these acids, such as set 29 (aniline), where we suspect the acids in Table 1 will also be anomalous, but further information is needed in these cases. We can bring acids with high  $\theta$  values into our general system, provided that we define amended  $\log K_A^H$  values to be used in sets 1, 2, 16, 17, and 18. We have therefore calculated a  $\Delta$ -value for those acids, defined by equation (4):

$$\Delta = \log K_A^H, \text{ calculated from equations in Table 2}$$

$$(\text{sets 1, 2, 16, 17, and 18}) -$$

$$\log K_A^H, \text{ given in Tables 3 and 4} \quad (4)$$

The  $\Delta$  value thus provides an estimate of the deviation from general behaviour of the acid-base combinations given in Table 1. There is not a great deal of information, but, as expected, all the  $\Delta$  values are negative. Within the rather considerable error

limits of  $\Delta$ , we can only say that on average  $\Delta$  is  $-0.318$  log units for the acids listed, other than for the alkylthiols. We can now bring these acids into the general scheme by defining a hydrogen-bond acidity parameter,  $\log K_A^{HE}$ , for use with acids where there is a higher electrostatic:covalent ratio in complexes than usual:

$$\log K_A^{HE} = \log K_A^H + \Delta \quad (5)$$

These  $\log K_A^{HE}$  values are also in Table 7. It must be stressed that only for complexation of these acids with certain bases (1, 2, 16, 17, and 18, as known to date) is it necessary to use the  $\log K_A^{HE}$  values. For complexation with ketones, esters, amides, etc., the normal  $\log K_A^H$  values in Tables 3 and 4 can be used.

Finally, it must be noted that we give  $\log K_A^H$  values in Table 3 to four decimal places, only to avoid rounding-off errors in the generation of equations listed in Table 2. Our estimate of inter-laboratory errors in the determination of  $\log K$  values in equation (1) is ca. 0.05 units, so that the average error in the  $\log K_A^H$  values obtained must be at least this value. Indeed, the standard deviations given in Table 3, and our overall standard deviations of 0.085 or 0.093 log units (above) confirm our estimate. The corresponding error in the derived  $\alpha_2^H$  values (see later) will be ca. 0.02 units, and here again we give some values to three decimal places merely to distinguish primary values from less reliable secondary values.

## Discussion

One of the key features of the present work is the discovery that when  $\log K$  for one set in Table 1 is plotted vs.  $\log K$  for any other set, there results a series of lines, Figure 1, that intersect near a given point. Whether or not there is an exact point of

intersection is crucial to the construction of a scale of hydrogen-bond basicity on the same lines as the construction of the present scale of acidity. A simple geometrical figure shows that a general scale of hydrogen-bond basicity can be generated if, and

only if, (a) all the lines in Figure 1 are parallel or (b) all the lines in Figure 1 intersect at a given point. Should the lines in Figure 1 be randomly orientated, then no general scale of hydrogen-bond basicity is possible. It is quite clear, both by inspection,

and by consideration of the standard deviation shown in Figure 2, that the lines in Figure 1 are certainly not parallel, whilst both Figures 1 and 2 indicate that the set of lines does intersect at or near a given point. Indeed, if all the lines are forced through this magic point, then the s.d. of all the 589 points in sets 1–28 rises from 0.085 to only 0.093 log units. We know also that an exactly similar plot to that shown in Figure 1 arises in the construction of a hydrogen-bond basicity scale, and that the magic point, -1.1 log units, is exactly the same as found in this work.<sup>59</sup>

At first sight, such a magic point as in Figure 1 appears rather odd since it implies a situation in which acids with a log  $K$  value of -1.1 against one base have the same log  $K$  value against any other base that gives rise to such intersecting lines. It must be remembered, however, that although the log  $K_A^H$  constants refer specifically to hydrogen bonding, a quite variable electrostatic:covalent ratio in the complexes is allowed. As the log  $K$  (or log  $K_A^H$ ) value becomes more and more negative, so the extent of electrostatic bonding of the dipole-dipole type (or even dispersion interaction) becomes dominant. Hence at around log  $K = -1.1$ , with  $K$  on the molar scale, the complex can no longer be regarded as a hydrogen-bond complex at all. A number of very small equilibrium constants have been recorded in the literature, often by application of a

