At the end of the 6-wk feeding period, the body weight (mean ± SE) of the MCT-fed group was 422.4 ± 4.7 g and that of the LCT-fed group was 439.5 ± 5.1 g. Body weight gain was significantly lower ($p < .025$) in the MCT-fed rats (152.4 ± 5.1 g), compared to those fed the LCT diet (169.5 ± 4.9 g).

Adiposity. Table 2 shows that all fat depots were significantly smaller in rats fed the MCT diet compared to rats fed the LCT diet. Total dissectible fat measured as the combined weights of all four depots was 25% less ($p < .001$) in the rats fed MCT (30.2 g ± 0.55) than in those fed LCT (37.2 g ± 0.65). Fat cell size values were significantly reduced in the MCT-fed rats, but fat cell number was not altered.

Thermogenesis. Resting oxygen consumption in MCT-fed rats was significantly higher than that of the LCT-fed group (9.5 ± 0.7 vs 7.2 ± 0.7; $p < .05$). Under maximal NE stimulation, oxygen consumption rose significantly above respective resting values in both MCT- (44%) and LCT (52%)-fed rats. However, despite maximal NE stimulation, the MCT-fed rats showed significantly higher oxygen consumption than the LCT-fed group (13.7 ± 0.5 vs 11.1 ± 0.4; $p < .05$), as shown in Table 3.

DISCUSSION

The present study confirms the thermogenic effect of overfeeding a MCT diet in rats, which we previously reported (10). It further demonstrates that the MCT-enhanced thermogenesis persists even after excision of IBAT. The thermogenic effect of MCT agrees with reports in the literature on the thermogenic effect of other dietary items such as carbohydrates (13,14), proteins (15) and fats (16). Dietary fats were reported recently to differ in their thermogenic response. A diet with unsaturated fatty acids contributing 10% of dietary energy exhibited higher thermogenic response compared to a diet containing equal amounts of saturated fatty acids (17). Excess polyunsaturated fatty acid feeding (corn oil) exhibited lower efficiency of weight gain as compared to beef tallow (18). The above-mentioned studies and our present data suggest that increase in thermogenesis can be effectuated

TABLE 2

Mean Fat Cell Size and Mean Weight (± SE) of Four Main Fat Depots Dissected from Rats with Interscapular Brown Adipose Tissue Excised and Overfed (50% Above Maintenance) for 6 Wk Diets Containing 50% of Calories Either as MCT or LCT

Diet	Fat cell size (μg/cell)	Epididymal (g)	Perirenal (g)	Omental (g)	Dorsal (g)
LCT	0.52 ± 0.010	8.33 ± 0.9	9.33 ± 0.45	4.78 ± 0.15	14.74 ± 1.1
MCT	0.30 ± 0.012	6.51 ± 0.6	7.82 ± 0.24	3.75 ± 0.14	12.1 ± 1.2

by including a thermogenic dietary component despite equicaloric feeding.

Diet-induced thermogenesis (DIT) reported so far in rats has been attributed to BAT activity or, more specifically, to IBAT activity. The argument that brown fat is activated in overfed animals stems from the observation that DIT has similar manifestations to nonshivering thermogenesis observed in cold-adapted rodents. The weight increases of IBAT after "cafeteria" feeding and after exposure to cold were among the criteria on which such a resemblance was based. The present study shows that enhanced thermogenesis and decreased body fat deposition occur in the absence of IBAT activity. This agrees with many reports in the literature questioning the role of IBAT in DIT (19,20). In comparison with "cafeteria feeding," the increments in oxygen consumption over the resting values were similar in both MCT- and LCT-fed rats. However, the absolute values of NE-stimulated oxygen consumption for MCT were significantly higher than those for LCT. Thus, the higher RMR values of MCT-fed rats compared to LCT-fed rats were maintained after NE stimulation, confirming the effect of the MCT diet on RMR values.

Thus, MCT overfeeding leads to a decrease in body weight gain and body fat compared to LCT overfeeding in rats with IBAT excised. The decrease seems to be due to increased oxygen consumption in MCT-fed rats. IBAT removal did not seem to influence the increased thermogenic response to MCT overfeeding.

NE stimulation of oxygen consumption above basal values did not differ among the MCT- and LCT-overfed rats. This result agrees with the reports by Rothwell and Stock and others (5,6,21) showing that cafeteria feeding in rats is accompanied by more increased responsiveness to NE stimulation than can be entirely accounted for by increased BAT activity. In this study, the IBAT, which constitutes over one-third of the total BAT of the rat (22), was absent, and hence increased responsiveness to NE was not observed. However, absolute values for NE stimulation of oxygen consumption in MCT-overfed rats remained higher than those for LCT-overfed rats, indicating an independent effect of MCT diet on RMR and demonstrating that higher NE-stimulated oxygen consumption values cannot be attributed always to BAT activity. The recent reports in the literature and the results of the present study suggest that, in comparing thermogenic effects of diets, two criteria should be taken into consideration: the caloric content of the diet and the biochemical nature of its components. Both seem to affect the thermogenic response of the animal. Feeding different dietary items while maintaining caloric content seems to affect oxygen consumption, the mechanism of which appears related to the distinct metabolic pathways followed by these dietary components. This thermogenic effect appears to be independent of IBAT activity. However, comparing overfeeding with ad libitum feeding may show an effect on increased responsiveness to NE stimulation, a phenomenon already proven to be accounted for by BAT activity (21). Whether this increased responsiveness to NE stimulation in cafeteria-fed rats is due to either the higher caloric content of the cafeteria diet or to the considerable differences between the components of the cafeteria and the laboratory chow diets needs further investigation.

The question remains: What mechanism is responsible for the increase in oxygen consumption in MCT-fed rats? Following digestion and absorption, MCT-derived free fatty acids bound to albumin are transported directly to the liver via the portal vein (23). In the liver, they are oxidized rapidly, resulting in enhanced ketogenesis as well as CO_2 and ATP production (24). The thermogenic consequences of fatty acid-derived ketogenesis have been demonstrated in isolated rat hepatocytes (25,26). In a recent study in man, the ingestion of MCT, in contrast to LCT-containing meals, was associated with hyperketonemia and increased oxygen consumption (27). The increased synthesis of ketones from acetyl CoA in the liver provides for an additional mechanism for rapid disposal of fatty acids that is not coupled directly to ATP formation, but rather to a "reversed electron transfer" system causing stimulation of hepatic oxygen consumption (26).

Dietary lipids, in particular unsaturated fat, promote the development of many experimental tumors. However, no mechanisms to fully explain these effects have been elucidated. Recent reports, which we summarize here, suggest a role for gap junction-mediated intercellular communication in the process of tumor promotion. We also review tumor-promoting effects of dietary fat on experimental, particularly mammary, carcinogenesis. Our main focus is to review recent data examining the inhibitory effects of unsaturated fatty acids on metabolic cooperation in Chinese hamster V79 cells. These data suggest that inhibition of junctional communication may be involved mechanistically in the promotion of tumors by high levels of dietary unsaturated fat. Finally, potential mechanisms by which unsaturated fatty acids inhibit metabolic cooperation are examined.
Lipids 22, 445-454 (1987).

It has been suggested that environmental factors and conditions may be causally related to many cancers in humans (1,2). In recent years the nutritional aspects of cancer causation have been one of the most intriguing and extensively examined environmental factor(s) in cancer research. Epidemiological evidence has indicated that the incidence of breast cancer among women is related to many nutritional components, in particular the intake of dietary fat. Strong positive correlations between total dietary fat consumption and breast cancer incidence and death rates have been reported (3-11). Other types of cancers also have been related to the intake of dietary fat (3,4,6,8,11).

Such epidemiological evidence has been substantiated by widespread reports that high levels of dietary fat stimulate tumor development in many experimental cancer systems (for reviews, see refs. 6,12,13). The tumor-promoting capacity of high fat diets has been examined extensively. However, any mechanisms to explain these effects remains controversial. Recently, it has been suggested that unsaturated fatty acids may directly influence tumor cell growth processes by inhibiting gap junction-mediated intercellular communication (14). In our report, tumor-promoting effects of dietary fat on experimental cancer are reviewed. In addition, the effects of fatty acids on metabolic cooperation are reviewed, and the possible role inhibition of gap junction-mediated intercellular communication in high fat diet-induced tumor promotion is addressed.

EXPERIMENTAL MAMMARY TUMOR PROMOTION BY DIETARY FAT

The tumor-promoting effects of dietary fat have been well documented using many experimental mammary tumor systems. In 1942, Tannenbaum first described a relationship between dietary fat and the development of spontaneous mammary tumors in mice (15). In the 1960s and 1970s, many laboratories confirmed and extended his initial observation using many different murine mammary tumor models. Elevated levels of dietary fat consistently and significantly stimulate the development of spontaneous, carcinogen-induced and transplantable mammary cancers (Table 1; for reviews, see refs. 6,12,13). In general, animals fed high levels of dietary fat (20% by weight) develop more tumors (increased tumor multiplicity) at a higher frequency (increased tumor incidence) and more rapidly (reduced latency period for tumor appearance) than animals fed a moderate (5%) or low (0.5%) fat diet. The tumorigenesis of virtually every mammary tumor model examined is enhanced by consumption of elevated dietary fat.

The promotion of cancer by high levels of dietary fat is not restricted to, nor specific for, mammary cancer. Development of other experimental cancers is also enhanced by high fat diets. High dietary fat enhances rat colon carcinogenesis induced by 7,12-dimethylbenz(*a*)anthracene (DMBA), dimethyl hydrazine (DMH) and other carcinogens (16–19). Diets with high levels of polyunsaturated fat stimulate rat pancreatic carcinogenesis induced by azaserine (20) as well as the growth of AK3T3 sarcoma cell line tumors in mice (21). Mouse tumors of the integument (22), lymphatic system (23), lung (23) and central nervous system (24) are also promoted by dietary fat.

Most reports suggest that dietary fat enhances mammary tumor development by acting at the promotional stage of the tumorigenic process. The level of fat intake after carcinogen administration ("initiation") is more important in enhancing mammary tumorigenesis than the level before (7,25). Dietary fat exhibits many characteristics of classic tumor promoters as defined by Berenblum (26), including dose-response relationships and reversibility (14,27–29). Also, when high fat dietary treatment is delayed up to 20 wk after carcinogen (DMBA) administration, increased mammary tumor development is still observed in rats fed a high fat diet (30). Treatment of rats with a high dietary fat regimen for equal (3-wk) time periods similarly promotes mammary tumor development, whether the dietary treatment is initiated 0, 2 or 4 wk after DMBA administration (14). Furthermore, Ip and Sinha (31), using explanted mammary glands treated with DMBA, demonstrated that the fat level in recipient rats' diet was more important in subsequent mammary tumor development than that in donor rats' diet. The growth enhancement of many transplantable murine mammary tumors (i.e., already transformed) by high levels of dietary fat also suggests that dietary fat acts at the growth promotional phase of tumorigenesis.

The type of dietary fat is important for the enhancement of mammary tumorigenesis by high fat diets. In general, diets high in polyunsaturated fat appear to promote experimental murine mammary tumor development more than diets high in saturated fat (32–35). Because linoleic acid was the major component of most polyunsaturated fats and oils in these studies, it has been suggested that the role of linoleate itself may be important. Spontaneous mammary tumorigenesis in C3H/St mice is enhanced by increasing the level of linoleic acid at the expense of other fatty acids in the diet (36). Also, linoleic and linolenic, but not oleic, acids appear to be important in the stimulation of DMBA-induced rat mammary tumorigenesis (37). However, Carroll reported that DMBA-induced rat mammary tumorigenesis was similar for rats fed 20% high fat diets containing primarily either oleic acid (olive oil) or linoleic acid (sunflowerseed oil) (7). Also, Dayton et al. (38) found no marked differences in the ability of diets containing high-oleic and high-linoleic safflower oil to promote DMBA-induced rat mammary tumorigenesis. The importance of unsaturation in the promotion of mammary tumorigenesis by dietary fat may be limited, since it appears that once a minimum requirement for unsaturated (essential) fatty acids is met, the total amount of fat, whether saturated or unsaturated, is what determines the influence of high fat levels (7). However, in vitro studies by Kidwell and colleagues have shown that unsaturated fatty acids enhance, whereas saturated fatty acids inhibit, the growth of normal and neoplastic rat mammary epithelium in cell culture (39–41). Also, addition of oleic, linoleic and arachidonic acids stimulates the growth of X563.5 mouse melanoma cells in vitro (42). Preliminary results from our laboratory also indicate that linoleic acid stimulates the growth of V79 Chinese hamster cells in vitro (unpublished data).

The orientation of the double bond as well as the chain length have recently been shown to have an influence on in vivo mammary tumor promotion by dietary fat. Diets with *trans*-unsaturated and with saturated fatty acids are similar in their mammary tumor-promoting capacities (43). Also, a report by Cohen et al. (44) suggests that the mammary tumor-promoting effect of high dietary fat is diminished by substitution of medium chain triglycerides for the more common long chain unsaturated triglycerides.

While the promotion of mammary tumorigenesis by high levels of dietary fat is well documented, any mechanism by which dietary fat promotes mammary tumorigenesis is unclear. Some investigators have suggested that indirect endocrine-related mechanisms (i.e., increased secretion of prolactin and/or estrogen) are involved (45–49). This concept has been reviewed and evaluated (12,13). Reports that consumption of a high fat diet alters circulating levels of prolactin and/or estrogen during certain stages of the estrous cycle have been inconsistent: both increased (47–51) and unchanged (52–55) levels have been reported. In many of these studies, hormone levels were assessed using single-point determinations during different stages of the estrous cycle as well as potentially stressful blood sampling techniques that may have influenced circulating prolactin levels. Also, the small sample size in many reports makes interpretation of observed differences difficult. Aylsworth et al. (55), using in-dwelling right atrial cannulas and repeated blood sampling techniques from "unstressed" animals during the entire estrous cycle, found no difference in circulating prolactin levels in rats fed a high (20%) or moderate (4.5%) fat diet. Indirect endocrine-related mechanisms cannot account for the promotion of mammary tumorigenesis by dietary fat for additional reasons: The development and growth of hormone (pituitary and ovarian)-unresponsive or independent mammary tumors is enhanced by high dietary fat (56–59). Also, the development and growth of many experimental tumors that do not appear to be influenced by the endocrine system are enhanced by high dietary fat (17–21), suggesting that similar mechanisms are involved that do not include the endocrine system. In addition, when circulating levels of estrogen and prolactin are controlled by endocrine and drug manipulations, high fat diets still promote mammary tumorigenesis (60). Also, when serum prolactin levels are similarly elevated in hypothalamic median eminence lesioned rats, mammary tumor development is still enhanced in animals fed a high fat diet (51).

Another proposed mechanism is an increased mammotrophic hormone responsiveness in incipient mammary gland tumor tissue. Cave and Erickson-Lucas (61) have reported that prolactin receptors in NMU-induced mammary tumors are increased in rats fed a 20.0% (high) fat diet compared to a 0.5% (low) fat diet. However, these differences could reflect reduced hormone receptor levels in rats fed the low fat diet, which may be marginally deficient in essential fatty acids. In fact, no differences are

observed in prolactin receptor levels of DMBA- or NMU-induced mammary tumors in rats fed a 20.0% high fat diet or a 4.5% control fat diet (62,63). Ip and Ip (64) reported that estrogen receptor levels in mammary tumors were the same in rats fed moderate (5.0%) and high (20.0%) levels of dietary fat but were reduced in rats fed a low (0.5%) fat diet. Also, progesterone receptor levels were unaffected by dietary fat. Thus, while dietary fat consumption may subtly influence endocrine secretion and/or the responsiveness of incipient mammary tumor tissue to mammotrophic hormones, the processes do not appear to be influenced sufficiently to affect the genesis and/or growth of murine mammary tumors (12,13).

The immune system plays an integral role in the tumorigenic process (65) and has been implicated in mediating the effects of high dietary fat in mammary tumorigenesis. Diets high in polyunsaturated fats suppress immune function (66). Diets high in polyunsaturated fatty acids have been reported to prolong skin allografts in rodents (67), to enhance immunosuppressive therapy following renal transplantation (68), to decrease macrophage activity (69) and to reduce peripheral lymphocyte concentrations (70). However, other reports show no effects on immune activity (71–74). Thus, while mediation of the promotion of mammary tumorigenesis by high levels of dietary fat through immunosuppression is an attractive concept, the complexities of this system and the inconsistencies of the data prevent an adequate assessment of the hypothesis.

Prostaglandins also have been implicated in the promotion of mammary tumorigenesis by dietary fat. Since linoleic and linolenic acids are precursors in the biosynthesis of certain prostaglandins, diets with elevated levels of these fatty acids may provide the substrate for increased synthesis of those prostaglandins. Dupont et al. (75) reported a positive relationship between dietary levels of linoleate and prostaglandin biosynthesis. Also, indomethacin, an inhibitor of prostaglandin biosynthesis (76), can block the stimulatory effects of high dietary fat on mammary tumorigenesis (77,78).

Because certain unsaturated fatty acids stimulate, whereas saturated fatty acids inhibit, the growth of cell cultures of normal and neoplastic rat mammary glands (39–41), dietary lipids may directly stimulate mammary tumor development and growth. The lipid composition of mammary tumors reflects qualitatively and quantitatively the fatty acid content of the diet (78–80). Changes in fatty acid composition of cell membranes may influence cellular biophysical phenomenon, including membrane fluidity, macromolecular mobility, receptor availability, enzyme activation, cyclic nucleotide and prostaglandin biosynthesis and amino acid and carbohydrate transport processes. These changes may provide conditions favorable to inducing cell division or may interfere with the processes that control cell division. Thus, the mitogenic signal that ultimately results in increased mammary tumor development and growth may be the alteration of the lipid composition of the cellular membrane itself.

INTERCELLULAR COMMUNICATION AND TUMOR PROMOTION

The development of many experimental tumors following application of a carcinogen (initiator) at subthreshold levels depends upon subsequent treatment with a "noncarcinogenic" tumor promoter. Classically, when DMBA or another carcinogen is applied to mouse skin at subthreshold doses, a high incidence of local tumors is observed only in animals subsequently treated with a tumor promoter that is noncarcinogenic when applied alone (81,82). This observation has been expanded and adapted to include tumor promotion in other tissues. For example, in mammary carcinogenesis, development of tumors following DMBA or NMU treatment is dependent upon subsequent exposure to mammotrophic hormones (83,84). Removal of pituitary or ovarian influences results in nearly complete suppression of mammary tumor development (85,86). An understanding of how the growth of these initiated, potentially tumorigenic cells is suppressed or, conversely, how tumor promoters are able to reverse this suppression and allow for development of the tumor, would contribute to understanding the tumorigenic process.

One theory to explain suppression of the proliferation of initiated, latent tumor cells is that normal cells surrounding the transformed or initiated foci exert a growth inhibitory influence. Indeed, growth of transformed C3H10T1/2 cells is inhibited when they are cocultured with nontumorigenic "normal" cells in vitro (87,88). This effect is overcome when tumor promoter 12-0-tetradecanoyl-phorbol-13-acetate (TPA) is added to the culture medium (89,90).

Intercellular communication is thought to be involved in a wide variety of developmental processes and in control of cellular growth and differentiation (91–93). Recently it was suggested that intercellular communication may also have a role in tumor promotion (94). A specific type of intercellular communication, metabolic cooperation, involves the passage of low molecular weight and possibly growth-regulating molecules through membrane structures called gap junctions. In 1979, Yotti et al. (95) and Murray and Fitzgerald (96) independently reported that metabolic cooperation between cells in culture is blocked by the classical tumor promoter TPA. Since these initial reports, many other tumor-promoting compounds have been shown to inhibit metabolic cooperation (94,97–107). Table 2 lists compounds that inhibit gap junction-mediated intercellular communication. A diverse range is listed, including naturally occurring compounds, environmental toxicants and/or pollutants, drugs, food additives and nutritionally related compounds. Thus, inhibition of intercellular communication by tumor promoters is not limited to related compounds, nor is it specific to a certain class of compounds. Also, correlations linking the efficacy of these compounds as tumor promoters to their ability to block metabolic cooperation in vitro have been described (94,107). Accordingly, a hypothesis has evolved whereby the enhanced proliferation of "initiated" cells and subsequent tumor development induced by tumor promoters (e.g., TPA) is caused by inhibiting intercellular communication, resulting in a blockade of the transfer of growth inhibitory signals via gap junctions. Increased proliferation of initiated cells in the presence of tumor promoters allows these cells to gain a selective growth advantage and increases the probability for further mutational events, resulting in autonomous, promoter-independent growth (i.e., tumor progression).

TABLE 2

Tumor Promoters That Inhibit Intercellular Communication[a]

	Tumor-promoted tissue
Naturally occurring compounds	
TPA (and other tumor-promoting phorbol esters)	Skin
Teleocidin	Skin
Bile acids (deoxycholic, lithocholic acids)	Colon
T-2 toxin	Esophagus
Aplasiatoxin	Skin
Environmental toxicants and/or pollutants	
2,4,5,2′,4′,5′ Hexabromobiphenyl	Liver
2,4,5,2′,4′,5′ Hexachlorobiphenyl	Liver
Benzoyl peroxide	Skin
Anthralin	Skin
Di-(2-ethyrexyl)-phthalate	Liver
Chlordane	Liver
Cigarette smoke condensates	Skin
Lindane	Liver
2,4-Dinitrofluorobenzene	Skin
DDT-(1.1.1-trichloro-2,2-bis p-chlorophenyl ethane)	Liver
Kepone	Liver
Aldrin	Liver
Dieldrin	Liver
Mirex	Liver
NTA-(trisodium nitrilotriacetate monohydrate)	Kidney
Drugs, food additives	
Phenobarbitol	Liver
Chlorpromazine	Liver
BHT (butylated hydroxytoluene)	Liver
Nutritionally related compounds	
Saccharin	Urinary bladder
Cyclamates	Urinary bladder
Unsaturated fatty acids	Mammary gland, others
Retinoic acid (high concentrations)	Skin

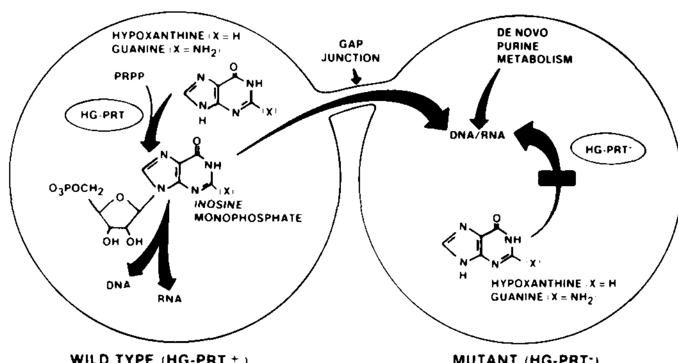

FIG. 1. Diagram illustrating the principle of the V79 Chinese hamster cell metabolic cooperation assay to measure gap junction-mediated intercellular communication (ref. 94).

IN VITRO METABOLIC COOPERATION ASSAY SYSTEM

An in vitro assay system to examine the influence of various environmental compounds on intercellular communication and to study the mechanisms of tumor promotion was developed by Trosko and colleagues (108,109). Gaudin et al. (110) observed that TPA enhanced the recovery of ultraviolet (UV) light-induced 6-thioguanine (hypoxanthine guanine phosphoribosyl-transferase-deficient [HG-PRT$^-$])-resistant Chinese hamster cells in culture. It was subsequently shown by Yotti et al. (95) that the enhancement of recovery of 6-thioguanine (6-TG)-resistant mutant cells was due to a blockade of metabolic cooperation by TPA.

Metabolic cooperation, on which our in vitro assay is based, is the phenomenon in which low molecular weight and possibly growth-regulating molecules are passed from the cytoplasm of one cell to an adjacent cell via membrane structures called gap junctions. The phenomenon is schematically illustrated in Figure 1. HG-PRT is an enzyme involved in the purine salvage pathway. Normal wild-type V79 Chinese hamster cells that contain HG-PRT (HG-PRT$^+$), grown in vitro in culture medium containing 6-TG, take up 6-TG, phosphoribosylate it to a lethal metabolite (6-thioguanosine monophosphate), are unable to proliferate and die. However, V79 Chinese hamster cells that have been mutated by x-irradiation or UV radiation and lack HG-PRT (HG-PRT$^-$) are unable to metabolize 6-TG and therefore continue to proliferate in medium containing 6-TG. (Because HG-PRT is a nonessential enzyme, metabolism of these cells is otherwise normal.) When wild-type (HG-PRT$^+$) V79 cells are cocultivated with mutant (HG-PRT$^-$) V79 cells in medium containing 6-TG, the HG-PRT$^+$ cells take up the 6-TG, phosphoribosylate it and transfer the lethal metabolite (6-TG monophosphate) via gap junctions to the mutant HG-PRT$^-$ cells if they are in physical contact. Transfer of 6-TG monophosphate is dependent upon the presence and proper functioning of gap junctions. Sufficient transfer of 6-TG monophosphate will kill the HG-PRT$^-$ cells. Therefore, recovery of the mutant HG-PRT$^-$ V79 cells is inversely related to the amount of metabolic cooperation between HG-PRT$^+$ 6-TG-sensitive (6-TG^S) and HG-PRT$^-$ 6-TG-resistant (6-TG^R) cells (i.e., increased recovery of HG-PRT$^-$ 6-TG^R cells indicates decreased metabolic cooperation). Addition to the culture medium of chemicals that decrease metabolic cooperation will result in increased recovery of 6-TG^R cells. As stated previously, a number of known tumor promoters inhibit the transfer of 6-TG monophosphate from 6-TG^S to 6-TG^R V79 Chinese hamster cells and increase the recovery of HG-PRT$^-$ cells (i.e., inhibit metabolic cooperation).

Figure 2 summarizes the experimental protocol of the V79 metabolic cooperation assay system. Details of the procedure have been published elsewhere (108,109); they are summarized as follows: Cytotoxicity is initially tested by examining the effect of various fatty acid doses on the colony-forming ability of 100 V79 Chinese hamster cells in 6-cm tissue culture dishes. All fatty acids are dissolved and diluted in 100% ethanol and are added to the cultures about 3 hr after the cells are seeded. Dilutions are made such that the final concentration of ethanol in the culture medium is less than 0.5%. Cultures are incubated in humidified air with 5% CO_2 at 37 C until colonies have grown big enough to be scored visually (usually 7–9 days), with medium changes after three and six days. The culture medium is a modified Eagle's minimal essential

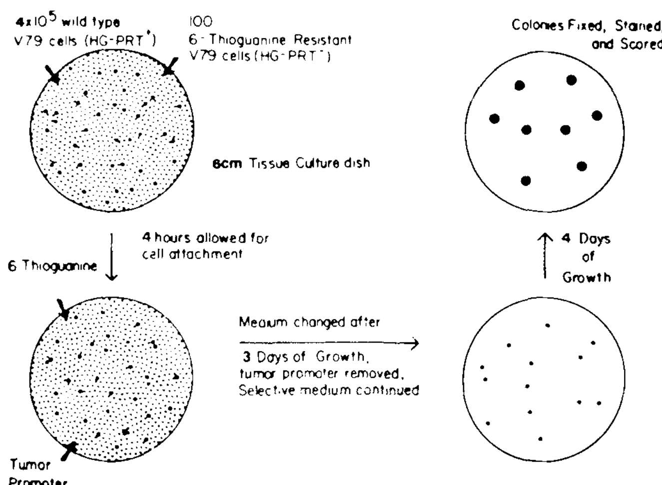

FIG. 2. Diagram describing the experimental protocol of V79 cell metabolic cooperation assay (ref. 94).

medium with Earle's salts, supplemented with 100% increase of all nonessential amino acids, 50% increase in all vitamins and essential amino acids except glutamine, 1.0 mM sodium pyruvate, antibiotics (100 IU penicillin and 100 IU streptomycin per ml medium) and 3% fetal bovine serum. Colonies are rinsed with 0.85% saline, fixed and stained with crystal violet and scored visually.

Once appropriate noncytotoxic dose ranges are established, the effect of various fatty acids on metabolic cooperation is assessed. Wild-type HG-PRT$^+$ 6-TG^S cells are seeded in 6-cm dishes (4×10^5 cells per plate) with 100 HG-PRT$^-$ 6-TG^R cells in 5 ml of culture medium. After 3–4 hr, various doses of the test fatty acids are added. Ethanol is added (final concentration of 0.5%) to a series of plates as a solvent control. TPA (1–2 ng/ml) is added to another series of plates as a positive control. After test chemicals have been added, 6-TG (10 μg/ml) is added to all plates. Cells are cultured for three days, after which the culture medium is changed and replaced with selective culture medium containing only 6-TG (10 μg/ml). Culture medium is changed once again on day 6. Cytotoxicity is confirmed by testing the effect of the same concentrations of fatty acids on the colony-forming ability of 100 6-TG^R metabolic cooperation-deficient (MC$^-$) mutants (111) cocultured with 4×10^5 6-TG^S cells in 6-cm tissue culture dishes in the presence of 6-TG (10 μg/ml). This method allows for more accurate assessment of cytotoxicity since, unlike the previous cytotoxicity evaluation (i.e., 100 6-TG^R cells cultured alone), the cell density conditions are identical to those used in the metabolic cooperation determinations.

FATTY ACID EFFECT ON METABOLIC COOPERATION

In view of the promotion of mammary tumorigenesis by high fat diets and the possible role of inhibition of gap junction-mediated intercellular communication in tumor promotion, a series of experiments was conducted to assess the influence of fatty acids on metabolic cooperation (14,112). It is apparent from the data presented in Figures 3–5 that unsaturated fatty acids inhibit metabolic cooperation at noncytotoxic concentrations, whereas

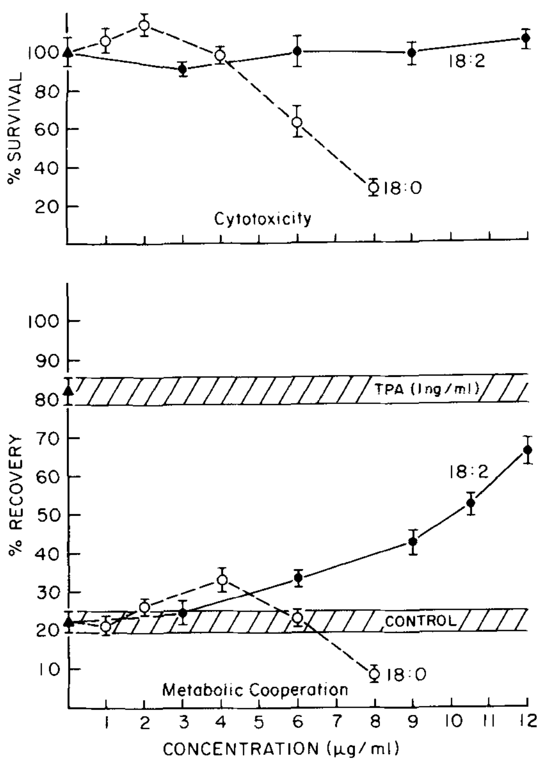

FIG. 3. Effect of linoleic acid (18:2) and stearic acid (18:0) on cytotoxicity (% survival) and on metabolic cooperation (% recovery) between Chinese hamster V79 cells. Negative (solvent) and positive (TPA-treated) controls shown in shaded areas with SEM (Ref. 112).

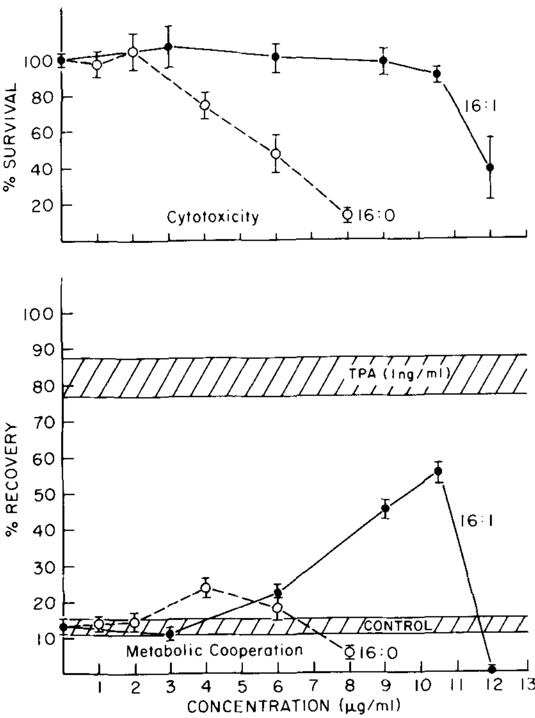

FIG. 4. Effect of palmitoleic acid (16:1) and palmitic acid (16:0) on cytotoxicity (% survival) and metabolic cooperation (% recovery) between Chinese hamster V79 cells (ref. 112).

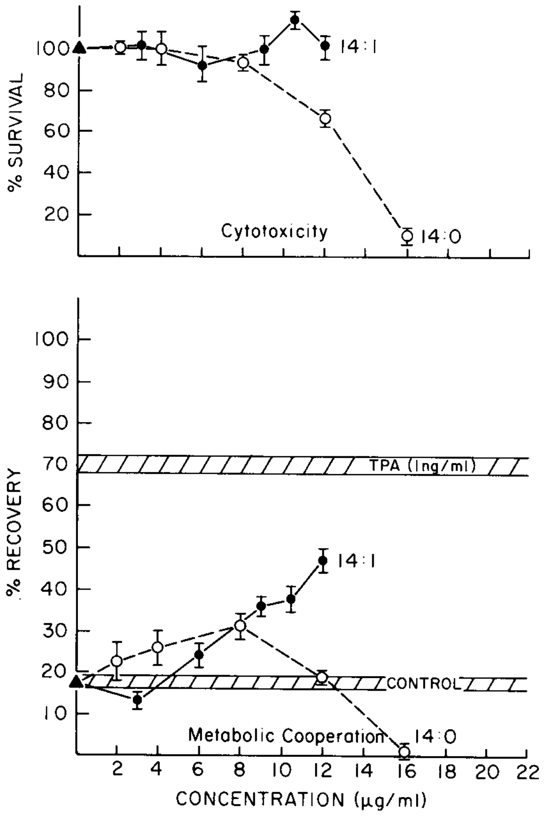

FIG. 5. Effect of myristoleic acid (14:1) and myristic acid (14:0) on cytotoxicity (% survival) and on metabolic cooperation (% recovery) between Chinese hamster V79 cells (ref. 112).

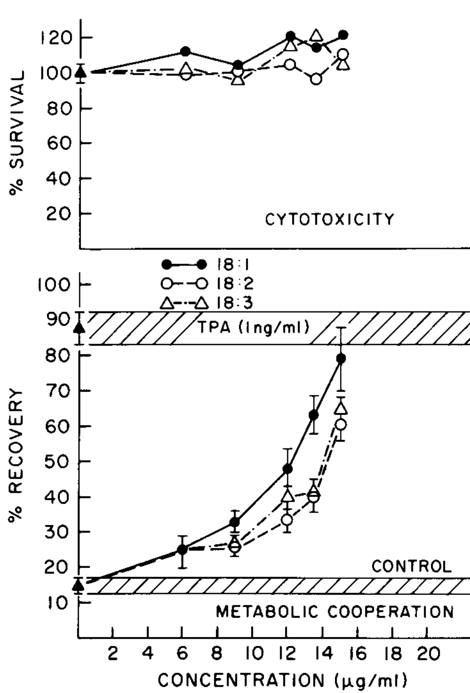

FIG. 6. Importance of the degree of unsaturation on the inhibition of metabolic cooperation by unsaturated fatty acids. Effects of oleic (18:1), linoleic (18:2) and linolenic acids (18:3) on cytotoxicity (% survival) and metabolic cooperation (% recovery) between Chinese hamster V79 cells (ref. 112).

saturated fatty acids fail to do so at any concentration. The unsaturated fatty acids—linoleic (18:2; Fig. 3), palmitoleic (16:1; Fig. 4) and myristoleic (14:1; Fig. 5)—significantly increase the recovery of 6-TG^{R} cells cocultured with 6-TG^{S} cells in a concentration-dependent manner at noncytotoxic concentrations. However, the saturated fatty acids—stearic (18:0; Fig. 3), palmitic (16:0; Fig. 4) and myristic (14:0; Fig. 5)—failed to significantly influence the recovery of 6-TG^{R} cells at noncytotoxic concentrations. Other unsaturated 18-carbon fatty acids, linolenic (18:3) and oleic (18:1), also inhibit metabolic cooperation, resulting in increased recovery of 6-TG^{R} cells (Fig. 6).

To assess the importance of the degree of unsaturation in inhibiting metabolic cooperation by unsaturated fatty acids, the abilities of 18:1, 18:2 and 18:3 to increase 6-TG^{R} cell recovery were evaluated. Figure 6 shows that no relationship exists between degree of unsaturation and inhibition of metabolic cooperation. Oleic acid (18:1) appears slightly more efficacious than linoleic (18:2) or linolenic (18:3) acids, which are about equal, in inhibiting metabolic cooperation.

There is an apparent association between the ability of unsaturated fatty acids to inhibit metabolic cooperation and the carbon chain length. When fatty acids with the same degree of unsaturation (i.e., one double bond) but different chain lengths are compared, those with longer chain lengths inhibit metabolic cooperation more than those with shorter chain lengths. Figure 7 shows that

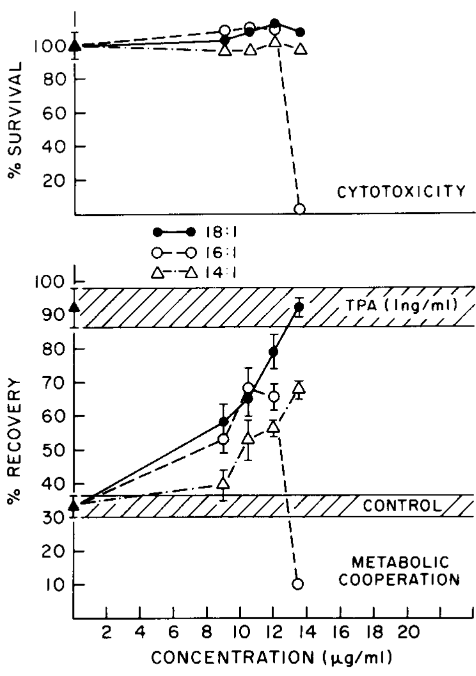

FIG. 7. Influence of carbon chain length on the inhibition of metabolic cooperation by unsaturated fatty acids. Effects of oleic (18:1), palmitoleic (16:1) and myristoleic acids (14:1) on cytotoxicity (% survival) and metabolic cooperation (% recovery) between Chinese hamster V79 cells (ref. 112).

oleic acid (18:1) inhibits metabolic cooperation more than palmitoleic (16:1) or myristoleic (14:1) acids. Palmitoleic acid (16:1) appears to inhibit metabolic cooperation slightly more than myristoleic acid (14:1).

Geometric isomerism also appears important in determining the effect of unsaturated fatty acids on metabolic cooperation. Fatty acids with the *cis*-double bond orientation are more efficacious than the corresponding *trans*-oriented fatty acids. *Cis*-oleic acid (*cis* 18:1) is much more effective than elaidic acid (*trans* 18:1) (Fig. 8), and *cis*-palmitoleic acid (*cis* 16:1) is more effective than palmitelaidic acid (*trans* 16:1) (Fig. 9). However, the differences between *cis* and *trans* 16:1 are much less dramatic than those between *cis* and *trans* 18:1. These data thus suggest that the *cis* double bond orientation appears important in the inhibition of metabolic cooperation by certain unsaturated fatty acids, but less important for other fatty acids.

To further examine the influence of fatty acids on intercellular communication, the effect of medium (11-carbon) and short (6-carbon) chain fatty acids on metabolic cooperation was assessed. Both undecanoic (11:0) and undecylenic (11:1) acids significantly inhibit metabolic cooperation (Fig. 10). However, compared with oleic acid (18:1), the inhibition of metabolic cooperation by 11:0 and 11:1 is apparent only at much higher concentrations. Hexanoic (6:0) and sorbic (6:2) acids do not influence metabolic cooperation at concentrations up to 100 μg/ml (Fig. 11) or 200 μg/ml (data not shown). Thus, it appears that the importance of unsaturation and the ability of fatty acids to inhibit metabolic cooperation is reduced in medium and short chain fatty acids.

CONCLUSIONS

High levels of dietary fat clearly promote many types of experimental cancers and are implicated in the etiology of some human cancers. Many mechanisms, including endocrine-related and immune-mediated ones, have been proposed to explain the promoting influence of high polyunsaturated fat diets on mammary tumorigenesis. A review of available information indicates that a direct influence of dietary fat promoting growth of incipient mammary tumor tissue is the most likely interpretation. One way in which unsaturated fatty acids may directly influence the growth regulation of mammary tumor tissue, and thereby promote tumor development, is by inhibiting gap junction-mediated intercellular communication. This inhibition is associated with many known tumor promoters. Indeed, unsaturated fatty acids such as oleic, linoleic, linolenic, palmitoleic and myristoleic inhibit metabolic cooperation, a process that depends on gap junction-mediated intercellular communication. While there is no apparent relationship between the degree of unsaturation of fatty acids and their ability to inhibit metabolic cooperation, long chain unsaturated fatty acids (i.e., C18) are more effective than medium (C11) or short (C6) chain ones. The *cis* double bond orientation is important for certain fatty acids to inhibit metabolic cooperation. Also, unsaturation is less important in medium and short chain fatty acids than in longer (≥C14) chain ones.

The mechanism by which unsaturated fatty acids inhibit metabolic cooperation is unclear. Incorporation of unsaturated fatty acids into cell membranes may alter

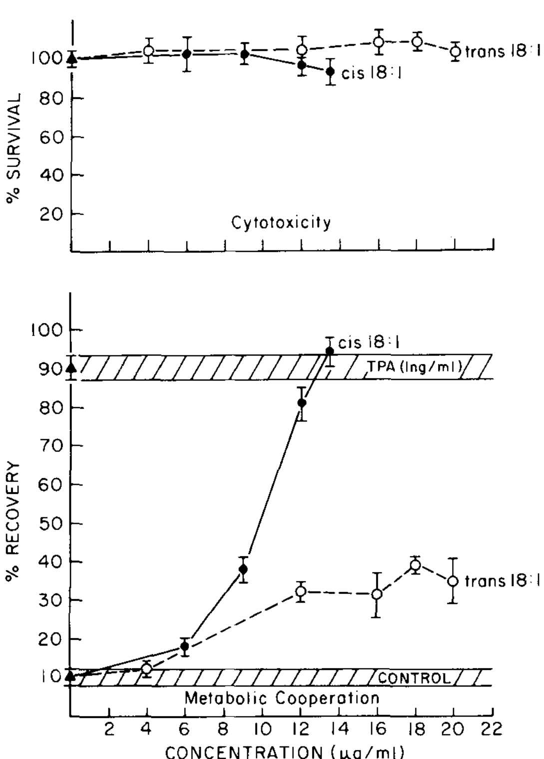

FIG. 8. Importance of *cis*-double bond orientation on the inhibition of metabolic cooperation by unsaturated fatty acids. many biophysical properties of the membrane, including membrane fluidity, receptor and macromolecular availability and transport mechanisms. Since gap junctions are membrane structures, changes in the membrane microenvironment could alter their functional capacity. Incorporation of unsaturated fatty acids into the membrane increases fluidity (80), which could result in a destabilization of gap junction structure and thereby cause a decrease in gap junction-mediated intercellular communication (i.e., metabolic cooperation). However, since no greater inhibitory effects were observed with more unsaturated fatty acids (i.e., 18:1, 18:2, 18:3), such mechanisms involving membrane fluidity are unlikely.

Unsaturated lipid may also inhibit intercellular communication by altering enzyme activity, in particular, the Ca^{2+}-activated, phospholipid-dependent, diacylglycerol-sensitive protein kinase C. Protein kinase C is a widely distributed cyclic AMP-independent protein kinase (or group of kinases) recently implicated in mediating many cellular processes, including tumor promotion, in normal and neoplastic tissues (113,114). Its activity is increased by tumor promoters that inhibit intercellular communication (such as TPA) and by diacylglycerol compounds that contain unsaturated fatty acids (113,115-118). Recently, Gainer and Murray (119) and Aylsworth et al. (112) reported that unsaturated diacylglycerol compounds inhibit metabolic cooperation, suggesting a role for protein kinase C in the control of intercellular communication.

Linoleic and linolenic acids may influence the biosynthesis of certain prostaglandins and thereby affect a variety of cellular processes, including intercellular communication (120). However, the inhibition of metabolic cooperation by other unsaturated fatty acids thought to be not involved in prostaglandin biosynthesis (oleic, palmitoleic, and myristoleic acids) suggests that altered prostaglandin biosynthesis is not involved in mediating these effects.

Finally, lipid peroxidation products may also have a role in mediating the inhibitory effects of unsaturated fatty acids on metabolic cooperation. Oxygen free radicals generated by peroxidation of unsaturated fatty acids may cause dysfunction of gap junction structures, thereby reducing gap junction-mediated intercellular communication. However, mechanisms involving lipid peroxidation also are unlikely, because no increased inhibition of metabolic cooperation was observed with fatty acids containing increasing degrees of unsaturation.

[Received September 3, 1986]

The Influence of Dietary Medium Chain Triglycerides on Rat Mammary Tumor Development[1]

L.A. Cohen* and **D.O. Thompson**[2]
Division of Nutrition and Endocrinology, American Health Foundation, Naylor Dana Institute for Disease Prevention, Dana Road, Valhalla, NY 10595

The N-nitrosomethylurea rat mammary tumor model was used to compare the tumor-promoting effects of a high-fat (HF) diet containing a 3:1 mixture of medium chain triglycerides (MCT) and corn oil with that of a HF and a low-fat (LF) corn oil diet. The serum and tumor lipid content and fatty acid (FA) composition were also determined in the three dietary groups. It was found that the MCT-containing diet failed to promote tumor development compared with the HF corn oil group. Tumor incidence in the HF-MCT group was similar to that of the LF corn oil group (5% fat, w/w), but significantly decreased compared to the HF corn oil group. Total serum cholesterol levels were significantly depressed in the HF corn oil group compared to the HF-MCT and LF corn oil groups. Analysis of serum and tumor FA profiles indicated that the HF corn oil group exhibited approximately twice the amount of linoleic acid (LA) as the other two treatment groups. Differences among the three groups in the major FA metabolite of LA, arachidonic acid, were minimal. These results are consistent with the hypothesis that tumor promotion by dietary fat is more a function of the type than the amount of fat ingested. In addition, they indicate that MCT, due at least in part to their unique structural and physiological properties, exert markedly different effects on mammary tumor development than conventional long chain unsaturated fatty acids.
***Lipids 22,* 455-461 (1987).**

Numerous epidemiological and experimental studies suggest that dietary fat is an important determinant of breast cancer risk (1,2). Studies in laboratory animals have shown that the influence of dietary fat is exerted primarily on the promotion stage of mammary carcinogenesis (3), a finding that may be reflected in the fact that the association between fat intake and increased risk is most pronounced in women over 40 (2).

Moreover, experimental studies by us (4), Carroll et al. (3,5-7) and others (8-15) have shown that the kind and amount of fat ingested determine the rate of development of chemically induced and transplantable mammary tumors. In these studies, it was shown that a certain proportion of essential polyunsaturated fatty acids (PUFA) appears to be required for optimal tumor-enhancing effects, and that high-fat (HF) diets containing coconut oil, which consists primarily of short and medium chain saturated fatty acids and a small quantity (<2%) of linoleic acid (LA), lack the ability to promote mammary tumor development compared to HF diets rich in PUFA.

As the above evidence suggests, the degree of saturation and possibly the chain length of constituent fatty acids can modify the effect of HF diets. Hence, it appeared appropriate to test the effects of a specifically designed diet containing high levels of medium chain triglycerides (MCT) on the development of chemically induced mammary tumors. (Medium chain fatty acids [MCFA] are obtained by hydrolysis of coconut oil—6:0 [<2%], 8:0 [7%], 10:0 [6%], 12:0 [50%], 14:0 [20%], 16:0 [8%], 18:0 [2%], 18:1 [5%], 18:2 [0.8%]—followed by fractional distillation of the resulting fatty acid mixture to obtain a mixture of 6:0 [1-2%], 8:0 [65-75%], 10:0 [25-35%], 12:0 [1-2%] fatty acids. The MCFA are then esterified to glycerol in the presence of a Zn catalyst to generate the triglyceride [17].)

In the present study, the N-nitrosomethylurea (NMU)-induced rat mammary tumor model was used to compare the tumor-promoting effects of diets containing low and high levels of corn oil with a HF diet containing a 3:1 mixture of MCT and corn oil. Since dietary MCT have been reported to alter circulating serum lipid levels (16,17) and to modify the metabolism of linoleic acid (18,19), serum total cholesterol and triglycerides and serum and tumor fatty acid profiles were also assessed.

MATERIALS AND METHODS

Tumor induction. Ninety inbred virgin female F344 rats, aged 28 days (Charles River Breeding Laboratories, North Wilmington, Massachusetts) were maintained on the standard NIH-07 diet (Zeigler Bros., Gardners, Pennsylvania) (20) until 50 days of age. All animals were then randomized into three groups of 30 animals each by recognized procedures (21) to equalize initial mean weights. On day 50 of age, all animals received a single dose of NMU (50 mg/kg body wt) by tail vein injection. The NMU (Ash Stevens Inc., Detroit, Michigan) was dissolved in a few drops of 3% acetic acid, and NMU was brought up to volume in distilled H_2O, yielding a stock solution of 10 mg/ml administered within 2 hr of formulation (22). Two days after carcinogen administration, animals were transferred to experimental diets and remained on them for the duration of the experiment.

At weekly intervals beginning four weeks after NMU injection, each rat was weighed, and the position and date of appearance of palpable tumors were recorded.

HF and low-fat (LF) diets. The adjusted HF diet used in these experiments is based on the recommendations of the Committee on Laboratory Animal Diets of the National Academy of Sciences (23-25), with slight modifications.

It has been found in our laboratory and those of others that rats adjust food intake so that similar energy intake is maintained, despite the fact that diets may differ substantially in energy density. Hence, animals will eat quantitatively less of a HF than LF diet. Consequently, unless the proportions of the other components in the diet are adjusted, animals fed a HF diet will take in substantially less protein, fiber, vitamins, minerals, etc., than

those fed a LF diet. The adjustment recommended by the Committee on Laboratory Animal Diets was incorporated into our experimental protocol. The adjusted diet formulation ensured that animals fed a HF diet took in the same amount of vitamins, minerals and fiber as in the LF diet and that adequate antioxidant activity was present in the form of vitamin E, Se (as a cofactor of glutathione peroxidase) and vitamin A in each dietary group. The increase in fat in the HF diet was compensated for by a decrease in the amount of starch-dextrose (26) (Table 1). The HF and LF diets consisted of 23% and 5.0% corn oil. These percentages were designed to mimic the American (high risk) diet (40–45% of total calories as fat) and the Japanese (low risk) diet (16% of total calories as fat during the years 1957–1959) (2).

The LF diet was designed to provide ca. 5–6 cal/day of fat, based on an estimated consumption of 45–50 cal/day, (27) or ca. 12% of total. The HF diet, on the other hand, provided ca. 20–21 cal/day as fat, or 45% of total calories. All dietary ingredients were obtained from Dyets Inc. (Bethlehem, Pennsylvania) and were mixed in-house in our diet kitchen. Diets were formulated in 4-kg lots and stored in plastic bags at 4 C in the dark until used.

Animals were housed three to a cage in plastic cages covered with filter tops in a room controlled for temperature (24 C ± 2 C), light (12-hr cycle) and humidity (50%) and were administered diets (in powdered form) and tap water ad libitum.

Histopathology. Approximately 22 wk after NMU administration, all rats were killed by decapitation, and serum was collected following centrifugation of whole blood. Serum was stored at −20 C until assayed. Palpable tumors were excised and cut into two pieces—one of which was stored in liquid N_2 for fatty acid analysis and the other fixed in buffered formalin—blocked in paraffin and then sectioned and stained with hemotoxylin and eosin. Histological diagnosis of mammary tumors was based on the criteria outlined by Young and Hallowes (28).

Statistical evaluation of tumor data. Differences in tumor-free survival time among the three treatment groups were analyzed by the Kaplan-Meier Product Limit Method using a Fortran program provided by G. G. Gart and colleagues (29). Differences in tumor incidence were assessed by Fisher's Exact test (one-tail) and in tumor multiplicity by analysis of variance (ANOVA) after log transformation of the tumor count data. Overall, weight gains among the three treatment groups were compared by a two factor (diet and time) ANOVA with repeated measures (30).

Biochemistry. Nonfasting serum total cholesterol and triglycerides were determined by the use of a Gilford 3500 computer-directed auto analyzer by standard procedures (31,32).

Serum fatty acid analysis was carried out as described previously (4,33). Essentially, pooled serum samples (five/group) were extracted by a modified Radin (34) technique using hexane-isopropanol as the extraction solvent. The extracted lipid was then transmethylated using BF_3 (35), and the methyl esters of the fatty acids were separated by GLC. For tumor lipid analysis, frozen tumor tissue was pulverized under liquid N_2 in a mortar and pestle and then extracted in a similar manner as serum. The total lipid extract was then separated into neutral and phospholipid fractions using a silica gel column (4,36). The column was eluted first with chloroform (neutral lipid) and then a chloroform/methanol/water (65:26:4, v/v/v) mixture (phospholipid). The efficiency of extraction and separation was 94% for neutral lipids and 97% for phospholipids.

RESULTS

Tumor incidence, latency and multiplicity. Animals fed the MCT-containing diet exhibited a significantly lower total mammary tumor incidence when compared to animals fed a HF:corn oil diet (60% vs 87%, $p < 0.03$) (Table 2). However, when palpable adenocarcinomas alone were counted, the difference in incidence failed to attain statistical significance (57% vs 77%, $p < 0.08$). Likewise, when HF corn oil and LF corn oil-fed animals were compared in terms of total palpable mammary tumors, statistical significance was barely missed (66% vs 87%, $p < 0.06$); however, when only palpable adenocarcinomas

were counted, differences in tumor incidence did not reach the level of statistical significance (60% vs 77%, $p > 0.10$).

Analysis of time-to-first-tumor curves (Fig. 1) indicated clearly that mammary tumors appeared more rapidly in the HF corn oil group than in the HF-MCT and LF-corn oil groups. The stepwise survival curves exhibited by the latter two groups were indistinguishable, whereas there was a significant delay in tumor appearance in these groups when compared to the HF-corn oil curve. The median times to first tumor in the HF-corn oil, HF-MCT and LF-corn oil groups were 90, 120 and 120, respectively (Table 3). Tumor multiplicity was similar in each group (Table 4), and no difference in tumor size was seen in the different treatment groups (data not shown).

Biochemistry. With regard to serum lipid concentrations, mean nonfasting cholesterol levels were significantly lower in animals fed 23% corn oil compared to those fed either 5% corn oil or the corn oil–MCT diet. No significant differences were found in serum triglycerides for any of the three treatment groups (Table 5).

Cox's test for adjusted trends, $p < 0.0035$. Pairwise comparisons: Cox's Test (conservative). 23% corn vs 5% corn, $p < 0.0099$; 23% corn vs MCT, $p < 0.0086$); 5% corn vs MCT, $p < 0.9$.

The fatty acid profiles of serum lipids differed primarily in the quantity of linoleic acid (18:2) present. Animals fed 23% corn oil diets exhibited twice the amount of LA as those fed 5% corn oil or MCT-containing diets. Differences in 14:0, 16:0, 16:1, 18:3 and 20:4 fatty acids were also noted (Table 6), though these were of a lower degree of magnitude.

Comparison of the fatty acid profiles in tumor neutral lipids (Table 7) indicated that the spectrum of fatty acids closely reflected that of the diet, particularly with regard to the essential fatty acid linoleic acid (18:2n-6); 10:0 and 12:0 fatty acids were detected only in the MCT group and at very low levels.

Comparison of phospholipid fatty acid profiles (Table 8) in NMU-induced tumors revealed a marked difference compared to neutral lipid profiles. In general, AA levels were higher than LA levels in the phospholipid fraction. When the phospholipid profiles of the three treatment groups were compared, it could be seen that LA still exhibited higher levels compared to the LF-corn oil and the HF-MCT groups. No differences were seen in AA levels, which tended to be highly variable both within and between groups.

Animal weight gains were similar in each group (Table 9), indicating that differences in type or quantity of

dietary fat did not alter food consumption patterns. Direct measurement of food consumption confirmed this finding: LF-fed animals consumed 11–12 g/day while HF-fed animals consumed 8–10 g/day.

DISCUSSION

This study indicates that a HF diet containing high levels of MCFA does not enhance the development of mammary tumors, in contrast to a HF diet containing the more common long chain fatty acids. Possible mechanisms underlying the observed effects of the MCT-containing diet may be either direct or indirect. A direct mechanism can be envisaged based on the unique physicochemical and biological properties of MCT. Although lipid in nature, MCT are absorbed and transported by the body in a manner more characteristic of carbohydrates than lipids. In contrast to long chain fatty acids, MCT do not enter lymph or chylomicrons, are not incorporated into membranes and are rapidly oxidized by the mitochondria via a carnitine-independent, rather than a carnitine-dependent, mechanism (16,17,37). The presence of only small amounts of MCFA in serum or tumor lipids of MCT-fed animals indicates that MCFA are rapidly absorbed and oxidized rather than stored in tissues. Hence, because of the unique physiological properties of MCT, the HF-MCT diet may exert biological effects more like those of a LF than a HF diet.

MCT may also act via indirect mechanisms involving actions at hormone receptors and/or essential fatty acid metabolism. With regard to the former, it has been shown by Knazek et al. (38) and Cave and Erickson-Lucas (39) that feeding MCT to rats lowered the number of prolactin receptors in both hepatic tissue and mammary tumors. Since prolactin is a recognized promoting substance in mammary tumorigenesis (40,41), its tumor growth-promoting effects could be attenuated by limiting, via dietary means, the number of receptors in the target organ available for activation by circulating prolactin. With regard to the latter, there have been several reports that MCT influence essential fatty acid metabolism (18,19). They have been shown, for example, to exert a sparing effect on the LA requirement for relief of the symptoms of essential fatty acid deficiency. These findings are of particular interest since essential fatty acids and their metabolism to prostaglandins appear to play a role in both the HF effect and the essential fatty acid deficiency syndrome (10,42,43–45).

Differences in serum and tumor fatty acid profiles in the three treatment groups were seen mainly in the LA content, which was significantly elevated in the HF-corn oil group. Of all the major fatty acids, only LA was elevated in the 23% corn oil animals. This fact is probably a reflection of its status as an essential fatty acid—that is, it cannot be synthesized de novo or from dietary precursors by the body, and therefore must be performed in the diet (43). Since Δ^6-desaturase (the rate-limiting enzyme in the pathway from LA to arachidonic acid [AA] and ultimately the whole range of prostaglandins), is subject to inhibition by long chain fatty acids (46), consumption of a HF-corn oil diet may suppress the activities of the fatty acid desaturases and/or chain-elongating enzymes and thereby slow the conversion of LA to its various metabolites. However, in the absence of any direct data on the fatty acid desaturases, one can only speculate on the metabolic basis for the observed differences in fatty acid patterns reported in the present study.

The fact that AA levels in tumor phospholipids (the primary precursor for intracellular prostaglandins) were similar in all three groups, despite the observed differences in tumor yield, casts doubt on the possibility that mammary tumor promotion may be regulated by the amount of AA available in membrane phospholipids for conversion to prostaglandins (43,47,48), and also on the possibility that dietary MCT modulate the metabolism of LA to AA in mammary tumors.

The intake of MCT has been associated with reductions in tissue and serum cholesterol (16). In this study, animals receiving the MCT-containing HF diet exhibited significantly higher, rather than lower, serum cholesterol compared to animals receiving 23% corn oil. The reason for this is uncertain. It may be because MCT limit cholesterol deposition in tissues (4) and the observed high serum cholesterol levels may therefore be due to a reapportionment of cholesterol from the tissue to the serum compartments. The suppression of serum cholesterol levels by diets high in polyunsaturated fat, such as corn oil, is a well-established phenomenon, although the mechanism by which this occurs is uncertain (49,50).

In conclusion, this study emphasizes the importance of viewing dietary lipids not only in terms of their physicochemical characteristics, i.e., chain length, degree of saturation and levels of isomerization, but also in terms of their specific physiological roles in body metabolism. In this regard, MCT, which are unique among triglycerides in their mode of absorption and transport, should provide a valuable tool for further exploration of the role of dietary fat in breast cancer development.

Chiral Discrimination in the Exchange of α-Tocopherol Stereoisomers Between Plasma and Red Blood Cells

S.C. Cheng[a], G.W. Burton[a], K.U. Ingold[a,*] and D.O. Foster[b]
Divisions of [a]Chemistry and [b]Biological Sciences, National Research Council Canada, 100 Sussex Dr., Ottawa, Canada, K1A 0R6

The transport of 2*R*,4′*R*,8′*R*-α-tocopherol and 2*S*,4′*R*,8′*R*-α-tocopherol from plasma into rat red blood cell membranes occurs with essentially no chiral discrimination. The previously demonstrated (10) preference of red blood cell membranes favoring 2*R*,4′*R*,8′*R*-α-tocopherol over the 2*S*,4′*R*,8′*R* stereoisomer is shown to be due to better retention of the former compound, i.e., to preferential retention of natural vitamin E.
Lipids 22, 469–473 (1987).

It is generally accepted that vitamin E owes its bioactivity to its ability to inhibit lipid peroxidation in vivo (1). The major component of natural vitamin E, 2*R*,4′*R*,8′*R*-α-tocopherol (*RRR*-α-T), has long been known to show a greater activity in various animal bioassays than synthetic 2*RS*,4′*RS*,8′*RS*-α-tocopherol (*all-rac*-α-T) (1). Each of the eight diastereoisomers of α-T has been shown to have a different activity in the rat fetal gestation-resorption assay, with the natural stereoisomer, *RRR*-α-T, being the most active (2). However, the range in bioactivities is not large. Thus, although the major differences in the biopotencies of the α-T stereoisomers appear to originate in the chirality of carbon atom 2 (3–8), 2*S*,4′*R*,8′*R*-α-tocopherol (*SRR*-α-T) still has ca. 30% of the activity of *RRR*-α-T (2).

There appear to have been no real attempts to explain or explore the origin of the different bioactivities of the α-T stereoisomers. To us, the magnitude of the *RRR*-α-T/*SRR*-α-T difference appeared far too small to be due to some enzyme- or protein-mediated chemical or physical (e.g., transport) process (9). We therefore undertook and have recently reported the results of an in vivo "competitive" experiment involving these two stereoisomers (10). Three-week-old male rats were raised on a standard vitamin E–free diet to which we had added 36 mg of *RRR*-α-T acetate per kg of chow. After four weeks, the diet was changed to one based on the same chow but with the natural α-T acetate replaced by 18 mg 5,7-$(CD_3)_2$-*RRR*-α-T + 18 mg 5-CD_3-*SRR*-α-T acetates per kg of chow. Analyses of blood and tissue samples taken at various times yielded the ratio d_6-*RRR*-α-T/d_3-*SRR*-α-T, which gives a measure of the discrimination in favor of the natural isomer, *RRR*-α-T/*SRR*-α-T, in the sample. One of the more interesting results from this study related to the degree of chiral selectivity in blood plasma and red blood cells (RBC). Both the plasma and the RBC discriminated in favor of natural α-T, and the *RRR*-α-T/*SRR*-α-T ratio increased with time. However, the RBC membranes were more selective than the plasma lipoproteins at all times: the ratio, $[(RRR\text{-}\alpha\text{-T})/(SRR\text{-}\alpha\text{-T})]_{RBC}/[(RRR\text{-}\alpha\text{-T})/(SRR\text{-}\alpha\text{-T})]_{plasma}$, was equal to 1.35 ± 0.13 throughout the five months of the experiment (10). The observed greater chiral selectivity of RBC membranes compared with plasma might arise from a variety of kinetic phenomena, including (i) *RRR*-α-T is preferentially transferred from plasma to RBC; (ii) *SRR*-α-T is preferentially transferred from RBC to plasma; and (iii) both (i) and (ii) occur. In this paper, we report the results of experiments designed to distinguish among these three possibilities.

MATERIALS AND METHODS

Materials. The syntheses of the deuterium-labeled α-tocopherols have been described previously (10).

Methods. Three groups of experiments were conducted. In all experiments 3-wk-old male Sprague-Dawley rats bred at the NRCC specific pathogen-free facility were weaned and placed on a standard AIN-76 diet [major components: sucrose, 50%; casein, 20%; corn starch, 15%; tocopherol-stripped corn oil, 5% (11)] that contained extra menadione [10 times the level in the original diet (12,13)] and 36 mg α-T acetate (α-T-Ac) per kg of diet. The control diet contained 36 mg of unlabeled *RRR*-α-T-Ac per kg (diet 0). For the first experiment, a diet was used that contained 36 mg of 5-CD_3-*RRR*-α-T-Ac (d_3-*RRR*-α-T-Ac) per kg (diet 1). For the second experiment, a diet was used that contained 18 mg of 5,7-$(CD_3)_2$-*RRR*-α-T-Ac (d_6-*RRR*-α-T-Ac) plus 18 mg of 5-CD_3-*SRR*-α-T-Ac (d_3-*SRR*-α-T-Ac) per kg (diet 2). For the third experiment, the diet contained 12 mg of d_6-*RRR*-α-T-Ac plus 24 mg of d_3-*SRR*-α-T-Ac per kg (diet 3).

Typically, one rat raised on the control diet (diet 0) and one rat of identical age raised on one of the deuterium-labeled α-T-Ac diets were used in each experiment. Blood (~10 ml), obtained from nonfasted animals by heart puncture under halothane anesthesia, was collected over 200 μl of phosphate buffer containing disodium ethylenediaminetetraacetate (10 mg) and immediately placed in a bucket of ice. Equal volumes of blood from the two animals were placed in centrifuge tubes and spun at 12,000 × g for 10 min at 4 C. The plasma was separated and to it was added 1.67 mg glucose/ml plasma (an amount approximately equivalent to 1 mg/ml of reconstituted blood). The red blood cells were washed by resuspension in ice-cold phosphate-buffered saline (5 mM, pH 7.4), spinning at 270 × g for 10 min, removal of the supernatant and repetition of the whole procedure twice. At the end of the last wash, the red blood cells were packed by centrifugation at 12,000 × g for 10 min. The temperature of the plasma and packed RBC was then raised to 37 C by shaking in a water bath for 15 min. The RBC from one rat were then mixed with the plasma from the other rat (total volume ca. 10 ml; hematocrit 37 ± 1%) with the temperature being maintained at 37 C. Samples (1 ml each) were withdrawn at intervals and centrifuged, the plasma (~0.4 ml) was collected and the RBC were washed three times with phosphate-buffered saline as described above (the period of centrifugation after each wash was reduced to 5 min). Lipid was extracted from the plasma by the usual ethanol/heptane procedure (10,14,15) and from the RBC by the sodium dodecyl sulfate (SDS) method (10,15). The direct extraction of lipid

from the RBC was performed by first adding sodium ascorbate (ca. 100 mg) to the packed RBC followed by SDS (0.1 M, 4 ml), ethanol (5 ml) and *n*-heptane (2 ml). The heptane extract was passed through an analytical high performance liquid chromatograph (15), and the eluent containing the α-T fraction was collected. The α-Ts were then converted to their trimethylsilyl ether derivatives prior to analyses for d_0-, d_3- and d_6-α-T by gas chromatography/mass spectrometry. These steps were performed as described previously (10).

We note that total concentrations of the α-Ts in the plasma and RBC used in an experiment are not required in the calculation of the discrimination factors for the relative rates of transfer of *RRR*-α-T vs *SRR*-α-T (see below).

RESULTS

Our initial experiment on α-T exchange was chosen to compare our procedure using deuterium-labeled α-T with literature data of Bjornson et al. (16), who used a tritium-labeled α-T. Plasma and RBC from a rat fed for 64 days after weaning on diet 1 (d_3-*RRR*-α-T-Ac) were mixed with RBC and plasma, respectively, from a rat fed diet 0 (d_0-*RRR*-α-T-Ac) for the same length of time. Following the procedure of Bjornson et al. (16), we plotted experimental values of log $\{([d_3]_t-[d_3]_\infty)/([d_3]_0-[d_3]_\infty)\}$ against time, where $[d_3]$ represents the concentration of d_3-*RRR*-α-T and the subscripts t, 0 and ∞ refer to times t, the start of the experiment and the time at which equilibrium had been reached (ca. 12 hr), respectively. The concentration of d_3-*RRR*-α-T was measured in both RBC and plasma. The RBC contain a smaller "pool" of α-T than the plasma (ca. 30–50% of the plasma "pool" in blood from fasted rats (17,18) but typically ca. 20% in the reconstituted blood from the nonfasted rats used in our experiments). There was therefore a correspondingly greater change in the relative concentration of RBC d_3-*RRR*-α-T than plasma d_3-*RRR*-α-T, and thus the RBC yielded more reliable kinetic data. For the transfer of d_3-*RRR*-α-T from labeled plasma into unlabeled RBC, the semilog plot for d_3 uptake by RBC had a slope of 0.31 hr^{-1} (loss from plasma gave a slope of 0.25 hr^{-1}). The RBC slope yields a half-life for exchange (toward equilibrium) of *RRR*-α-T between plasma and RBC, $\tau_{1/2}$, of 0.69/0.31 = 2.2 hr. These results are in perfect agreement with those of Bjornson et al. (16) for their plasma → RBC experiment, namely, slope = 0.31 hr^{-1}, $\tau_{1/2}$ = 2.2 hr. Similarly, for the transfer of d_3-*RRR*-α-T from labeled RBC into unlabeled plasma, the semilog plot of d_3 loss by the cells had a slope of 0.28 hr^{-1} (uptake by plasma gave a slope of 0.20 hr^{-1}) corresponding to $\tau_{1/2}$ = 2.5 hr. For their RBC → plasma experiment, Bjornson et al. (16) give slope = 0.32 hr^{-1}, $\tau_{1/2}$ = 2.2 hr. The excellent agreement between our results and theirs gave us confidence in the reliability of our experimental procedures.

For the competitive experiments involving d_6-*RRR*-α-T and d_3-*SRR*-α-T, we measured only the initial rates of uptake (or loss) of these two tocopherols (i.e., for the first 5–10% at the overall approach to equilibrium). This made it possible to determine separately the stereoisomeric discrimination occurring upon transfer of α-T from plasma to RBC and vice-versa (see Appendix). Typically, measurements of the relative concentrations of d_6-*RRR*-α-T and d_3-*SRR*-α-T (and, of course, d_0-*RRR*-α-T) in the plasma and RBC were taken every 10 min for 1 to 1.5 hr. Because of the preference of blood for the natural stereoisomer of α-T (10), there was about twice as much d_6-*RRR*-α-T as d_3-*SRR*-α-T in the plasma and RBC of the rats raised on diet 2 ([d_6-*RRR*-α-T-Ac]/[d_3-*SRR*-α-T-Ac] = 1.0). However, for the rats on diet 3 ([d_6-*RRR*-α-T-Ac]/[d_3-*SRR*-α-T-Ac] = 0.5), the plasma and RBC contained quantities of these two stereoisomers that were more nearly equal. For example, a rat raised for 38 days on diet 3 had [d_6-*RRR*-α-T]/[d_3-*SRR*-α-T] ratios of 0.96 and 1.49 in its plasma and RBC, respectively. [The differential selectivity favoring the natural stereoisomer in the RBC, i.e., 1.49/0.96 = 1.55 is within the range found previously for rats consuming diet 2 (10).] The percentage concentrations of d_6-*RRR*-α-T and d_3-*SRR*-α-T in plasma and RBC following the mixing of plasma and RBC from this rat with the RBC and plasma, respectively, from a rat raised for 38 days on diet 0 (d_0-*RRR*-α-T-Ac) are given in Table 1. These data are quite typical.

TABLE 1

Concentrations of d_6-*RRR*-α-T and d_3-*SRR*-α-T as a Percentage of the Total α-T in Plasma and RBC Before and at Various Times After Mixing Plasma and RBC from a Rat Raised 38 Days on Diet 3 and a Rat Raised 38 Days on Diet 0

RRR-α-T, 2*R*,4′*R*,8′*R*-α-tocopherol; *SRR*-α-T, 2*S*,4′*R*,8′*R*-α-tocopherol; RBC, red blood cells.

Let us consider first RBC containing d_6-*RRR*-α-T and d_3-*SRR*-α-T (plus some d_0-*RRR*-α-T), which are mixed with plasma containing only d_0-*RRR*-α-T. We define a quantity, $D^{RBC \to P}$, that represents the time-independent degree of discrimination (if any) in favor of transport of d_6-*RRR*-α-T over that of transport of d_3-*SRR*-α-T from the RBC to the plasma (RBC→P). If we are monitoring the loss of the two stereoisomers from the RBC, we can write (see Appendix):

$$\left[\frac{(RRR)_0 - (RRR)_t}{(SRR)_0 - (SRR)_t}\right]^{RBC} \left[\frac{(SRR)_0}{(RRR)_0}\right]^{RBC} = (D^{RBC \to P})^{RBC} \qquad [1]$$

In this equation, *RRR* and *SRR* refer to percentage concentrations of d_6-*RRR*-α-T and d_3-*SRR*-α-T, respectively, subscripts refer to the time of the measurement (0 = start of the experiment) and the superscript RBC reminds us that these are measurements on RBC. (Initial concentrations can be used because the run is carried on to only 5 or 10% of final equilibration.) Values of $(D^{RBC \to P})^{RBC}$ calculated from each individual measurement are given in Table 1.

On the other hand, if we are monitoring the gain of the two stereoisomers by the plasma, we write:

$$\left[\frac{(RRR)_t}{(SRR)_t}\right]^{P} \left[\frac{(SRR)^0}{(RRR)_0}\right]^{RBC} = (D^{RBC \to P})^{P} \qquad [2]$$

where the superscript P reminds us that these are measurements on the plasma. Individual values of $(D^{RBC \to P})^{P}$ are given in Table 1. The mean values of $(D^{RBC \to P})^{RBC}$ and $(D^{RBC \to P})^{P}$ should, of course, be equal. For the RBC to plasma transfer experiments the agreement between these two independently derived quantities is generally rather good (see Table 2), because it is relatively easy to measure the gain of the two stereoisomers by the plasma since their initial concentration in the plasma is 0. The measurement of $(D^{RBC \to P})^{RBC}$ is also fairly reliable because the total "pool" of α-T in RBC (in the reconstituted blood) is lower than in the plasma (17,18). The decrease in the quantities of deuterated α-tocopherols can therefore be determined fairly reliably.

For the companion pairs of experiments in which plasma containing the deuterated α-tocopherols was mixed with RBC containing only d_0-*RRR*-α-T, we can define a quantity, $D^{P \to RBC}$, that represents the time independent degree of discrimination (if any) in favor of transport of d_6-*RRR*-α-T over that of transport of d_3-*SRR*-α-T from plasma to RBC. If we are monitoring the gain of the two stereoisomers by RBC, we write:

$$\left[\frac{(RRR)_t}{(SRR)_t}\right]^{RBC} \left[\frac{(SRR)_0}{(RRR)_0}\right]^{P} = (D^{P \to RBC})^{RBC} \qquad [3]$$

while for the loss of the stereoisomers by the plasma, we write:

$$\left[\frac{(RRR)_0 - (RRR)_t}{(SRR)_0 - (SRR)_t}\right]^{P} \left[\frac{(SRR)_0}{(RRR)_0}\right]^{P} = (D^{P \to RBC})^{P} \qquad [4]$$

Values for these two quantities for each individual measurement are given in Table 1.

Once again, the mean values for $(D^{P \to RBC})^{RBC}$ and $(D^{P \to RBC})^{P}$ should be equal. However, in this type of experiment, generally only $(D^{P \to RBC})^{RBC}$ can be fairly reliably determined. There is relatively little change in the concentrations of

TABLE 2

Summary of Initial α-T Isotopic Compositions as a Percentage of the Total α-T in the Labeled Blood Fraction and of Calculated Discrimination Factors Favoring Transport of d_6-*RRR*-α-T over Transport of d_3-*SRR*-α-T from RBC to Plasma and from Plasma to RBC

α-T, α-tocopherol; RBC, red blood cells.

[a]Mean values for the six experiments ± S.E. of this mean are $(D^{RBC \to P})^{RBC}$ = 0.78 ± 0.05; $(D^{RBC \to P})^{P}$ = 0.78 ± 0.05; $(D^{P \to RBC})^{RBC}$ = 1.04 ± 0.15; $(D^{P \to RBC})^{P}$ = 1.04 ± 0.06.

d_6-*RRR*-α-T and d_3-*SRR*-α-T in the plasma, so the measurement of $(D^{P \to RBC})^P$ is usually subject to somewhat larger errors.

Results of our six d_6-*RRR*-α-T/d_3-*SRR*-α-T competitive kinetic experiments are summarized in Table 2.

DISCUSSION

As mentioned in the introduction, we have previously shown that in vivo the *RRR*-α-T/*SRR*-α-T ratio is higher in RBC than in the surrounding plasma (10). Our present results identify the major kinetic reason for the RBC biodiscrimination: RBC preferentially retain the natural stereoisomer. That is, *SRR*-α-T is transported from the RBC to the plasma more rapidly than *RRR*-α-T: $(D^{RBC \to P})^{RBC} = (D^{RBC \to P})^P = 0.78 \pm 0.05$ (mean of the six experimental results ± S.E. of mean). If there is any biodiscrimination in the transport from plasma to RBC, it appears to favor very slightly the transport of *RRR*-α-T: $(D^{P \to RBC})^{RBC} = 1.04 \pm 0.15$, $(D^{P \to RBC})^P = 1.04 \pm 0.06$ (mean of the six experimental results ± S.E. of mean, see Table 2). However, this preference for entry of *RRR*-α-T into RBC is well within our experimental error. Were biodiscrimination by RBC due solely to preferential retention of *RRR*-α-T, our earlier in vivo results would require that $D^{RBC \to P} = 0.74 \pm 0.07$. This value is consistent with our present direct measurement of this quantity, 0.78 ± 0.05.

The preferential retention of (natural) *RRR*-α-T by RBC must not be taken as providing supporting evidence for the existence of specific binding sites for *RRR*-α-T in these cells, as suggested by Kitabchi and Wimalasena (19). After all, the degree of biodiscrimination is rather small. We believe it to be of a magnitude consistent with the degree of chiral discrimination that might be exerted as a "solvent effect" by the chiral molecules that go to make up the RBC membrane (phospholipids, cholesterol, proteins, etc.). That is, the chirality "sensed" by tocopherol in the more structured environment of the RBC membrane is greater than in the lipid milieu of the low density lipoprotein. An attempt to check on this point by partitioning the deuterated tocopherols between a silanized glass surface (16,20) and RBC suspended in phosphate-buffered saline was unsuccessful. No transfer between the surface and the RBC could be observed.

Finally, there was no indication in the exchange experiments that the α-T located on the inside of the RBC exchanged more slowly than the α-T on the outside of the cell. Specifically, there was no indication of biphasic kinetics or of the existence of a pool of nonexchanging α-T. This implies that the half-life, $t_{1/2}$, for movement of α-T from the inside monolayer of the RBC membrane to the outside monolayer is less than 10^4 sec and probably is less than 10^3 sec. We have previously shown that motion of α-T between the inside and outside monolayers of unilamellar phospholipid vesicles is slow on the nuclear magnetic resonance time scale (21). Assuming α-T behaves similarly in RBC and liposomes, we conclude that 10^{-3} sec $< t_{1/2} \leqslant 10^3$ sec. The very broad limits on the rate of α-T "flip-flop" reflect the current state of knowledge concerning the dynamics of α-T in membranes.

[Received December 1, 1986]

APPENDIX: DERIVATION OF THE DISCRIMINATION PARAMETER, D

When deuterium-labeled *RRR*- and *SRR*-stereoisomers are present initially either entirely in RBC or entirely in plasma, the initial rate of loss of each stereoisomer from the labeled blood component can be written as

$$\frac{d(RRR)}{dt} = -k_R(RRR)_0 \qquad [5]$$

$$\frac{d(SRR)}{dt} = -k_S\,(SRR)_0 \qquad [6]$$

where k_R and k_S are rate constants for loss of the *RRR*- and *SRR*-stereoisomers, respectively. The discrimination parameter, D, is defined as

$$D = \frac{k_R}{k_S} \qquad [7]$$

Substituting for k_R and k_S in [7],

$$D = \frac{\dfrac{d(RRR)}{dt}}{\dfrac{d(SRR)}{dt}} \cdot \frac{(SRR)_0}{(RRR)_0}$$

For a small time interval, Δt,

$$D \cong \frac{\dfrac{\Delta(RRR)}{\Delta t}}{\dfrac{\Delta(SRR)}{\Delta t}} \cdot \frac{(SRR)_0}{(RRR)_0}$$

$$\text{i.e.,}\quad D \cong \frac{(RRR)_0 - (RRR)_t}{(SRR)_0 - (SRR)_t} \cdot \frac{(SRR)_0}{(RRR)_0} \qquad [8]$$

Similarly, an equation can be written corresponding to the discrimination in the gain of the two stereoisomers by the unlabeled blood component.