*g.l.c.* method. Thus against dioctyl ether,<sup>61</sup> log  $K$  values are -0.55 ( $CH_2Cl_2$ ), -0.98 ( $CH_3CCl_3$ ), -0.92 ( $CBr_4$ ), and -1.18 ( $CCl_4$ ). Clearly, the last two values must correspond to molecular complexes, probably of the dipole-dipole type, but also the complexes with  $CH_3CCl_3$  or  $CH_2Cl_2$  must include a large element of dipole-dipole interaction, rather than simple hydrogen-bonding. Hence if the extent of hydrogen-bonding is very small in complexes as log  $K \rightarrow -1.1$ , it is not surprising that all hydrogen-bond acids appear equally strong (or equally weak) towards a given base.

The identification of the magic point leads to an important practical consideration, in that it is now comparatively easy to define the constants  $L_B$  and  $D_B$  in equation (2) for a set of acids against a new base. Instead of a rather large number of acids covering a wide range of log  $K$  values being required, the line can now be identified easily using the magic point of intersection plus log  $K$  values for but a few acids against the given base. Thus we are able to include in our general system, sets such as 31–43, where there are only a restricted number of log  $K$  values. Another practically useful consideration is in the setting up of a hydrogen-bond acidity scale with a lower limit of zero, since all that is needed is an adjustment of 1.1 units to log  $K_A^H$ , as explained below.

<sup>a</sup> All calculated from  $\log K$  values against DMSO in tetrachloromethane, except where indicated. <sup>b</sup> From  $\log K$  values against HMPT in tetrachloromethane.

In Part 2 of this series,<sup>37</sup> we compared  $\log K$  values for hydrogen bonding against NMP in TCE with various parameters characteristic of proton transfer, *viz.*  $pK_a$  values in water, ionisation constants in DMSO, and gas-phase proton transfer  $\Delta G^\circ$  (or  $\Delta H^\circ$ ) values. We found no general connection between the  $\log K$  values and any measure of proton transfer. There is little point in repeating the various plots shown in Part 2, but we can now state that the more extensive results in the present work confirm entirely our previous conclusion on the lack of a general connection between hydrogen-bonding (as  $\log K_A^H$ ) and proton transfer. However, there are a number of family-dependent correlations that might be valuable in the conversion of  $pK_a$  into  $\log K_A^H$ , or *vice versa*. We give some of the more extensive correlations of  $\log K_A^H$  against  $pK_a$ , or  $\sigma$  values.

$$\log K_A^H(\text{carboxylic acids})^* = 3.69 - 0.47 pK_a \quad (6)$$

$$r = -0.976 \quad \text{s.d.} = 0.22 \quad n = 9$$

\* Omitting 2-bromobenzoic acid, where internal hydrogen-bonding leads to a lower  $\log K$  value than calculated.

† Omitting t-butyl alcohol.

‡ Note that the  $\log K$  value for water refers only to 1:1 water base complexes.

$$\log K_A^H(m\text{-phenols}) = 8.13 - 0.66 pK_a \quad (7)$$

$$r = -0.980 \quad \text{s.d.} = 0.09 \quad n = 11$$

$$\log K_A^H(m\text{-phenols}) = 1.63 + 1.35 \sigma_I + 0.63 \sigma_R \quad (8)$$

$$r = 0.995 \quad \text{s.d.} = 0.05 \quad n = 11$$

$$\log K_A^H(p\text{-phenols}) = 5.56 - 0.39 pK_a \quad (9)$$

$$r = -0.965 \quad \text{s.d.} = 0.11 \quad n = 14$$

$$\log K_A^H(p\text{-phenols}) = 1.64 + 1.38 \sigma_I + 1.01 \sigma_R \quad (10)$$

$$r = 0.992 \quad \text{s.d.} = 0.06 \quad n = 14$$

$$\log K_A^H(\text{alkanols})^\dagger = 4.42 - 0.25 pK_a \quad (11)$$

$$r = -0.973 \quad \text{s.d.} = 0.20 \quad n = 13$$

It is of interest to note that the overall spread of  $\log K_A^H$  values, from  $-1.1$  up to  $3.3$  for 4-nitro-3-trifluoromethylphenol, is very much less than that of  $pK_a$  values (*ca.* 58 log units from 48 for methane to  $-10$  log units for perchloric acid). Since the proton is only partially transferred during hydrogen-bond formation, it is not surprising that the spread of  $\log K_A^H$  values is much less than the spread of  $pK_a$  values. However, another factor that will tend to introduce an upper limit to  $\log K_A^H$  is the propensity of strong hydrogen-bond acids to act also as proton-transfer agents, so that it becomes almost impossible to measure hydrogen-bond complexation constants, for these acids.