Effects of Phorbol Esters, A23187 and Vasopressin on Oleate Metabolism in Isolated Rat Hepatocytes

Takahide Nomura*, **Masakatsu Tachibana**, **Hiroko Nomura**, **Masaru Chihara** and **Yasumichi Hagino**
Department of Pharmacology, Fujita-Gakuen Health University, School of Medicine, Kutsukake-cho, Toyoake, Aichi 470-11, Japan

Studies were conducted to compare the metabolic effects of vasopressin, 4β-phorbol-12-myristate-13-acetate (PMA) and A23187 on ketogenesis and oleate metabolism in isolated hepatocytes from fed rats. Vasopressin inhibited the formation of acid-soluble products from [1-^{14}C]oleate (0.25 mM, 0.5 mM and 1 mM), the inhibition being most marked at low (0.25 mM) concentration of oleate. Conversion of [1-^{14}C]oleate into $^{14}CO_2$ and esterified products was stimulated by vasopressin. The stimulatory effect of this hormone on $^{14}CO_2$ production was most marked at high (1 mM) concentration of oleate, whereas that on [1-^{14}C]-oleate esterification was most marked at low (0.25 mM) concentration of oleate. These vasopressin actions were abolished when hepatocytes were incubated in the absence of calcium in the medium. Our results strongly suggest that both increase in esterification and increase in oxidation to CO_2 contribute to the anti-ketogenic action of vasopressin when oleate is added as substrate, although the relative extent of their contribution varies according to the oleate concentration. The anti-ketogenic action of vasopressin was mimicked by PMA but not by A23187. PMA also caused a stimulation of [1-^{14}C]oleate esterification although the effect was diminished at 1 mM [1-^{14}C]oleate. A23187 failed to affect [1-^{14}C]oleate esterification. The metabolic effects of PMA were elicited in the absence of extracellular calcium, too. Conversion of [1-^{14}C]oleate into $^{14}CO_2$ was only slightly increased by both PMA and A23187 when 1 mM [1-^{14}C]oleate was added as substrate. The marked stimulatory effect of vasopressin on $^{14}CO_2$ production from [1-^{14}C]oleate was not reproduced even by the combination of PMA and A23187. The possible involvement of protein kinase C and calcium mobilization in the regulation of oleate metabolism is discussed.
Lipids 22, **474–479 (1987).**

Vasopressin has been demonstrated not to change the hepatic level of cyclic AMP (1) but to act through the hydrolysis of phosphatidylinositol 4,5-bis-phosphate (2–4). Indeed, evidence is accumulating that vasopressin increases inositol trisphosphate (5,6) as well as diacylglycerol (7–9) in isolated rat hepatocytes. Inositol trisphosphate is a second messenger for intracellular Ca^{++} mobilization (5,6,10,11), whereas diacylglycerol acts as a second messenger to activate calcium-activated, phospholipid-dependent protein kinase, protein kinase C (12,13). The calcium ionophore A23187 can cause Ca^{++} mobilization in hepatocytes (14). The tumor-promoting phorbol esters such as 4β-phorbol-12-myristate-13-acetate (PMA) can activate protein kinase C by substituting for diacylglycerol (13,15). These two compounds, therefore, appear to be good probes for investigating the possible role of a bifurcated transducing mechanism in the action of vasopressin.

Vasopressin affects oleate metabolism in isolated hepatocytes of fed rats, i.e., it inhibits ketogenesis from oleate (16,17), stimulates the conversion of [1-^{14}C]oleate into $^{14}CO_2$ (18) and increases [1-^{14}C]oleate esterification (16). However, no general consensus exists as to which transducing mechanism is responsible for each of these vasopressin actions. Furthermore, it remains controversial as to how these metabolic effects are interrelated. The present study was, therefore, designed to compare the effects of vasopressin, phorbol esters and A23187 on ketogenesis and oleate metabolism in isolated hepatocytes of fed rats and to gain further insight into the hormonal regulation of oleate metabolism.

MATERIALS AND METHODS

Animals. Male Wistar rats (300–400 g) were used. All animals were subjected to a 12-hr light/12-hr dark cycle, with the light period starting at 7:00 a.m., for at least 7 days prior to the experiment. The rats were allowed free access to water and standard laboratory food (Oriental Yeast Co., Tokyo, Japan).

Isolation and incubation of hepatocytes. Preparation of hepatocytes commenced between 9:00 and 10:00 a.m. by the method of Berry and Friend (19) with the modifications described by Harris (20). Calcium-depleted cells were prepared by omitting $CaCl_2$ from the Krebs-Henseleit buffer used for washing. They were incubated in Krebs-Henseleit buffer containing 1 mM ethyleneglycol-bis-(β-aminoethyl ether)N,N′-tetraacetic acid (EGTA) but no calcium. Phorbol esters and calcium ionophore A23187 were dissolved in dimethyl sulfoxide. The concentration of dimethyl sulfoxide in the incubation medium was always 1% (v/v). Incubations were carried out at 37 C for 30 min with 70–90 mg wet weight of hepatocytes in 25-ml Erlenmeyer flasks in a final volume of 2 ml of incubation medium and were terminated with $HClO_4$.

Analytical methods. Metabolite assays were conducted on KOH-neutralized $HClO_4$ extracts. The following metabolites were determined spectrophotometrically by standard enzymatic methods: glucose (21), lactate and pyruvate (22), and acetoacetate and β-hydroxybutyrate (23). Ketogenesis was expressed in terms of an accumulation of total ketone bodies (acetoacetate plus β-hydroxybutyrate). The measurements of $^{14}CO_2$ production and the formation of radioactive acid-soluble products (mainly ketone bodies) were performed essentially as described by Christiansen et al. (24) and Yount and Harris (25). The extent of [1-^{14}C]oleate esterification was determined as described by McCune et al. (26).

Materials. [1-^{14}C]Oleate was obtained from New England Nuclear (Boston, MA). Collagenase (Type II) was obtained from Worthington Biochemical Corp. (Freehold, NJ). [Arginine]vasopressin was purchased from Peptide Institute (Minoh, Japan). Phorbol esters were obtained from Sigma Chemical Co. (St. Louis, MO). A23187 was

from Calbiochem (San Diego, CA). Nucleotides, coenzymes and crystalline enzymes were obtained from Boehringer Mannheim (Mannheim, FRG) or from Sigma.

Statistical analysis. The results are expressed as means ± SEM. Statistical evaluation of the data was made by means of Student's t-test for paired data.

RESULTS

Effects of vasopressin, PMA and A23187 on glucose release, glycolysis and ketogenesis in the presence of 0.5 mM oleate. Metabolic effects of 10^{-7} M vasopressin, 10^{-6} M PMA and 10^{-5} M A23187 in the presence of 0.5 mM oleate are summarized in Table 1. Vasopressin stimulated glucose release and lactate and pyruvate accumulation in the presence of 0.5 mM oleate. The ratio of lactate/pyruvate, an index of the NAD^+ redox state in the cytoplasm, was significantly decreased (more oxidized) by vasopressin. Production of total ketone bodies was suppressed by this hormone. Along with the inhibition of ketogenesis, the ratio of β-hydroxybutyrate/acetoacetate, an index of the NAD^+ redox state in the mitochondria, was also decreased (more oxidized). The present results are in good agreement with the vasopressin actions previously observed in the presence of 1 mM oleate (16,17). A23187 produced a marked increase in glucose release like vasopressin, whereas PMA caused only a slight increase in it. Lactate and pyruvate accumulation was stimulated by both PMA and A23187, although the effect of the latter was more potent. A23187 significantly decreased the ratio of lactate/pyruvate, while PMA did not affect it. Ketogenesis from oleate was inhibited by PMA but not affected by A23187. Furthermore, PMA caused a decrease in the ratio of β-hydroxybutyrate/acetoacetate. The combination of PMA and A23187 produced an additive stimulation of lactate and pyruvate accumulation. Increase in glucose release by A23187 and inhibition of ketogenesis by PMA were not affected by the addition of PMA and A23187, respectively.

Effects of vasopressin, PMA and A23187 on glucose release, glycolysis and ketogenesis in the absence of oleate. Metabolic effects of 10^{-7} M vasopressin, 10^{-6} M PMA and 10^{-5} M A23187 in the absence of oleate are summarized in Table 2. The effect of vasopressin on glucose

[a]Incubations were conducted for 30 min. Results are expressed as the mean ± SEM for five hepatocyte preparations from fed rats (μmol/30 min/g wet wt). Values in parentheses are percent of control. *, $P < 0.05$, compared with control incubations.

release was mimicked by A23187. PMA slightly increased glucose release. Corvera and García-Sáinz (27) reported that A23187 but not PMA stimulated glucose release in isolated hepatocytes of fed rats. The slight increase in glucose release by PMA observed in the present study may reflect the inactivation of glycogen synthase by PMA (28,29). Vasopressin and A23187 exerted no effect on lactate and pyruvate accumulation in the absence of oleate. In contrast, PMA caused a significant increase in lactate and pyruvate accumulation in the absence of oleate, also. The lactate/pyruvate ratio was significantly ($P < 0.05$) increased (more reduced) by A23187 (control; 2.7 ± 0.1, A23187; 4.3 ± 0.3, N = 5), whereas neither PMA nor vasopressin affected it (data not shown). Endogenous ketogenesis (i.e., in the absence of exogenous oleate) was not affected by vasopressin or PMA. However, A23187 produced a marked stimulation of endogenous ketogenesis. The combination of PMA and A23187 did not modify the metabolic effects induced by PMA or A23187 alone.

Dose response of PMA on ketogenesis and glycolysis in the presence of oleate. Increasing concentrations of PMA caused a progressive inhibition of both ketogenesis from 0.5 mM oleate and the formation of acid-soluble products from 0.5 mM [1-^{14}C]oleate (Fig. 1). The maximal effect was seen at 10^{-6} M and was equivalent to 26% inhibition for ketogenesis and 21% inhibition for the formation of acid-soluble products. In accordance with these effects, PMA produced a marked stimulation of lactate and pyruvate accumulation. The maximal effect was seen at 3×10^{-7} M and was equivalent to a 65% increase. In contrast with PMA, the inactive phorbol ester 4α-phorbol-12,13-didecanoate (4α-PDD; 10^{-5} M) did not affect these metabolic processes (Fig. 1).

Effects of vasopressin, PMA and A23187 on the oxidation and esterification of different concentrations of [1-^{14}C]oleate in isolated hepatocytes. The hormonal response of hepatocytes is known to be modified according to the concentrations of added oleate (30). Thus we decided to investigate the effects of agents on the metabolism of various concentrations of [1-^{14}C]oleate, i.e., 0.25 mM, 0.5 mM and 1 mM. The results are summarized in Table 3. Vasopressin (10^{-7} M) inhibited the formation of acid-soluble products from [1-^{14}C]oleate at all three oleate concentrations. Furthermore, the lower the concentration of [1-^{14}C]oleate, the stronger the inhibition, on the basis of percent of control. Vasopressin caused a significant stimulation of $^{14}CO_2$ production from 0.5 mM and 1 mM [1-^{14}C]oleate. The most striking stimulation was observed at 1 mM [1-^{14}C]oleate, whereas vasopressin did not affect $^{14}CO_2$ production at 0.25 mM [1-^{14}C]oleate. Oleate esterification was significantly increased by vasopressin. This action of vasopressin became more marked the lower the oleate concentration. PMA (10^{-6} M) mimicked the inhibitory effect of vasopressin on the formation of acid-soluble products from [1-^{14}C]oleate. The inhibition by PMA also became more marked the lower the concentration of oleate. The esterification of 0.25 mM and 0.5 mM [1-^{14}C]oleate was increased by PMA. The stimulatory effect of PMA on [1-^{14}C]oleate esterification was attenuated with increased concentration of oleate. No significant stimulation of esterification was observed at 1 mM [1-^{14}C]oleate. PMA modestly increased $^{14}CO_2$ production from 1 mM [1-^{14}C]oleate, while it slightly decreased that from 0.25 mM [1-^{14}C]oleate. A23187 (10^{-5} M) exerted only a small effect on [1-^{14}C]oleate metabolism, i.e., a slight decrease in the formation of acid-soluble products from 0.25 mM and 0.5 mM [1-^{14}C]oleate and a slight increase in $^{14}CO_2$ formation from 1 mM [1-^{14}C]oleate.

Metabolic effects of PMA and vasopressin in calcium-depleted hepatocytes. The metabolic actions of vasopressin—i.e., increase in glucose release, stimulation of lactate and pyruvate accumulation, inhibition of ketogenesis, decrease in the formation of acid-soluble products from [1-^{14}C]oleate (0.25 mM) and the stimulation of [1-^{14}C]oleate (0.25 mM) esterification (Tables 1 and 3)—were abolished when hepatocytes were incubated in Krebs-Henseleit buffer containing 1 mM EGTA but no calcium (Table 4). We observed that the effects of vasopressin on 0.5 mM [1-^{14}C]oleate metabolism (Table 3) were also abolished by calcium depletion (data not shown). In contrast with vasopressin, PMA elicited the metabolic actions even in the absence of Ca^{++}, although

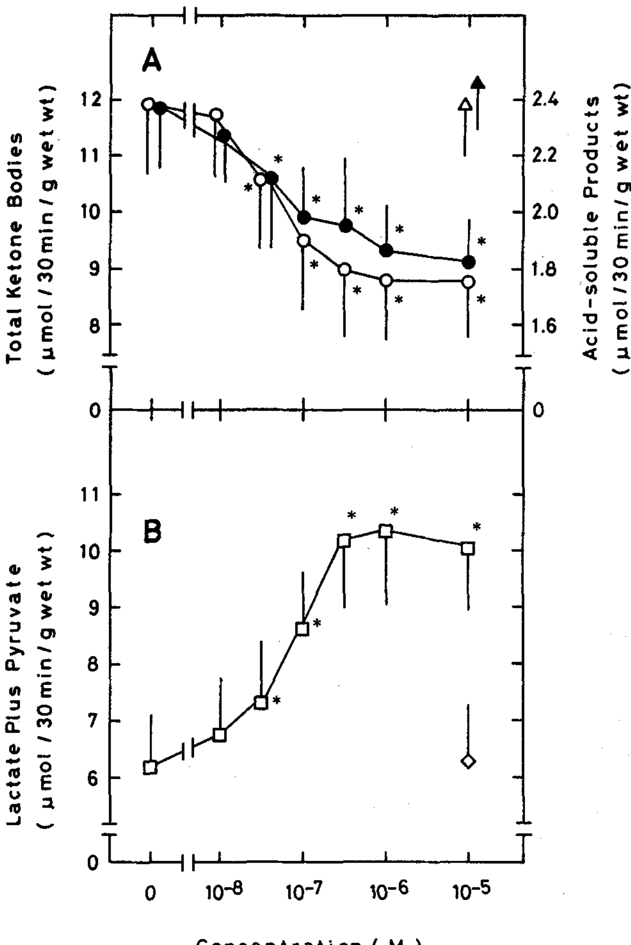

FIG. 1. Effects of phorbol esters on total ketone bodies, acid-soluble products and lactate plus pyruvate. Oleate was 0.5 mM. [1-^{14}C]Oleate was added for the measurement of acid-soluble radioactive products. Incubations were conducted for 30 min. A: effects of 4β-phorbol-12-myristate-13-acetate (PMA, ○) and 4α-phorbol-12,13-didecanoate (4α-PDD, △) on total ketone bodies; effects of PMA (●) and 4α-PDD (▲) on acid-soluble products. B: effects of PMA (□) and 4α-PDD (◇) on lactate plus pyruvate. Each point represents the mean ± SEM of 3-4 hepatocyte preparations. *, $P < 0.05$, compared with control incubations.

the effects on ketogenesis and on the formation of acid-soluble products were somewhat attenuated (Table 4). Stimulation of glucose release by A23187 was completely eliminated by Ca^{++} depletion, whereas that of lactate and pyruvate accumulation was partially eliminated (Table 4).

DISCUSSION

The underlying mechanism of the anti-ketogenic action of vasopressin is not yet understood. Sugden et al. (18) documented that the inhibition of ketogenesis by

[a]Calcium-depleted hepatocytes were prepared as described in Materials and Methods. They were incubated for 30 min in Krebs-Henseleit buffer containing 1 mM EGTA but no calcium. Results are expressed as the mean ± SEM for four or five hepatocyte preparations from fed rats. Values in parentheses are percent of control. *, $P < 0.05$, compared with control incubations.

[b]Oleate was 0.5 mM. Results are expressed as μmol/30 min/g wet wt.

[c]Since the effects of vasopressin and PMA on these parameters in the presence of calcium were found to be most marked at 0.25 mM [1-^{14}C]oleate (Table 3), the effect of calcium depletion was studied under this concentration. Results are expressed as μmol oleate utilized/30 min/g wet wt.

[d]Since the agents produced less marked or no effects in the presence of calcium (Tables 1 and 3), effects of calcium depletion were not studied.

vasopressin is not a consequence of an increased rate of esterification but is related to increased oxidation of oleate to CO_2. Their conclusion was based on the observation that the increase in esterification of [1-^{14}C]oleate was not dependent on the presence of Ca^{++}, whereas the other effects of vasopressin were. Here, however, we emphasize the involvement of the enhancement of oleate esterification as well as the stimulation of CO_2 production from oleate in the anti-ketogenic action of vasopressin for the following lines of reasoning: First, the suppression by vasopressin of the formation of acid-soluble products from 0.25 mM [1-^{14}C]oleate occurred without any change in $^{14}CO_2$ production but with the stimulation of esterification (Table 3). Second, the data given in Table 3 indicate that the decreased rate of production of acid-soluble products from [1-^{14}C]oleate (0.5 mM and 1 mM) in response to vasopressin can be explained by the sum of the increased rates of $^{14}CO_2$ formation and [1-^{14}C]oleate esterification. Third, it is clear in the present study that the effects of vasopressin on [1-^{14}C]oleate metabolism are all dependent on the presence of Ca^{++} (Table 4). Our previous results (17) demonstrated that vasopressin failed to affect the esterification of 1 mM [1-^{14}C]oleate and with our present results indicate that the role of [1-^{14}C]oleate esterification in the anti-ketogenic action of vasopressin gradually tends to diminish, whereas that of oxidation of [1-^{14}C]oleate to $^{14}CO_2$ increases as the concentration of [1-^{14}C]oleate increases. It has been reported that increased $^{14}CO_2$ production is caused as a consequence of decreased β-oxidation of [1-^{14}C]oleate (31,32). Therefore, increased $^{14}CO_2$ formation from 0.5 mM and 1 mM [1-^{14}C]oleate in response to vasopressin may be not the cause but the result of inhibition of ketogenesis by this hormone.

Our results clearly show that PMA mimicks the effects of vasopressin on oleate metabolism, i.e., inhibition of ketogenesis from oleate, suppression of the formation of acid-soluble products from [1-^{14}C]oleate and stimulation of [1-^{14}C]oleate esterification. We found that another active tumor promotor, 4β-phorbol-12,13-didecanoate (4β-PDD; 10^{-6} M), also significantly inhibited ($P < 0.05$) the formation of acid-soluble products (control; 1.67 $\pm$ 0.21 μmol/30 min/g wet wt, 4β-PDD; 1.30 $\pm$ 0.15 μmol/30 min/g wet wt, n = 3) and stimulated ($P < 0.05$) esterification (control; 1.24 $\pm$ 0.32 μmol/30 min/g wet wt, 4β-PDD; 1.61 $\pm$ 0.21 μmol/30 min/g wet wt, n = 3), when 0.5 mM [1-^{14}C]oleate was added as substrate. The inactive phorbol ester 4α-PDD failed to affect ketogenesis from oleate (Fig. 1). These findings, therefore, strongly suggest that protein kinase C plays an important role in vasopressin actions. Vaartjes and de Haas (33) reported a similar inhibition of ketogenesis from oleate and stimulation of oleate esterification in response to PMA. Kojima et al. (34), on the other hand, documented that PMA alone did not affect the formation of acid-soluble products from [U-^{14}C]palmitate. At this time, we can offer no explanations for the discrepancy between our results and those of Kojima et al. (34). Table 3 shows that the inhibition of the formation of acid-soluble products from 0.25 mM [1-^{14}C]oleate in response to PMA can be attributed to the stimulation of [1-^{14}C]oleate esterification. However, at high concentrations (0.5 mM and 1 mM) of [1-^{14}C]oleate, the contribution of oleate esterification and CO_2 production to the anti-ketogenic action of PMA is less marked than that of vasopressin. We observed that PMA caused a significant inhibition of $^{14}CO_2$ formation from 0.25 mM [1-^{14}C]oleate (Table 3). Vaartjes and de Haas (33) observed similar inhibition with 0.5 mM [1-^{14}C]oleate. We suspect that the decreased CO_2 production as well as suppressed formation of acid-soluble products may be balanced by the accelerated oleate esterification at low concentration of oleate.

In contrast with PMA, A23187 had little effect either on ketogenesis from oleate (Table 1) or on [1-^{14}C]oleate metabolism (Table 3). This suggests that intracellular calcium mobilization is not likely to affect oleate metabolism. Acceleration of endogenous ketogenesis by A23187 (Table 2) was abolished by calcium depletion (data not shown). Calcium mobilization may therefore be involved in the mechanism. Further elucidation of the substrate for the ketone bodies is required.

Neither A23187 nor PMA mimicked the marked stimulatory effect of vasopressin on $^{14}CO_2$ production (Table 3). It remains to be seen whether or not other mediator(s), such as cyclooxygenase product(s), are involved in the regulation.

All three agents stimulated lactate and pyruvate accumulation in the presence of oleate (Table 1). Lactate and pyruvate are known to have an anti-ketogenic action (35). Nevertheless, A23187 failed to affect ketogenesis from oleate. Our data therefore suggest that the stimulated accumulation of lactate and pyruvate does not necessarily lead to a suppression of ketogenesis. Almås et al. (36) reported that the anti-ketogenic action of vasopressin was not the result of increased lactate production. Recently, it has been reported that PMA (33,37) and vasopressin (17,38,39) stimulate fatty acid synthesis but A23187 does not affect it (39). Part of the inhibition of ketogenesis by PMA and vasopressin may be related to the increased fatty acid synthesis, i.e., the elevation of malonyl-CoA levels (40).

We stress that the ability of PMA to affect oleate metabolism was observed even in the absence of extracellular calcium (Table 4). This suggests that PMA stimulates protein kinase C, which has a low requirement for Ca^{++} (15). In contrast to PMA, the effects of vasopressin on oleate metabolism were eliminated by calcium depletion (Table 4). However, if the effects of vasopressin on [1-^{14}C]oleate metabolism (except for $^{14}CO_2$ production) were mediated through the activation of protein kinase C (discussed above), why were these vasopressin actions all abolished by calcium depletion? Bocckino et al. (9) documented that Ca^{++} depletion decreases the ability of vasopressin to increase diacylglycerol. Therefore, Ca^{++} probably mediates some effects of vasopressin on diacylglycerol accumulation. It is also suggested that the involvement of a Ca^{++}-activated kinase(s) is required to elicit vasopressin actions in oleate metabolism.

[Received December 4, 1986]

FAB MS/MS for Phosphatidylinositol, -glycerol, -ethanolamine and Other Complex Phospholipids

Nancy J. Jensen, Kenneth B. Tomer and Michael L. Gross*
Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588

Fast atom bombardment (FAB) of phosphatidylinositol, phosphatidylethanolamine, cardiolipin, phosphatidic acid and phosphatidylglycerol produces a limited number of very infomative negative ions. Especially significant is the formation of $(M-H)^-$ ions and ions that correspond to the carboxylate portions of these molecules. FAB desorption in combination with collisional activation allows for characterization of fragmentation and determination of structural features. Collisional activation of the carboxylate anion from complex lipids is especially informative. Structural characterization of the fatty acids can be achieved as the released saturated carboxylate anions undergo highly specific charge remote fragmentations that are entirely consistent with the chemistry of carboxylate anions desorbed from free fatty acids. This permits both identification of the modification and assignment of its location on the acid chain. FAB-desorbed alkyl acetyl glycerophosphocholines (platelet-activating factor) do not produce $(M-H)^-$ ions. However, significant high mass ions are formed, and these can be collisionally activated for structural characterization.
Lipids 22, 480–489 (1987).

A variety of mass spectrometry methods has proven useful to analyze phospholipid compounds (1). One method recently shown to be quite useful is fast atom bombardment (FAB) in combination with tandem mass spectrometry (MS/MS) (1–5). We first reported the use of FAB and MS/MS for analysis of phospatidylcholine (2,3) and in subsequent work explored its use for phosphatidylserine (1) and phosphatidylinositol (4). The present work continues the study of phosphatidylinositol and extends these studies to other complex lipids.

Since its development in the early 1980s by Barber et al. (6), FAB has proven to be a very useful desorption method for many labile biomolecules. A number of workers have used FAB for desorbing phospholipid cations (7–16). It was found that $(M+H)^+$ ions of substantial abundance are formed by this method. Although the positive ion mode is used more commonly, FAB mass spectra of negative phospholipid ions also have been studied (1–5,11,17). Phosphatidylcholine typically desorbs to give three high mass anions formed by losses of various portions of the choline moiety and two low mass ions that are the free fatty acid carboxylates from the original complex lipid (1–4). Phosphatidylserine (1,4) and phosphatidylinositol (4,5,17) yield abundant $(M-H)^-$ ions and carboxylate ions corresponding to the two fatty acid components.

Although MS/MS has proven successful for both structural characterization and mixture analysis of a wide range of compounds, reports of its use for phospholipid analysis have been limited (1–5,18). Batrakov et al. (18) used MS/MS methods with electron ionization (EI) to study phospholipids. Typically, molecular ions are either stable or not formed under EI conditions; however, certain high mass ions that are suitable for mixture characterization are produced (18). In addition to our work with FAB MS/MS for analysis of phosphatidylcholines and phosphatidylserine (1–3), both our group (4) and Sherman et al. (5) reported the application of such methods to the study of phosphatidylinositol. The relatively abundant $(M-H)^-$ ions generated by FAB desorption of phosphatidylserine and phosphatidylinositol are well suited to this analysis method. Sherman et al. (5) demonstrated that the fatty acid composition of isomeric phosphatidylinositols can be determined by analyzing the daughter ion spectra even if the constituent fatty acids are similar (e.g., two constituents could be either 18:1 and 18:1, or 18:0 and 18:2). The determination can be made if MS-II has approximately unit resolution, as was demonstrated by using a BEB triple sector MS/MS instrument.

MS/MS methods offer obvious advantages in mixture analysis or for samples of questionable purity. Analysis of spectra of negative daughter ions provides information that is complementary to positive ion analysis. Additional advantages pertain to negative ions because (i) they usually desorb to yield simpler spectra than do positive ions; (ii) they more readily yield ions in the molecular ion region [e.g., $(M-H)^-$ for some compounds, such as phosphatidylserine]; and (iii) they produce abundant carboxylate fragments from complex lipids having esterified acid substituents. Selection and collisional activation of the carboxylate anions is particularly informative. We showed that the identity of the acid, the presence of structural modifications on the acid chain and the identity and location of such modifications may be readily determined from the collisionally activated decomposition (CAD) spectra of carboxylate anions (2,3,19–23).

In this work, we extend previous investigations of phosphatidylinositol and investigate the application of negative ion FAB MS/MS methods to the study of phosphatidylethanolamine, phosphatidylglycerol, cardiolipin, phosphatidic acid and platelet-activating factor (PAF) and its analogs. PAF is an especially interesting phospholipid because it is biologically active.

EXPERIMENTAL PROCEDURES

The Kratos MS-50 triple sector mass spectrometer used in this study is described elsewhere (24). This instrument is equipped with a standard Kratos FAB source and an Ion Tech gun and was operated as described previously for negative ion FAB and CAD analysis (4).

Materials. 1-*O*-(9-Octadecenyl)-2-*O*-acetyl-*sn*-glycero-3-phosphocholine was obtained from Bachem (Bubendorf, Switzerland). Other phospholipids were from Sigma Chemical Co. (St. Louis, Missouri). 1-*O*-Hexadecyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine (PAF), dipalmitoyl *N,N*-dimethyl-phosphatidylethanolamine, dipalmitoyl phosphatidylethanolamine, dipalmitoyl phosphatidic acid, distearoyl phosphatidic acid and dipalmitoyl phos-

phatidylglycerol were obtained as characterized compounds. Fatty acid compositions of phosphatidylinositol from soybean and cardiolipin from bovine heart were not specified by the commercial source.

Triethanolamine, dithiothreitol and dithioerythreitol were obtained from Aldrich (Milwaukee, Wisconsin). Triethanolamine was used as a matrix as supplied. Dithiothreitol and dithioerythritol were mixed in a 5:1 ratio to form the DT matrix.

RESULTS AND DISCUSSION

Negative ions were chosen for this study for several reasons. First, collisionally activated fatty acid fragments produced from complex lipids should yield the same highly distinctive structural information as do the free fatty acid carboxylates desorbed by using FAB. Second, in the positive ion mode, relatively abundant $(M-H)^+$ ions are generated along with $(M+H)^+$ ions of fatty acids, and the former will overlap with other fatty acid fragments containing one or more sites of unsaturation (11). Third, less fragmentation is often observed for negative ions, and hence the process of selecting ions for collisional activation is facilitated.

MS/MS offers the opportunity to study mixtures of both fatty acids and more complex lipids, which is especially useful for samples of questionable purity.

Phosphatidylinositol. The spectra of typical negative phosphatidylinositol ions (**A**) desorbed by FAB have abundant $(M-H)^-$ anions and ions corresponding to the constituent fatty acid carboxylates in the original complex lipid.

A

As the spectrum in Figure 1A shows, phosphatidylinositol from soybeans is a mixture. The principal components are those phosphatidylinositols that give $(M-H)^-$ ions of m/z 833 and 857. However, species that give $(M-H)^-$ ions of m/z 831, 859 and 861 are also present.

Structural characterization of these mixture components as phosphatidylinositols is achieved by selecting and collisionally activating each ion. The principal daughter ions formed from the $(M-H)^-$ ion are carboxylates from the acyl chains, the m/z 241 ion (inositol phosphate–H_2O), the m/z 299 ion formed by loss of both acyl chains (structure **B**), the m/z 297 ion (formally the ion m/z 299-2H), ions formed by the loss of R_1CH_2COOH or R_2CH_2COOH and ions formed by the loss of R_1CHCO and R_2CHCO. The formulas of the ions of m/z 299 and 297 were established as $C_9H_{16}O_9P$ and $C_9H_{14}O_9P$, respectively, by high resolution peak matching.

B

The spectrum of the $(M-H)^-$ ion m/z 833 shown in Figure 1B is representative. Daughter ions of m/z 255 and 279 (labeled b and c in the figure) are carboxylate anions of the 16:0 and 18:2 acid chains, respectively; the m/z 553 ion (e) results from the loss of the 18:2 acid, and the m/z 577 ion (the principal component of peak f) results from the loss of the 16:0 acid. The peak labeled f in the CAD spectrum is broadened considerably, indicating that it may represent multiple ions. The ion m/z 571 is present in the FAB spectrum and hence may be a lesser component of the peak f. This ion is formed by the loss of $C_{16}H_{29}CHCO$ from the $(M-H)^-$ ion. The ion of m/z 595 is the result of the loss of $C_{14}H_{29}CHCO$ from the $(M-H)^-$ ion. Daughter ions of m/z 241 (a) and of m/z 299/297 (d), as noted above, are formed for all phosphatidylinositols and must arise from the glycerol inositolphosphate portion of the molecule. Unfortunately, the resolution of MS-II is not sufficient to resolve doublets spaced by 2 μ. However, the broadened nature of the peaks coupled with the fact that both the m/z 297 and 299 ions are found in the FAB mass spectrum support the existence of a doublet.

Selection by using MS-I and collisional activation of the ions formed by ketene loss and those formed by acid loss from the $(M-H)^-$ ion reveal an important difference in fragmentation behavior. The ions formed by ketene loss fragment to yield a significantly abundant ion of m/z 315 (C_3H_5O + inositol phosphate). The ions formed by loss of RCH_2COOH from the $(M-H)^-$ ion yield no appreciable m/z 315 ion, but rather the ion of m/z 297.

In a similar manner, ions of m/z 831 and 857 in the mixture were characterized as phosphatidylinositols composed of acid chains 16:0, 18:3 and 18:2, 18:2, respectively. Those giving $(M-H)^-$ ions of m/z 859 fragment to produce broadened peaks for the carboxylate daughter ions, which indicates that two species are involved, one with 18:2, 18:1 and the other with 18:3, 18:0 acid chains. Similarly, the $(M-H)^-$ ions of m/z 861 appear to include both 18:2, 18:0 and 18:1, 18:1 species. Clearly, an MS/MS instrument having unit resolution for MS-II would be a significant advantage in studying these phosphatidylinositols.

In addition to the daughter ions described above, a series of high mass daughter ions is present. The fragmentation that produces the ion series appears to be yet another example of the phenomenon we have described as remote-charge-site fragmentation (19–23). Upon collisional activation, closed-shell species that bear long alkyl chains yield a series of fragments arising by losses of the elements of C_nH_{2n+2} from the alkyl terminus remote from the charge site. These charge-remote fragmentations appear to occur via a highly specific 1,4 elimination of H_2, as was previously described (20). The presence of a structural modification

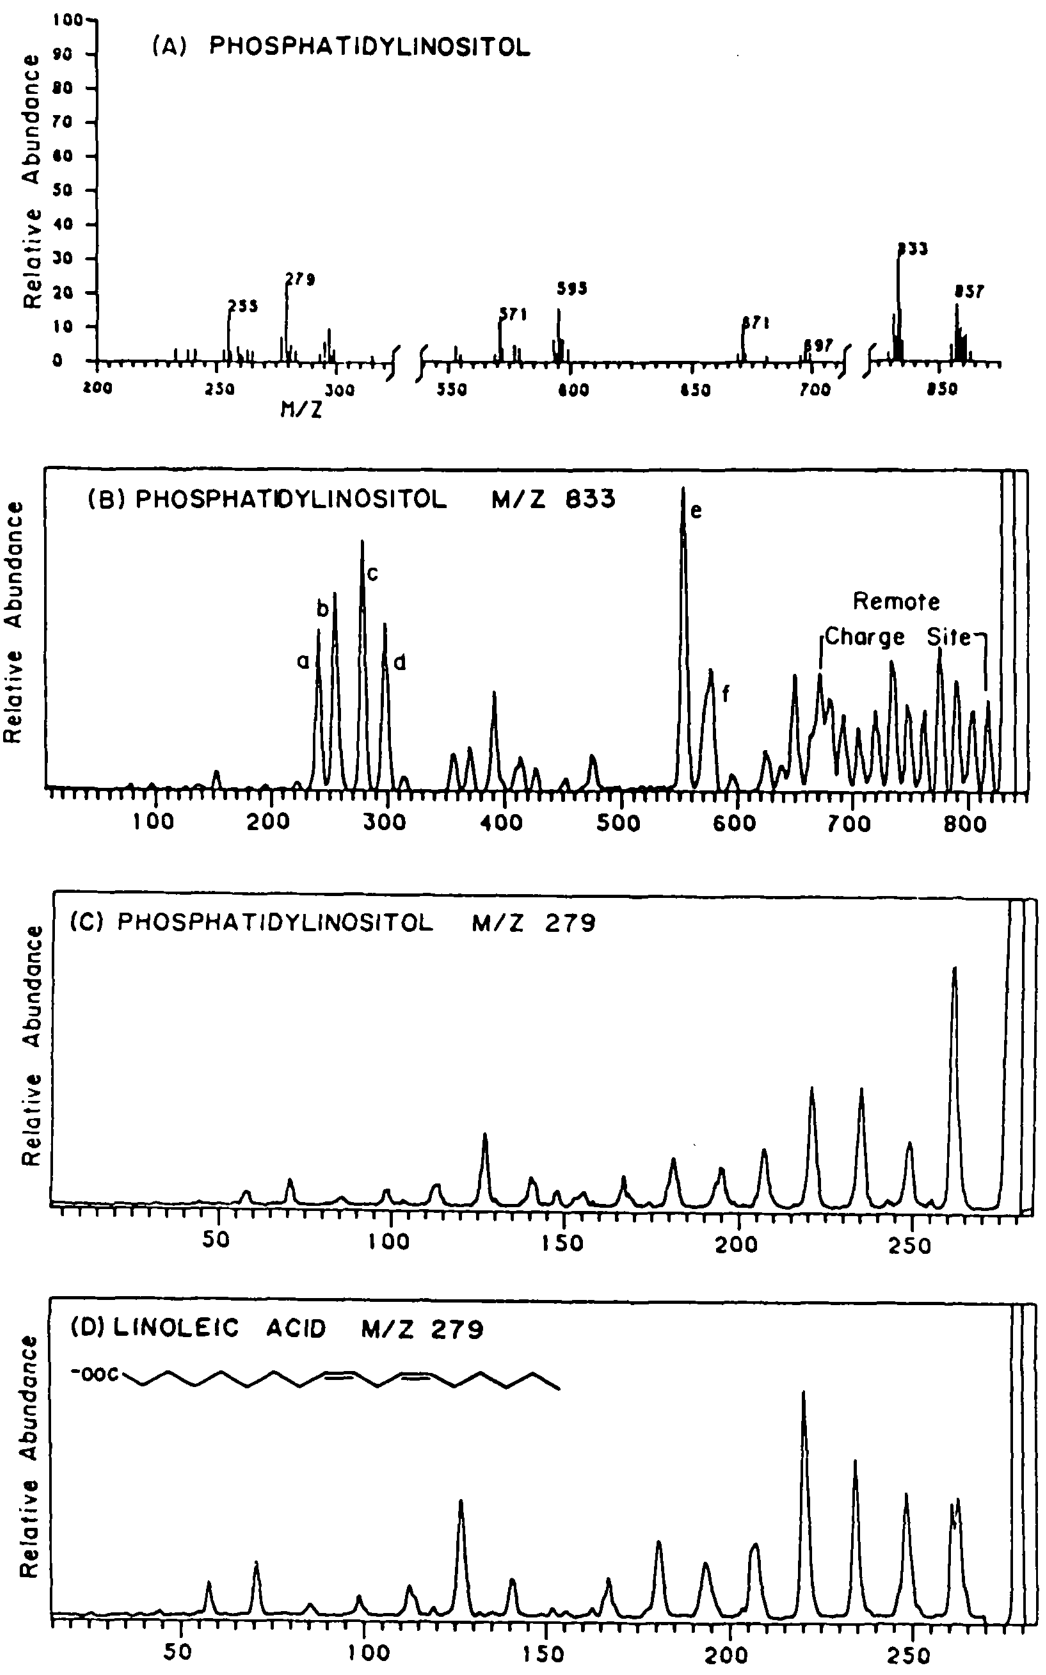

FIG. 1. (A) Mass spectrum of the negative ions produced by fast atom bombardment desorption of a mixture of phosphatidylinositols from soybeans. Ions in the region m/z 830–865 are $(M-H)^-$ ions of the inositols. (B) Spectrum of the daughter ions produced by collisionally activating the $(M-H)^-$ ion, m/z 833. (C) Spectrum of the daughter ions produced by collisionally activating the fragment ion of m/z 279. (D) Spectrum of the daughter ions produced by collisionally activating the $(M-H)^-$ ion, m/z 279, of authentic linoleic acid.

such as branching or a double bond alters the fragmentation pattern. For example, carboxylate anions having a double bond do not transfer a vinylic hydrogen and the double bond is not cleaved. Hence, the fragmentation is interrupted at the site of the double bond.

If only one long alkyl chain is present in the ion of interest, this type of fragmentation provides for highly specific structural characterization of the alkyl chain. Unfortunately, the $(M-H)^-$ anions of phosphatidylinositol contain two long alkyl chains. The remote-charge-site fragmentation of the $(M-H)^-$ ion is of diminished analytical value because it involves the fragmentation of one alkyl chain in competition with the parallel fragmentation of the other.

However, if the carboxylate anion fragments formed as a result of FAB desorption of phosphatidylinositol are selected and collisionally activated, they undergo the expected remote-charge-site fragmentations that allow for specific structural characterization of the acid chain. For example, collisional activation of the ion of m/z 279 (Fig. 1C) and comparison with an authentic sample of linoleic acid $(M-H)^-$ anion of m/z 279 (Fig. 1D) permits identification of the 18:2 acid as linoleic acid. The only notable difference between the two spectra is more abundant water loss for the fragment ion than for the linoleate ion desorbed from the pure acid. The abundant water loss is not unique to this sample, as it is observed typically for collisionally activated linoleate fragment ions. Collisional activation of the ions of m/z 255, 281 and 283 verified their structures as palmitic, oleic and stearic acid carboxylates, respectively. The abundances of the daughter ions formed by water loss are not significantly different than those from the $(M-H)^-$ of the pure acids.

The reason that the water loss is enhanced for the more highly unsaturated fragment ion but not for the others is not understood. However, water loss is a metastable process for carboxylate anions, whereas the remote-charge-site fragmentation is a high energy process seen only under conditions of collisional activation (20). Because the two processes are distinct, perhaps energy differences between the carboxylate desorbed from a free fatty acid and the ion generated as a fragment from a complex lipid are significant.

Characterization of the acid chains of a specific phosphatidylinositol in a mixture by MS/MS is straightforward if isomeric species (e.g., oleic and vaccenic) are not present. Collisional activation of the $(M-H)^-$ anion yields abundant daughter ions that reflect the masses of each of the two carboxylate chains. Carboxylate anions may then be selected for specific characterizations. If, however, two isomeric acid carboxylates are liberated from two different phosphatidylinositols, three stages of tandem mass spectrometry, MS/MS/MS (25), would be necessary to characterize the acid chain for each specific intact lipid.

The FAB MS/MS method offers several advantages over conventional methods in terms of specificity of structural information that may be obtained, especially with regard to the identities of the fatty acids. Because a phosphatidylinositol mixture was analyzed and authentic pure samples were not available, it was not possible to draw conclusions regarding the position of attachment of the acid chains on the phosphatidylinositol. However, on the basis of our previous work with phosphatidylcholine, it is very likely that relative abundances of selected daughter ions of the $(M-H)^-$ ion may indeed reveal such information (1–4).

Although the emphasis of this work is to explore the use of FAB MS/MS methods for qualitative identification and structural characterization of phospholipids, some consideration of quantification was made. For the soybean phosphatidylinositol mixture that was analyzed without prior separation or derivatization, ions corresponding to ca. 95% of the inositol components identified by Myher and Kuksis (26) were observed. Furthermore, the entire FAB MS/MS analysis of the major components of the mixture including collisional activation of the $(M-H)^-$ ions of various inositols was completed in an afternoon. This procedure is much more rapid than conventional methods that involve thin layer chromatographic, enzymatic hydrolysis, separation of hydrolysis products, derivatization of component fatty acids, preparation of trimethylsilyl derivatives of diacylglycerols and then analysis by gas chromatography (26).

Quantification of lipids with FAB MS/MS is not a straightforward process. In previous work with bile salts (27) and fatty acids (23), we found that desorption and/or response may vary considerably between two closely related species [i.e., a 1:1 mixture of two fatty acids may not show $(M-H)^-$ ion abundance in a 1:1 ratio]. However, quantification is possible if an appropriate set of standards is used (27). It is likely that this approach would be necessary for quantification of phosphatidylinositols. Although the relative abundances of the phosphatidylinositol $(M-H)^-$ ions remain relatively constant over the lifetime of the samples, we find that the ion of m/z 833 (the most abundant ion) is ~ 35% of the ions having a mass above m/z 830 (assuming equal response). Myher and Kuksis however report that the component giving this ion is ~ 60% (26).

Thus, although ca. 95% of the expected ions are observed, the distribution of the inositols calculated from the FAB data appears to be different from the reported values (26). This does not negate the value of the FAB MS data, but does underscore the need for caution in quantitative interpretation of the FAB spectrum and the need for use of a series of standards.

Phosphatidylglycerol. Dipalmitoyl phosphatidylglycerol (structure **C**) is representative of phospholipids in which the phosphate is linked with a second unsubstituted glycerol as the head group.

\end{array}
$$

C

The negative ion mass spectrum is similar to that of phosphatidylinositol because abundant $(M-H)^-$ ion and ions attributed to the carboxylate fragments are the principal ions observed for both (Fig. 2A). Ions of

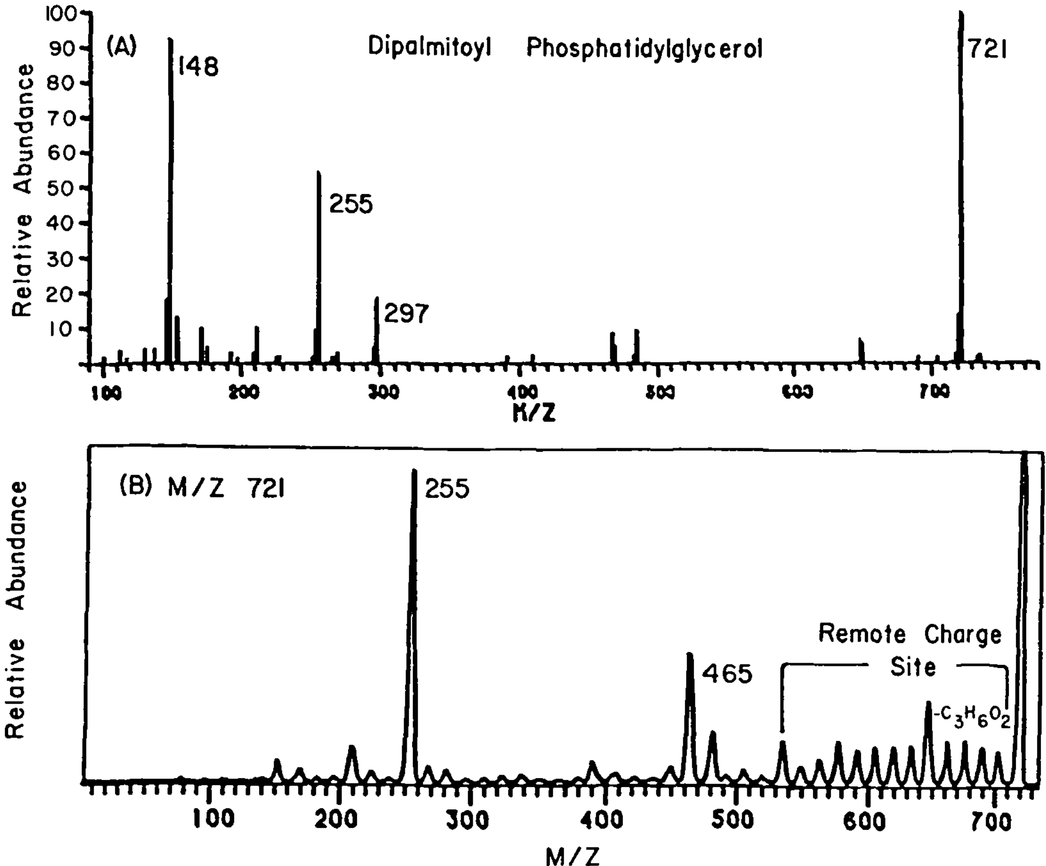

FIG. 2. (A) Mass spectrum of negative ions produced by fast atom bombardment desorption of dipalmitoyl phosphatidylglycerol. (B) Spectrum of daughter ions produced by collisionally activating the $(M-H)^-$ ion, m/z 721.

m/z 148 and m/z 297 are from the triethanolamine matrix.

Collisional activation of the $(M-H)^-$ ion of m/z 721 yields several informative daughter ions (Fig. 2B). The fragment of m/z 647 is formed by loss of $C_3H_6O_2$, presumably involving the loss of the unsubstituted glycerol portion of the molecule with H-transfer to the phosphate oxygen; another of m/z 465 is formed by loss of RCH_2COOH; the ion of m/z 483 is formed by the loss of RCHCO; and another of m/z 255 is attributed to the carboxylate anion. The formulas of the ions of m/z 465 and 483 were established as $C_{22}H_{42}O_8P$ and $C_{22}H_{44}O_9P$ by high resolution peak matching. Remote-charge-site fragmentation is also seen to produce a series of high mass daughter ions formed by losses of C_nH_{2n+2}. Because the constituent acids are the same, the pattern is simple and reflects the saturated nature of each acid. However, as noted for the phosphatidylinositols, remote-charge-site fragmentation of the collisionally activated $(M-H)^-$ anion is of more limited structural value when the acids are different because the fragmentations occurring from the two acyl portions of the molecule are competitive.

The acid chain is best characterized by collisionally activating the carboxylate fragment; for example, the ion of m/z 255 for dipalmitoyl phosphatidylglycerol. The ion undergoes remote-charge-site fragmentation to lose a series of C_nH_{2n+2} fragments and to give a pattern of daughter ions that is characteristic of the palmitic acid $(M-H)^-$ ion.

Cardiolipin. Cardiolipin (structure **D**) is a more complex relative of phosphatidylglycerol.

$R_1-CH_2-C(=O)-O-CH_2$ / $R_2-CH_2-C(=O)-O-CH$ / $H_2C-O-P(=O)(OH)-O-CH_2-CH(OH)-CH_2-O-P(=O)(OH)-O-CH_2$ / $HC-O-C(=O)-CH_2-R_4$ / $H_2C-O-C(=O)-CH_2-R_3$

D

Significant ions in the FAB mass spectrum of one example (Fig. 3A) are those of m/z 1448, 833, 695, 415 and 279. Two points should be noted with regard to these data. First, the highest mass ion observed approaches the mass limit of routine scans on the instrument used. Hence, verification that this was indeed the highest mass ion and that the nominal mass is 1448 u was accomplished using high mass calibration with CsI (the mass of the monoisotopic ion is 1447 u). Second, the spectrum shown is for the second sample of cardiolipin studied. The first sample that we obtained from a commercial source showed these ions as well as sodium adduct ions. The sodium contamination is not a major problem for spectral interpretation because the presence of Na^+ is readily identified by ions spaced by 22 u. However, high sodium ion levels disperse the ionization and reaise the detection limits.

Selection and collisional activation of the principal ions permit further characterization of the compound. The $(M-H)^-$ ion, m/z 1448, fragments to yield ions of m/z 833, 695, 415 and 279, the major ions of the FAB mass spectrum (Fig. 3B). Because the specific composition of the cardiolipin sample was not known, the CAD spectrum provides strong evidence that the sample is indeed a single compound. Formation of the ion of m/z 833 may be attributed to loss of the acyl glycerol portion of one phosphatidic acid group to give daughter ions of structure E.

F

For complex lipids, daughter ions in the mass range of m/z 255 to 311 can usually be attributed to carboxylate anions. The decomposition of the $(M-H)^-$ ion produces only the m/z 279 ion in this mass range. Thus, it is implied that all four acid groups of the cardiolipin are 18:2 acids. Characterization of the ion m/z 279 as the carboxylate anion of linoleic acid is achieved by comparing the collisionally activated decomposition of this ion with that of authentic linoleic acid (compare Figs. 3C and 1D). As for the decomposition product of m/z 279 from the phosphatidylinositol, the water loss is more abundant for the fragment ion than for the fatty acid carboxylate desorbed from the free acid (see above). However, all other fragmentations are comparable.

Collisional activation of the m/z 695 and 415 ions provides further information regarding their structures. The ion of m/z 695, presumably phosphatidic acid, fragments to yield the daughter ions m/z 443 (phospatidic acid – $RCHCO)^-$, m/z 415 (phosphatidic acid – $RCH_2COOH)^-$ and m/z 279 $(RCH_2COO)^-$. The only major daughter ion formed by collisionally activating the ion m/z 415 ion is the ion of m/z 279, which is assigned as the carboxylate anion.

Phosphatidic acid. Phosphatidic acids are the simplest type of phosphoglycerides. They have a glycerol backbone that is esterified with fatty acids at two of the hydroxy groups and a phosphate at the third (see structure **F**). Their fragmentation behavior would be expected to parallel that of the phosphatidic acid portion of the more complex cardiolipin (ion of m/z 695 discussed above). The FAB mass spectra of the distearoyl and dipalmitoyl phosphatidic acids show prominent $(M-H)^-$, $(M-H-RCHCO)^-$ and carboxylate anion daughter ions. These are ions of m/z 647, 409 and 255 for dipalmitoyl phosphatidic acid and ions of m/z 703, 437 and 283 for distearoyl phosphatidic acid.

Collisional activation of the $(M-H)^-$ ions of dipalmitoyl phosphatidic acid causes formation of three daughter ions that correspond to those formed from the phosphatidic acid portion of the cardiolipin molecule (m/z 695 ion). The most abundant daughter ion is the carboxylate anion. The other two daughter ions result from the losses of RCHCO and RCH_2COOH, and the latter loss is slightly favored. For dipalmitoyl phosphatidic acid, these ions are of m/z 255, 409 and 391, respectively. Collisional activation of m/z 409 yields an ion of m/z 153, which arises from the loss of RCH_2COOH from the m/z 409 parent ion, $(M-H-RCHCO)^-$. The acid constituent is determined to be palmitic acid on the basis of collisional activation of the m/z 255 ion, which undergoes the remote-charge-site fragmentation characteristic of a sixteen-carbon saturated acid. Collisional activation of the three distearoyl phosphatidic acid ions yields corresponding results.

Phosphatidylethanolamine. Dipalmitoyl phosphatidylethanolamine and dipalmitoyl *N,N*-dimethyl-phosphatidylethanolamine are examples of phosphoglycerides in which ethanolamine is esterified to the phosphate to form the polar head group (structure **G**).

G

The FAB mass spectrum of dipalmitoyl ethanolamine in triethanolamine matrix is characterized by ions of m/z 732, 716, 690, 647 and 255 (Fig. 4A). The latter three ions may be accounted for as the $(M-H)^-$ ion, $(M-H-C_2H_5N)^-$ ion and the carboxylate anion, respectively. The two higher mass ions appear to be adducts between the ethanolamine head group and the matrix. This assumption is supported by three pieces of evidence. First, these ions are not present if the sample is placed in DT matrix (see Fig. 4A inset). Second, if the two high mass ions are collisionally activated, the daughter ions associated with the carboxylate chains of the ions are identical to those produced by collisional activation of the $(M-H)^-$ ion. Third, the FAB mass spectrum of dipalmitoyl *N,N*-dimethyl phosphatidylethanolamine in triethanolamine matrix is characterized by only ions of m/z 718, 647 and 255; $(M-H)^-$, $(M-H-C_4H_9N)$ and the carboxylate anion, respectively. No high mass adduct ions corresponding to those of m/z 732 and m/z 716 are seen for the *N,N*-dimethyl compound. The absence of adduct ions suggests that matrix molecules are H-bonded via the NH hydrogen atoms. Although the matrix problem with triethanolamine and the unsubstituted ethanolamine does not limit selection and collisional activation of the ions of interest, the adduct ions may be confusing in the analysis of an unknown mixture.

The collisionally activated $(M-H)^-$ ion of m/z 690 of dipalmitoyl phosphatidylethanolamine fragments to yield daughter ions of m/z 452, $(M-H-RCHCO)^-$; m/z 434, $(M-H-RCH_2COOH)^-$; m/z 255, (the carboxylate anion); and a series of high mass daughter ions (see Fig. 4B). The series of high mass daughter ions is that produced by remote-charge-site fragmentation. The high energy requirement for producing remote-charge-site decompositions is again verified by the absence of these ions in the conventional FAB mass spectrum. The ion of

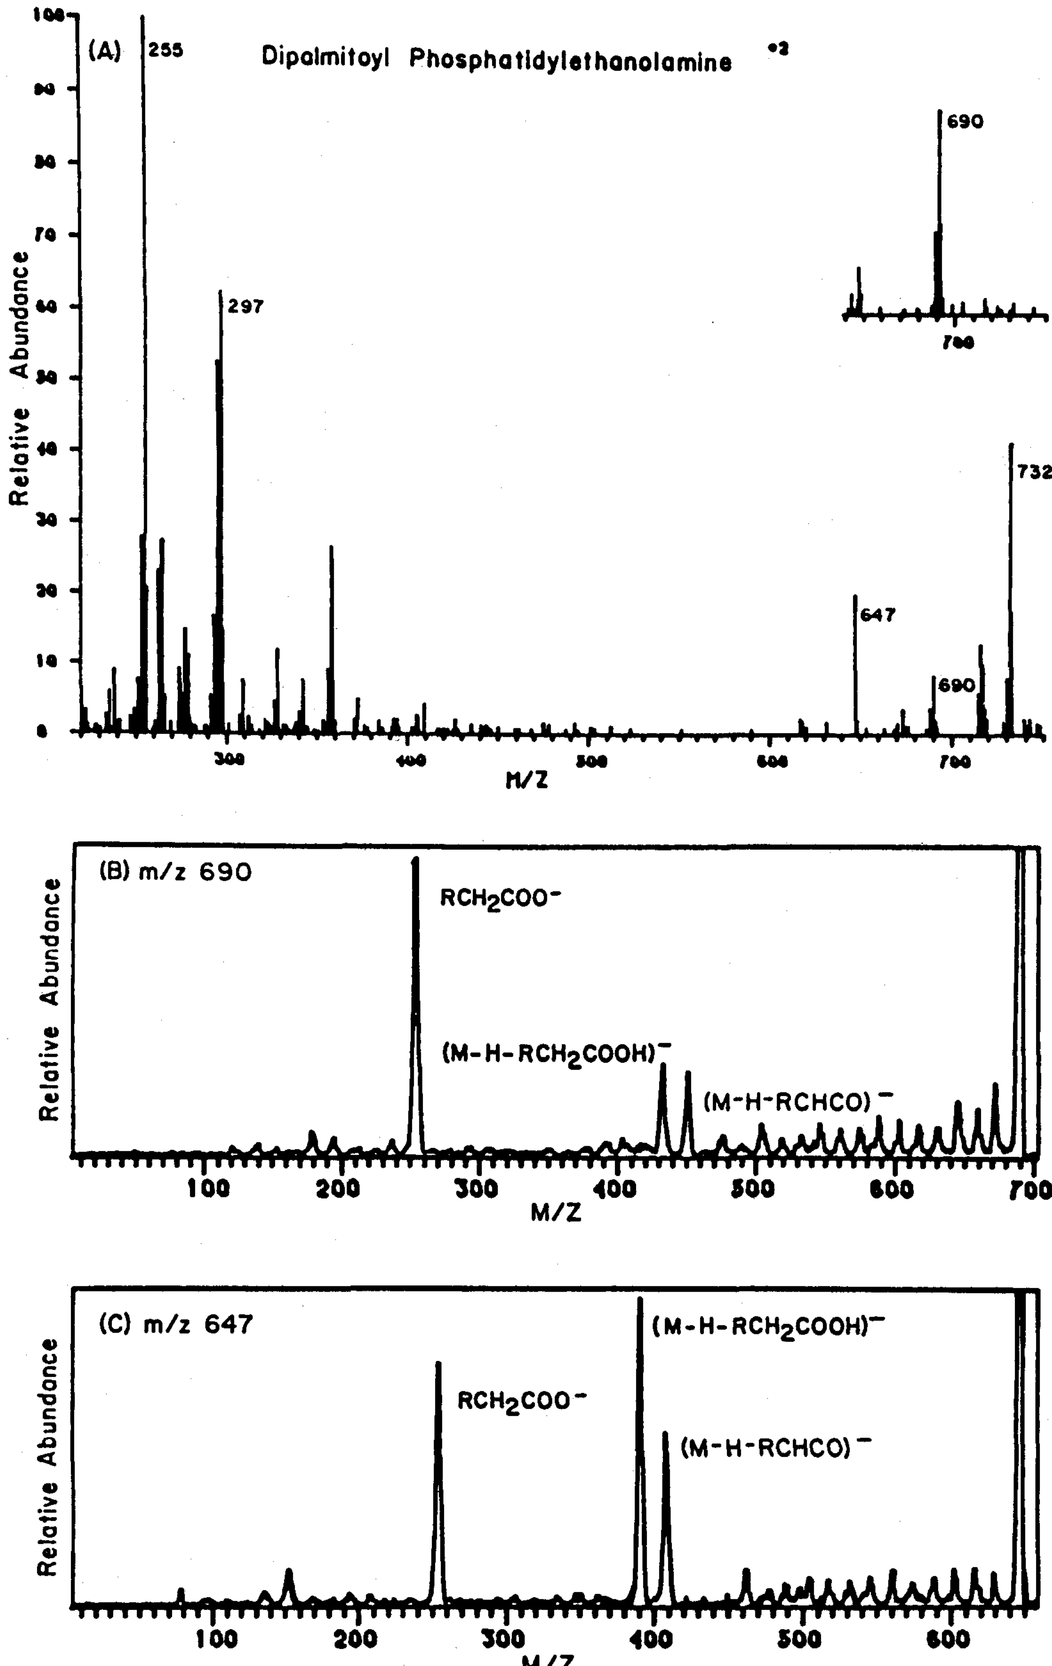

FIG. 4. (A) Mass spectrum of negative ions produced by fast atom bombardment of dipalmitoyl phosphatidylethanolamine. Inset shows spectrum in the mass range m/z 630–750 for sample in DT matrix. (B) Spectrum of the daughter ions produced by collisionally activating the $(M-H)^-$ ion, m/z 690. (C) Spectrum of the daughter ions produced by collisionally activating the fragment ion of m/z 647.

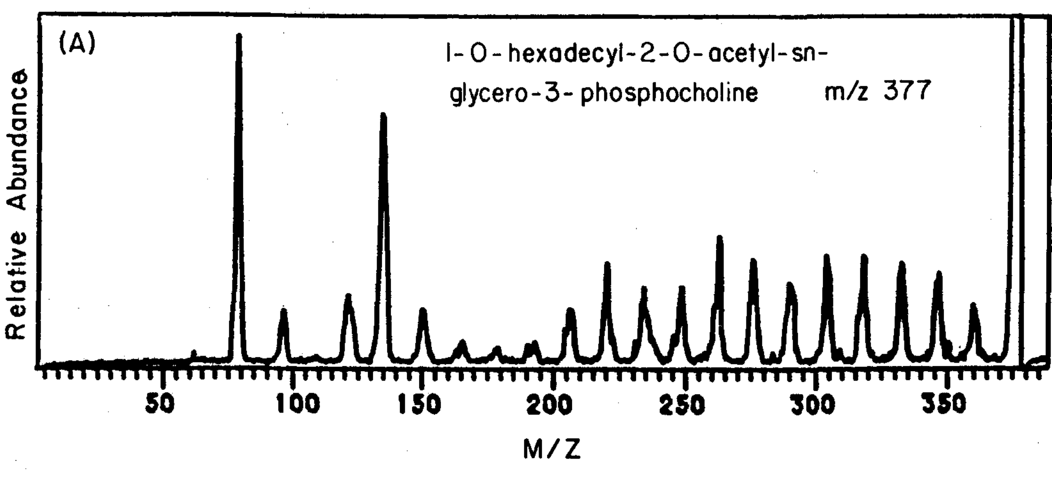

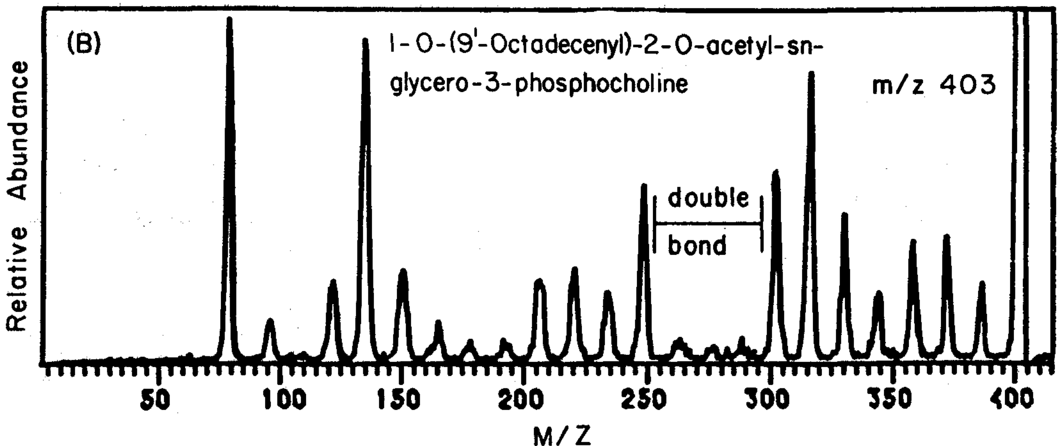

FIG. 5. Spectrum of the daughter ions produced by collisionally activating the fragment ions of (A) m/z 377 of hexadecyl PAF and (B) m/z 403 of the 9-octadecenyl platelet-activating factor analog.

m/z 647 from phosphatidylethanolamine fragments upon collisional activation to yield the same principal daughter ions as does the $(M-H)^-$ ion (Fig. 4C), but the relative abundances of these ions are altered. For the $(M-H)^-$ ion, the formation of the carboxylate anion is favored, but the abundance of the acid carboxylate relative to ions formed by the losses of RCHCO and RCH_2COOH is substantially diminished for the $(M-H-C_4H_9N)^-$ ion. Furthermore, the loss of RCH_2COOH is favored over the loss of RCHCO by a factor of 3:2 for the $(M-H-C_4H_9N)^-$ ion, whereas these ions are produced in nearly equal abundance from the $(M-H)^-$ ion. The ion of m/z 255 is readily characterized as the palmitate anion as it undergoes the typical remote-charge-site fragmentation of the long chain, unbranched, saturated acid. The collisionally activated fragmentations of the principal ions of dipalmitoyl *N,N*dimethyl-phosphatidylethanolamine parallel those of the unsubstituted phosphatidylethanolamine.

Platelet-activating factor and its analogs. 1-*O*-Hexadecyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine (PAF; structure **H**) and 1-*O*-(9'-octadecenyl)-2-*0*-acetyl-*sn*-glycero-3-phosphocholine (structure **I**) differ from the more common phosphatidylcholines because the long aliphatic chain at the one position is attached by an ether rather than an ester linkage. Five major ions are seen in the FAB mass spectra of these compounds. These ions are of m/z 508, 463, 437, 377 and 153 for the hexadecyl PAF and of m/z 534, 489, 463, 403 and 153 for the 9-octadecenyl analog. These ions may be accounted for as $(M-CH_3{}^+)^-$, [M − HN

CH_2O-CH_2 (hexadecyl chain)
$CH-O-C(=O)-CH_3$
$CH_2-O-P(=O)(O^-)-O-CH_2-CH_2-\overset{+}{N}(CH_3)_3$

H

CH_2OCH_2 (9-octadecenyl chain)
$CH-O-C(=O)-CH_3$
$CH_2-O-P(=O)(O^-)-O-CH_2-CH_2-\overset{+}{N}(CH_3)_3$

I

$(CH_3)_3{}^+]^-$, $(M-C_5H_{12}N^+)^-$, $[M-(C_5H_{12}N^+ + CH_3COOH)]^-$ and $C_3H_6PO_5^-$. The three highest mass ions are analogous to those previously observed for phosphatidylcholines for which the fatty acid chains are esterified to glycerol (1–3). However, there are no significantly abundant ions that may be directly attributed to only the alkyl ether portion of the molecule. This is in sharp contrast to the fragmentation of the phospholipids for which the long chain is esterified to the glycerol backbone. Cleavage of the ester linkage and formation of the carboxylate anion are often the principal fragmentations of these molecules (1–3).

PAF and its analogs, in a manner similar to phosphatidylethanolamine, form adduct ions with the triethanolamine matrix. The adduct ion, (M + 62), is very abundant. Hence, DT was used instead of triethanolamine as the matrix for the analysis.

Collisional activation of the three highest mass ions (i.e., the ions of m/z 508, 463 and 437) of the hexadecyl PAF yields the same fragmentation. All fragment to give two daughter ions by the loss of the acetyl moiety. One ion is formed by the loss of CH_3CHCO and the other by the loss of CH_3COOH. The 9-octadecenyl high mass ions fragment in the same moderately informative fashion.

However, collisional activation of the $[M-(C_5H_{12}N^+ + CH_3COOH)]^-$ ion, the ions of m/z 377 and 403 for hexadecyl PAF and the 9-octadecenyl PAF analog, respectively, causes remote-charge-site fragmentation, which permits specific characterization of the alkyl chain (Fig. 5). For the saturated hexadecyl ion, the entire series of C_nH_{2n+2} losses for the sixteen-carbon chain (Fig. 5A) is observed, although relative abundances are decreased as the ether linkage is approached. The presence and position of a double bond in the octadecenyl chain are identified by the very low abundance of three daughter ions (see Fig. 5B) (19,20). The position of the double bond in the C_{18} chain is readily assigned to be eight carbons from the alkyl terminus by correlating the daughter ions of the series with the carbon atoms of the alkyl chain starting with the highest mass daughter ion and the terminal carbon of the chain.

In summary, the combination of FAB for producing negative ions and MS/MS for collisionally activating them is useful for determining phospholipids and their fatty acid components. This is demonstrated by the results in this paper as well as those in our previous publications on phospholipids (1–3) and other complex lipids (28). The method is particularly useful for characterizing fatty acid components directly from the complex lipid without a prior degradation or derivatization. As demonstrated for the phosphatidylinositol, the method is applicable to mixtures, and sample purity is not critical.

[Received November 28, 1986]

Fatty Acid Composition of Seeds from the Australian *Acacia* Species[1]

A.J. Brown, V. Cherikoff and D.C.K. Roberts
Human Nutrition Unit, Department of Biochemistry, University of Sydney, 2006, Australia

Presented are the lipid content and fatty acid composition of 20 species of edible Australian *Acacia* seeds. Aborigines reportedly have used at least 18 of these as foods. Seed lipid content ranged from 3% to 22%, with an average of 11% on a dry weight basis. Linoleic (12–71%), oleic (12–56%) and palmitic (7–35%) acids were the major fatty acids. Smaller proportions of behenic, stearic and vaccenic acids were detected. Seventeen of the 20 species were found to have polyunsaturated to saturated (P/S) fatty acid ratios greater than 1, with four species having ratios in excess of 4. The persistent arils attached to the seeds of certain Australian *Acacias* and containing a portion of the total lipid were associated with a significantly reduced proportion of linoleic acid in the total seed material. This observation was explained by the aril lipid possessing a markedly different fatty acid composition from that of the seed lipid. For comparison, seeds from two non-Australian *Acacia* species (*A. farnesiana* and *A. cavenia*) were analyzed. Australian and non-Australian were found to exhibit markedly different fatty acid profiles.
Lipids 22, 490–494 (1987).

The leguminous plant family Mimosaceae contains over 1,000 *Acacia* species. *Acacia* is a genus of mainly shrubs or small trees found in many parts of the tropics and southern temperate regions (1). *Acacia* species have been put to many uses, notably for dyes, soaps, perfumes, timber, forage and soil conditioning. For instance, the highly scented flowers of *A. farnesiana* are used in the south of France for perfume manufacture (2). The thorns of *A. farnesiana* have been used by some aboriginal peoples to deaden the pain of snakebite (3). The nitrogen-fixing capability of *A. holosericea* has been found useful in land rehabilitation after mining in the Northern Territory of Australia (4), and the foliage and pods of some species (*A. aneura, A. farnesiana, A. victoriae*) are valuable supplements to stock feed (1,2). In addition, milled seeds from *A. coriacea* have been used to supplement wheat flour in the production of a palatable bread (5).

The seeds of some Australian *Acacias* used as food by aborigines have been assessed for gross nutritional composition (6–8) and have been shown to contain significant amounts of lipid. Yet seeds from only four species, not recorded as edible, have been analyzed for fatty acids (9,10). This study reports the fatty acid composition of seeds from 20 Australian *Acacia* species. For comparison, two nonindigenous species were also analyzed.

MATERIALS AND METHODS

Seed collection. Seeds from all but two of the Australian *Acacia* species analyzed were selected on the basis of their reported use as aboriginal foods (11). Seeds from *A. concurrens* and *A. crassicarpa*, not reported as edible, were included to compare with the "edible" species. Two non-Australian *Acacia* species were also analyzed: *A. farnesiana,* collected in India, and *A. cavenia,* a Chilean species grown in the Royal Botanic Gardens, Sydney, Australia. Seeds from the remaining species were collected throughout Australia, mostly in the Northern Territory (Fig. 1). Some seeds were collected with the help of local aborigines as part of the bush food analysis program of the University of Sydney; others were supplied by CSIRO Division of Forest Research (Canberra, Australian Capital Territory) and by M.L. Farrar Pty Ltd (Nowra, New South Wales).

Sample storage and handling. Seeds were stored at ambient temperature for up to 6 weeks before milling in a Fritsch Pulverisette food mill (John Morris Scientific Pty Ltd, Sydney, Australia). The flours were freeze-dried and stored at −15 C.

Lipid extraction. Lipids were extracted from varying amounts (2 to 5 g) of the milled, freeze-dried samples using chloroform/methanol (2:1, v/v) and a wash according to the method of Folch et al. (12,13). After removal of solvent, the lipids were dissolved in petroleum ether (bp 40–60 C, 2 × 10 ml) and transferred to a tared flask, the solvent was evaporated under reduced pressure and the lipids were quantified gravimetrically. The lipids were redissolved in petroleum ether and stored in glass vials under nitrogen at −15 C.

Preparation of fatty acid methyl esters. Replicate samples of the lipid (10 to 100 mg) were saponified, and the fatty acids were methylated using a method based on that of Oulaghan and Wills (14). If not analyzed immediately, the fatty acid methyl esters in CH_2Cl_2 were stored under nitrogen at −15 C.

Gas chromatography. The esters were analyzed by flame ionization gas chromatography (Hewlett Packard HP 5890A capillary gas chromatograph), using a BP10 capillary column (12.5 m × 0.22 mm id) with hydrogen as carrier gas (flow rate 2.8 ml/min; oven temp 180 C; injector temp 250 C; detector temp 300 C).

Mean percentage fatty acid composition was calculated after integration (HP 3392A integrator) by using response factors derived from results with standard mixtures of known composition run on the same column under identical conditions. The standard fatty acid mixtures were obtained from Supelco (Bellefonte, Pennsylvania).

Using a methyl silicone fluid column at an oven temperature of 160 C, vaccenic acid (18:1n-7; $RRT_{18:0} = 0.892$) was resolved from oleic acid (18:1n-9; $RRT_{18:0} = 0.880$) and identified by cochromatographing with standard *cis*-vaccenic acid methyl ester (Sigma, St. Louis, Missouri).

RESULTS AND DISCUSSION

The *Acacia* seeds analyzed contained between 3% (*A. crassicarpa*) and 22% (*A. adsurgens, A. tetragonophylla*) lipid on a dry weight basis (Table 1), with an average lipid content of 11 + 5% (mean + SD, n = 20).

The polyunsaturated to saturated (P/S) fatty acid ratios

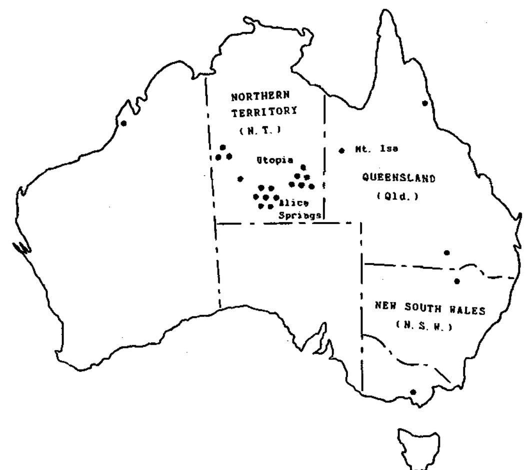

FIG. 1. Collection sites for the Australian *Acacia* seeds; n = 23 (species are listed in Table 2).

ranged from 0.3 to 4.9. Seventeen of the 20 Australian *Acacia* species had P/S ratios greater than 1; four had ratios in excess of 4. The polyunsaturated fatty acids comprised almost exclusively linoleic acid (18:2n-6), with linolenic acid (18:3n-3) accounting for less than 2% of the total fatty acids (Table 1).

In 14 of the *Acacia* seed lipids analyzed, linoleic acid was the major fatty acid (41–71%), with oleic acid and its isomer, vaccenic acid (13–35%), and palmitic acid (7–16%) being most of the remaining fatty acids. Behenic acid (22:0) was also present (2–7%), a phenomenon often associated with Leguminosae seeds (15).

The fatty acid profiles for these 14 *Acacia* seed lipids were in general agreement with those found by other workers. In particular, they were similar to the profiles obtained by Rivett et al. (10) for seeds from three other Australian *Acacias (A. alata, A. dealbata, A. drummondii). A. cyclops*, a native Australian plant introduced to South Africa as an anchorage for the windswept soil of Cape Flats, contained similarly high proportions of linoleic acid (68%) with oleic and palmitic acids being the other major components (10% and 6%, respectively) (10).

The remaining six Australian species (*A. adsurgens, A. coriacea, A. cowleana, A. crassicarpa, A. ligulata, A. tetragonophylla*) analyzed in our study differed from the general trend. They contained significantly lower proportions of linoleic acid (12–36%), significantly higher proportions of oleic acid and its n-7 isomer, vaccenic acid (41–61%), and higher proportions of palmitic acid (16–35%). The slight variations in latitude, altitude and other growing conditions should not cause such differences, since the collection sites were quite similar (Fig. 1). In addition, two samples of *A. holosericea* analyzed from different collection sites (Alice Springs in the Northern Territory and Mt. Isa in Queensland) (Fig. 1) had almost identical fatty acid compositions. A similar situation resulted for the two different samples of *A. victoriae* analyzed (Table 1), indicating that factors such as latitude are unlikely to be responsible for this difference.

Effect of arils on composition. An aril, elaiosome or funicle is the short stalk attaching the seed to the pod; in some *Acacia* species, it remains with the seed. Several *Acacia* species were noted to possess large arils relative to the seed, and in these, aril lipid contributed greatly to the total lipid of the seed material (99% for *A. crassicarpa)* (Table 1). O'Dowd and Gill (16) have measured the lipid content (but not fatty acid composition) of arils and seeds from five of the species (*A. aneura, A. cowleana, A. ligulata, A. longifolia* and *A. tetragonophylla*) reported here. In their results, the percentage of aril lipid in the total seed lipid ranged from 5% (*A. aneura*) to 76% (*A. tetragonophylla*).

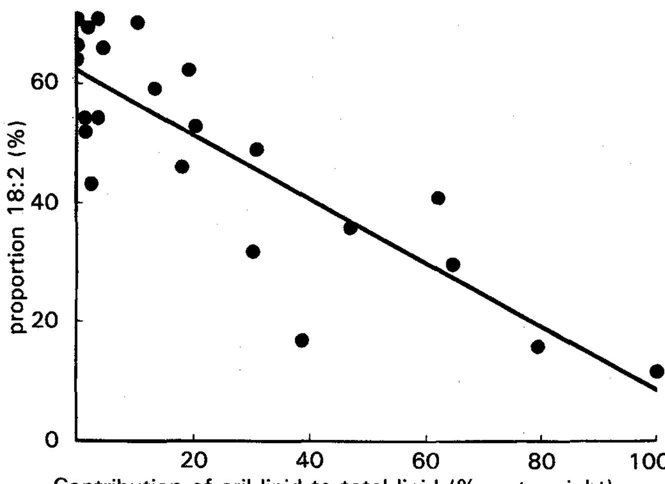

FIG. 2. Linear relationship between the linoleic acid proportion and the extent to which the aril contributes to the total seed lipid for Australian *Acacia* species. n = 23; equation of line: y(%) = 62 − 0.53x, r = −0.840, p < 0.01.

In the aril fatty acids of four *Acacia* species (*A. adsurgens, A. coriacea, A. cowleana* and *A. tenuissima*), oleic acid and its isomer (18:1n-7) constituted over 50% of the total fatty acids; palmitic acid was the other major constituent (23–35%) (Table 2). Linoleic acid was present only in small proportions (2–6%), and there was little or no behenic acid. Black et al. (9) reported similar proportions for the aril lipid composition of *A. cyclops.*

In this study, a significant negative correlation ($r = -0.840$, $p < 0.01$) was found between the linoleic acid proportion and the extent to which aril lipid contributed to total seed lipid (Fig. 2). With an increasing contribution from the arils to the total lipid content of the seed material, there is a decrease in the linoleic acid proportion and a corresponding increase in palmitic and oleic acids. In support of this, *A. cowleana* seeds analyzed without arils were found to be richer in linoleic acid than the arillate sample and correspondingly lower in oleic and palmitic acids (Table 1).

Australian vs non-Australian Acacia species. We analyzed the non-arillate seeds from a Chilean *Acacia* (*A. cavenia*) grown in Sydney, Australia. It contained 54% linoleic acid, which is lower than would be expected for non-arillate Australian species (Fig. 2, intercept 62%). *A. farnesiana* seeds collected from India were also analyzed. Its seeds, like *A. cavenia,* were non-arillate and, like this Chilean species, the Indian sample contained only 54% linoleic acid.

Fatty acid analyses of seeds from seven African *Acacia* species have been reported. Six were from northern Sudan (17), and the seventh was a South African native (18). By comparison, Australian species of *Acacia* generally have higher proportions of linoleic acid and correspondingly lower proportions of oleic and palmitic acids than their African counterparts. We find no mention of persistent arils in the African species analyzed; hence, genetic factors seem a more probable cause for the differences observed. In support of this contention, we note that *A. cyclops* (9), an Australian native introduced to South Africa, exhibits a characteristically "Australian" fatty acid profile.

These data substantiate the suggestion (19) that the Australian *Acacia* may be taxonomically distinct from *Acacias* originating elsewhere in the world.

Mixtures of triglycerides containing deuterium-labeled hexadecanoic acid (16:0), octadecanoic acid (18:0), *cis*-9-octadecenoic acid (9c-18:1), *cis*-9,*cis*-12-octadecadienoic acid (9c, 12c-18:2) and *cis*-12,*trans*-15-octadecadienoic acid (12c,15t-18:2) were fed to two young-adult males. Plasma lipid classes were isolated from samples collected periodically over 48 hr. Incorporation and turnover of the deuterium-labeled fats in plasma lipids were followed by gas chromatography-mass spectrometry (GC-MS) analysis of the methyl ester derivatives. Absorption of the deuterated fats was followed by GC-MS analysis of chylomicron triglycerides isolated by ultracentrifugation.

Results were the following: (i) endogenous fat contributed about 40% of the total fat incorporated into chylomicron triglycerides; (ii) elongation, desaturation and chain-shortened products from the deuterated fats were not detected; (iii) the polyunsaturated isomer 12c,15t-18:2 was metabolically more similar to saturated and 9c-18:1 fatty acids than to 9c,12c-18:2; (iv) relative incorporation of 9c,12c-18:2 into phospholipids did not increase proportionally with an increase of 9c,12c-18:2 in the mixture of deuterated fats fed; (v) absorption of 16:0, 18:0, 9c-18:1, 9c,12c-18:2 and 12c,15t-18:2 were similar; and (vi) data for the 1- and 2-acyl positions of phosphatidylcholine and for cholesteryl ester fractions reflected the known high specificity of phosphatidylcholine acyltransferase and lecithin:cholesteryl acyltransferase for 9c,12c-18:2.

These results illustrate that incorporation of dietary fatty acids into human plasma lipid classes is selectively controlled and that incorporation of dietary 9c,12c-18:2 is limited. These results suggest that nutritional benefits of diets high in 9c,12c-18:2 may be of little value to normal subjects and that the 12c,15t-18:2 isomer in hydrogenated fat is not a nutritional liability at the present dietary level.
***Lipids 22*, 495–504 (1987).**

Hydrogenated vegetable oil, which is used for the production of margarines, cooking oils and shortenings, contains a variety of mono- and polyunsaturated fatty acid isomers. In a recent report prepared for the Food and Drug Administration, per capita consumption in the U.S. of *trans* fatty acids from hydrogenated vegetable oils was estimated at about 8 g/day or ca. 6% of total fat (1). Results summarized in various review articles indicate that previous studies with specific isomeric fatty acids have investigated mainly the metabolism of the *trans* and *cis* positional isomers of octadecenoic acid and *trans,trans*-octadecadienoic acid isomers (1–4). Relatively few studies have investigated the *cis,trans*- and *trans,cis*-octadecadienoic acid isomers. No human nutritional or metabolic data are available for the geometrical isomers of 12,15-octadecadienoic acid, which are formed from linolenic acid during partial catalytic hydrogenation (5).