Equations (6)–(11) set out a number of general relationships. We now discuss a few important individual solutes. Water is not a particularly strong hydrogen-bond acid in its monomeric state: the  $\log K_A^H$  value of  $0.536$  is only of the same order as that for methanol ( $0.603$ ) or ethanol ( $0.442$ ), and less than many NH acids.<sup>‡</sup> Bulk water, of course, is a powerful hydrogen-bond acid (*i.e.* by comparison with dilute aqueous solutions of other acids) but how much of the bulk water/monomer water difference is due to a mass-law effect and how much to any intrinsic effect is not known. Chloroform is another well known hydrogen-bond acid in the bulk form that is only a very weak acid as a monomeric solute ( $\log K_A^H = -0.185$ ). Indeed, carbon acids generally are very much weaker hydrogen-bond acids than their  $pK_a$  values would suggest. The nitrogen acids cover a wide range of hydrogen-bond acidity. Although we have no values for simple aliphatic primary or secondary amines, their  $\log K_A^H$  values must be quite negative. It has very recently been suggested, on various grounds, that ammonia possesses virtually no proton-donating properties.<sup>62</sup> We think it reasonable to regard hydrogen bonding in liquid amines as lying on the border with non-specific dipolar stabilisation. As proton donors, simple amines join alkyl thiols at the limit of detectability. However, electron-withdrawing substituents can transform NH acids into strong hydrogen-bond acids: thus tetrachloropyrrole is stronger than acetic acid or most phenols. On the other hand, SH acids seem to be considerably weaker than expected. Even thiophenol ( $pK_a = 6.5$ ) is a very poor hydrogen-bond acid, whilst the calculated  $\log K_A^H$  values for simple thiols ( $-1.18$ ) suggest that these solutes have almost no true hydrogen-bond acidity.

The coefficients of  $pK_a$  in equations (6), (7), (9), and (11) may be regarded as pseudo-Bronsted coefficients; pseudo, in that hydrogen-bonding in tetrachloromethane is being compared with full proton transfer in water. Hence, while they cannot quantify the extent of proton transfer on hydrogen-bond formation, they can be used accurately to compare its relative extent between classes. In addition to values for carboxylic acids ( $0.47$ ), *m*-phenols ( $0.66$ ), *p*-phenols ( $0.39$ ), and alkanols ( $0.25$ ), we also have approximate values for unactivated nitrogen acids

**Table 6.** Determination of  $\log K_A^H$  values for carboxylic acids.

(0.11), and for carbon acids (0.054).<sup>\*</sup> These pseudo-Brønsted coefficients turn out to be remarkably variable, ranging from 0.66 for *m*-phenols to less than a tenth of this value for carbon acids. Qualitatively, their magnitude appears to reflect the extent to which the developing anionic charge is immediately able to delocalise; carboxylic acids and carbon acids represent the extremes in this respect. In between lie the alkanols, the oxygen atoms of which are well able to support an isolated negative charge, and the nitrogen acids, the nitrogen atoms of which are much less capable of this. The high pseudo-Brønsted coefficients for phenols is particularly interesting. Some light is thrown on this by the dual-substituent parameter analysis given in equations (8) and (10), where  $\sigma_I$  and  $\sigma_R$  are the Hammett inductive and resonance substituent constants, respectively. The relative importance of the resonance component is very surprising, 32% for *m*-phenols and 42% for *p*-phenols, indicating a degree of resonance involvement not far short of that for full proton transfer. At the other extreme, the very low pseudo-Brønsted coefficient for carbon acids represents a minimal degree of proton transfer in which no resonance component is conceivable.