An objective of this study was to compare in humans the relative absorption and incorporation of *cis*-12,*trans*-15-octadecadienoic acid (12c,15t-18:2) to hexadecanoic acid (16:0), octadecanoic acid (18:0), *cis*-9-octadecenoic acid (9c-18:1) and *cis*-9,*cis*-12-octadecadienoic acid (9c,12c-18:2). The study also provided an opportunity to determine the extent to which deuterium-labeled fatty acids can be used to follow their conversion to other fatty acids and to investigate the biological control exerted on the utilization of deuterium-labeled 9c,12c-18:2, 16:0, 18:0, 9c-18:1 and 12c,15t-18:2.

EXPERIMENTAL PROCEDURES

Protocol. The two subjects were male Caucasians, ages 24 and 25. Medical histories indicated no congenital ailments or recent medical problems. The subjects had not taken any medication for at least three weeks before the deuterated fats were fed. Weight/height ratios were 24.5 and 23.6 kg/m^2. Blood pressure (120/80 and 117/73), serum cholesterol (145 and 166 mg/dl) and fasting triglyceride (TG) (52 and 58 mg/dl) data were within normal ranges, as were all other clinical blood profile data. This information and a general physical examination confirmed that each subject was in excellent health, that neither suffered from metabolic abnormalities, and that both were representative of the normal population. In addition to these data, the fatty acid compositions of individual phospholipid classes were similar to published values (6–8), and the concentrations of phosphatidylcholine (PC) (1.7 and 1.4 mg/ml) and free fatty acid (0.09 and 0.06 mg/ml) were consistent with reported data (7,9).

Subjects were requested to follow the standard diet recommended for diabetics for one week prior to feeding the mixture of deuterium-labeled fats to aid them in selecting a diet of ca. 40% percent fat, 40% carbohydrate and 20% protein. Dietary histories confirmed that food selection was typical of American diets as reported in the Hanes and USDA surveys (10,11). No detectable changes in the subjects' weights were observed during this period, which indicated a stable energy balance. The subjects were fasted for 10 hr before eating the meals containing the mixture of deuterium-labeled TG.

The weight, identity and location of the deuterium labels for the six deuterium-labeled fatty acids in the TG mixtures are listed in Table 1. The synthesis and purification of these fats have been described previously (12–15). Mixtures of the deuterium-labeled TG were heated to ca. 65 C. A blender was used to emulsify the triglycerides with 30 g calcium caseinate, 30 g dextrose and 15 g sucrose in 200 ml of water, which had been warmed to 65 C. This mixture was fed at 8 a.m. in place of the subjects' normal breakfast. A light lunch at 12:30 p.m. (subject 1) and at 11:45 a.m. (subject 2) and a

normal evening meal at 6:30 p.m. were consumed.

Blood samples (ca. 20 ml each) for plasma lipid class fatty acid analysis were obtained by venipuncture at 0, 2, 4, 6, 8, 12, 15, 24 and 48 hr. Serum samples (ca. 15 ml each) were collected at 2, 4, 6, 8, 12 and 15 hr for isolation of chylomicron TG. The chylomicron TG fractions (S_F 400) were isolated at 23 C from the serum samples by centrifugation at 25,000 rpm for 74 min (5.74×10^6 g-min) in a Beckman SW41 swinging bucket rotor as described previously (16).

[a]Percentages of deuterated fatty acids in chylomicron triglycerides are normalized to 100% for comparison with fed mixture percentages.

Lipid isolation, derivatization and analysis. Total lipids were extracted with 2:1 chloroform/methanol (17), and known weights of triheptadecanoin, cholesteryl heptadecanoate, heptadecanoic acid (17:0) and diheptadecanyl-L-α-phosphatidylcholine were added as internal standards to the total lipid extract to aid in determining actual concentrations (mg/ml) of the deuterated fatty acids in these plasma lipid classes. The free acid of 17:0 was added to the other plasma lipid classes after their isolation by thin layer chromatography (TLC). Internal standards were not added to the chylomicron extracts from subject 1.

Preparative TLC was used for isolation of TG, cholesteryl ester (CE), free fatty acid, phosphatidylethanolamine (PE), PC and phosphatidylserine (PS) lipids (18,19). Methyl esters of the isolated lipids were prepared by heating with a 5% HCl-methanol solution (20). In order to determine the distribution of the deuterium-labeled fatty acids in the 1- and 2-acyl position of PC, a portion of the isolated PC was treated with phospholipase A_2 (21), and the reaction products were separated by TLC and esterified. The methyl esters of these lipid classes were analyzed by gas chromatography (GC) and gas chromatography-mass spectrometry (GC-MS). A Varian model 3400 gas chromatograph, equipped with a 100 m × 0.25 mm SP2560 fused silica capillary column (Supelco, Bellefonte, Pennsylvania) and a flame ionization detector, was used to analyze many of the samples to confirm the quantitation of the methyl ester data obtained by GC-MS. Operating conditions were split ratio, 1:100; linear veloc-

ity of helium, 21 cm/sec; detector and injection temperature, 235 C. The column oven temperature was linearly programmed from 165 to 220 C at 3 C/min with an initial hold of 15 min and a final hold of 30 min.

Fatty acid percentages and concentrations for both labeled and unlabeled fatty acid esters were obtained by GC-MS analysis with a Finnigan model 4500 quadrupole mass spectrometer operated in a chemical ionization mode with isobutane as the ionization reagent (22). The gas chromatograph-mass spectrometer was equipped with a Supelcowax 10 fused silica column (30 m × 0.32 mm; Supelco) and was temperature programmed from 165 C to 265 C at 5 C/min with a 20-min final hold. A GC-MS chromatogram of a standard mixture is shown in Figure 1. This figure illustrates the monitored ions and the relative retention of the deuterated and nondeuterated fatty acid methyl esters. Fatty acid methyl ester data for chain lengths shorter than 16 and longer than 20 carbons were not collected, so as to minimize GC-MS data collection and procession time. The methyl ester peaks were identified by comparison to GC retention times for known standards and from molecular weight data. Analyses of mixtures of known composition were used to determine the accuracy of the GC-MS data. Analyses of various mixtures of known composition that contained deuterium-labeled and nonlabeled fatty esters were used to simulate the composition of the actual samples. A 5% relative standard deviation was obtained when each of the deuterium-labeled fatty esters was present at 1% of the total sample.

Calculation of selectivity ratio data. Selectivity ratios are calculated according to the following equation: selectivity ratio = experimental ratio/fed ratio, where experimental ratio equals the ratio for two deuterium-labeled fats in a lipid fraction, and the fed ratio equals the ratio for the same two deuterium-labeled fats in the fed mixture. If the value for the selectivity ratio is less than 1.0, the reciprocal is calculated and the value is given a negative sign.

A selectivity ratio with negative sign denotes discrimination against incorporation of the deuterium-labeled fatty acid in the numerator, while a positive selectivity ratio indicates preferential incorporation. The use of the reciprocal for negative selectivity ratios avoids the problem of compressing negative values between 0.0 and 1.0 while allowing the positive selectivity ratios to have a range between 1.0 and infinity. Thus a selectivity ratio of ±1.0 indicates no difference between the ratio of the fats in the sample compared to the ratio in the fed mixtures. Dividing the experimental ratio by the fed ratio adjusts the value of the experimental ratio for unequal amounts of deuterium-labeled fats used in the fed mixtures. This calculation facilitates data comparison from subjects fed mixtures of deuterium-labeled fats containing different ratios.

RESULTS

Absorption of deuterium-labeled saturated and unsaturated fatty acids. The chylomicron TG data in Figure 2

[a]NV: no value, because deuterated 12c,15t-18:2 or 18:0 was not detected. TG, triglyceride; CE, cholesteryl ester; FFA, free fatty acid; PE, phosphatidylethanolamine; PS, phosphatidylserine; PC, phosphatidylcholine.

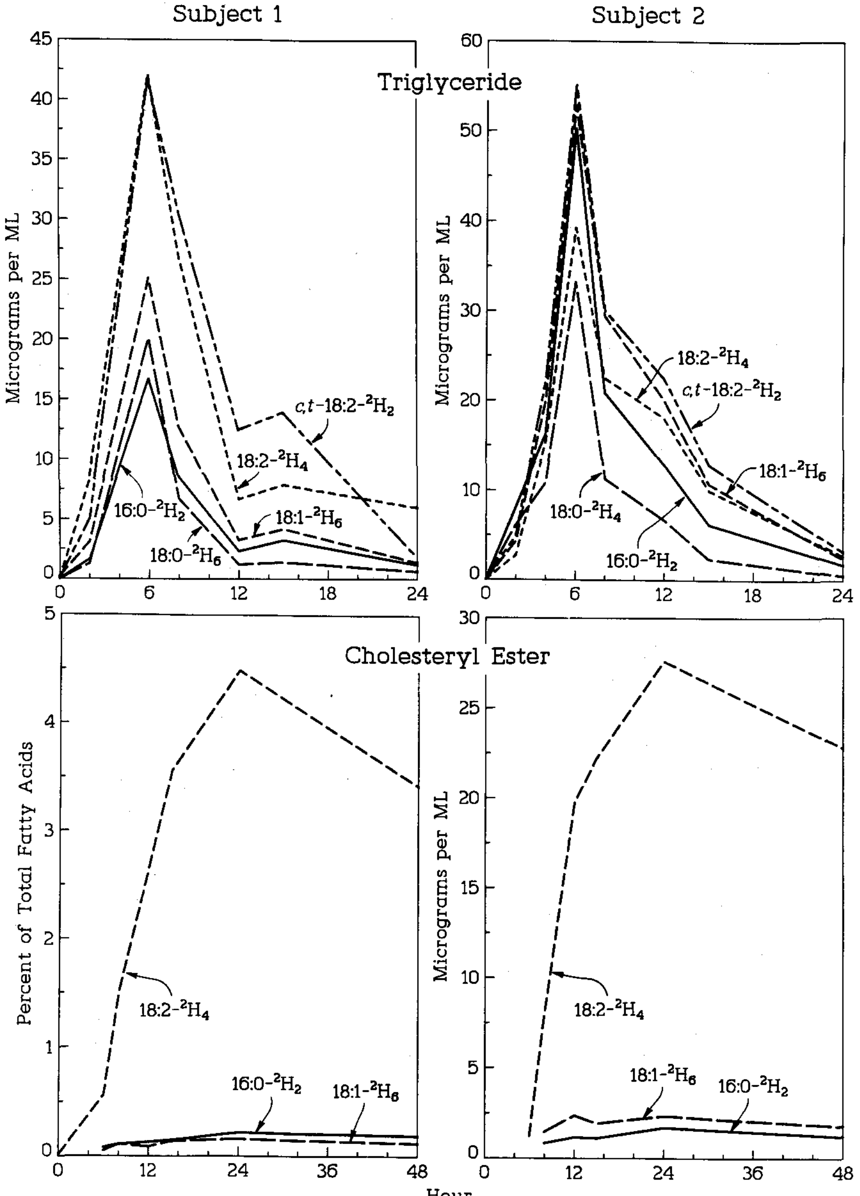

FIG. 3. Uptake and disappearance of deuterium-labeled 16:0, 18:0, 9c-18:1, 9c,12c-18:2 and 12c,15t-18:2 into human plasma triglyceride and cholesteryl ester. Micrograms per ml refer to micrograms of deuterated fatty acid per ml of plasma. Percent of total fatty acids indicates percent isotopic enrichment in the total fatty acids.

are plotted as the percentage of deuterium-labeled fatty acid in the total sample for subject 1 and as micrograms of deuterated fat per ml of plasma for subject 2. The composition of the deuterium-labeled fatty acids in the chylomicron TG samples containing the maximum percent enrichment were normalized to 100% and compared to the composition of the fed mixture in Table 2. Selectivity ratios are given in Table 3 and are based on the total areas under the curves shown in Figure 2. These data are used to reflect preferential removal of one fatty acid relative to another.

The major difference between the chylomicron TG data for the two subjects was the maximum total enrichment. This difference is 23% (61% in subject 1 vs 38% in subject 2). Since previous data for 10 subjects fed various amounts of deuterium-labeled fatty acids (23–27) indicated ~60% maximum total enrichment in chylomicron TG samples, this difference is probably due not to the difference in total amount of deuterium-labeled fatty acid fed but rather to the dilution of deuterated fats in the 6-hr chylomicron sample from subject 2 by fat present in the meal he consumed at 11:45 a.m.

The overall similarity of the curve shapes, combined with the selectivity ratios in Table 3 and the deuterium-labeled fatty acid composition data in Table 2 provides good evidence that absorptions of the various deuterium-labeled fatty acids were essentially equal.

Incorporation of saturated and unsaturated fatty acids into plasma lipids. Plasma TG, CE, PE and PC data are plotted in Figures 3 and 4. These data provide a comparison of the relative incorporation and removal of deuterated 16:0, 18:0, 9c-18:1, 9c,12c-18:2 and 12c,15t-18:2.

Examples of both mg/ml and percent enrichment data for incorporation of deuterium-labeled fatty acids are included. These data show that the relative rate of clearance of 12c,15t-18:2 is similar to other fats commonly present in the diet. Variations in percentages and amounts of the individual deuterium-labeled fatty acids incorporated into the same lipid class for the different subjects are due largely to the difference in percentages of deuterated fats in the fed mixtures. The differences between the various lipid classes from the same subject are due to differences in the selectivity of the enzyme systems involved with the metabolism of these fatty acids.

The selectivity ratios summarized in Table 3 have been adjusted for differences in composition of the fed mixtures. These data reflect the relative incorporation of deuterated fats into the various plasma lipids. The selectivity ratios for 12c,15t-18:2 are plotted in Figure 5 to illustrate the differences between incorporation of this fatty acid relative to 16:0, 18:0, 9c-18:1 and 9c,12c-18:2. From these data and the data in Figures 3 and 4, a number of interrelationships are apparent:

(i) Differences between the selectivity ratios in Figure 5 for the deuterium-labeled fatty acids incorporated into plasma TG and free fatty acid samples are small compared to the differences for the phospholipid fractions. The selectivity ratios for the TG and free fatty acid fractions indicate less than a 1.5-fold difference in the uptake and removal of 12c,15t-18:2 compared to 16:0, 18:0, 9c-18:1 and 9c,12c-18:2. These selectivity ratios indicate that those enzymes involved in metabolism of TG and free fatty acids are relatively insensitive to fatty acid structure and have a minor role in regulation of lipid class fatty acid composition.

(ii) The plasma CE results were unexpected; only 9c,12c-18:2-^{2}H was incorporated to an appreciable extent, and neither 18:0-^{2}H nor 12c,15t-18:2-^{2}H were detected. The enrichment of 9c-18:1-^{2}H and 16:0-^{2}H was also low (0.1–0.2%), as shown in Figure 3. Thus, the selectivity ratios for 18:0-^{2}H and 12c,15t-18:2-^{2}H cannot be calculated, and the selectivity ratios that involve 9c-18:1 and 16:0 have large relative standard errors because of the difficulty of accurately quantitating percent enrichment at the 0.1% level.

(iii) The isotopic enrichment data for 12c,15t-18:2 in Figure 4 and the selectivity ratios plotted in Figure 5 for PE indicate about a two-fold preference for incorporation of 12c,15t-18:2-^{2}H relative to 16:0-^{2}H and an obvious discrimination against 12c,15t-18:2-^{2}H incorporation relative to 18:0-^{2}H and 9c,12c-18:2-^{2}H. Preferential incorporation of 18:0-^{2}H and 9c,12c-18:2-^{2}H into PE is also evident from the selectivity ratios for 9c,12c-18:2 in Table 3 and the isotopic enrichment data in Figure 4.

(iv) The major feature of the PS data is the six- to tenfold preferential incorporation of deuterated 18:0 relative to 12c,15t-18:2. Preferential incorporation of 18:0-^{2}H is reflected by the selectivity ratios in Figure 5 for 18:0-^{2}H vs deuterated 16:0, 9c-18:1 and 9c,12c-18:2. This strong preferential incorporation for 18:0 is the major reason why the 12c,15t-18:2 selectivity ratio for plasma PS is intermediate between 16:0 and 9c-18:1 and clearly different from 18:0.

(v) PC was the only lipid class that appeared to preferentially incorporate 12c,15t-18:2 relative to 9c-18:1. Comparison of the actual isotopic enrichment data in Figure 4 for the various deuterated fatty acids indicate that this positive selectivity ratio for 12c,15t-18:2 vs 9c-18:1 was due to the low incorporation of 9c-18:1 into PC rather than to a selective incorporation of 12c,15t-18:2. The 12c,15t-18:2 vs 9,12c-18:2 selectivity ratio indicates a four- to sixfold preference for incorporation of 9c,12c-18:2. These data are evidence that 12c,15t-18:2 is a poor substrate relative to 9c,12c-18:2 for acylation of PC. The fact that the 12c,15t-18:2 isomer has a methylene-interrupted diene structure but a *trans* double bond in the 15 position (omega-3) further demonstrates the preference of PC acyltransferase for all *cis* polyunsaturated fatty acid structures.

(vi) The small negative selectivity ratios in Table 3 and Figure 5 for 12c,15t-18:2 vs 16:0 and 18:0 indicate that the specificity of PC acyltransferase for 12c,15t-18:2 and saturated fatty acids is similar. The three- to sixfold preferential incorporation of 12c,15t-18:2 relative to 9c-18:1 and 9c,12c-18:2 into the 1-acyl position of PC is similar to the reported differences for saturated and unsaturated fatty acids (28).

(vii) The selectivity ratios in Table 3 and Figure 5 for 2-acylPC reflect the well-known preference for incorporation of 9c,12c-18:2 and exclusion of saturated fatty acids (28). From these selectivity ratios, the specificity of PC acyltransferase for 12c,15t-18:2-^{2}H was closest to 9c-18:1. Comparison of the differences in the various selectivity ratios for the 1- and 2-acylPC positions indicates the possibility of two PC acyltransferases, as suggested by others based on differences in Km values for 1- and 2-acylPC (29,30).

Of interest is the fact that the relative percentages of the deuterium-labeled fatty acid incorporated were not closely related to the overall fatty acid composition of the PC samples. For example, the PC samples contained 24–27% 16:0, 12–14% 18:0, 12–13% 9c-18:1, 29–31% 9c,12c-18:2 and 12–15% 20:4. In comparison, percentages for the deuterium-labeled fats in the PC samples were 10–14% 16:0, 10–19% 18:0, 2–5% 9c-18:1, 50–60% 9c,12c-18:2 and 14–17% 12c,15t-18:2. These data indicate that 9c,12c-18:2 located at the 2-acyl position of PC is exchanged more rapidly than fatty acids at the 1-acyl position of PC by a deacylation-reacylation mechanism, but the overall fatty acid composition is not greatly altered.

The data in Table 3 allow a comparison of all the possible combinations of selectivity ratios for the various fatty acids in the fed mixtures. Since the selectivity ratios are corrected for differences in the fatty acid content of the fed mixtures, they should be the same. Thus, differences in the selectivity ratios for lipid fractions from subject 1 and subject 2 may provide insight into how the ratio of the various fatty acids in the diet influences the relative incorporation of each of the fatty acids. Support for this suggestion is provided by the relatively close agreement of the TG selectivity ratios for the two subjects and the large differences for many of the phospholipid selectivity ratios. Small differences of ± 0.4, such as those for the plasma TG ratios, can be attributed to accumulation of experimental or analytical errors. Differences larger than ± 0.4 reflect differences that could be due to the composition of the deuterated fat mixture. The 9c,12c-18:2/16:0 selectivity ratios for PE and PC indicate incorporation of about twice as much 9c,12c-18:2 as 16:0 for subject 2, who received the low 18:2 diet. Similarly, the

9c,12c-18:2/9c-18:1 ratio is three times higher for plasma PC from subject 2, and the 18:2/16:0 and 18:2/9c-18:1 ratios are both much higher for the CE fraction from subject 2. These data suggest that 9c,12c-18:2 is incorporated more selectively when 9c,12c-18:2 is present at lower concentrations in dietary fat. However, the validity of this suggestion remains to be confirmed because available data is limited.

A similar trend is noted for the 12c,15t-18:2 selectivity ratios plotted in Figure 5; the ratios for the phospholipid classes were generally more extreme for the subject fed the mixture containing the lower amount of 9c,12c-18:2. Subject 1 received 2.9 times more deuterium-labeled 9c,12c-18:2 on a weight basis than subject 2, but the amount of 9c,12c-18:2 incorporated into PC and PE samples from subject 1 was 20–100% less than expected compared to the PC and PE data for subject 2. Thus, for the subject receiving the mixture with the higher deuterium-labeled 9c,12c-18:2 content, relatively less deuterium-labeled 9c,12c-18:2 was incorporated compared to deuterium-labeled 12c,15t-18:2.

These data are consistent with animal data that indicate if the diet is high in 9c,12c-18:2, there are control mechanisms that increase the β-oxidation rates for 9c,12c-18:2 (31) and limit incorporation of 9c,12c-18:2 into phospholipids (32–34). These mechanisms are apparently available to control phospholipid fatty acid composition within relatively narrow ranges in the presence of dietary fat with wide variation in fatty acid composition. The important implication of these data is that a diet with a high polyunsaturate/saturate ratio will increase the 9c,12c-18:2 content of phospholipids less than would be

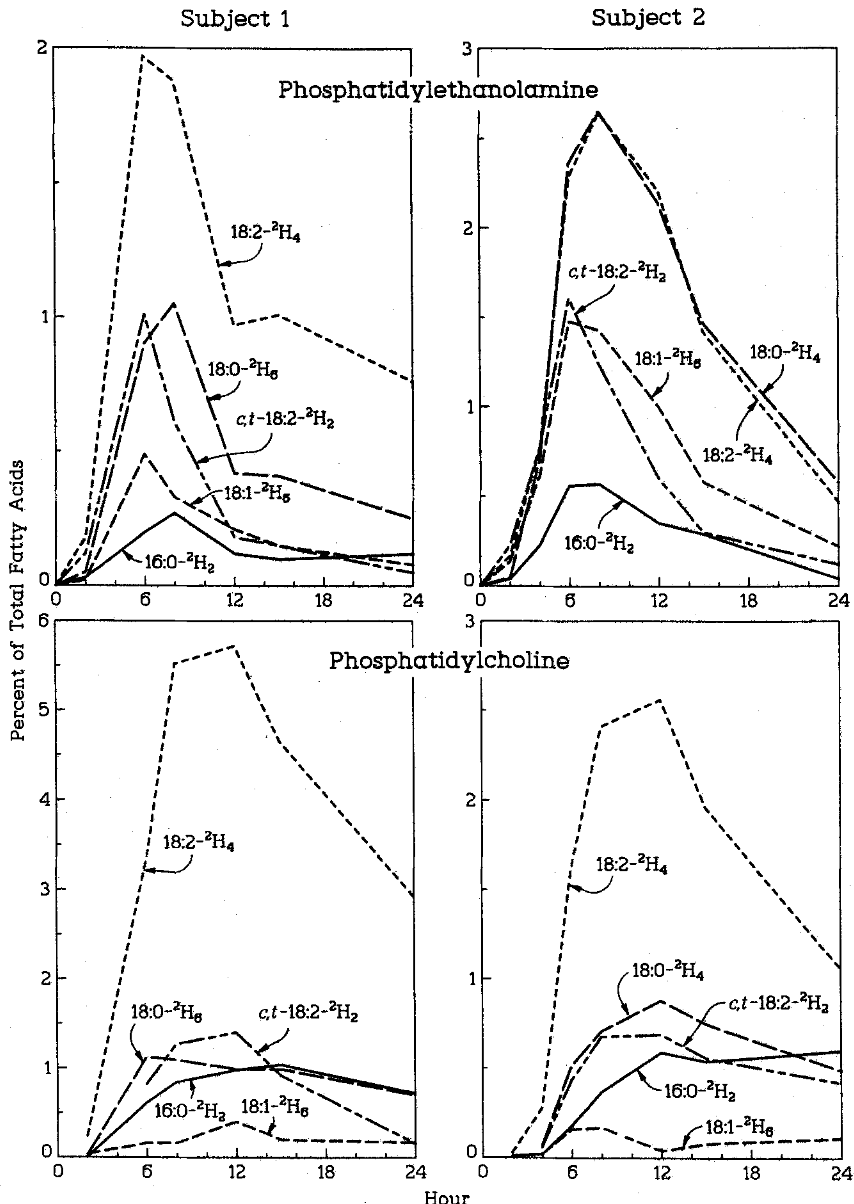

FIG. 4. Uptake and disappearance of deuterium-labeled 16:0, 18:0, 9c-18:1, 9c,12c-18:2 and 12c,15t-18:2 into human plasma phosphatidylethanolamine and phosphatidylcholine. Percent of total fatty acids indicates percent isotopic enrichment in the total fatty acids.

expected compared to a diet with a low polyunsaturate/saturate ratio.

Conversion of deuterium-labeled fats. The major fatty acids present in the plasma lipid classes were examined for the presence of deuterium-labeled fatty acids other than those in the fed mixtures. None of the lipid classes contained detectable amounts (above .01% enrichment) of deuterium-labeled fatty acid other than those fed.

DISCUSSION

Since only two subjects were studied, the data cannot be statistically evaluated as representative of the normal population. However, based on clinical data and medical histories, we believe the metabolism of these deuterated fatty acids is typical for young-adult males. This conclusion is supported by plasma cholesterol, TG and phospholipid concentrations and by fatty acid composition data (not shown) for the various lipid classes.

Our experimental design allows each subject to serve as his own control. This permits direct comparison of the incorporation of each of the five deuterated fatty acids in individual subjects. This design also negates many of the confounding problems of biological variation.

Absorption. The chylomicron TG data in Figure 2 and Table 2 are evidence that the relative absorptions of the deuterium-labeled fatty acids were similar. The only difference was a slight skew of the saturated vs unsaturated fatty acid curves, which suggests a slightly more rapid absorption of 16:0 and 18:0. The chylomicron TG data are plotted in Figure 2 as percentage of each deuterated fatty acid in the total fatty acids for subject 1 and as micrograms of each deuterated fatty acid per ml of serum for subject 2. These data show that either form of representing the data provides plots that are suitable for assessing the relative absorption of the deuterated fatty acids. Plotting the data as micrograms of deuterated fatty acid per ml of plasma yields sharper curves because the amount of non-deuterium-labeled endogenous TG in the chylomicrons increases as the deuterated fatty acids are being absorbed.

Absorption of the deuterium-labeled 18:0 and unsaturated fatty acids was similar, which was unexpected because other studies have reported that trioctadecanoin is poorly absorbed (35–37). The only explanation we can propose for the difference between these data and previous results is that care was taken to ensure that the deuterium-labeled trioctadecanoin, which melts above body temperature, was well emulsified by mixing at temperatures above the melting point of trioctadecanoin, which permits even distribution on to the caseinate. This procedure would be expected to prevent formation of crystalline particles of trioctadecanoin, which would be resistant to hydrolysis by pancreatic lipase.

The presence of non-deuterium-labeled fatty acids in the chylomicron TG samples is attributed to incorporation of endogenous TG during formation of the chylomicron particles. The value of about 40% non-deuterium-labeled fatty acid in the 4- to 6-hr chylomicron TG samples has been a consistent feature of all of our previous chylomicron TG data (23–27). It is also in agreement with rat data, which indicated that as much as 50% of the fat incorporated into chylomicron TG is from an endogenous source (38).

The mixing of dietary and stored or endogenous fat alters the ratio of fatty acids in the chylomicron TG prior to their subsequent metabolism. The implication is that this process may be an important step in the modulation of dietary fatty acid composition and is a mechanism by

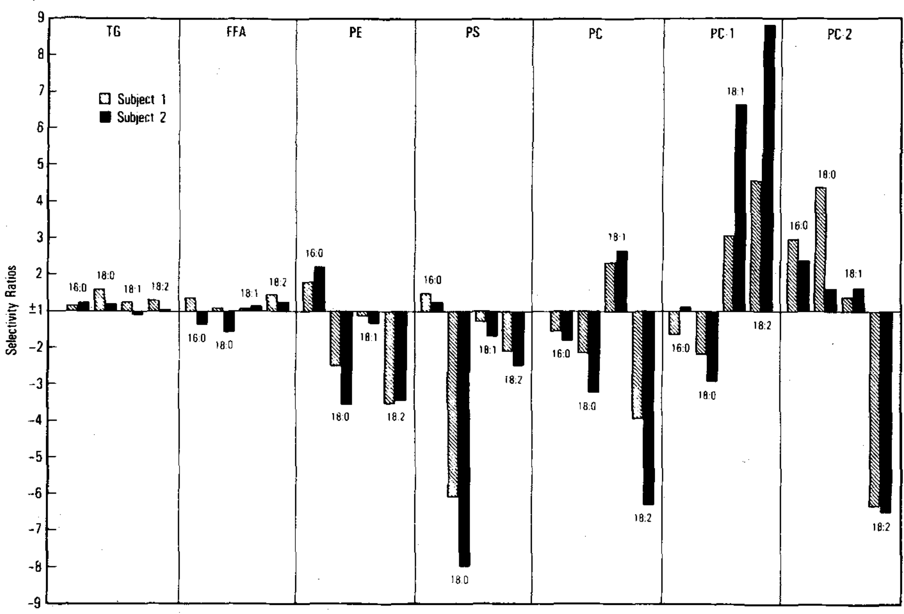

FIG. 5. Selectivity ratios for comparison of the incorporation of deuterium-labeled 12c,15t-18:2 relative to 16:0, 18:0, 9c-18:1 and 9c,12c-18:2 into plasma triglyceride (TG), free fatty acid (FFA), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylcholine (PC), 1-acylphosphatidylcholine (PC-1) and 2-acylphosphatidylcholine (PC-2).

which the body partly compensates for wide variation in dietary fatty acid composition.

Interconversion. In this study, interconversion products such as deuterium-labeled 16:1, 18:0, 18:1, 20:3 and 20:4, were not detected in any of the lipid classes. The GC-MS methodology was capable of qualitatively detecting these deuterium-labeled fatty acids at a 0.04% enrichment level. The PC samples were, in particular, carefully analyzed for 20:4 because deuterium-labeled 20:4 should be concentrated in PC. The percentage of 20:4 in the PC samples from these subjects varied between 10 and 13% and the concentration of PC was between 1.4 and 1.7 mg/ml. Since the concentration of 20:4 in PC is ca. 0.15 mg/ml, we calculate that, if a concentration of ca. 60 ng/ml of deuterium-labeled 20:4 were present in the PC samples, we would have been able to detect it. Based on a total blood volume of ca. 3000 ml, only 0.18 mg of the 15 g (subject 1) and 5 g (subject 2) of 18:2-$^2H_4$ fed would have needed to be converted to 20:4-$^2H_4$ to be detected. This amount corresponds to a conversion of 0.0012% (subject 1) and 0.0036% (subject 3) of the 18:2-$^2H_4$ fed. The absence of detectable levels of 20:4 indicates that the rate of conversion of 18:2-$^2H_4$ to 20:4-$^2H_4$ is extremely low in normal subjects.

From these data, it appears that if various deuterium-labeled fatty acids and their precursors are fed in the same mixture, interconversions of one deuterated fatty acid to another will not cause a major problem with the quantitation of the deuterated fatty acids in the fed mixture. For example, if 20:4-$^2H_4$ and 18:2-$^2H_4$ are both fed, the conversion of 18:2-$^2H_4$ to 20:4-$^2H_4$ is so small that the endogenously formed 20:4-$^2H_4$ will not cause an error in the measurement of exogenous 20:4-$^2H_4$ incorporated into plasma lipids. In a similar manner, these data indicate that the rates of conversion of exogenous deuterated 18:0 to 9c-18:1 and of deuterated 16:0 to 18:0 and c-16:1 are low. These results indicate that fatty acid interconversion rates are generally too low to be followed by this particular experimental approach, although in earlier human studies with deuterium-labeled 18:1 isomers, conversion of 16:1 was observed (26,27). The reason for the lack of detectable deuterium-labeled fatty acid interconversion products may be a combination of low elongation and desaturation rates and a slow, gradual release of the products from the liver into the plasma.

Turnover and incorporation of deuterium-labeled fatty acids in plasma lipids. The plots in Figures 3 and 4 for TG, CE, PC and PE graphically show that turnovers of all of the deuterated fatty acids were similar, irrespective of whether a specific fatty acid was selectively incorporated. The data indicate that differences in the selectivity ratios plotted in Figure 5 are due mainly to enzyme selectivities associated with incorporation rather than to differences in turnover rates. The times at which maximum isotopic enrichment occurred in the various lipid classes were consistent for lipid classes from both subjects. The examples given are for data plotted as micrograms of each deuterated fatty acid per ml of plasma and as percentage of each deuterated fatty acid present in the total fatty acids. Examples of both types of plots are shown to demonstrate that the variation in levels of isotopic enrichment in these fractions is reflected on both a percentage and a concentration basis. The similarity between the data from the two subjects was generally good. However, note that almost three times more 9c,12c-18:2-^2H was fed to subject 1 than to subject 2 and that the 18:2 selectivity ratios for PC and PC-1 in Figure 5 for subject 1 are lower than for subject 2. This difference suggests that the composition of the dietary fatty acids has some influence on the amount of each individual fatty acid incorporated. The influence of the dietary fatty acids is most obvious if the low isotopic enrichment (ca. 0.5%) for 9c-18:1-$^2H_6$ in the PC fraction shown in Figure 4 is compared to PC data from previous studies where 9c-18:1 was fed with the *cis* and *trans* isomers of 10- and 11-18:1 (26,27). In these studies, three to four times as much (1.5–2.0%) 9c-18:1-^2H was incorporated.

The importance of dietary 9c,12c-18:2 is evident from the plasma CE data in Figure 3. The proportions of deuterated 9c,12-18:2, 9c-18:1 and 16:0 incorporated into the plasma CE fraction are much different than the fatty composition normally reported for CE. This suggests that dietary 9c,12c-18:2 is utilized preferentially relative to endogenous 9c,12c-18:2 for esterification of cholesterol.

Plasma lipid selectivity ratios. The selectivity ratios are calculated from the areas under the curves after the data are plotted, as shown in the examples in Figure 3 and 4. The selectivity ratios are thus, in effect, weighted averages of several data points. Overall, the selectivity ratios depicted in Table 3 and Figure 5 indicate a strong biological control of fatty acid utilization in healthy males and a general discrimination against incorporation of 12c,15t-18:2 into plasma phospholipids. For example, the incorporation of 12c,15t-18:2 into total PE, PS and PC is decidedly discriminated against compared to 9c,12c-18:2 and 18:0, but 12c,15t-18:2 is preferentially incorporated into PE and PS relative to 16:0. Most of the selectivity ratios for the phospholipids are negative, and there are no large positive values for the neutral lipids, suggesting that the 12c,15t-18:2 isomer was utilized mainly for energy. The lack of any large positive selectivity ratio for 12c,15t-18:2 was consistent with the failure to detect this isomer in human tissue lipid extracts (39). Thus, based on these selectivity ratios and previous tissue fatty acid composition data, it appears unlikely that 12c,15t-18:2 has any significant impact on cell membrane function or on cell enzyme activities at the low levels present in hydrogenated fats.

In addition, the selectivity ratio and isotopic enrichment data imply that for a high intake of dietary 9c,12c-18:2, excess 9c,12c-18:2 is diverted into either storage or β-oxidation pathways, and the influence of a diet high in 9c,12c-18:2 on the 9c,12c-18:2 content of phospholipids is not linear with the increase in the polyunsaturate/saturate ratio once cell and membrane requirements for 9c,12c-18:2 are met.

[Received November 5, 1986]

Tamoxifen-Induced Modification of Serum Lipoprotein Phospholipids in the Cockerel

W. Carl Breckenridge* and **C.B. Lazier**
Department of Biochemistry, Dalhousie University, Halifax, Nova Scotia, Canada

The administration of tamoxifen (Tam), a nonsteroidal antiestrogen, or of a diphenylmethane derivative of Tam that does not bind to the estrogen receptor (DPPE) of cockerels results in a marked decrease in the concentration of serum lipoprotein constituents with an apparent alteration in phospholipid composition. To establish the nature of changes in phospholipids, the molecular species of phosphatidylcholine (PC) and sphingomyelin (Sph) were isolated and characterized. Between 9 and 18 hr following the administration of Tam or DPPE, there was a marked decrease in the proportion of molecular species of serum PC containing C16 and C18 fatty acids, but there was an increase in the proportion of molecular species containing C20 and C22 polyunsaturated fatty acids. Fatty acid analyses revealed that this change was due to an increase in arachidonic and docosahexaenoic acids at the expense of oleic and linoleic acids. These proportional changes were due to an absolute decrease in serum of PC molecular species containing palmitic and stearic acids in association with oleic and linoleic acids with very little change in the absolute concentration of molecular species containing arachidonic and docosahexaenoic acids. By contrast, the composition of Sph, which contained palmitic acid as the major fatty acid, was not altered during treatment. It is concluded that the short-term effect of Tam and DPPE on plasma phospholipids of the cockerel is due to a selective conservation of PC containing long chain polyunsaturated fatty acids.
Lipids 22, 505–512 (1987).

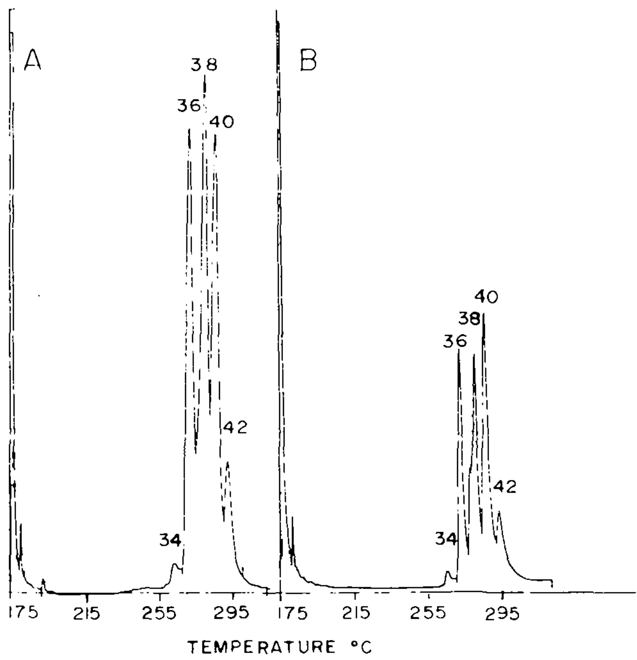

FIG. 1. Gas liquid chromatographic profile of trimethylsilylethers of diacylglycerols from phosphatidylcholine of cockerel serum. (A) Control birds fed ad libitum and injected with propyleneglycol. (B) Birds fed ad libitum and injected with Tam 9 hr prior to blood sampling. Carbon numbers are representative of the retention time equivalent to triacylglycerol with the respective number of acyl carbon atoms.

Phospholipids constitute a major lipid class in plasma, where they function to package neutral lipids in the lipoproteins (1) and to maintain amphipathic helices in apoproteins (2,3), which function as activators of key enzymes in lipoprotein metabolism or as cellular receptor recognition sites (4) for removal of lipoproteins from the circulation. A wide diversity of molecular species of phospholipids is found in plasma lipoproteins (5–7). Although it is generally considered that exchange/transfer proteins promote the equilibration of phospholipid molecular species among lipoproteins (8), there is clear evidence that sphingomyelin (Sph) does not equilibrate completely among lipoproteins (9), while there is a tendency for the more polyunsaturated phosphatidylcholines (PC) to be preferentially associated with high density lipoproteins (HDL) (7,10,11). There is little information concerning the importance of specific phospholipid molecular species in influencing the biological activity of apolipoproteins. Indeed, most studies of apolipoprotein function have been conducted with relatively saturated phospholipids (2–4), which may confer biophysical characteristics on the apolipoprotein structure that are distinct from those of phospholipids containing polyunsaturated fatty acids.

The turnover of plasma phospholipids among plasma lipoproteins has not been extensively studied due to the rapid equilibration of label among lipoproteins. It is generally believed that a major portion of the phospholipids enters the plasma compartment with chylomicrons and very low density lipoproteins (VLDL). During lipolysis of triacylglycerols, a portion of the phospholipid is shed to HDL while another portion, which is relatively enriched in Sph, moves with apo B to low density lipoproteins (LDL) (12–14). The mechanisms for control of the molecular species composition of plasma PC are poorly understood, but dietary fatty acids (7,15) and selective metabolic pathways for PC biosynthesis in the liver (1) may play a role.

As part of an investigation into the effects of nonsteroidal antiestrogen agents on cockerel serum lipoproteins, we noted a rapid alteration in the pattern of phospholipid molecular species of lipoproteins (Lazier, C.B, and Breckenridge, W.C., submitted for publication). The present investigation was undertaken in

Abbreviations: Tam, tamoxifen; DPPE, N,N-diethyl-2[(4-phenylmethyl)-phenoxy]ethanamine; PC, phosphatidylcholine; Sph, sphingomyelin; VLDL, very low density lipoproteins; LDL, low density lipoproteins; HDL, high density lipoproteins; PE, phosphatidylethanolamine.

order to determine the exact effect of these agents on the composition of plasma lipoprotein phospholipids.

MATERIALS AND METHODS

Animals and injections. Male chickens (White Leghorn, 500–600 g) were hatched in local facilities and kept in quarters lighted for 12 hr daily. Food (standard chicken chow) and water were given ad libitum, except as noted in the text.

Tamoxifen (Tam) and N,N-diethyl-2[(4-phenylmethyl)-phenyoxy]ethanamine (DPPE) HCl were prepared at a concentration of 25 mg/ml in propyleneglycol. Tam (as the citrate) was obtained from Sigma Chemical Co. (St. Louis, MO). DPPE was a gift from Dr. Lorne Brandes (University of Manitoa, Winnipeg, Manitoba, Canada), who prepared it by the procedure given in ref. 16. The birds were injected at a dose of 100 mg/kg body weight. Controls or fasting birds were injected with propyleneglycol.

Injections of Tam citrate and DPPE in propyleneglycol or of the vehicle alone were given into the breast muscle. For the 9-hr treatment, the injections were made at 08:00 and the animals were killed at 17:00. For the 18-hr treatment, injections were routinely given at 16:00, and the animals were killed at 10:00 the next day. The lights were turned off from 19:00 to 07:00. For initial studies at 4 hr and 48 hr, the animals were injected at 10:30 and 16:00, respectively.

Preparation of serum and lipoprotein fractions. Serum was prepared from trunk blood, which was allowed to clot for 1 hr at 2 C and then was centrifuged for 20 min at 15,000 × g. Lipoproteins were isolated for 3–5 ml of serum by ultracentrifugation (17) in a Beckman 50:3 rotor under the following conditions: (a) VLDL at a density of 1.006 g/ml at 40,000 rpm for 18 hr; (b) LDL between a density of 1.006 and 1.063 g/ml at 40,000 rpm for 20 hr; (c) HDL between a density of 1.063 and 1.21 g/ml at 40,000 for 24 hr. The lipoprotein fractions were collected in 1–2 ml portions, dialyzed against saline and analyzed for lipid composition.

Analysis of lipids. The lipids in the lipoprotein fractions were quantitated by gas liquid chromatography of total lipid profiles as described elsewhere (8). In brief, phospholipase C, which converts PC, lysoPC and Sph to diglyceride, monoglycerides and ceramides, respectively, was added to aliquots of serum lipoproteins containing 50–300 mg of lipid along with the Tris buffer (pH 7), calcium chloride (1.2 ml of 10% solution) and ethyl ether (1 ml). After digestion under vigorous agitation, an internal standard (tridecanoin) was added in chloroform, and the lipids were partitioned in chloroform/methanol according to the method of Folch et al. (19). The choloroform was evaporated, and the lipid residue was treated with Trisil BSA Formula P (50–300 ml) to silylate hydroxyl groups. The lipid profiles were analyzed in an automated Hewlett-Packard 5840 gas chromatograph using nickel columns (1/8 × 20 in.) packed with 3% OV-1 on Gas Chrom Q (Applied Sciences Lab). The columns were programmed from 170 to 350 C. Response factors were established for each component by analysis of standards. For analysis of molecular species, PC and Sph were purified by thin layer chromatography, converted to diacylglycerols and ceramides, respectively, by digestion and phospholipase C and then analyzed as trimethylsilyl ethers (9,13). The fatty acids of isolated PC and Sph were analyzed by gas liquid chromatography of the methyl esters following transmethylation of the phospholipid with 6% w/v H_2SO_4 in anhydrous methanol (9). The analysis was completed on a 15-m fused silica column containing DB-225 as the liquid phase at a film thickness of 1 μ. Conditions of operation were column temperature, 195 C; injection temperature, 225 C; detector temperature, 250 C; and carrier gas N_2 at 10 ml/min, H_2 at 15 ml/min, and air at 250 ml/min. Peaks were identified by retention time based on chromatography with standard fatty acids or for minor peaks by plots of relative retention times.

RESULTS

Tam has been used extensively as an antiestrogen agent because of its ability to bind competitively to the estrogen receptor. In addition to this characteristic, it also binds with high affinity to a poorly characterized site in microsomal membranes of liver (antiestrogen binding sites). Recent studies (Lazier, C.B., and Breckenridge, W.C., submitted for publication) showed that Tam

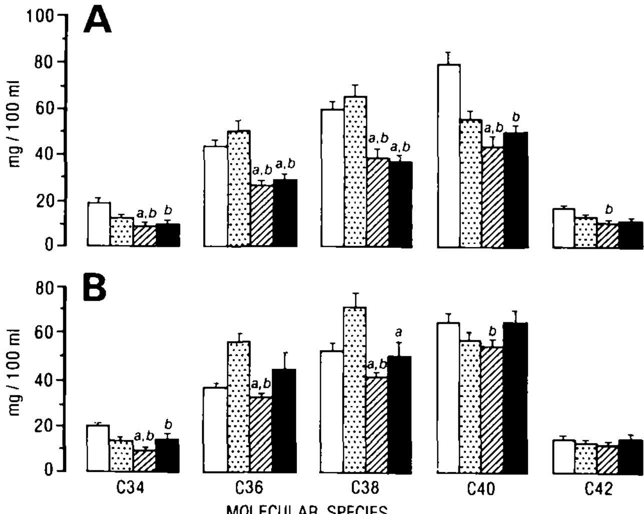

FIG. 3. Absolute concentrations of phospholipid molecular species in cockerel serum. A and B are 9 and 18 hr, respectively, after injection of propyleneglycol with fasting (open column); propyleneglycol with ad libitum feeding (dotted column); Tam with ad libitum feeding (hatched column); and DPPE with ad libitum feeding (solid column). *a*, Significantly different (p <0.01) from propyleneglycol control, fed ad libitum. *b*, Significantly different (p <0.01) from fasted control.

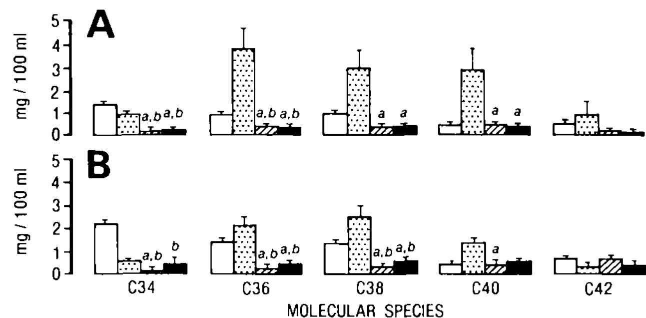

FIG. 4. Absolute concentrations of phospholipid molecular species in cockerel serum very low density lipoprotein. A and B are 9 and 18 hr, respectively, after injection of propyleneglycol with fasting (open column); propyleneglycol with ad libitum feeding (dotted column); Tam with ad libitum feeding (hatched column); and DPPE with ad libitum feeding (solid column). *a*, Significantly different (p <0.01) from propyleneglycol control, fed ad libitum. *b*, Significantly different (p < 0.01) from fasted control.

and a derivative of Tam (DPPE), which does not bind to the estrogen receptor but binds to the antiestrogen binding site, lower plasma cholesterol, triacylglycerol and phospholipid concentrations. As shown in Table 1, the administration of Tam and DPPE to cockerels results in a marked suppression of LDL and HDL lipid mass at 9 hr. Although the Tam also suppresses lipid mass at 18 hr, the effect of DPPE disappears by this time. Neither drug gave an effect at 4 hr, while the effect of Tam disappears by 48 hr (data not shown). Although fasting and Tam and DPPE treatment all reduce VLDL, there is little influence of fasting on LDL and HDL concentrations. DPPE but not Tam causes a small reduction in food consumption by the birds at 9 hr (Lazier, C.B., and Breckenridge, W.C., submitted for publication).

Although there is a large decrease in lipoprotein mass, there is a relatively slight change in lipoprotein composition. After 9 hr of treatment with Tam and DPPE, LDL was slightly richer in cholesteryl ester at the expense of triacylglycerol compared to the control (propyleneglycol) or fasting (Table 2). At 18 hr this effect was absent. The proportion of free cholesterol to phospholipid is lower in fasted samples (9 hr, 0.220; 18 hr, 0.241) than in samples from propyleneglycol (0.336 and 0.321), Tam (0.336 and 0.382) and DPPE (0.411 and 0.371) treatment. There is a slight increase in cholesteryl ester at the expense of triacylglycerol in HDL from Tam or DPPE treatment at 9 hr compared to controls (Table 3). The relative concentration of phospholipid is slightly lower in the fasted samples compared with the other treatments, while the cholesterol/phospholipid ratio of HDL was slightly lower (0.059–0.069) for the fasted birds than for the other three treatment groups (0.074–0.091). Thus, these data indicate that a large decrease in plasma triacylglycerol influences the triacylglycerol content in LDL as well as HDL. The alteration in the cholesterol/phospholipid ratio appears to be influenced by fasting more than by the other treatments.

Previous studies had suggested a change in the molecular species composition of the phospholipids (Lazier, C.B., and Breckenridge, W.C., submitted for publication). To investigate this aspect in more detail, PC and Sph were resolved by thin layer chromatography and analyzed for molecular species composition. Qualitative assessment of the thin layer plates revealed that PC and Sph were the major phospholipids, with small amounts of lysoPC and phosphatidylethanolamine (PE). The latter two phospholipid classes were not investigated further. The molecular species of PC are resolved (Fig. 1) into five carbon number groups consisting of C34 (16,16 fatty acid composition), C36 (16,18), C38 (18,18 and 16,20), C40 (18,20 and 16,22) and C42 (17,21). The carbon number identifies the retention time of the trimethylsilyl ethers in relation to tricylglycerols with the designated number of total acyl carbon atoms. There is a substantial increase in peaks 40 and 42 relative to 36 and 38 in the PC from Tam-treated birds compared with the propyleneglycol treatment. The proportion of C40 and C42 in HDL is higher in Tam- or DPPE-treated birds than in propyleneglycol controls (Table 4). The proportion of long chain molecular species is also higher in fasting conditions. It is important to note that the molecular species in LDL and HDL from propyleneglycol-treated birds are very similar in LDL and HDL. However, in fasting conditions and in treatment with Tam and DPPE, the HDL have larger proportions of C40 and C42 than LDL. The increase in the long chain molecular species is associated primarily with an increase in the proportion of arachidonic and docosahexaenoic acids (Table 5) at the expense of oleic and linoleic acids. The amount of palmitic and stearic acids is a relatively constant in all samples.

Sph molecular species (Fig. 2) contain C34 as the major component (60–70%), with C42 as the other significant constituent. The carbon number distribution in control animals for LDL is C34 (73%), C36 (8.8%), C38 (1.2%), C40 (2.8%) and C42 (14.2%), while HDL has C34 (59.2%), C36 (10.2%), C38 (3.9%), C40 (4.3%) and C42 (22.0%). This distribution is due to a high

content of palmitic (60–70%) and lignoceric acids (10–20%), with minor amounts of stearic, oleic, arachidic and behenic acids accounting for the other fatty acids. There is no extensive change in the Sph composition during treatment.

The results clearly show a marked change in the composition of the molecular species of PC, in which C36 and C38 are decreased in relation to C40 and C42. To assess whether the change in these proportions was due to a decrease in the absolute amounts of C36 and C38, the total amount of phospholipid molecular species was determined from the total lipid profiles for serum (Fig. 3), VLDL (Fig. 4), LDL (Fig. 5) and HDL (Fig. 6) for each treatment group (5–9 birds per treatment or time). Each peak is the sum of the mass of diacylglycerol and ceramides for the respective carbon number. For example, C34 represents the palmitoyl ceramide peak of Sph and cochromatographs with C34 diacylglycerol from PC. The makeup of each peak was estimated from the analysis of the ceramides from Sph and diacylglycerols from PC (Figs. 1 and 2, Tables 4 and 5) and distribution of these components in relation to the composition of the phospholipid in the total lipid profile. In the total lipid profile it was calculated that C34 was derived largely from ceramide (80%), while peaks C36, C38 and C40 were 90%, 97% and 95% diacylglycerol, respectively. C42 is a mixture of ceramide and diacylglycerols. Thus the changes in the absolute amounts of C36, C38 and C40 in the total lipid profile are a good estimate of changes in the absolute amounts of PC with these carbon numbers.

Nine hr following treatment with Tam or DPPE, there was a 40–50% decrease in the absolute mass of serum phospholipids (Fig. 3) of the molecular species C36 and C38 compared to the propyleneglycol controls or fasting birds. There is a small decrease in C40 and no change in C42. This effect persists for Tam at 18 hr but has disappeared for DPPE. Thus the enrichment in long chain molecular species of serum PC noted in Table 3 is due to a selective decrease in the absolute amount of molecular species containing C16 and C18 fatty acids. On the basis of the fatty acid composition and the molecular species profile, it is concluded that this loss is due to a decrease of molecular species containing palmitic or stearic acid in combination with oleic or linoleic acid.

The content of all molecular species in VLDL is extremely low due to the virtual elimination of VLDL by Tam or DPPE (Fig. 4). There is about a 50% reduction in C34, C36, C38 and C40 molecular species in LDL at 9 hr for both DPPE and Tam (Fig. 5). Thus, there is a general reduction in all phospholipid classes in keeping with a reduction in LDL mass. While the DPPE effect disappears by 18 hr, the Tam effect persists at 18 hr for C34, C36 and C38 but is eliminated by 48 hr (data not shown). Tam and DPPE treatment cause a pronounced decrease of C36 and C38 of HDL in comparison to propyleneglycol-treated controls (Fig. 6). Fasting tends to cause an increase in C40 compared with all other treatment groups. The effect of Tam and DPPE is apparent at 9 and 18 hr. Since HDL comprises a much larger portion of the total plasma phospholipid than LDL, it essentially determines the overall composition noted for total serum. The concentration of HDL phospholipids is higher in fasting compared to the other treatments for all the major molecular species at 9 hr. At 18 hr the absolute amounts tend to be lower than the propyleneglycol control and similar to Tam and DPPE.

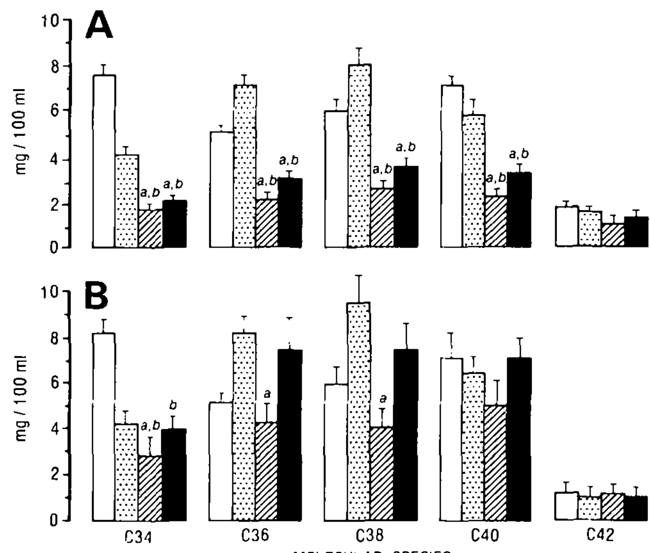

FIG. 5. Absolute concentrations of phospholipid molecular species in low density lipoprotein. A and B are 9 and 18 hr, respectively, after injection of propyleneglycol with fasting (open column); propyleneglycol with ad libitum feeding (dotted column); Tam with ad libitum feeding (hatched column); and DPPE with ad libitum feeding (solid column). *a*, Significantly different (p <0.01) from propyleneglycol control, fed ad libitum. *b*, Significantly different (p <0.01) from fasted control.

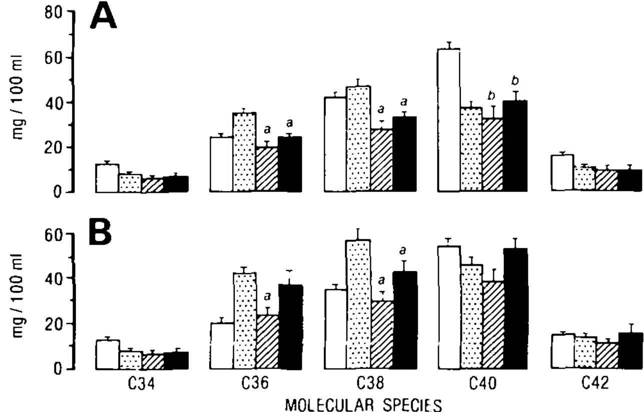

FIG. 6. Absolute concentrations of phospholipid molecular species in high density lipoprotein. A and B are 9 and 18 hr, respectively, after injection of propyleneglycol with fasting (open column); propyleneglycol with ad libitum feeding (dotted column); Tam with ad libitum feeding (hatched column); and DPPE with ad libitum feeding (solid column). *a*, Significantly different (p <0.01) from propyleneglycol control, fed ad libitum. *b*, Significantly different (p <0.01) from fasted control.

These results show that Tam and DPPE have two important effects that differ from the effect of fasting. Although fasting and Tam and DPPE treatment reduce plasma triacylglycerols and VLDL mass, only Tam and DPPE cause a reduction in LDL and HDL phospholipid mass in comparison to the propyleneglycol control. The decrease is due largely to a selective decrease in molecular species containing palmitic or stearic acid in combination with oleic or linoleic acid, with very little change in the absolute amount of molecular species containing

arachidonic and docosahexaenoic acids. A comparable effect with fasting is achieved only after an 18-hr fast. The data are consistent with retention of long chain polyunsaturated phospholipids through selective synthetic or catabolic processes.

DISCUSSION

The mechanisms controlling serum lipoprotein phospholipid concentration and composition in humans or experimental animal models are only partially understood (1). Studies of lipoprotein and phospholipid synthesis in choline deficiency (20,22), in dietary cholesterol loading (22) or during hormonal modulation with estrogen in the chick (23–25) suggest that the synthesis of many of the lipoprotein constituents is coordinated and that phospholipid synthesis is required for release of lipoproteins. Very little is known about the regulation of molecular species composition other than an obvious dietary effect of unsaturated fatty acids (7,15). The cockerel represents a convenient model for the study of lipoprotein metabolism because the lipoprotein classes and apolipoproteins have many similarities to those of the human (26), except that exogeneous lipid absorbed in the gut is transported via the portal vein as portomicrons (27). Furthermore, the unusual lipoproteins associated with the egg-laying cycle in the female are absent, but can be induced in cockerel by the administration of estrogen (26).

The marked changes in the composition of lipoprotein phospholipids of the cockerel within 9 hr of treatment with Tam or DPPE provide an interesting model to assess the effect on lipoprotein composition of rapid changes in the molecular species composition of phospholipids. The lipid composition of lipoproteins of cockerels injected with propyleneglycol vehicle but fed ad libitum compare well with other investigations (23,26,28). The lower content of triacylglycerol in LDL and HDL in Tam and DPPE treatment compared with the propyleneglycol control is probably due to the marked decrease in plasma triacylglycerol and VLDL concentrations during treatment. Cholesterol tends to decrease or increase the order parameters for fatty acyl chains of bilayer phospholipids in the gel or the liquid crystalline state, respectively, while increasing unsaturation of the fatty acid chains tends to decrease the order parameters (29). Furthermore, a change in the amount of unsaturated fatty acids in cell membranes is balanced by an increase in the cholesterol content in order to maintain the order parameters of the fatty acyl chains (30). Although there is a rather dramatic alteration in the molecular species of PC, there is no clear trend in the ratio of cholesterol to phospholipid in the

[a]HDL, high density lipoprotein; LDL, low density lipoprotein. Molecular species of diacylglycerols of PC are identified on the basis of their retention time equivalent to triacylglycerols. Each carbon number species of diacylglycerol contains a total acyl carbon number that is 2 less than the present designation (i.e., C34 contains a total of 32 acyl carbon atoms.)

[b]Conditions and abbreviations are as given in Table 1. Results are from the analyses of pooled lipoproteins from 5–8 birds in each treatment group. Estimates of absolute amounts for individual birds are given in Figures 3–6.

lipoproteins. While fasting and Tam and DPPE treatment all increase the relative amount of polyunsaturated fatty acid in the PC, fasting samples have the lowest ratio of cholesterol to phospholipid, while Tam and DPPE treatment have the highest values. Thus it is unclear whether the increased fluidity imparted tothe lipoproteins by the increase in the polyunsaturated fatty acids is balanced by an increase in the content of unesterified cholesterol.

Although the mechanism for the modulation of the molecular species of PC in this model is not clear from these studies, a number of possibilities may be considered. As discussed elsewhere (Lazier, C.B., and Breckenridge, W.C., submitted for publication), Tam competes with estrogen for the estrogen receptor. Estrogen action is very low in the cockerel. Futhermore, DPPE does not compete for the estrogen receptor (16), but induces the same effect on lipoproteins as Tam. Thus it is probable that the influence of both compounds on lipoproteins may not be via the estrogen receptor and inhibition of the estrogen effect on lipoprotein synthesis, but by some other mechanism, possibly involving other high affinity sites (antiestrogen binding sites) in the liver, or other sites such as protein kinase C, which

is inhibited by Tam with a Ki in the micromolar range (31).

Tam inhibits the estrogen-induced synthesis of VLDL apo B (32), but has no effect on general protein synthesis in cockerel liver. The low levels of LDL and HDL during treatment may be due to decreased formation of LDL and HDL through lipolysis of VLDL. It is unlikely that an alteration in molecular species of HDL phospholipids that is associated with an overall decrease in lipoprotein mass would be due to a selective removal of lipoproteins of specific phospholipid composition. A general reduction in the synthesis of HDL precursor phospholipids is a more plausible explanation. Reports of direct synthesis of HDL precursor lipids and apolipoproteins by chick liver (33) have also shown that the HDL in the Golgi are largely spherical structures and have many similarities to plasma HDL. Recent investigations (1) in cultured rat hepatocytes indicate that PC is synthesized by the CDP-choline diacylglycerol pathway as well as by methylation of PE, which is formed by CDP-ethanolamine diacylglycerol pathway or from decarboxylation of phosphatidylserine. However, PC that is destined for lipoproteins appears to arise primarily from pools of phospholipids synthesized by the CDP-choline pathway and from methylation of PE that is derived from decarboxylation of phosphatidylserine. Early in vivo data for phospholipid metabolism suggested (34) that rat liver and plasma PC, which contained linoleic acid, were formed by the CDP-choline pathway, whereas PC-containing polyunsaturated fatty acids were formed via methylation of PE. Further studies of phospholipid biosynthesis in this model will be required to resolve whether Tam and DPPE inhibit selectively certain pathways of phospholipid biosynthesis in order to produce the alteration in molecular species.

ACKNOWLEDGMENTS

We thank Dr. Lorne Brandes for supplying DPPE. Grant support was from the Medical Research Council of Canada. Technical support was given by Rose Abraham and Kim Lonergan and assistance with manuscript preparation by Cathy Stubbert.

Effects of cholestyramine on biliary secretion of cholesterol, phospholipids and bile acids and fecal excretion of sterols and bile acids were examined in Wistar male rats. Six rats were fed a basal diet, and the other six were fed a basal diet supplemented with 5% cholestyramine for eight days. Bile flow and biliary secretion of bile acids and phospholipids (per hour per rat) decreased with cholestyramine treatment, while biliary cholesterol secretion (per hour per rat) remained unchanged. In the biliary bile acid composition, a marked increase of chenodeoxycholic acid with a concomitant decrease of β-muricholic acid was observed in cholestyramine-treated rats. Fecal excretion of total sterols and bile acids increased about three- and four-fold, respectively, after cholestyramine treatment. The increase of fecal bile acids derived from cholic acid was more predominant than that derived from chenodeoxylcholic acid, resulting in an increase of the cholic acid group/chenodeoxycholic acid group ratio.

Lipids 22, 513–516 (1987).

Cholestyramine is a nonabsorbable bile acid–binding anion exchange resin, and its administration brings about interruption of the enterohepatic circulation of bile acids (1). Clinically, cholestyramine is widely used as a hypocholesterolemic agent in man (2,3).

Gustafsson et al. (4) reported that cholestyramine treatment stimulated HMG CoA reductase and cholesterol 7α-hydroxylase, the rate-limiting enzymes in cholesterol and bile acid synthesis, in germ-free rats. They also examined fecal bile acid compositions and found that cholic acid synthesis was stimulated to a greater extent than chenodeoxycholic acid synthesis. In contrast to the results in the germ-free rats, Huff et al. reported that the fecal excretion of cholic acid was unchanged, whereas that of dihydroxy bile acids were increased several times by cholestyramine feeding in conventional rats (5).

It has been reported that biliary secretion of bile acids and phospholipids decreased while biliary cholesterol secretion remained unaltered by cholestyramine treatment in baboons and hamsters (6,7). In guinea pigs, cholestyramine treatment has been shown to lower the ratio of bile acid to cholesterol in the bile and to induce gallstones (8). However, the effects of cholestyramine on biliary lipid secretion in rats are controversial (9,10). Turley et al. reported that cholestyramine treatment had no effect on biliary lipid secretion (9). On the other hand, Innis reported that biliary bile acid secretion increased, but that biliary secretion of cholesterol and phospholipids was unchanged (10).

To clarify the effect of cholestyramine on bile acid metabolism in conventional rats, we analyzed biliary lipid secretion and fecal excretion of sterols and bile acids, with special reference to bile acid compositions of bile and feces in conventional rats fed cholestyramine diets. The results indicated that biliary secretion of bile acids and phospholipids decreased, while biliary cholesterol secretion was unchanged, and that cholic acid synthesis increased to a greater extent than did chenodeoxycholic acid synthesis in cholestyramine-treated conventional rats. In addition, we discuss the conversion of chenodeoxycholic acid to β-muricholic acid during the enterohepatic circulation on the basis of the changes of the bile acid compositions induced by cholestyramine treatment.

MATERIALS AND METHODS

Animals. Male Wistar rats weighing about 220 g were used. They were maintained in an air-conditioned room (25 ± 1 C, 50–60% humidity) with free access to water. Six control rats were fed a basal diet (Type MF, Oriental Yeast Co., Tokyo, Japan), and the other six were fed a basal diet supplemented with 5% cholestyramine. The composition of the basal diet was as follows: 24.0% protein, 5.1% lipids, 54.5% carbohydrate, 3.2% fiber, 6.2% ash and 7.0% water. The content of cholesterol was 0.09%. Rats were individually caged and given the diet for eight days. Feces were collected for two days before rats were killed. On the ninth day rats were anesthetized by intraperitoneal sodium pentobarbital injection (50 mg/kg), and the bile duct was cannulated with PE-10 polyethylene tubing (Clay Adams, Franklin Lakes, New Jersey) to collect bile for 2 hr.

Biliary lipid determination. Biliary bile acids, cholesterol and phospholipids were determined as reported previously (11–13). Bile was extracted with ethanol; one volume of bile was poured into 20 vol of ethanol, boiled about 5 min and filtered after cooling down to room temperature. An aliquot of the filtrate was evaporated to dryness under a stream of nitrogen, and the residue was hydrolyzed in 3 ml of 1.25 N NaOH for 6 hr at 120 C. Cholesterol was extracted with diethyl ether; bile acids were then extracted with diethyl ether after acidification with 2 N HCl. Cholesterol was determined by gas liquid chromatography (GLC) on a 1% SE-30 column. Bile acids were converted to methyl ester trifluoroacetate derivatives and determined by GLC using 1.5% QF-1 and 1.5% AN-600 columns. Phospholipids were determined by the method of Gomori (14). Lithogenic index was calculated by the formula of Thomas and Hofmann (15).

Fecal sterol and bile acid determination. Fecal sterols and bile acids were determined as described previously with a slight modification (11–13). Feces were homogenized in water; an aliquot was extracted with 15 ml of ethanol at 90 C for 1 hr three times and with 5 ml of petroleum ether twice at room temperature. Extracts were filtered, combined and evaporated to dryness under reduced pressure. The residue was hydrolyzed in 4 ml of 1.25 N NaOH at 120 C for 6 hr. After extraction of sterols

with 3 vol of diethyl ether three times, the hydrolysate was acidified to pH 1–2 with 2 N HCl and bile acids were extracted with 3 vol of diethyl ether three times. The sterols and bile acids were quantified by GLC. Absorption efficiency was calculated as follows: 100 × (1-daily fecal bile acid excretion/daily biliary bile acid secretion) (16).

Statistical analysis. The results are expressed as mean ± SEM. Student's t-test was used to determine statistical significance.

RESULTS

Table 1 shows the effects of cholestyramine on body weight, bile flow, biliary secretion of cholesterol, phospholipids and bile acids and the lithogenic index. Body weight gains were not different between the two groups. The bile flow and biliary secretion of phospholipids and bile acids decreased in the cholestyramine-fed rats when they were expressed in terms of ml or mg per hr per rat. The concentration of bile acids decreased, but those of cholesterol and phospholipids remained unchanged. The lithogenic index increased in the treated rats. Biliary bile acid compositions are compared in Table 2. The biliary bile acids in the control rats consisted of cholic acid (50.2%), β-muricholic acid (17.8%), chenodeoxycholic acid (6.5%), hyodeoxycholic acid (6.3%), ursodeoxychoic acid (5.8%), deoxycholic acid (4.9%), α-muricholic acid (2.2%) and small amounts of the other bile acids. In the cholestyramine-fed rats, chenodeoxycholic acid markedly increased (25.9%), β-muricholic acid decreased (5.3%), α-muricholic acid increased (5.7%) and hydeoxycholic acid almost disappeared. The ratio of cholic acid and its related bile acids to chenodeoxycholic acid and its related bile acids (CA group/CDCA group ratio) remained unchanged.

The fecal excretion of sterols increased about three-fold (Table 3) and that of bile acids about four-fold (Table 4) after cholestyramine treatment. ω-Muricholic acid (31.2%), hyodeoxycholic acid (21.1%), deoxycholic acid (17.6%) and lithocholic acid (9.6%) were the major components in the fecal bile acids of the control rats. Cholestyramine treatment increased deoxycholic acid (46.0%) and lithocholic acid (29.9%) and decreased ω-muricholic acid (3.9%) and hydeoxycholic acid (2.4%), resulting in a marked increase of CA group/CDCA group ratio. The absorption efficiency (the ratio of daily intestinal bile acid absorption to daily biliary bile acid secretion) was reduced to a great extent in cholestyramine-treated rats.

DISCUSSION

Cholestyramine had no effect on biliary lipid composition in obese subjects or patients with gallstones and showed lithogenic effect in normal subjects, while it decreased cholesterol saturation in patients with primary hyperlipoproteinemia (17–20). In rats, Turley et al. (9,21) reported no changes in bile flow or biliary lipid secretion in the rats fed 2% cholestyramine diets for two weeks. Innis (10) reported that biliary bile acid secretion was increased in the rats fed 3% cholestyramine diets for about three weeks, but bile flow and biliary secretion of cholesterol and phospholipids were unchanged. These studies were done with female Sprague-Dawley rats. In contrast, our present study with male Wistar rats showed that bile flow and biliary secretion of bile acids and phospholipids decreased but biliary cholesterol secretion remained unchanged when rats were fed 5% cholestyramine diets for eight days. Similar results have been reported in baboons and hamsters (6,7). These conflicting results in rats might be due to the difference in sex or in dose and duration of cholestyramine treatment.

In the present study, the fecal excretion of bile acids and neutral sterols increased significantly by cholestyramine treatment, which is in agreement with other reports (4,5,22). The increase of the CA group/CDCA

group ratio in feces of the cholestyramine-fed rats is compatible with the result in germ-free rats (4). In man, synthesis of cholic acid also increased to a greater extent than that of chenodeoxycholic acid by cholestyramine treatment (23). Provided that bile acid metabolism of rats fed cholestyramine is in a steady state after eight days, the increase of the CA group/CDCA group ratio implies much more increase of cholic acid synthesis than chenodeoxycholic acid synthesis. These results agree with the concept that cholic acid is formed from newly synthesized cholesterol to a greater extent than chenodeoxycholic acid (11,24,25). The difference of binding affinity of various bile acids to cholestyramine might not be responsible for the increase of the CA group/CDCA group ratio in feces because cholestyramine has been reported to bind taurocholic acid less effectively than taurochenodeoxy cholic acid (26).

There was no difference between the CA group/CDCA group ratios in the bile of control and cholestyramine-treated rats. As previously reported (13), the ratio in the bile is higher than that in feces in untreated rats, probably due to more efficient active transport of cholic acid than of chenodeoxycholic acid in the lower ileum (27). Absorption efficiencies in control and cholestyramine-treated rats were 95% and 38%, respectively (Table 4). The CA group/CDCA group ratio in the bile was similar to that in the feces of cholestyramine-treated rats (1.40 vs 1.05), while the ratios in control rats were much different (1.34 vs 0.39). These data suggest that absorption of bile acids, especially cholic acid, was prevented by cholestyramine. The biliary excretion of bile acids in the rats with biliary drainage for eight days was around 2 mg/hr (unpublished data); the value was similar to that found in the present experiments with cholestyramine given for eight days, suggesting that a major part of biliary bile acids was composed of newly synthesized bile acids in the cholestyramine-treated rats.

Chenodeoxycholic acid markedly increased and β-muricholic acid decreased in the biliary bile acid composition after cholestyramine treatment. This result in conventional rats corresponds well to the increase of chenodeoxycholic acid in the feces in cholestyramine-

treated germ-free rats (4). Chenodeoxycholic acid has been reported to be transformed into β-muricholic acid through α-muricholic acid in bile fistula rats (28,29) and isolated hepatocytes (30,31). The first step of this conversion is 6β-hydroxylation of chenodeoxycholic acid. An in vitro study on the 6β-hydroxylase system using microsomes obtained from cholestyramine-treated and untreated rats showed that cholestyramine treatment exerted little influence on the activity (32,33). As mentioned above, a major part of biliary bile acids was newly synthesized bile acids in cholestyramine-treated rats, so it seems likely that newly synthesized chenodeoxycholic acid is not utilized as a substrate of chenodeoxycholic acid 6β-hydroxylase before its first secretion into bile. Botham and Boyd (30) demonstrated that when rats were totally biliary drained for 44 hr, chenodeoxycholic acid content of the bile showed a rapid fall in the first 10 hr and then a rise beginning after 24 hr, whereas β-muricholic acid content of the bile also fell rapidly during the first 10 hr but showed no significant rise afterward. These results in bile fistula rats agree with our results in cholestyramine-treated rats.

In the biliary bile acid composition of the present experiments, α-muricholic acid increased in addition to the marked increase of chenodeoxycholic acid and the decrease of β-muricholic acid by interruption of enterohepatic circulation of bile acids due to cholestyramine treatment. α-Muricholic acid has been reported to be converted to β-muricholic acid through a 7-keto intermediate (34,35). Therefore, it is conceivable that β-muricholic acid is formed from chenodeoxycholic acid and even from α-muricholic acid during the enterohepatic circulation in normal rats.

In conclusion, biliary secretion of bile acids and phopholipids decreased, while that of cholesterol remained unchanged in conventional rats fed cholestyramine diets. Cholestyramine treatment also brought about an increase of fecal excretion of sterols and bile acids and an increase of CA group/CDCA group ratio in the fecal bile acid composition, which implies much more increase of cholic acid synthesis than chenodeoxycholic acid synthesis. There was a marked increase of chenodeoxycholic acid with a concomitant decrease of β-muricholic acid in the bile of cholestyramine-treated rats, suggesting the formation of β-muricholic acid from chenodeoxycholic acid during the enterohepatic circulation.

Rats were fed lard-enriched (17%) or corn oil–enriched (17%) diets and were compared with rats fed a low fat (4.5%) diet. Cardiac protein, DNA, phospholipid (PL) and fatty acid (FA) compositions were analyzed. Neutral phospholipase A, lysophospholipase and creatine kinase activities in the membrane and cytosolic compartments were also investigated.

No significant modification of cardiac protein, DNA nor PL was observed among the three groups. Some alterations appeared in the FA composition. A lard-enriched diet induced a significant increase of 22:5n-3 and 22:6n-3 in heart phosphatidylcholine (PC) and phosphatidylethanolamine (PE), whereas a linoleic acid–rich diet induced a specific increase of 22:4n-6 and 22:5n-6 in these two major PL.

Compared to rats fed the low fat diet, membrane-associated phospholipase A activity, measured by endogenous hydrolysis of membrane PC and PE, showed a significant increase (+45%) for both PL in rats fed corn oil. However, the activity of membrane-associated phospholipases, measured with exogenous [1-^{14}C]dioleoyl PC, was not different among the three groups of rats. Cytoplasmic activity was decreased in rats fed corn oil, and lysophospholipase and creatine phosphate kinase activities were not significantly affected by diet.

FA modification of the long chain n-6 FA induced by corn oil may be responsible for the observed increase in phospholipase activity. Physiological implications are suggested in terms of membrane degradation and prostaglandin production.
Lipids 22, 517–522 (1987).

Cellular membranes act not only as a biological barrier but also as a finely tuned system that controls ion permeability, membrane-associated enzymes, receptors and eicosanoid production. Any alteration of membrane lipid composition may lead to cellular metabolic disorders. In normally functioning membranes, phospholipid (PL) as well as fatty acid (FA) composition are perfectly regulated. However, it is possible by dietary manipulations to alter the membrane FA composition. The heart is a tissue responsive to lipid modification of the diet. Polyunsaturated oils have a beneficial effect on the cardiovascular system (1–3). This had led several researchers to study the effect of polyunsaturated fat of either vegetable (4–8) or fish (9–11) origin on heart lipid composition. It was observed that a diet enriched in polyunsaturated fatty acids (PUFA) (18:2n-6, 18:3n-3) did not affect the PL composition of cardiac membranes or the polyunsaturated/saturated (P/S) ratio of FA. However, significant alterations were observed in PUFA of the n-3 and n-6 series. In general, a diet enriched in 18:2n-6 induced an elevation of the n-6/n-3 ratio, whereas a diet enriched in 18:3n-3 had the opposite effect (4–8). A significant decrease of this ratio was also observed when rats were fed menhaden or tuna oils, which contain substantial amounts of n-3 PUFA (10,11).

These modifications can have physiological consequences. It is known that membrane-bound enzyme activity can be influenced by the nature of lipids in the proximal micro-environment of the protein (12,13). This is probably related to the degree of unsaturation of FA, which determines, in part, the membrane fluidity and allows the motion of the enzyme in the lipid bilayer (13). Mammal studies have shown that dietary lipid manipulation could modify the activities of some membrane-associated enzymes, such as cation-transporting ATPase (13).

Another important group of membrane-bound enzymes is phospholipase A. Its activity has been described in rat (14–17) and hamster (18) hearts in the membranous systems of the cell (14–17). In addition, a cytosolic phospholipase A (19) and C (20) have been partially characterized in heart. Attention is focused on these enzymes because it is thought that in ischemic heart the observed increase of membrane PL degradation (21,22) could result from activation of intracellular cardiac phospholipases

(23,24). This event, associated with an increase of lysoPL, could further induce an excess of calcium in the cytosol, leading to electrophysiological disorders (25). Almost no information is available on the regulation of these activities in heart. The natural substrate of cellular phospholipase A is essentially membrane PL, and any chemical modification of these lipids may affect their activities. For example, it has been shown in vitro that phospholipase A activity of a homogenate of hamster heart is considerably increased by the level of unsaturation of FA esterified in the *sn*-2 position (18). This was the case also for the erythrocyte phospholipase A (26). Our purpose in this work was to study the effect of a PUFA-rich or PUFA-poor diet on the phospholipase A activities in rat heart in relation to PL and FA composition.

MATERIALS AND METHODS

Animals, diets and feeding procedures. Three groups of 15 male Wistar rats (IFFA-CREDO, L'Arbresle, France) weighing 190–210 g were used. Each group was divided into five cages of three rats. One group was fed a low fat diet containing 4.5% (w/w) fat consisting of a lard and corn oil mixture, giving a P/S ratio of 1.2. A second group received a lard diet (14.8%, w/w) enriched with corn oil (2.2%, w/w), which served as a source of essential FA; the P/S ratio was 0.4. The third group was fed corn oil (17%, w/w); the P/S ratio was 5. The composition of the diets and their FA compositions are given in Tables 1 and 2, respectively. The rats were fed ad libitum for 8 wk and had free access to water.

Heart tissue treatment. After the feeding period, the rats were weighed and guillotined, and their hearts were excised quickly. The hearts were extensively rinsed at 4 C in Tris HCl buffer, 20 mM (pH 7.5), containing 0.22 M mannitol and 70 mM sucrose. Extraventricular tissues and vessels were removed. Hearts were weighed and pooled by three with respect to the cage distribution. They were finely minced; one-third was reserved for homogenization and the rest was subjected to lipid extraction.

The homogenization was performed at 4 C in mannitol buffer (10%, w/w) using a polytron (Kinematica-PT 10) for 2 sec at a rheostat setting of 6. The homogenate was centrifuged at 100,000 × g for 1 hr at 4 C to separate all the membrane fractions (M) from the cytosolic fraction. All fractions were immediately stored at −60 C. The lipids were extracted from fresh tissue at 4 C according to the method of Tam et al. (18). Lipids were extracted in the presence of 0.01 N HCl to minimize loss of lysoPL and 0.05% butylated hydroxytoluene as an antioxidant. Lipids were stored at −20 C under nitrogen until high performance liquid chromatographic (HPLC) and gas liquid chromatographic (GLC) analyses.

HPLC and GLC. Choline and ethanolamine containing PL were separated by HPLC using a Waters-Associate liquid chromatographic system (Milford, Massachusetts). PL were separated as previously described (27). The analysis was performed on an NH_2-Lichrosorb 10 μm (Merck, Darmstadt, Federal Republic of Germany using a mixture of n-hexane, isopropanol, methanol and water as solvent system. The elution order was phosphatidylcholine (PC), sphingomyelin (SPH), lysophosphatidylcholine (LPC), phosphatidylethanolamine (PE) and lysophosphatidylethanolamine (LPE); the separation was achieved in 45 min. PL were quantified by phosphorus determination (28).

[a]Polyunsaturated to saturated fatty acid ratio.

Fatty acid methyl esters (FAME) of PC and PE were prepared by 5% sulfuric acid in methanol at 50 C under N_2 for 3 hr. FAME were extracted twice with n-hexane and analyzed by a gas liquid chromatograph (Girdel 3000, Paris, France) equipped with a peak integrator (Delsi, Enica 10, Suresne, France) and a 50-m capillary column (Spirawax FS 1493, Spiral, Dijon, France). Injector and detector temperatures were set at 220 C, and the oven was temperature programmed (5 min at 180 C, 1 C/min to 205 C and 25 min at 205 C). FAME were identified by comparison to retention time of standards (Interchim, Paris, France).

Phospholipase and lysophospholipase assays. Phospholipase activity on endogenous PL was assayed as recently described (29). Briefly, the membrane fraction (M) (800 μl), obtained from ultracentrifugation at 100,000 × g, was incubated at 37 C at pH 8.4 with 8 mM calcium for 1 hr. Reaction was stopped by adding chloroform/methanol (2:1, v/v), and lipids were extracted according to the method of Folch et al. (30). All extraction steps were performed at 4 C to avoid chemical autolysis of PL. The extracts were submitted to HPLC analysis. Activity was calculated by measuring the decrease of lipid phosphorus in the PC and PE. The contribution of thermal degradation of endogenous PL in measurement of phospholipase A activity was considered. Extracted cardiac PL were resuspended in the buffer and dispersed by sonication. They were incubated at 37 C for 1 hr, extracted and separated on HPLC as described above. Compared with a sample at 4 C, no significant thermal degradation of PC and PE was observed, indicating that no nonenzymic hydrolysis occurred during the phospholipase assay.

Due to the very low concentration of PL in the cytoplasm, labeled exogenous substrate was needed to measure the cytoplasmic phospholipase A activity. Membrane-bound phospholipase A activity was also measured using labeled exogenous PC. The assay with exogenous PC was performed as previously described (17) at pH 8.4 using [1-^{14}C]dioleoylPC (N.E.N., Paris, France) with a specific activity of 6.35 Bq/nmol. The substrate was dis-

persed by sonication in the form of unilamellar liposomes. All the enzymatic measurements were linear with respect to protein concentration and time. A sample without protein served as a blank.

Lysophospholipase was assayed at pH 8.0 as previously described (17) using [1-^{14}C]lysopalmitoylPC (N.E.N.) (14.7 Bq/nmol LPC). Creatine phosphate kinase activity after activation with N-acetyl L-cystein was performed as described by Szasz et al. (31). Assays were measured using an automatic Multistat III (Instrumentation Laboratory, Spokane, Washington) at 30 C.

Miscellaneous. Cholesterol was determined with the cholesterol esterase–cholesterol oxidase kit (Boehringer Mannheim GmbH, Mannheim, FRG) using a two-point kinetic method (32). Assays were performed with an automatic Multistat III at 30 C. Proteins were determined according to the method of Lowry et al. (33). Desoxyribonucleic acid content was measured as described by Volkin and Cohn (34).

DioleoylPC, lysopalmitoylPC and all PL standards were obtained from Sigma (99% pure) (Coger, Paris, France). Solvents were of HPLC grade and were filtered through 0.2 μm Millipore filter before use.

Statistical analysis. Results presented in the tables are means ± SEM of five groups of three pooled rat hearts. Statistical significance of mean differences between dietary groups was investigated by analysis of variance.

RESULTS

Over the 8-wk feeding period, there was no significant difference ($p>0.05$) in body (402 ± 11 g) and heart (1.1 ± 0.1 g) weights between rats on the low fat diet and those on fat-enriched diets.

Table 3 shows the effect of diets on the protein/DNA ratio, total lipid phosphorus and cholesterol content. No significant variation was observed in any of these parameters among the three groups of rats.

The PC and PE compositions are shown in Table 3. Neither the lard-enriched nor the corn oil–enriched diet produced changes in PL composition, which agrees with previous studies performed with other types of fat (7,8,10). The FA compositions of PC and PE are given in Table 4. The saturated FA were resistant to dietary manipulation both in PC and PE inasmuch as the percentages of palmitic and stearic acid were not significantly altered by the diets. The same observation goes for the P/S ratio, which confirms recent data obtained with rats fed other vegetable oils (4,6,7).

Significant alterations in the PUFA, however, were induced by the diets. In the PC, linoleic acid (18:2n-6) was significantly reduced in rats fed the linoleic acid–poor diet (lard). By contrast, the metabolic products of this acid, formed by elongation and desaturation (20:4n-6, 22:4n-6 and 22:5n-6), were not significantly modified by the lard-rich diet. This supports the idea that, in PC, linoleic acid is efficiently converted into C20 and C22 n-6 PUFA, to maintain their concentrations in the normal cell. The same suggestion can be made for PE, where a 2.4-fold reduction of 18:2n-6 (compared to the low fat group) was observed with the lard-enriched diet. Except for a slight decrease of the 20:4n-6 (20%), the C22 n-6 species were maintained at levels comparable to those of the low fat diet. In the same way, a linoleic acid–rich diet (corn oil) produced a significant increase of the C22 n-6 PUFA in PC and PE, which supports an efficient conversion of linoleic acid into C22 n-6 PUFA. Feeding a lard-enriched diet resulted in a dramatic increase of the PUFA n-3 family in both PC and PE. In the PC, this increase is about threefold compared to the low fat group and twofold in the PE.

Phospholipase, lysophospholipase and creatine phosphate kinase activities were measured in the total cardiac membrane fraction (Table 5) and in the cytoplasm. The endogenous hydrolysis of membrane PL showed that PE was better hydrolyzed than PC independent of the diet given. The specific activity, expressed per mg of DNA, was about 30% higher for PE compared to PC in rats fed low fat and corn oil diets, and 70% higher in rats fed the lard diets. When comparing the specific activity of the phospholipase A among the three diet groups, the corn oil–enriched diet induced a significant increase in phospholipase A activity compared to that of the low fat diet. The hydrolysis of PC was about 48% higher in rats fed corn oil compared to that of the low fat diet. Similarly, the hydrolysis of PE was increased by 42% compared to

Values are means ± SEM; n = 5 for each group, and each n represents a pool of three rat hearts. Differences in horizontal means in a class of phospholipids without a common superscript are statistically significant (*, p <0.05; **, p <0.01). If no superscript appear in a row, the differences of the mans are not statistically significant (p>0.05).

that of the low fat diet. Consequently, the sum of the hydrolysis of PC and PE was increased by 45%, and the total activity (nmol PL hydrolyzed/hr/g heart) was significantly increased (P<0.01) by 58% (3,054 in rats fed corn oil vs 1,931 in rats fed low fat diet). In general, rats fed lard diets tended toward a slight increase of enzyme activity, but this increase was not significant (p>0.05) compared to rats fed a low fat diet. The total activity per g of heart was 2,226 nmol PL hydrolyzed/hr in the group fed the lard diet and was significantly different (p<0.01) from the corn oil group.

The phospholipase activity of the membrane fraction using exogenous [1-^{14}C]dioleoylPC is given in Table 5. For all three diets, the measured specific activity was seven- to ninefold lower than that obtained with the endogenous method, confirming recent data obtained with rat heart homogenates (29). However, with the exogenous substrate, no significant diet modifications of phospholipase specific activity were observed. Therefore, in this kind of study, the use of endogenous substrate allowed observation of changes in enzyme activity induced by diet.

The phospholipase activity in the cytoplasm was investigated in the three groups of animals. Compared to the low fat group, a significant decrease of 35% in the specific activity (per mg of DNA) was induced by the corn oil diet, while the decrease in total activity (per g of heart) was 30%. The lard diet did not alter significantly cytoplasmic phospholipase A activity. Lysophospholipase activity was investigated both in the total membrane fraction (Table 5) and in the cytoplasm. Lard and corn oil diets did not significantly modify the membrane-bound lysophospholipase specific activity nor the cytoplasmic lysophospholipase activity.

Creatine phosphate kinase was chosen as an associated-membrane enzyme not involved in lipid metabolism. Although its activity tended to increase with high fat diets (Table 5), it was not significant (p>0.05).

DISCUSSION

Diet-induced changes in FA composition of heart PL have been investigated recently, and the data show that oils of vegetable or fish origin induce alterations in the proportions of the n-3 and n-6 families in PUFA (4–10). Such modifications in heart lipids might be responsible for some alterations in membrane function, such as mitochondrial ATPase activity (35) or sarcolemma-bound enzyme activity (36). The purpose of this study was to investigate the possible influence of two different kinds of fat, lard and corn oil, on lipolytic cardiac enzymes involved in PL catabolism.

Both lard- and corn oil–enriched diets induced no modification in the content of protein, DNA, total PL and cholesterol. In addition, the distribution between the PC and PE remained unchanged. This agrees with previous data obtained with other edible oils (4,6,7,10) and emphasized the ability of heart tissue to regulate its protein and lipid membrane composition even under diet lipid manipulation.

However, diet-induced FA modifications were evident in the proportion of PUFA in the PC and PE. A linoleic acid–poor diet (lard) induced a marked increase in the n-3 PUFA family (22:5n-3 and 22:6n-3) both in PC and PE, probably because the FA desaturase system has a better affinity for n-3 than n-6 FA (37). Consequently, in the presence of a lard-enriched diet, the n-6/n-3 ratio was reduced by a factor of more than 2 both in PC and PE.

TABLE 5

Membrane-Associated Phospholipase A, Lysophospholipase and Creatine Phosphate Kinase Activities in Hearts from Rats fed Various Diets

	Phospholipase (endogenous method)			Phospholipase, exogenous method nmol FA/hr/mg DNA	Lysophospholipase, nmol FA/hr/mg DNA	Creatine phosphate kinase units/mg DNA
	nmol PC/hr/ mg DNA	nmol PE/hr/ mg DNA	nmol PE + PC/hr mg DNA			
Low fat	356.7 ± 54.0[a*]	483.7 ± 33.0[a*]	840.4 ± 65.1[a**]	120.5 ± 9.1	915.0 ± 42.0	5857 ± 558
Lard	365.8 ± 14.0[a*]	634.4 ± 30.5[ab]	1000.0 ± 32.6[a*]	138.8 ± 6.5	1155.1 ± 61.9	7052 ± 310
Corn oil	529.9 ± 47.5[b*]	686.6 ± 70.0[b*]	1215.0 ± 73.0[b*]	133.6 ± 8.5	1081.9 ± 101.0	7072 ± 637

Values are means ± SEM; n = 5 for each group (except n = 4 for lysophospholipase assay in the control), and each n represents the pool of three rat hearts. Symbols of significance are identical to those of Table 4. Phospholipase activity is expressed as nmol of phospholipid hydrolyzed (endogenous method) and as nmol of [1-^{14}C]oleic acid liberated (exogenous method). Lysophospholipase is expressed as nmol of [1-^{14}C]oleic acid liberated. For creatine kinase one unit corresponds to a μmol of creatine phosphate hydrolyzed/min.

This decrease has also been obtained with rats fed sheep kidney fat (6,7) or low erucic acid rapeseed oil (4), which are rich in either palmitic or oleic acid, respectively, like lard.

A decrease in linoleic acid in PC and PE could also be explained by the fact that the levels of 22:4n-6 and 22:5n-6 (metabolic products of 18:2n-6) were maintained at levels comparable to that of the control. In the same way, rats fed a linoleic acid–rich diet showed significantly increased levels of 22:4n-6 and 22:5n-6, associated in PE with a slight decrease of 20:4n-6. Other authors also have reported high increases of 22:4n-6 and 22:5n-6 (4,38) and almost no change in 20:4n-6 (4,7,38) in rats fed linoleic acid–rich oil. These data suggest that 22:4n-6 and 22:5n-6 could have some physiological function in the heart, especially in PE, which would justify maintaining these high levels.

Experimental evidence suggests that membrane FA alteration in various tissues might modify the activity of some membrane-bound enzymes (13). We have investigated this possibility with cardiac phospholipases and lysophospholipases. It is interesting to note that in each group of rat hearts, PE is better hydrolyzed than PC. This could be explained by the higher content of PUFA in PE and the preference of cardiac phospholipases for greater unsaturation (18). This would be supported by the general observation that corn oil induced a significant rise in phospholipase activity in the membrane-bound fraction for both PC (+48%) and PE (+42%). This rise in activity does not appear to be the result of an increase in enzyme synthesis since the activity, measured on exogenous [1-^{14}C]dioleoyl PC, was not increased in rats fed corn oil. Interestingly, the use of endogenous membrane PL as substrate, permitted measurement of increased phospholipase activity. This might indicate that the enzyme was more active, because corn oil induced some specific alterations in the physicochemical properties of membrane PL.

In rats fed corn oil, the observed increase of 22:4n-6 and 22:5n-6 in both PC and PE and the increase of 18:2n-6 in PE may influence the phospholipase activity in two manners. First, it is known that small changes in the unsaturation of membrane PL may produce a modification in the enzyme conformation or motion, inducing in some cases a higher Vmax. This phenomenon has been observed for heart membrane-bound enzymes (36,37) and some other enzymes (12,13), such as the microsomal acyl CoA:cholesterol acyltransferase in liver (39). In this way, phospholipase A–susceptible domains have been proposed in platelet membranes (40,41). These domains would be preferentially attacked by phospholipase A and could be created by modification of FA unsaturation. Second, membrane PL are also the substrate of membrane-bound phospholipases. Since their unsaturation may influence heart phospholipase activity (17,18), it is possible that the diet-induced changes provide a better enzyme activity on the substrate.

In conclusion, we suggest that specific alterations induced by corn oil in some FA of the n-6 family lead to an increase of membrane-associated phospholipase activity. At this stage of investigation, it is impossible to predict if this increase of activity might be responsible for some membrane-associated electrophysiological disorders. Indeed, even if lysoPL are produced in higher proportions, lysophospholipases are probably sufficiently active to rapidly remove these compounds (17). This is confirmed by the fact that lysoPC and lysoPE contents of heart did not change under the various diet conditions.

On the other hand, the observed increase of phospholipase A activity in rats fed corn oil may have physiological consequences in heart prostaglandin production. The content of arachidonic acid in heart PL was not increased even when rats were fed a linoleic acid–rich diet. Such a result can be achieved by an increased conversion to longer chain fatty acids, as discussed above, and a greater liberation of arachidonic acid, the precursor of prostaglandins, by a more active phospholipase. The results presented here should be considered in light of other studies showing that manipulation of dietary lipids affects heart prostaglandin synthesis (42–44), in particular prostacyclin (PGI_2) production, which increases in a linoleic acid–rich diet (43,44). The rise in PGI_2 may have a beneficial effect on heart function (45–47).

The effects of very low fat diets (<7% energy) enriched with different sources of long chain (C20 and C22) polyunsaturated fatty acids (PUFA) on plasma lipid levels and plasma fatty acid composition were studied in 13 healthy volunteers. Three diets provided 500 g/day of tropical Australian fish (rich in arachidonic acid and docosahexaenoic acid), southern Australian fish (rich in docosahexaenoic acid) or kangaroo meat (rich in linoleic and arachidonic acids). The fourth diet was vegetarian, similarly low in fat but containing no 20- and 22-carbon PUFA. Subjects ate their normal or usual diets on weeks 1 and 4 and the very low fat diets in weeks 2 and 3. Weighed food intake records were kept, and weeks 2, 3 and 4 were designed to be isoenergetic with week 1.

Plasma cholesterol levels fell significantly on all diets within one week. There were reductions in both low density (LDL) and high density lipoprotein (HDL) cholesterol levels, with effects on HDL cholesterol being more consistent. There were no consistent or significant effects on total triglyceride levels despite the high carbohydrate content of the diets. On all diets the percentage of linoleic acid fell in the plasma phospholipid and cholesteryl ester fractions, while the percentage of palmitic acid in the phospholipids and cholesteryl esters and palmitoleic acid in the cholesteryl ester fraction rose on all diets. The percentage of arachidonic acid rose in the phospholipid and cholesteryl esters on the two diets that were good sources of this fatty acid (tropical fish and kangaroo meat). The percentage of docosahexaenoic acid also rose on the two diets that were the richest sources of this fatty acid (the fish diets), and the percentage of eicosapentaenoic acid rose in the phospholipid and cholesteryl esters in proportion to the dietary level of this fatty acid (southern fish > kangaroo > tropical fish). The changes in fatty acid composition were almost completely reversed within seven days of returning to the usual higher fat diets.
Lipids 22, 523–529 (1987).

We have previously shown that two types of diets traditionally eaten by aborigines from the northern coastal regions of Australia are associated with a threefold increase in the proportion of arachidonic acid in plasma lipids (1,2). The first was a diet derived almost exclusively from tropical seafood (1), which we have subsequently analyzed and found to be a rich source of arachidonic acid (1,3). The second diet was one in which kangaroo meat and freshwater fish (linoleic and arachidonic acid-rich) were the major sources of fat (2). Both diets were very low in fat despite being rich in fish and red meat (2,4). Plasma triglycerides fell on both diets, and bleeding time increased (1,2). Plasma cholesterol levels, which were not high initially, were not significantly affected by the diets, even when they were rich in lean red meat.

The aim of the present study was to follow up these original observations by examining under controlled conditions the effects on plasma lipoprotein lipids and plasma fatty acid composition of four diets similarly low in fat but containing quite different polyunsaturated fatty acids (PUFA): three contained either 500 g/day of tropical fish (rich in arachidonic and docosahexaenoic acids), southern Australian fish (rich in docosahexaenoic acid) or kangaroo meat (rich in linoleic and arachidonic acids). The fourth diet was vegetarian, with a similarly low fat content and polyunsaturated/saturated ratio but containing no long chain (>20 carbon) PUFA.

METHODS

Thirteen healthy, weight-stable subjects (seven women and six men) participated in these studies. They had a mean age of 31.3 ± 2.8 years and a mean body mass index of 21.2 ± 0.5 kg/m^2. Each subject participated in 1–4 diet studies with a break of at least three months between diets. The protocol was approved by the Ethics Committee of the Royal Melbourne Hospital, Victoria, Australia.

Diets. The four experimental diets were designed to meet two objectives, namely, to provide a minimum of fat (<7% of total energy intake) and to be isoenergetic such that no loss of body weight occurred over the 2-wk period. An experienced research dietitian instructed each subject individually to eat a wide variety of suitable foods to ensure the nutritional adequacy and maximize the palatability of each diet. Subjects were familiar with all food items apart from the fish and kangaroo meat that were supplied. An extensive list of recipes was provided with each diet. Allowable foods included skim milk and other nonfat dairy products. Grains and cereal products such as bread and pasta were encouraged. All vegetables and fruits except avocado and olives were allowed. Legumes, except soybeans, were also encouraged. Sugars, jams, soft drinks and candies were used as a source of energy. Fats, oils, nuts, meat and fish (other than those supplied) as well as commercial foods with added fat were excluded from the diet. Due to the high bulk and low energy density of the experimental diets, subjects with a high basal energy requirement (>2500 kcal/day) found it difficult to maintain their energy intake. In an attempt to overcome this problem, high energy supplementary drinks (high carbohydrate, no fat, 250 kcal each) were recommended. Subjects were advised to have one drink after breakfast and another before retiring at night. Every subject was provided with a set of kitchen scales and standard food-record sheets. All food and beverages consumed over each 2-wk diet period plus the pre- and

TABLE 1

Sample 2000-kcal Low Fat Menus

3 Sample breakfasts (common to all four diets)

300 g oatmeal porridge 100 ml skim milk 2 tsp sugar 2 medium peaches 1 slice wholemeal toast 10 g marmalade jam	200 ml skim milk 200 g baked beans (homemade) 2 slices wholemeal toast	200 ml orange juice 60 g very low fat muesli (homemade) 150 ml skim milk 2 slices wholemeal toast 15 g nonfat cottage cheese 10 g yeast extract

Tropical fish	Southern fish	Kangaroo	Vegetarian
Midday meal			
250 g Barramundi, poached with green peppercorns, capers and Dijon mustard 150 g tossed salad (lettuce, onion, tomato, cucumber, radishes, peppers, large pear)	250 g Rock Ling, poached in mango sauce with dry white wine and nonfat yogurt 150 g baked potato 70 g pumpkin, steamed 60 g spinach, steamed	250 g Kangaroo in curry sauce (no oil) 100 g nonfat yogurt 200 g steamed rice ½ cantaloupe	4 slices wholemeal bread 2 tsp prepared mustard 80 g salad vegetables (tomato, mung beans, grated carrot, beetroot) 1 medium banana
Evening meal			
250 g Barramundi, chow-mein style (1 T. sherry, 1 T. soy sauce) 150 g mixed vegetables 200 g rice noodles	250 g Nanagai, grilled with lemon juice 250 ml split pea soup 1 wholemeal bread roll tossed salad (oil-free dressing)	250 g kangaroo shasliks 100 g steamed potato 70 g broccoli 60 g carrot 200 g fruit salad 100 g nonfat yogurt	1 bowl minestrone soup (no oil) 2 cups cooked spaghetti 180 g tomato and vegetable sauce 150 g tossed salad, no dressing
Snacks (in addition to above meals three snacks were eaten each day)			
(e.g.) 2 slices of bread or 1 crumpet with jam or honey	small banana plus 200 ml nonfat yogurt	400 ml carbonated soft drink or 250 ml high energy supplement drink	2 Rye Vita crackers with 20 g nonfat cottage cheese 30 g tomato plus 40 g dried apricots

postcontrol weeks were recorded. Typical 2000-kcal menus for each diets are presented in Table 1. The breakfasts and most snacks were interchangeable. Dietary analyses were performed using the Microdiet Computer Software package based on the British Food Tables (5). The fat content of the tropical fish, southern fish and kangaroo meat was determined by analysis in our laboratory (3,6).

The daily intake of saturated and monounsaturated fatty acids and linoleic acid were calculated using the Microdiet data base. The levels of the 20- and 22-carbon PUFA were calculated from our own data of the total lipid content and fatty acid composition of a variety of foods.

Experimental protocol. Each diet study ran for four weeks. Fasting blood samples were taken before the study began and at weekly intervals after for the measurement of plasma lipoprotein lipid and fatty acid compositions. During the first week the subjects remained on their usual diets, weighing and recording food intake. They began the experimental diets during the second and third weeks and returned to their usual diets for the fourth week. Weighed food-intake records were maintained throughout the four weeks. Body weights were also monitored regularly.

Lipoprotein lipid analysis. Concentrations of cholesterol and triglyceride in fasting plasma were measured enzymatically after enzymatic hydrolysis on a Cobas-B10 Centrifugal Analyser using commercially available kits (Cholesterol Enzymatic Merckotest, E. Merck, Darmstadt, FRG; Triglyceride Rapid Test, Roche, Basle, Switzerland). The normal range for cholesterol concentrations in fasting plasma is 3.5–6.0 mmol/l and for triglycerides is 0.5–2.0 mmol/l. Very low density lipoproteins (VLDL) were separated by 16-hr ultracentrifugation of plasma at 40,000 rev/min in a Beckman L-50 Ultracentrifuge. High density lipoproteins (HDL) were separated within 2 hr of blood collection from other plasma lipoproteins that had been precipitated by heparin-manganese chloride. Lipids in low density lipoproteins (LDL) were calculated from the difference between whole plasma and VLDL and HDL (7). Cholesterol concentrations were determined for all three lipoprotein fractions. Triglyceride concentrations were measured in whole plasma and VLDL only.

Plasma fatty acid analysis. Fasting blood samples were collected in heparinized tubes, and the lipids were extracted from the plasma by chloroform/methanol extraction (8). Internal standards of cholesterol heptadecanoate (Nu-Chek-Prep, Elysian, MN) and di-hepta-decanoyl-phosphatidylcholine (Sigma Chemical Co., St. Louis, MO) were added to the plasma samples prior to lipid extrac-

tion. The lipid extracts were separated by thin layer chromatography (1,2), and the fatty acid methyl esters of the cholesteryl ester and phospholipid fractions were formed as described previously (9). The fatty acid methyl esters were separated using an 8 m × 0.22 mm ID fused silica bonded phase (BP-20) capillary column (SGE, Melbourne, Australia). The gas liquid chromatograph was equipped with flame ionization detectors and was programmed from 100 to 190 C at 8 C/min with a helium carrier gas flow rate of 50 cm/sec. Standard methyl esters (Nu-Chek-Prep) were routinely chromatographed to determine the identity of the fatty acid methyl esters and to determine the detector response to the different esters. Quantitative response factors were determined (using Nu-Chek-Prep standards) and were used in the calculation of the data. The capillary column provided adequate separation of the following critical methyl esters: 18:3n-3 from 20:0 and 20:1; 20:5n-3 from 22:0 and 22:1; 20:4n-6 from 20:3n-6 and 20:3n-3.

Statistical analyses. The paired t-test was used to compare results within a study, and the unpaired t-test to compare results between studies. All results are expressed as mean ± SEM; significance was taken as $p < 0.05$.

RESULTS

The changes in dietary composition during the dietary studies are shown in Table 2. Although there was a trend for energy intake to fall on all four diets, it was not statistically significant. However, on all diets except the kangaroo diet, energy intake increased significantly when the baseline diet was resumed, although there were no significant differences between the two baseline periods (weeks 1 and 4). The marked fall in proportion of energy derived from fat on all diets was compensated for by increased carbohydrate intake in the vegetarian diet and increased protein and carbohydrate intakes on the other three diets containing lean meat or fish. Cholesterol intake was extremely low on the vegetarian diet, but unchanged on the other three diets relative to the baseline periods. Dietary fiber increased on all diets, the effect being most marked with the vegetarian diet. The P/S ratio increased from 0.4 on the baseline diet to over 1 on the vegetarian, tropical fish and kangaroo diets and to almost 2 on the southern fish diet.

Fasting cholesterol fell 19–24% over the 2-wk period, with the most pronounced fall occurring in the first week of the diet (Table 3). The effect of the diets on cholesterol levels appeared to be equally rapidly reversible on all diets, and levels had risen significantly within one week of resuming the baseline diet for all diets except tropical fish. The fall in total cholesterol on these diets was due to reductions in both HDL and LDL cholesterol, with effects on HDL cholesterol being more consistent. The HDL-cholesterol levels fell significantly on all four diets and rose significantly within one week of resuming the baseline diet. LDL-cholesterol levels behaved in a similar fashion for all diets except tropical fish, where the fall on the diet was less pronounced (and not statistically significant) and more attenuated in that it remained low one week after resuming the baseline diet. The ratios of LDL/HDL cholesterol over the study period are shown in Table 4. Although there was a trend to higher ratios during all four diets, there were no statistically significant effects.

Triglyceride levels in fasting plasma and VLDL were not affected by the diets (Table 5). There were trends toward higher triglyceride levels on all diets; however, they were not statistically significant. The exception was on the tropical fish diet, where there was a significant increase in triglyceride levels after one week that disappeared by two weeks.

The fatty acid composition of the foods used in supplementing the low fat diets is given in Table 6. Kangaroo meat and tropical and southern Australian fish are all low in fat with a high proportion of PUFA. Kangaroo meat contains predominantly n-6 PUFA, with linoleic and arachidonic acids being the most abundant. However, it is important to note that kangaroo meat contains significant amounts of n-3 PUFA (linolenic acid and its more polyunsaturated derivatives). Tropical fish are rich in both the n-6 and n-3 PUFA, with arachidonic and docosahexaenoic acids being the most abundant. Southern Australian fish, in contrast, contain predominantly the n-3 PUFA, with docosahexaenoic acid being the most abundant.

TABLE 5

Triglyceride Concentrations in Fasting Total Plasma and VLDL During the Dietary Studies (mmol/l, mean ± SEM)

Diet	Baseline (day 0)	Diet (day 7)	Diet (day 14)	Postdiet (day 21)
Total plasma triglycerides				
Southern fish (10)	0.72 ± 0.04	0.71 ± 0.06	0.76 ± 0.04	0.62 ± 0.05
Tropical fish (11)	0.77 ± 0.10	0.89 ± 0.07*	0.84 ± 0.05	0.74 ± 0.05
Kangaroo (10)	0.85 ± 0.10	1.21 ± 0.24	1.16 ± 0.24	0.96 ± 0.13

Kangaroo (10)	0.31 ± 0.07	0.52 ± 0.17	0.46 ± 0.16	0.43 ± 0.09
Vegetarian (7)	0.24 ± 0.06	0.32 ± 0.05	0.33 ± 0.06	0.27 ± 0.05

* $p < 0.05$ (paired t-test comparing baseline diet with the other diets).

The estimated daily dietary intake of saturated, monounsaturated and the different PUFA is shown in Table 7. In the baseline periods, the intake of saturated, monounsaturated and linoleic acids was 31, 30 and 13 g/day, respectively. In all experimental periods, the levels of each of these three groups of fatty acids declined to about 2–3 g/day. The baseline diet contained 20- and 22-carbon PUFA of both the n-6 and n-3 types with arachidonic and docosahexaenoic being the most significant. The vegetarian diet contained no 20- and 22-carbon PUFA, whereas the other three low fat diets were particularly enriched in the long chain PUFA derived from the main foods characteristic of each diet; southern fish with eicosapentaenoic and docosahexaenoic acids, tropical fish with arachidonic and docosahexaenoic acids and kangaroo meat with arachidonic, eicosapentaenoic and docosapentaenoic acids.

The changes in fatty acid composition of plasma phospholipids and cholesteryl esters after two weeks on the four experimental diets is presented in Table 8. Some changes appeared to be in response to the low fat diet per se, since they occurred in all four diets, while other changes (particularly those pertaining to the long chain PUFA) were quite diet-specific. In both phospholipids and cholesteryl esters, the proportion of linoleic acid fell, while that of palmitic and palmitoleic acid rose during all diets and returned to baseline values within one week of resuming the normal diet. The changes observed in the C20 and C22 PUFA reflected the fatty acid composition of the major dietary components; the proportion of arachidonic acid increased on the two diets that were good sources of this PUFA (tropical fish and kangaroo meat); the proportion of docosahexaenoic acid rose in both plasma lipid fractions on the two diets that were good sources of this PUFA (southern fish and tropical fish); and eicosapentaenoic acid increased most markedly on the southern fish diet. The quantitatively largest changes in fatty acid composition were the fall in linoleic acid and the increases in arachidonic and docosahexaenoic acids. The fatty acid changes from day 0 to day 14 were almost completely reversed within 7 days after subjects resumed their normal diets.

DISCUSSION

In this study of the effects on lipoprotein lipids and fatty acid composition in fasting plasma during four very low fat diets enriched with different long chain PUFA, some effects (consistently observed on all four diets) appeared to be simply attributable to the low dietary fat, while others (specific to the different diets) were attributable to differences in long chain PUFA composition.

The changes in lipoprotein composition in response to all four diets were similar. There was a rapid reduction in total cholesterol within one week and a slower return toward baseline values one week after resuming the normal diet. The fall in total cholesterol was due to falls in both LDL- and HDL-cholesterol levels, with the effects being more consistent on HDL cholesterol. Indeed, there was a trend to increased LDL/HDL cholesterol ratios on all four diets, although it was not statistically significant. These results are consistent with the observations of

[a]Baseline, day 0; diet, day 14; postdiet, day 21.

others showing reductions in both LDL and HDL cholesterol on diets that either are low in fat (10) or have a high P/S ratio (11). It appears that monounsaturated fatty acids (oleic acid as in olive oil) are unique in specifically lowering LDL cholesterol while leaving HDL cholesterol relatively unaffected (12). In the present study, consistent reductions in plasma cholesterol occurred rapidly in normo-cholesterolemic subjects consuming low fat diets with quite different cholesterol intakes (11–316 mg/day) and appear to be explained entirely by the very low fat contents.

High carbohydrate intakes are associated with increased triglyceride and reduced HDL-cholesterol concentrations (13). In the present study, all diets were associated with consistent falls in HDL-cholesterol, but there were no significant effects on triglycerides. In view of the well-documented triglyceride-lowering effect of fish and n-3 PUFA (14), it may be significant that the greatest trends toward increased triglycerides (not statistically significant) were observed on the two diets that did not contain fish (kangaroo and vegetarian). The relatively high dietary fiber intake (from fruit and vegetables) may have also helped prevent the rise in triglycerides (15).

Another consistent finding on all diets was the substantial reduction in the percentage of linoleic acid in both the cholesteryl ester and phospholipid fractions and the increase in the palmitic acid percentage in the phospholipid and cholesteryl ester fractions and palmitoleic acid percentage in the cholesteryl ester fraction. The reductions in linoleate were evident in all subjects within seven days of starting the low fat diets and were even more marked by 14 days. Following the resumption of the normal high fat diets the percentage of linoleate returned to the prediet values. The linoleic acid content of all the low fat diets was considerably reduced compared with the normal high fat diet values, and this presumably acounts for the reduction in the percentage of linoleic acid in the plasma lipids. Some workers have estimated that the dietary requirements of linoleic acid in man are greater than the values found on the present low fat diets (16); however, there was no evidence of any significant amounts of 20:3n-9 in the plasma in these studies.

There were other changes in plasma lipid fatty acid profiles in this study that were quite diet-dependent. The three diets containing 20- and 22-carbon PUFA showed a marked alteration of fatty acid profiles, with an obvious positive relationship between the presence of particular dietary 20- and 22-carbon PUFA and the increase in the percentage of those PUFA in the phospholipid and cholesteryl ester fractions. There was no change in the percentage of 20- and 22-carbon PUFA on the vegetarian diet, suggesting that the increase of these PUFA in the plasma lipids on the other low fat diets was due to their presence in the diet.

Despite very low levels of the dietary 20- and 22-carbon PUFA (0.3–1.1 g per day), there was a significant increase in the proportion of these fatty acids in the plasma lipids. The data also show that there is a marked difference in the incorporation of dietary 18-carbon PUFA and dietary 20-and 22-carbon PUFA in man. This is particularly evident on the kangaroo diet, where the level of 18:2n-6 was twice that of 20:4n-6 in the meat, yet the percentage of 20:4n-6 rose and that of 18:2n-6 fell in the plasma lipids. This difference has been noted previously in our field studies (2). Differences between the incorporation of dietary 20:4n-6 and 22:6n-3 relative to their respective 18-carbon precursors have been noted previously in experimental animals (17–20) and also more recently in man for 20:5n-3 and 22:6n-3 compared with 18:3n-3 (21).

Since the predominant PUFA in the Western diet are 18-carbon PUFA (22), it has been assumed that most of the tissue 20- and 22-carbon PUFA originate from the conversion of the 18-carbon EFA in the liver. However, there has been some discussion as to the relative importance of dietary long chain PUFA, since it has been argued that the conversion process of 18- to 22-carbon PUFA in man is an inefficient process (23–25). The present results using very low fat diets show that small amounts of dietary 20- and 22-carbon PUFA (0.3–1.1 g/day) can have a significant effect on the plasma fatty acid composition in man.

ACKNOWLEDGMENTS

This work was supported by grants from the Fishing Industry Research Committee (Department of Primary Industry, Commonwealth of Australia) and the National Heart Foundation of Australia. We thank Southern Game Meats, Sydney, Australia for providing the kangaroo meat.

[Received October 20, 1986]

Effect of Choline, Ethanolamine and Serine Supplementation on the Membrane Properties of *Microsporum gypseum*

R. Pandey, R.S. Verma[1] and **G.K. Khuller***
Department of Biochemistry, Postgraduate Institute of Medical Education and Research, Chandigarh-160012, India

Phospholipid bases, choline and ethanolamine, when supplemented in the growth medium of *Microsporum gypseum* resulted in an increase in the corresponding phospholipid and total phospholipid content. However, when serine was supplemented, marginal changes were observed. The fatty acid profile of phospholipids remained almost unchanged. The uptake of lysine, leucine and aspartic acid in the spheroplasts of choline- and ethanolamine-grown cells was higher as compared to the control. 1-Anilinonaphathalene-8-sulfonate (ANS) binding to the spheroplast membrane, as calculated from Scatchard plots, demonstrated an increase in the number of binding sites in choline- and ethanolamine-grown cells, while a decrease was observed in the serine-supplemented cells. The results are discussed in terms of the effect of phospholipid polar head group composition on the membrane structure and function of this fungus.
Lipids 22, 530-534 (1987).

Several factors, such as growth, temperature and composition of the medium, have previously been utilized to modulate the phospholipid composition of the membranes of various microorganisms (1). Less attention has been focused on determining the exact role of lipids and phospholipids in the structure and function of dermatophyte membranes. Dermatophytes, a group of filamentous, pathogenic fungi, have been studied extensively for their lipid composition and lipid-metabolizing enzymes and phospholipid metabolism (2). Several antifungal drugs are known to bind the membrane components, namely, fatty acids, sterols and phospholipids (1,3,4); hence, it becomes essential to study the role of phospholipids in the structure and function of dermatophyte membranes. While information is available on the role of lipids in amino acid accumulation in dermatophytes, no attention has been given to the structural aspects of the membranes (5,6) as influenced by lipid content. In this study, different nitrogenous phospholipid bases (choline, ethanolamine and serine) have been used to modulate the phospholipid composition of a dermatophyte, *Microsporum gypseum*. These compounds have been known to enrich the cell membrane with corresponding phospholipids (phosphatidylcholine and phosphatidylethanolamine) in *Saccharomyces cerevisiae* and *Candida albicans* (7,8). Further attempts have been made to correlate the alterations produced in phospholipids with the structural and functional changes in the membranes.

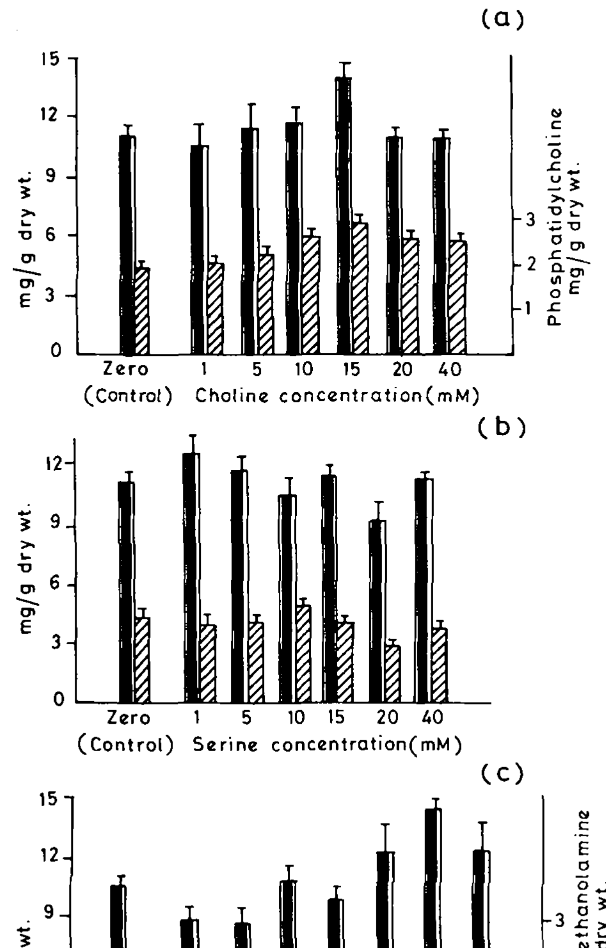

FIG. 1. Effect of supplementation of nitrogenous bases on the total (TPL) and individual corresponding phospholipid levels. (a) Effect of choline supplementation on TPL (solid column) and phosphatidylcholine (hatched column) levels; (b) effect of serine supplementation on TPL (solid column) and phosphatidylserine + phosphatidylinositol (PS+PI; hatched column) levels; and (c) effect of ethanolamine supplementation on TPL (solid column) and phosphatidylethanolamine (PE; hatched column) levels.

MATERIALS AND METHODS

Materials. Labeled amino acids, [U-^{14}C]L-lysine (sp act 126 mCi/mmol), [U-^{14}C]L-leucine (sp act 62 mCi/mmol) and [U-^{14}C]L-aspartic acid (sp act 152 mCi/mmol), were obtained from BARC (Bombay, India). Lysine, leucine and aspartic acids were purchased from Sigma Chemical Co. (St. Louis, MO). Novozyme 234 was from M/S Novo Industries (Bagsvaerd, Denmark). Ficoll-paque was purchased from Pharmacia Fine Chemicals Co. (Uppsala, Sweden). 1-Anilinonaphthalene-8-sulfonate (ANS), Mg salt, was obtained from Fluka (Buchs, Switzerland). Membrane

filters (0.45 μM) and a 12-place sampling manifold used for the amino acid accumulation experiment were obtained from Whatman Inc. (London, U.K.) and Millipore Inc. (Bedford, MA), respectively. All other chemicals used were of the highest purity available.

Growth of culture. M. gypseum, obtained from the Mycological Reference Laboratory, School of Hygiene and Tropical Medicine, (London, U.K.) was maintained on Sabouraud's dextrose agar slants. It was grown for experimental purposes in Sabouraud's broth (4% glucose, 1% peptone, pH 5.4–5.6) at 27 C as surface cultures. Choline, ethanolamine and serine were supplemented in the medium at different concentrations. The cells were harvested 16 days after inoculation in mid-log phase and processed for lipid extraction and membrane studies by the following methodology.

Quantitation of phospholipids. The lipids were extracted from the cells by Folch's extraction procedure (9). Total phospholipids were quantitated by the method of Bartlett, as modified by Marinetti (10). The individual phospholipids were separated by single dimension thin layer chromatography using the solvent system chloroform/methanol/7N NH_3 (65:25:4,v/v/v). Total phospholipids separated from the neutral lipids were used for fatty acid analysis. Fatty acids were converted into their methyl esters by transesterification with methanol in the presence of thionyl chloride, as described earlier (11). The methyl esters were separated on a Pye Unicam Model 104 Gas Chromatograph, using a flame ionization detector and column containing 10% diethylene glycol succinate on CAW (100–200 mesh) with nitrogen as a carrier gas at a flow rate of 40 ml/min. The fatty acids were quantitated by triangulation.

Preparation of spheroplasts. Spheroplasts were prepared by the procedure of Larroya et al. (12) with some modification. Log phase cells were incubated under sterile conditions with Novozyme 234 (30 mg/g wet wt of mycelium) in a conical flask in 10 mM citrate phosphate buffer (pH 6.5) containing 145 mM NaCl for 12–15 hr in a shaker at 30 C. Formation of spheroplasts was monitored microscopically. The incubation mixture was removed by centrifugation at 1000 g for 10 min to recover the cells. The pellet was washed twice with citrate phosphate buffer as mentioned above. The spheroplasts were

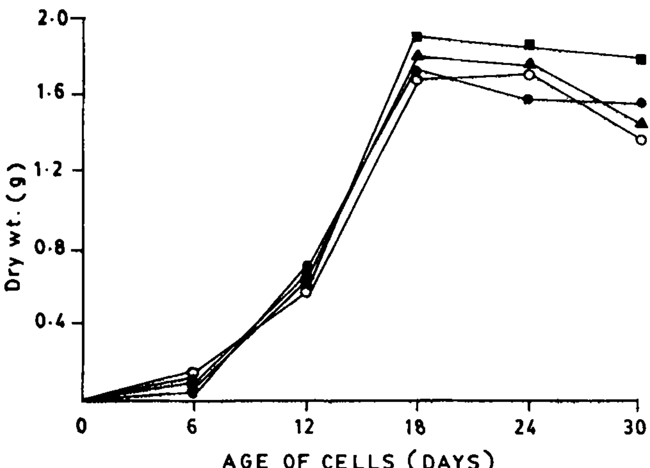

FIG. 2. Effect of supplementation of nitrogenous bases (at optimum concentration) on the growth pattern of *M. gypseum*.

purified by centrifugation on a Ficoll-paque density gradient at 400 g for 15 min. The spheroplast fraction, free of cell debris, was used for further studies (amino acid uptake and structural studies with fluorescent probe ANS).

Amino acid uptake studies. Amino acid uptake by spheroplast was examined according to a method standardized in our laboratory. In brief, spheroplasts containing 100–150 μg protein were incubated at 27 C for 7 min (optimum time) in 10 mM citrate phosphate buffer (pH 6.5) containing 145 mM NaCl; 800 nmol of labeled amino acid (sp act 0.2 μCi/μmol) was added to bring the total assay volume to 200 μl. The Kt values for lysine, leucine and aspartic acid were found to be 2.0, 2.3 and 2.8 mM, respectively. The reaction was started by the addition of respective amino acid, stopped by the addition of chilled buffer and rapidly filtered through 0.45 μM membrane filters. The filter paper was washed twice, dried and counted for radioactivity in a toluene-based fluid in a Packard Tricarb Liquid Scintillation Counter. Protein was estimated by the method of Lowry et al. (13).

Structural studies with ANS. ANS was used to study the structural changes in the spheroplast membrane pre-

pared from variously grown *M. gypseum* cells. The basic assay mixture consisted of a total volume of 1 ml in 10 mM citrate phosphate buffer (pH 6.5) containing 145 mM NaCl, 50 μM ANS and spheroplast protein ranging from 20–250 μg. The readings were taken as an emission spectrum in a Shimadzu RF-540 spectrofluorimeter with a recorder. Quartz cuvettes of 1.5 ml capacity and 0.5 cm light path were used for the study. Zero correction and spectrum correction were applied and the number of binding sites were calculated from the Scatchard plots (14) drawn as described elsewhere (15).

RESULTS AND DISCUSSION

Phospholipids of the cell are almost exclusively present in the cellular membranes in most microorganisms. Any change in the growth medium or conditions is likely to result in alterations in the normal structure and function of the membrane. The phospholipid composition can be altered in vivo, either (i) by inclusion of fatty acids and other additives in the medium, which results in an altered fatty acyl chain composition or (ii) by including the precursors of phospholipid polar head groups in the growth medium (16). In this investigation, we have followed the latter approach to examine the influence of polar head groups of phospholipids on the membrane functions in *M. gypseum* cells, as the first approach has already been adapted for this fungus (17).

Phosphatidylserine (PS) plus phosphatidylinositol (PI), phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were found to be the major phospholipids in *M. gypseum*; this differed from our earlier reports (5,6) because of age of the culture, separation techniques and composition of the medium. Optimum concentrations for the supplementation of the nitrogenous phospholipid bases, namely, choline, serine and ethanolamine, were determined by measuring the levels of total and corresponding phospholipids. As PI was a minor component with mobility close to PS, they were pooled. Figure 1 shows that 15, 10 and 40 mM concentrations of choline, serine and ethanolamine, respectively, were found to be optimum concentrations, as total phospholipid and corresponding phospholipid content has maximum alterations at these concentrations vs the control where no additive was supplemented in the medium. However, the increase in PS + PI on serine supplementation was marginal. The *M. gypseum* cultures grown in the medium supplemented

with nitrogenous bases did not demonstrate any difference in the growth pattern (Fig. 2), as observed earlier with *S. cerevisiae* (7). Hence, cells were harvested in the mid-log phase after 16 days of growth. Supplementation of the choline analogues like N,N-dimethylethanolamine, N-monomethylethanolamine and ethanolamine also did not significantly affect the growth of C_6 glial cells in culture (16).

Total phospholipid levels increased significantly with choline and ethanolamine, but no significant change was observed with serine (Table 1). Supplementation of choline and ethanolamine has also been demonstrated to enhance the total phospholipid content in *S. cerevisiae* (7). The levels of PC and PE increased significantly on ethanolamine supplementation, although only PC content increased when choline was supplemented. The levels of other phospholipids were not altered significantly under these conditions. The increase in the PS + PI fraction on serine supplementation was not significant, but PE levels decreased significantly. In *C. albicans* and *S. cerevisiae,* choline and ethanolamine supplementation altered the PC and PE content, respectively (1,8), identical to our observations with *M. gypseum.*

The fatty acid profile, as well as the ratio of unsaturated to saturated (U/S) fatty acids, did not change significantly with supplementation of these nitrogenous bases (Table 2). However, a significant decrease (40%) was observed in oleic acid content with supplementation of choline and ethanolamine. The insignificant changes observed in phospholipid fatty acids provide a system to study the functional role of phospholipid polar head groups in membranes of *M. gypseum.* Similar observations have been reported with C_6 glial cells (16) where supplementation of polar head groups resulted in alteration in the phospholipids, but no change was seen in the fatty composition. In the absence of any major change in fatty acid composition and enrichment of methylated phospholipids like PC, it is expected that choline- and ethanolamine-supplemented cells will have more permeable membranes (18,19).

The functional properties of the membranes in response to changes in phospholipid composition were studied by measuring the uptake of a basic, neutral and acidic amino acid under optimal conditions. The uptake of all three amino acids (lysine, leucine and aspartic acid) increased in the spheroplasts prepared from choline- and ethanolamine-grown cells about 1.5- to 2-fold, while in serine-supplemented cells, it did not change significantly (Table 3). There have been various reports on the functional aspects of polar head group–induced alterations in the phospholipids and the rigidifying or fluidizing effects on the membrane have been demonstrated. In *C. albicans* and *S. cerevisiae,* choline and ethanolamine supplementation modulates the phospholipid composition in such a way that the amino acid uptake is inhibited in supplemented cells, irrespective of the variations in the PC/PE ratio (8). The amino acid uptake alters with a change in the carbon source, addition of ethanol or alteration of growth temperature (6). Although the PC/PE ratio plays a crucial role in the functioning of the membrane, there are various other components such as proteins, glycoproteins and sterols that have an overall combined effect on the membrane structure and functions.

Changes in the phospholipid composition and function have not been correlated with the structural organization of the membranes. There have been reports on the effect of supplementation of the media with choline and ethanolamine, but no information is available with serine. The Scatchard plot analysis shows increased binding sites in spheroplasts prepared from choline- and ethanolamine-supplemented cells (Fig. 3). Trivedi et al. (8) have demonstrated a decrease in the number of binding sites with choline and ethanolamine supplementation in two different strains of *S. cerevisiae,* but our results showed an increase in *M. gypseum,* although the number in serine-grown cells was lower vs unsupplemented cells. As is apparent from the phospholipid composition of vari-

TABLE 4

Effect of Supplementation of Phospholipid Bases on the Number of Binding Sites for ANS[a] on *M. gypseum* Spheroplasts

Type of cells (base supplemented)	No. of binding sites (nmol/mg protein)
None (control)	180
Choline (15 mM)	240
Serine (10 mM)	152
Ethanolamine (40 mM)	198

[a]ANS, 1-anilinonaphthalene-8-sulfonate.

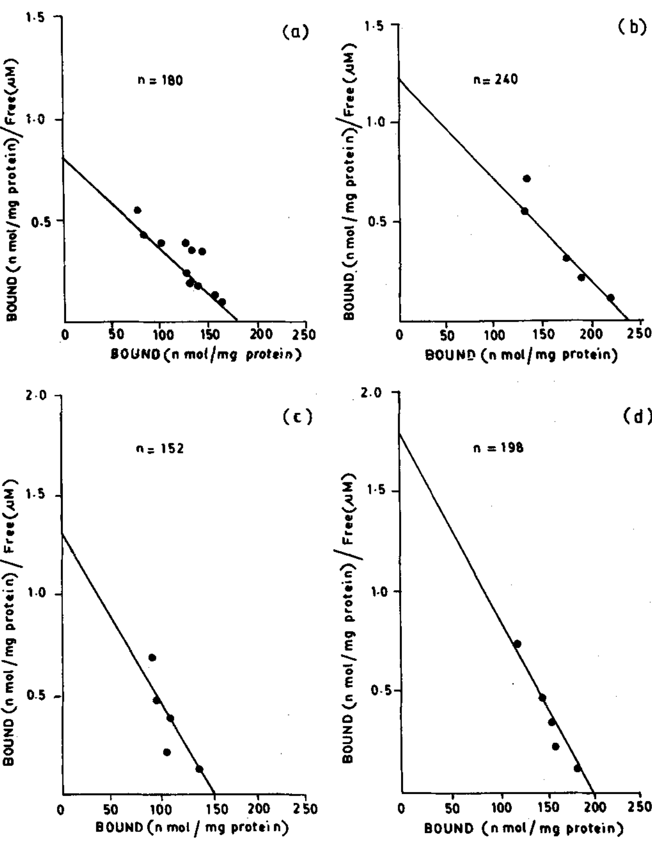

FIG. 3. Scatchard plots of 1-anilinonaphthalene-8-sulfonate binding with *M. gypseum* spheroplasts (based on experiments carried out in duplicate) of (a) control cells; (b) choline-grown cells; (c) serine-grown cells; and (d) ethanolamine-grown cells.

ously grown cells (Table 1), the levels of PC increased in choline-supplemented cells and both PC and PE increased in ethanolamine-grown cells, but PE decreased in serine-supplemented cells. At physiological pH, PE is slightly negatively charged compared to PC, which is neutral and exists in zwitterionic form (20). Hence, the binding of ANS, which itself is anionic at neutral pH, would be increased in membranes having more PC than PE. Thus, high PC content in choline- and ethanolamine-grown cells may be responsible for the increase in the number of binding sites in these cells vs unsupplemented cells. Similarly, the decrease in the number of binding sites in serine-grown cells may be due to another anionic component, PS + PI, which has a role in the overall membrane surface charge. Lower phospholipid content in serine-supplemented cells of *M. gypseum* may also be the reason for the observed decrease in the number of binding sites in these cells. The changes observed in the ANS binding pattern may also be due to either the changed hydrophobic environment around the embedded dye or the altered hydrophobic environment around the integral membrane proteins (21,22). It has been shown that ANS does not enter the cell interior and is mainly bound to the membrane surface (23); hence, the observed changes demonstrate a role of phospholipids and proteins in cell membrane.

In brief, it can be concluded from this study that supplementation of phospholipid bases results in the enrichment of PC or PE in the membranes of *M. gypseum* without inducing any significant alteration in the fatty acid composition of phospholipids. Functional and structural changes could be correlated with the phospholipid polar head group composition.

Slow Recovery of the Fatty Acid Composition of Sciatic Nerve in Rats Fed a Diet Initially Low in n-3 Fatty Acids

J.M. Bourre[a,*], A. Youyou[a], G. Durand[b] and G. Pascal[b]
[a]INSERM U-26, Hopital Fernand Widal, Paris, France and [b]INRA-CNRZ, Jouy-en-Josas, France

The sciatic nerve of rats fed sunflower oil (6 mg 18:3-n-3/100 g of diet) presented dramatic alterations in the long chain polyunsaturated fatty acids in comparison with those fed soy oil (130 mg 18:3n-3/100 g of diet). In both 15-day-old and 60-day-old animals fed sunflower oil, 22:6n-3 (cervonic acid) was four-fold less, 22:5n-6 was 10-fold greater; adrenic acid (22:4n-6) was slightly greater and arachidonic acid (20:4n-6) was close to that in rats fed soy oil. The percentage distribution of total polyunsaturated fatty acids as well as the individual saturated and monounsaturated fatty acids were the same in both groups.

When the sunflower oil–fed animals were switched to a soy oil–containing diet for either 15 or 60 days, the percentage distribution of 22:6n-3 increased slowly to reach the control value 2.5 months later. Conversely 22:5n-6 decreased slowly. The decay of 22:5n-6 was more rapid than the increase of 22:6n-3.
***Lipids 22,* 535–538 (1987).**

The fluidity of the lipid environment appears to modulate the activity of membrane-bound enzymes; this fluidity is controlled by essential polyunsaturated fatty acids (PUFA). Increased PUFA, particularly arachidonic acid, were found in endoneurial phosphatidylethanolamine of both developing and regenerating rat sciatic nerve, suggesting a close association between PUFA and peripheral nerve myelination (1). Alterations of PUFA during damage paralleled changes in phospholipid fatty acid composition (2).

The effect of essential fatty acid (EFA) deficiency on rat peripheral nerve myelin has been previously analyzed (3). After 8 mo on the deficient diet, 20:3n-9 was found in the major myelin phospholipids. The level of 18:1n-9 was increased and the levels of 18:2n-6 (linoleic acid), 20:4n-6 (arachidonic acid) and 22:4n-6 (adrenic acid) were decreased. The ratio of 20:4n-6 to 20:3n-9 was clearly depressed by an EFA deficiency (3).

No significant differences in morphology, histology, rate of axonal transport or conduction velocity of peripheral nerve were demonstrated between EFA deficient and control rats (4). Therefore, it would appear that dietary EFA deficiency in postweaned rats can induce fatty acid alterations in peripheral nerve myelin without resulting in detectable changes in function or structure. An excellent review of the lipid composition of normal and degenerating nerve has been recently published (5).

The essentiality of PUFA for the central nervous system has been extensively studied (6–14). The specific role of n-3 fatty acids has been recently reexamined. Interestingly, a pathogenesis of deficiency in linolenic acid has

tr, Traces. Dietary lipid fatty acid composition was analyzed by gas chromatography of methyl esters under the following conditions: Packard model 427 gas chromatograph; glass capillary column; stationary phase FFAP; gas pressure vector H_2, 0.6 bar; temperature, 190 C; detection by flame ionization.

been described in the monkey (15) and in man (16). A syndrome of modern society has been put forward as a deficiency in acids of the n-3 series (17).

Our previous studies have shown that a diet lacking in α-linolenic acid (sunflower or peanut oil) can modify the PUFA composition in all the cellular and subcellular fractions of brain lipids examined. The percentage distribution of total PUFA remains unchanged, the sharp drop in 22:6n-3 being counterbalanced by an increase in 22:5n-6 (18,19). With a change from a diet containing sunflower oil to one containing soy oil, the uptake of n-3 fatty acids is remarkably slow, e.g., it takes several months before the cerebral organelles recover a normal quantity of cervonic acid (22:6n-3) (20).

However, little attention has been paid to n-3 PUFA in the peripheral nerve. This work was undertaken to determine (i) the specific alterations of peripheral nerve fatty acids in rats fed a diet rich in n-6 fatty acids but deficient in n-3 fatty acids and (ii) to assess the speed of the recovery of the n-3 fatty acid composition induced when a diet containing n-3 fatty acids is reintroduced.

Our preliminary results have shown that when rats are fed a diet deficient in n-3 fatty acids (peanut or sunflower oil), both peripheral nerve and muscle contain reduced amounts of n-3 fatty acids; more specifically, 22:6n-3 is replaced by 22:5n-6 (21).

In each experiment, fatty acid determination was performed in triplicate on 8 pooled nerves. At least 3 experiments were performed.

were fed with a semisynthetic diet containing 1.5% sunflower oil (6 mg % α-linolenic acid). Two weeks before mating, one group (2/3 of the animals) was continued on that diet, while the other group was changed to a diet in which sunflower oil was replaced by 1.9% soy oil (130 mg % α-linolenic acid). Both oils and diets contained ca. 940 mg n-6 fatty acids. Since animals fed either diet ate similar amounts of food, they ate the same amount of n-6 fatty acids. Soy oil–fed rats received ca. 22 times more n-3 fatty acids than animals fed sunflower oil. The composition of the oils and the diets is shown in Tables 1 and 2. Under these experimental conditions, the α-linolenic acid deficiency (sunflower oil–fed rats) had no effect on fecundity (% of pregnant females), fertility (number of pups/litter), pup birth weight, food intake and weight of pregnant or lactating females, or pup growth during suckling. However, this deficiency did cause abnormally high rates of perinatal mortality from birth to postpartum day 3 (22). Three days after delivery the litters (fourth generation) were adjusted to 10 animals. After weaning, the young rats received the same diet as their mother. At 15 days of age, half the animals fed sunflower oil were fed soy oil from then on. In these animals, the n-3–deficient diet was therefore substituted by an n-3–normal diet. The same procedure was performed on other animals at 60 days. Thus, we determined the speed of recovery of fatty acid composition in young and in adult animals. Only male animals were used throughout. The sciatic nerves were very carefully dissected to avoid any contamination by adipose tissue.

Analytical methodology. The sciatic nerve was dissected outward, and lipids were extracted by sonication in chloroform/methanol (2:1, v/v) (23,24) and methylated (25). Fatty acid methyl esters were separated by gas liquid chromatography (GLC) on an open tubular capillary column coated with FFAP (0.30 mm in diameter, 45 m long), using a flame ionization detector. Identification of fatty acids was performed with commercial standards by the means of relative retention times. Areas were calculated with an ICAP integrator (LTT, Paris, France).

RESULTS AND DISCUSSION

Fatty acid analysis (Table 3). The sciatic nerve of sunflower oil–fed animals (6 mg % n-3 fatty acids) presented dramatic alterations in the very long chain polyunsaturated fatty acids in comparison to soy oil–fed (130 mg % n-3 fatty acids) animals. The n-3/n-6 ratio was six- and four-fold less in 15- and 60-day-old animals fed sunflower oil. In both 15-day-old and 60-day-old animals, 22:6n-3 was ca. five- and four-fold less, respectively; conversely, 22:5n-6 was 10-fold greater in sunflower oil–fed animals (22:4n-6 was greater; 20:4n-6 was close to normal). The percentage distribution of PUFA to total fatty acids was normal in sunflower oil–fed animals, as were individual saturated and monounsaturated fatty acids.

In agreement with Yao (30), we found that during development 20:4n-6 and 22:6n-3 decreased and 18:1n-9 increased. The values we obtained compared favorably with previously published results (26–32).

A control group was obtained by feeding animals with regular diet (standard chow). No significant difference was found between this group and animals fed with soy oil.

This study was performed on whole nerve, and contami-

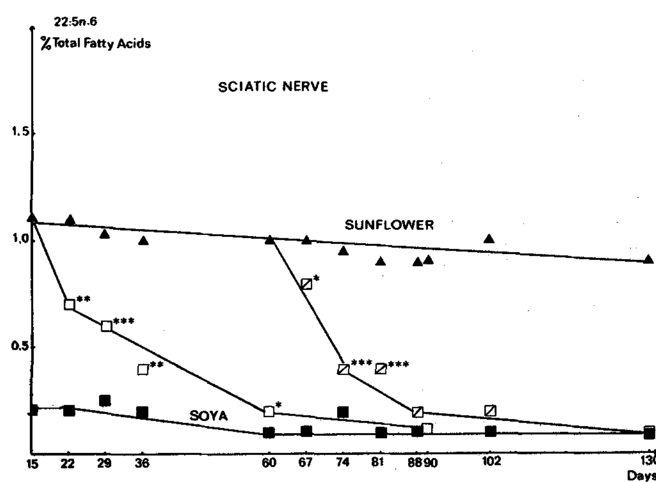

FIG. 1. Recovery of fatty acid composition (mg %) as measured by the amount of cervonic acid (22:6n-3) in animals fed soy oil, sunflower oil or soy oil replacing sunflower oil in either 15-day-old or 60-day-old rats. Dietary lipid fatty acid composition was analyzed by gas chromatography of methyl esters under the following conditions: Packard model 427 gas chromatograph; glass capillary column; stationary phase FFAP; gas pressure vector H_2, 0.6 bar; temperature, 190 C; detection by flame ionization. Solid squares, soy-fed animals; triangles, sunflower-fed animals; open squares, animals initially fed sunflower oil, then fed soy oil when 15 days old; hatched squares, animals initially fed sunflower oil, then fed soy oil when 60 days old. *, $p < 0.05$; **, $p < 0.005$; ***, $p < 0.001$; 552 animals were used. Values at each time point represent mean for at least 4 samples. Each sample consisted of sciatic nerves from 4 rats.

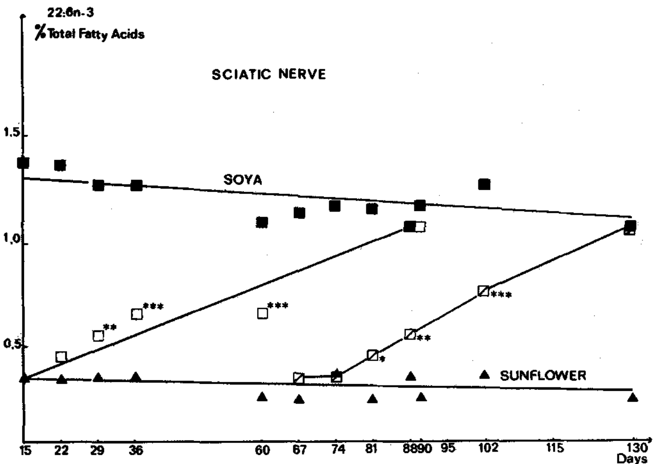

FIG. 2. Recovery of fatty acid composition (mg %) as determined by the amount of 22:5n-6 in animals fed soy oil, sunflower oil or soy oil replacing sunflower oil in either 15-day-old or 60-day-old rats. Dietary lipid fatty acid composition was analyzed by gas chromatography of methyl esters under the following conditions: Packard model 427 gas chromatograph; glass capillary column; stationary phase FFAP; gas pressure vector H_2, 0.6 bar; temperature, 190 C; detection by flame ionization. Solid squares, soy-fed animals; triangles, sunflower-fed animals; open squares, animals initially fed sunflower oil, then fed soy oil when 15 days old; hatched squares, animals initially fed sunflower oil, then fed soy oil when 60 days old. *, $p < 0.05$; **, $p < 0.005$; ***, $p < 0.001$; 552 animals were used. Values at each time point represent mean for at least 4 samples. Each sample consisted of sciatic nerve from 4 rats.

nation by adipose tissue was carefully eliminated. However, endoneurium, perineurium and epineurium were not separated. Thus, specific alteration in one of these elements is not excluded as they present differences in lipid composition (5,32).

Recovery of altered fatty acid composition. Figure 1 shows changes for 22:6n-3 and Figure 2 for 22:5n-6 after changing the dietary oil from sunflower to soy oil. As no significant differences were found for the other fatty acids, the curves are not shown. However, 22:4n-6 was found to be increased in sunflower oil–fed animals, and the recovery after starting soy oil was slow in 60-day-old animals. In the 15-day-old animals, the decrease was hardly significant, and thus the recovery was difficult to estimate. The high level of 22:4n-6 in sciatic nerve in comparison with brain is to be noted. Sciatic nerves of adult animals fed sunflower oil contained a slightly increased percentage distribution of saturated and monounsaturated very long chain fatty acids. When the sunflower oil–fed animals received a diet containing soy oil at either 15 or 60 days, the percentage distribution of 22:6n-3 increased slowly to reach the control value after 2.5 months (Fig. 1). Conversely, 22:5n-6 decreased slowly throughout (Fig. 2). Interestingly, in adult animals, the recovery did not start from the day on which the diet was changed, but there was a delay of 20 days. In contrast, in young animals, the recovery started from a few days after changing the diet, but the recovery was statistically significant only after 14 days. It is interesting to note that the recovery as measured by the decay of 22:5n-6 was more rapid than with increase of 22:6n-3. This very low speed of recovery of PUFA composition of sciatic nerve after deprivation of n-3 fatty acids was unexpected. We have previously shown (20) that all brain subfractions (myelin, synaptosomes, mitochondria and microsomes) recover very slowly but all at the same speed. Thus, the peripheral nervous system responds to dietary fatty acid changes in a manner similar to the central nervous system.

The slow recovery could be due to the slow turnover of major membranes in the peripheral nervous system. Another explanation could be that the rate-limiting factor is the reduced in situ synthesis of n-3 fatty acid synthesis from α-linolenic acid due to low desaturase activity.

In addition, nervous tissue contains a very minute amount of α-linolenic acid, and studies of brain cells in culture have suggested that the only truly essential fatty acid for these cells is probably 22:6n-3 (33). Thus, another explanation for the low recovery of fatty acid composition could be either a limited transport through the blood-nerve barrier or a restricted synthesis of 22:6n-3 by the liver or reduced dietary origin.

METHODS

An Improved Method for the Colorimetric Assay of Lipase Activity Using an Optically Clear Medium

[a]Laboratoire de Genie Enzymatique, ENSCM, Montpellier Cedex, France, and [b]Division Chimie des Corps Gras, IRHO/CIRAD, Montpellier Cedex, France

Lipase activity can be spectrophotometrically measured in an optically clear medium using long chain fatty thioesters of 1-mercapto-2,3-propanediol or 2-mercaptoethanol as substrates. With hexamethylphosphoric triamide solutions of these thiosubstrates, the Michaëlis-Menten constants of lipase from *Rhizopus arrhizus* were determined. The effects of calcium chloride and of bovine serum albumin on the enzyme activity were established.
Lipids 22, 539-541 (1987).

A surprisingly large number of different procedures has been reported for determining the activity of various lipase preparations (see recent review by Jensen [1]). This could imply that many of the present methods are not entirely satisfactory.

The most frequently used procedures are based on titrimetric determination of the acids liberated by the action of the enzyme, using either water-soluble or water-insoluble esters as substrates (2-5). Higher sensitivity than that of the titrimetric assay can be obtained using radioactively labeled substrates (6,7), but these procedures, of course, require the availability of labeled compounds.

A very interesting method for measuring lipases and phospholipases uses the bioluminescent assay (8). This method, however, involves a second enzymatic reaction (luciferase), the pH dependence of which is quite different from that of the lipase assay.

The colorimetric assay based on the development of the characteristic color of p-nitrophenol due to hydrolysis of its colorless esters provides a sensitive test of esterase activity (9). However, because of the low solubility of long chain fatty acid esters, the method is preferably applicable to esterase. The use of thioesters (Fig. 1) of fatty acids, associated with Ellman's reagent (10), has been investigated (11,12). Unfortunately, these thioesters are water-insoluble and require dispersing agents and special treatment before the colorimetric analysis (13,14).

We report here on an improved method using an optically clear medium for the colorimetric assay of lipase activity with long chain fatty acid thioesters.

MATERIALS AND METHODS

Reagents. Lipase of *Rhizopus arrhizus* was purchased from Gist-Brocades (Seclin, France) and used without further purification. Hexamethylphosphoric triamide (HMPA) and 5,5′-dithio-*bis*(2-nitrobenzoic) acids (DTNB) were obtained from Aldrich France (Strasbourg, France). All other chemicals were reagent grade, obtained from commercial sources.

Palmitoyl chloride. One hundred g (0.39 mol) of palmitic acid and 100 g (0.84 mol) of thionyl chloride were refluxed overnight. After removing the excess thionyl chloride under vacuum, the residue was distilled to give 93.8 g (0.35 mol) of colorless liquid (bp 18, 150 C).

Thioglycerol S-palmitate (1). 1-Mercapto-2,3-propanediol (10.8 g, 0.1 mol) and dry pyridine (5 g, 0.06 mol) were dissolved in 100 ml of anhydrous diethyl ether. The solution was cooled to 0 C, and 7 g (0.025 mol) of palmitoyl chloride in 30 ml of anhydrous diethyl ether was added dropwise. The mixture was left to stir at room temperature for 2 hr, then was washed four times with 50 ml of cold water and dried over sodium sulfate. Fifteen g of crude product containing a mixture of different acylated compounds were chromatographed on silica gel 60 (Merck, Darmstadt, Federal Republic of Germany; petroleum ether/diethyl ether, 90:10, v/v). The pure thioester obtained has physical properties identical to those described previously (11): IR ($CHCl_3$) 3400 (broad), 2940, 2870, 1700, 1460, 1080 cm^{-1}; mp, 78 C.

Mercaptoethanol S-palmitate (2). Dry pyridine (5 g, 0.06 mol) was added to a solution of 2-mercaptoethanol (8 g, 0.1 mol) in 100 ml of dry diethyl ether. Palmitoyl chloride (7 g, 0.025 mol) in 300 ml of dry diethyl ether was added dropwise at 0 C. The reaction mixture was left to stir at room temperature, then was washed four times with 50 ml of water and dried over sodium sulfate. Ten g of crude material was obtained after removing the organic solvent under vacuum. After being chromatographed on silica gel 60 (Merck; petroleum ether/diethyl ether, 90:10, v/v), 3.2 g (9.7 mmol) of pure product were isolated. IR ($CHCl_3$) 3490 (broad), 2950, 2860, 1690, 1460, 1110 cm^{-1}, mp, 55 C.

Enzyme activity assay. The measuring cuvette contained 100 μl of a HMPA thiosubstrate solution, 100 μl of a DTNB solution (initial concentration, 20 mg/ml in HMPA), 300 μl of HMPA and 2.4 ml of Tris buffer (initial concentration, 0.05 M; pH 8). The reaction mixture was kept at 37 C, and 100 μl of aqueous lipase solution was added. The absorbance was recorded immediately at 412 nm ($\varepsilon = 14.8\ 10^3\ l.mol^{-1}.cm^{-1}$) for 2 to 3 min. A linear increase of the absorbance was observed during this recording time.

RESULTS

Due to their insolubility in water, compounds 1 and 2 cannot be used directly in the assay medium. In the past, this problem was overcome through use of a biphasic system and emulsifiers (14). In our approach, we searched for hydrophilic organic solvents. It is known that lipases can function in an aqueous medium containing up to 20% of organic solvent, and recently Zaks and Klibanov reported that lipases can maintain their activity also in anhydrous organic solvents (16). HMPA solutions of compounds 1 and 2 give an optically clear medium and develop a yellow color in the presence of lipase activity.

We studied the influence of different amounts of HMPA in the assay solution. As can be seen in Figure 2, maximum activity was obtained for 15% (v/v) HMPA. At this concentration, the medium remained optically clear.

We recorded the initial velocity obtained for thioesters 1 and 2 when the substrate concentration was greater than that of the enzyme. In Figure 3, the data are recorded in a log/log scale because of the large amplitude of the enzyme concentration. Both thioesters show a straight line obeying the equation

$$\log v = \log [E] + B$$

$$\text{where } B = \log K : v = K [E]$$

Based on kinetic measurements with these compounds, Michaëlis-Menten constants were determined (Table 1 and Fig. 4).

When one compares the Km values, the substrate recognition appears to be the same for both products 1 and 2, while the greatest Vmax value is obtained with compound 2.

The molarity of Tris buffer is an important factor. As can be seen in Figure 5, maximum velocity was obtained at 0.05 M concentration.

Calcium ions have been shown to enhance the activity of certain lipases (17), although their mode of involvement is not definitely known. Calcium could directly modify the behavior of the enzyme (18), but it also modifies the solubilization of the free fatty acid formed during hydrolysis (1). The same has been proposed for the effect of bovine serum albumin (BSA). The effects of calcium chloride and BSA were, therefore, taken into account in our method. As can be seen in Figure 5, no noticeable

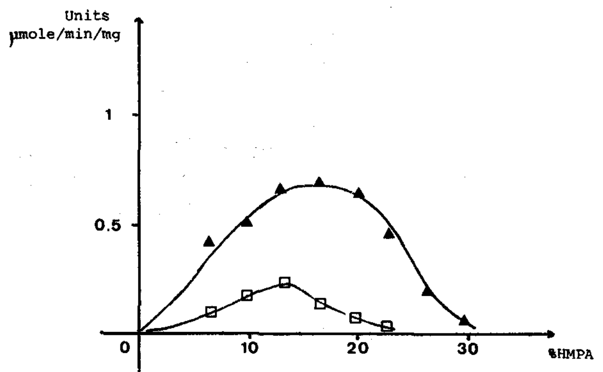

FIG. 2. Effect of hexamethylphosphoric triamide (HMPA) concentration on lipase activity. Experiments were carried out with concentration of compounds 1 (□) and 2 (▲) of 3.5×10^{-4} M and concentration of enzyme of 6×10^{-4} g/l.

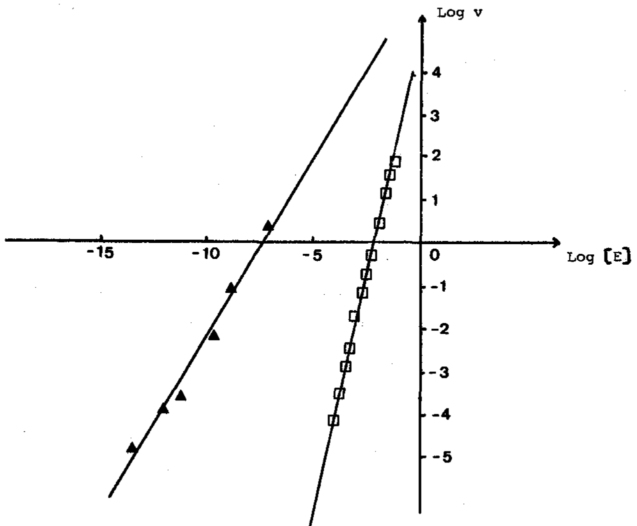

FIG. 3. Effect of increasing enzyme concentration depending on initial velocity with compound 1 (□) and compound 2 (▲). The reaction is linear with enzyme concentration up to 1.2×10^{-4} g/l for compound 1 and 1.6×10^{-4} g/l for compound 2.

TABLE 1

Michaëlis-Menten Constants of Lipase from *Rhizopus arrhizus*[a]

	Substrate	
	Thioglycerol S palmitate (1)	2-Mercaptoethanol S palmitate (2)
K_M mol/l	5.94 10^{-5}	9 10^{-5}
Vmax µmol/min/mg	0.246	0.713
Relative Vmax	1	3

[a]Experiments were carried out using commercial lipase from Gist-Brocades, France.

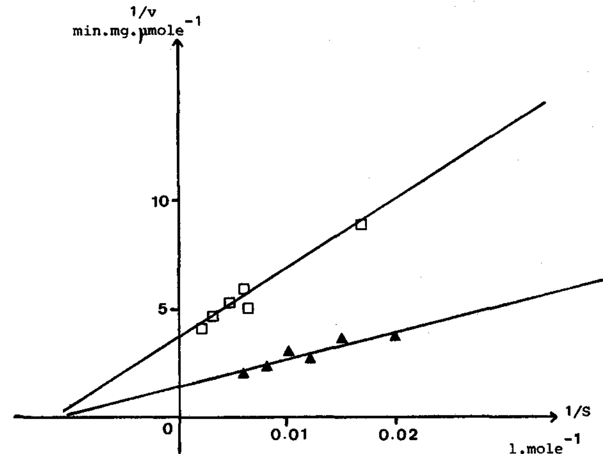

FIG. 4. Michaëlis-Menten treatment of kinetic data for compound 1 (□) and compound 2 (▲).

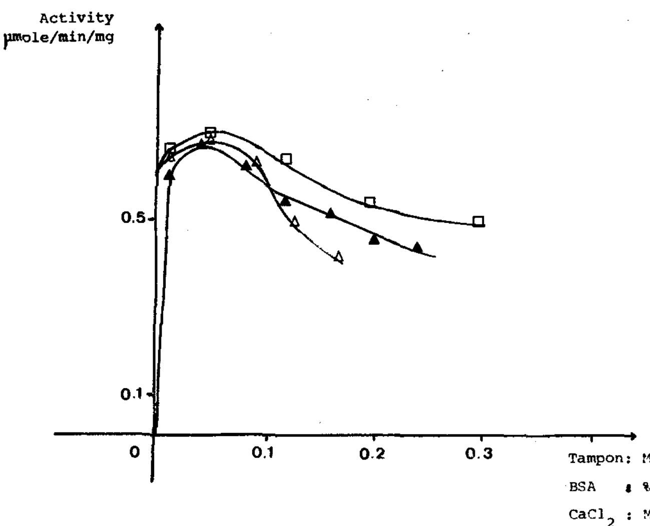

FIG. 5. Effect of buffer molarity (▲), amount of bovine serum albumin (BSA) (□) and calcium chloride molarity (△) on enzyme activity using compound 2.

effect was detected. The observed phenomenon is not sufficiently significant to justify the systematic use of calcium chloride or BSA for improving the sensitivity of the assay.

DISCUSSION

The use of acyl thioesters of mercaptoglycerol in the presence of DTNB has previously been reported (11,14). These authors showed that the results obtained are truly representative of lipase activity. A Japanese patent has recently been registered (19). None of the procedures described, however, is single-step; all require a separation step before lipase activity is measured. With the optically clear medium obtained through using HMPA as the cosolvent of fatty acid thioesters, we eliminated this disadvantage, making it possible to record enzyme activity within 2 min. To compare the sensitivity of this new method with that of the traditional titrimetric assay, we took kinetic measurements of commercial lipase according to the known assay (18). The specific activity that was determined by the titrimetric assay is expressed by a higher number than the one for the improved spectrophotometric method. This may be due to the different types of substrates used (olive oil vs thioesters). However, the spectrophotometric assay is more sensitive. It is possible

TABLE 2

Comparison of the Minimum Amount of Lipase Detected by Different Methods

	Substrate		
	Olive oil	Compound 1	Compound 2
Vmax units/mg	30	0.246	0.713
Minimum amount of lipase (mg/ml)	1	0.075	0.032

to detect lipase activity at levels 10 to 30 times lower when using compounds 1 and 2, respectively (Table 2).

In conclusion, with the improved spectrophotometric method, small amounts of lipase activity can be measured and more assays can be carried out within a short period of time.

Lack of Regression of Preestablished Gallstones in Mice

Anton C. Beynen*
Department of Laboratory Animal Science, State University, Utrecht, and Department of Human Nutrition, Agricultural University, Wageningen, The Netherlands

Feeding a high cholesterol, high cholic acid diet to mice for 28 days caused increased concentrations of plasma and liver cholesterol and formation of gallstones. Removal of cholesterol and cholic acid from the diet led to normalization of plasma and liver cholesterol within 28 days. Regression of the preestablished gallstones did not occur within 107 days.
Lipids 22, 542–543 (1987).

In various animal models, such as hamsters (1–4), prairie dogs (5) and mice (6,7), selective dietary manipulation causes gallstone formation. In hamsters, gallstones previously induced by feeding a lipid-free diet containing sucrose and casein are solubilized when casein is replaced by soybean protein (3). Gallstone dissolution also occurred when part of the sucrose component was replaced by pectin (4). In prairie dogs, dietary cholesterol–induced gallstones were found to disappear after removal of cholesterol from the diet (5). It thus appears that in these animal models regression of preestablished gallstones will occur after proper dietary change. In the studies mentioned (3–5), regression was seen within seven weeks after institution of the litholytic diet.

In a study in which a high cholesterol, high cholic acid diet was fed to seven inbred strains of mice (8), we fortuitously found the C57BL/U strain to be the only one that developed gallstones. The objective of the present study was to see whether preestablished gallstones in these inbred mice disappear when cholesterol and cholic acid are removed from the diet.