We have used the equations mentioned above, together with results in Tables 3 and 4 to identify a hitherto unsuspected

stereoelectronic effect. Succinimide is a considerably poorer proton donor than expected; this is plausibly due to lone-pair repulsion between the incoming proton acceptor and the carbonyl groups on succinimide itself. We have previously noted that carboxylic acids are no stronger as proton donors than simple phenols, and have attributed this to resonance stabilisation in the carboxylate anion, which will disproportionately favour full proton transfer over hydrogen-bonding.<sup>37</sup> The present results suggest an additional cause: carboxylic acids are weaker than expected as proton donors through the identical repulsive effect that operates in succinimide. Another class of anomalously weak proton donor<sup>37</sup> for which a similar explanation can be adduced is the sulphonamides. The resonance theory as the sole explanation of the relative carboxylic acid/phenol hydrogen-bond strengths is further weakened by the similar pseudo-Brønsted coefficients for these solutes, and by the large resonance component in the phenol hydrogen bonding as revealed by our analysis of equations (8) and (10). Whilst resonance must play some part, we now attribute to stereoelectronic repulsion much or most of the anomalous weakness as hydrogen-bond donors of carboxylic acids, sulphonamides, cyclic amides and possibly other classes of a similar sort yet to be examined. This conclusion may have considerable consequences, e.g. in discussion of the binding of such compounds to biological receptor sites.

Classical steric effects play only a small role in influencing hydrogen-bond acidity. Thus all primary alcohols, even neopentyl alcohol, have almost the same  $\log K_A^H$  value. Introduction of a 2-isopropyl or 2-*t*-butyl group into phenol lowers  $\log K_A^H$ , but not by very much.<sup>†</sup> However 2,6-dimethylphenol or 2-methyl-6-*t*-butylphenol are weaker than phenol by *ca.* one log unit, and 2,6-di-isopropylphenol and 2,6-di-*t*-butylphenol are so weak that we had to exclude them from our general analysis.

We can conclude by stating that we have been able to set up a reasonably general scale of solute hydrogen-bond acidity, and that such a scale has little overall connection with solute proton-transfer ability. Within certain families it is possible to estimate  $\log K_A^H$  values from, e.g.,  $pK_a$  values, see equations (6)–(11), but outside these families proton-transfer quantities are not reliable indicators of hydrogen-bond acidity. Finally, we note that the  $\log K_A^H$  scale is based on  $\log K$  values in tetrachloromethane. In a later publication we hope to extend the scale to cover other inert solvents.

*Construction of an  $\alpha_2^H$  Scale.*—It is now well-established<sup>41,42</sup> that a large number of physicochemical and biochemical processes involving a series of solutes can be interpreted using a multiple linear-regression equation that contains terms reflecting solute hydrogen-bonding. Two general equations have been put forward, equations (12) and (13). The former

<sup>\*</sup> We do not give the full equation for these two classes because they are based on only four and three points, respectively. However, the  $pK_a$  coefficients, we feel, are worthy of discussion.

<sup>†</sup> Note that the very low  $\log K$  value for 2-methoxyphenol (0.109) is probably due to internal hydrogen-bonding in the phenol.

seems adequate for the description of processes in condensed phases,<sup>41-48</sup> whilst the latter is the more satisfactory in dealing with processes of the gas  $\rightarrow$  liquid or gas  $\rightarrow$  solid type.<sup>49</sup>

$$SP = SP_0 + s\pi_2^* + a\alpha_2 + b\beta_2 + mV_2 \quad (12)$$

$$SP = SP_0 + s\pi_2^* + a\alpha_2 + b\beta_2 + l \log L^{16} \quad (13)$$

In equations (12) and (13),  $SP$  is some solubility or solubility-related property,  $SP_0$  is a constant,  $\pi_2^*$  is the solute dipolarity,  $\alpha_2$  the solute hydrogen-bond acidity,  $\beta_2$  the solute hydrogen-bond basicity,  $V_2$  a solute volume parameter, and  $\log L^{16}$  the solute Ostwald absorption coefficient on hexadecane.