MATERIALS AND METHODS

Female and male mice, aged 7 to 38 weeks, of the C57BL/U strain were used. The strain is fully inbred; it is maintained at the Department of Laboratory Animal Science, Utrecht, The Netherlands. The mice were kept in wire-topped, polycarbonate cages (2 to 14 animals per cage) with a layer of sawdust as bedding. The cages were located in a room with controlled lighting (light, 06.00–20.00 hr; dark, 20.00–06.00 hr), constant temperature (18–20 C) and constant relative humidity (55–65%).

All mice had been fed a commercial pelleted mouse diet (RMH-B®, Hope Farms, Woerden, The Netherlands). On day 0 of the experiment, the mice of each sex were divided into a control and a test group with similar age distributions. The control mice (24 males, 37 females) were fed the commercial diet. The test groups (37 males, 23 females) were fed a pelleted lithogenic diet consisting of the commercial diet (92.5%, w/w), olive oil (5%), cholesterol (2%) and cholic acid (0.5%). Food and water were provided ad libitum.

On days 22, 23, and 27, mice were examined by veterinarians to assess possible discomfort; results have been published elsewhere (9). On day 28, 12 mice of each sex and diet group were chosen randomly for blood sampling and gallbladder examination. Blood samples were taken in the nonfasting state (between 09.00 and 13.00 hr) by orbital puncture into heparinized tubes under light diethyl ether anesthesia. Then, the anesthetized animals were killed by cervical dislocation, and the livers were removed. The gallbladder was examined visually for the presence of gallstones.

From day 28 on, the remaining control mice continued to receive the control diet for another 107 days. On day 135, they underwent the procedure described above. Mice that had been fed the lithogenic diet were transferred to the control diet. Six or seven animals were chosen for autopsy at days 56, 70, 93 and 135 of the experiment.

Plasma total cholesterol was determined enzymatically using a kit (Monotest®) supplied by Boehringer Mannheim GmbH (Mannheim, FRG). Liver cholesterol was extracted and analyzed according to the procedure of Abell et al. (10).

RESULTS AND DISCUSSION

Table 1 shows that feeding the lithogenic diet for 28 days caused increases in plasma cholesterol concentrations of 44 and 82% in male and female mice, respectively. Liver cholesterol had increased dramatically. There was a 20-fold increase in both males and females. The lithogenic diet increased liver weight. Hepatomegaly, expressed as percentage increase in liver wet weight, was about 50%. The enlarged livers showed a grey-white appearance.

After 28 days, the lithogenic diet significantly induced the formation of gallstones in male and female mice, the incidences being 11 and 8 out of 12 animals, respectively (Table 1). The gallstones within the gallbladder could be observed by the naked eye; they were present as spherical aggregates with diameters ranging between 0.1 and 0.8 mm. The gallbladders of the mice fed the lithogenic diet were markedly expanded by the accumulation of bile fluid. The stones moved freely within the bladder. Ebihara and Kiriyama (7), also using a high cholesterol, high cholic acid diet, reported similar observations in male ICR mice, and the gallstones were found to be typical cholesterol gallstones.

Table 1 also shows data of mice placed on the control diet after 28 days on the lithogenic diet. After another 28 days (day 56 of the experiment) on the control diet, plasma cholesterol had fallen toward control values in female mice, but was still somewhat increased (by about 10%) in the males. This increase in the male mice persisted throughout the experiment; it was not due to a time effect because plasma cholesterol concentrations remained constant in the mice fed the control diet during the entire experiment.

Within 28 days on the control diet (day 56) following the lithogenic diet, liver cholesterol concentrations had already dropped to values seen in animals fed the control diet all the time. Liver weight probably returned to control values, although at certain days (70 and 93), liver

93	F	6	22.8 ± 5.3	2.26 ± 0.19	1.4 ± 0.4	9.5 ± 0.7	6/6
135	M	6	27.9 ± 1.7	2.21 ± 0.11	1.9 ± 0.1	7.5 ± 0.9	4/6
135	F	7	25.0 ± 3.1	2.23 ± 0.29	1.5 ± 0.2	8.9 ± 1.1	6/7

Results expressed as means ± SD. On day 0, mice were divided into two groups per gender. Control mice (24 males, 23 females) remained on the commercial (control) diet; the other groups (37 males, 37 females) were transferred to the lithogenic diet. On day 28, some mice on both control and lithogenic diets were autopsied. The remaining mice were either maintained longer on the control diet or transferred from the lithogenic to the control diet for another period of up to 107 days. On day 23, one male mouse in the group on the lithogenic diet died.

weight may still have been somewhat increased in the males.

Table 1 shows that despite normalization of plasma and liver cholesterol concentrations, there was no regression of gallstones. Even after a period of 107 days (day 135) on the control diet the animals invariably displayed gallstones. Within 28 days (day 56) on the control diet, gallbladders were no longer expanded, and gallstones were packed together in the bladder.

It is unfortunate that we do not have information about the composition and concentration of biliary lipids. In any event, it is very difficult to obtain samples of bile fluid from mice fed the control diet, irrespective of whether these animals bear gallstones or not, because the total volume of bile fluid is extremely small. The inbred mice used in this study show a relatively small serum cholesterol response to a high cholesterol diet (8). Six inbred strains (8) that were more susceptible to cholesterol feeding were found not to develop gallstones. Possibly, susceptibility to cholesterol-induced hypercholesterolemia and gallstone formation are inversely related to some extent.

It is clear from this study using mice that gallstones previously induced by feeding high amounts of cholesterol and cholic acid do not disappear, at least not within 107 days, when cholesterol and cholic acid are removed from the diet. In contrast, earlier work using prairie dogs (5) and hamsters (3,4) has suggested that preestablished gallstones may dissolve within seven weeks after feeding a litholytic diet. This discrepancy may be related to the use of different animal species and/or different lithogenic and litholytic diets.

Purification of High Affinity Fatty Acid Receptors in Rat Myocardial Sarcolemmal Membranes

Satoshi Fujii, Hideaki Kawaguchi and Hisakazu Yasuda*
Department of Cardiovascular Medicine, Hokkaido University School of Medicine, Sapporo, Japan

High affinity receptors for fatty acid were purified from rat cardiac sarcolemmal membrane using gel filtration, DEAE-cellulose chromatography and affinity chromatography. The purified protein was homogeneous on polyacrylamide gel electrophoresis with the molecular weight of 60 kDa. Binding studies revealed the presence of a single class of high affinity binding sites with an apparent dissociation constant of 1.0 μM and a maximal binding capacity of 12.1 pmol/μg protein.
Lipids 22, 544–546 (1987).

Cytosolic proteins, which are capable of binding fatty acids, have been identified in various tissues, e.g., intestinal mucosa, liver and myocardium (1–3); these are called fatty acid binding proteins (FABP). These cytosolic proteins are considered to aid fatty acid distribution to various pools and pathways, affecting many enzyme reactions.

Fatty acid incorporation through the membrane phospholipid bilayer has been considered to be a simple diffusion process (4,5). However, *Escherichia coli* is reported to have a transport system for fatty acids (6), and kinetic studies suggested that at least a portion of the cellular fatty acid uptake is carrier-mediated (7). Furthermore, membrane receptors responsible for fatty acid binding are isolated in rat liver plasma membrane (8) and kidney basolateral membrane (9). These studies indicate that fatty acid transport across membrane is at least partly a carrier-mediated process. We report here data that have led us to conclude that rat heart sarcolemmal membranes contain a single class of high affinity receptors for fatty acids, which was purified to apparent homogeneity.

MATERIALS AND METHODS

Materials. [^{14}C]Palmitic acid (58 mCi/mmol) was obtained from Amersham International (Arlington Heights, IL); biochemicals were from Sigma (St. Louis, MO); salts and solvents were from Wako (Tokyo, Japan); Sephadex G-75 and Sepharose 4B were from Pharmacia (Uppsala, Sweden); DE-52 was from Whatman (Springfield, U.K.); Lipidex-1000 was from Packard (Downers, Grove, IL) and Bio-Beads SM-2 were from Bio-Rad (Richmond, CA).

Preparation of sarcolemmal vesicles. Rats were anesthetized with ether and hearts were excised and cooled in ice-cold saline; the tissue samples were finely minced with scissors and homogenized in sucrose (0.3 M) containing $MgSO_4$ (5 mM) buffered with imidazole-HCl (10 mM, pH 7.0). Sarcolemmal vesicles were purified by a method analogous to the one described by Reeves and Sutko (10). The yield of the membrane vesicles, starting with ventricular tissue from 20 rats, was 20–30 mg of protein. They showed a sevenfold increase over the crude homogenate in the activity of ouabain-sensitive (Na^+ + K^+)-stimulated, Mg^{2+} dependent ATPase (E.C. 3.6.1.3), widely considered to be the marker for sarcolemmal membranes, and a very low enrichment of cytochrome c oxidase and Ca^{2+}ATPase, the markers for mitochondria and sarcoplasmic reticulum.

Binding of [^{14}C]fatty acids. [^{14}C]Fatty acid binding was determined by the method of Glatz and Veerkamp (11). Unless otherwise stated, incubation mixtures consisted of 1 μM [^{14}C]palmitate, Pi/KCl (0.1 M KCl/0.05 M potassium phosphate, pH 7.5) and protein in a total volume of 0.45 ml. Nonspecific binding was evaluated in parallel incubations of FABP denatured by prior incubations for 4 hr at 70 C. To obtain specific binding, this value was always subtracted from the initial value. All incubations were carried out at 37 C for 15 min. The reactions were stopped by adding 0.05 ml of Lipidex suspension (0.1 g dry Lipidex/ml 0.05 M potassium phosphate), which adsorbs unbound fatty acids. Following vigorous mixing and centrifugation, 0.4 ml of the supernatant was withdrawn and the radioactivity was measured. Before precise FABP activity assay, detergent was removed by Bio-Beads SM-2.

Purification of FABP. Sarcolemmal vesicles were solubilized with 1% (v/v) Triton X-100. After centrifugation at 100,000 × g for 60 min, the Triton-extracted supernatant was delipidated on a Lipidex column (2.6 × 16 cm) (10) and gel-filtered through a Sephadex G-75 column (2.6 × 70 cm) with buffer A (Pi/KCl/0.25% Triton X-100). FABP-rich fractions were pooled and applied to a DE-52 column (2.1 × 15 cm) equilibrated with buffer A. After being washed with buffer A, the column was developed with a linear gradient of 0.1 M—0.6 M KCl in buffer A (200 ml). FABP-rich fractions were pooled and applied to a Bio-Beads SM-2 column (1.5 × 5 cm) equilibrated with Pi/KCl to remove Triton X-100. The sample was then applied to an oleate-Sepharose 4B column (1.5 × 6 cm) prepared by the method of Peters et al. (12) and equilibrated with Pi/KCl. Then the column was washed with the same buffer; no FABP activity was eluted. The column was then developed with Pi/KCl containing 0.5% Triton X-100. Detergent was removed by Bio-Beads SM-2, and the FABP-rich samples were pooled and concentrated by ultrafiltration (UK-10, Toyo, Tokyo, Japan) and used as final FABP.

Other methods. Protein was determined by the method of Sedmak and Grossberg (13), and polyacrylamide gel electrophoresis was carried out using the system of Maizel (14).

RESULTS

Purification of FABP. The results of purification are summarized in Table 1. Of the total protein in the membrane fractions, ca. 89% was recovered after solubilization. The final recovery of FABP was 17.2% of the total activity, and its specific activity was 10.4 pmol/μg protein. SDS-polyacrylamide gel electrophoresis patterns from the

TABLE 1

Purification of FABP from Rat Myocardial Sarcolemmal Membrane

Steps	Total protein (mg)	Total activity (pmol)	Specific activity (pmol/μg protein)[a]	Yield (%)	Purification (-fold)
Membrane	27.0	6750	0.25	100	1
Triton extract	13.1	6008	0.46	89	1.8
Sephadex G-75	2.07	3578	1.73	53.0	6.9
DE-52 chromatography	0.69	2093	3.05	31.8	12.2
Oleate-AH Sepharose 4B	0.11	1161	10.4	17.2	41.6

[a]Measured with 1 μM [^{14}C]palmitate at 37 C.

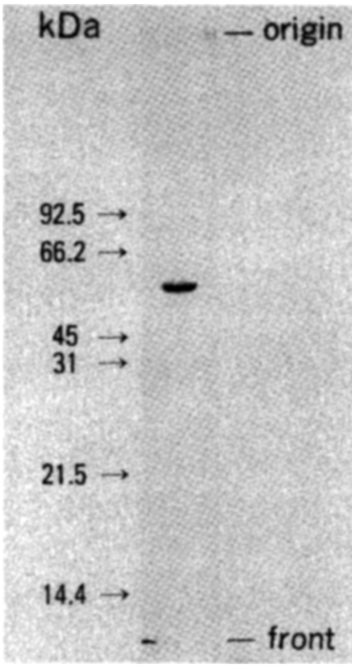

FIG. 1. Electrophoresis of 10 μg of FABP on 0.1% SDS-10% polyacrylamide gel. Proteins of known subunit molecular weight used to calibrate in the gel system included lysozyme (14.4 kDa), soybean trypsin inhibitor (21.5 kDa), carbonic anhydrase (31 kDa), ovalbumin (45 kDa), bovine serum albumin (66.2 kDa) and phosphorylase B (92.5 kDa).

solubilized proteins revealed multiple bands. In contrast, the final eluate from the Sepharose 4B column contained, after reduction, only a single band of estimated molecular weight of 60 kDa (Fig. 1). Purified FABP was stored at −70 C and was stable for up to 4 wk.

Amphiphilicity of FABP. On gel filtration through Sephadex G-75, purified FABP was eluted in a single peak in the presence of Triton X-100, but in several peaks scattered in the absence of the detergent (data not shown), indicated purified FABP forms aggregates in the absence of the detergent. On polyacrylamide gel electrophoresis, purified FABP did not enter the gel in the absence of 0.25% Triton X-100 containing electrode buffer (data not shown). Purified FABP was completely adsorbed to the oleate–Sepharose 4B column in the absence of the detergent, and eluted with 0.5% Triton containing buffer. These results indicate the amphiphilic nature of the purified FABP.

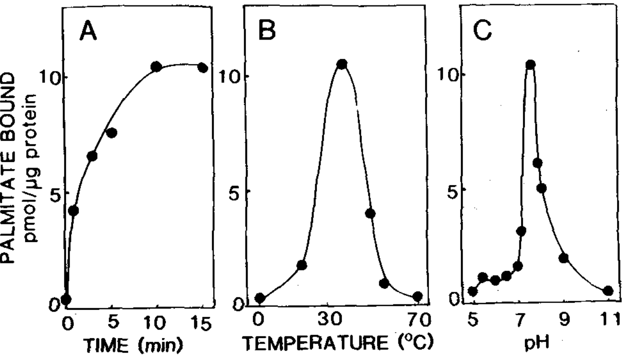

FIG. 2. Time-(A), temperature-(B) and pH-(C) dependence of FABP activity. FABP activity was measured with modifications given below. (A) Incubation for varying time at 37 C with 5 μg FABP (pH 7.6). (B) Incubation at varying temperature for 15 min with 5 μg FABP (pH 7.6). (C) Incubation at varying pH and 37 C for 15 min with 5 μg FABP. Identical pH was observed in potassium- and sodium-phosphate buffers.

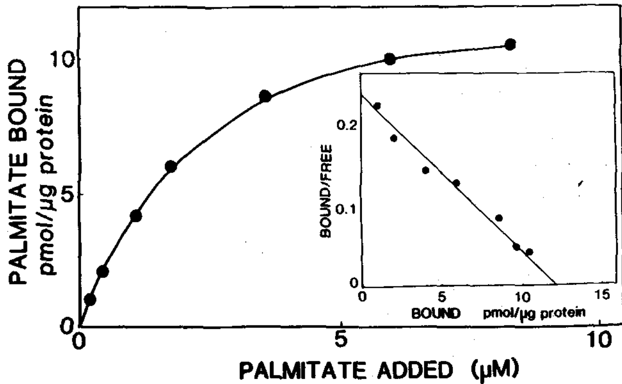

FIG. 3. Binding of palmitate by FABP. Results of a representative experiment is shown. Purified FABP samples (8 μg) were incubated with various concentrations (0.2–8.4 μM) of [^{14}C]palmitate; n = 7. Inset: Scatchard analysis of the binding of palmitate by FABP. The ratio of bound to free [^{14}C]palmitate against the concentration of bound [^{14}C]palmitate is shown. Kd = 1.0 μM, Bmax = 12.1 pmol/μg protein.

Fatty acid binding properties. Several characteristics of the fatty acid binding capacity were investigated. FABP showed rapid and complete binding until 10 min of incubation and optimal binding activity at 37 C and pH 7.6 (Fig. 2). The binding was linear in the range of

TABLE 2

Inhibition by Unlabeled Ligands for [^{14}C]Palmitate Binding to FABP

Inhibitor	Inhibition (%)
Palmitate	25.5
Stearate	14.8
Oleate	20.0
Arachidonate	19.3
Palmitoyl CoA	30.3
CoA	3.5
Cholesterol	2.1
Phosphatidylcholine	3.8

Purified FABP (5 μg) was preincubated for 15 min at 37 C with unlabeled ligands (5 μM in all cases) prior to the addition of [^{14}C]palmitate (1 μM). Inhibition (%) is the ratio to the binding activity without unlabeled ligand.

5-50 μg of the protein. Equilibrium binding of [^{14}C]palmitate to FABP was saturable, and Scatchard analysis revealed the presence of a single class of high affinity binding sites for FABP (Fig. 3). An apparent dissociation constant (Kd) of 1.0 μM and a maximal binding capacity of 12.1 pmol/μg protein were determined. Thus, the purified FABP showed a high affinity for palmitate. The ability of various unlabeled fatty acids, their CoA derivatives, cholesterol and phosphatidylcholine to displace [^{14}C]palmitate from FABP was studied (Table 2). FABP showed a high affinity for palmitoyl CoA but not for free CoA. Various fatty acids showed considerable inhibition, but cholesterol or phosphatidylcholine showed no inhibition at all.

DISCUSSION

These studies demonstrate that rat sarcolemmal membrane has a single protein with a high affinity for fatty acid, which has a molecular weight of 60 kDa and a single class of high affinity binding sites. Based on its molecular weight and the binding capacity, this protein is clearly distinguished from the protein responsible for fatty acid binding shown in rat liver plasma membranes (8), which has a molecular weight of 40 kDa and binding capacity of 3.2 pmol/μg membrane protein for oleate, or the recently reported partially purified FABP in *E. coli* membranes, which has a molecular weight of 26.5 kDa and binding capacity of 3.0 pmol/μg membrane protein for palmitate (15). The results show also that this protein is different from the cytosolic cardiac FABP (16,17), which is a soluble protein with a molecular weight of ca. 14 kDa and large binding capacity for various fatty acids. The affinity of this sarcolemmal FABP for fatty acids has many properties expected of physiologically important binding proteins. The existence of an apparent saturable heat-sensitive binding site with a high affinity for fatty acids is compatible with the appealing hypothesis that fatty acids cross the sarcolemmal membrane by a membrane-associated carrier-mediated transport system and then bind to the soluble cytosolic cardiac FABP previously described. Further studies will be required to determine the role of sarcolemmal FABP in the regulation of myocardial lipid metabolism.

[Received January 26, 1987]

In Vivo Incorporation of Labeled Fatty Acids in Rat Liver Lipids After Oral Administration

J. Leyton, P.J. Drury and **M.A. Crawford**
Nutritional Biochemistry Unit, The Institute of Zoology, Regent's Park, London N.W.1 4RY, England

Striking differences were found in the compartmentalization of fatty acids into liver lipid fractions. The saturated fatty acids—lauric, myristic, palmitic and stearic—were incorporated into phosphoglycerides at faster rates with increasing chain lengths, while triglyceride incorporation was almost uniform. The degree of incorporation of the unsaturated fatty acids into phosphoglycerides (structural) compared to triglyceride (storage and energy) was the converse of their oxidation rates. The incorporation of oleic, linoleic and α-linolenic acids was mainly into triglyceride, whereas dihomo-γ-linolenic acid and arachidonic acid were preferentially incorporated into phosphoglycerides. The data suggest that distribution of each fatty acid is different depending on its destination for structural or energy function.
Lipids 22, 553-558 (1987).

Investigations on comparative metabolism of fatty acids in whole body systems (1,2), perfused organs (3) and myocardial preparations (4,5) indicate that cellular uptake and oxidation of fatty acids varied with degree of unsaturation and chain length. Studies carried out in this laboratory have shown that the different fatty acids are oxidized at different rates in weanling rats. Since part of the nonoxidized fatty acids taken up from the circulation is converted to tissue structural lipids (6,7), it is important to know how the fatty acids are distributed in the different lipid fractions.

Animal membrane lipids consist basically of cholesterol and phosphoglycerides, which are the determinants of membrane fluidity (8). The contribution of the phosphoglycerides to the fluidity of membrane depends on the balance between individual phosphoglycerides and the nature of the fatty acyl groups. The fatty acyl-CoA structure (length, unsaturation, double bond position, configuration of bond lengths) plays a significant role in governing the properties of membranes (9,10), lipoprotein complex formation (11) and activities of enzymes. The neutral lipids store fatty acids for energy, but a proportion may also be transferred to structural pools. Sinclair (12) showed that in suckling rats aged 1–15 days, about 25% of the liver triglycerides consists of long chain polyunsaturated fatty acids, compared to less than 8% in adult rats. However, a higher proportion of arachidonic and docosahexaenoic acids was incorporated into liver phosphoglycerides than into triglycerides in suckling rat pups.

The study reported here examined further the incorporation and compartmentalization of fatty acids into individual phosphoglycerides and neutral lipids, after the main oxidative phase, 24 hr following oral administration of labeled lauric (12:0), myristic (14:0), palmitic (16:0), stearic (18:0), oleic (18:1n-9), α-linolenic (18:3-n-3), linoleic (18:2n-6), γ-linolenic (18:3n-6), dihomo-γ-linolenic (20:3n-6) and arachidonic acids (20:4n-6).

Abbreviations: CPG, choline phosphoglycerides; EPG, ethanolamine phosphoglycerides; SPG, serine phosphoglycerides; IPG, inositol phosphoglycerides; RSA, relative specific activity; MCT, medium chain triglycerides.

MATERIALS AND METHODS

Animals. For the early part of the experiment, Sprague-Dawley female rats of the CFY strain were bred in the Institute of Zoology; after weaning at 21 days, they were used for the metabolic experiments. However, at a later date, weanling rats of the same genetic strain were obtained from Benton and Kingman (Yorkshire, U.K.).

The rats were kept under controlled conditions with a 12-hr light-dark cycle, a temperature range of 19–23 C and relative humidity of ca. 55%. Animals were fed a special low calorie RM3 breeding diet obtained from the Special Diet Service (Witham, Essex, U.K.) containing 3.2% fatty acids, whose composition was 12:0 (0.05%), 14:0 (0.19%), 14:1 (0.1%), 16:0 (0.3%), 16:1 (0.1%), 18:0 (0.1%), 18:1 (1.0%), 18:2n-6 (1.0%), 18:3n-3 (0.16%) and 20:4n-6 (0.16%).

Weaned rats, 23–26 days old and weighing 60–80 g, were used in these experiments. All experiments within a series were performed at the same time of day to avoid diurnal variations. Animals were kept in the metabolic chamber for 24 hr and had free access to food and water. Labeled [1-^{14}C]lauric acid (26 mCi/mmol), [1-^{14}C]palmitic acid (58 mCi/mmol), [1-^{14}C]stearic acid (60 mCi/mmol), [1-^{14}C]oleic acid (57 mCi/mmol), [1-^{14}C] linoleic acid (57 mCi/mmol), [1-^{14}C]α-linolenic acid (50 mCi/mmol) and [1-^{14}C]arachidonic acid (50 mCi/mmol) were purchased from Amersham International Ltd. (Amersham, Bucks, U.K.). [1-^{14}C]Myristic acid (54.5 mCi/mmol) was obtained from Fluorochem Ltd. (Gosport, U.K.). [1-^{14}C]γ-Linolenic acid (55 mCi/mmol) and [1-^{14}C]dihomo-γ-linolenic acid (55 mCi/mmol) were obtained from Roche Product Ltds. (Hert, U.K.). All were judged 98% pure by radio gas liquid chromatography except linoleic (96%) and dihomo-γ-linolenic (99%) acids. Radiolabeled fatty acid (6 μCi) was introduced into a vial containing 0.2 ml olive oil, and the solvent was evaporated under a stream of N_2. The oil and isotope mixture was then administered orally to the rat through a Jackson catheter (Arnold, Veterinary Product Ltd., Reading, U.K.).

Preparation of the metabolic chamber. After oral administration of the labeled fatty acid, the rat was immediately placed in the "metabolic chamber" (Jencon Ltd., Berk, U.K.). A current of dry carbon dioxide–free air was pumped through the metabolic chamber by a Hyflo Technical Model C pump (Scientific Suppliers, London), carrying with it the expired $^{14}CO_2$ from the rat. The expired $^{14}CO_2$ was dried by being passed through concentrated sulphuric acid and trapped in two collection columns containing a mixture of methoxyethanolamine/ethanolamine (2:1, v/v), 500 ml in the first column and 300 ml in the second column.

In vivo recovery of $^{14}CO_2$. From the first collection

Results are expressed as mean ± SEM.
[a]Expressed as percentage of the administered dose.

column, 10-ml aliquots of trapping agent were removed at 1, 3, 7 and 24 hr. At 24 hr, 10 ml was also removed from the second column to account for any overflow of labeled CO_2 from the first column. From each sample, four 2-ml aliquots were removed and added to scintillation vials containing 10 ml scintillation fluid (0.81 g Scintimix 2, [25% PPO, 5% dimethyl POPOP], dissolved in a 180-ml mixture of toluene/methoxyethanolamine/ethanolamine [100:70:10, v/v/v]) and counted.

Lipid extraction. After 24 hr, the rats were killed by decapitation, and the livers were removed, washed in ice-cold saline, blotted dry, and then weighed. Lipids were extracted using the method of Folch et al. (13). The liver was homogenized with a 20-fold volume of chloroform/methanol (2:1, v/v) containing 10 mg of butylated hydroxytoluene (BHT)/l as an antioxidant, which was then flushed with nitrogen and left to extract overnight at 4 C. The homogenate was filtered through Whatman No. 1 filter paper, and the residue was washed with an additional 10 ml of chloroform/methanol (2:1, v/v). The filtrate was transferred to separation funnel and diluted to 100 ml with chloroform/methanol (2:1, v/v), mixed with 20 ml of 0.85% sodium chloride (v/v), shaken and left to partition overnight at 4 C. The lower organic phase was transferred to a round-bottom flask and evaporated with N_2 in a Rotavap-R (Buchi, Orme Scientific, Middleton, Manchester, U.K.), under reduced pressure at 37 C. The lipid extract was redissolved in 20 ml of chloroform, flushed with N_2 and stored at 4 C. Two 2-ml aliquots were removed from the lipid extract and transferred to scintillation vials. The solvent was evaporated under N_2, 10 ml scintillation fluid (Unisolve 1, Koch-Light Laboratories, Buckinghamshire, U.K.) was added and the samples were counted.

Thin layer chromatography. The lipid classes were separated by thin layer chromatography using Silica Gel G for neutral lipid and Silica Gel H for phosphoglyceride separation. A 2.5-ml aliquot of liver lipid extract containing ca. 10 mg of lipid was evaporated to dryness under N_2, redissolved in a small volume of chloroform (10 μl) and applied to the plate as a narrow band using a capillary tube.

The solvents used for phosphoglyceride separation were chloroform/methanol/n-propanol/methylacetate/0.25% potassium chloride (25:10:25:25:9, v/v/v/v/v). The solvents used for the separation of neutral lipids were petroleum spirit/diethyl ether/glacial acetic acid/methanol (85:15:2.5:1, v/v/v/v). Samples were always run with known standards. The phosphoglyceride fractions were identified by placing the plate in a tank of iodine vapor in which they appeared as brown bands. The neutral lipids plate was sprayed with a methanolic solution of dichlorofluorscein (0.2%, v/v), and the lipid fraction was identified under UV light. The separated lipid classes were then scraped into scintillation vials. Ten ml of scintillation fluid (Unisolve 1) was added, and the samples were counted.

Radioactivity was measured by scintillation counting using a Model SL30 liquid scintillation counter (Intertechnique, Plaisir, France). The counting efficiency for the lipid and trapping agent was normally about 85% and was determined by addition of an internal standard [1-^{14}C]hexadecane and by external standard channel ratio mode. Using this method, the recovery of radioactivity from the plates was greater than 90% for each fatty acid.

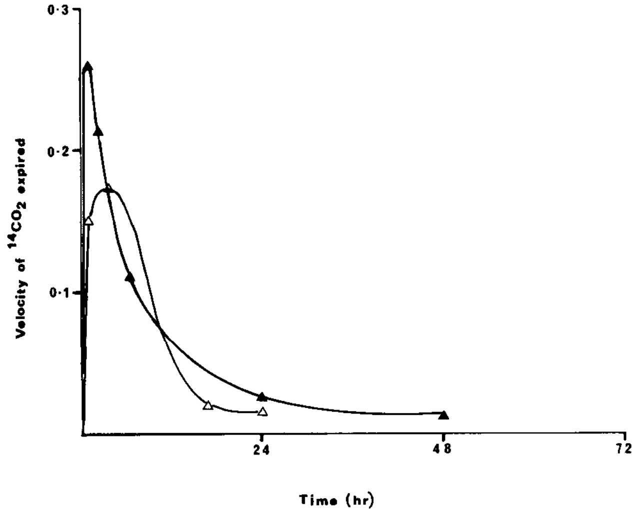

FIG. 1. Velocity time curves for the oxidation of [^{14}C]linoleic acid (▲) and [^{14}C]myristic acid (△) were measured by plotting the gradient of the percentage of expired $^{14}CO_2$ curve against time.

RESULTS

Oxidation of labeled fatty acids. The oxidation of the labeled fatty acids was determined from the expired $^{14}CO_2$ over a 24-hr period after oral administration. The results shown in Table 1 are the cumulative amounts of expired $^{14}CO_2$ recovered as a function of time and expressed as a percentage of the administered dose. In the saturated fatty acid group, lauric and myristic acids were oxidized to a greater extent than palmitic and stearic acids ($P < 0.01$). Of the unsaturated fatty acids, α-linolenic acid and oleic acid were both preferentially oxidized over linoleic acid ($P < 0.01$). Desaturation of linoleic acid to γ-linolenic acid resulted in a significant reduction ($P < 0.01$) of oxidation of the latter to 27%. All the C_{18} fatty acids were preferentially oxidized ($P < 0.01$) over the 20 carbon chain length except γ-linolenic acid ($P < 0.05$).

In a plot of the gradient of the percentage of expired CO_2 curve against time, maximum velocity was reached at 6 hr for linoleic acid and myristic acid and fell to a low level by 24 hr. The result (Fig. 1) shows the rate of CO_2 expired per unit of time, indicating most of the oxidation of fatty acids was completed by 24 hr.

Liver phosphoglyceride fraction. The profile of the labeled fatty acids in the four phosphoglyceride classes obtained from the liver is shown in Figure 2. A significant amount of the radioactivity ($P < 0.001$) was found to be associated with choline phosphoglycerides (CPG) and ethanolamine phosphoglycerides (EPG) compared to the serine phosphoglycerides (SPG) and inositol phosphoglycerides (IPG). In the CPG and EPG fractions, the saturated fatty acids were incorporated in this order: stearic acid > palmitic acid > myristic acid > lauric acid. For the unsaturated fatty acids, the order was arachidonic acid > dihomo-γ-linolenic acid > γ-linolenic acid > linoleic acid > α-linolenic acid > oleic acid into phosphoglycerides. Increasing desaturation and elongation of the fatty acids paralleled increasing incorporation into phosphoglycerides and also reflected their oxidation rates. For example, arachidonic acid, which was oxidized the least (13.9% in 24 hr), was incorporated the most into phosphoglycerides, whereas lauric acid, which was oxidized the most (63.0% in 24 hr), was incorporated the least ($P > 0.001$).

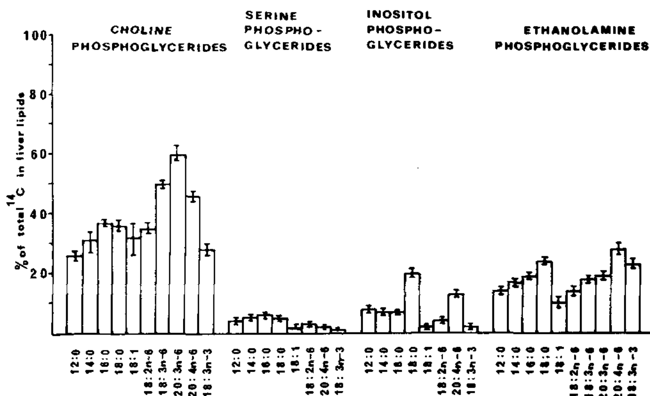

FIG. 2. The in vivo incorporation of labeled fatty acids into rat liver phosphoglycerides 24 hr after oral administration. Phosphoglycerides were separated by thin layer chromatography and radioactivity incorporated into the phosphoglyceride fractions measured by scintillation counting. The results of each fraction are expressed as a percentage of the total activity recovered. Vertical bars give the SEM for a total of 8 tissues analyzed for each fatty acid.

Liver neutral lipids. Figure 3 shows the incorporation of labeled fatty acids into triglycerides and total phosphoglycerides. Oleic acid was most significantly incorporated ($P < 0.001$) into triglyceride (63.4%), compared to its incorporation into total phosphoglycerides (34.0%). Of the n-6 family of fatty acids, linoleic acid was preferentially incorporated into triglycerides compared to its long chain derivatives. By contrast, the saturated fatty acids (C_{12}, C_{14}, C_{16} and C_{18}) showed almost uniform distribution into triglycerides.

Incorporation into liver phosphoglycerides in terms of relative specific activity (RSA). Table 2 compares the incorporation of labeled fatty acids into phosphoglycerides and triglycerides, relative to the actual amounts of phosphoglycerides present in the rat liver (percentage activity recovered divided by percentage distribution in rat liver

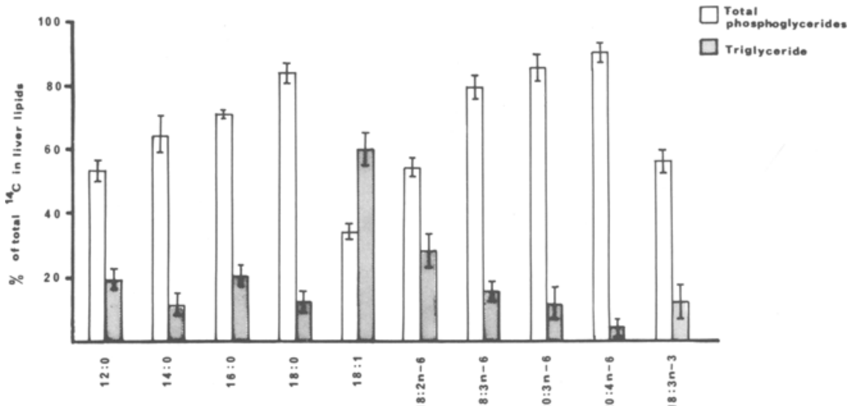

FIG. 3. The in vivo incorporation of labeled fatty acids into rat liver lipids 24 hr after oral administration. Total phosphoglycerides were calculated by adding up the individual phosphoglyceride fractions. Liver triglycerides were obtained by neutral lipid separation on thin layer chromatography. The results are expressed as a percentage of the total activity recovered. Vertical bars give the SEM for a total of 8 tissues analyzed for each fatty acid.

TABLE 2

Relative Specific Activity of Labeled Fatty Acids Incorporated into Rat Liver 24 Hours after Oral Administration[a]

	[¹⁴C] Fatty acids

TG	0.4 (n=6)	0.3 (n=8)	0.5 (n=10)	0.2 (n=8)	1.5 (n=12)	0.8 (n=9)	0.4 (n=8)	0.7 (n=8)	0.3 (n=8)	0.1 (n=8)

[a]Values are expressed as percent activity recovered divided by the percentage distribution of phosphoglycerides and triglyceride present in the rat liver (per g of tissue).

[b]SPH, sphingomyelin; CPG, SPG, IPG and EPG are choline, serine, inositol and ethanolamine phosphoglycerides, respectively; TG, triglyceride.

phosphoglycerides). Although the CPG fraction contained the largest amounts of activity in the phosphoglycerides, the RSA data suggested that the SPG fraction was especially active for the saturated fatty acids, whereas the IPG fraction was selectively rich in arachidonic acid. The RSA for linoleic acid was found to be substantial in the SPG fraction. The RSA for the fatty acid composition in CPG and EPG fractions were similar. There was very little cholesteryl ester in the rat liver lipids; the data are not reported because the counts were too low for confidence.

DISCUSSION

Oxidation of fatty acids. Whether dietary fatty acids are oxidized for energy or used in structural lipids depends on various factors, which may include selective mechanisms, type of fatty acid and the metabolic activity and hormonal and nutritional status of the animal. Studying changes in fatty acid incorporation into lipids is also complicated kinetically in vivo, since labeled fatty acids are subsequently diluted by endogenous fatty acids. However, in our experiments, we were dealing with growing animals in a normal metabolic condition in which comparisons were being made between the behavior of different fatty acids under the same dietary conditions.

The oxidation rates of the labeled administered fatty acids are unlikely to have been influenced by the dietary fatty acids for several reasons: (i) The animals were fed a low fat diet (3.2% of the diet). (ii) The diet contents of myristic (0.2%), α-linolenic (0.2%) and arachidonic acids (0.2%) were similar, but the oxidation rates of the fatty acids were quite different, with [¹⁴C]α-linolenic acid being catabolized at a substantially higher rate than 20:4n-6. (iii) Oleic and linoleic acids both were present in the diet at 1.0%. However, their labeled counterparts showed a significant difference in oxidation rates, with oleic acid being oxidized much faster than linoleic acid. (iv) Palmitic acid was present in the diet in higher amounts (0.3%) than stearic acid (0.1%). Had the fatty acids present in the diet acted to dilute the label, then one would have expected palmitic acid to be diluted and oxidized at a slower rate then stearic acid, but the converse was true, with stearic acid being oxidized at the slowest rate of the saturated fatty acids. The differential metabolism of the fatty acids was due to their inherent properties. There was simply no consistency with the small amounts of fatty acids in the diet and the rates of oxidation. The different rates of fatty acid oxidation were also consistent with the different incorporation into storage (triglycerides) and structural (phosphoglycerides).

The amount of labeled fatty acid excreted in the feces was very low (1% of the administered labeled fatty acids) after 24 hr and serves only as a partial index of fatty acid absorption by the gut. Higher activity may be present in the intestine and colon: however, this was not measured. The activity excreted in the urine was slightly higher (about 3% of the administered dose).

Compartmentalization. The results obtained for the incorporation of fatty acids into rat liver lipids are presented with the realization that a time-course study would have made clear the interpretation of fatty acid compartmentalization. However, given the logistics and the time involved in the analytical procedure and because most of the fatty acids reached their slowest rate of oxidation at 24 hr, we decided to measure the incorporation at this time point.

The data describing the incorporation of fatty acids into liver phosphoglycerides were expressed in percentages. The results show that a strongly selective mechanism exists to direct fatty acids into different lipid pools. Examination of labeled fatty acid profiles in the phosphoglyceride fractions showed that liver CPG and EPG contained much higher percentages of labeled fatty acids than SPG and IPG.

Relative specific activity (RSA). Since the lipid frac-

tions are present in different amounts in the liver, the data representing the distribution of fatty acids describes only how much of an individual fatty acid has been incorporated in a specific direction. But since SPG and IPG are present in only small amounts, they may be taking up a fatty acid more actively and thus have a high activity per unit. This type of information can be obtained by expressing the radioactivity per mole, or RSA.

Saturated fatty acids. The RSA data indicated a high incorporation of activity into the SPG and IPG fraction, especially for the saturated fatty acids. The high RSA in SPG and IPG suggests different turnover rates for the individual phosphoglyerides. The results from this study showed that stearic and palmitic acids were incorporated into SPG in preference to the medium chain triglyceride (MCT) fatty acids. Coots (1), who measured the oxidation of stearic acid, found that a significant amount was incorporated into lymph phosphoglycerides. The preferential incorporation of stearic and palmitic acids into phosphoglycerides (2) might also explain the slower oxidation for the long chain saturated fatty acids.

Polyunsaturated fatty acids. Linoleic acid was found to be preferentially incorporated into triglycerides compared to its long chain derivatives, 20:3n-6 and 20:4n-6, which were incorporated mainly into phosphoglycerides. Sinclair (12) also found that in suckling rats, linoleic acid was incorporated into triglyceride, and much of it was derived from the dam's milk. The high turnover rate for triglyceride (14) may well account for the rapid rate of oxidation for 18:2n-6. α-Linolenic acid was also found to be incorporated into triglycerides and is consistent with the observations that the high oxidation rates of the C_{18} is associated with the triglyceride.

The special place of oleic acid. The results from this study showed that oleic acid was preferentially incorporated into triglycerides. Similar findings have also been reported in the perfused heart (15), where oleic acid was incorporated more into phosphatidic acid, suggesting substrate specificity for diacylglycerol acyltransferase (16). Yan and Sun (17) injected labeled oleic acid intracerebrally and found that it was initially incorporated into triglyceride. However, after 80 min, the activity in phosphoglycerides gradually increased with simultaneous reduction in the triglycerides.

Oleic acid is an important monounsaturated fatty acid in the developing human fetal brain (18). It also accounts for the major fatty acid in human milk (19), ranging from 30 to 40% (20). Both 18:1n-9 and its metabolic product, nervonic acid (24:1n-9), are major fatty acids found in mature myelin, which appears in the nervous system in the later stages of brain development. These observations suggest that oleic acid can perform two different functional roles. It can serve first as an energy source, as indicated by the high oxidation rate, and second as a substrate for cell growth and development.

Compartmentalization of the C_{20} fatty acids. Unlike the C_{18} fatty acids, the C_{20} long chain PUFA showed preferential incorporation into phosphoglycerides. The RSA data showed that IPG was selectively rich in arachidonic acid, indicating a faster rate of uptake and turnover of this phosphoglyceride fraction. The slow oxidation and high rate of incorporation of arachidonic acid into structural lipids also imply a long half-life. Evidently, the turnover rate for the different fatty acids will be different for the different fatty acids.

Hassam and Crawford (21) found that up to a third of the radioactivity recovered from the liver and plasma lipid fractions 24 hr after dosing with labeled dihomo-γ-linolenic acid (DHLA) was still present as DHLA. Therefore, besides being metabolized to arachidonic acid and the 22-carbon chain length derivatives, it is also available for incorporation as DHLA into tissue lipids.

Similar data have been reported for the compartmentalization of linolenic and arachidonic acids and other PUFA in cultured rabbit-aorta smooth muscle cell (22). The CPG fraction incorporated the highest proportion of the fatty acids. These investigators did not calculate specific activity data, but had they done so, it is likely their IPG and SPG incorporation would have been similar to ours. Morisaki and coworkers (22) found no evidence of desaturation of γ-linolenic acid. While eicosapentaenoic acid was elongated to docosapentaenoic acid, it was not desaturated further to docosahexaenoic acid. Their data on a specific cell type are similar to our observation of the differential compartmentalization of the essential fatty acids in rats and human leukocytes (23) and human placenta (24), suggesting that our in vivo data reflect a general phenomenon at a cellular level.

The fundamental observation made in this work and in other studies is that compartmentalization of fatty acids profoundly influences the metabolic direction and use to which a fatty acid is put. The evidence gained for specificity in compartmentalization and, indeed, the converse evidence for use in energy suggests that the individual fatty acids may need to be considered as separate individuals.

It has been popular to use MCT clinically in treating patients recovering from surgery and trauma, and where there is a need for cell repair and growth, in both enteral and parenteral nutrition. However, our data imply that the MCT fatty acids, while being useful for energy, may not be so for cell structural repair, and consequently can only have limited value. By contrast, oleic acid is oxidized as fast as the fatty acids of MCT, but can also be used for phosphoglycerides and for cell structures. It should be possible to use a lipid, such as olive oil (which is high in oleic, palmitic, stearic and linoleic acids), to satisfy the need for energy as well as cell growth and to repair simultaneously.

Partial Purification and Characterization of Free and Immobilized Lipases from *Mucor miehei*[1]

Birgitte Huge-Jensen[a,*] **Donna Rubano Galluzzo**[b] and **Robert G. Jensen**[b]
[a]Novo Industri A/S, Bagsvaerd, Denmark, and [b]Department of Nutritional Sciences, University of Connecticut, Storrs, Connecticut

An extracellular lipase, a glycoprotein, produced by fermentation with a selected strain of *Mucor miehei* has been partially purified in two forms, A and B. The two forms have a high degree of antigenic identity and have similar pH-activity profiles with tributyroylglycerol as a substrate with optima at pH 7. They differ as follows: A, in contrast to B, requires activation at alkaline pH before analysis; A binds with concanavalin-A more completely than B; the net charges are slightly different at pH 8; and the isoelectric points are different. Our results indicate that the B lipase is formed by partial deglycosylation of the A lipase and that this influences the activity toward emulsions.

In addition, the two enzymes have been immobilized by adsorption. These preparations and the soluble forms were highly specific for primary esters of triacylglycerols (TG); they usually hydrolyzed TG of 12:0, 14:0, 16:0, and 18:1 more rapidly than those of 4:0, 6:0, and 8:0 and 10:0 in mixtures of monoacid TG (4:0 to 18:1); and they were not stereospecific for TG. Immobilization altered the specificity of the preparations somewhat, in that slightly more 14:0 and 16:0 were released.
Lipids 22, 559–565 (1987).

Enzymatic modification of foods and other materials has occurred either spontaneously or deliberately for generations. The relatively recent availability of large quantities of enzyme preparations has broadened the search for industrial applications of enzymes and simultaneously for enzymes with desirable characteristics such as thermostability and certain specificities. For several reasons, including relative ease of production, many of these enzymes are obtained from microbial fermentations. These aspects, with emphasis on lipases, have recently been discussed by Kilara (1).

During our search for microbial lipases with industrial applications, we selected a strain of *M. miehei* for further study. This mold produces an active extracellular lipase (2). Results from preliminary experiments suggested that there were at least two different forms of the enzyme. In this paper, we report the partial purification of two of these soluble forms. These were immobilized, and the four preparations were partially characterized. The purifications and immobilizations were done in Denmark and the specificity studies in Connecticut. Preliminary data on use in industrial applications and some characterization of the lipase have been presented (3,4). We believe that this is among the few reports (5,6) on the characteristics of immobilized lipases and the first on the A and B forms of *M. miehei* lipases.

MATERIALS AND METHODS

Purification: materials and determinations. DE-cellulose 52 was purchased from Whatman Chemical Separation Ltd. (Kent, England); DEAE-Sepharose, Phenyl-Sepharose, concanavalin A (ConA)-Sepharose and Sepharose 4B were obtained from Pharmacia Fine Chemicals (Piscataway, NJ).

Lipase activity was measured with pH-stat essentially as described by Brockman (7) except that 0.5% polyvinylpyrrolidone was used as an emulsion stabilizer. Substrates were tributyroylglycerol (Novo method AF95.1/3-GB) and olive oil (method AF182.2/3-GB). (These designations are given for those who may use the Novo methods; otherwise they are very similar to [7].) Units of activity are 1 LU (lipase unit), the amount of enzyme that liberates 1 μmol of titratable 4:0/min under standard conditions, and 1 NLU (Novo lipase unit), the amount of enzyme that liberates 1 μmol of tritratable fatty acid from olive oil/min under standard conditions. Note that these Novo methods require that the *Mucor* lipase be diluted in alkaline buffer (pH 10.5) prior to analysis. This buffer did not interfere with subsequent analyses. Protein determination was performed according to Lowry et al. (8) with bovine serum albumin as a standard.

Purification of lipase A. (All steps were carried out at 5 C.) The supernatant from the culture broth of a selected strain of *M. miehei*, with mycelia and low molecular weight substances removed, was used for production of a crude powder. (a) Step 1: anion exchange chromatography. A solution (200 ml) of 5% of the crude powder was made up with deionized water, adjusted to pH 7 with NaOH and applied to a column (2.5 × 40 cm) of DE-cellulose 52 previously equilibrated with 0.5 M Tris-HCl buffer (pH 7.0). After the unbound proteins were washed out with the buffer, the bound proteins, including lipase, were eluted with a gradient of decreasing pH (initial buffer pH 7.0 to 0.1 M maleate, pH 3.5). The main lipolytic fraction obtained (pH 5.4) was adjusted to pH 7.0 and concentrated to 1/5 volume by ultrafiltration prior to lyophilization. Ultrafiltration was done with an Amicon UF cell using a membrane with a nominal molecular weight cutoff of 10,000.

(b) Step 2: affinity chromatography. A 250-mg volume of powder from the DE-cellulose chromatography was diluted in 2 ml 0.02 M Tris-HCl buffer, pH 7.4, containing 0.3 M NaCl, 2 mM $CaCl_2$ and 1 mM $MgCl_2$, and was applied to a column of conA-Sepharose (1.6 × 20 cm) equilibrated with the buffer. The column was washed with the initial buffer for unbound proteins, and the bound lipase eluted with a gradient of 0 to 0.5 M α-D-methyl mannoside in the buffer (400 ml). The flow rate was 20 ml/hr, and fractions of 5 ml were collected. The pooled

TABLE 1

Purification of Lipase A from *Mucor miehei*

Purification steps	Yield, % based on LU values[a]	Protein content (%)	Specific activity			
			LU/mg preparation	LU/mg protein	NLU/mg[b] preparation	NLU/mg protein
Crude powder	100	42	157	374	100	238
DE-cellulose 52 chromatography	77	67	1700	2540	1073	1601
ConA-Sepharose chromatography	57	66	3590	5440	2300	3500

[a]LU (lipase unit) is the amount of enzyme that liberates 1 μmol of 4:0/min (see text).
[b]NLU (Novo lipase unit) is the amount of enzyme that liberates 1 μmol of fatty acid from olive oil/min (see text).

TABLE 2

Purification of Lipase B from *Mucor miehei*[a]

Purification steps	Yield, % based on LU values[b]	Protein content (%)	Specific activity			
			LU/mg preparation	LU/mg protein	NLU/mg[c] preparation	NLU/mg protein
Crude powder	100	42	157	374	100	238
DEAE-Sepharose chromatography	72	80	945	1180	600	750
Phenyl-Sepharose chromatography	32	100	3000	3000	1900	1900

[a]Lipase B is formed by partial deglycosylation of lipase A (see Table 1 and text).
[b]LU (lipase unit) is the amount of enzyme that liberates 1 μmol of 4:0/min (see text).
[c]NLU (Novo lipase unit) is the amount of enzyme that liberates 1 μmol of fatty acid from olive oil/min (see text).

lipase fractions were desalted and concentrated to a 1/10 volume by ultrafiltration prior to lyophilization.

Purification of lipase B. (All steps were carried out at 5 C, except for the pretreatment in step 2.) (a) Step 1: anion exchange chromatography. This was performed as described for lipase A, but with the following modifications: The column (2.5 × 40 cm) was DEAE-Sepharose, the final buffer was 0.1 M glycine-HCl pH 3.0 and the low pH (4.5) of the lipase fraction obtained was not adjusted prior to ultrafiltration. (b) Step 2: hydrophobic interaction chromatography. A solution (50 ml) containing 2% of the DEAE Sepharose purified powder in 0.2 M ammonium acetate, pH 4.7, was stirred for 30 min at 3 C. Sufficient ammonium acetate was then added to bring the concentration to 0.8 M. This solution, cooled to 5 C, was applied to a column (2.5 × 40 cm) of Phenyl-Sepharose equlibrated with 0.8 M ammonium acetate buffer, pH 5.1. The unbound proteins were washed out with the buffer prior to elution of the column with deionized water. The eluted lipase fraction (pH not adjusted) was concentrated to a 1/10 volume by ultrafiltration prior to lyophilization.

Sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE). This was performed as described in Bio-Rad's manual (9) for the Laemmli system, using Bio-Rad vertical slab gel cell model 220. The separating gel was a gradient of 7–20% polyacrylamide. The mercaptoethanol-treated samples were boiled for 2 min before application to the gel. As reference proteins, the electrophoresis calibration kit for molecular weight determination of low molecular weight proteins from Pharmacia was used.

Isoelectric focusing (IEF). This was performed on LKB's Multiphore apparatus using ready-made polyacrylamide gels as described in LKB's manual (10). The IEF calibration kit from Pharmacia was used for reference proteins.

Crossed immunoelectrophoresis (CIE). CIE was performed as described by Hojby and Axelsen (11) using 0.02 M barbital buffer, pH 8.0. The polyspecific antibodies were produced in rabbits against the crude enzyme powder. Tandem-CIE was performed as described by Kroll (12), using 0.02 M barbital buffer pH 8.0.

Crossed immunoaffinity electrophoresis (CIAE). This was performed by modification of the CIE method as follows: The buffer used was 0.01 M Tris-maleate, pH 7.4. An intermediate gel (1 cm broad) was interposed between the first-dimensional gel and the antibody-containing gel. This intermediate gel contained 25 μl conA-Sepharose/cm^2 on the test plate. The control plate had the conA-Sepharose replaced by Sepharose 4B. Before use, the

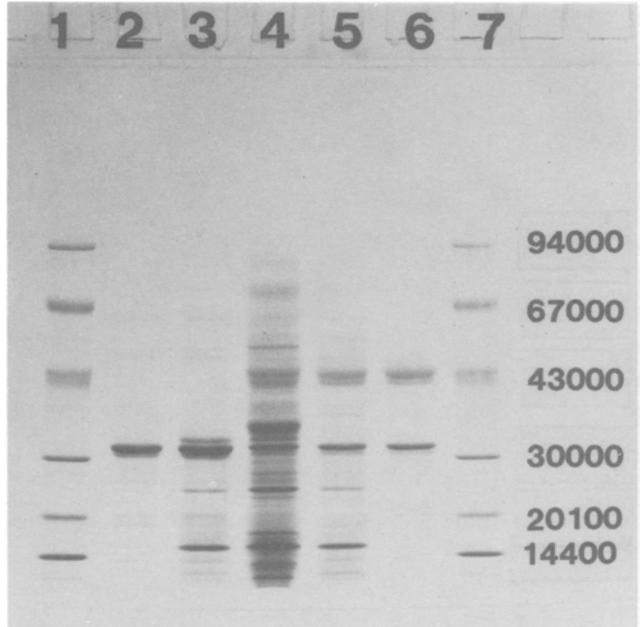

FIG. 1. SDS-PAGE of lipase preparations obtained from the various purification steps. (1) and (7), respectively, 18 μg of the total reference proteins; (2) 25 μg of the conA-Sepharose purified lipase A preparation; (3) 63 μg of the DE-cellulose 52 purified lipase A preparation; (4) 375 μg of the crude powder; (5) 63 μg of the DEAE-Sepharose purified lipase (A/B) preparation; (6) 25 μg of the Phenyl-Sepharose purified lipase B preparation. Proteins were stained with Coomassie Brilliant Blue.

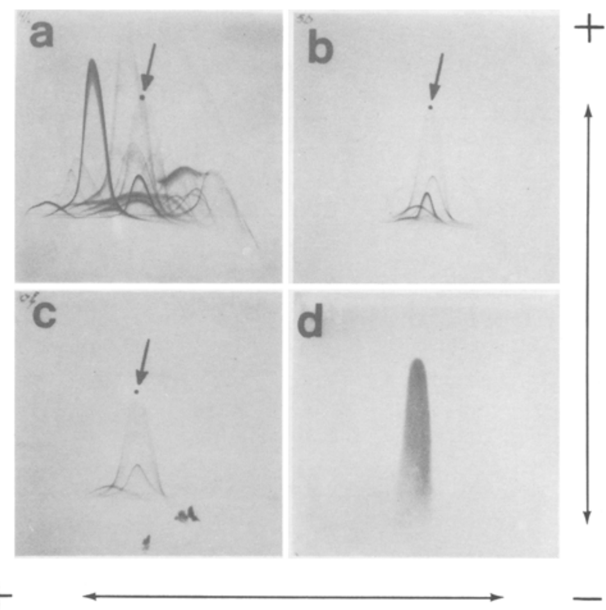

FIG. 2. Crossed immunoelectrophoresis (CIE) of purification steps of lipase A. a, b and c are CIE-stained with Coomassie Brilliant Blue. The arrow indicates the lipase-containing immunoprecipitate, detected as described for d. Part d is the duplicate CIE of b but with tributyroylglycerol overlayer, where the lipase peak shows as a clearing zone. The antigens applied were as follows: a, 100 μg of crude powder; b and d, respectively, 10 μg of DE-cellulose 52 purified lipase A preparation; c, 5 μg of conA-Sepharose purified lipase A preparation. 500 μl of the polyspecific antibodies were applied on each CIE. In the figures, cleared zones appear as dark areas because a dark background was used during photography. Otherwise, the zones cannot be visualized.

conA-Sepharose as well as the Sepharose 4B were equilibrated with the buffer containing 1 mM $MgCl_2$ and 1 mM $CaCl_2$ and then were added as a 50% slurry to the agarose gel.

Overlayer technique for detection of lipase activity. Bands and precipitates in IEF and CIE/CIAE, which contained lipases, were detected as follows: Immediately after the electrophoretic run, the plate was incubated with ~1.5 mm overlayer gel (1% agarose) containing a tributyroylglycerol emulsion at a final concentration of 1% tributyroylglycerol. The overlayer gel buffer was 0.1 M Tris-HCl, pH 7.5. Incubation time varied from 2–6 hr at 45 C. Binding of antibodies did not interfere with activity. Lipase activity appeared as cleared zones. In the figures, the cleared zones appear as dark areas, because a dark background was used during photography. Otherwise, the zones cannot be visualized.

Preparation of immobilized lipase A and B. Each of the lipases A (from the conA-Sepharose chromatography) and B (from the Phenyl-Sepharose chromatography) was immobilized on Duolite ES 562 resin (Rohm and Haas, Philadelphia, PA) according to patent application No. 0 140 542. The conditions used for the immobilization were pH 6.0 and 2 hr at 5 C. The intention was to immobilize 14 mg of lipase A preparation and 18 mg of lipase B preparation on 1 gram carrier each. Direct specific activity determinations on these immobilized preparations were not possible. Indirect determinations were done.

Determination of specificities. Positional specificity was determined by thin layer chromatographic (TLC) separation and then visualization of extracts from digestions of trioleoylglycerol. In these, the relative amounts of 1(3)

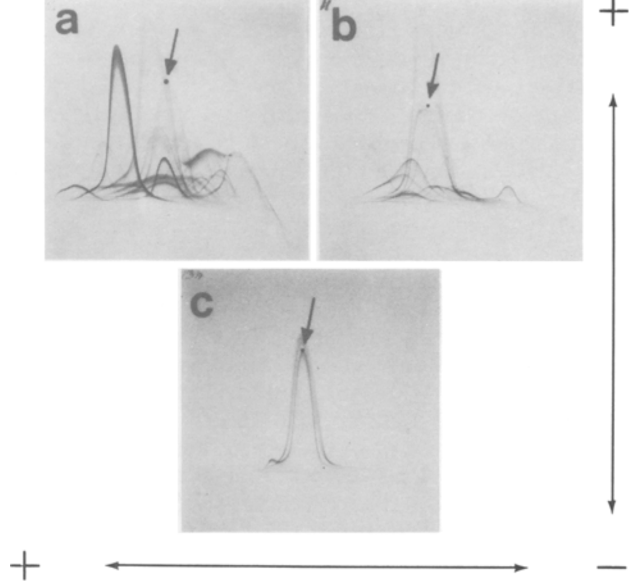

FIG. 3. Crossed immunoelectrophoresis (CIE) of purification steps of lipase B. The antigens applied were as follows: a, 100 μg of crude powder; b, 20 μg of DEAE-Sepharose purified lipase (A/B) preparation; c, 4.4 μg of phenyl-Sepharose purified lipase B preparation. 500 μl of the polyspecific antibodies were applied on each CIE. The CIE were stained with Coomassie Brilliant Blue. The arrow indicates the lipase containing immunoprecipitate, detected as described in Fig. 2.

TABLE 3

Activation Factors[a] of Lipase Preparations Based on LU Values[b]

Purification steps	Lipase preparations A	Lipase preparations B
Crude powder	6.3	6.3
Anion-exchange chromatography	6.3	1.7
Affinity chromatography	5.6	1.1

[a]Activation factor refers to ratio of activities of the enzyme when diluted in glycine buffer, pH 10.5, and in water, respectively, prior to analysis.

[b]LU (lipase unit) is the amount of enzyme that liberates 1 μmol of 4:0/min (see text).

and 2-monooleoylglycerol and 1,2-(2,3) and 1,3-dioleoylglycerol were ascertained by inspection and the real amounts by gas liquid chromatography (GLC) after recovery and conversion to methyl 18:1 with methyl 15:0 as an internal standard (13).

Confirmation was obtained by digestion of the synthetic triacylglycerol (TG), 1,3-dioleoyl-2-palmitoyl glycerol (18:1-16:0-18:1) and 1,3-dipalmitoyl-2-oleoylglycerol (16:0-18:1-16:0). The fatty acids were recovered and identified by GLC (13,14). Fatty acid specificity was determined as described by Wang et al. (15). Equimolar mixtures of the monoacid TG (20 μmol each) of 4:0, 6:0, 8:0, 10:0, 12:0, 14:0, 16:0 and 18:1 were hydrolyzed. The residual TG were recovered and separated by temperature-programmed GLC (155 to 350 C) and an 1/8″ × 18″ SS column containing 100/120 mesh Chromosorb coated with 1.0% Dexsil (Supelco, Bellefonte, PA). On-column injection and a cold injector port were required. Nonenzymatic blanks were used to check recoveries of the TG.

For stereospecificity, the specific rotation of the entire extract of a trioleoylglycerol digestion was determined in hexane with a Perkin-Elmer polarimeter sensitive to 1/10000°. In the absence of unequal amounts of optically active 1,2- or 2,3-*sn*-diacylglycerols and with adequate amounts of both, there should be no rotation, hence no stereospecificity (13,16).

Digestions of the substrates were done for the specified times at 40 C. Amounts of enzyme preparations and lengths of incubation were used that would provide 20–60% digestion with times of 1–10 min. For 50 mg of 18:1-18:1-18:1, 16:0-18:1-16:0 and 18:1-16:0-18:1, the following amounts of enzymes were used: soluble A, 88 LU or 58 NLU; soluble B, 94 LU or 59 NLU; immobilized A, 10 mg equivalent to 0.14 mg of Soluble A; immobilized B, 10 mg equivalent to 0.18 mg of soluble B. The buffer was 0.25 M Tris (pH 8.0) containing 1.0% gum arabic. The substrates were emulsified, after being melted when necessary, with a Branson sonicator. The substrates 18:1-16:0-18:1 and 16:0-18:1-16:0 were synthesized as described by Jensen and Pitas (17). Analyses with pancreatic lipase have shown that TG synthesized by these methods are 98–99% positionally correct. The monoacid TG of 4:0, 6:0, 8:0, 10:0, 12:0, 14:0, 16:0 and 18:1 were purchased from Sigma Chemical Co. (St. Louis, MO), and purity was determined by TLC (17).

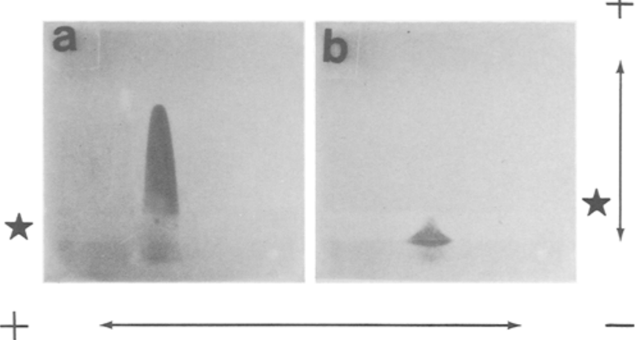

FIG. 4. Crossed immunoaffinity electrophoresis (CIAE), with tributyroylglycerol overlayers. Lipase peaks show as clearing zones. The intermediate gel (★) was without conA-Sepharose in a and contained conA-Sepharose in b. Applied antigen was 100 μg of crude powder on each CIAE. Applied antibodies as in Figs. 2 and 3. A typical CIAE of lipase A (a similar pattern is seen for the conA-Sepharose purified lipase preparation).

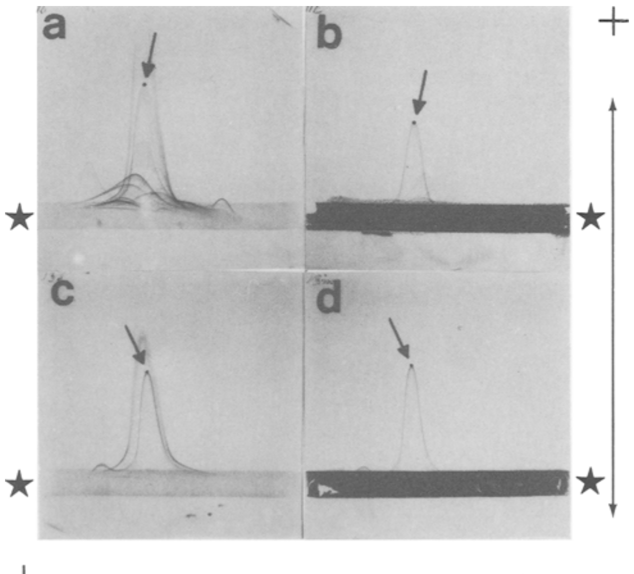

FIG. 5. Crossed immunoaffinity electrophoresis (CIAE), stained with Coomassie Brilliant Blue. The arrow indicates the lipase containing immunoprecipitate, detected as described in Fig. 2. The antigens applied were as follows: a and b, respectively, 20 μg of DEAE-Sepharose purified lipase A/B preparation; c and d, respectively, 4.4 μg of phenyl-Sepharose purified lipase B preparation. Applied antibodies as Figs. 2 and 3. The intermediate gels (★) were without conA-Sepharose in a and c and contained conA-Sepharose in b and d. This figure together with Fig. 4 shows decreasing affinity to conA-Sepharose of lipase, when it is converted from the A form to the B form.

RESULTS AND DISCUSSION

Conversion of the lipase from the A form to the B form was done by keeping the lipase fractions obtained from purification steps 1 and 2 at low pH during recovery and by treating the enzyme at low pH at an elevated temperature prior to step 2 as described previously. Lipase activity bands and peaks in IEF and CIE/CIAE, respectively, were identified by performing duplicates of the electrophoretic runs. These duplicates were used for the substrate overlayers and compared with the Coomassie-

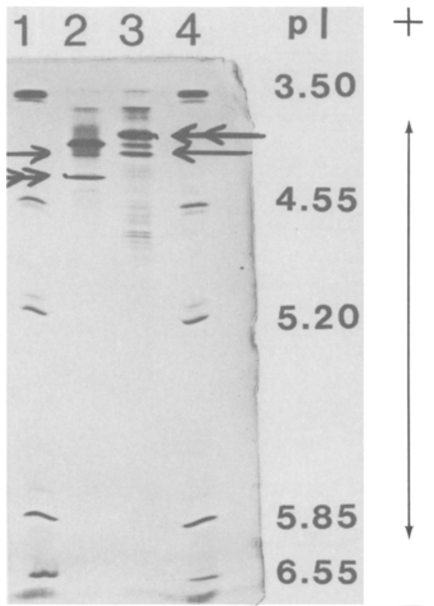

FIG. 6. Isoelectric focusing (IEF) of lipase A and B, stained with Coomassie Brilliant Blue. Lanes 1 and 4, respectively, about 65 μg of the total reference proteins. Lane 2, about 40 μg of the phenyl-Sepharose purified lipase B preparation; lane 3 about 40 μg of the conA-Sepharose purified lipase A preparation. Double arrow: main lipase activity band; single arrow: weak lipase activity band, as detected by means of tributyroylglycerol overlayer on a duplicate IEF. The isoelectric points (pI) of these bands were estimated on the basis of the reference proteins.

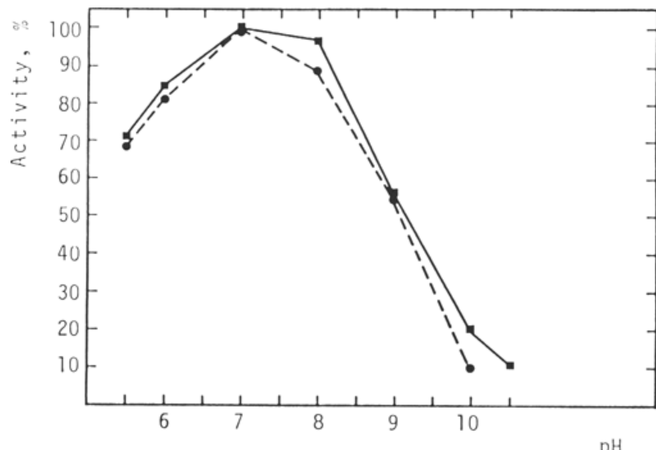

FIG. 7. Effect of pH on activity on tributyroylglycerol, 30 C, pH-stat method (7) using the appropriate analysis pH values. (■) Lipase A, conA-Sepharose purified preparation. (●) Lipase B, phenyl-Sepharose purified preparation.

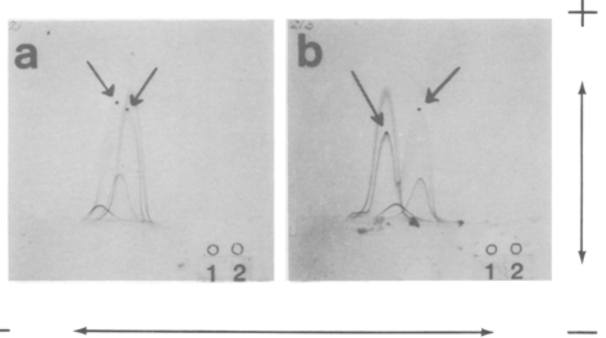

FIG. 8. Tandem-crossed immunoelectrophoresis, stained with Coomassie Brilliant Blue. Arrows indicate lipases, detected as described in Fig. 2. Applied antibodies as in Fig. 2. (a) Well 1, 5 μg of conA-Sepharose purified lipase A preparation. (b) Well 1 and well 2, reverse order of (a).

stained plates. The purifications were followed by activity measurements on both 4:0-4:0-4:0 and olive oil as well as by the electrophoretic methods SDS-PAGE and CIE. Tables 1 and 2 summarize the purification steps and yields of lipases A and B, respectively. Figures 1, 2 and 3 show the successive purifications of lipase from the multiprotein mixture in the crude powder with removal of many nonlipase proteins in the starting material. In Figure 3c, the antigenically different protein is not a lipase. Since the conversion of A to B was incomplete, the intermediate A/B appears as a broad peak in Figure 3b.

The differences in lipolytic and molecular behavior of the lipases were investigated by determining activities on water dilutions of the enzyme preparations as well as by CIAE. In Table 3 we present data on differences between lipases A and B in activity ratios when they are diluted in glycine buffer, pH 10.5, and in water, respectively, prior to analysis. It is obvious that lipase B needs no "activation" at high pH, whereas lipase A does. In Figures 4 and 5 we show the relative affinities of lipases A and B toward conA-Sepharose. A typical CIAE of lipase A, which had a high degree of affinity to conA-Sepharose, indicating that the lipase is a glycoprotein, is shown in Figure 4. The marked decreasing affinity to conA-Sepharose, when the lipase is converted from A form to the B form (A/B) due to partial deglycosylation, is given in Figure 5.

In Figure 5 (IEF), we depict the different isoelectric points (pI) of lipases A and B. The pI of the main lipase band in the lipase A preparation is 3.9, whereas it is 4.3 in the lipase B preparation. The more distinct band in B has a pI of 4.0, but does not have lipase activity. These results, combined with the findings of the slightly different net charges at pH 8 (cf. Fig. 8), indicate that the titration curves of the two lipases cross each other somewhere between pH 8.0 and 4.3.

Effect of pH on activities of lipase A and B on tributyroylglycerol was also investigated using the appropriate analysis pH-values in Novo method AF 95.1/3 GB. Figure 7 shows similar pH-activity profiles of the two lipases, both having optima at pH 7.0. Only a minor difference is seen at pH 8.0, where lipase B has slightly lower activity than lipase A.

Figure 8 (tandem-CIE) clearly shows a high degree of antigenic identity between lipases A and B, as defined in ref. 12. Their immunoprecipitates fuse into a double peak, practically without any spurs. A difference in the morphology of the immunoprecipitates is seen, though. The reverse orders of the well positions of lipase A and B in the first dimension gel also visualize the greater anodic mobility of B.

The results indicate that the B-form of the lipase is derived by partial deglycosylation of the A-form and that this influences the activity mode on emulsions. Lipase B is the "activated" form, but by the recovery yields in Ta-

TABLE 4

Composition of Fatty Acids Produced by Digestion of 18:1-16:0-18:1[a] and 16:0-18:1-16:0 with Several Preparations of *Mucor miehei* Lipase[b]

Substrate and composition of fatty acids (mol%)	Lipase preparation			
	Soluble A	Immobilized A	Soluble B	Immobilized B
18:1-16:0-18:1				
16:0	17.7	17.9	20.3	17.2
18:1	82.3	83.1	79.7	82.8
16:0-18:1-16:0

bles 1 and 2 it seems to be less stable than lipase A. We postulate that this partial deglycosylation at low pH of the original lipase is due to enzymatic reactions.

All preparations were highly specific for the primary positions of 18:1-18:1-18:1 as indicated by the absence of 1(3)-monoacylglycerols (MG) and 1,3-diacylglycerols (DG) in boric acid-TLC plates of extracts from short digestions of 10 min. The profiles of digestion products were similar for all preparations; rapid appearance of free fatty acids and 1,2(2,3)-DG accompanied by disappearance of TG at 4 and 8 min. Not much MG was produced at 4 min, but the amounts increased dramatically at 8 min, reflecting the accumulation of 2-MG. These will convert to 1-MG by acyl migration and will eventually be hydrolyzed, resulting in glycerol, which we did not determine. By 8 min, 30–50% of the TG was gone and by 12 min the amounts were less than 10%.

Confirmation of specificity for the primary positions of TG was obtained by analyses of the fatty acids liberated by the lipolyses of 18:1-16:0-18:1 and 16:0-18:1-16:0 (Table 4). In both cases, all preparations released much greater amounts (79.7–94.7 mol%) of the acids in the primary

positions than 67 mol%, the quantity that would be produced by a nonspecific lipase (13). Interestingly, there was a slight preference for 16:0 as compared to 18:1 in the primary positions.

We analyzed the whole extracts of digestions of 18:1-18:1-18:1 with a sensitive polarimeter but found no deviations from zero specific rotation (13). We used this technique in our study on human lingual lipase (16), finding a rotation denoting the presence of *sn*-1,2-DG. It is possible that enantiomeric MG as well as DG could be responsible for rotation, but since we observed no rotation, further investigation was not needed.

In contrast to Wang et al., who found specificity by a breast milk lipoprotein lipase (15) and a bile salt–stimulated lipase (18) for the shorter fatty acids in mixtures of monoacid TG ranging from 4:0 to 18:1, we observed the opposite. The percent digestions of the 4:0, 6:0, 8:0 and 10:0 TG were almost always lower than those of 12:0, 14:0, 16:0 and 18:1 with all preparations except Sol B. These data are presented in Table 5. In contrast to soluble A, immobilized A released more 14:0 and 16:0 than the other acids, including 18:1. This also occurred with the B preparations, but to a lesser extent. It is possible that the enzymes showed some preference for 14:0 and 16:0. This is supported by the results from the digestions of 16:0-18:1-16:0 and 18:1-16:0-18:1, previously mentioned and also in Table 4.

In summary, there are distinct differences in some characteristics including specificity for fatty acids among the several preparations. Neither deglycosylation of *M. miehei* lipase A to produce B nor immobilization of either preparation altered other specificities studied.

In order to investigate the effect of hepatic cholesterol flux on biliary bile acids, Triton WR 1339 and orotic acid were administered to rats, and the biliary cholesterol, phospholipids and bile acids were analyzed together with serum lipoproteins and hepatic lipids. Triton, which raised serum very low density lipoprotein and lipid levels and decreased serum high density lipoprotein liver lipid levels, increase the biliary cholic acid group/chenodeoxycholic acid group ratio (CA/CDCA) in the bile without affecting the total amount of bile acids and the other biliary lipids. Orotic acid, which decreased serum lipid and lipoprotein concentrations and increased liver lipid levels, increased the biliary excretion of cholesterol and phospholipids, but produced no significant change in the total amount of bile acids and in the CA/CDCA ratio in bile.
Lipids 22, 566–571 (1987).

The liver plays a central role in the regulation of the cholesterol metabolism. A considerable portion of cholesterol in the body pool is synthesized in the liver and released into the blood serum in the form of very low density (VLDL) and high density (HDL) lipoprotein. The liver, on the other hand, takes up cholesterol from plasma, metabolizes it to bile acids and secretes these into bile. This cholesterol flux from the liver and plasma is considered to influence cholesterol degradation and synthesis. Increased efflux of cholesterol from the liver enhances hepatic cholesterol synthesis, while increased influx inhibits it (1,2).

Precursor cholesterol for biliary cholesterol and bile acids is supplied from at least three sources: newly synthesized cholesterol in the liver, stored cholesterol in the liver and cholesterol derived from plasma lipoproteins. It has been suggested that newly synthesized hepatic cholesterol is a preferred source for bile acids (3–5). However, 10–20% of biliary cholesterol is estimated to arise from the newly synthesized pool of cholesterol (6,7), although larger amounts of cholesterol and bile acids have been derived from the newly synthesized cholesterol after prolonged bile drainage (6–8). Therefore, some manipulation of cholesterol and bile acid metabolism, such as cholesterol feeding (9,10), administration of bile acid sequestering resins (11–14) or bile drainage (6,8), should change the contribution of newly synthesized cholesterol to biliary cholesterol and bile acids.

Triton WR 1339 is known to reduce the influx of plasma cholesterol into the liver (15–19), and orotic acid is known to inhibit the efflux of hepatic cholesterol (20,21). These changes in the cholesterol flux between liver and plasma affect bile acid metabolism. Therefore, in the present experiments, we administered Triton WR 1339 and orotic acid to rats and examined the changes in biliary cholesterol, phospholipids and bile acids as well as in serum lipoprotein and liver lipid levels.

MATERIALS AND METHODS

Male Sprague-Dawley rats weighing about 250 g were housed in an air-conditioned room under artificial light from 7 a.m. to 7 p.m. and were given a balanced regular stock diet (Type MF, Oriental Kobo Co., Tokyo). Triton WR 1339 at 40 mg/100 g body weight was dissolved in 0.5 ml saline and injected intraperitoneally (ip) to interrupt cholesterol influx into the liver. Control rats received the same volume of saline ip. After 20-hr fasting, the rats were used for the experiments.

In another set of experiments, 15 g of powdered regular diet supplemented with 2% orotic acid was given to rats daily for 7 days to inhibit the cholesterol efflux from the

liver. Control rats were fed the same amount of regular diet without orotic acid. On the last day, 15 g of the diet containing 2% orotic acid or the control diet was given to the rats 12 hr prior to the experiment.

Bile was collected by biliary drainage for 30 min under sodium pentobarbital anesthesia (50 mg/kg, ip) (9), and then blood was drawn from the abdominal aorta by syringe. The liver was removed immediately after perfusion with 10 ml of cold saline through the portal vein.

Serum total and free cholesterol (22), triglycerides (23) and phospholipids (24) were determined by enzymatic colorimetric tests, and HDL cholesterol was estimated by an enzymatic method after removal and VLDL and low density lipoprotein (LDL) by the addition of phosphotungstic acid and $MgCl_2$ (25).

Serum lipoproteins were separated by ultracentrifugation as described by Hatch and Lees (26). VLDL was obtained by flotation of half the volume of the serum sample. For this purpose, NaCl solution with a density of 1.006 g/100 ml was layered on top of the serum and centrifuged at 100,000 × g for 16 hr in a Hitachi 65P ultracentrifuge. Half the volume of the NaCl solution on top of the serum was removed as the VLDL fraction. LDL was separated by centrifugation at 100,000 × g for 20 hr after adjusting the density to 1.064 by addition of KBr solution with a density of 1.182. HDL was obtained after centrifugation at 100,000 × g for 40 hr from the serum adjusted to a density of 1.21 by addition of KBr solution with a density of 1.478. In the case of the Triton-treated rats, VLDL separations were repeated three times to obtain the VLDL fraction completely. Lipid concentrations in the lipoprotein fractions were determined by enzymatic colorimetric assays (22–24), and apoprotein concentrations were measured by the Lowry method (27).

Cholesterol and bile acids in the bile were analyzed by gas liquid chromatography (28), and phospholipids were determined by the method of Haeflmyar and Fried (29) after extraction with hot ethanol. Lithogenic indices of the biles were calculated by the methods of Admirand and Small (30) and Holzbach et al. (31). Liver lipids were extracted by the Folch procedure (32); total lipids, total cholesterol, triglycerides and phospholipids were determined as reported previously (33). Statistical analyses were carried out using Student's t-test.

RESULTS

Table 1 shows the serum lipid concentrations of the rats treated with Triton and with orotic acid. The serum triglyceride concentration in the Triton-treated rats increased to about 15 times that of the control rats, and the total cholesterol and phospholipids increased 6.2 and 5.2 times, respectively. By contrast, the HDL cholesterol decreased to about one-tenth of that of the control, suggesting that the serum cholesterol was contained exclusively in the VLDL and LDL fractions after the treatment with Triton. As the serum-free cholesterol concentration was elevated to 31.5-fold that of the control, the percentage of the esterified cholesterol decreased to 24.3%, while the control showed a value of 84.9%.

On the other hand, orotic acid markedly decreased the serum lipid levels. The total cholesterol, triglycerides and phospholipids showed values of 38.8, 18.3 and 34.8% of those of the control rats, respectively. The HDL choles-

terol was also decreased to 49.4% of the control, suggesting that the cholesterol in VLDL and LDL decreased to about one-fifth of that of the control. The percentage of the esterified cholesterol vs total cholesterol was not affected by orotic acid administration.

The effect of Triton on apoproteins and lipids in serum lipoproteins is shown in Tables 2 and 3. The VLDL concentration in the treated rats increase 16.8-fold over the control, and the percentages of free cholesterol and triglycerides in VLDL increased while that of apoproteins decreased. The LDL concentration and free cholesterol increased, but apoproteins and esterified cholesterol decreased. The HDL concentration, on the contrary, markedly decreased to about one-fifth of that of the control. Free cholesterol and triglycerides in HDL increased, those of esterified cholesterol and phospholipids decreased, and that of apoproteins remained unchanged.