The parameters  $\pi_2^*$ ,  $\alpha_2$ , and  $\beta_2$  are most conveniently defined such that as the particular solute property becomes very small, the parameter approaches zero. We can quite simply arrange this for hydrogen-bond acidity by adjusting the  $\log K_A^H$  scale by exactly the magic point value of  $-1.1$  units. Since the  $\alpha_2$  scale is merely a scale of relative solute hydrogen-bond acidity, the range of scale is unimportant. In order to have a convenient range, and in order that the range should be compatible with that for the  $\beta_2$  scale, we have used the same factor of 4.636 to

$$\alpha_2^H = (\log K_A^H + 1.1)/4.636 \quad (14)$$

obtain an  $\alpha_2$  scale that we denote as  $\alpha_2^H$ . Since  $\log K_A^H$  is so easily transformed into  $\alpha_2^H$ , there is little point in giving separate  $\alpha_2^H$  values for all 186 solutes in Tables 3 and 4. However, we can make a number of simplifications in constructing an  $\alpha_2^H$  scale; for example, within experimental error  $\log K_A^H$  for all simple primary alcohols is the same, and hence but one  $\alpha_2^H$  value will suffice for these solutes. In Table 8 are listed  $\alpha_2^H$  values for a few selected solutes including cases where some simplification is possible. From Tables 3 and 4 it is possible to obtain  $\alpha_2^H$  values for some 186 solutes, and further  $\alpha_2^H$  values can be deduced *via* the correlations given in equations (6)–(11). Also in Table 8 are  $\alpha_2^{HE}$  values derived from the  $\log K_A^{HE}$  values in Table 7.\* Because the particular acids concerned are all rather weak, there are not very large differences between  $\alpha_2^H$  and  $\alpha_2^{HE}$  and it is possible that in multiple correlations these differences would hardly be significant.

In addition to all the above results, there are available values of  $\log K$  for the complexation of a large number of carbon acids with various bases in tetrachloromethane, obtained by Lorand *et al.*<sup>64</sup> using an n.m.r. method. We have not been able to include these results in Tables 3 and 4 because they have been obtained at 308 K rather than at 298 K. However, it is possible to correct the  $\log K$  values to 298 K using  $\Delta H^\circ$  values that we have estimated by comparison with other literature values.<sup>1-3</sup> In Table 9 we give details of these corrections as well as our calculated  $\log K_A^H$  and  $\alpha_2^H$  values for these carbon acids. For a number of acids, there is quite good agreement between values of  $\alpha_2^H$  in Table 9 and those we have obtained before (*e.g.*  $\text{CHCl}_3$ ,  $\text{CHBr}_3$ , and  $\text{ClHC}=\text{CCl}_2$ ), but for the solute  $\text{PhC}\equiv\text{CH}$ , the value of 0.04 for  $\alpha_2^H$  in Table 9 seems much too low, and that of 0.12 (Tables 4 and 8) is preferred.

\* Ruostesuo *et al.*<sup>63</sup> have recently determined  $\log K$  values for the complexation of some phenols and alcohols, carbazole, indole, and pyrrole with a number of bases in tetrachloromethane. For the bases  $\text{Ph}_3\text{PO}$ ,  $(\text{MeO})_3\text{PO}$ , and  $(\text{PhO})_3\text{PO}$  there result excellent plots of  $\log K$  vs.  $\log K_A^H$ . However for the bases  $\text{Ph}_3\text{PS}$  and  $\text{Ph}_3\text{PSe}$ , the  $\log K$  values for carbazole, indole, and pyrrole are larger than expected. This may result from a lower electrostatic component in the complexes than usual, and suggests that another set of complexation constants (between the acids in Table 1 and bases  $\text{Ph}_3\text{PS}$ ,  $\text{Ph}_3\text{PSe}$ , *etc.*) are excluded from our general scheme.

Table 9. Calculation of  $\log K_A^H$  and  $\alpha_2^H$  values from results by Lorand *et al.*<sup>64</sup>

<sup>a</sup> Observed<sup>64</sup> values of log  $K$ . <sup>b</sup> Calculated values of log  $K$  using the  $\Delta H^\circ$  values in kcal mol<sup>-1</sup> given. <sup>c</sup> This value seems too low, and that calculated from log  $K_A^H = -0.56$  in Table 4,  $\alpha_2^H = 0.12$  is preferred.