The VLDL concentration in the rats fed orotic acid decreased to one-tenth of that of the control, as shown in Table 2, where the composition ratios of the surface components such as apoproteins, free cholesterol and even phospholipids decreased but that of triglycerides in-

creased (Table 3). The LDL concentration also decreased with the reduction in the composition ratios of esterified cholesterol and phospholipids and with an increase in the triglycerides. The HDL concentration decreased to about half of the control; the percentage of free cholesterol increased but that of phospholipids decreased.

The liver weight of the Triton-treated rats decreased to 9.5 ± 0.27 g from 11.1 ± 0.29 g in the control ($p < 0.01$), but that of the orotic acid–treated rats increased to 16.3 ± 0.78 g from 14.1 ± 0.36 g in the control ($p < 0.01$). Triton decreased the total lipid level in the liver, but orotic acid markedly increased it (Table 4). Although only the triglyceride concentration decreased in the liver of Triton-treated rats, both the triglyceride and total cholesterol concentrations in the orotic acid–treated rats increased markedly.

Table 5 shows the changes in bile flow and levels of cholesterol, phospholipid and bile acid in the Triton- and orotic acid– treated rats. Triton induced no change in the bile flow and biliary cholesterol, phospholipid and bile acid levels, but orotic acid increased the bile flow and biliary secretion of cholesterol and phospholipids. The bile acid secretion in the orotic acid–treated rats showed a tendency to increase, but the change was statistically insignificant.

Lithogenic indices calculated by the methods of Admirand and Small (30) and Holzbach et al. (31) were not affected in the Triton treatment. In the orotic acid–treated rats, maximal cholesterol solubilities estimated by both methods tended to increase. Lithogenic indices therefore were not altered significantly by orotic acid administration despite the tendency to increase.

The biliary bile acid composition in these rats is given in Table 6. In the Triton-treated rats, 3α,12β-dihydroxy-7-oxo-5β-cholanoic acid increased and β-muricholic acid decreased, resulting in an increase of the cholic acid (CA) group and a decrease of the chenodeoxycholic acid (CDCA) group. The increase of cholic acid and deoxycholic acid and the decrease of chenodeoxycholic acid were statistically insignificant, but the ratio of the CA/CDCA group increased in the Triton-treated rats (2.19 vs. 1.54, $p < 0.05$). On the other hand, orotic acid caused no significant change in the biliary bile acid composition.

DISCUSSION

Both Triton WR 1339 and orotic acid affect the distribution of lipids between plasma and liver. Triton reduced the hepatic uptake of lipids from plasma lipoproteins by inhibiting the interaction between VLDL and lipoprotein

lipase (15–17) or between HDL and lecithin: cholesterol acyltransferase (LCAT) (18,19).

Elevation of the percentages of triglycerides and cholesterol in the VLDL fraction indicate an increase of large-sized VLDL, from which lipid moieties are not eliminated by lipoprotein lipase. The marked increase of VLDL causes some VLDL contamination of other lipoprotein fractions. Despite repeated separation of VLDL, a relatively triglyceride-rich HDL is obtained, because some triglyceride appears to be transferred from VLDL to HDL (34–36). It also will generate LDL particles in which esterified cholesterol in the core portion is substituted for triglyceride.

The decreased percentage of esterified cholesterol in serum indicates an impairment of LCAT activity, but the decrease of HDL concentration brought about by the reduction of HDL formation from VLDL (37–39) is also responsible for the reduction of the LCAT effect, because cholesterol is esterified on HDL surfaces (35,40,41). Since cholesterol is transferred from HDL to VLDL and LDL (34–36), the reduction of the esterified cholesterol content in HDL should lead to a decrease in the percentage of esterified cholesterol in VLDL and LDL.

It is not clear why the content of triglyceride in VLDL and LDL was elevated but those of protein and lipid were decreased by orotic acid administration. Orotic acid is known to specifically inhibit the release of VLDL from liver, but does not affect the intestinal relaease of chylomicrons and VLDL (42,43). Since chylomicron production in the intestine may be negligible after 12-hr fasting of rats and LDL may not be transformed from chylomicron, intestinal lipoproteins may not have participated in such compositional changes in VLDL and LDL in the present experiment. Therefore, the metabolism of triglyceride-rich lipoproteins from the liver should be affected indirectly by orotic acid.

Since Triton treatment inhibits cholesterol uptake by the liver from plasma without interfering with VLDL secretion from the liver (44,45), the hepatic cholesterol content is reduced, which in turn stimulates cholesterol synthesis in the liver. Actually, hepatic lipid synthesis was shown to be enhanced by Triton administration (15,46,47), although some reports have shown that the lipid synthesis was not affected (16,48,49). More recently, Fears and Umpleby (50) reported that hepatic cholesterol synthesis was stimulated, but the triglyceride synthesis remained unchanged after Triton treatment. In the present experiment, liver triglyceride decreased after the treatment but cholesterol did not, suggesting that the compensatory synthesis of cholesterol is more sensitive than that of triglyceride. Since phospholipids, which are an important membrane constituent of cells, are contained in VLDL far less than triglycerides, the effect of Triton treatment on phospholipids will be less significant than that on triglycerides. Consequently, newly synthesized or stored cholesterol in the liver will become the preferred precursor for bile acid synthesis. In addition, it has been reported that newly synthesized cholesterol in the liver is preferably metabolized to CA rather than to CDCA (3,51,52). Glucose feeding after fasting (53), oral administration of bile acid sequesting resin (11,14) or phytosterol (54), and bile drainage (6,8) stimulate bile acid, especially CA, synthesis. In the present experiment, the CA/CDCA ratio of the biliary bile acids was increased by Triton administration, suggesting that the CA synthetic pathway is stimulated by the compensatory increase of cholesterol synthesis.

On the other hand, orotic acid is considered to inhibit the glycosylation of apolipoproteins in the liver (20) and to decrease the release of VLDL into the circulation, inducing fatty liver and hypolipidemia in rats (20,21). VLDL and HDL are formed in both the liver and intestine, but VLDL secretion from the liver is five to eight times faster than that from the intestine (55), while a considerably larger amount of HDL is secreted from the intestine (56). Therefore, the decrease in serum VLDL should be

more marked than that of HDL in the orotic acid–treated rats. In addition, HDL formation from VLDL should be reduced when the serum VLDL level is low. This may cause a decrease of serum HDL after orotic acid treatment.

In the present experiment, the biliary bile acid secretion and CA/CDCA ratio were not influenced by orotic acid, but the secretions of cholesterol and phospholipids increased. Cholesterol feeding in excess to rats also causes accumulation of cholesterol and triglycerides in the liver and increases biliary secretions of bile acids and cholesterol (9,10). Thus, cholesterol accumulation in the liver probably enhances the excretion of biliary cholesterol. As for the bile acid composition, cholesterol feeding stimulates the CDCA synthetic pathway and leads to decrease in the CA/CDCA ratio of the bile (9,10). In the present experiment, the CA/CDCA ratio as well as the total amounts of excreted bile acids were not affected significantly in orotic acid–treated rats. Although accumulation of cholesterol in the liver is caused by either an increase of cholesterol influx or a decrease of cholesterol outflux, and the bile acid metabolism is influenced by the increase of liver cholesterol, the change of bile acid metabolism produced by the increase of cholesterol influx might be different from that induced by the decrease of cholesterol efflux. However, Tokmakjian and Haines (57) recently reported that orotic acid stimulated hepatic cholesterol synthesis. Although we expected that the CA/CDCA ratio would decrease in the orotic acid–treated rats, our results did not show this. If orotic acid does increase the cholesterol synthesis in the liver, as they have shown, this might have cancelled the decrease in the CA/CDCA ratio.

ACKNOWLEDGMENT

We thank Miss F. Koyama for help in preparing the manuscript.

Effects of di-(2-ethylhexyl)adipate (DOA) and di-(2-ethylhexyl)phthalate (DEHP), plasticizers for polyvinylchloride products, on concentrations and compositions of hepatic phospholipids were studied in rats. When administered to rats at a 2% level for 2 wk, both DOA and DEHP caused a hepatomegaly, an increase in hepatic phospholipids and a decrease in the ratio of phosphatidylcholine (PC) to phosphatidylethanolamine (PE). In the comparable study with mice, the alkyl moiety of DOA was found to be responsible for these alterations. DOA and DEHP specifically altered fatty acid compositions of PC and PE: there was an increase in oleic and palmitic acids and a decrease in stearic and docosahexaenoic acids in PC and an increase in arachidonic acid at the expense of docosahexaenoic acid in PE. In addition, DOA caused an increase in the trienoic and tetraenoic molecular species in PC and an increase in the 1-palmitoyl-2-arachidonyl (16:0//20:4) species in PE. Thus, the effects of DOA on the lipid dynamics resembled those observed with DEHP, although the magnitude was slightly moderated.
Lipids 22, 572-577 (1987).

Di-(2-ethylhexyl)phthalate (DEHP) is a chemical additive commonly used in the manufacture of plastic products. The widespread distribution of this compound in the environment and in animal tissues has attracted attention to its possible toxic effect (1). Recently DEHP has been reported to cause hepatic peroxisomal proliferation and hepatic tumors in rats (2,3). Alteration of lipid metabolism (4–8) and inhibition of various enzymes (9,10) in animal models have also been reported. In view of these untoward effects, less toxic substitutes for DEHP have been applied in products such as polyvinylchloride plastic medical appliances. Di-(2-ethylhexyl)adipate (DOA) is one such substitute.

Since DEHP modifies several aspects of lipid metabolism in rats (4–8,11–14) and rabbits (7), it seems important to clarify the effects that DOA exerts on lipid metabolism in the experimental animal model. Bell (15) recently showed that DOA works as an inhibitor of hepatic cholesterogenesis and thus exhibits plasma cholesterol–lowering activity.

The present study was undertaken to examine the effects of DOA on the profiles of hepatic and plasma lipids, and the results were compared with those produced by DEHP. The effects of adipate and 2-ethylhexanol, the constituents of DOA, were also examined.

TABLE 1

Effects of DOA and DEHP on Growth Parameters' Serum and Liver Components and Liver Catalase Activity in Rats (Experiment 1)

Groups	Control	DOA	DEHP
Initial weight (g)	156 ± 3[a]	156 ± 4[a]	156 ± 3[a]
Weight gain (g/2 wk)	74 ± 4[a]	57 ± 4[a]	31 ± 12[c]
Food intake (g/day)	17.7 ± 0.4[a]	16.8 ± 0.8[a]	13.6 ± 0.9[b]
Liver weight (g)	12.3 ± 0.5[a]	13.7 ± 0.6[a]	13.6 ± 0.9[a]
Liver weight (g/100 g body wt)	5.3 ± 0.1[a]	6.5 ± 0.2[b]	7.9 ± 0.2[c]
Liver components (mg/g liver)			
Phospholipids	17.6 ± 0.7[a]	23.0 ± 0.7[b]	26.7 ± 0.9[c]
Triglyceride	5.8 ± 0.3[a]	6.3 ± 0.1[a]	4.8 ± 0.3[b]
Cholesterol	2.1 ± 0.1[a]	2.0 ± 0.1[a]	2.0 ± 0.2[a]
Protein	149 ± 8[a]	179 ± 5[b]	183 ± 7[b]
Glycogen	88 ± 11[a]	54 ± 4[b]	39 ± 5[c]
Catalase activity			
(units/mg protein)	30.7 ± 1.6[a]	59.4 ± 4.6[b]	ND
(units × 10/liver/100 g body wt)	23.3	67.5	ND
Plasma lipids (mg/dl)			
Phospholipids	128 ± 18[a]	106 ± 4[a]	100 ± 9[a]
Triglyceride	143 ± 15[a]	123 ± 7[a]	85 ± 5[b]
Cholesterol	69 ± 2[a]	75 ± 6[a]	62 ± 5[a]

DOA, di-(2-ethylhexyl)adipate; DEHP, di-(2-ethylhexyl)phthalate; ND, not determined. Male rats were fed ad libitum semipurified diets supplemented with either 2% DOA or DEHP for 2 wk. Values are the means ± SE of 5 rats. Values not sharing the same superscript letter within the same row are significantly different at $p < 0.05$.

Abbreviations: DOA, di-(2-ethylhexyl)adipate; DEHP, di-(2-ethylhexyl)phthalate; PC, phosphatidylcholine; PE, phosphatidylethanolamine; GLC, gas liquid chromatography; TLC, thin layer chromatography.

MATERIALS AND METHODS

Animal experiments. Experiment 1: Six-week-old male Wistar rats (Kyudo Co., Saga, Japan), weighing ca. 156 g, were fed ad libitum the purified basal diet (5) or the basal diet supplemented either with 2% DOA or DEHP. The basal diet consisted (in percent) of vitamin-free casein, 20.0; corn oil, 5.0; cellulose, 4.0; mineral mixture, 4.0; vitamin mixture, 1.0; choline chloride, 0.15 and sucrose to 100. Mineral and vitamin mixtures according to Harper (16) were purchased from Oriental Yeast Co. (Tokyo). DOA and DEHP were from Wako Pure Chemical Industries (Osaka), and the purity was checked by gas liquid chromatography (GLC) with an electron capture detector using a OV-1 column (4); only one peak was detected for both chemicals. Food intake and body weight were measured every day. After 2 wk of feeding, rats were killed by decapitation; livers were excised, rinsed with physiological saline and weighed.

Experiment 2: To assess the effects of the constituents of DOA on liver phospholipid metabolism, 5-week-old ddy mice (Kyudo Co.) weighing ca. 31 g were fed a 20% casein (basal) diet containing either adipate, 2-ethylhexanol (ethylhexanol), a mixture of adipate and ethylhexanol or DOA for 1 wk. The dietary level of these supplements was equivalent to 1% DOA on the molar basis.

Lipid analysis. Liver and serum lipids were extracted and purified by the procedures of Folch et al. (17) and Bligh and Dyer (18), respectively, and were analyzed for phospholipid and triglyceride as reported elsewhere (4,5). Cholesterol was analyzed by the enzymatic method (Cholesterol C-Test, Wako Pure Chemical Industries, Osaka). For separation of individual phospholipids of the liver, total lipid extracts were initially developed on 0.25-mm thick Silica Gel H plates containing 1 mM $NaHCO_3$ under argon in a solvent system of acetone/diethylether (1:3, v/v) to separate neutral lipids from phospholipids, and then were developed in a solvent system of chloroform/methanol/acetic acid/water (25:15:4:2, v/v/v/v) containing 0.02% butylated hydroxytoluene as an antioxidant. After a brief exposure to iodine vapor, the spots corresponding to phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol + phosphatidylserine, sphingomyelin, lysoPC and phosphatidic acid were scraped off for the analysis of phosphorus and fatty acid composition (5).

Analysis of molecular species of phospholipids and fatty acid composition. The PC and PE extracted from the plates by the mixture of chloroform/methanol/acetic acid/water (50:39:4:2, v/v/v/v) were hydrolyzed by phospholipase C, and resulting diglycerides were immediately acetylated with acetic anhydrous in pyridine (19,20). The monoacetyldiglycerides were fractionated into molecular species according to the degree of unsaturation by two-step argentation thin layer chromatography (TLC) (19,20). The efficiency of the fractionation was checked by GLC after transmethylation. Pentadecanoic acid was used as an internal standard. Fatty acid compositions of methyl esters from various lipid fractions were determined by GLC on 10% DEGS coated on Chromosorb W (3 mm × 2 m, Gasukuro Kogyo Inc., Tokyo) using a Shimadzu Gas Chromatograph GC-8A. The C-R3A data processor (Shimadzu) was used to data processing. The retention time of each methyl ester was compared with those of the known standards (16:0, 18:0, 18:1, 18:2, 20:4 and 22:6). Based on the relative abundance of molecular species, fatty acid composition of each fraction and the positional distribution of the acyl group, the molecular species compositions were estimated.

Measurement of protein and glycogen. Protein was determined by the method of Lowry et al. (21) using bovine serum albumin as a standard. Liver glycogen was measured as reported previously (5).

Assay of catalase activity. Catalase [EC.1.11.1.6] activity of the liver homogenate was determined spectrometrically (22) at 20 C.

Statistical analysis. Results were shown as the means ± standard error. Comparisons between groups were made by Student's t-test (23).

RESULTS

Effects of DOA and DEHP on growth parameter and liver weight (Experiment 1). Feeding diets containing 2% DOA or DEHP for 2 wk resulted in growth retardation (Table 1). Food intake was also reduced by DEHP but not by DOA. Relative liver weight was increased by feeding plasticizers, in particular DEHP. A marked enlargement of liver by DEHP has been reported previously (4–9).

Effects of DOA and DEHP on the contents of liver lipids, glycogen and protein and on catalase activity (Experiment 1). Feeding DOA resulted in a significant increase in the content of phospholipids and a significant decrease in that of glycogen in the liver (Table 1). The hepatic phospholipids of rats fed DOA increased to 130% of the control value. The increase was attributed mainly to that in PC and PE, which together comprised 75% of the total phospholipids; changes in other components being marginal if any (Table 2). However, the percentage composition of phospholipids was less influenced by the treatment, although the ratio of PC to PE decreased significantly due

TABLE 2

Effects of DOA and DEHP on Hepatic Phospholipid Compositions of Rats (Experiment 1)

Phospholipid	Control (mg/g liver)	DOA (mg/g liver)	DEHP (mg/g liver)
LPC + SPH	0.4 ± 0.0^a (2.4)	0.5 ± 0.1^a (2.2)	0.8 ± 0.1^a (3.0)
PC	9.3 ± 0.3^a (53.0)	11.9 ± 0.2^b (51.7)	12.3 ± 3.5^b (46.3)
PI + PS	2.5 ± 0.1^a (14.1)	2.8 ± 0.1^b (12.2)	3.5 ± 0.1^c (13.0)
PE	4.1 ± 0.1^a (23.4)	6.1 ± 0.3^b (26.4)	8.3 ± 0.5^c (30.9)
PA	1.3 ± 0.1^a (7.2)	1.7 ± 0.1^b (7.5)	1.8 ± 0.1^b (6.9)

Phospholipids were separated by thin layer chromatography and determined as described in Materials and Methods. Values are the means ± SE of 5 rats. Values not sharing the same superscript letter within the same row are significantly different at $p < 0.05$. DOA, di-(2-ethylhexyl)adipate; DEHP, di-(2-ethylhexyl)phthalate; PC, phosphatidylcholine; LPC, lysoPC; SPH, sphingomyelin; PI, phosphatidylinositol; PS, phosphatidylserine; PE, phosphatidylethanolamine; PA, phosphatidic acid.

See Tables 1 and 2. DOA, di-(2-ethylhexyl)adipate; DEHP, di-(2-ethylhexyl)phthalate; tr, trace. Liver phosphatidylcholine and phosphatidylethanolamine were separated as described in Materials and Methods. Minor fatty acids (less than 1% of the total fatty acids detected) were excluded from the table. Values are the means ± SE of 5 rats. Values not sharing the same superscript letter within the same row are significantly different at $p < 0.05$.

TABLE 4

Effects of DOA and DEHP on the Molar Relative Abundance of Liver Phosphatidylcholine and Phosphatidylethanolamine of Rats (Experiment 1)

Molecular classes	Control	DOA	DEHP
Phosphatidylcholine			
Saturated	3.7 ± 0.3^{a}	1.8 ± 0.1^{b}	1.5 ± 0.2^{c}
Monoenoic	13.4 ± 1.8^{a}	16.0 ± 0.3^{a}	22.8 ± 0.4^{b}
Dienoic	17.0 ± 0.4^{a}	16.6 ± 0.4^{a}	16.4 ± 0.3^{a}
Trienoic	3.2 ± 0.2^{a}	6.2 ± 0.2^{b}	6.6 ± 0.2^{b}
Tetraenoic	47.0 ± 0.1^{a}	50.1 ± 0.6^{b}	49.2 ± 0.5^{b}
Hexaenoic	14.6 ± 1.5^{a}	10.4 ± 0.5^{b}	7.0 ± 0.4^{c}
Phosphatidylethanolamine			
Saturated	0.5 ± 0.1^{a}	0.5 ± 0.2^{a}	0.4 ± 0.0^{a}
Monoenoic	2.2 ± 0.5^{a}	3.2 ± 0.3^{a,b}	3.6 ± 0.3^{b}
Dienoic	7.1 ± 0.3^{a}	6.3 ± 0.9^{a}	6.4 ± 0.4^{a}
Trienoic	2.3 ± 0.3^{a}	3.2 ± 0.1^{a}	2.4 ± 0.3^{a}
Tetraenoic	51.4 ± 1.9^{a}	58.3 ± 2.0^{b}	66.5 ± 1.6^{c}
Hexaenoic	33.4 ± 1.7^{a}	24.3 ± 1.9^{b}	16.5 ± 1.1^{c}

See Tables 1 to 3. DOA, di-(2-ethylhexyl)adipate; DEHP, di-(2-ethylhexyl)phthalate. Each molecular class was isolated by argentation thin layer chromatography, and the percentage concentration was determined by the internal standard (pentadecanoic acid) method. Values are the means ± SE (n = 4–5). Values not sharing the same superscript letter within the same row are significantly different at $p < 0.05$.

to a reciprocal change in these phospholipids. A similar but more profound response was observed in rats given DEHP, consistent with reported data (5,6,12). No demonstrable difference due to DOA was observed in the hepatic triglyceride level. The plasticizers caused a slight but significant increase in the concentration of liver protein. Hepatic catalase activity in rats fed DOA increased, suggesting an induction of peroxisomes. The induction of this enzyme has already been reported for DEHP, monoethylhexylphthalate and ethylhexanol (14,24).

Effects of DOA and DEHP on plasma lipids (Experiment 1). The plasma concentrations of phospholipids and triglyceride tended to decrease after feeding DEHP or DOA compared with the controls (Table 1). The magnitude of the decrease was more prominent in the DEHP than in the DOA groups. There was no significant difference in the cholesterol level among the three groups.

Effects of DOA and DEHP on the fatty acid composition of liver PC and PE (Experiment 1). Table 3 summarizes the effects of DOA and DEHP on the fatty acid compositions of hepatic PC and PE. Administration of DOA and DEHP altered the fatty acid compositions of these phospholipids, in particular in the latter; in the PC fraction, the proportion of oleic and palmitic acids increased at the expense of stearic and docosahexaenoic acids. In the PE fraction, DEHP caused an increase in the proportion of arachidonic acid and a decrease in palmitic and docosahexaenoic acids. The DOA effect on PE was less clear, and decreased proportion of docosahexaenoic acid was the sole variable. A similar change in the fatty acid composition of phospholipids has also been observed in the hepatic microsomes and mitochondria (Yanagita, T., unpublished data).

Effects of DOA and DEHP on the molecular species of liver PC and PE (Experiment 1). Table 4 gives the proportion of molecular species of hepatic PC and PE. Six different groups of acetyldiacylglycerol derivatives with different degrees of unsaturation were obtained, i.e. saturated, monoenoic, dienoic, trienoic, tetraenoic and hexaenoic species. The fatty acid profiles indicate that the most striking change induced by DEHP in the molecular classes of PC was an increase in the monoenoic and trienoic classes and a decrease in hexaenoic classes, whereas in PE the monoenoic and tetraenoic classes increased and the hexaenoic class decreased. DOA also altered the molecular species compositions of these phospholipids similarly, but to a lesser extent.

Based on the relative abundance of molecular species (Table 4), the fatty acid composition of each fraction and the positional distribution of the acyl group, the molecular species composition was estimated (Tables 5 and 6). Fifteen major (more than 2% of total PC and PE populations) molecular species were found. The relative abundance of the molecular species of PC in the liver of the control rats was comparable with that reported by other workers (19,25).

The DEHP treatment in general resulted in an increase in the PC molecular species containing palmitic acid and a decrease in those containing stearic acid. In addition, there was a predictable decrease in the molecular species containing docosahexaenoic acid, irrespective of the partner fatty acids, palmitic or stearic acids.

Alteration of the molecular species composition of PC by DOA was comparable with those produced by DEHP, although the magnitude of alteration was considerably low.

Both plasticizers also induced the change in the molecular species composition of hepatic PE (Table 6). A marked

change by the DEHP treatment was an increased proportion of the tetraenoic species, particularly the (18:0//20:4) PE and the decreased proportion of hexaenoic species, particularly the (16:0//22:6) PE. Thus, DEHP altered the (18:0//20:4) species in the PC and PE fractions in a different manner, a decrease in the former and an increase in the latter. The effect of DOA on the PE species was rather moderate and was again most obvious in the hexaenoic species.

Effects of adipate and ethylhexanol on liver phospholipids (Experiment 2). There were no significant differences in body weight gain and food intake in all groups. The increase in the concentration of hepatic phospholipids by DOA was again detected in mice. The increased concentration of hepatic phospholipids was also found in mice fed either ethylhexanol or a mixture of adipate and ethylhexanol, whereas the effect of adipate did not appear (Table 7). These results thus indicate that the alkyl moiety of the adipate ester is responsible for the effect of DOA. A similar result has been obtained in the corresponding study with DEHP (6).

DISCUSSION

In the present study, both DOA and DEHP induced quantitative and qualitative alterations of the hepatic phospholipids: an increase in the concentration of phospholipids and a change in the proportion of individual phospholipids. The modification of the phospholipid pattern by DEHP corresponded to that reported for liver microsomes and mitochondria (5). The alteration of the PC to PE ratio induced by DOA and DEHP is at least interpreted as the results of the increased synthesis of PC and PE from diglyceride accompanying the decreased conversion of PE to PC. In fact, the incorporation of [^{3}H]glycerol in vivo and in vitro and of [^{14}C]acetate in vitro into liver phospholipids increased after feeding DEHP or DOA (Yanagita, T., et al., in preparation). The activities of glycerol-3-phosphate acyltransferase and CTP:phosphocholine cytidyltransferase, the rate-limiting enzymes of glycerophospholipid biosynthesis (25–28), in liver microsomes were also simultaneously induced in rats treated with DEHP (39). The possibility of the decreased conversion of PE to PC remains to be confirmed.

Both plasticizers also caused an alteration of the proportion of palmitate/stearate and oleate/stearate of phospholipids. It is likely that DOA and DEHP could induce the stimulation of the fatty acid synthesis (13), although this is controversial (7,15). DEHP also presumably increases the activity of stearoyl-CoA desaturase of liver microsomes (14), thus resulting in the increase in the percentage of oleic acid and the decrease in that of stearic acid (Table 3). Other characteristic changes in the fatty acid compositions were an increase in arachidonic acid in PE from rats fed DEHP and a decrease in docosahexaenoic acid in PC and PE from rats fed DEHP or DOA.

The fatty acid composition indicates that these plasticizers caused the alteration of the profile of the molecular species of liver PC and PE (Tables 5 and 6). When an increase in the concentration of PC and PE is taken into account, the changes in the species of the (16:0//18:1) PC, the (16:0//18:2) PC, the (16:0//20:4) PC and the (16:0//20:4) PE were further accentuated. Alternatively, a change in the proportion of the (18:0//20:4) PC and the (18:0//18:2) PC disappeared.

For formation of the monoenoic and dienoic species of liver PC and PE, a de novo synthesis appears responsible (26), while the tetraenoic species are synthesized mainly from 1-acyl-lyso derivatives (29,30). The hexaenoic species of hepatic PC appears to be derived mainly from PE by successive methylation (31,32). In fact, the changes caused by the plasticizers are related to both the enhance-

DOA, di-(2-ethylhexyl)adipate. Male mice were fed each diet for 1 week. Each chemical added to the basal diet was adjusted to be quivalent to 1% DOA on the molecular basis. Values are the means ± SE of 6 mice. Values not sharing the same superscript letter within the same column are significantly different at $p < 0.05$.

ment of de novo synthesis (39) and the induction of microsomal 1-acylglycerophosphorylcholine acyltransferase (33). Thus, the observed alterations of hepatic phospholipids could result from the complex interplay of a number of enzymatic systems involved in phospholipid synthesis and the pool size and the metabolic turnover of the individual components.

Phospholipids are the integral components of the biological membranes and influence the function of the membranes, as shown by their role in the hepatic microsomal drug-metabolizing systems (34) or in the activities of microsomal UDP-glucuronyltransferase and glucose-6-phosphatase (35,36). However, we have found that mannose-6-phosphatase, an enzyme located to the lumenal face of microsomal membranes, is highly latent in liver microsomes from both DEHP-fed and control rats, due to a hindrance of the substrate to the site of hydrolysis (37). An asymmetric distribution of phospholipids in liver microsomal membranes with PC predominantly in the cytoplasmic face and a slight excess of PE in the lumenal face appears to remain apparently unchanged, even after treatment with DEHP (39).

In conclusion, the present study showed that DOA or DEHP induced the quantitative and qualitative alteration of hepatic phospholipids. These changes were less prominent in rats treated with DOA than in those treated with DEHP. The difference in the hydrolytic rate and/or the diverse effect of metabolites of DOA and DEHP (38) might imply these differences. The effect of DOA was essentially attributable to its alkyl moiety, ethylhexanol but not adipate as in the case of DEHP (6).

The synthesis of alkyl chain-substituted thiazanones from oxo fatty esters and a long chain aldehyde is reported. Four oxo compounds—methyl 10-oxoundecanoate, methyl 9-oxooctadecanoate, methyl 9,10-dioxooctadecanoate and octadecanal—were allowed to react with β-mercaptopropionic acid in the presence of ammonium carbonate in benzene to give the corresponding 4-*m*-thiazanones in high yields. The structures of these compounds were confirmed by combustion and spectral data.
Lipids 22, 578-582 (1987).

Thiazanones are six-membered heterocyclic compounds containing one nitrogen and one sulphur atom with a carbonyl function. Fatty acids possessing a chain-substituted thiazanone ring have not yet been reported in the literature. Only a few methods are available for the synthesis of thiazanones: 2-amino(imino)-4-oxo-5,6-dihydro-1,3-thiazinium bromide was prepared by heating β-bromopropionyl chloride [$Br(CH_2)_2COCl$] and ammonium thiocyanate followed by reaction with ammonia (1), 2-*p*-chlorophenyl-3-alkyl-4-*m*-thiazanones were obtained by treatment of mercaptals with *p*-chlorobenzaldehyde (2), and benzothiazinones were synthesized by condensation of *o*-mercaptobenzamide with methyl acetylenedicarboxylate (3). A number of 1,3- and 1,4-benzothiazinones have been evaluated for their central nervous system (CNS) depressant activity (4). Incorporation of the thiazanone ring in fatty acid chain is expected to enhance the application of these derivatives. Recently, we have reported the synthesis of fatty chain-substituted 4-thiazolidinones (5). In continuation of our work on derivatization of keto fatty acids (6), we synthesized chain-substituted thiazanone derivatives by condensing keto fatty esters and a long chain aldehyde with β-mercaptopropionic acid in the presence of ammonium carbonate.

Long chain oxo compounds, having a carbonyl function at penultimate (methyl 10-oxoundecanoate, I), internal (methyl 9-oxooctadecanoate, II), vicinal dioxo (9,10-dioxooctadecanoate, III) and terminal (1-octadecanal, IV) positions were used for the synthesis of thiazanone derivatives.

MATERIALS AND METHODS

All mp were observed on Koffler apparatus and were uncorrected. The spectroscopic and chromatographic methods were the same as detailed in our previous paper (5) except where specified. Lithium aluminium hydride ($LiAlH_4$, >98%), chromic anhydride, methylene chloride and pyridine were supplied by E. Merck (Darmstadt, FRG) and β-mercaptopropionic acid by Sigma Chemical Co. (St. Louis, MO). The methyl esters of long chain oxo acids were prepared by refluxing them with absolute methanol and a few drops of sulphuric acid. The abbreviations s, t, m, and br denote singlet, triplet, multiplet and broad, respectively. Petroleum ether refers to a fraction of bp 40-60 C, and ether refers to diethyl ether.

Preparation of oxo fatty acids (I-III). 10-Oxoundecanoic (I, mp 58-59 C) and 9,10-dioxooctadecanoic (III, mp 86 C) acids were prepared according to the methods discussed in an earlier paper (5). 9-Oxooctadecanoic acid (II) was obtained from pure *Wrightia tinctoria* seed oil (7) using Gunstone's partitioning procedure (8). 9-Hydroxy-12-octadecenoic acid isolated from this seed oil was hydrogenated by palladium on charcoal in ethyl acetate to give 9-hydroxyoctadecanoic acid (mp 80-81 C) which, on Jones' oxidation (10), afforded 9-oxooctadecanoic acid [mp 79-80 C; lit. (8) 79.5 C]. IR (CCl_4): 1710 (acid carbonyl), 1720 cm^{-1} (chain carbonyl).

Preparation of octadecanal (IV). Methyl stearate (10 g) was dissolved in dry ether (500 ml) and slowly added to a stirred suspension of $LiAlH_4$ (2 g) in dry ether (200 ml). After stirring for a further 10 min at room temperature, excess of $LiAlH_4$ was destroyed by the cautious addition of wet ether and then water. Dilute H_2SO_4 (2 l, 2M) was subsequently added and the octadecanol was isolated. On crystallization from petroleum ether this gave a white solid in 90% yield mp 58-58.5 C [lit. (11), 59 C].

Octadecanol was oxidized to octadecanal by chromic anhydride (12). To a stirred mixture of pyridine (9.65 ml, 0.12 mol) and methylene chloride (150 ml), chromic anhydride (6 g, 0.06 mol) was added, and the temperature was kept below 25 C using an ice bath. After 15 min, the mixture cleared to a dark red solution. Octadecanol (2.6 g, 0.01 mol) in methylene chloride (15 ml) was added in portions, and the mixture turned dark brown. After 30 min, the solvent was removed in vacuo, and the residue was extracted with ether. The ethereal layer was washed successively with 10% aqueous NaOH, 10% HCl, sat. $NaHCO_3$ solution and water and dried to give 98% octadecanal (IV) mp 37-38 C [lit. (11) 38 C]. IR (CCl_4): 2715 (aldehydic C-H stretch), 1735 cm^{-1} (CHO); ^1H NMR ($CDCl_3$): δ 0.88 (3, t, CH_3), 1.3 (30, br s, chain methylene), 3.6 (2, m, CH_2CHO), 9.6 (1, br m, CHO).

Conversion of oxo fatty esters to thiazanones. The thiazanones (Ia-IVa) were synthesized from their corresponding oxo fatty esters (I-IV). A mixture of dry benzene (50 ml) and β-mercaptopropionic acid (6.45 g) was refluxed in a round-bottom flask using a Dean Stark separator for 3 hr. Excess of β-mercaptopropionic acid was used to obtain IIIa from III. Oxo fatty acid ester (1.0 g) and ammonium carbonate (11.0 g) were added to the cooled mixture (5). A vigorous reaction took place. The contents were refluxed, and the progress of reaction was monitored by thin layer chromatography (TLC). At the end of the reaction, the solvent was removed under reduced pressure. The residue was extracted with ether, washed with 10% $NaHCO_3$ solution and dried over anhydrous sodium sulphate. The product thus obtained was crystallized from petroleum ether/benzene (4:1, v/v).

The experimental and spectral data of respective thiazanones are summarized in Table 1.

RESULTS AND DISCUSSION

The oxo compounds (I–IV) on treatment with β-mercaptopropionic acid in the presence of ammonium carbonate following the procedure of Paryzek et al. (13) yielded the corresponding 4-*m*-thiazanones (Ia–IVa) as shown in Scheme 1.

The IR spectrum of Ia (Table 1) revealed characteristic bands at 3170 (NH stretching), 1735 and 1660 (ester and lactam carbonyl), 1405 (C-N stretch), 1225 (C-S wagging), 720 (NH wag.) and 670 cm^{-1} (C-S stretch). These values are in agreement with the structure of Ia. The ^1H NMR spectrum of Ia exhibited two sharp singlets at δ 1.55 for terminal ω-methyl protons and at δ 3.68 for ester methyl protons. The ring protons gave triplet signals at δ 2.85 (CH_2-S) and 2.55 (CH_2CONH) while NH proton appeared at δ 8.6 as a broad singlet. The methylene protons alpha to ring and ester carbonyl appeared at δ 1.75 and 2.30, respectively. The chain methylene protons absorbed at δ 1.30 as a broad singlet. On the basis of these data, the product Ia was formulated as 2-8′-carbomethoxyoctyl-2-methyl-4-*m*-thiazanone.

Thiazanone IIa gave similar IR and ^1H NMR characteristics as Ia except for the appearance of terminal methyl and four methylene protons (α- to ring) at δ 0.88 and 1.65, respectively. The product IIa was characterized as 2-7′-carbomethoxyheptyl-2-nonyl-4-*m*-thiazanone.

Similarly, the thiazanone (IVa) located at a terminal position displayed almost the same diagnostic peaks in IR and ^1H NMR spectra as observed in Ia and IIa. The only characteristic ^1H NMR peak observed was at δ 4.52 for the methine proton attached to C-2 position of the ring. The product IVa was identified as 2-heptadecyl-4-*m*-thiazanone.

The thiazanone (IIIa) obtained from the vicinal dioxo ester (III) exhibited a clear single spot on the TLC plate. It showed IR absorption bands at 3185 (NH stretch), 1740 and 1660 (ester and lactam carbonyl), 1405 (C-N stretch), 770 (NH Wag.) 1230 and 640 (C-S wag. and stretch), along with a free carbonyl band at 1715 cm^{-1}. The ^1H NMR spectrum exhibited a multiplet at δ 2.27 integrating for four methylene protons α- to chain and ester carbonyls. The two methylene protons alpha to the ring appeared at δ 1.65 along with other usual peaks observed for IIa. These data clearly confirmed that one of the two carbonyl groups of IIIa has not taken part in the reaction even on prolongation of reaction time and use of excess of the reagent. On the basis of these data, product IIIa was

I, II, IV → Ia, IIa, IVa (reagents (i), (ii))

I, Ia : R = CH_3 ; R′ = $(CH_2)_8COOCH_3$
II, IIa : R = $CH_3(CH_2)_8$; R′ = $(CH_2)_7COOCH_3$
IV, IVa : R = $CH_3(CH_2)_{16}$; R′ = H

III → IIIa (reagents (i), (ii))

III, IIIa : R = $CH_3(CH_2)_7$; R′ = $(CH_2)_7COOCH_3$
(i)= $SHCH_2CH_2COOH$, (ii) = $(NH_4)_2CO_3$ / benzene

SCHEME 1. Synthesis of fatty thiazanones.

characterized as an isomeric mixture of 2-7′-carbomethoxyheptyl-2-1′-oxononyl-4-*m*-thiazanone/2-(8′-carbomethoxyl-1′-oxooctyl)-2-octyl-4-*m*-thiazanone. From the foregoing discussion, it can be inferred that only one carbonyl group participates in the reaction. Since both the carbonyl functions are in the middle of the chain, an isomeric mixture of products was expected that could not be resolved by chromatographic methods. It appeared that steric hindrance (5) caused by the introduction of one thiazanone ring made the adjacent carbonyl function unable to undergo further attack by the reagent.

Mass fragmentation of thiazanones. Very few reports are available for the detailed mass spectral studies of thiazanones. Russian workers (14) have studied the mass fragmentation of 2-anilino-5,6-dihydro-4H-1,3-thiazin-5-one and observed that the cleavage mainly occurs at the C-N bond. We also recently studied the basic fragmentation of thiazolidinones derivatives of fatty acids (5). We now discuss the mass spectra (MS) of thiazanones (Ia–IVa), which were found not to be much different from thiazolidinones (5) except for one more methylene group in the ring. The compositions of fragment ions were supported by accurate mass measurement studies. The composition and relative intensity of fragment ions are indicated in parentheses.

MS of Ia (Fig. 1): m/z 301 (M^+,$C_{15}H_{27}O_3NS$, 59.6), 286 (M-CH_3, 26.8), 270 (M-OCH_3, 98.3) 268 (M-SH, 37.0), 229 (M-$CH_2CH_2CONH_2$, 9.8), 214 (M-$COCH_2CHS$, 99.1), 212 (M-$COCH_2CH_2SH$, 99.1), 196 (M-C_3H_7ONS, 98.7), 183 (214-OCH_3, 49.5), 182 (214-CH_3OH, 95.0), 158 (M-$C_8H_{15}O_2$, 57.0), 131 (A+1, 97.0), 130 (A, base peak), 112 (A-CO, 59.8) and 89 ($COCH_2CH_2SH$, 44.7).

Ia

MS of IIa (Fig. 2): m/z 399 (M^+, $C_{22}H_{41}O_3NS$, 6.7), 368 (M-OCH_3, 7.0), 366 (M-SH, 4.7), 351 (M-CH_3SH, 5.6), 338 (M-C_2H_5S, 6.5), 327 (M-$CH_2CH_2CONH_2$, 10.7), 324 (M-$COCH_2SH$, 3.8), 312 (M-$COCH_2CHS$, 35.2), 310 (M-$COCH_2CH_2SH$, 8.6), 295 (M-C_3H_6NOS, 4.6), 272 (C, 9.0), 242 (B, 10.5), 240 (C-CH_3OH, 4.0), 239 (C-SH, 4.8), 200 (B-CH_2CO, 65.7), 185 (B-$NHCOCH_2$, 29.5), 170 (B-$NH_2COCH_2CH_2$, 52.3), 71 (C_3H_5ON, 80.0) and 55 (C_3H_3O, base peak).

IIa

MS of IIIa (Fig. 3): m/z 413 (M^+, $C_{22}H_{39}O_4NS$, 10.0), 382 (M-OCH_3, 5.4), 380 (M-SH, 3.9), 353 (M-CH_2CH_2S, 2.2), 341 (M-$CH_2CH_2CONH_2$, 9.7), 326 (M-$COCH_2CHS$, 3.6), 324 (M-$COCH_2CH_2SH$, 9.0), 315 (McLafferty, 4.5), 309 (M-C_3H_6ONS, 4.3), 300 (M-C_8H_{17}, 8.5), 273 (D+H, 11.7), 272 (D, 35.1), 271 (McLafferty, 80.1), 240 (D-32, 34.2), 229 (F+H, 3.7), 228 (F, base peak), 185 (G, 21.6), 153 (G-32, 3.9) and 141 (E, 23.4).

IIIa

FIG. 1. Mass spectrum of 2-8′-carbomethoxyoctyl-2-methyl-4-*m*-thiazanone (Ia).

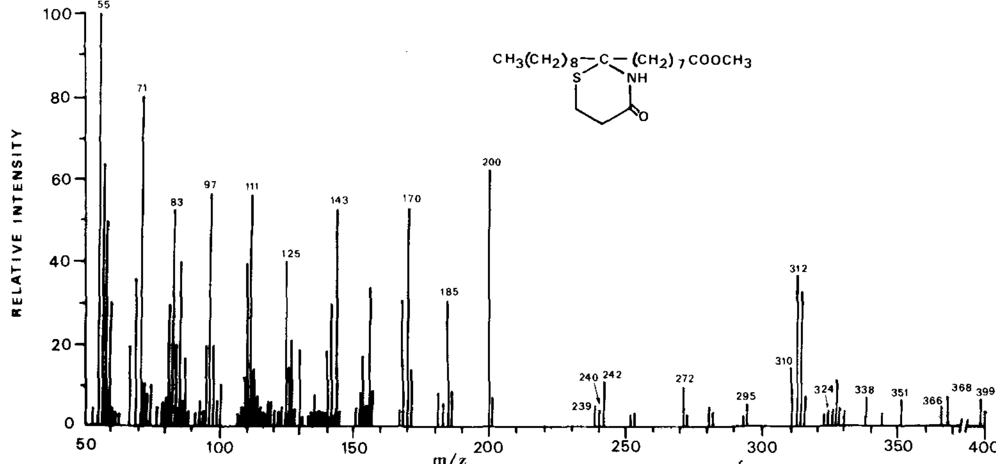

FIG. 2. Mass spectrum of 2-7′-carbomethoxyheptyl-2-nonyl-4-*m*-thiazanone (IIa).

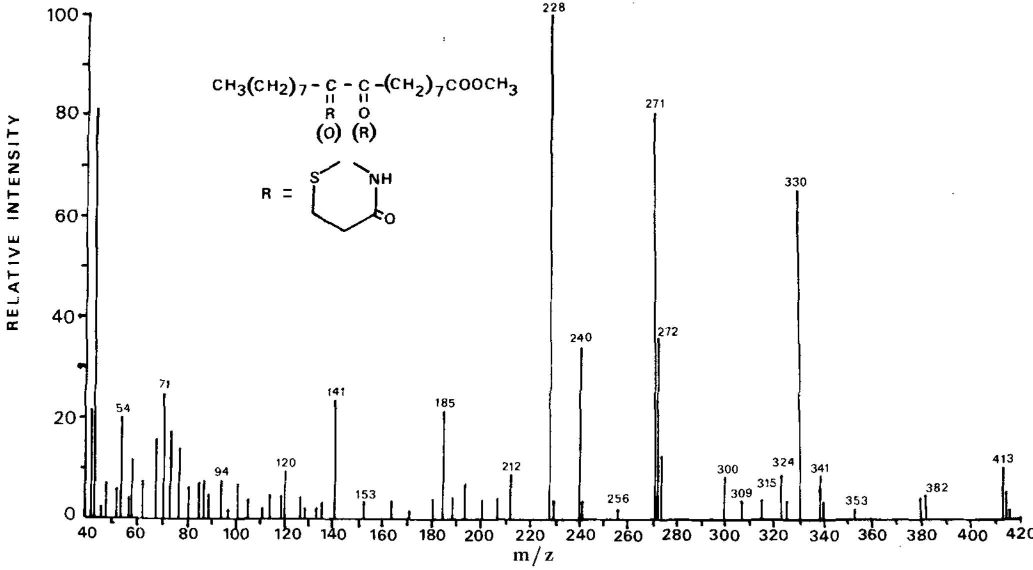

FIG. 3. Mass spectrum of 2-7′-carbomethoxyheptyl-2-1′oxononyl-4-*m*-thiazanone/2(8′-carbomethoxyl-1′-oxo-octyl)-2-octyl-4-*m*-thiazanone (IIIa).

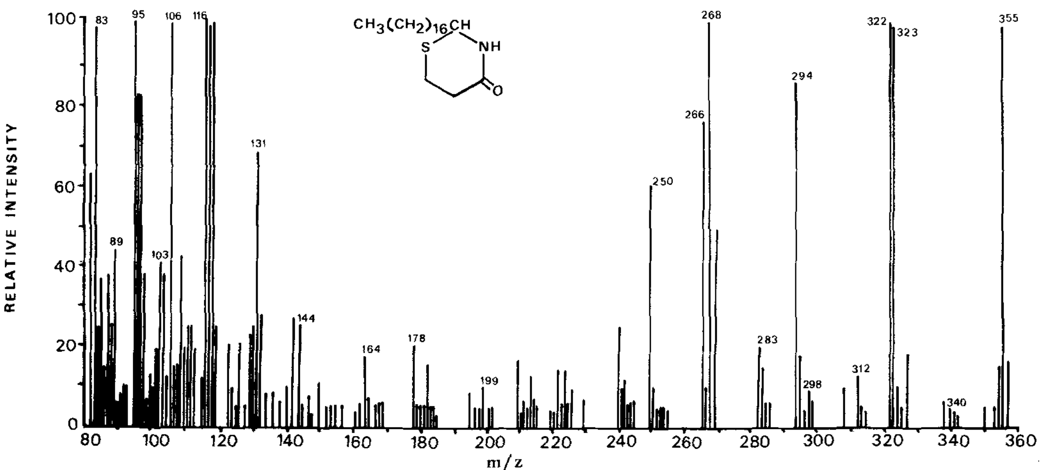

FIG. 4. Mass spectrum of 2-heptadecyl-4-*m*-thiazanone (IVa).

MS of IVa (Fig. 4): m/z 355 (M^+, $C_{21}H_{41}ONS$, 99.0), 340 (M-NH, 5.1), 323 (M-32, 99.1), 322 (M-SH, 99.5), 312 (M-NHCO, 12.2), 298 (M-$NHCOCH_2$, 9.1), 294 (M-C_2H_5S, 84.6), 283 (M-$CH_2CH_2CONH_2$, 20.4), 268 (M-$COCH_2CHS$, 98.1), 266 (M-$COCH_2CH_2SH$, 75.5), 251 (M-C_3H_6ONS, 10.2), 117 (M-$C_{17}H_{34}$, 98.8), 116 (H, base peak), 103 (C_3H_4ONS, 37.7) and 89 (C_3H_5OS, 42.8).

IVa

These MS studies revealed that cleavage alpha to the heterocyclic ring and toward the ester carbonyl gave the base peak in the case of Ia and IIIa. The compound IVa gave a base peak by alpha cleavage on the alkyl chain side of the ring. M-$COCH_2CH_2SH$ appears to be the diagnostic peak of thiazanones, which arises by the cleavages of the 1,2 and 3,4 bonds. The cleavages at the 2,3 and 1,6 bonds afforded another characteristic peak, M-$CH_2CH_2CONH_2$, of lower intensity. These two peaks are triggered by the loss of two methylene groups, a carbonyl function together with either SH or NH_2 from the molecular ion and thus confirm the structure of the thiazanone ring. Other peaks of interest were M-SH and M-$COCH_2CHS$.

The thiazanones synthesized here may be evaluated for CNS depressant effect. The lipophilization of thiazanone ring may enhance their activity.

[Received November 12, 1986]

Effect of Cold Environment on Hepatic Microsomal Δ6 and Δ9 Desaturase Activity of Male Rats

Ana Ves Losada* and **Raul O. Peluffo**[1]
Instituto de Investigaciones Bioquimicas de La Plata (INIBIOLP), CONICET-UNLP, Facultad de Ciencias Medicas, Calles 60 y 120, (1900) La Plata, Argentina

Male rats maintained at 24 C and then shifted to 5 C for 5 days increased food intake and decreased in growth rate and food conversion. No modification was observed in Δ6 desaturase activity, while Δ9 desaturase activity decreased after this period of time. These results were confirmed by liver microsomal and mitochondrial fatty acid composition. The phospholipid composition of liver microsomes was unaltered, whereas in mitochondria, phosphatidylcholine and sphingomyelin decreased and phosphatidylethanolamine increased due to the cold environment. The influence of food intake and weight changes on fatty acid metabolism was studied using (i) rats maintained at 5 C with restricted food intake to match the food intake of those kept at 24 C with food ad libitum and (ii) rats maintained at 24 C whose food intake was also restricted so that their growth rate would be the same as that of rats maintained at 5 C with food ad libitum, respectively. These results indicate that the negative metabolic balance state of these cold conditions is not an active factor modifier of Δ6 desaturase activity, whereas it decreases Δ9 desaturase activity, reflecting the lipogenic characteristics of the latter enzyme.
Lipids 22, 583-588 (1987).

Different types of organisms from microorganisms to higher plants and poikilotherm animals respond to alterations in environmental temperature by modifying fatty acid composition and, thus, the physicochemical properties of their membranes. In some microorganisms, such as *Candida utilis* (1,2), *Bacillus megaterium* (3) and *Tetrahymena* (4), and in higher plants (5), polyunsaturated fatty acid synthesis is increased in response to a decrease in the environmental temperature.

It has also been demonstrated that the Δ6 desaturase activity of fish *(Pimelodus maculatus)* liver microsomes is greater in animals adapted to lower temperature (6). The effect of temperature on membrane fluidity is not as obvious in homeothermic animals as it is in poikilotherms.

Previous laboratory studies (7) in which female rats were adapted to warm temperature (30-32 C) for 20-25 days and then shifted to cooler temperature (13-15 C) for different periods of time showed that Δ9 desaturase activity decreased after 24 hr of cold exposure, while Δ6 desaturase activity was increased after this period of time. Male rats adapted to the same conditions did not show significant changes either in Δ6 or Δ9 desaturase.

Taking into account these results, it was thought that differences in Δ6 and Δ9 desaturase activity might appear in male rats by means of a change in the environment at temperatures lower than 12 C. In addition, we attempted to determine if the food intake and/or decreased weight gain of the animals kept in the cold environment might contribute to the changes in lipid desaturation and composition. For this purpose, male rats were transferred from 24 C to 5 C, and Δ6 and Δ9 desaturase activities and lipid composition of microsomes and mitochondria were determined.

MATERIALS AND METHODS

Materials. [1-^{14}C]Palmitic acid (53.8 mCi/mmol, 99% radiochemically pure), [1-^{14}C]stearic acid (56.0 mCi/mmol, 99% radiochemically pure) and [1-^{14}C]linoleic acid (54.7 mCi/mmol, 98.5% radiochemically pure, 1% *trans* isomer) were purchased from New England Nuclear (Boston, MA). Cofactors used for the enzymatic reactions were provided by Sigma Chemical Co. (St. Louis, MO), and all unlabeled fatty acids were from Nu-Chek-Prep Inc. (Elysian, MN). Silica Gel H (Kiesegel 60H) was purchased from Merck (Darmstadt, FRG). All chemicals and solvents were analytical grade.

Animal treatment. Male Wistar rats of 60-70 days of age weighing 180-200 g were maintained on a commercial standard pellet diet (Nutrimento rat chow 3, Escobar, Argentina) and tap water ad libitum and were housed in individual cages unless indicated otherwise. The fatty acid composition of the diet was as follows: 16.7% 16:0 (palmitic acid), 0.8% 16:1 (palmitoleic acid), 4.9% 18:0 (stearic acid), 21.8% 18:1 (oleic acid), 52.4% 18:2n-6 (linoleic acid) and 4.3% 18:3n-3 (linolenic acid).

When the influence of body weight changes and food intake on fatty acid metabolism was studied, experiments were carried out using four groups of four rats each monitoring daily weights and food intake. Group I comprised rats maintained at 22-24 C fed ad libitum (control ad libitum); group II was rats maintained in a cold temperature-controlled room at 5-6 C fed ad libitum (cold ad libitum); group III was rats maintained at 5-6 C whose food intake was restricted to match the food intake of group I (cold pair-fed to group I); and group IV was rats maintained at 24 C whose food intake was restricted so that their growth rate would match the growth rate of group II (control pair-weighed to group II). Food-restricted rats maintained at 5-6 C in group III were studied to determine whether changes in desaturation or lipid composition in rats maintained at the cold temperature might be due to increased food intake.

Since rats maintained in a cold environment have relative hyperphagia but gain less weight than those at 24 C, the food-restricted rats at 24 C (group IV) were studied to determine if changes in desaturation or lipid composition in rats maintained at cold temperatures might be due to their decreased growth rate and relatively increased fat mobilization. All animals were subjected to a daily photoperiod of 12 hr light and 12 hr darkness (midnight being the midpoint of the dark period). After five days under these conditions, animals were killed at 8 a.m. to equalize circadian effects (8), and liver microsomes and mitochondria were isolated.

Fractionating procedures: preparation of microsomes. Microsomes were prepared from rats killed by decapitation. Livers were rapidly removed and homogenized in a cold solution (3:1, v/w) containing 0.25 M sucrose, 0.15 M KCl, 62 mM potassium phosphate buffer (pH 7.4), 5 mM $MgCl_2$ and 1.4 mM N-acetyl-L-cysteine. The homogenate was centrifuged at 10,000 × g for 20 min; the pellet was discarded and the resulting supernatant was centrifuged at 100,000 × g for 60 min to obtain the microsomal pellet. The microsomal fraction was resuspended in the same homogenizing solution to an appropriate protein concentration. In some instances, pellets were frozen and stored at −80 C for several weeks before use. All microsomal preparations were carried out at 0–4 C. When frozen in concentrated form (15 mg of microsomal protein/ml of homogenizing solution), enzyme activities were stable for up to a month. All subsequent assays and composition analyses used these microsomal membrane fractions.

Preparation of mitochondria. A portion of the liver was chilled immediately after removal by immersion in 0.25 M sucrose and 10 mM potassium phosphate buffer (pH 7.4) and was homogenized at 0–4 C (9:1, v/w). Liver mitochondria were prepared by differential centrifugation according to the method of Hogeboom (9).

Enzymatic assays. The Δ9 (16:0 → 16:1 and 18:0 → 18:1) and Δ6 (18:2n-6 → 18:3n-6) desaturase enzyme assays were carried out by measuring the conversion rate of the [1-^{14}C]labeled fatty acid substrate into the corresponding [1-^{14}C]labeled fatty acid product. Only the exogenous substrate added to the incubation mixture was considered for calculation of the enzymatic activity, since the amount of endogenous substrate (<7 nmol; only 1.5% [w/w] of microsomal lipids in all groups was free fatty acids) was negligible compared to the 50 nmol of exogenous substrate. Reactions were initiated by adding microsomal protein to preincubated flasks containing 0.25 M sucrose, 0.15 M KCl, 0.04 M potassium phosphate buffer (pH 7.2), 1.41 mM N-acetyl cysteine, 0.04 M KF, 1.3 mM ATP, 0.06 mM CoA, 0.87 mM NADH, 5 mM $MgCl_2$, 5 nmol of [1-^{14}C]labeled and 45 nmol of unlabeled acid in a final volume of 1.6 ml. For Δ9 desaturase assay, palmitic and stearic acids were used as substrates with 1.5 and 2 mg of microsomal protein. The substrate for Δ6 desaturase assays was linoleic acid and 3 mg of microsomal protein was used. The protein was determined by the Lowry procedure using crystalline bovine serum albumin as standard (10). The reaction mixture was incubated with constant shaking at 36 C for 15 min. The desaturation reaction was stopped by adding 2 ml of 10% KOH in ethanol. The fatty acids were recovered by saponification of the incubation mixture (45 min at 82 C), acidification and extraction with petroleum ether (bp 30–40 C). The fatty acids were esterified with methanolic 3 M HCl (1 hr at 64 C). The analyses were carried out by gas liquid radiochromatography in a Packard apparatus, Model 893, equipped with a proportional counter using 6P 10% SP-2330 on Chromosorb WAW (100–120 mesh) (11). A control assay without the addition of microsomes was done and no desaturation was observed.

Microsomal and mitochondrial lipid composition. Total microsomal and mitochondrial lipids were extracted using the method of Folch et al. (12), and methyl esters were prepared and analyzed by gas liquid chromatography (GLC) as previously described (13) in a Hewlett-Packard model 5840-A chromatograph, equipped with the 5840-A 6C terminal and using a 6-ft column filled with 10% SP 2330 on 100–200 mesh Chromosorb WAW. Peaks were identified by comparison of retention times with standards.

Phospholipids were separated by two-step thin layer chromatography (TLC) procedure using Silica Gel H plates (14). After the plate was exposed to iodine vapors, the phospholipid fractions were scraped off for quantification by colorimetric determination of phosphorus (15).

Statistical analysis. All results were tested for statistical significance by Student's t-test for paired comparison with control.

RESULTS

Food intake, growth rate, food conversion and liver weight in animals in a cold environment. Table 1 summarizes the daily food intake, growth rate and liver weight in the four groups. Although the rats kept at 5 C with food ad libitum (group II) showed an increase of 25% in food intake, they had a decrease in growth rate and food conversion of 74% and 86%, respectively, as a consequence of an increase in catabolism. In the cold environment, food calories are preferentially used maintaining body temperature.

Group III, animals maintained at 5 C with the same food intake as animals at 24 C, showed a decrease in the growth rate, food conversion and liver weight of 142%, 162% and 32%, respectively. The negative metabolic balance due to cold was even greater in this group as a consequence of the decrease in calories provided by the restricted food intake.

Rats of group IV, animals at 24 C and with food intake restricted to match the group-I growth rate, showed a decrease in food conversion and liver weight of 126% and 30%, respectively, since the restriction in food intake provoked an increase in the catabolism of endogenous substrates. The increased catabolism of groups II, III and IV must have been accompanied by increased lipolysis.

Influence of cold, temperature, food intake and growth rate on desaturation. The effect of cold and food restriction on the fatty acid desaturase activities is shown in Figure 1.

The enzymatic activity of Δ6 desaturase was not modified in the group at 5 C with food ad libitum, while it increased when food intake was restricted either at 5 C (group III) or at 24 C (group IV). Animals on the diet given ad libitum at 5 C (group II) showed a marked decrease not only in food conversion but also in the enzymatic activity of Δ9 desaturase.

It is hardly probable that the increase in food intake of rats kept at low temperatures should cause the changes observed in the enzymatic activity of Δ9 desaturase, since the restriction in food intake at 5 C (group III) emphasized rather than annulled the changes. On the other hand, the decrease in the growth rate of rats in the cold environment would be an important factor, since in rats kept at 24 C with a similar growth rate (group IV), a decrease in Δ9 desaturase enzymatic activity was also observed.

Groups showing a marked decrease in food conversion (II, III and IV) also had decreased Δ9 desaturase activity.

When rats were kept at 5 C for 15 days instead of five with food ad libitum, a behavior similar to that shown

TABLE 1

Effect of Temperature and Food Restriction on Food Intake, Growth Rate, Food Conversion and Liver Weight

	Group I, control ad libitum (n = 10)	Group II, cold ad libitum (n = 10)	Group III, cold pair-fed to group I (n = 4)	Group IV, control pair-weighed to group II (n = 4)
Starting weight (g)	197.0 ± 15.1	174.8 ± 14.4	192.5 ± 13.1	176.8 ± 16.0
Food intake (g/g)	0.108 ± 0.003	0.135 ± 0.004*	0.100 ± 0.004	0.064 ± 0.004*
Growth rate (g/day)	6.38 ± 0.36	1.68 ± 0.51*	−2.70 ± 0.30*	0.95 ± 0.70*
Food conversion	54.02 ± 5.03	7.48 ± 4.58*	−32.4 ± 4.4*	−13.7 ± 8.0*
Liver weight (g)	9.92 ± 0.80	8.44 ± 0.90	6.70 ± 0.35**	6.90 ± 0.42**

Food intake (daily food intake/body weight); growth rate (daily increase in body weight); food conversion (growth rate/food intake × 100) and liver weight. Animal treatments are described in Materials and Methods. Results are the mean ± S.E. n, represents the number of animals for each group. Significant differences from control: *, $p < 0.001$; **, $p < 0.01$.

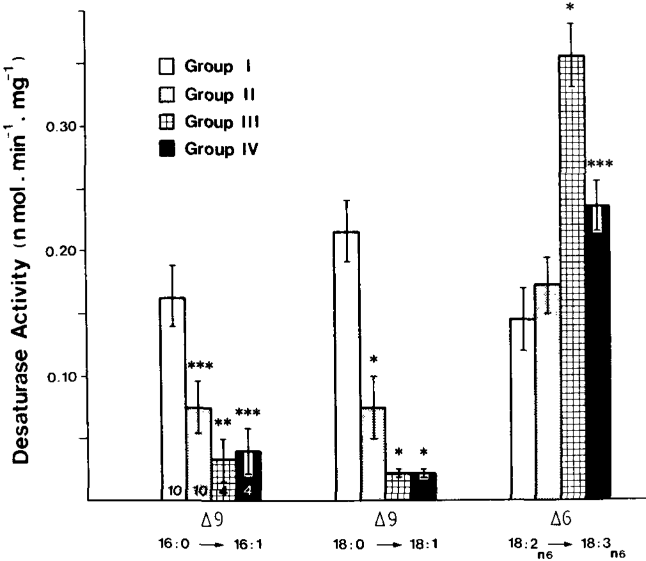

FIG. 1. Effect of environmental temperature and food restriction on hepatic microsomal fatty acid desaturase activity. Desaturase enzyme assays were carried out as described in Materials and Methods. Group I, control ad libitum; group II, cold ad libitum; group III, cold pair-fed to group I; group IV, control pair-weighed to group II. Results are shown as mean ± S.E. The number of animals in each group is shown in the first set of bars. Significantly different from controls: *, $p < 0.001$; **, $p < 0.01$; ***, $p < 0.05$.

in Figure 1 was observed in the enzymatic activity of Δ9 and Δ6 desaturases (results not shown).

Microsomal and mitochondrial lipid composition. Tables 2 and 3 show the lipid fatty acid composition of hepatic microsomes and mitochondria, respectively. The modifications observed in fatty acid composition of liver microsomes and mitochondria were generally similar.

The rats at 5 C with food ad libitum (group II) showed in both fractions increased percentage of 18:0 and decreased 18:1. Only in mitochondria did the percentage of 16:1 decrease significantly, and so did the unsaturation index in microsomes. These changes agree with the decrease found in microsomal Δ9 desaturase enzymatic activity in the same group.

In group III, the same modifications as in group II were observed in the percentages of 16:1, 18:0 and 18:1 in lipids of liver microsomes and mitochondria. As in group II, these changes are the consequences of a decrease in the enzymatic activity of Δ9 desaturase shown by group III. Only the microsomes had an increase in the percentage of 20:4n-6, which agreed with the one observed in the enzymatic activity of Δ6 desaturase (regulatory enzyme in the biosynthesis of polyunsaturated acids) (16).

Group IV presented an increased percentage of 18:0 and decreased 16:1 both in microsomes and mitochondria. The percentage of 18:1 decreased only in mitochondria. These changes are the consequences of the decrease observed in Δ9 desaturase enzymatic activity. Besides, both fractions showed an increase in the percentage of 20:4n-6 that could be attributed to an increase observed in the Δ6 desaturase enzymatic activity.

Table 4 shows the phospholipid composition of hepatic microsomes and mitochondria of rats kept at 24 C (group I) and 5 C (group II) on food ad libitum. No modification was observed in the phospholipid composition of liver microsomes, whereas in mitochondria the percentages of phosphatidylcholine (PC) and sphingomyelin (SM) decreased and that of phosphatidylethanolamine (PE) increased in rats kept in the cold environment. The changes found in liver mitochondria of rats kept at 5 C resembled those found in mitochondria of brown adipose tissue of rats kept at 4 C (17).

DISCUSSION

When a rat is exposed to a cold environment, adaptation processes are initiated characterized by shivering or nonshivering thermogenesis, depending on the conditions (18), tending to lower heat loss and to increase its production. There is an increase in thermogenesis (19), and the supply of substrates comes from an increase in fatty acid mobilization (by lipolysis of white and brown adipose tissue) (20–22) and from glucose (by liver glycogenolysis and gluconeogenesis) (23,24). In this substrate mobilization, the sympathetic nervous system takes part via catecholamines (18). Together with endogenous substrates, the exogenous ones coming from increased food intake also contribute to thermogenesis. This is the reason that when male rats are exposed to cold for five days, food intake increases and growth rate and food conversion decrease, since calories are preferentially used in heat production to keep body temperature.

TABLE 2

Effect of Environmental Temperature and Food Restriction on Liver Microsomal Fatty Acid Composition in Male Rats

Fatty acid (%)	Group I, control ad libitum	Group II, cold ad libitum	Group III, cold pair-fed to group I	Group IV, control pair-weighed to group II

PS	2.6 ± 0.2	2.5 ± 1.3	1.9 ± 1.1	0.10 ± 0.02

PC, phosphatidylcholine; PE, phosphatidylethanolamine; CL, cardiolipin; PI, phosphatidylinositol; SM, sphingomyelin; PS, phosphatidylserine. Phospholipids were separated as described in Materials and Methods. Results are expressed as the mean ± S.E. The number of samples analyzed is 3 for microsomal and 5 for mitochondrial fraction. Significant differences from control: *, $p < 0.001$; **, $p < 0.01$.

Δ6 Desaturase activity. Concerning the effect of environmental temperature on desaturating activity, no modification due to cold was observed either in Δ6 desaturase activity or in the percentage of linoleic acid in liver microsomal and mitochondrial lipids of male rats fed ad libitum. Hughes and York also observed no changes in the Δ6 desaturase enzymatic activity due to temperature in the lean mouse (25). These results also agree with those found by González et al. (7) when male rats were shifted from 30-32 C (adapted to that temperature for 20 days) to 12 C for five days, since in this case no modifications in the Δ6 desaturase were observed either. These results indicate that metabolic changes induced by an environmental temperature decrease expressed by a thermogenesis increase are not active factor modifiers of Δ6 desaturase activity. However, in female rats adapted to the same conditions, an increase in the enzymatic activity of Δ6 desaturase due to cold was observed and, in this change, estradiol levels would be involved (26). On the other hand, when the enzymatic activity in male rats was depressed by a hyperglycidic diet and animals were shifted from 24 C to 12 C, an increase was observed in Δ6 desaturase enzymatic activity due to cold environment (27).

The increase in Δ6 desaturase enzymatic activity observed in animals on a restricted diet, both at 5 C and at 24 C, was unexpected, and it was difficult to elucidate since fasting inhibits enzymatic activity (28,29). These results, as has been pointed out by Faas and Carter, emphasize the importance of food intake as another factor to be taken into account for the complex control of the desaturating system (30,31).

Δ9 Desaturase activity. González et al. found that Δ9 desaturase enzymatic activity was not modified when male rats were shifted to 13-15 C after being previously adapted to 30-32 C, whereas in female rats adapted to the same conditions, they observed a decrease in that desaturating activity (7). We have observed, however, that when male rats were kept at 5 C on food ad libitum (group II), the Δ9 desaturase activity decreased. This lowering was confirmed by a decrease in the percentages of 16:1 and 18:1 and an increase in 18:0 in the fatty acid composition of both liver microsomes and mitochondria. In rats kept at 5 C on a restricted diet (group III), the decrease in the Δ9 desaturase enzymatic activity was even more marked than at 5 C on food ad libitum. Moreover, a decrease in Δ9 desaturase activity was also detected in animals on a restricted food intake at 24 C (group IV).

In group II, there was a negative metabolic balance (decreased food conversion) and an increase in food intake to provide substrates for the thermogenesis process, which was increased by the cold temperature. In group III, the negative metabolic balance was even greater than in group II, since there was increased catabolism of endogenous substrates in the thermogenesis process due to the restriction imposed on food intake. Finally, group IV rats also had a negative metabolic balance to counterbalance food intake restriction enhancing the use of endogenous substrates.

In groups II, III and IV, characterized by a negative metabolic balance, the Δ9 desaturase enzymatic activity was diminished. It is known that Δ9 desaturase is very sensitive to nutritional (29,32-36) and hormonal (30,31,37,38) factors. Moreover, it is considered a lipogenic enzyme, since during fasting, when there is a negative metabolic balance and lipolysis is increased, its enzyme activity is decreased (29). In addition, lipogenic diets are the most efficient ones in increasing the abovementioned activity (29,36). Lipogenesis and Δ9 enzymatic activity respond in the same way to regulatory factors (39).

Therefore, it can be considered that the decrease observed in the Δ9 desaturase enzymatic activity in male rats at 5 C is the consequence of the negative metabolic balance state set off by these conditions.

[Received October 29, 1986]

Formation of Diacyl and Alkylacyl Glycerophosphocholine in Rabbit Alveolar Macrophages

Takayuki Sugiura*, Nobuyuki Sekiguchi, Yasuhito Nakagawa and **Keizo Waku**
Faculty of Pharmaceutical Sciences, Teikyo University, Sagamiko, Kanagawa 199-01, Japan

The incorporation of various labeled precursors into alkenylacyl, alkylacyl and diacyl phospholipids in rabbit alveolar macrophages was studied. The incorporation rates of the individual precursors were shown to be quite different among the three subclasses of phospholipids. [^{3}H]Glycerol, [^{14}C]16:0, [^{14}C]18:1, [^{14}C]18:2 and [^{32}P]-orthophosphate were preferentially incorporated into choline glycerophospholipids (CGP), especially into diacyl glycerophosphocholine (GPC), indicating that the de novo synthesis of diacyl GPC is extremely high. Considerable portions of the radioactivities of [^{14}C]16:0, [^{14}C]18:1, [^{14}C]18:2 and [^{32}P]orthophosphate were also found in alkylacyl GPC, the incorporation being higher than or comparable to that in the case of diacyl glycerophosphoethanolamine (GPE). We then examined the activities of cholinephosphotransferase and ethanolaminephosphotransferase, and found that the activity of cholinephosphotransferase was remarkably high in macrophage microsomes compared with that in microsomes from several other tissues. This suggests that diradylglycerols were preferentially utilized by cholinephosphotransferase, which is consistent with the results obtained for intact cells. We confirmed that a considerably higher amount of diacyl GPC as well as alkylacyl GPC was formed through this enzyme reaction with macrophage microsomes than with brain microsomes. The high formation of alkylacyl GPC could be responsible, at least in part, for the accumulation of this unique ether phospholipid, a stored precursor form of platelet-activating factor in macrophages.
Lipids 22, 589–595 (1987).

Recently, it has been shown that considerable amounts of alkenyl and alkyl ether phospholipids are present in several types of inflammatory and immunological cells, such as macrophages, polymorphonuclear leukocytes, lymphocytes and platelets (reviewed in ref. 1). The occurrence of high amounts of alkylacyl GPC in these cells is particularly noteworthy, since the levels of alkylacyl GPC in other mammalian tissues are generally very low (1). The results of recent studies have revealed that this unique alkyl ether phospholipid is a stored precursor form of a potent lipid mediator, platelet-activating factor (PAF), and a degradation product of PAF in various types of cells (reviewed in ref. 2). Furthermore, alkenyl and alkyl ether phospholipids contain several times higher amounts of C_{20} and C_{22} polyunsaturated fatty acids than diacyl species in certain cell types (1). Ether phospholipids could be important pools of these polyunsaturated fatty acids in cells. In fact, large amounts of 20:4 were released from both diacyl and ether phospholipids in various types of cells upon stimulation (3–7).

Although the significance of alkylacyl GPC in inflammatory and immunological cells has recently received much attention, little information is yet available on the metabolism of alkylacyl GPC in these types of cells. In particular, very little is known about the de novo synthesis of this unique alkyl ether lipid, abundant in white blood cells and platelets. Moreover, previous studies on the metabolism of alkenylacyl, alkylacyl and diacyl phospholipids were mainly performed on the phospholipids in nervous tissues and tumor cells, and there has so far been no precise comparative study on the metabolism of diacyl and ether phospholipids in inflammatory and immunological cells.

In this study, we investigated the incorporation of various labeled precursors for the glycerol backbone, fatty acyl residues and polar head groups into alkenylacyl, alkylacyl and diacyl phospholipids in rabbit alveolar macrophages. The activities of the de novo synthetic enzymes, cholinephosphotransferase and ethanolaminephosphotransferase, were also examined using endogenous or exogenous diradylglycerols. The active formation of diacyl and ether-containing CGP was discussed.

MATERIALS AND METHODS

Chemicals. All chemicals were of analytical grade, and solvents were distilled before use. The precoated silica gel plates were purchased from Merck (Darmstadt, FRG). [1(3)-^{3}H]Glycerol (3 Ci/mmol), [1-^{14}C]palmitic acid (58 mCi/mmol), [1-^{14}C]stearic acid (60 mCi/mmol), [1-^{14}C]oleic acid (57 mCi/mmol), [1-^{14}C]linoleic acid (57 mCi/mmol), [5,6,8,9,11,12,14,15-^{3}H]arachidonic acid (100 Ci/mmol), [methyl-^{14}C]choline chloride (50.5 mCi/mmol) and [1-^{3}H]ethanolamine hydrochloride (23 Ci/mmol) were purchased from Amersham (Amersham, UK). [U-^{14}C]Docosahexaenoic acid (160 mCi/mmol), CDP-[methyl-^{14}C]choline (42.35 mCi/mmol) and CDP-[2-^{14}C]ethanolamine (27 mCi/mmol) were from New England Nuclear (Boston, MA). ^{32}P-Orthophosphate (carrier-free) was from the Japan Isotope Center (Tokyo, Japan). Selachylalcohol (1-monooleyl glycerylether) was purchased from Serdary Research Lab. (Ontario, Canada). Docosahexaenoic acid (22:6) was from Nu-Chek-Prep (Elysian, MN). HEPES was obtained from Wako Pure Chemical Industry (Tokyo, Japan). Eagle's minimal essential medium (MEM) was obtained from Nissui Seiyaku Co. (Tokyo, Japan). Oleic acid (18:1), arachidonic acid (20:4), oleic anhydride, 1,2-dioleoyl-*sn*-glycerol, essentially fatty acid–free bovine serum albumin (BSA), CDP-choline and CDP-ethanolamine were obtained from Sigma (St. Louis, MO). 1-Alkyl(18:1)-2-oleoyl-*sn*-glycerol was prepared as follows: selachylalcohol was acylated with oleic anhydride in pyridine/chloroform (1:5, v/v) at room temperature for 12 hr. The

Abbreviations: CGP, choline glycerophospholipids; EGP, ethanolamine glycerophospholipids; IGP, inositol glycerophospholipids; SGP, serine glycerophospholipids; Sph, sphingomyelin; lyso-bis-PA, lyso-bis-phosphatidic acid; CL, cardiolipin; GPC, glycero-3-phosphocholine; GPE, glycero-3-phosphoethanolamine; PAF, platelet-activating factor; BSA, bovine serum albumin; TLC, thin layer chromatography; GLC, gas liquid chromatography. Fatty chains are designated in terms of number of carbon atoms:number of double bonds, e.g., 18:1 for oleic acid.

resultant 1-alkyl-2,3-diacylglycerol was purified by thin layer chromatography (TLC) with development with petroleum ether/ethyl ether/acetic acid (90:10:1, v/v/v), and then hydrolyzed with Rhizopus delemar lipase (Seikagaku Kougyo Co., Tokyo, Japan) to remove the fatty acid at the 3-position, as described previously (8). The 1-alkyl-2-acyl compound was purified by TLC with development with petroleum ether/ethyl ether/acetic acid (60:40:1, v/v/v), and then extracted from the silica gel with chloroform/methanol (1:1, v/v). The quantities of diradylglycerols were determined from the fatty acyl moieties as fatty acid methyl esters by gas liquid chromatography (GLC) (8,9).

Cells. Macrophages were prepared from healthy female rabbits (New Zealand white, 2.5–3 kg) as described previously (9). The macrophages were washed three times with saline after the removal of contaminating erythrocytes by means of osmotic lysis. The purity of the cells was above 95%, as judged on microscopic examination.

Incorporation of labeled precursors. Macrophages were suspended in 20 mM HEPES-MEM medium (pH 7.2) at 10^6 cells/ml. [^{3}H]20:4, [^{14}C]22:6 and [^{3}H]ethanolamine were diluted with the respective nonradiolabeled fatty acid at 50 mCi/mmol prior to use. The labeled fatty acids (1 μCi) were dissolved in 250 μl of 0.2% BSA-containing saline, and [^{3}H]glycerol (5 μCi), [^{32}P]orthophosphate (100 μCi), [^{14}C]choline (1 μCi) and [^{3}H]ethanolamine (1 μCi) were dissolved in 250 μl of saline. Each labeled compound (250 μl) was added to 5 ml of cell suspension. The incubation was carried out at 37 C for 60 min and terminated by adding 20 ml of chloroform/methanol (1:2, v/v).

Lipid analyses. Total lipids were extracted by the method of Bligh and Dyer (10). Individual phospholipids were separated by two-dimensional TLC with development with chloroform/methanol/28% NH_4OH (65:35:5, v/v/v) for the first dimension and chloroform/acetone/methanol/acetic acid/water (5:2:1:1.3:0.5, v/v/v/v/v) for the second dimension. Neutral lipids were separated by TLC with development with petroleum ether/ethyl ether/acetic acid (80:20:1, v/v/v). The alkenylacyl, alkylacyl and diacyl lipid classes were separated as 1,2-diradyl-3-acetylglycerol derivatives as described elsewhere (7,8). In brief, CGP and EGP were first hydrolyzed with phospholipase C *(Bacillus cereus)* to remove the polar groups. The resultant diradylglycerols were further acetylated with acetic anhydride and pyridine. The 1,2-diradyl-3-acetylglycerols were separated into the alkenylacyl, alkylacyl and diacyl classes by TLC with development with petroleum ether/ethyl ether/acetic acid (90:10:1, v/v/v) and then with toluene. The lipid spots were visualized under ultraviolet light after spraying with 0.001% primuline in acetone/water (4:1, v/v) and then were scraped off from the silica gel plate into counting vials. The radioactivity was estimated with a scintillation counter (Aloka, Model LSC 903) using a scintillation fluid, as described earlier (11). In some experiments, the successive mild alkaline and acid hydrolysis method was used to determine the radioactivities of alkenylacyl, alkylacyl and diacyl compounds. Lipid phosphorus was estimated by the method of Rouser et al. (12).

Preparation of microsomal fraction. Microsomal fraction was prepared from various tissues and cells. Rabbit alveolar macrophages were prepared from rabbits that had been injected with 1.0 ml of Freund's complete adjuvant 3 wk prior to sacrifice. Pig lymphocytes were prepared from pig mesenteric lymph nodes as described previously (8). Both types of cells were washed three times with saline. Various tissues and cells were homogenized in a Potter-Elvejhem homogenizer with a Teflon pestle in 0.25 M sucrose–0.1 M Tris-HCl buffer (pH 7.4) containing 1 mM EDTA. The homogenate was centrifuged at 10,000 × g for 20 min twice. The supernatant was collected and ultracentrifuged at 105,000 × g for 60 min. The pellet was resuspended in 0.1 M Tris-HCl buffer (pH 7.4) containing 1 mM EDTA and then washed once at 105,000 × g for 60 min. The pellet (microsomal fraction) was resuspended in the same buffer and stored at −20 C. The protein content was estimated by the method of Lowry et al. (13).

Enzyme assays. The activities of cholinephosphotransferase and ethanolaminephosphotransferase were determined by the modified method of Lee et al. (14). The incubation mixture contained CDP-[methyl-^{14}C]choline or CDP-[2-^{14}C]ethanolamine (0.5 mM, 0.025 μCi), $MgCl_2$ (8 mM), BSA (0.5 mg), EGTA (0.5 mM) and microsomes (0.5 mg protein) in 0.5 ml of 0.1 M Tris-HCl buffer (pH 8.0), with endogenous diradylglycerols as the substrates. When exogenous diradylglycerols were used as the substrates, the incubation mixture consisted of CDP-[methyl-^{14}C]choline or CDP-[2-^{14}C]ethanolamine (0.02 mM–0.2 mM), $MgCl_2$ (8 mM), BSA (0.5 mg), EGTA (0.5 mM), 1-alkyl-2-acylglycerol or 1,2-diacylglycerol (4 mM) and microsomes (0.1 mg protein) in 0.5 ml of 0.1 M Tris-HCl buffer (pH 8.0). The alkylacylglycerol or diacylglycerol was sonicated in 0.04% Tween 20 in water with a Branson sonifier (four periods of 10 sec each) immediately before use. The incubation was performed at 37 C for 30 min and terminated by adding chloroform/methanol (1:2, v/v). The lipids were extracted and then separated by TLC with development with chloroform/methanol/water (65:25:4, v/v/v). The radioactivities in the CGP and EGP fractions were estimated as described above. Portions of CGP and EGP were further fractionated by means of the successive mild alkaline and acid hydrolysis method (15) to determine the radioactivities of alkenylacyl, alkylacyl and diacyl compounds.