We have found it quite impossible to correlate the log  $K_A^H$  or  $\alpha_2^H$  values for the total set of carbon acids in Tables 3, 4, and 9. We suspect also that the small, but finite,  $\alpha_2^H$  values calculated for the aromatic carbon acids in Table 9 possibly reflect dipole-dipole interactions rather than hydrogen-bond complexation. For two groups of carbon acids, however, we have been able to set up correlations of  $\alpha_2^H$  against  $\sigma_1$  that may be of use in the prediction of further  $\alpha_2^H$  values. The halogenated compounds shown in Table 10 lead to the correlation

$$\alpha_2^H = -0.114 + 0.922\sigma_1 \quad (15)$$

$$r = 0.910 \quad \text{s.d.} = 0.02 \quad n = 18$$

but it should be noted that the correlation collapses if compounds containing CN or NO<sub>2</sub> groups are included.

The substituted alkynes listed in Table 11 can be examined as a group, the resulting correlation with  $\sigma_1$  being

$$\alpha_2^H(\text{RC}\equiv\text{CH}) = 0.110 + 0.348\sigma_1 \quad (16)$$

$$r = 0.926 \quad \text{s.d.} = 0.03 \quad n = 9$$

A solute hydrogen-bond acidity scale,  $\alpha_m$ , has been constructed by Kamlet and co-workers,<sup>41-49</sup> based on log  $K$  values for complexation with pyridine *N*-oxide in cyclohexane,<sup>4</sup> and extended through various back-calculations involving equation (12). Although the origins of the  $\alpha_m$  and  $\alpha_2^H$  scales are different, there is a fair measure of agreement between them especially for solutes with moderate or low values, see Table 12. At the higher end of the scales,  $\alpha_m$  tends always to be larger than  $\alpha_2^H$ . We have carried out a number of regressions using equations (12) or (13)

CHCl <sub>2</sub> CO <sub>2</sub> Me	0.31	0.13 <sup>c</sup>
c-C <sub>3</sub> HCl <sub>5</sub>	0.26	0.12 <sup>c</sup>

<sup>a</sup> Values of  $\alpha_2^H$  from Tables 3 and 4 except where shown. <sup>b</sup> Excluded as an obvious outlier. By comparison with CHCl<sub>3</sub> and CHBr<sub>3</sub>,  $\alpha_2^H$  should be ca. 0.19, and from equation (15) a value of 0.20 is calculated. <sup>c</sup> From Table 9.

**Table 11.** Values of  $\alpha_2^H$  for some alkynes.<sup>a</sup>

R in RC≡CH	$\sigma_1$	$\alpha_2^H$
n-Pe	-0.01	0.13
Me <sub>3</sub> C	-0.01	0.13
Ph	0.12	0.12
ClCH <sub>2</sub>	0.20	0.19
BrCH <sub>2</sub>	0.20	0.19
ClMe <sub>2</sub>	0.18	0.15
PhCO	0.30	0.19
NC	0.57	0.34
EtOCO	0.30	0.19 <sup>b</sup>

<sup>a</sup> From Tables 3 and 4 except where shown. <sup>b</sup> Table 9.

**Table 12.** Some comparisons of the  $\alpha_m$  and  $\alpha_2^H$  scales.<sup>a</sup>

Solute	$\alpha_m$	$\alpha_2^H$
Benzoic acid	0.75	0.59
Acetic acid	0.71	0.55
Hexanoic acid	0.55	0.54
4-Nitrophenol	0.93	0.82
4-Fluorophenol	0.65	0.63
Phenol	0.61	0.60
Methanol	0.35	0.37
Ethanol	0.33	0.33
Propan-2-ol	0.31	0.32
t-Butyl alcohol	0.29	0.32
Aniline	0.16	0.26
Alkyl thiols	0.10	0.00
Alkylamines	0.00	0.00

<sup>a</sup> Values of  $\alpha_m$  from refs. 41–49 and M. J. Kamlet, unpublished work.

and have confirmed that essentially the same correlation equation is obtained using either  $\alpha_m$  or  $\alpha_2^H$ . It seems therefore that replacement of the  $\alpha_m$  scale with the more extensive  $\alpha_2^H$  scale could be undertaken quite simply.

### Acknowledgements

We are grateful to Dr. J.-L. M. Abboud, Dr. M. J. Kamlet, Dr. C. Laurence, Dr. K. F. Purcell, and Dr. R. W. Taft for

communication of unpublished work, and we thank the SERC for a CASE award (to D. V. P.).