RESULTS AND DISCUSSION

Incorporation of various labeled precursors into individual phospholipids. Table 1 shows the incorporation rates into the cellular phospholipid fraction of various fatty acids. [^{3}H]20:4 and [^{14}C]22:6 were incorporated very rapidly into the cellular lipid fractions during the incubation. On the other hand, the incorporation rates of [^{14}C]16:0, [^{14}C]18:0, [^{14}C]18:1 and [^{14}C]18:2 were relatively slow.

Table 2 shows the distribution of the radioactivities of labeled precursors among individual phospholipids. [^{3}H]Glycerol, [^{32}P]orthophosphate, [^{14}C]16:0, [^{14}C]18:1 and [^{14}C]18:2 were preferentially incorporated into CGP. Radioactivities other than those in CGP were low, except for that of [^{14}C]18:2 in lyso-bis-phosphatidic acid (lyso-bis-PA). Large portions of the radioactivities of [^{3}H]20:4, [^{14}C]22:6 and [^{14}C]18:0 were also distributed in CGP, although considerable radioactivities were found as well in EGP ([^{3}H]20:4, [^{14}C]22:6 and [^{14}C]18:0), lyso-bis-PA ([^{3}H]20:4 and [^{14}C]22:6) and IGP ([^{3}H]20:4 and [^{14}C]18:0). These observations indicate that the formation of CGP,

TABLE 1

Incorporation Rates of Various Labeled Fatty Acids into Cellular Phospholipid Fraction[a]

Fatty acids	%	nmol
[^{14}C]16:0	7.5 ± 0.7	0.26
[^{14}C]18:0	8.9 ± 0.4	0.30
[^{14}C]18:1	7.6 ± 0.3	0.27
[^{14}C]18:2	15.9 ± 0.5	0.56
[^{3}H]20:4	54.9 ± 0.5	2.20
[^{14}C]22:6	79.9 ± 1.2	3.20

[a]Macrophages (10^6 cells/ml) were incubated with various labeled fatty acids (0.2 μCi/ml) at 37 C for 60 min as described in Materials and Methods. The values represented the incorporation rates (% and nmol/10^6 cells) of exogenously added labeled fatty acids into cellular phospholipid fraction. The mean percentages ± SD were calculated for three determinations.

particularly that via the de novo pathway, is very active compared with that of other phospholipids in this type of cell. The relatively high incorporation of [^{3}H]20:4 and [^{14}C]18:0 into EGP and IGP could be closely related to the fact that these phospholipids contain high amounts of 18:0, especially at the 1-position, and 20:4, at the 2-position. In contrast, the level of the 18:0 acid in CGP has been shown to be very low in this type of cell (9). Albert and Snyder (5) have already shown the preferential labeling of CGP with [^{14}C]16:0, [^{14}C]18:1, [^{14}C]18:2 and [^{14}C]20:4 in comparison with other phospholipids in rat alveolar macrophages.

Incorporation of various labeled precursors into subclasses of CGP and EGP. No precise data are available on the incorporation of various labeled precursors, except for 20:4 and 22:6 into alkenylacyl, alkylacyl and diacyl phospholipids in inflammatory and immunological cells. Table 2 shows the distribution of the radioactivities of various precursors among the alkenylacyl, alkylacyl and diacyl classes of CGP and EGP. The proportions of alkenylacyl, alkylacyl and diacyl compounds were 5.6%, 32.5% and 61.9% for CGP, and 61.2%, 8.1% and 30.7% for EGP, respectively, as reported previously (9). It should be noted that the incorporation rates of individual precursors were quite different between the subclasses of CGP and EGP. Most of the radioactivities of [^{3}H]-glycerol, [^{14}C]16:0, [^{14}C]18:0, [^{14}C]18:1, [^{14}C]18:2, [^{32}P]-orthophosphate and [^{14}C] choline were found in diacyl species in CGP, indicating that the de novo synthesis of diacyl GPC is extremely high for this type of cell. The radioactivity in diacyl GPE was also highest among the subclasses of EGP labeled with [^{3}H]glycerol, [^{14}C]16:0, [^{14}C]18:0, [^{14}C]18:1 and [^{14}C]18:2. Interestingly, significant portions of the radioactivities of various precursors were found in alkylacyl GPC, which is a stored precursor form of PAF. For instance, 6.1% ([^{14}C]16:0), 2.6% ([^{14}C]18:1), 1.6% ([^{14}C]18:2) and 2.5% ([^{32}P]orthophosphate) of the respective radioactivities in total phospholipids were distributed in alkylacyl GPC (Tables 2 and 3). The incorporation rate of [^{14}C]18:1 into alkylacyl GPC was calculated to be almost comparable to that into diacyl GPE (2.2% of the radioactivities in total phospholipids). These observations suggest that significant amounts of alkylacyl GPC are formed via the de novo pathway in this type of cell. In the case of [^{3}H]glycerol, however, it is necessary to take into account the fact that ether phospholipids are only synthesized via the dihydroxyacetone phosphate pathway (2). This may explain, at least in part, the generally low incorporation of [^{3}H]glycerol into ether-containing compounds. Furthermore, the low specific activity of alkenylacyl GPE labeled with [^{3}H]glycerol could be due to the fact that alkenylacyl GPE is formed from alkylacyl GPE through desaturation of the alkyl chain.

It is noteworthy that the distributions of the radioactivities of [^{32}P]orthophosphate and [^{14}C]ethanolamine in ether-containing EGP were somewhat higher than those of [^{3}H]glycerol, [^{14}C]16:0, [^{14}C]18:0, [^{14}C]18:1 and [^{14}C]18:2 (Table 3). These observations suggest that the polar head group of ether-containing EGP is turned over rapidly compared with that of diacyl species. The exchange of the phosphoryl base moiety rather than the base group could solely take place, since high labeling was observed with both [^{32}P]orthophosphate and [^{3}H]ethanolamine. This is also the case for alkenylacyl GPC labeled with [^{32}P]-orthophosphate and [^{14}C]choline. The backward action of

CGP, EGP, IGP and SGP: choline, ethanolamine, inositol and serine glycerophospholipids, respectively; Sph, sphingomyelin; lyso-bis-PA, lyso-bis-phosphatidic acid; CL, cardiolipin; PA, phosphatidic acid.

[a]Macrophages (10^6 cells/ml) were incubated with various labeled precursors (0.2 μCi/ml for fatty acids, 0.2 μCi/ml for [^{3}H]glycerol and 20 μCi/ml for [^{32}P]orthophosphate) at 37 C for 60 min. The incubation was terminated by adding chloroform/methanol (1:2, v/v), and then the total lipids were extracted by the method of Bligh and Dyer (10). Individual phospholipids were separated by two-dimensional thin layer chromatography as described in Materials and Methods. The mean percentages ± SD were calculated for three determinations.

[a]Macrophages (10^6 cells/ml) were incubated with various labeled precursors at 37 C for 60 min. The alkenylacyl, alkylacyl and diacyl subclasses of CGP and EGP were separated as described in Materials and Methods. The mean percentages ± SD were calculated for three determinations. The values in parentheses are the relative specific activities (cpm %/wt %) of three subclasses of CGP and EGP, respectively.
[b][^{14}C]Choline for CGP and [^{3}H]ethanolamine for EGP.

phosphotransferases or phospholipase C could be involved in the turnover of polar head groups in ether-containing compounds. The relatively high turnover of phosphate in ether-containing phospholipids has also been reported for Ehrlich ascites tumor cells (16), Krebs II ascites cells (17) and rabbit neuronal or glial cells (18). However, the biological significance and the precise mechanism of these findings still remain to be clarified.

Contrary to the case for other labeled fatty acids, considerable labeling of alkylacyl GPC and alkenylacyl GPE was observed with [^{3}H]20:4 and [^{14}C]22:6 (Table 3). This suggests that the incorporation mechanism for [^{3}H]20:4 and [^{14}C]22:6 is quite different from those in the case of other labeled fatty acids. In fact, the percent distributions of the radioactivities of [^{14}C]18:2 among alkenylacyl, alkylacyl and diacyl GPC and GPE did not seriously change up to 120 min (data not shown), whereas that of [^{3}H]20:4 changed markedly during the incubation (Fig. 1). The radioactivity in diacyl GPC decreased after 15 min, although 25% of the radioactivity remained in the form of free [^{3}H]20:4. The radioactivities in alkenylacyl GPE and alkylacyl GPC continued to gradually increase. Similar incorporation profiles were observed for 22:6 in rabbit alveolar macrophages (data not shown).

The alteration in the distribution of the radioactivities among diacyl and ether phospholipids could be due to the transacylation of polyunsaturated fatty acids between phospholipids (19-30). It is likely that large portions of 20:4 and 22:6 in ether phospholipids are incorporated via the transacylation pathway in addition to the Lands pathway. We have already shown that macrophage microsomes contain a high transacylase activity, which was almost comparable to the activity of acyl-CoA:1-alkyl-GPC acyltransferase (30). The most effective acyl donor in the transacylation system was diacyl GPC (30) and so the very active formation of diacyl GPC (Tables 2 and 3 and Fig. 1) may be coupled with the transfer of polyunsaturated fatty acids to ether lysophospholipids through the transacylation reaction. However, the possibility cannot be ruled out that portions of polyunsaturated fatty acids, especially 22:6, were esterified to ether phospholipids through the de novo synthetic pathway, since both 20:4-CoA and 22:6-CoA were effective substrates for the acylation of 1-alkyl-*sn*-glycero-3-phosphate (31). In addition, it is evident that 22:6-containing diradylglycerols were preferentially utilized in the formation of EGP by ethanolaminephosphotransferase (32,33). These 22:6-containing diradylglycerols could be formed via the de novo pathway. In fact, very rapid and transient labeling of diradylglycerols with [^{14}C]22:6 has been observed in this cell (27).

Formation of CGP and EGP by choline- and ethanolaminephosphotransferases. As demonstrated in Tables 2 and 3, various precursors were very rapidly incorporated into CGP, particularly the diacyl subclass, in rabbit alveolar macrophages. This observation prompted us to further investigate the enzyme activity involved in the de novo synthesis of CGP, and to compare it to that in

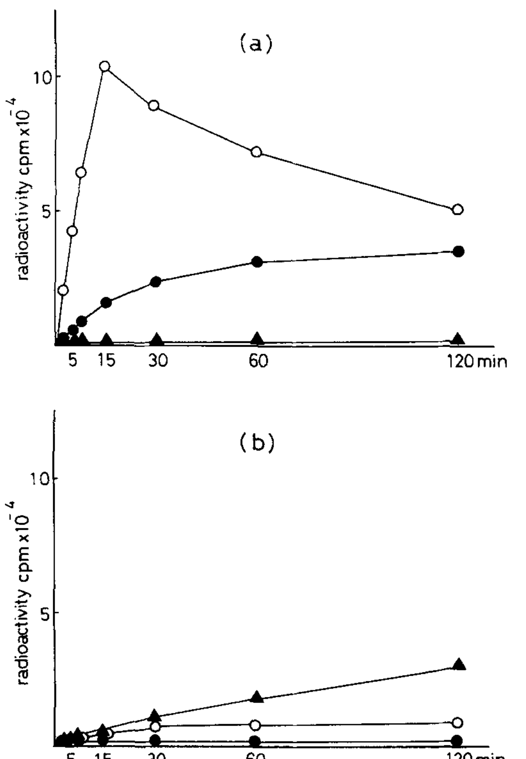

FIG. 1. The incorporation of [^{3}H]20:4 into the alkenylacyl, alkylacyl and diacyl subclasses of choline glycerophospholipid (a) and ethanolamine glycerophospholipid (b). Macrophages (10^6 cells/ml) were incubated with [^{3}H]20:4 (0.2 μCi/ml) at 37 C. Lipids were extracted and then fractionated as described and in Materials and Methods. The data are representative of three separate experiments. Alkenylacyl (▲), alkylacyl (●) and diacyl (○) subclasses.

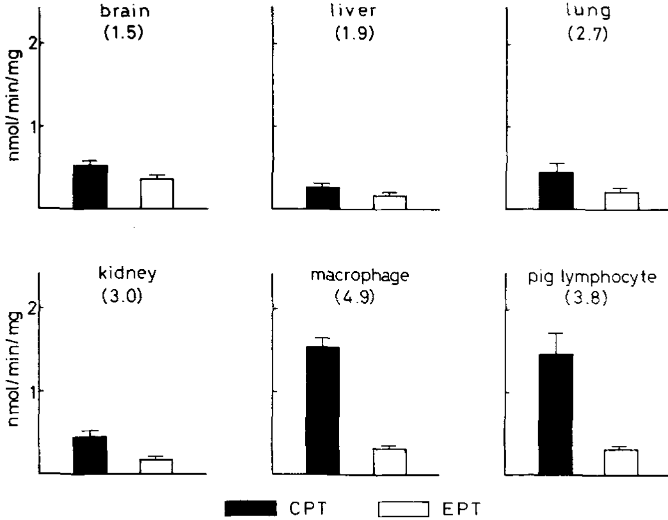

FIG. 2. The formation of choline and ethanolamine glycerophospholipids by cholinephosphotransferase (CPT) and ethanolamine-phosphotransferase (EPT) in microsomes prepared from various rabbit tissues and pig lymphocytes. Endogenous microsomal diradylglycerols were used as substrates as described in Materials and Methods. The mean values ± SD were calculated for three determinations. The values in parentheses are the ratios of the activity of CPT to that of EPT.

other tissues. First, we examined the activities of cholinephosphotransferase and ethanolaminephosphotransferase, which catalyze the final step of the de novo synthesis of CGP and EGP, respectively, with endogenous microsomal diradylglycerols as substrates. The formation of [^{14}C]labeled CGP and EGP from CDP-[^{14}C]choline and CDP-[^{14}C]ethanolamine was proportional to the amounts of protein added to 5 mg (in the absence of exogenous diradylglycerols) and 0.1 mg (in the presence of diradylglycerols) (data not shown). The reaction was also linear with time up to 30 min when 0.5 mg (in the absence of exogenous diradylglycerols) and 0.1 mg (in the presence of diradylglycerols) of microsomal protein was employed. Hence, the microsomal protein and the incubation time were limited to 0.5 mg (without exogenous diradylglycerol) and 0.1 mg (with exogenous diradylglycerol) and 30 min, respectively, in the following experiments.

Figure 2 shows the activities of the choline- and ethanolaminephosphotransferases in microsomal fraction from several rabbit tissues and cells and pig lymphocytes with endogenous diradylglycerols as substrates. Comparable activities of cholinephosphotransferase were observed for microsomal fractions from the brain, lung and kidney. The activity in liver was somewhat lower than those in these three tissues. On the other hand, macrophage microsomal fraction exhibited remarkably higher cholinephosphotransferase activity. The formation of labeled CGP by macrophage microsomes was ca. 3–6 times higher than that by microsomes from brain, liver, lung and kidney. Similar high activity was detected for pig lymphocyte microsomal fraction. As for ethanolaminephosphotransferase, the differences in the activities were not so pronounced between macrophage microsomal fraction and those from other tissues as in the case of cholinephosphotransferase. The activities were rather similar for the liver, kidney and lung microsomal fractions. The macrophage microsomal fraction and the brain and pig lymphocyte microsomal fractions exhibit ethanolaminephosphotransferase activity only ca. two times higher compared with these three tissues.

Although the levels of diradylglycerols available in the microsomal fraction may affect the rates of formation of CGP and EGP, the limited quantities of membrane lipids did not allow for accurate measurement of the amounts of endogenous diradylglycerols. Nevertheless, we confirmed that macrophage microsomal fraction exhibits considerably higher cholinephosphotransferase activity than brain microsomal fraction with 4 mM exogenous diacylglycerol or alkylacylglycerol. The Vmax of cholinephosphotransferase were 16.6 nmol/min/mg (macrophages) and 3.3 nmol/min/mg (brain) with diacylglycerol and 14.3 nmol/min/mg (macrophages) and 4.0 nmol/min/mg (brain) with alkylacylglycerol, respectively. The apparent Km values for CDP-choline were 41.2 μM (macrophages) and 36.6 μM (brain) with diacylglycerol and 51.3 μM (macrophages) and 40.0 μM (brain) with alkylacylglycerol, respectively.

These observations suggest that endogenous diradylglycerols were preferentially utilized by cholinephosphotransferase rather than ethanolaminephosphotransferase in rabbit alveolar macrophages. This is in good agreement with the results shown in Table 2 showing that various labeled precursors were preferentially

TABLE 4

Formation of the Alkenylacyl, Alkylacyl and Diacyl Subclasses of CGP and EGP by Phosphotransferases[a]

	Macrophages (pmol/min/mg)		Brain (pmol/min/mg)	
	CPT	EPT	CPT	EPT
Alkenylacyl	121 ± 28	60 ± 6	116 ± 20	109 ± 11
Alkylacyl	195 ± 33	92 ± 16	27 ± 7	32 ± 5
Diacyl	1253 ± 181	168 ± 33	315 ± 55	238 ± 30

CGP, choline glycerophospholipid; EGP, ethanolamine glycerophospholipid; CPT, cholinephosphotransferase; EPT, ethanolaminephosphotransferase.

[a]The formation of the subclasses of CGP and EGP by microsomes was examined with endogenous diradylglycerols as substrates. The alkenylacyl, alkylacyl and diacyl phospholipids were separated as described in Materials and Methods. The mean values ± SD were calculated for three determinations.

incorporated into CGP. Pig lymphocytes also exhibit higher cholinephosphotransferase activity and the preferential labeling of CGP with various labeled precursors (Sugiura, T., unpublished results). Furthermore, certain types of white blood cells have been shown to synthesize CGP actively (34-38). It seems possible that the high turnover of CGP in these cells is related to some biological function.

Formation of alkenylacyl, alkylacyl and diacyl subclasses of CGP and EGP by phosphotransferases. Then we separated CGP and EGP, newly formed through the action of the phosphotransferases with endogenous diradylglycerols, into the alkenylacyl, alkylacyl and diacyl subclasses. Table 4 shows the formation of the three subclasses of CGP and EGP by macrophage and brain microsomal fraction. Marked formation of diacyl GPC was observed with macrophage microsomes. Although a considerable amount of alkylacyl GPC was synthesized by macrophage microsomes, the formation was lower with brain microsomes. The ratio of the formation of alkylacyl GPC with macrophage microsomal fraction versus that with brain microsomal fraction was 7.2. On the other hand, the ratios of the synthesis of diacyl, alkylacyl and alkenylacyl GPE with macrophage microsomal fraction to those with brain microsomal fraction were 0.7, 2.9 and 0.6, respectively.

The activities of cholinephosphotransferase and ethanolaminephosphotransferase toward endogenous and exogenous diacylglycerol and alkylacylglycerol have been studied by several investigators (14,39-47). Freysz et al. (47) demonstrated the relatively higher affinity of ethanolaminephosphotransferase for CDP-ethanolamine than that of cholinephosphotransferase for CDP-choline, in the presence of alkylacylglycerol in chicken brain. They suggested that alkylacylglycerol was preferentially utilized by ethanolaminephosphotransferase to yield alkylacyl GPE, followed by desaturation to form alkenylacyl GPE, differing from the case of diacylglycerol. In fact, it is well known that brain tissues contain high amounts of ether-containing compounds only in EGP (1). We showed here that endogenous alkylacylglycerol was effectively utilized by both cholinephosphotransferase and ethanolaminephosphotransferase in macrophage microsomal fraction. The relatively high synthetic rates of alkylacyl GPC could be closely related to the remarkably high cholinephosphotransferase activity in macrophages. It has already been assumed that the same enzyme catalyzes the transfer of CDP-choline to either alkylacylglycerol or diacylglycerol (14,39-43,45,47). Furthermore, it seems possible that the active formation of alkylacyl GPC (Tables 2-4) could be responsible, at least in part, for the high abundance of this phospholipid in macrophages, although the degradation of alkylacyl GPC in these cells has not yet been examined. Pig lymphocytes also contain high amounts of alkylacyl GPC (8) and exhibit high cholinephosphotransferase activity (Fig. 2). Alkylacylglycerol could be utilized not only for the synthesis of ether-containing EGP but also for that of alkylacyl GPC in these types of cells.

In any case, the high synthesis and accumulation of alkylacyl GPC in macrophages is of particular importance, since alkylacyl GPC is regarded as the stored precursor form of PAF, which is now considered to be an important lipid mediator in inflammation and hypersensitivity. Several investigators have pointed out the possible involvement of PAF in the pathogenesis of asthma (48-51). Alveolar macrophages have been presumed to be the important source of PAF in asthmatic subjects (48). Thus, the metabolic regulation of alkylacyl GPC in alveolar macrophages under physiological or pathological conditions seems to be an important point in connection with the biosynthesis and release of PAF. It has been considered that PAF is synthesized from alkylacyl GPC deposited in inflammatory and immunological cells through a deacylation-acetylation reaction (2). On the other hand, several investigators have demonstrated that 1-alkyl-2-acetyl-3-*sn*-glycerol was metabolized by cholinephosphotransferase to form PAF in microsomes from various rat tissues (52) and intact platelets (53,54). The high cholinephosphotransferase activity in macrophages seems also to be effective for the synthesis of PAF through the phosphotransferase pathway, although the enzymes catalyzing the transfer of CDP-choline to 1-alkyl-2-acetylglycerol and 1-alkyl-2-acyl(long chain) glycerol, respectively, were shown to be different in their sensitivity to dithiothreitol (14,52).

Taken together, it has been shown that both de novo synthesis and the remodeling of the fatty acids of either diacyl or alkylacyl GPC were very active in rabbit alveolar macrophages. The high cholinephosphotransferase activity and transacylation activity could account, at least in part, for the high formation of these phospholipids. The accumulation of arachidonic acid-containing alkylacyl GPC seems to be favorable for providing sufficient amounts of arachidonic acid and 1-alkyl-GPC (lyso PAF) for lipid mediator synthesis in this type of cell upon stimulation (3-7).

[Received December 15, 1986]

METHODS

Rapid Separations of Diacyl- and Dialkylglycerol Enantiomers by High Performance Liquid Chromatography on a Chiral Stationary Phase

Toru Takagi* and **Yutaka Itabashi**
Department of Chemistry, Faculty of Fisheries, Hokkaido University, Hakodate 041, Japan

Rapid and practical separations of 1,2- and 2,3-diacyl- and dialkyl-*sn*-glycerol enantiomers as their 3,5-dinitrophenylurethane derivatives were carried out by normal-phase high performance liquid chromatography on a chiral stationary phase, N-(*R*)-1-(α-naphthyl)ethylaminocarbonyl-(*S*)-valine chemically bonded to γ-aminopropyl silanized silica. Complete separations of the racemates into enantiomers were achieved for both of the diacyl- and dialkylglycerols within 10 min using a stainless steel column (25 cm long) packed with the 5-μ particles, an isocratic elution with a mixture of hexane/ethylene dichloride/ethanol as a mobile phase and a UV detector. The *sn*-1,2-enantiomers were eluted ahead of the corresponding *sn*-2,3-enantiomers. Satisfactory separation of the *sn*-1,3-diacylglycerols from the corresponding enantiomers and the separation of the homologues differing in acyl and alkyl groups were also observed. The formations of hydrogen bonding and charge transfer complex between the urethane derivatives and the stationary phase may contribute to the enantiomer separations.
Lipids 22, 596–600 (1987).

A few studies have been published on identification and resolution of enantiomeric diacylglycerols. Bus et al. have resolved the signals from ester groups at the center of chirality of diacylglycerol acetates and butyrates by proton magnetic resonance spectroscopy in combination with a chiral reagent (1). Myher and Kuksis have resolved enantiomeric diacylglycerols via X-phosphatidylcholines and phospholipase C and have identified the individual molecular species of each enantiomer type by capillary gas liquid chromatography on a polar liquid phase (2). Optical rotatory dispersion and circular dichroism have also been commonly used for the analysis of enantiomeric acyl- and alkylglycerols (3,4). These techniques are powerful tools for the investigation on stereochemistry of acyl- and alkylglycerols, but are not simple or practical for obtaining the enantiomer composition of a mixture. Thus, there is considerable interest in chromatographic methods for the determination of enantiomeric acyl- and alkylglycerols (5).

The recent development of chiral stationary phases and chiral reagents for chromatography has permitted separations of various enantiomers (6). Michelsen et al. have reported the complete separations of mono- and dialkylglycerols and partial separation of diacylglycerols as their diastereomeric 1-(1-naphthyl)ethylurethane derivatives by high performance liquid chromatography (HPLC) on an achiral stationary phase (7). The incompletely separated diacylglycerol peaks could not be identified with optically pure samples. We have recently reported the enantiomer separations of long-chain monoacyl- (8), monoalkyl- (9) and diacylglycerols (10) as their 3,5-dinitrophenylurethane derivatives by HPLC on a chiral stationary phase, N-(*S*)-2-(4-chlorophenyl)isovaleroyl-D-phenylglycine bonded to silica gel. Although complete separations for monoacyl- and monoalkylglycerols were obtained within 15 min on the 25-cm long column, a longer column (75 cm long) and extremely long elution times (several hr) were required to obtain clear-cut separation for diacylglycerols on the same stationary phase.

Ôi and Kitahara have developed various chiral stationary phases for HPLC, which showed characteristic enantioselectivity for derivatives of amino acids, amines, carboxylic acids and alcohol enantiomers (11). We have found that some of these chiral phases also have enantioselectivity for diacyl- and dialkylglycerols as their 3,5-dinitrophenylurethane derivatives. This paper presents a rapid and practical HPLC method for the enantiomer separations of the long chain diacyl- and dialkylglycerol derivatives on a chiral stationary phase, N-(*R*)-1-(α-naphthyl)ethylaminocarbonyl-(*S*)-valine bonded to silica gel (11).

MATERIALS AND METHODS

Samples. Synthetic 1,2-diacyl-*rac*-, 1,3-diacyl-*sn*- and 1,2-dialkyl-*rac*-glycerols used in this study (Table 1) were obtained from Sigma (St. Louis, MO), P.L. Biochemicals (Milwaukee, WI) and Bachem AG (Bubendorf, Switzerland), respectively. Prior to use, only 1,2-diacyl-*rac*-glycerol samples were purified by thin layer chromatography (TLC) on borate treated silica gel (12). Optically active 1,2- and 2,3-diacyl-*sn*-glycerols synthesized in our laboratory on the basis of the method of Howe and Malkin were also used (13).

The 3,5-dinitrophenylurethane derivatives were prepared by reaction of the samples of less than 1 mg with 3,5-dinitrophenyl isocyanate (Sumitomo Chemical Co., Osaka, Japan) of about 2 mg in dry toluene (4 ml) in the presence of dry pyridine (40 μl) at ambient temperature for 1 hr. The crude urethane derivatives of diacyl- and dialkylglycerols were purified by TLC on Silica Gel GF plates (20 × 20 cm, 0.25-mm thick, Analtech Inc., Newark, DE) using hexane/ethylene dichloride/ethanol (40:10:3, v/v/v and 40:10:1, v/v/v, respectively). Prior to use, the plates were activated at 110–120 C for 2 hr.

HPLC. HPLC separation was carried out with a Shimadzu LC-6A instrument equipped with a SCL-6A system controller (Shimadzu Co., Kyoto, Japan) and a chiral column (stainless steel, 25 cm × 4 mm i.d.) packed with 5-μ particles of N-(*R*)-1-(α-naphthyl)ethylaminocarbonyl-(*S*)-valine chemically bonded to γ-aminopropyl silanized silica, Sumipax OA-4100 (Sumitomo Chemical). A Guard-pac precolumn module with a silica insert (Millipore Co., Milford, MA) was attached to the inlet of the chiral column. The analysis was done isocratically using a mixture of hexane/ethylene dichloride/ethanol (80:20:1, 150:20:1 or 250:20:1, v/v/v) as the mobile phase at a constant flow rate of 1 ml/min, which produced a pump pressure of about 500 psi. Prior to use, the mobile phase was filtered with a 2-μ PTFE membrane filter (Millipore). Usually, 1 μl of the samples dissolved in

[a]Vr, retention volume (ml) corrected by subtracting the column void volume (2.68 ml).
[b]α, Separation factor (the ratio of the capacity ratios).
[c]Rs, peak resolution. $Rs = 2(t_1 - t_2)/(W_1 + W_2)$, where t = retention time (min) and w = peak width (min).

chloroform was injected into the column through a Rheodyne Model 7125 loop (20 μl) injector. Peaks were monitored at 0.02 AUFS with a Shimadzu SPD-6A variable wavelength (195–350 nm) UV detector having an 8-μl flow cell. Chromatograms, peak area percentages and retention times were obtained with a Chromatopac C-R3A (Shimadzu). The column void volume was determined by measuring the retention volume of pentane with a RI detector, Shodex Model SE-51 (Showa Denko Co., Tokyo, Japan).

RESULTS AND DISCUSSION

Derivatives. Diacylglycerols react readily with 3,5-dinitrophenyl isocyanate without acyl migration in toluene solution in the presence of pyridine at ambient temperature. The resulting urethane derivatives have a sufficient absorption for HPLC detection over a wide range of UV wavelengths (8,10). The reaction of the dialkylglycerols with the isocyanate also proceeds quantitatively under the same conditions. The urethanes (Rf 0.63 for 1,2-dioctadecyl-*rac*-glycerol) were separated clearly from by-products (Rf 0 and 0.13), using hexane/ethylene dichloride/ethanol (40:10:1, v/v/v) as solvent. The by-products of Rf 0.13 appeared as a yellow band without UV irradiation. The Rf value of the corresponding diacylglycerol urethane derivatives in the same solvent system was somewhat lower—0.52. The faster mobility of dialkylglycerols without derivatization was also observed on Silica Gel TLC (5).

Separation. Figure 1 shows the HPLC chromatograms of optically active and inactive diacylglycerols as their 3,5-dinitrophenylurethane derivatives on a chiral column, OA-4100. Only the chromatogram of the racemate gave two clearly separated peaks with a 1:1 peak area ratio (Fig. 1A). The retention times of the former and later peaks (Fig. 1A) were in agreement with those of the *sn*-1,2- and *sn*-2,3-enantiomers (Figs. 1B and 1C), respectively. The identification of the peak components was also carried out by their complete overlapping in co-injection of the racemate with each enantiomer. Similar separation patterns were also observed for other racemic diacylglycerols used.

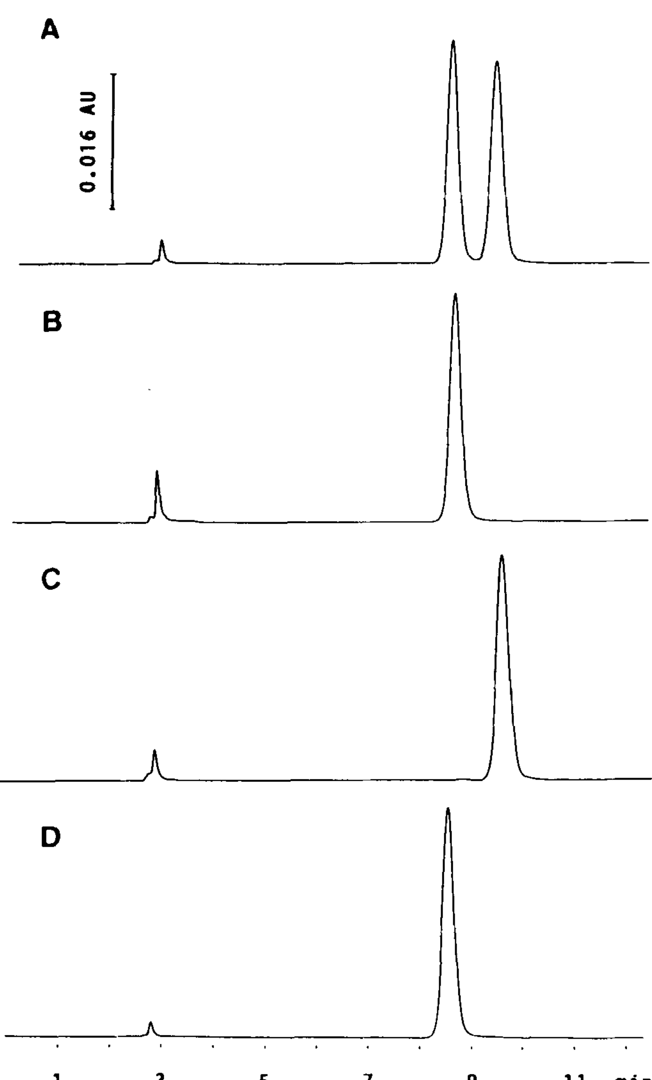

FIG. 1. Separation of diacylglycerol isomers as 3,5-dinitrophenylurethane derivatives on a chiral column, OA-4100. A, 1,2-dipalmitoyl-*rac*-glycerol; B, 1,2-dipalmitoyl-*sn*-glycerol; C, 2,3-dipalmitoyl-*sn*-glycerol; D, 1,3-dipalmitoyl-*sn*-glycerol. Mobile phase, hexane/ethylene dichloride/ethanol (80:20:1, v/v/v). Detection, 254 nm UV.

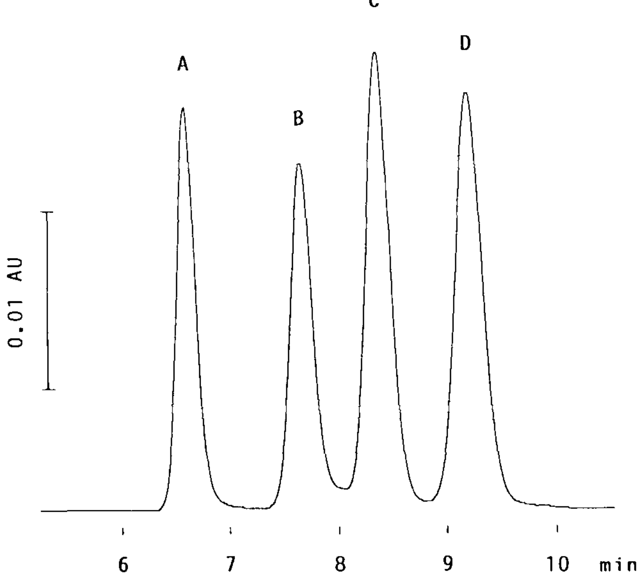

FIG. 2. Separations of dialkyl- and diacylglycerol enantiomers as 3,5-dinitrophenylurethane derivatives on a chiral column, OA-4100. A, 1,2-dioctadecyl-*sn*-glycerol; B, 2,3-dioctadecyl-*sn*-glycerol; C, 1,2-distearoyl-*sn*-glycerol; D, 2,3-distearoyl-*sn*-glycerol. Mobile phase, hexane/ethylene dichloride/ethanol (80:20:1, v/v/v). Detection, 254 nm UV.

As with diacylglycerol enantiomers, dialkylglycerol enantiomers were also separated completely with better resolution in a shorter elution time under the same conditions (Fig. 2). The faster elution of the dialkylglycerol urethane derivatives on the chiral silica column is probably due to their lesser polarity. The higher resolution of the dialkylglycerol enantiomers was also reported previously in the HPLC separation of the diastereomeric 1-(1-naphthyl)ethylurethane derivatives on an achiral silica column (7). By UV detection, each enantiomer of the racemic diacyl- and dialkylglycerols separated on OA-4100 showed a 1:1 peak area ratio at different wavelengths, which supports the effective separations of the racemic diacyl- and dialkylglycerols into their enantiomers without isomerization during the derivatization procedures and the HPLC analysis. Almost single peaks for 1,2-, 2,3- and 1,3-diacyl-*sn*-glycerols (Figs. 1B–1D) also support the absence of isomerization between the isomers. Thus, the chromatograms (Figs. 1 and 2) are characterized by complete separations of the racemates into the enantiomers within 10 min, with sharp and symmetrical peaks and faster elutions of *sn*-1,2-enantiomers than the corresponding *sn*-2,3-enantiomers. The faster elutions of the *sn*-1,2-enantiomers suggest stronger diastereomeric interactions with the stationary phase. In this study, a 0.2–0.5 nmol amount of the urethane derivatives was usually introduced into the column and was detected at 254 nm, a fixed wavelength in universal UV detectors. The detection at near 230 nm approximately doubled the sensitivity, but the peaks from the solvent chloroform, which appeared near 2.8 min, increased greatly.

The *sn*-1,3-isomers eluted just before the *sn*-1,2-enantiomers with partial separation (Fig. 1D) under the conditions used. This separation was improved by lengthening the elution time, which was obtained by reducing the mobile phase polarity (Fig. 3). The faster elution of the *sn*-1,3 isomer on the chiral silica column is mainly due to the lower polarity, because a similar observation for diacylglycerols was obtained in TLC on silica gel (5). The urethane derivatives of 2-monoacyl-*sn*-glycerols also showed a faster elution than those of 1-monoacyl-*rac*-glycerols on a chiral silica column, OA-2100 (8). The OA-4100 column used in this study showed 7,500 theoretical plates for the 2,3-dipalmitoyl-*sn*-glycerol peak. This value was reduced to 6,800 after 100 injections, but the enantiomers were still separated completely within 10 min.

Table 1 gives the HPLC data for isomeric diacyl- and dialkylglycerols as their 3,5-dinitrophenylurethane derivatives on OA-4100. The separations were examined using three mobile phases, hexane/ethylene dichloride/ethanol [(A) 80:20:1, (B) 180:20:1 and (C) 250:20:1, v/v/v],

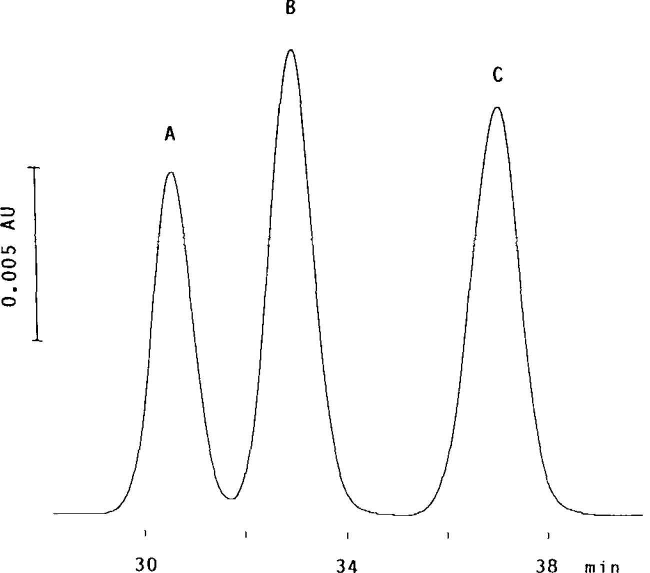

FIG. 3. Separation of 1,3-diacyl-*sn*-glycerols and the enantiomers as 3,5-dinitrophenylurethane derivatives on OA-4100. A, 1,3-dipalmitoyl-*sn*-glycerol; B, 1,2-dipalmitoyl-*sn*-glycerol; C, 2,3-dipalmitoyl-*sn*-glycerol. Mobile phase, hexane/ethylene dichloride/ethanol (150:20:1, v/v/v). Detection, 254 nm UV.

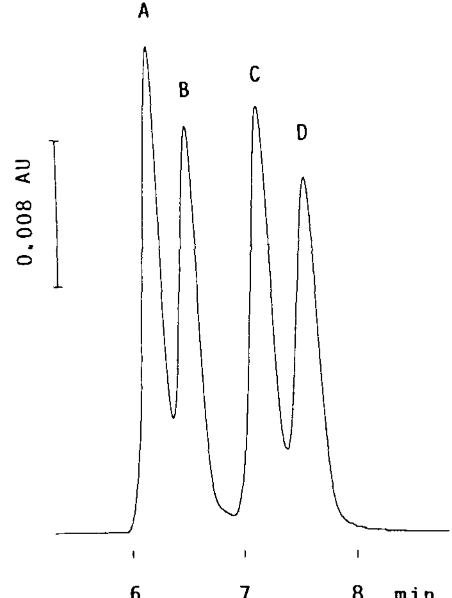

FIG. 4. Carbon number separation of dialkylglycerol enantiomers as 3,5-dinitrophenylurethane derivatives on a chiral column, OA-4100. A, 1,2-dioctadecyl-*sn*-glycerol; B, 1,2-dihexadecyl-*sn*-glycerol; C, 2,3-dioctadecyl-*sn*-glycerol; D, 2,3-dihexadecyl-*sn*-glycerol. Mobile phase, hexane/ethylene dichloride/ethanol (80:20:1, v/v/v). Detection, 254 nm UV.

which gave progressively longer elution times in order of A, B and C. In general, the elution times decrease with increasing polarity of the mobile phase in the normal-phase HPLC on the chiral silica columns. Of these mobile phases, mobile phase B gave the highest peak resolution for diacylglycerol enantiomers, as indicated by Rs values 2.2–2.3. On the other hand, mobile phase C gave the best separations for dialkylglycerol enantiomers (Rs 4.3–4.4) and for isomeric *sn*-1,3- and *sn*-1,2-diacylglycerols (Rs 2.0–2.3). Rapid and complete enantiomer separations for both of diacyl- and dialkylglycerols were achieved using mobile phase A.

In addition to the enantiomer separation, the OA-4100 column gives the carbon number separation of the acyl and alkyl groups and the separation of saturated and unsaturated species, which will be also caused by the silica gel support. Figure 4 shows the carbon number separation of the enantiomer homologues of dialkylglycerols on OA-4100 using mobile phase A. Apparently, the resolution of the peaks of the homologues differing by four alkyl carbons (Rs 1.1, not given in Table 1) is low compared with the resolution of the enantiomer peaks (Rs 2.8–3.1). The separation factor of the homologues differing by four alkyl carbons was 1.09 in each *sn*-1,2- and *sn*-2,3-enantiomer, as calculated from the data in Table 1. Almost equal values (1.08–1.11) were also obtained for those of the diacylglycerol homologues. Figure 5 shows the separation of saturated and unsaturated diacylglycerol enantiomers on OA-4100. As with the saturated diacylglycerols, the dioleoylglycerol racemate was also separated completely within 10 min into the enantiomers with almost equal separation factor 1.15 and peak resolution 2.0, using mobile phase A. The separation factors 1.09–1.11 of the diacylglycerols differing by two double bonds, that is, distearoyl- and dioleoylglycerols, are almost equal to those 1.08–1.11 of the diacylglycerols differing by four

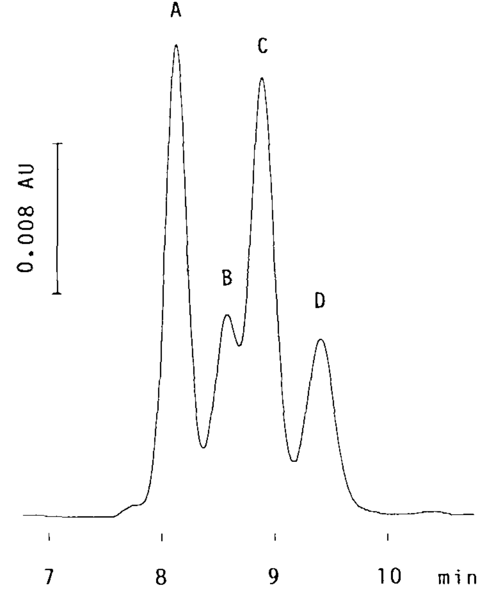

FIG. 5. Separation of saturated and unsaturated diacylglycerol enantiomers as 3,5-dinitrophenylurethane derivatives on OA-4100. A, 1,2-distearoyl-*sn*-glycerol; B, 1,2-dioleoyl-*sn*-glycerol; C, 2,3-distearoyl-*sn*-glycerol; D, 2,3-dioleoyl-*sn*-glycerol. Mobile phase, hexane/ethylene dichloride/ethanol (80:20:1, v/v/v). Detection, 254 nm UV.

acyl carbons, such as dipalmitoyl- and distearoylglycerols. Thus, the HPLC of a mixture of saturated and unsaturated diacylglycerols on the chiral column gives complex chromatograms. Therefore, preliminary separations by reversed-phase HPLC, argentation TLC and others are necessary to obtain accurate enantiomer composition of a mixture of saturated and unsaturated species.

FIG. 6. Chemical structure of the OA-4100 stationary phase.

Figure 6 shows the structure of the OA-4100 stationary phase. This phase contains a chiral urea group and a chiral 1-(α-naphthyl)ethyl group, which have the abilities to serve either as a donor or an acceptor in hydrogen bonding and to serve as a π-donor, respectively (11). Thus, the diastereomeric hydrogen bonding association and π-π donor-acceptor interaction between the stationary phase and the solutes may contribute to the enantiomer separations of diacyl- and dialkylglycerols. In comparison with OA-2100 used previously (8–10), OA-4100 has two more NH groups in the molecule, which may facilitate the hydrogen bonding association with the carbonyl groups in the solutes. The introduction of an NH group as the urethane derivatives into diacyl- and dialkylglycerols may also contribute to the excellent enantiomer separations. In addition, the naphthyl group in OA-4100 may form more easily the charge transfer complex with the 3,5-dinitrophenyl group in the urethane derivatives than the chlorophenyl group in OA-2100.

ACKNOWLEDGMENT

We are grateful to Dr. N. Ôi for useful suggestions on chiral columns.

Lipid Composition and Amino Acid Transport in a Nystatin-Resistant Mutant of *Aspergillus niger*

Chitra Mazumder, Manikuntala Kundu, Joyoti Basu and **Parul Chakrabarti***
Department of Chemistry, Bose Institute, Calcutta, India

A nystatin-resistant mutant of *Aspergillus niger* has been isolated and used as a model system to study the effect of altered sterol levels on lipid composition, transport behavior and physical properties of membrane lipids. There is a decrease in the sterol to phospholipid ratio in the mutant compared to the wild type. Although there is no qualitative change in phospholipid composition, the mutant contains a higher amount of phosphatidylcholine and a lower amount of phosphatidylethanolamine compared to the wild type. The most significant change is the elevated level of linoleic acid in the mutant, concomitant with a decreased level of oleic acid. These adaptive changes to nystatin resistance are manifested in the altered thermotropic behavior of membrane lipids as studied by the steady-state fluorescence polarization technique. These changes are also associated with altered membrane permeability as evidenced by the change in V_{max} values for uptake of some amino acids in the mutant compared to the wild type.
***Lipids 22,* 609–612 (1987).**

Polyene antibiotics have been shown to interact with membrane sterols of fungal cells (1,2). Various polyene antibiotics such as nystatin and amphotericin B have been used to get resistant strains of fungi containing low levels of sterols (3,4). However, detailed studies on the interrelationships among altered sterol content, overall lipid composition, physical properties of membranes and transport phenomena in fungi remain to be carried out. In the present study, a nystatin-resistant mutant of *Aspergillus niger* has been isolated and used as a model system to study some of the effects of altered sterol level on lipid composition, physical properties and functions of membranes. The results of our present studies with this mutant suggest that, concomitant with altered sterol level, there is overall modulation in the phospholipid and fatty acid composition of the mutant. These alterations in membrane lipids may be responsible for the altered rates of uptake of various amino acids in the mutant compared to the wild type *A. niger.*

MATERIALS AND METHODS

Materials. Nystatin, 1,6,diphenyl-1,3,5-hexatriene (DPH) and standard lipids were purchased from Sigma Chemical Co. (St. Louis, MO). Standard fatty acid methyl esters were purchased from Nu-Chek-Prep (Elysian, MN); Silica Gel G and Silica Gel H were from E. Merck (Darmstadt, FRG); and 1,6-ditertiarybutyl-p-cresol was from Aldrich Chemicals (Milwaukee, WI). All ^{14}C-labeled amino acids were obtained from the Bhaba Atomic Research Centre, Trombay, India. All other solvents and reagents used were of analytical grade.

Growth of organism. Wild-type *A. niger* V_{35} was collected from the stock culture of the Department of Microbiology of the Bose Institute. Stock cultures of V_{35} were grown at 28 C on solid agar slants of Czapek-Dox medium (5) containing the following (g/l of distilled water): glucose, 40.0; $NaNO_3$, 2.0; KH_2PO_4, 1.0; $MgSO_4 \cdot 7H_2O$, 0.5; KCl, 0.5; $FeSO_4 \cdot 7H_2O$, 0.01; and $ZnSO_4 \cdot 7H_2O$, 0.01. Media for slants were solidified with 2% (w/v) agar.

Isolation of a nystatin-resistant mutant. Nystatin-resistant cells were obtained according to the method of Nobre et al. (6), where cells were grown in the presence of increasing concentrations of nystatin. The inoculum was a suspension of conidia at a concentration of 10^7 cells/ml. Resistance was induced by serial transfer at the following drug concentrations (U/ml): 11, 22, 44, 88, 176, 352, 704, 1408, 2816, 5632 and 8550. The minimum inhibitory concentrations of the wild type and the nystatin-resistant mutant were found to be 17 U/ml and 8550 U/ml, respectively. A mutant 500-fold more resistant to nystatin than the wild type was obtained.

Isolation of conidia. Conidial cell suspensions were prepared by harvesting conidia into sterile distilled water and filtering through glass-wool to remove mycelial fragments. The cell suspensions were then centrifuged at 30,000 × g to pellet down the conidia, which were washed thoroughly with excess distilled water and lyophilized.

Extraction of lipids. Lipids were extracted from washed and freeze-dried cells following the method of Folch et al. (7). Antioxidant 2,6-ditertiary butyl-p-cresol (50 mg/l) was added to the solvents to prevent oxidation. Lipids were stored in chloroform at −20 C in the presence of nitrogen.

Lipid analysis. Neutral and polar lipid fractions were separated by preparative thin layer chromatography (TLC) using Silica Gel G and acetone as developing solvent. Individual phospholipids were separated by preparative TLC on Silica Gel H according to the method of Skipski et al. (8) using the solvent system chloroform/methanol/acetic acid/water (25:15:4:2, v/v/v/v). Individual components were extracted and the phosphorus content was estimated according to the method of Ames and Dubin (9). Neutral lipid extracts were fractionated by TLC as described previously (10) using the solvent system petroleum ether/diethyl ether/acetic acid (90:10:1, v/v/v). Free sterol was eluted with chloroform/methanol (4:1, v/v) and estimated colorimetrically by the method of MacIntyre and Ralston (11) using ergosterol as standard.

Fatty acid analyses. Fatty acids isolated from phospholipids obtained from the conidia of both the wild type and the mutant were analyzed by gas liquid chromatography. Phospholipids were hydrolyzed, and methyl esters were prepared from the liberated free fatty acids by the method of Luddy et al. (14). These were identified against appropriate standards and quantitated by electronic integration on a 15% diethylene glycol succinate column (3 mm id × 1.5 m), using nitrogen at a flow

Abbreviations: DPH, 1,6-diphenyl-1,3,5-hexatriene; TLC, thin layer chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; PI, phosphatidylinositol; CL, cardiolipin.

rate of 50 ml/min at an operating temperature of 170 C on a Shimadzu(GCR1A) gas chromatograph fitted with a dual flame ionization detector and an automatic data processor RPRG1.

Liposome preparation. Phospholipids and sterols extracted from the different systems were mixed in the molar ratio in which they were present in each of these systems. Desired lipid mixtures and DPH were dissolved in chloroform at a lipid to probe ratio of 750:1. A thin film was made under nitrogen and then dried under vacuum for 4 hr. The mixture was resuspended in 10 mM phosphate buffer, pH 6.0, and sonicated in a water-bath sonicator (12). The final DPH concentration was 1 μM.

Steady-state fluorescence pllarization. Fluorescence polarization was measured in a Perkin-Elmer fluorescence spectrophotometer (excitation wavelength, 360 nm; emission wavelength, 430 nm). Polarization values (P) were determined according to ref. 13:

$$P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}}$$

where $I_{\parallel}$ and $I_{\perp}$ are the intensities of parallel and perpendicular polarized light, respectively. These were calculated according to the above relation. The standard deviation of each polarization value was 0.002. Temperatures were maintained within ± 0.5 C. Since the contribution due to scattering determined using lipid samples of identical composition without DPH was found to be less than 2% of total emitted light at 430 nm, no correctons were made.

Transport assay. Cells were grown in solid Czapek-Dox medium as described before. Conidia were isolated, washed and suspended in 1 ml of 10 mM phosphate buffer (pH 6.0) at concentration of 4×10^7 cells/ml. Uptake was started by the addition of different concentrations of ^{14}C-labeled amino acid (50 μCi/μmol) and stopped after 2 min by adding 10 ml of ice-cold water. Two min were found to be within the linear range of uptake. The diluted suspension was rapidly filtered through 0.45 μM Millipore filter (HAWP 025 00), and the filter was dried and counted in an LKB liquid scintillation counter (Mini Beta 1211) using a toluene-based scintillation fluid.

Statistical analysis. Student's t-test was used to assess levels of significance. Values of $P < 0.01$ were considered to be significant.

RESULTS

Lipid analyses. Since phospholipids and sterols are the major lipid components modulating the properties of biomembranes, these were analyzed in the conidia of both the wild type and the nystatin-resistant mutant of *A. niger.* The free sterol contents were found to be 5.6% and 3.6% of the total lipid of the wild type and the mutant, respectively. There was no qualitative change in phospholipid composition in the conidial lipids of the mutant compared to the wild type. However, the amount of phosphatidylethanolamine (PE) was found to decrease in the mutant, concomitant with an increase in phosphatidylcholine (PC) (Table 1). Phosphatidylinositol (PI) and phosphatidylserine (PS) could not be separated using the solvent system described.

Analysis of the fatty acid of the total phospholipid of the mutant and the wild type revealed significant alteration of fatty acid composition. The phospholipids of the mutant were found to contain elevated levels of linoleic acid (18:2) compared to the wild type. The level of oleic acid (18:1) was, on the other hand, lower in the mutant than in the wild type (Table 2).

Fluorescence polarization studies. These were carried out with liposomes prepared from isolated conidial phospholipids and sterols of both the mutant and the wild type. A discontinuity in the fluorescence polarization plots was observed at 18 C in the case of the mutant, while no discontinuities were observed in the case of the wild type (Fig. 1).

Amino acid transport. In the present study, uptake of the amino acids leucine, lysine, glutamic acid and aspartic acid was studied in the wild type and the nystatin-resistant mutant of *A. niger.* From the Lineweaver-Burk plots, a comparison of the K_m values for the uptake of a particular amino acid showed no significant differences between the mutant and the wild type (0.16 mM for aspartic acid, 0.2 mM for glutamic acid, 0.2 mM for lysine and 0.13 mM for leucine) (Fig. 2). However, V_{max} values for the uptake of some amino acids showed differences between the two types of cells. The V_{max} values for uptake of aspartic acid, lysine and leucine were higher in the mutant than the wild type (Table 3), while there was no significant change in the V_{max} values for glutamic acid uptake.

TABLE 1

Lipid Composition of the Conidia of Wild Type *A. niger* and Its Nystatin-Resistant Mutant

Strain	Phospholipid (μg/g dry weight)				PC/PE (ratio)	Sterol/phospholipid (μmol/μmol)
	PC	PE	CL	PI + PS		
Wild	2.5 ± 0.12	2.92 ± 0.16	0.42 ± 0.21	0.75 ± 0.32	0.86	0.83
Mutant	2.85 ± 0.21	1.76 ± 0.13	0.26 ± 0.11	0.64 ± 0.26	1.62	0.6

PC, phosphatidylcholine; PE, phosphatidylethanolamine; CL, cardiolipin; PI, phosphatidylinositol; PS, phosphatidylserine. Determinations of lipid phosphorus and identification of different phospholipids were performed as described in Materials and Methods. Phosphorus contents were multiplied by 25 to obtain content of the total phospholipids. In the case of cardiolipin, this value was further divided by 2. Values are mean ± S.D. of five different sets of determinations.

TABLE 2

Fatty Acid Composition of Phospholipids of the Conidia of Wild Type and Nystatin-Resistant *Aspergillus niger*

Fatty acid	% of total	
	Wild	Mutant
16:0	25.72 ± 0.52	25.45 ± 0.43
18:0	3.35 ± 0.29	3.38 ± 0.32
18:1	31.85 ± 0.39*	25.69 ± 0.31*
18:2	31.57 ± 0.51**	37.64 ± 0.46**
18:3	1.04 ± 0.37	1.97 ± 0.35

Fatty acid analysis was performed as described in Materials and Methods. Individual fatty acids present in amounts less than 1% of the total fatty acids have not been shown. Values are mean ± S.D. of five sets of determinations. *, P < 0.001; **, P < 0.001.

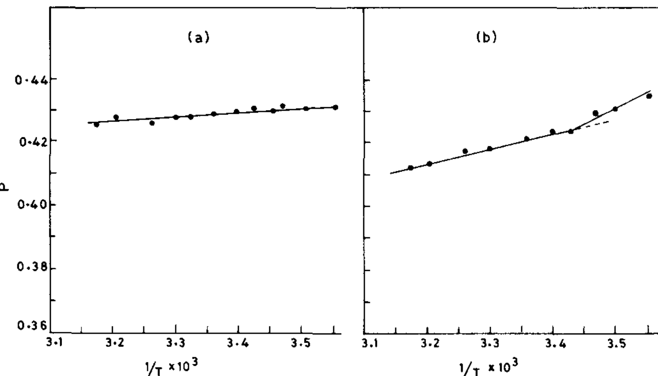

FIG. 1. Fluorescence polarization plots of liposomal membranes of *A. niger*: (a) wild type, (b) nystatin-resistant mutant. Fluorescence polarization measurements were carried out as described in Materials and Methods.

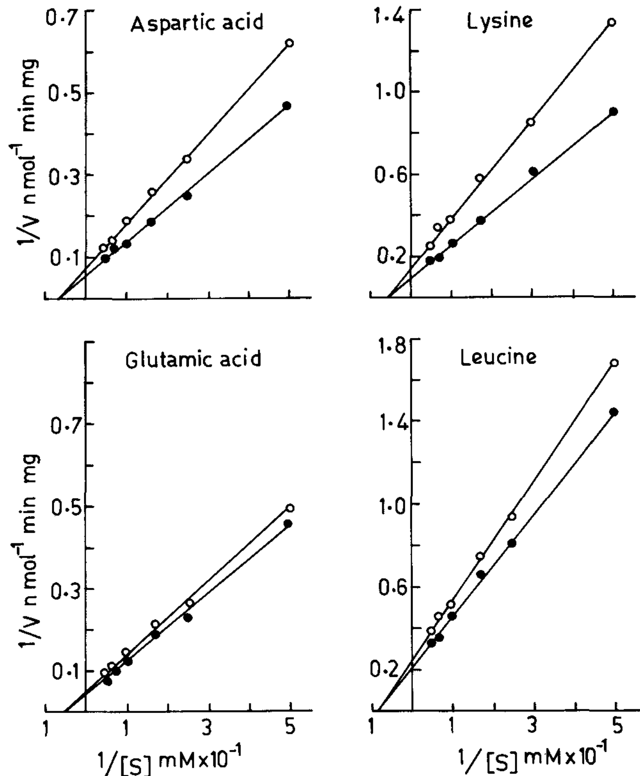

FIG. 2. Various concentrations of each amino acid were prepared using a specific activity of 50 μCi/μmol. Transport assay was carried out as described in Materials and Methods. Transport rates have been expressed per mg dry weight of cells for the wild type (○) and the nystation-resistant mutant (●).

DISCUSSION

Sterols have long been recognized as important membrane constituents responsible for modulating the functions of eukaryotic membranes (15,16). However, the precise way in which they regulate the physical properties and biochemical functions of cell membranes still remains to be understood. In the present case, a nystatin-resistant mutant of *A. niger* was isolated. The sterol/phospholipid molar ratio is lower for the conidial lipids of the mutant compared to the wild type. Some of the effects of altered sterol content have been reported here. The overall phospholipid composition suggests that the mutant adapts to a certain extent to changes in the sterol content by altering levels of individual phospholipid species. The observed increase in PC content and simultaneous decrease in PE content in the mutant compared to the wild type is one of the responses of *A. niger* to adaptation to growth in the presence of nystatin. Even more significant than the change in phospholipid composition is the altered fatty acid composition of the mutant. Studies with the yeast *Saccharomyces cerevisiae* have also shown that exogenous sterol modulates yeast plasma membrane phospholipid and fatty acid composition (17).

TABLE 3

V_{max} Values for Uptake of Some Amino Acids in *A. niger* V_{35} and Its Nystatin-Resistant Mutant

Amino acid	V_{max} (nmol/min/mg)	
	Wild	Mutant
Leucine	4.16 ± 0.25*	5 ± 0.16*
Lysine	6.25 ± 0.32*	10 ± 0.21*
Glutamic acid	20 ± 0.32^{NS}	20 ± 0.22^{NS}
Aspartic acid	12.5 ± 0.12*	16.5 ± 0.16*

Transport assay was carried out as described in Fig. 2. Values are mean ± S.D. of five independent determinations. NS, Nonsignificant; *, P < 0.01.

The nature of the fatty acyl chain of phospholipids is one of the most important factors modulating membrane fluidity and integrity. The polarization values decreased with increasing temperature, indicating an increase in probe mobility with increasing temperature. The slopes of the plots show that the rate of this decrease with temperature was higher in the case of the mutant, suggesting increased relative mobilities of lipids (Fig. 1). This is consistent with the increased level of unsaturation and decreased level of sterol in the mutant compared to the wild type. Liposomes of the wild type show no

discontinuity in plots of fluorescence polarization. However, liposomes of the mutant show physical changes in membrane lipids characterized by a discontinuity in fluorescence polarization plots, suggesting a gel-liquid crystalline transition. Compensatory changes in the fatty acyl chains of phospholipids, associated with sterol depletion, have been shown in LM-cell sterol mutants (18). Such depletion leads to decrease in the high melting phospholipids in the plasma membrane of LM-cells. Our findings suggest that such an adaptation is necessary in the present case also to preserve essential membrane functions and growth of the organism. It will also be interesting to see whether changes in fatty acid composition are related to any qualitative changes in sterols in the nystatin-resistant mutant. The effects of supplementing LM-cell mouse fibroblasts with different cholesterol analogues have shown that secondary changes in fatty acid composition occur, probably to prevent phase separation, since different sterols partition to varying extents among different phospholipid domains (19-21). However, it appears from the present results that there is a coordinated regulation of sterol, phospholipid and fatty acid composition in *A. niger* that is reflected in the altered physical properties of the conidial lipids of the nystatin-resistant mutant.

A preliminary effort to explore the effect of altered lipid composition as a result of sterol depletion on the biochemical functions of the mutant was made by studying the transport of two acidic, one neutral and one basic amino acid in both the wild type and the mutant. Our results show that the transport of different amino acids is affected to different extents by altered sterol content and overall changes in lipid composition associated with nystatin-resistance in *A. niger.* Since different permeases are known to be responsible for uptake of different amino acids in *Aspergillus* species (22-24), results of the present study suggest that these permeases, by virtue of occupying different microenvironments in the lipid bilayer, are affected to different extents by changes in lipid composition. However, in general, there is a change in membrane permeability as evidenced from the increased V_{max} values for uptake of lysine, leucine and aspartic acid in the mutant as compared to the wild type. These results agree with the findings of several workers with both artificial and natural cellular membranes that altered sterol levels lead to a change in membrane permeability and in membrane-associated functions such as the activities of membrane-bound enzymes (25-29).

[Received February 23, 1987]

Interaction of (n-3) and (n-6) Fatty Acids in Desaturation and Chain Elongation of Essential Fatty Acids in Cultured Glioma Cells

Harold W. Cook* and **Matthew W. Spence**
Departments of Pediatrics and Biochemistry and Atlantic Research Centre for Mental Retardation, Dalhousie University, Halifax, Nova Scotia, B3H 4H7, Canada

Recent research in various biological systems has revived interest in interactions between the (n-6) and (n-3) essential fatty acids. We have utilized cultured glioma cells to show that linolenic acid, 18:3(n-3), is rapidly desaturated and chain elongated; 20:5(n-3) is the major product and accumulates almost exclusively in phospholipids. We examined effects of various (n-6), (n-3), (n-9) and (n-7) fatty acids at 40 μM concentration on desaturation and chain elongation processes using [1-^{14}C]18:3(n-3) as substrate. In general, monoenoic fatty acids were without effect. The (n-6) fatty acids (18:2, 18:3, 20:3, 20:4 and 22:4) had little effect on total product formed. There was a shift of labeled product to triacylglycerol, and in phospholipids, slightly enhanced conversion of 20:5 to 22:5 was evident. In contrast, 22:6(n-3) was inhibitory, whereas 20:3(n-3) and 20:5(n-3) had much less effect. At concentrations <75 μM, all acids were inhibitory. Most products were esterified to phosphatidylcholine, but phosphatidylethanolamine also contained a major portion of 20:5 and 22:5. We provide a condensed overview of how the (n-6) and (n-3) fatty acids interact to modify relative rates of desaturation and chain elongation, depending on the essential fatty acid precursor. Thus, the balance between these dietary acids can markedly influence enzymes providing crucial membrane components and substrates for biologically active oxygenated derivatives.
Lipids 22: 613-619 (1987).

In recent years, there has been a renewed interest in linolenic acid [18:3(n-3)] and its metabolites and in the interactions between the (n-3) and (n-6) families of fatty acids in various biological systems (1-3). In particular, the (n-3) fatty acids that constitute a major portion of the polyunsaturated fatty acids in fish oils have been shown to have potential influences on lowering levels of circulating lipids (1-7), on platelet aggregation (4,8,9) and on the cardiovascular system in general (1,4,10). Much of this interest has arisen from studies with Greenland Eskimos, in which a correlation has been indicated between a lower incidence of coronary heart disease and longer bleeding times and their relatively high consumption of (n-3) fatty acids from marine sources compared to control populations (3,11,12). Recent evidence supports potential interaction of (n-3) acids with (n-6) fatty acids influencing the immune system (1,13) and tumor incidence and growth (14-16).

The relatively high levels of (n-3) acyl chains in the central nervous system, retina and testes (17) support a specific role for these acids in such specialized tissues. The (n-3) are less effective than (n-6) fatty acids in altering classical signs of essential fatty acid deficiency (1,2), indicating that they are not equivalent in their actions. A human case ascribed to deficiency of 18:3(n-3) has been reported (19), although concern has been expressed as to whether this was specific to the (n-3) acids (20,21).

On both nutritional and metabolic levels, much attention has focused on competition between the (n-3) and (n-6) families and resulting alterations in the products formed from them. Competition between (n-3) and (n-6) fatty acids for desaturation and chain elongation steps has been described in in vivo (22-25) and in vitro (25-30) experiments. The (n-3) acids, particularly eicosapentaenoic acid [20:5(n-3)], can compete with 20:4(n-6) in eicosanoid (e.g., prostaglandin and thromboxane) formation (31,32), can form products with different biological properties (e.g., leukotrienes) (33), or can produce products (e.g., prostacyclin I_3) with similar activating properties (10).

In previous studies, we used neuroblastoma and glioma cells in culture to examine the metabolism and interaction of (n-3) and (n-6) fatty acids in an experimental model system that can be carefully modulated and controlled. Both cell lines have the capacity for Δ6 and Δ5 desaturation and the alternating chain elongation steps involved in metabolism of these acids. With 18:2(n-6), the major products are 20:3(n-6) and 20:4(n-6), and with 18:3(n-3) the major product is 20:5(n-3), with lesser amounts of 20:4(n-3) and 22:5(n-3). No 22:6(n-3) (docosahexaenoic acid) is formed due to an absence of Δ4 desaturase in these transformed cells. We have described the relative metabolism and distribution of the substrates and products in intracellular lipids (34), major differences in the alteration of 18:2(n-6) metabolism by various unlabeled fatty acids (35), some aspects of the mechanism of activation of 18:2(n-6) metabolism (36) and the kinetics of the subcellular distribution and turnover of 18:2(n-6) (37).

In the present study, we examined desaturation, chain elongation and esterification of 18:3(n-3) and its derivatives and the effects of a variety of monoenoic, (n-3) and (n-6) fatty acids on these processes. These results have been combined with previous observations to provide a condensed overview of the complex interactions between these two families of essential fatty acids.

MATERIALS AND METHODS

Materials. All chemicals and reagents used were of the finest grade obtained from commercial suppliers. [1-^{14}C]-18:3(n-3) (55 mCi/mmol) and [1-^{14}C]18:2(n-6) (59 mCi/mmol) were purchased from DuPont Canada Inc. (NEN Products, Lachine, Quebec). Purity of these acids, determined by several analytical procedures described previously (38), was >97%. Nonradioactive fatty acids, lysophosphatidylcholine and other lipid standards were purchased from Serdary Research Laboratories (London, ON), Sigma Chemical Co. (St. Louis, MO) and Supelco (Bellefonte, PA). [^{3}H-Methyl]lysophosphatidylcholine, obtained as a by-product of synthesis of [^{3}H-methyl]sphingomyelin, was purified and characterized (>97.5% pure) using replicate

thin layer chromatographic (TLC) development as previously described (39). Fatty acid solutions (20 mg/ml) were maintained under N_2, and purity was monitored by gas liquid chromatography (GLC) of methyl esters. All solvents were high performance liquid chromatography grade from Fisher.

Glioma cell cultures. C-6 glioma cell lines were maintained in 150-cm² flasks (Corning Glass Works, Corning, NY) in 45 ml Dulbecco's modified Eagle's medium containing 10% fetal bovine serum (Gibco Canada Ltd., Burlington, ON) and penicillin: streptomycin solution (100 units and 100 μg/ml, respectively) (35). Cells were maintained at 37 C in a humidified atmosphere of 95% air/5% CO_2 and were subcultured every 5–7 days. For incorporation and metabolism studies, cells were transferred to 60-mm diameter dishes at a density of 0.5–1.0 × 10^6 cells in 5 ml medium. After 72 hr the medium was removed and replaced with 2.0 ml Dulbecco's modified Eagle's medium without fetal bovine serum. After another 24 hr, mixtures of [1-^{14}C]fatty acids and unlabeled fatty acid suspended by sonication at 37 C in sterile 5% bovine serum albumin were added in a 100-μl volume to give a final fatty acid concentration of 2 μM (2 × 10^6 dpm) for the [1-^{14}C]fatty acid and 40 μM for the unlabeled fatty acids (unless otherwise specified). Cells were incubated for 2 or 4 hr at 37 C.

Extraction and analysis of lipids. Details of the extraction and analyses procedures have been published previously (35,37,40,41). In brief, after incubation the cells were harvested, washed with phosphate-buffered saline and centrifuged. An aliquot was removed for analysis of protein by the method of Lowry et al. (42) with bovine serum albumin as standard; an aliquot of medium and cell washes were counted for total medium radioactivity. The cell pellet was extracted and radioactivity in an aliquot of extract quantitated by liquid scintillation counting. The lipid extract was separated into neutral lipid and phospholipid fractions by silicic acid chromatography and further resolved by TLC (41). Fatty acyl methyl esters were separated and quantitated using radio-GLC and a radioactivity flow monitor as described (35,43).

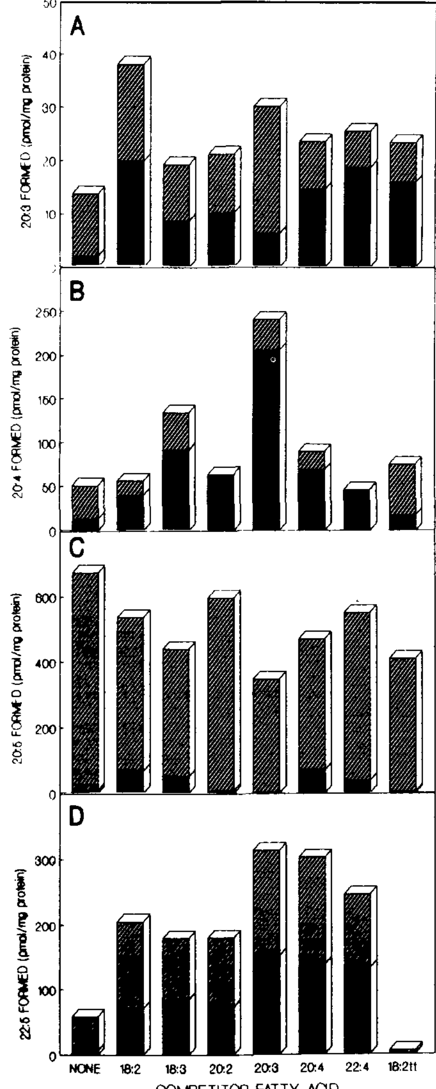

FIG. 1. Influence of various unlabeled (n-6) fatty acids on the formation of individual products by desaturation and chain elongation of [1-^{14}C]18:3(n-3) in cultured glioma cells. Cells were incubated for 2 hr with 0.5 μCi [1-^{14}C]18:3(n-3) and 40 μM unlabeled fatty acid as indicated under each bar along the horizontal axis. For controls no exogenous unlabeled fatty acid was added. Cells were extracted and lipids were fractionated on silicic acid columns. Neutral lipid and phospholipid fractions were transesterified and fatty acid methyl esters were analyzed by radio gas liquid chromatography. (A) Label in 20:3; (B) label in 20:4; (C) label in 20:5; (D) label in 22:5. Solid bar, neutral lipid; shaded bar, phospholipid. Values are the mean for the following replicate experiments: control (none), n = 14; 20:4(n-6), n = 10; 18:2(n-6), n = 8; all others, n = 4. In the fatty acid abbreviations, the number before the colon designates the number of carbon atoms in the acyl chain and the number following the colon indicates the number of double bonds. The (n-X) nomenclature designates the position of the first double bond from the methyl end (for more details see ref. 44); t indicates *trans* double bonds; all others are *cis* double bonds.

RESULTS

Effects of various fatty acids on 18:3(n-3) metabolism. When C-6 glioma cells were incubated with 2 μM [1-^{14}C]18:3(n-3), the labeled fatty acid was rapidly incorporated into the cell; uptake within 2 and 4 hr was 69% and 81% of total incubated fatty acid, respectively. In the neutral lipid fraction, >95% of the label was in triacylglycerol, and free fatty acid accounted for <2% of the label. As previous studies with [1-^{14}C]18:2(n-6) as substrate (35,36) had shown that 40 μM of stimulatory fatty acids gave maximal increase in desaturation, chain elongation and esterification, fatty acids were examined at 40 μM for their effect on metabolism of [1-^{14}C]18:3(n-3). Unlabeled fatty acid reduced total uptake of label by 5–20% at 2 hr, but by 4 hr consistently gave <10% reduction. All unlabeled fatty acids produced a greater incorporation into the neutral lipid fraction.

When competing unlabeled fatty acids were grouped [i.e., (n-6) acids compared to (n-3) acids], distinctly different effects on the metabolism of [1-^{14}C]18:3(n-3) were noted (summation of all products in Figs. 1 and 2). The (n-6) fatty acids gave very little change in total product formed, although there was greater esterification to triacylglycerol. An exception was the *trans,trans*-isomer of 18:2(n-6), which reduced product formation and esterification to phospholipid by >30%. Of the (n-3) acids

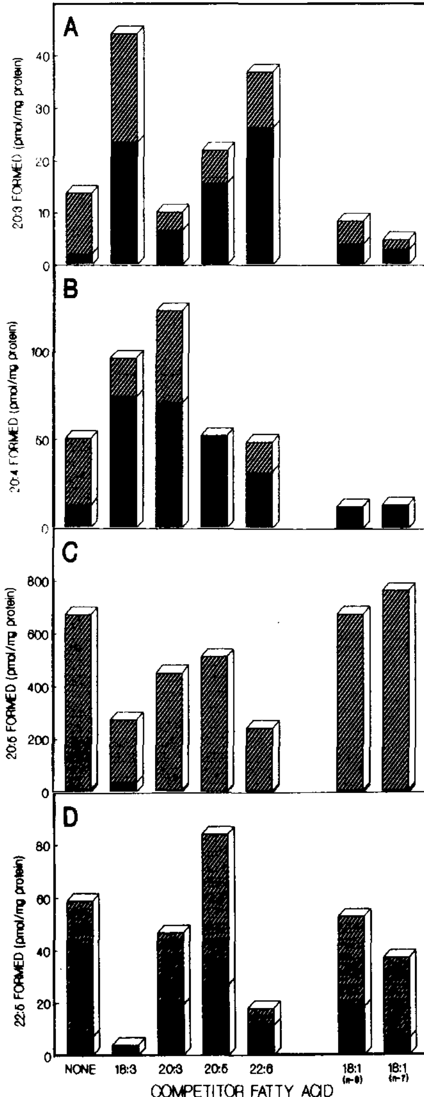

FIG. 2. Influence of various (n-3) and monoenoic fatty acids on the formation of individual products by desaturation and chain elongation of [1-^{14}C]18:3(n-3). Fatty acid methyl esters were obtained and analyzed as described for Fig. 1. (A) Label in 20:3; (B) label in 20:4; (C) label in 20:5; (D) label in 22:5. Solid bar, neutral lipid; shaded bar, phospholipid. Values are the mean for the following replicate experiments: control (none), n = 14; 18:3(n-3) and 22:6(n-3), n = 6; all others, n = 4.

tested, 18:3(n-3) and 22:6(n-3) gave the greatest reduction. [For comparison, unlabeled 18:3(n-3) has been treated as any other competitor, although "substrate or isotope dilution" is primarily responsible for the greater esterification of unaltered labeled substrate to neutral lipid and an overall reduction in product formation.] The 20:3(n-3) and 20:5(n-3) fatty acids were less inhibitory to product formation, but did reduce the amount of product esterified to phospholipid by >25%. The amount of product esterified to triacylglycerol was less in the presence of (n-3) acids than with (n-6) acids. 18-Carbon monoenoic isomers [oleic acid, 18:1(n-9), and *cis*-vaccenic acid, 18:1(n-7)] had very little influence on product formation and relative esterification.

The effects of various unlabeled fatty acids on the accumulation and esterification of individual products from [1-^{14}C]18:3(n-3) are shown in Figure 1 [unlabeled (n-6) fatty acids] and Figure 2 [unlabeled (n-3) fatty acids, 18:1(n-9) and 18:1(n-7)]. Labeled 20:5(n-3) accounted for >85% of the product formed in control incubations and even for the most altered condition accounted for >50% of total product. This major product was esterified almost exclusively to phospholipid. All (n-6) and (n-3) competitor acids reduced accumulation of labeled 20:5(n-3); exceptions were the two monoenoic isomers. The second most abundant labeled product was 22:5 formed by chain elongation of labeled 20:5. Except for *trans,trans*-18:2(n-6), which was markedly inhibitory to labeled 22:5 formation, all (n-6) acids increased formation of 22:5 and its esterification to both phospholipid and neutral lipid, particularly the latter. Accumulation of other labeled products (20:3 and 20:4) was altered variably. Labeled 20:3 was increased by all (n-6) acids, but at maximal stimulation this accounted for <4% of total labeled product. Unlabeled 20:3(n-6) gave a major increase in the accumulation of labeled 20:4 in the neutral lipid fraction.

The unlabeled (n-3) acids all reduced accumulation of labeled 20:5 in phospholipids (Fig. 2). Formation and esterification of labeled 22:5 to neutral lipid increased with all unlabeled (n-3) acids. All (n-3) acids gave increased levels of labeled 20:3 and 20:4, particularly in the neutral lipid fraction. In most of these studies, 18:4 was not well resolved from the [1-^{14}C]18:3(n-3) substrate peak in radio-GLC analyses, appearing as a shoulder that was not reliably quantitated. At most, labeled 18:4 accounted for <4% of the product. Only with unlabeled 20:3(n-6) or 20:3(n-3) was there evidence of increased accumulation of labeled 18:4 in phospholipid (twofold) and neutral lipid (four- to sixfold).

Effects of varying the concentration of fatty acids on [1-^{14}C]18:3(n-3) and [1-^{14}C]18:2(n-6) metabolism. Several unlabeled fatty acids were examined over a concentration range of 10–200 μM for effects on [1-^{14}C]18:3(n-3) metabolism. All unlabeled acids decreased product formation and esterification to phospholipid in a concentration dependent manner. The most inhibitory was the 22:6(n-3), producing >85% inhibition of total product formation at 200 μM. In contrast, 20:3(n-3) was least inhibitory over the concentration range tested. Unlabeled 20:4(n-6) gave a dramatic shift of total product to the neutral lipid fraction but altered total product formation by <15%. Other unlabeled acids all exhibited their primary effect on neutral lipid labeling at 40 μM or less. When individual labeled products in the phospholipids were examined (Fig. 3), a concentration-dependent decrease in labeled 20:5 was seen. The enhanced formation of labeled 22:5 seen with unlabeled 18:3(n-6) or 20:4(n-6) decreased at concentrations >40 μM.

In previous studies (35,36), the influence of a wide variety of fatty acids on the metabolism of [1-^{14}C]18:2(n-6) was tested, but in those studies 20:5(n-3) was not examined. In the present study, markedly different effects of varying concentrations of the two unlabeled fatty acids, 20:3(n-3) and 20:5(n-3), were observed when the metabolisms of [1-^{14}C]18:3(n-3) and [1-^{14}C]18:2(n-6) were compared (Fig. 4). Alteration of labeled 18:2(n-6) metabolism required >40 μM concentrations of these two unlabeled acids, whereas inhibition of [1-^{14}C]18:3(n-3)

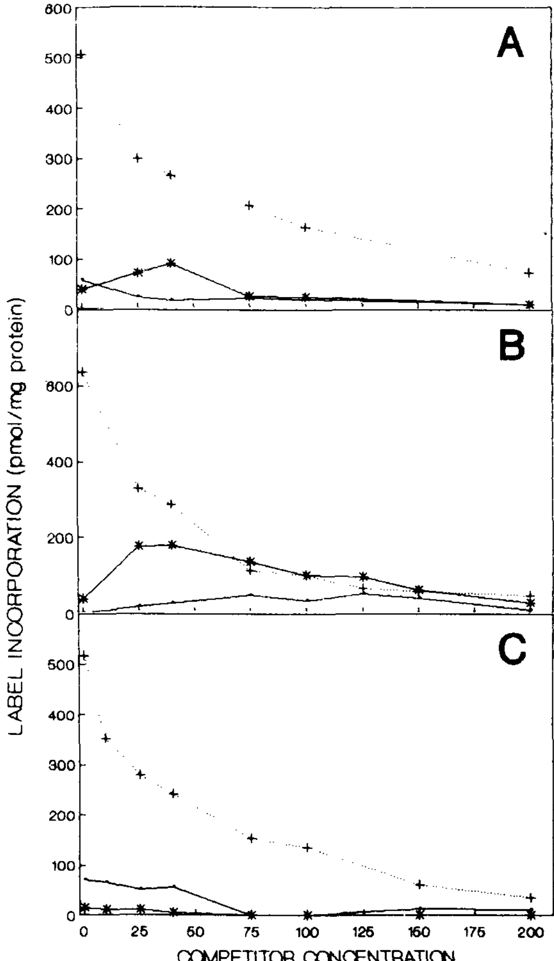

FIG. 3. **Influence of varying concentrations of fatty acids on the formation of individual products from [1-^{14}C]18:3(n-3) and their esterification to phospholipid. Glioma cells were incubated for 2 hr with 1 μCi [1-^{14}C]18:3(n-3) and various concentrations of unlabeled fatty acids. Lipid extracts were separated on silicic acid columns. Fatty acid methyl esters obtained from the neutral lipid and phospholipid fractions were analyzed by radio gas liquid chromatography. (A) Unlabeled 18:3(n-6) as competitor; (B) 20:4(n-6) as competitor; (C) 22:6(n-3) as competitor. Label in 20:4, —●—; label in 20:5, ···+···; label in 22:5, —*—.**

metabolism was observed even at the lowest concentration tested.

Product distribution in individual lipids and the influence of lysophosphatidylcholine. When distribution of products in individual lipids was examined (Fig. 5), most of the label was found in phosphatidylcholine; this was slightly reduced in the presence of unlabeled 20:4(n-6). Phosphatidylethanolamine also contained a large portion of the product, particularly 22:5. Triacylglycerol (panel E) contained similar amounts of each of the products, and esterification to triacylglycerol was increased in the presence of 40 μM 20:4(n-6). With 40 μM [^{3}H]lysophosphatidylcholine in the incubation, 9–13% of the [^{3}H]label from lysophosphatidylcholine was incorporated into the cell lipid extract; of this, >87% was in phosphatidylcholine. The presence of lysophosphatidylcholine had relatively little influence on the formation and esterification of products; there was a slight increase (6–16%) in label esterified to phosphatidylcholine, with corresponding slight decrease in label in phosphatidylethanolamine and triacylglycerol.

DISCUSSION

Complex interactions between fatty acids of the (n-3) and (n-6) polyunsaturated families have been shown in the desaturation, chain elongation and esterification reactions in our cultured glioma cells. Condensed summaries of the results of this and our previous studies (35,36) are presented in Table 1 (incorporation into phospholipid) and Table 2 (incorporation into neutral lipid). Previously we

Results are shown for 40 μM competitor fatty acid. Control values are for 4 hr incubations with 18:2(n-6) as substrate and for 2 hr incubation with 18:3(n-3). —, No change (<±10%); ↑, 1.1- to 1.5-fold increase; ↑↑, >1.5-fold increase; ↓, 10–30% decrease; ↓↓, 30–95% decrease.

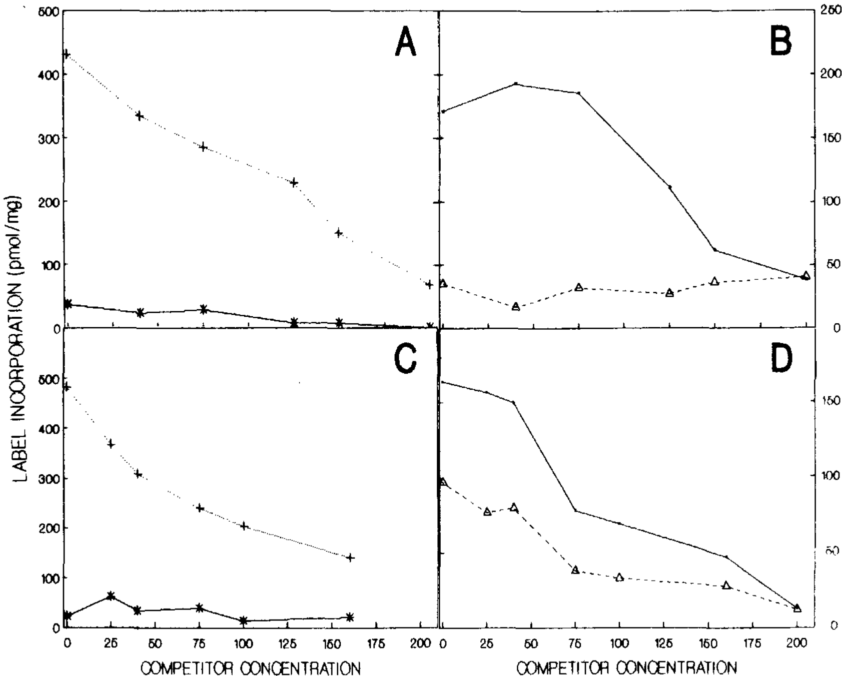

FIG. 4. Influence of varying concentrations of 20:3(n-3) or 20:5(n-3) on the metabolism of [1-^{14}C]18:3(n-3) or [1-^{14}C]18:2(n-6) in glioma cells. Cells were incubated with 1 μCi [1-^{14}C]18:3(n-3) (panels A and C) for 2 hr or with 1 μCi [1-^{14}C]18:2(n-6) (panels B and D) for 4 hr in the presence of varying concentrations of 20:3(n-3) (panels A and B) or 20:5(n-3) (panels C and D). Lipids were extracted, separated on silicic acid columns, transesterified and analyzed by radio gas liquid chromatography. Labeled products in the phospholipid fraction were 20:3, — —△— —; 20:4, —●—; 20:5, ····+····; 22:5, —*—.

investigated potential mechanisms behind the marked stimulation of 18:2(n-6) metabolism by (n-6) fatty acids (36). We concluded that only part of the interaction may relate to the relative availability of phospholipid and neutral lipid acceptors and competition for these acceptors by a mixture of fatty acid isomers. Triacylglycerol appears to serve as a preferred donor of acyl chains for further desaturation and chain elongation. However, we also concluded that there must also be a highly specific effect of certain individual fatty acid isomers on the functional desaturation-chain elongation-esterification complex; some fatty acids with similar specificities for esterification to phospholipid and neutral lipid [e.g., 20:3(n-6) and 20:3(n-3)] have markedly different effects on the desaturation and chain elongation of 18:2(n-6).

In this study, we concentrated on the metabolism of 18:3(n-3). The major product of desaturation and chain elongation of 18:3(n-3) in glioma cells was 20:5, which was almost exclusively esterified to phospholipids, even when the distribution of other products markedly shifted to triacylglycerol. On a quantitative basis, 20:5 showed the largest change in the presence of other fatty acids, although in some instances greater changes relative to control values were seen with the minor products. The (n-6) fatty acids had little effect on total product formation but appeared to be better competitors for a limited phospholipid pool, diverting products from phospholipid to triacylglycerol. There was an increased accumulation of 22:5 with an approximately corresponding decrease in 20:5. The 20:3(n-6) appeared to have somewhat special properties as a competitor acid in that it markedly lowered 20:5 accumulation and enhanced 20:3, 20:4 and 22:5 accumulation, the latter to levels almost equivalent to 20:5. Accordingly, even within families, fatty acids differing only by the number of double bonds had markedly different effects.

The effects of individual acids seemed even more specific to the (n-3) fatty acids. Primarily by isotope or substrate dilution, exogenous 18:3(n-3) reduced accumulation of products in phospholipid with some increase in esterification of 20:3, 20:4 and 20:5 to triacylglycerol. [This is in distinct contrast to the marked substrate stimulation seen with 18:2(n-6) metabolism, where addition of 40 μM unlabeled 18:2(n-6) gave a three- to sixfold stimulation; 35,36.] The 20:3(n-3) decreased product formation from 18:3(n-3) but caused some accumulation of 20:4 in both phospholipid and neutral lipid, unlike its distinctive lack of effect on 18:2(n-6) metabolism. The 20:5(n-3) slightly decreased all of the products of 18:3(n-3) metabolism except for 22:5.

The most highly unsaturated fatty acid that accumulates from 18:3(n-3) metabolism in most tissues (but not in our transformed glioma cells) is 22:6(n-3). When supplied in the culture medium, this fatty acid was inhibitory at all concentrations tested. This inhibition, seen in other studies (33), represents a dramatic example of end-product feedback in the case with 18:3(n-3) as substrate, but also represents general inhibition as seen with 18:2(n-6) as substrate. (Special precautions were taken to avoid oxidation of this fatty acid, and three different commercial preparations were tested with similar results.)

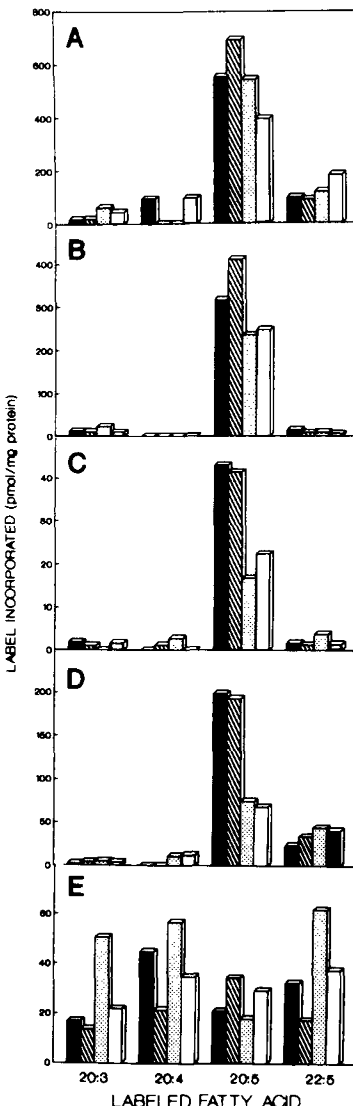

FIG. 5. Influence of lysophosphatidylcholine and 20:4(n-6) on the metabolism of [1-^{14}C]18:3(n-3) and distribution in various lipid fractions in glioma cells. Cells were incubated for 2 hr with 1 μCi [1-^{14}C]18:3(n-3) with the following additions to the medium: solid bar, control—no lysophosphatidylcholine or 20:4(n-6) added; hatched bar, 40 μM [^{3}H-methyl]lysophosphatidylcholine (2.5 μCi); dotted bar, 40 μM 20:4(n-6); open bar, 40 μM [^{3}H-methyl]lysophosphatidylcholine and 40 μM 20:4(n-6). Lysophosphatidylcholine and 20:4(n-6) were suspended in bovine serum albumin as described in Materials and Methods. Lipids were extracted and an aliquot was transesterified. The remainder was separated on thin layer chromatography; individual lipids were transesterified and methyl esters were analyzed on radio gas liquid chromatography. Labeled products are shown on the X-axis. (A) Label in total lipid; (B) label in phosphatidylcholine; (C) label in phosphatidylinositol; (D) label in phosphatidylethanolamine; (E) label in triacylglycerol.

Studies in experimental animals have indicated that the relative proportion of (n-6) and (n-3) fatty acids influences plasma and tissue lipid composition not only directly, by providing acyl chains for esterification to complex lipids, but also by altering the relative rates of conversion of fatty acids of the other family by desaturation and/or chain elongation. For example, an inverse relationship between 20:5(n-3) [but not 22:6(n-3)] and the ratio of 20:4(n-6) to 20:3(n-6) in plasma and liver lipids has been reported (23); the authors proposed that it is the 20:5(n-3) but not the 22:6(n-3) in fish oil that exerts an inhibitory effect on the conversion of 20:3(n-6) to 20:4(n-6). Such does not appear to be the case in our cells; 22:6(n-3) was strongly inhibitory and 20:5(n-3) had little effect on 18:2(n-6) conversion.

It is difficult to assign primary effects of competitive fatty acids specifically to an individual step in the desaturation-chain elongation-esterification sequence when a concerted action of these enzymes (35,36) may be involved. It appears that with 18:3(n-3) as substrate, an influence may occur at the Δ5 desaturation step resulting in a reduction in accumulation of 20:5, normally the major product, but enhanced chain elongation of 20:5 to 22:5 also contributes to this reduction. This contrasts with 18:2(n-6) metabolism, where overall product formation was enhanced as much as 10-fold (35) and Δ5 desaturation appeared to be stimulated. However, specific studies with [1-^{14}C]20:3(n-6) as substrate (35) did not directly support this; competitor acids had little effect compared to their major influences on the overall conversion of 18:2(n-6) to 20:4(n-6). On the other hand, accumulation of individual products seems to be greatly enhanced by the presence of exogenous precursors, suggesting that in some instances a particular step may be modulated. In the case of an end-product, such as 22:6(n-3), accumulation of each product or intermediate is reduced. Overall, the individual fatty acids seem to have greater influence than the availability of potential glyceride acceptors of the acyl chain products (such as lysophosphatidylcholine), although it may be that in the latter case the intracellular location of the appropriate form of the acyl chain acceptor may determine its effectiveness in altering 18:2(n-6) (36) or 18:3(n-3) metabolism.

In conclusion, our studies using radiolabeled substrates and unlabeled fatty acid competitors in intact cells have shown that the two families of (n-6) and (n-3) fatty acids interact differently to influence accumulation of different products or intermediates of desaturation and chain elongation, depending on the essential fatty acid precursor. Accordingly, the balance of these dietary fatty acids can markedly influence enzymes providing crucial membrane components and substrates for a variety of oxygenated, biologically active derivatives.

Labeled Oxidation Products from [1-^{14}C], [U-^{14}C] and [16-^{14}C]-Palmitate in Hepatocytes and Mitochondria

Chris Chatzidakis[a] and **David A. Otto**[a,b,*]

[a]Graduate Program in Nutrition, Rutgers, The State University of New Jersey, New Brunswick, New Jersey and [b]Department of Medical Education, Division of Research, The Baptist Medical Centers, Birmingham, Alabama

When [1-^{14}C], [U-^{14}C], and [16-^{14}C]palmitate were oxidized by isolated rat hepatocytes, there was a differential distribution of label as a percent of total oxidized products, such that $^{14}CO_2$ from [1-^{14}C] > [U-^{14}C] > [16-^{14}C]-palmitate and acid-soluble radioactivity from [16-^{14}C] > [U-^{14}C] > [1-^{14}C]palmitate. The oxidation of [2,3-^{14}C]succinate to $^{14}CO_2$ by isolated hepatocytes was only 9.1% of that from [1,4-^{14}C]succinate, demonstrating that the differences in distribution of labeled products are in part due to less $^{14}CO_2$ production from label in the even carbon positions entering the citric acid cycle. Apparent total ketone body production from [16-^{14}C]palmitate was markedly higher than [1-^{14}C] and [U-^{14}C]palmitate. In addition, the ^{14}C-acetone:$^{14}CO_2$ ratio derived from decarboxylation of labeled acetoacetate from [1-^{14}C]palmitate was less than 1 and positively correlated to the rate of fatty acid oxidation in hepatocytes. These findings indicate that the known preferential incorporation of the omega-C_2 unit of fatty acids into ^{14}C-ketone bodies also contributed to the differential distribution of labeled products and that this contribution was greatest at the lower rates of fatty acid oxidation. In isolated mitochondria, the distribution of label to $^{14}CO_2$ and acid-soluble radioactivity from [1-^{14}C], [U-^{14}C] and [16-^{14}C]palmitate was qualitatively similar to that seen with hepatocytes. The distribution of label from [1-^{14}C]acetylcarnitine to $^{14}CO_2$ and ^{14}C-ketone bodies by mitochondria was identical to that observed from [1-^{14}C]palmitate, indicating that the higher rates of $^{14}CO_2$ production from [1-^{14}C]palmitate cannot be explained by a preferential oxidation in the citric acid cycle of either extramitochondrial acetyl-CoA (generated in peroxisomes) or the carboxyl terminal of the fatty acid. As shown by others in cell-free systems, we observed that the total oxidation of [16-^{14}C]palmitate by hepatocytes and mitochondria was significantly less than [1-^{14}C] and [U-^{14}C]palmitate, suggesting either incomplete mitochondrial β-oxidation or incomplete degradation of peroxisomal oxidation products. The data indicate that this incomplete oxidation does not, however, contribute to the differential distribution of label to oxidized products.

Lipids 22, 620-626 (1987).

Fatty acids labeled in different carbon positions are commonly used to study the distribution of labeled oxidation products. In a preliminary study (1), we observed major differences in the distribution of label into CO_2 and acid-soluble products when [1-^{14}C], [U-^{14}C] and [16-^{14}C]palmitate were incubated with isolated hepatocytes and mitochondria from rat liver. From these experiments, it was clear that different conclusions regarding the rate of fatty acid utilization might be reached, depending on the position of label in the fatty acid. This is particularly relevant to studies quantitating the rate of fatty acid oxidation through the accumulation of a single product, such as $^{14}CO_2$ or ^{14}C-ketone bodies. To understand our preliminary observations, we conducted a more detailed study of this phenomenon.

Observations similar to those made in our preliminary study have been made by others in whole homogenates, postnuclear and mitochondrial fractions of various tissues (2) and isolated rat hepatocytes (3,4). In 1954, Brown et al. (5), using palmitic acid labeled in various carbon positions, indicated that an odd carbon of palmitic acid produced more $^{14}CO_2$ than did an even carbon in rat liver slices. Other laboratories (3,4,6,7) confirmed these findings. Additionally, Weinman et al. (8) found that more $^{14}CO_2$ is generated by the citric acid cycle from [1-^{14}C]acetyl-CoA than from [2-^{14}C]acetyl-CoA, which would be derived from odd and even labeled fatty acid carbons, respectively.

An alternate pathway in the liver for fatty acid-derived acetyl-CoA is toward acetoacetate synthesis. In 1944, Weinhouse et al. (9) reported that the incubation of [1-^{14}C]octanoate with rat liver slices produced acetoacetate labeled equally in the carboxyl and carbonyl carbons. Crandall et al. (10) showed that octanoate labeled in different carbon atoms gives rise to two different types of C_2 units. It was proposed that all C_2 units derived from a fatty acid chain, except the terminal C_2 units from the methyl end, are metabolically equivalent (11). Subsequent studies (12-17) demonstrated that the omega-terminal C_2 unit of fatty acids labeled in odd and even numbered carbons and of different chain lengths are preferentially incorporated into ketone bodies.

In the present investigation, we have looked in a single combined study at previously, but separately, studied phenomena to determine the contribution of each to the unequal distribution of labeled oxidation products from differentially labeled fatty acids. Additionally, these experiments bring to focus potential problems in the proper interpretation of data from labeled fatty acids in studies of fatty acid oxidation. These are problems that can lead to erroneous conclusions if the limitations of the methodology are not understood. Our studies also allow us to comment on the suitability of differentially labeled fatty acids for the study of fatty acid oxidation.

MATERIALS AND METHODS

Materials. ATP, NAD$^+$, coenzyme A, 3-hydroxybutyrate dehydrogenase, carnitine acetyl-transferase, malic dehydrogenase, DTT (dithiothreitol), MES [2-(N-morpholino) ethanesulfonic acid], palmitic acid and Tris (trizma base) were purchased from Sigma Chemical Co. (St. Louis, MO). [1-^{14}C], [U-^{14}C], [16-^{14}C]palmitate, [1-^{14}C]octanoate and [1,4-^{14}C], [2,3-^{14}C]succinic acid were purchased from New England Nuclear (Boston, MA). [1-^{14}C]acetyl-CoA was purchased from ICN Biochemicals (Irvine, CA). Bovine albumin (CRG-7, fatty acid-free) was from

*To whom correspondence should be addressed at Department of Medical Education, Division of Research, Baptist Medical Centers, 701 Princeton Ave., Birmingham, AL 35211.

Armour Pharmaceutical Co. (Tarrytown, NY). L-carnitine was generously provided by Dr. Yuzo Kawashima of the Otsuka Pharmaceutical Factory, Inc. (Tokushima, Japan). Hydrofluor was purchased from National Diagnostics (Somerville, NJ). All other chemicals were reagent grade.

Animals. Male Wistar rats (Charles River, Wilmington, MA) weighing 200–250 g at the time of use were maintained on Purina Rat Chow with free access to food and water. All animals were housed in rooms with controlled temperature and a 12 hr/12 hr, light/dark cycle (light from 7 a.m. to 7 p.m.).

Isolation and incubations of hepatocytes. Hepatocytes were prepared by the method of Berry and Friend (18), modified as described by others (19,20). To determine whether hepatocytes satisfied the criteria defined by Krebs et al. (20) for intact, metabolically active hepatocytes, ATP was measured (21) on the cell preparations. Hepatocytes (80–100 mg wet weight) were preincubated in a total volume of 1.5 ml for 45 min at 37 C in Krebs-Henseleit medium (22) containing 13.3 mM glucose, 13.3 mM lactate, 2.7 mM pyruvate and 1.3 mM L-carnitine under an atmosphere of 95% O_2/5% CO_2. Following preincubation, 0.5 ml of ^{14}C-palmitate/albumin complex in Krebs-Henseleit medium was added to a final concentration of 1.5 mM/4% (except where noted), bringing the final volume to 2.0 ml. Incubations after the addition of fatty acid were carried out for 15 min. Previous studies have indicated that this incubation system yields linear rates of fatty acid oxidation over the entire 15-min incubation period (23).

Isolation and incubation of liver mitochondria. Rat liver mitochondria were isolated from ad libitum-fed rats as previously described (24,25). The final pellet was resuspended in 0.25 M sucrose, 3 mM Tris/HCl (pH 7.4 at 4 C) to provide a concentration of ca. 20 mg of mitochondrial protein/ml. All mitochondrial preparations had a respiratory control ratio (26) above 5 with the substrates 5 mM glutamate plus 5 mM malate.

Mitochondria (ca. 5 mg of protein) were incubated at 37 C in a system of 94 mM sucrose, 60 mM KCl, 10 mM potassium phosphate, 5 mM Mg Cl_2, 3 mM ATP, 20 μM CoA, 1 mM DTT, 0.4 mM L-carnitine and 0.5 mM palmitate/1.5% albumin in a total volume of 2 ml at a pH of 7.1–7.2. Incubations were carried out for 15 min, during which time rates of fatty acid oxidation were linear (data not shown). Protein was measured according to Lowry et al. (27) with modifications (28).

Measurement of $^{14}CO_2$. Hepatocytes and mitochondria were incubated with the respective labeled substrates in sealed flasks that were fitted with centerwells containing folded filter paper. After incubations were terminated by the injection of 0.2 ml of cold 62.5% citric acid, 0.2 ml of 20% KOH was injected into the center wells (29). The sealed flasks were incubated at 37 C for an additional 1 hr to trap $^{14}CO_2$. The center wells were then removed and placed into scintillation vials containing 1 ml of H_2O and 10 ml of hydrofluor and were counted for radioactivity in a liquid scintillation counter.

Measurement of acid-soluble radioactivity and ^{14}C-ketone bodies. For the measurement of acid-soluble radioactivity and ^{14}C-ketone bodies, the reactions were terminated with 0.3 ml of cold 60% perchloric acid ($HClO_4$). Acid-soluble radioactivity was determined on hexane-washed perchloric acid extracts. After 0.5 ml of the $HClO_4$ extracts was removed for ^{14}C-ketone body determination, the remaining extracts were washed with 5 ml of hexane by vigorous shaking in tightly capped culture tubes and were centrifuged at 500 × g for 10 min. The top hexane layer was carefully aspirated and discarded. The extract was then washed for a second time following the same procedure. Hexane extraction removes any remaining ^{14}C-fatty acids. Aliquots of the washed extract were taken and counted for radioactivity. Total oxidized products refers to the sum of $^{14}CO_2$ plus the acid-soluble radioactivity.

The determination of ^{14}C radioactivity in ketone bodies was performed on neutralized (pH 6.0-6.5 with 4 M KOH, 0.25 M MES) perchloric acid extracts exactly by the method of Mewes et al. (30). This method allows for direct determination of radioactivity in the acetone and carboxyl moieties of acetoacetate after converting 3-hydroxybutyrate to acetoacetate in the presence of NAD^+ and 3-hydroxybutyrate dehydrogenase. After terminating the reaction with 5 N H_2SO_4, the acetoacetate formed was decarboxylated in sealed reaction vessels by heating to 100 C. The released ^{14}C-acetone and $^{14}CO_2$ were trapped in 1.5 ml of hydrazine lactate solution [10 ml of 90% DL-lactic acid + 4 ml of 100% hydrazine hydrate, pH 5–5.5 (30)] and 0.2 ml of 20% KOH, respectively, and counted for radioactivity. Statistical significance was determined using Student's t-test for unpaired data.

RESULTS AND DISCUSSION

The data in Table 1 demonstrate the differential distribution of label between $^{14}CO_2$ and acid-soluble radioactivity when isolated hepatocytes were incubated with [1-^{14}C], [U-^{14}C] and [16-^{14}C]palmitate. When expressed as a percent of total oxidized products, $^{14}CO_2$ production from [1-^{14}C] > [U-^{14}C] > [16-^{14}C]palmitate and the acid-soluble radioactivity from [16-^{14}C] > [U-^{14}C] > [1-^{14}C]palmitate. The total recoveries of label in products ($^{14}CO_2$ + acid soluble radioactivity) from [1-^{14}C] and [U-^{14}C]palmitate were not significantly different, indicating that both were oxidized at the same rate, but with different distribution of labeled carbon. Since ^{14}C-ketone body production from these fatty acids was also the same, these data suggest the difference was in the oxidation of labeled carbon entering the citric acid cycle. An experiment was conducted to determine if the difference in label distribution to $^{14}CO_2$ was the result of a lag in the rate of appearance of label in the even vs the odd carbon positions. We noted that the rate of appearance of $^{14}CO_2$ from [1-^{14}C] and [U-^{14}C]palmitate was linear throughout a 10-min incubation period, and the difference between the two labels (as observed in Table 1) was apparent from the earliest time point (0.5 min) to the end of the incubation period (data not shown). Therefore there is no lag in the appearance of label in the even vs the odd carbon positions, but these data do indicate that the system was in isotopic steady state. A single time point was measured in all subsequent experiments.

The apparent rate of total oxidation of [16-^{14}C]palmitate was significantly less than [1-^{14}C] and [U-^{14}C]palmitate, suggesting incompletely oxidation of the fatty acids. This is in contrast to earlier reports (3,4) where the total

TABLE 1

Distribution of Labeled Products from the Oxidation of [1-^{14}C], [U-^{14}C] and [16-^{14}C]Palmitate by Isolated Rat Hepatocytes

	Apparent rates of product production (nmol of ^{14}C-fatty acid converted to products/min/g cells)				
				^{14}C-Ketone bodies	
Substrate	$^{14}CO_2$	Acid-soluble radioactivity	Total oxidized products	Total production	^{14}C-Acetone:$^{14}CO_2$
1.5 mM [1-^{14}C]palmitate/4% albumin	38.2 ± 0.4 (15.6 ± 0.9%)	207.3 ± 13.6 (84.4 ± 0.9%)	245.5 ± 13.6	118.9 ± 11.7 (48.4 ± 6.3%)	0.81 ± 0.08
1.5 mM [U-^{14}C]palmitate/4% albumin	15.6 ± 0.7 (6.7 ± 0.5%)	217.3 ± 15.5 (93.3 ± 0.5%)	232.9 ± 15.5[a]	115.3 ± 0.1[a] (49.2 ± 4.4%)	2.91 ± 0.12
1.5 mM [16-^{14}C]palmitate/4% albumin	1.4 ± 0.3 (0.7 ± 0.2%)	199.9 ± 13.0 (99.3 ± 0.2%)	201.2 ± 12.8[b,c]	154.7 ± 21.0[b,c] (76.9 ± 9.7%)	—

Values are the mean of at least three separate hepatocyte preparations ± standard deviation. Values in parentheses represent the percentage of total oxidized products. Following a 45-min preincubation, heptocytes were incubated for 15 min at 37 C with the indicated fatty acid substrate as described in Materials and Methods.

[a]Not significantly different compared to [1-^{14}C]palmitate.

[b]Significantly different compared to [1-^{14}C]palmitate; $p < 0.01$.

[c]Significantly different compared to [U-^{14}C]palmitate; $p < 0.05$.

oxidation rates between [16-^{14}C] and [1-^{14}C]palmitate in isolated hepatocytes were found to be the same. A possible explanation for this discrepancy is that our incubation conditions and cell concentration differed from those used in these earlier studies.

Apparent total ketone body production from [16-^{14}C]-palmitate was much higher than that of [1-^{14}C] and [U-^{14}C]palmitate. These findings are consistent with earlier reports (12-17) that the last two carbons of fatty acids do not enter the acetyl-CoA pool but rather go preferentially to ketone body production. If the last two carbons of the fatty acid were preferentially incorporated into ketone bodies, these carbons would reside in the terminal methyl and carbonyl carbons of acetoacetate. That this occurs is supported by our observation that, in the presence of [1-^{14}C]palmitate, the ^{14}C-acetone:$^{14}CO_2$ ratio (the ratio of ^{14}C-acetone:$^{14}CO_2$ in the case of [1-^{14}C]-palmitate represents the distribution of label in the carbonyl vs the carboxyl carbons of acetoacetate) was less than 1 (0.81), suggesting a dilution of label in the carbonyl carbon of acetoacetate. The fact that the ^{14}C-acetone:$^{14}CO_2$ ratio with [U-^{14}C]palmitate was approximately equal to the theoretical ratio of 3 provides support for the validity of this method in the present study (see also Table 4).

The data of Table 1 also emphasize an important consideration when using fatty acids labeled in different carbon positions to measure rates of fatty acid oxidation. The calculation of true product production rates from labeled fatty acids requires that three basic assumptions be met: (i) that the labeled fatty acids (with the exception of those uniformly labeled) be completely oxidized; (ii) that all the labeled carbon undergoing β-oxidation enter a common acetyl-CoA pool before utilization (again, not a requirement of [U-^{14}C]palmitate), and (iii) that all labeled carbon, regardless of position, demonstrate the same distribution in the various products. Our data clearly show that these assumptions are not completely satisfied for any of the fatty acids used in these studies. Therefore, this must be considered when measuring rates of production of the individual products. In reference to this consideration, we have termed product production rates as "apparent" (see Tables 1 and 4). Since the data with [16-^{14}C]palmitate indicate that the oxidation is not complete, we have chosen to compare the distribution of labeled carbon between the differentially labeled fatty acids as a percent of total oxidized products (parentheses in Tables 1 and 4).

The experiments of Table 2 were conducted to determine whether the distribution of labeled products as shown in Table 1 could be explained, in part, by the position of the label in the fatty acid. We observed that $^{14}CO_2$ production from [2,3-^{14}C]succinate was only 9.1% of that from [1,4-^{14}C]succinate, a value that compares very favorably with that reported by Bessman et al. (31). It is known that several turns through the citric acid cycle would be required to convert all the label in [2,3-^{14}C]succinate to $^{14}CO_2$, compared to one turn for [1,4-^{14}C]succinate. In addition, Zaidise et al. (32) showed that about 95% of succinate utilized by hepatocytes does not complete one full turn through the citric acid cycle. Since [2,3-^{14}C]succinate would be derived from labeled carbon in the even position of the fatty acid ([U-^{14}C] and [16-^{14}C]palmitate) and [1,4-^{14}C]succinate from labeled carbon in the odd position ([1-^{14}C] and [U-^{14}C]palmitate), these data support the conclusion that the differences in the label distribution between [1-^{14}C], [U-^{14}C] and [16-^{14}C]palmitate are at least partially due to less $^{14}CO_2$ production from label in the even carbon positions of the fatty acid, with consequently more label remaining in the acid-soluble fraction.

However, if this were the only explanation, then based on the labeled succinate data one would expect $^{14}CO_2$ from [U-^{14}C] and [16-^{14}C]palmitate to be ca. 55% (50% + 0.5 × 9.1%) and 9.1%, respectively, of that from [1-^{14}C]palmitate (expressing $^{14}CO_2$ as a percentage of total oxidized products). $^{14}CO_2$ production from these fatty acids was less than expected (42.9% and 4.4%, respectively), indicating that other factors are involved in determining

TABLE 2

Comparison of $^{14}CO_2$ Production from Labeled Fatty Acid and Succinate by Isolated Hepatocytes

Substrate	$^{14}CO_2$ as percentage of total oxidized products[b]	DPM recovered as $^{14}CO_2$	$^{14}CO_2$ production as % of $^{14}CO_2$[a]	
			From [1-^{14}C]palmitate	From [1,4-^{14}C]succinate
1.5 mM [1-^{14}C]palmitate/4% albumin	15.6 ± 0.7%	—	100	—
1.5 mM [U-^{14}C]palmitate/4% albumin	6.7 ± 0.5%	—	42.9	—
1.5 mM [16-^{14}C]palmitate/4% albumin	0.7 ± 0.2%	—	4.4	—
1.5 mM palmitate/4% albumin and trace [1,4-^{14}C]succinate[c]	—	90,167 ± 8,798	—	100
1.5 mM palmitate/4% albumin and trace [2,3-^{14}C]succinate[c]	—	8,214 ± 298	—	9.1

Values from succinate experiments are the average of two experiments ± the range. Each experiment was conducted with triplicate incubations utilizing the same hepatocyte preparations of Table 1. Following a 45-min preincubation, hepatocytes were incubated for 15 min at 37 C with the indicated fatty acid and succinate substrate as described in Materials and Methods.

[a]Calculations were based upon the values for $^{14}CO_2$ from [1-^{14}C]palmitate and [1,4-^{14}C]succinate of columns one and two, respectively.

[b]Data taken from Table 1.

[c]Specific activities of [1,4-^{14}C] and [2,3-^{14}C]succinate were identical.

the distribution of labeled products between $^{14}CO_2$ and the acid-soluble pool. Taken together with the data of Table 1, it seems likely that the preferential use of the omega-terminal C_2 unit for ketone body synthesis provides an additional explanation for the differential distribution of labeled products.

Huth et al. (33) demonstrated that the [^{14}C]carbonyl/[^{14}C]carboxyl ratio of acetoacetate from [1-^{14}C] fatty acids was highest (approaching 1.0) in animals with metabolic states characterized by high rates of ketone body production. They indicated that changes in this ratio were positively correlated to changes in the activity of acetoacetyl-CoA thiolase in the reverse reaction. In other words, under metabolic states yielding low rates of ketone body production, the activity of acetoacetyl-CoA thiolase would be low and unable to equilibrate acetoacetyl-CoA (generated in β-oxidation from the last four carbons of the fatty acid) with the acetyl-CoA pool, and thus there would be direct use of the omega-terminal C_4 unit of the fatty acid for acetoacetate synthesis. With [1-^{14}C]palmitate, this would result in the unlabeled omega-terminal C_2 unit being incorporated into the carbonyl carbon of acetoacetate without first entering the common acetyl-CoA pool, causing a lower ^{14}C-acetone:$^{14}CO_2$ ratio.

To determine if this ratio would vary with respect to rates of fatty acid oxidation in isolated hepatocytes from animals in a single metabolic state, but incubated under different conditions (high fatty acid concentration ± glucagon and low fatty acid concentration), the experiments reported in Table 3 were conducted. In agreement with the observations of Huth et al. (33), these data show that the rate of fatty acid oxidation in hepatocytes is positively correlated with the ^{14}C-acetone:$^{14}CO_2$ ratio of acetoacetate. Even though this relationship is not statistically significant with the small sample size, there is clearly a trend for a decreasing ratio with a decrease in oxidation rate. These data provide additional evidence that the ^{14}C-acetone:$^{14}CO_2$ ratio reflects the degree of preferential incorporation of the omega-terminal C_2 unit of the fatty acid into ketone bodies.

The data in Table 4 show the distribution of labeled products from the oxidation of [1-^{14}C], [U-^{14}C] and [16-^{14}C]-palmitate in isolated rat liver mitochondria. The $^{14}CO_2$ from ^{14}C-palmitate was much less, as a percentage of the total oxidized products, than that seen in isolated hepatocytes (Table 1), indicating that acetyl-CoA generated from fatty acid oxidation in the absence of other substrates is directed principally toward ketone body synthesis. However, as seen with hepatocytes (Table 1), $^{14}CO_2$ from [1-^{14}C]palmitate is greater than that from [U-^{14}C] and [16-^{14}C]palmitate. Unlike hepatocytes, ^{14}C-ketone body synthesis, as a percent of total oxidized products, was not greater with [16-^{14}C]palmitate. This could be explained by the fact that the majority of label in these experiments is directed to ketone body synthesis, whether from the acetyl-CoA pool or the terminal C_2 unit of the fatty acid. The ^{14}C-acetone:$^{14}CO_2$ ratio of 0.79 for [1-^{14}C]palmitate does, however, support preferential use of the omega-terminal C_2 unit.

In isolated mitochondria (Table 4), both the total oxidation of [U-^{14}C]palmitate and [16-^{14}C]palmitate were significantly less than that of [1-^{14}C]palmitate. The data indicate that 21% of the fatty acid carbon entering β-oxidation was not completely oxidized to CO_2 or acid-soluble fragments {1 − (total oxidized products from [U-^{14}C]palmitate/total oxidized products from [1-^{14}C]-palmitate)}. Additionally, it can be calculated that 45% of the fatty acids entering β-oxidation were incompletely oxidized down to acid-insoluble fragments containing carbon 16 {1 − (total oxidized products from [16-^{14}C]palmitate/total oxidized products from [1-^{14}C]palmitate)}. Considering these two points together, it can be stated that at the end of the incubation, 21% of the fatty acid carbon starting β-oxidation remained in acid-insoluble fragments containing 45% of the starting carbon 16. The average length of these acid insoluble fragments can be calculated from the relationship, $0.21 = 0.45x$, where x is the average fractional length of the fragment, or ca. 0.5. Therefore, for a 16 carbon fatty acid, the average fragment length would be 8.

TABLE 3

Influence of the Rate of Fatty Acid Oxidation on the Ketone Body Acetone:CO_2 Ratio in Isolated Hepatocytes

Substrate	nmol [1-^{14}C]Palmitate converted to total oxidized products/min/g cells	Ketone body ^{14}C-acetone:$^{14}CO_2$ ratio[a]
1.5 mM [1-^{14}C]Palmitate/[b] 4% albumin + 2 μM glucagon	292.5 ± 51.0	0.92 ± 0.05
1.5 mM [1-^{14}C]Palmitate/[c] 4% albumin	245.5 ± 13.6	0.81 ± 0.08
0.5 mM [1-^{14}C]Palmitate/[d] 4% albumin	50.7 ± 8.8	0.74 ± 0.11

Values are expressed as the mean of at least three separate hepatocyte preparations ± standard deviation.

[a]A correlation coefficient of 0.889 was determined by linear regression analysis of the data, indicating the influence of the rate of total oxidation on the ketone body ^{14}C-acetone:$^{14}CO_2$ ratio.

[b]Following a 45-min preincubation in the presence of 1 μM glucagon and 1.33 mM L-carnitine, hepatocytes were incubated for 15 min at 37 C with 1.5 mM [1-^{14}C]palmitate plus an additional 1 μM glucagon.

[c]Data taken from Table 1.

[d]Following a 45-min preincubation in the presence of glucose, lactate, pyruvate, and carnitine, as described in Materials and Methods, hepatocytes were incubated for 15 min at 37 C with 0.5 mM [1-^{14}C]palmitate.

TABLE 4

Distribution of Labeled Products from the Oxidation of [1-^{14}C], [U-^{14}C] and [16-^{14}C]Palmitate in Isolated Rat Liver Mitochondria

	Apparent rates of product production (nmol converted to products/min/mg mitochondrial protein)				
				^{14}C-Ketone bodies	
Substrate	$^{14}CO_2$	Acid-soluble radioactivity	Total oxidized products	Total production	^{14}C-Acetone:$^{14}CO_2$
0.5 mM [1-^{14}C]Palmitate/1.5% albumin	0.07 ± 0.01 (1.3 ± 0.0%)	5.38 ± 0.41 (98.8 ± 0.1%)	5.45 ± 0.41	3.45 ± 0.28 (63.4 ± 5.6%)	0.79 ± 0.10
0.5 mM [U-^{14}C]Palmitate/1.5% albumin	0.03 ± 0.01 (0.7 ± 0.1%)	4.30 ± 0.34 (99.4 ± 0.1%)	4.33 ± 0.34[a]	2.86 ± 0.49 (66.0 ± 6.0%)[b]	3.06 ± 0.49
0.5 mM [16-^{14}C]Palmitate/1.5% albumin	0.01 ± 0.00 (0.3 ± 0.1%)	2.97 ± 0.42 (99.7 ± 0.0%)	2.98 ± 0.42[c,d]	1.86 ± 0.23 (62.4 ± 4.7%)[b]	—

Values are the mean of three separate mitochondrial isolations ± standard deviation. Values in parentheses represent the percent of total oxidized products. Mitochondria were incubated for 15 min at 37 C with the indicated fatty acid substrate as described in Materials and Methods.

[a]Significantly different compared to [1-^{14}C]palmitate; $p < 0.05$.

[b]Not significantly different compared to [1-^{14}C]palmitate.

[c]Significantly different compared to [1-^{14}C]palmitate; $p < 0.01$.

[d]Significantly different compared to [U-^{14}C]palmitate; $p < 0.05$.

It is interesting to note that octanoic acid and its CoA and carnitine esters have been reported to be only partially acid-soluble (34). We have found that hexane washing of perchloric acid extracts, under our conditions for preparing the acid soluble fraction, resulted in a loss of ca. 90% of labeled octanoate (data not shown). Thus, fatty acid fragments of 8 or more carbons would not be detected in the acid-soluble fraction. Since peroxisomal β-oxidation would specifically generate 8 carbon fragments (acyl moieties of 8 or fewer carbon atoms are not oxidized by peroxisomes [35]), our data is consistent with the suggestion that incomplete oxidation of palmitate observed in our studies was caused, at least to some extent, by an inadequate mitochondrial degradation of peroxisomal oxidation products. Veerkamp has made similar conclusions based upon work in cell-free systems (2). As we observed in Tables 1 and 4, one might expect from the above discussion that the differences between total oxidation of [1-^{14}C], [U-^{14}C] and [16-^{14}C]palmitate would be greater in isolated mitochondria than in hepatocytes, since the ability to transfer peroxisomal oxidation products to mitochondria should be diminished in the mitochondrial system. However, from our data, it cannot be ruled out that some, if not all, of the differences between total oxidation of differentially labeled palmitate were due to incomplete mitochondiral β-oxidation.

The data in Table 5 show the distribution of labeled products from the oxidation of [1-^{14}C]acetylcarnitine and

TABLE 5

Distribution of Labeled Products from the Oxidation of [1-^{14}C]Acetylcarnitine and [1-^{14}C]Palmitate in Isolated Rat Liver Mitochondria

Substrate	DPMs recovered as products		
	$^{14}CO_2$	^{14}C-Ketone bodies	$^{14}CO_2$:^{14}C-Ketone bodies
0.5 mM Palmitate/1.5% albumin and trace [1-^{14}C]acetyl-CoA plus 5.3 units of carnitine acetyltransferase [EC 2.3.1.7]	440 ± 13	16,404 ± 6,049	0.027 ± 0.012
0.5 mM [1-^{14}C]Palmitate/1.5% albumin plus 5.3 units of carnitine acetyltransferase	1,010 ± 6	43,642 ± 4,087	0.023 ± 0.002

Values are the mean of three replicates ± standard deviation from a representative experiment. Mitochondria were incubated for 15 min at 37 C with the indicated substrates. [1-^{14}C]Acetylcarnitine was produced during the incubation by the addition of [1-^{14}C]acetyl-CoA and carnitine acetyltransferase. 0.25 μCi of [1-^{14}C]acetyl-CoA was added.

[1-^{14}C]palmitate in isolated rat liver mitochondria. By measuring label appearing in $^{14}CO_2$ and ^{14}C-ketone bodies, we were able to determine whether acetyl-CoA generated extramitochondrially by peroxisomal oxidation and transported into the mitochondria enters the common acetyl-CoA pool or is preferentially directed toward the citric acid cycle. The latter possibility could offer an additional explanation for the higher rates of $^{14}CO_2$ production from [1-^{14}C] relative to [U-^{14}C] and [16-^{14}C]palmitate and from [U-^{14}C] relative to [16-^{14}C]palmitate. The data show, however, that both intra- and extramitochondrially generated acetyl-CoA are used equivalently, as indicated by the $^{14}CO_2$:^{14}C-ketone body ratios. This is in support of a single common acetyl-CoA pool. Even though the data of Table 4 suggest some contribution of peroxisomal oxidation to the overall rate, this does not appear to be involved in explaining the differential distribution of labeled oxidation products. These data also argue against the preferential use of acetyl units from the carboxyl terminal of [1-^{14}C]palmitate in the citric acid cycle.

CONCLUSIONS

The differential distribution of labeled products between [1-^{14}C], [U-^{14}C] and [16-^{14}C]palmitate in isolated rat hepatocytes and liver mitochondria can be explained (i) for the most part by the difference in $^{14}CO_2$ production from label in the odd or even carbon positions of fatty acid-derived acetyl-CoA entering the citric acid cycle and (ii) by the preferential incorporation of the omega-terminal C_2 unit of fatty acids into ketone bodies. (iii) The data support a single common mitochondrial acetyl-CoA pool regardless of whether the acetyl units are produced intra- or extramitochondrially. Therefore, the data are not consistent with an involvement of peroxisomal oxidation in the differential distribution of labeled products.

From these experiments we are also able to comment on the use of differentially labeled fatty acids for the study of fatty acid oxidation: (i) The use of [U-^{14}C]fatty acids gives the most accurate measurement of both the overall rate and extent of β-oxidation, particularly in mitochondrial and other cell-free systems in which oxidation may not be complete. It also best reflects incorporation of carbon into ketone bodies. However, citric acid cycle involvement would be underestimated. (ii) Use of [1-^{14}C]palmitate in our hepatocyte system gave data quite similar to [U-^{14}C]palmitate and more closely reflects citric acid cycle activity. (However, since cycle intermediates are continuously removed in a cellular system, it is unlikely that $^{14}CO_2$ production ever quantitatively reflects flux through this pathway.) Therefore, from a practical point of view, based on expense and availability, [1-^{14}C]fatty acids would be a better choice for studies of fatty acid oxidation in cells. In cell-free systems, however, one must consider the fact that fatty acid oxidation is probably not complete. It is clear from our data and that of others (2) that, regardless of the system or tissue used, one should always measure both $^{14}CO_2$ and acid-soluble radioactivity to determine accurate rates of *total* fatty acid oxidation. (iii) The use of [16-^{14}C]palmitate, or other omega-terminal labeled fatty acids for measuring the rate of fatty acid oxidation, is inappropriate due to the incomplete oxidation of fatty acids, especially in cell-free systems. Its use would also grossly underestimate $^{14}CO_2$ production and overestimate ^{14}C-ketone body production. However, combined with data obtained from [1-^{14}C] and [U-^{14}C]fatty acids, useful information on the degree of complete oxidation may be obtained, as illustrated in discussions above.

[Received January 14, 1987]

Cholesterol Autoxidation in Phospholipid Membrane Bilayers

Alex Sevanian* and **Laurie L. McLeod**
Institute for Toxicology and Department of Pathology, University of Southern California, School of Pharmacy, Los Angeles, California

Lipid peroxidation in unilamellar liposomes of known cholesterol-phospholipid composition was monitored under conditions of autoxidation or as induced by a superoxide radical generating system, γ-irradiation or cumene hydroperoxide. Formation of cholesterol oxidation products was indexed to the level of lipid peroxidation. The major cholesterol oxidation products identified were 7-keto-cholesterol, isomeric cholesterol 5,6-epoxides, isomeric 7-hydroperoxides and isomeric 3,7-cholestane diols. Other commonly encountered products included 3,5-cholestadiene-7-one and cholestane-3β,5α,6β-triol. Superoxide-dependent peroxidation required iron and produced a gradual increase in 7-keto-cholesterol and cholesterol epoxides. Cholesterol oxidation was greatest in liposomes containing high proportions of unsaturated phospholipid to cholesterol (4:1 molar ratio), intermediate with low phospholipid to cholesterol ratios (2:1) and least in liposomes prepared with dipalmitoylphosphatidylcholine and cholesterol. This relationship held regardless of the oxidizing conditions used. Cumene hydroperoxide-dependent lipid peroxidation and/or more prolonged oxidations with other oxidizing systems yielded a variety of products where cholesterol-5β,6β-epoxide, 7-ketocholesterol and the 7-hydroperoxides were most consistently elevated. Oxyradical initiation of lipid peroxidation produced a pattern of cholesterol oxidation products distinguishable from the pattern derived by cumene hydroperoxide-dependent peroxidation. Our findings indicate that cholesterol autoxidation in biological membranes is modeled by the peroxide-induced oxidation of liposomes bearing unsaturated fatty acids and suggest that a number of cholesterol oxidation products are derived from peroxide-dependent propagation reactions occurring in biomembranes.
Lipids 22, **627–636 (1987).**

The oxidation of cholesterol in biological systems has received considerable attention for many years. There is general agreement that cholesterol oxidation in cells can result from enzymatic processes, as well as from free radical-mediated membrane lipid peroxidation (1,2). The 7α-hydroxylation of cholesterol during bile acid synthesis (3) is an example of microsomal cytochrome P-450 catalyzed oxidation. In the presence of its cofactors NADPH and O_2, cytochrome P-450 monooxygenase catalyzes peroxidation of microsomal lipids (4–6). This lipid peroxidation is accompanied by cholesterol autoxidation with the formation of several products, including the isomeric cholest-5-ene-3β,7β- and cholest-5-ene-3β,7α-diols (3,7-diols) (4,5), with the latter contributing to the enzymatically derived cholest-5-ene-3β,7α-diol (3).

Free radical oxidation of cholesterol yields several products that are commonly encountered in tissues and microsomal preparations. The radical species responsible for cholesterol oxidation appear to derive from activated oxygen. Accordingly, specific radical generating systems, or defined dioxygen species, have been employed in cholesterol oxidation studies using membraneous and nonmembraneous preparations (7–12). Moreover, activated oxygen appears to be generated by cytochrome P-450 monoxygenase (13,14) with the induction of lipid peroxidation (14) and cholesterol oxidation (15).

A qualitative similarity is apparent among cholesterol oxidation products formed in several artificial systems as well as those isolated from peroxidized biomembranes. In many cases, the nature of oxidizing species remains ill defined, or in those instances where defined species were utilized, the matrix within which cholesterol oxidation took place differed from the organized state of lipids in biomembranes. A thorough review of cholesterol oxidation products formed in aqueous colloidal solutions vs products isolated from natural sources is presented by Smith (16).

Oxidation of cholesterol in model membranes has recently been described for iron-catalyzed (10,11) and hydrogen peroxide- or ultraviolet light-induced autoxidations (17). These studies employed long periods of imposed oxidation (up to 24 hr) and utilized phospholipids containing varying degrees of unsaturation. The model membranes were in the form of large multilamellar vesicles in two reports (10,11) and small unilamellar vesicles in the other (17). In the former studies the membrane arrangement likely permitted direct access of oxidants generated in the aqueous phase to only a small proportion of lipids. The later study was concerned primarily with the stability of cholesterol and the effect of antioxidants, whereas little attention was given to product formation.

In this report the identities of the major detectable oxidation products of cholesterol in unilamellar vesicles (liposomes) are described. In addition, specific free radical generating systems have been used to induce lipid peroxidation with subsequent examination of cholesterol oxidation products. These liposomes afford a reasonably exact formulation of lipid composition permitting a measure of control over the mode and extent of peroxidation, conditions that are not readily achieved using membranes from cells.

MATERIALS AND METHODS

Chemicals and reagents. Bovine liver phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were purchased from Sigma (St. Louis, MO), and the solvents in which they were delivered were evaporated under a stream of argon. These lipids were then stored in methylene chloride at a concentration 5 mg/ml under argon at −80 C.

Abbreviations: PC, phosphatidylcholine; PE, phosphatidylethanolamine; TBAR, thiobarbituric acid-reacting products; CuOOH, cumene hydroperoxide; HX, hypoxanthine; ADP, adenosine diphosphate; XO, xanthine oxidase; SOD, superoxide dismutase; TLC, thin layer chromatography; 7-keto, cholest-5-ene-3β-ol-7-one; 3,5-diene, 3,5-cholestadiene-7-one; α-CE, cholestan-5α,6α-epoxy-3β-ol; CT, 5α-6β-triol; 7-OOH, 3β-hydroxycholest-5-ene-7α-hydroperoxide; β-CE, cholestan-5β,6β-epoxy-3β-ol; HPLC, high pressure liquid chromatography; DPPC, dipalmitoylphosphatidylcholine; PI, peroxidizability index.

Various batches of these phospholipids were assayed for their content of thiobarbituric acid–reacting products (TBAR), and only samples containing no TBAR were used to prepare liposomes. Cumene hydroperoxide (CuOOH) and hypoxanthine (HX) were obtained from Aldrich (Milwaukee, WI); and cholesterol, adenosine diphosphate (ADP), xanthine oxidase (XO), bovine erythrocyte superoxide dismutase (SOD) and hematin were purchased from Sigma. 4[^{14}C]-Cholesterol was obtained from Amersham (Arlington Heights, IL) and repurified on a monthly basis by thin layer chromatography (TLC) as previously reported (18) to remove cholesterol oxidation products. A similar procedure was used to purify unlabeled cholesterol obtained from Sigma. The absence of cholesterol oxidation products was confirmed by gas and thin layer chromatography (19). The levels of cholesterol oxidation products were typically below our limits of detection.

Authentic cholesterol oxidation products: 3,7-diols, cholest-5-ene-3β-ol-7-one (7-keto), 3,5-cholestadiene-7-one (3,5-diene), cholestan-5α,6α-epoxy-3β-ol (α-CE) and 25-hydroxycholesterol were obtained from Sterloids (Wilson, NH). α-CE was found to be contaminated with 1% and 3% cholestan-3β,5α,6β-triol (CT) and cholesterol, respectively, and was further purified as described previously (20). CT was purchased from Sigma and was chromatographically pure. 3β-hydroxy-5α-cholest-6-ene-5α-hydroperoxide and 3β-hydroxycholest-5-ene-7α-hydroperoxide (7-OOH) were provided by Dr. Leland Smith. Cholestan-5β,6β-epoxy-3β-ol (β-CE) was prepared by reaction of cholesterol with metachloroperoxybenzoic acid in ether, as described previously (20). This reaction produces ca. 75% and 25% of the α- and β-CE diastereomers, respectively, requiring purification of β-CE by high pressure liquid chromatography (HPLC) (20).

Liposome preparation. Three different phospholipid formulations were used for preparing liposomes. These formulations were based on the type or proportions of phospholipids and consisted of either pure dipalmitoylphosphatidylcholine (DPPC), bovine liver PC or a mixture of PC and bovine liver PE in a molar ratio of 4:1. The phospholipids were mixed with cholesterol as methylene chloride solutions in quantities sufficient to achieve final desired molar ratios of phospholipid to cholesterol of either 2:1 or 4:1. At this point, a total of 8 μCi (at 56 μCi/μmol) of radiolabeled cholesterol was added to the sample. For a typical experiment, a total of 35 mg of lipid was mixed, and the solvent was evaporated under a stream of argon. The resulting film was suspended by vigorous mixing for 1 min in 2.4 ml of cold argon-saturated 10 mM Tris buffer containing 150 mM KCl at pH 7.4. The suspension was then transferred under an atmosphere of argon to a screw-cap polycarbonate tube. The lipid suspension was sonicated for 10–15 min in a cup-horn using a Heat Systems-Ultrasonics W-225R sonifier at a power setting of 20. The temperature throughout this period was maintained at 30 C (with the exception of DPPC liposomes, which were maintained at 38 C) using a circulator bath. The sample was then centrifuged for 30 min at 65,000 × g at 4 C. The supernatant was recovered for further use. All procedures were carried out under subdued light. The amount of phospholipid in each preparation was assayed by phosphorus determination (21). Confirmation of the ratio of PC and PE was accomplished by extraction and resolution of the phospholipids via TLC (22), recovery of phospholipids and measurement by phosphorus analysis (21). Cholesterol content was verified by HPLC as detailed.

Peroxidation of liposomes. The three types of liposomal preparations described were incubated in the presence of one of the four oxidizing systems described here. Incubations under these oxidizing conditions were carried out using 2.5 mg of lipid per sample suspended in a total volume of 1.0 ml Tris buffer.

(i) Autoxidation of the liposomes involved dispersing aliquots into aerated Tris buffer followed by incubation in a shaking water bath (80 oscillations/min) for intervals up to 4 hr at 37 C.

(ii) A standard enzymatic O_2^--generating system was used. This involved additions of ADP-Fe^{+3} (prepared by premixing ADP and $FeSO_4$ in water at a ratio of 12:1), where the final concentrations were 120 and 10 μM, respectively. The ADP-Fe^{+2} complex is known to autoxidize rapidly in water yielding ADP-Fe^{+3} (23,24). Incubations were begun by successive additions of 0.50 units XO and 500 μM HX (final concentration). Incubations of these and all other samples were as described for the autoxidation experiments noted above. Under these conditions, O_2^- generation, as measured via cytochrome C reduction (25), remained linear for 15 min at a rate of 1.9 μmol/min and subsided by 20 min. Prolonged incubations (i.e., intervals as long as 3 hr) are presumed to represent oxidations other than those induced by enzymatically generated oxyradicals. The dependence of lipid peroxidation on O_2^- formation was confirmed in preliminary experiments in which >85% of lipid peroxidation was prevented by the addition of 50 μg of SOD. Inhibition of lipid peroxidation by SOD indicates that O_2^- is fulfilling the dual role of maintaining iron in its reduced and catalytically active state and yielding secondary oxidizing species (26).

(iii) Cumene hydroperoxide (200 μM) and 50 μM hematin, prepared as described previously (27), were added to the liposome suspensions. Incubations were initiated by addition of a 100 μl sonicated solution of CuOOH in Tris buffer.

(iv) Irradiation using a ^{60}Co source was carried out by adding 200 μl samples of liposomes to 800 μl of distilled water (pH 7.0) in borosilicate screw-cap test tubes. The tubes were sealed under air or N_2O (20-min purging of samples in a glove bag) prior to subjecting the samples to γ-irradiation. The dose rate of our radiation source was 4.87 Gy/min, and samples were irradiated for set intervals up to 120 min.

Analysis of cholesterol oxidation products. At fixed time intervals, the incubations were terminated by removing 100 μl aliquots for determination of TBAR (28) and immediately thereafter adding 7 vol of chloroform/methanol (2:1, v/v) to the remaining sample. The mixture was briefly centrifuged to separate the organic phase, which was collected and saved. The upper aqueous phase was reextracted as above, and the organic phases were pooled and evaporated under nitrogen. Using this method, >98% of the radioactivity in all samples was extracted.

The dried lipids were suspended in 1.0 ml argon saturated toluene/ethyl acetate (3:2, v/v) and applied to 3-ml solid phase "Diol" extraction columns (Analytichem Corp., Harbor City, CA) conditioned with the same solvent. Eluents were collected under mild vacuum suction,

and the columns were washed with another 2 ml of toluene/ethyl acetate. The combined eluents were immediately evaporated under nitrogen and saved in hexane/benzene (95:5, v/v) under argon at −80 C. Using this technique, >99% of the radioactivity associated with cholesterol or its oxidation products was recovered. The columns were subsequently eluted with methanol to collect the phospholipids. No radioactivity was present in this fraction.

In some experiments, an aliquot of the toluene/ethyl acetate eluent (cholesterol fraction) was removed for TLC as described previously (18). This was done to isolate cholesterol and CT, the latter not being suitably resolved by the HPLC method described below. The identity of CT was confirmed using an authentic nonradiolabeled standard applied along with each sample. The details for recovering and measuring CT by TLC are presented elsewhere (18). The radioactive zones corresponding to cholesterol and CT were scraped from the plates, and the level of radioactivity in each sample was determined by liquid scintillation spectrometry.

The remainder of each cholesterol fraction was reduced to a 100-μl volume, of which 20 μl was subjected to HPLC. HPLC of cholesterol and its oxidation products was performed with a Perkin Elmer Series 4 liquid chromatograph fitted with two 3-μ particle size 100 × 4.6 mm columns (Chromanetics, Inc., Jessup, MD) in series that were eluted isocratically with hexane/isopropanol (95.8:4.2, v/v) at a flow rate of 1.5 ml/min. Detection of peaks was accomplished with an Erma Instruments differential refractometer. The eluent was subsequently delivered to a fraction collector set at 15-sec sampling intervals. The collected samples were then measured for radioactivity by liquid scintillation spectrometry. Using this approach, a radioactivity chromatogram was superimposed on the refractive index chromatogram of authentic cholesterol oxidation standards added to the samples prior to injection. A representative refractive index chromatogram of cholesterol and several oxidation products is shown in Figure 1.

The cholesterol content in each sample was determined following the chromatographic run using an external standard method. Corrections for variations in recovery were based on the radioactive counts in the original sample and the total radioactivity measured after HPLC (i.e., the sum of the radioactivity in all collected fractions). Recoveries ranged from 86 to 96%. The extent of cholesterol oxidation and the amounts of each oxidation product were estimated from the level of radioactivity associated with each peak. Calculations of the amount of each oxidation product were based on the radioactive counts associated with that product expressed as a percentage of the original cholesterol radioactivity. The cholesterol content in each sample was then multipled by the calculated percent for each oxidation product identified yielding a value, in micrograms, for each product formed. This method of calculation assumes that the specific activities of cholesterol and its oxidation products are equal. Verification of each oxidation product identified during the chromatographic run was made by "spiking" radioactive peaks with known amounts of authentic cholesterol oxide standards. The detection limit for most oxidation products by refractometry was 0.5 μg, whereas the limit for peak resolution measured via radioactivity was 3 times background (i.e., 36 dpm).

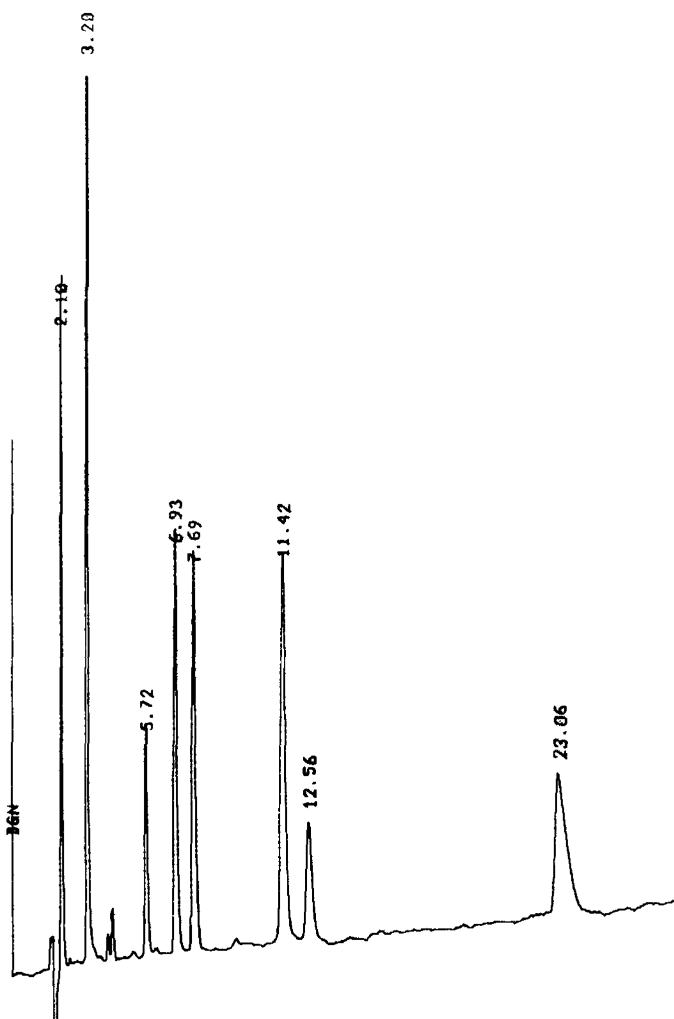

FIG. 1. A high pressure liquid chromatograph of cholesterol oxidation standards. The chromatographic conditions are described in the text. The eluent was monitored by differential refractometry and the integrator response was set at A = 128 for the tracing shown. The oxidation products are indicated by their retention times and are as follows: 2.10, 3,5 diene; 3.20, cholesterol; 5.72, 25-hydroxycholesterol; 6.93, α-CE; 7.69, β-CE; 11.42, 7-keto; 12.56, 7α-OOH; 23.06, 7α-diol.

The extent of cholesterol oxidation was indexed to the level of lipid peroxidation, as measured by TBAR. The level of lipid peroxidation and cholesterol oxidation was determined in all liposome preparations prior to and at various time intervals after the imposed oxidizing conditions already described. All samples were analyzed in duplicate, and values are expressed as the mean and standard deviation calculated from three to four independent experiments for each oxidizing condition described.

RESULTS

The incorporation of cholesterol into liposomes yielded small unilamellar vesicles with characteristics that have been described previously (29,30). The ratio of cholesterol to phospholipid varied no more than 15% from the prescribed ratios at the time of preparation. Furthermore,

ND, Not determined. Inadequate chromatography or insufficient numbers of samples prevented accurate determinations of products and quantitation.

[a]The levels of TBAR are expressed as equivalents of malonaldehyde and are calculated from the optical densities measured at 532 nm using a molar extinction coefficient of 1.56×10^4.

[b]Standard deviations not calculated as value represents the average of two measurements.

the type of phospholipid used had no effect on cholesterol assimilation, and the resulting liposomes were stable for the duration of the experiments described. In these experiments, we used either a 1:2 or 1:4 ratio of cholesterol to phospholipid, such that the liposomes differed in terms of the mole percent of cholesterol and degree of unsaturation. The fatty acyl composition of these PC/PE liposomes is described elsewhere (30).

Table 1 shows the major cholesterol oxidation products detected following γ-irradiation of liposomes consisting of a 1:4 molar ratio of cholesterol/phospholipid under an atmosphere of N_2O. In the absence of oxygen, the predominant radical species derived by γ-irradiation of water is ·OH (31). Several oxidation products were measured following irradiation periods as long as 90 min, however, most of these products were present in the original samples (0 min control) and were presumably formed during liposome preparation. This appeared to be the case for all liposome preparations in this report. Cholesterol oxidation was unavoidable during the preparative sonication of liposomes. The levels of oxidation products were low, however, there was some variability in content and proportions of products among different liposome batches. The total amount of cholesterol oxides at zero time were generally less than 0.1% of the total cholesterol content. Accordingly, these products would be undetectable by conventional HPLC methods, and the samples could mistakenly be assumed to be free of oxidized lipids. The only oxidation products to accumulate during γ-irradiation were α-CE and CT. Other cholesterol oxidation products either did not accumulate, or in some cases, decreased below the original levels during the course of irradiation. It should be noted that no TBAR were formed, and levels of 7-OOH remained unchanged over the course of irradiation.

A comparison of lipid peroxidation and cholesterol oxidation in the three liposomal formulations is presented in Table 2 for samples subjected to γ-irradiation under aerobic conditions. Under these conditions, the major oxidizing species formed are O_2^- via the e^-aq, ·OH and H_2O_2 derived from O_2^-. All the cholesterol oxides were found to accumulate in each of the liposomal systems examined. The extent of lipid peroxidation was greatest in the most unsaturated samples (1:4, cholesterol/phospholipid) where the levels of most cholesterol oxidation products and TBAR were as high at 20 min as those formed in 1:2 cholesterol/phospholipid after 60 min of irradiation. Cholesterol oxidation in the cholesterol:DPPC liposomes was least among the three systems studied; however, there was a distinct accumulation of 7-OOH that was not found in the more unsaturated systems. The principal products in all cases were α-CE, β-CE, 7-keto and 3,7-diol. Both α-CE and β-CE were produced in approximately equal proportions during oxidation of cholesterol/DPPC liposomes, whereas the formation of β-CE was favored in liposomes bearing a higher degree of unsaturation. Based on the limited number of lipid peroxidation products analyzed in this study, it appears that product complexity increases during oxidations in the presence of air and, to a lesser extent, as the lipid system becomes more unsaturated.

Subsequent experiments were then conducted using the chemical oxidizing systems. The O_2^- generating system, XO + HX + ADP-Fe^{+3}, is thought to produce a variety of oxidizing species capable of initiating lipid peroxidation (26). The exact species responsible for membrane lipid peroxidation has yet to be determined, although ·OH and perferryl radical are widely viewed as the likely agents. Use of CuOOH plus hematin is representative of lipid peroxide-induced lipid peroxidation. These reactions comprise the propagation stage of lipid peroxidation (14).

Table 3 presents a compilation of data found in Tables 4, 5 and 6, but for the sake of brevity, two oxidizing conditions are selected for comparison. The extent of cholesterol oxidation was found to be influenced by its content in liposomes and by the peroxidizability index (PI) of the component lipids (32). In DPPC/cholesterol liposomes, the only double bonds present are those of

cholesterol, and the PI is accordingly calculated as 0.50. The 1:2 cholesterol/phospholipid liposomes have a PI of 41.1, while the 1:4 cholesterol/phospholipid liposomes have a PI of 65.9. The values shown in Table 3 are expressed as the percentage of total cholesterol oxidized and are estimated from the sum of all cholesterol oxidation products measured. As in Tables 1 and 2, the extent of cholesterol oxidation was least in the DPPC and greatest in the 1:4 cholesterol/phospholipid liposomes. Cholesterol had a suppressive effect on lipid peroxidation, which could be predicted from the slow induction rates for autoxidation (33). Doubling the proportion of cholesterol (1:2 compared to 1:4 liposomes) reduced the level of lipid peroxidation (TBAR) by ca. 20%. Although a lower percentage of cholesterol was oxidized in the 1:2 liposomes, the actual amounts of cholesterol oxidation products were similar to that produced following oxidation of 1:4 liposomes. Thus, the dcrease in TBAR formation in the 1:2 cholesterol/phospholipid liposomes was accompanied by an increase in the amounts of cholesterol oxidized. It should be noted that a similar extent of cholesterol oxidation was achieved following 60-min treatments with ADP-Fe^{+3} + XO and 60 min of γ-irradiation in air.

The product profiles for the $O_2^{\overline{\cdot}}$-dependent and CuOOH-induced peroxidations are shown in Tables 4 through 6. During the initial periods of oxidation (<30 min), these oxidizing systems yielded remarkably different proportions of cholesterol oxidation products, however, with prolonged incubations the profile of oxidation products began to resemble each other. α-CE and β-CE were formed in approximately equal amounts during the early intervals of oxidation. As the incubation period progressed, the relative amounts of β-CE increased, and it became a major product, particularly in unsaturated lipid systems. In liposomes bearing unsaturated fatty acids, 7-OOH was an early oxidation product that gradually accumulated.

In saturated liposomes, the extent of 7-OOH accumulation was as great as any of the other products measured. Under virtually all conditions, 7-keto and, to a lesser extent, 3,7-diol were major products that formed with prolonged incubations. Small but consistently detectable amounts of 3,5-diene were found under these conditions, however, its content relative to other products was greatest in the DPPC/cholesterol liposomes.

The relative proportions of cholest-5-ene-3β,7β-diol and cholest-5-ene-3β,7α-diol (the 3,7-diols) and the corresponding 7α- and 7β-hydroperoxides (7-OOH) could not be established with certainty due to the limited resolution of these isomers by HPLC. Approximation of the levels of radioactivity associated with each peak indicated that equal amounts of each isomer were formed under all circumstances. These approximations are subject to error of 25 to 35% due to peak overlap. We also note the absence of 25-hydroxycholesterol formation under all the oxidizing conditions studied.

DISCUSSION

The characterization of cholesterol oxidation products following free radical-induced membrane lipid peroxidation was studied using unilamellar liposomes. These artificial membranes permitted the manipulation of lipid composition which in this study involved the formulation of discrete proportions of unsaturated phospholipids and cholesterol. Based upon total lipid content the amount of cholesterol added to the liposomes was similar to the proportions found in cell membranes. For example, the plasma membrane of hepatocytes contains ca. 12.9% cholesterol by weight (34,35), while this percentage is lower in endoplasmic reticulum (3.3%) (35) and mitochondria (1.5%) (36). In some cases, the proportions of cholesterol may be even higher than those cited above (37).

It is possible to subdivide the cholesterol oxidation products identified in this study into two categories based on whether lipid peroxidation was mediated by oxyradical-dependent initiation reactions or by lipid peroxide-dependent propagation reactions. Liposomes subjected to anaerobic γ-irradiation represented one extreme, where cholesterol is probably oxidized by ·OH attack and the likelihood for lipid peroxidation chain reactions is low. Under these conditions the only products to accumulate were α-CE and CT (Table 1). γ-Irradiation in the presence of air (or O_2^-· generation via xanthine oxidase) yields a more complex array of oxyradicals, however, the principal oxidants are likely to be ·OH (or a perferyl radical) and H_2O_2, since O_2^-· has been shown to be incapable of directly oxidizing cholesterol (38). The presence of oxygen also permits oxidations to proceed via propagation reactions. The degree of propagation reactions may be limited either by short incubation intervals or more effectively by minimizing the degree of lipid unsaturation. The variety and amounts of cholesterol oxides formed are also increased with either prolonged irradiation or increased lipid unsaturation. Under these conditions, propagation reactions largely contribute to the accumulation of lipid peroxidation products, measured as TBAR and a host of cholesterol oxides. A comparison of data from Tables 1 and 2 indicates that in the absence of lipid peroxidation the yields of cholesterol oxidation products are low, where net formation of only two products is seen. By contrast, provision of oxygen permits considerable lipid peroxidation and an increased number of cholesterol oxidation products.

The free radical reactions involved in lipid peroxidation appear to be reflected by the types of cholesterol oxidation products. For example, in the absence of 7-OOH most of the other oxidation products are not encountered. There is, however, one important exception to this, i.e., α-CE formation after anaerobic γ-irradiation occurs in the absence of other products (Table 1). This indicates that 7-OOH are not produced under anaerobic conditions via ·OH, and, accordingly, no derived products are encountered. The absence of peroxidative chain reactions is expected during anaerobic irradiation and should be suppressed in a largely saturated lipid matrix such as the DPPC/cholesterol liposomes. However, a variety of cholesterol oxidation products are found after aerobic oxidation of DPPC/cholesterol liposomes, indicating the involvement of oxyradical initiation reactions. We note that in saturated liposomes subjected to aerobic oxidations, 7-OOH accumulates as a significant product (Tables 2 and 6), in agreement with the findings of Muto et al. (11). It is plausible that 7-OOH is more stable in saturated lipids where its decomposition is determined largely by interactions with other cholesterol molecules. Products such as 7-keto, 3,7-diol and the isomeric cholesterol epoxides may arise by reactions of 7-OOH with itself (39) or with O_2^- where both 7-OOH and O_2^- are generated by the aerobic oxidations described.

Lipid peroxidation via CuOOH plus hematin can be contrasted from the initiation-type reactions discussed above. Peroxidation was rapidly induced following addition of CuOOH, and the profile of cholesterol oxidation products after short incubation intervals (≤30 min) resembled those obtained after longer incubations (≥60 min) with the O_2^-·-generating system. Under otherwise similar conditions, peroxide-dependent (CuOOH) oxidations produce a more rapid accumulation of TBAR, 7-OOH and derived products 7-keto and 3,7-diol, than O_2^--dependent oxidations. During the first 10 min of O_2^--dependent oxidation (Table 4 and 5), less oxidation products form, and with the exception of the 3,5-diene, approximately equal amounts of each product are detected. Beyond 30 min (when O_2^- is no longer being generated), the pattern of oxidation changes considerably and the cholesterol epoxides, 7-keto and 3,7-diols predominate. The oxidation profile resembles that obtained by autoxidation (although the amounts of each product are greater under these conditions of imposed oxidation), suggesting that lipid peroxidation is proceeding via autoxidation at these later incubation periods.

The yields of the α- vs β-CE are indicative of the prevailing process of cholesterol oxidation. Both isomers form under limited oxyradical-induced peroxidation. It appears that γ-irradiation under aerobic conditions or peroxidation via O_2^-· give rise to similar levels of epoxide isomers. Extensive peroxidation, assessed by high TBAR levels, clearly favors β-CE formation. In this respect, peroxyl species have been shown to mediate cholesterol oxidation by lipoxygenase (40) with marked β-stereoselectivity toward the cholesterol hydroperoxide and epoxide products. Gumulka et al. (41) proposed that the proportions of α- and β-CE provide a clue to the processes involved in cholesterol oxidation. They observed a predominance of β-CE following autoxidation, lipid peroxidation and

ozonization, whereas α-CE was preferentially formed by one-atom oxidants such as epoxidases and peracids. This contention is verified by our observations, and although the ratios of α- to β-CE in this study are lower than those reported previously (8,39,41,42), the directions of change are similar.

The formation of the isomeric epoxides by oxidation of cholesterol with H_2O_2 and other organic peroxo-compounds has been reported (8). Cholesterol epoxidation by reaction with hydroperoxides has been documented in organic solvents, aqueous dispersions (11,39,43), and considerable epoxidation also takes place when cholesterol is added to dispersions of lipid hydroperoxides isolated from hepatic microsomes (44). In each of these cases β-CE formation was predominant. Membranes consisting of only saturated fatty acids (Tables 2 and 6) may support cholesterol oxidation via oxyradicals, but cannot effectively produce lipid peroxides and sustain propagation reactions. The oxidation reactions are, therefore, limited to direct attack by oxyradicals (as in O_2^--dependent initiation of lipid peroxidation) or to interactions between oxidized cholesterol radicals. This results in a much reduced level of cholesterol oxidation and is accompanied by the formation of equal amounts of α- and β-CE. γ-Irradiation under anaerobic conditions (Table 1), or irradiation of DPPC/cholesterol liposomes in the presence of oxygen (Table 2), also yield equal amounts of α- and β-CE.

Based on these findings, we submit that oxyradical-induced cholesterol oxidation resembles the one-atom oxidants previously noted. These "initiation" reactions likely proceed by radical attack of the α-surface of cholesterol, while attack by peroxo-compounds (e.g., fatty acid hydroperoxides of phospholipids) preferentially involves the β surface, as originally proposed by Teng and Smith (2). The isomeric selectivity of oxyradicals vs peroxyl-mediated epoxidations may be explained on the basis of cholesterol orientation in membranes. According to Vandenheuval (45), cholesterol is embedded into the membrane bilayer with its α surface facing and at a 5–6 Å distance from the glycerol-phosphate backbone of an adjacent phospholipid. This places the α surface of the 5,6 double bond in relative proximity to oxyradicals generated in the aqueous phase, however, the radical species responsible for epoxidation remains to be identified. The β surface, on the other hand, is oriented toward adjacent fatty acyl groups facing the membrane interior. Attack by oxyradicals would be hindered by the proximate C-19 methyl group of cholesterol and the hydrophobic environment surrounding the β surface of the 5,6 double bond. In this arrangement the double bond is estimated to be 4–5 Å from an ω-3 double bond of a neighboring polyunsaturated fatty acid. Lipid peroxidation involving these polyunsaturated fatty acids would thus favor reaction of the peroxides with the β surface of cholesterol.

In addition to cholesterol epoxide formation, considerable amounts of CT and 3,5-diene were detected. The only known source for CT is the isomeric cholesterol epoxides, and under the conditions used in this study, CT could only be formed by spontaneous hydrolysis of the epoxides. However, the previously reported rates for spontaneous hydrolysis of either epoxide isomer (18,46) appear to be too slow to produce the amounts of CT detected. Nevertheless, an accumulation of CT would be consistent with cholesterol oxidation in the wake of lipid peroxidation and cholesterol epoxide formation. Formation of 3,5-diene has been proposed to derive from 7-OOH via dehydration of 7-keto (47). It appears that accumulation of 3,5-diene, relative to other products, is favored under conditions where 7-OOH can undergo decomposition without participating in further chain reactions. These conditions prevail in a saturated lipid matrix (Table 6) or under anaerobic conditions (Table 1).

Our findings are in general accordance with those of Terao et al. (10) and Muto et al. (11). They concluded that cholesterol was cooxidized with unsaturated fatty acids and that peroxyl and alkoxyl radicals derived from unsaturated fatty acids were largely responsible for the generation of the cholesterol oxides. The 7-keto and 3,7-diol products, also found as major products in these earlier studies, were proposed to derive from thermolytic decomposition of 7-OOH. The other major products were the isomeric cholesterol epoxides, which were proposed to arise from alkoxyl and peroxyl-radical attack of cholesterol in a process showing marked β-stereoselectivity (11).

Lipid peroxidation in tissues is expected to be minimized by a plethora of antioxidants and scavengers that prevent both radical initiation and chain reactions. The detection of low levels of lipid peroxidation products in living systems may be considered proof for low-level free radical reactions. If this is indeed the case, then the cholesterol oxidation profile from biological systems should resemble the oxyradical profiles described in this report. Based on cholesterol epoxide content, in vivo lipid peroxidation should be accompanied by approximately equal β- vs α-CE ratios. Available evidence, though sparse (19,48,49), supports this hypothesis. It may be possible to examine the course of lipid peroxidation in more complex systems containing cholesterol by "finger-printing" the oxidation products in a manner similar to that described in this report.

[Received October 14, 1986]

Liver Subcellular Fatty Acid Profiles of Chicks Fed Diets Containing Hydrogenated Fats and Varying Linoleate Levels[1]

A.M. Rogel and **B.A. Watkins**
Department of Animal Sciences, Washington State University, Pullman, WA 99164-6320

Day-old male broiler chickens were fed semipurified diets containing 5% lipid from one of four different lipid sources: corn oil (CO), partially hydrogenated soybean oil (HSBO), a spent restaurant grease (SRG) and a purified mixture of triolein, tripalmitin and tristearin (OPS). Diets CO and HSBO contained adequate amounts of linoleic acid, but diets SRG and OPS were deficient in linoleate. In addition, SRG and HSBO contained *trans* isomers of 16:1 and 18:1. The diets were fed for 3 wk to determine the effects of low linoleate levels and *trans* isomers on fatty acid profiles in liver microsomes, mitochondria and cytosol. Chicks fed HSBO had the highest body weights, while those fed SRG and OPS had the lowest. The incidence and severity of dermatitis were similar for all treatments. The proportions of linoleate and arachidonate in lipids from liver subcellular fractions were reduced significantly in chicks fed OPS and SRG; however, levels of 20:3ω9 were not increased. Feeding HSBO, which is high in both linoleate and linolenate, resulted in higher levels of 18:3ω3 and 20:5ω3 in liver subcellular fractions and lower levels of 20:4ω6 than those seen in chicks fed CO. The isomeric forms of 18:1 present in the partially hydrogenated fats (HSBO and SRG) appeared to be incorporated into the lipids of liver fractions. The results of this study show that dietary lipids influence fatty acid profiles of chick liver microsomes, mitochondria and cytosol. Decreases in linoleate and arachidonate in these organelles occur before overt essential fatty acid (EFA) deficiency signs in chicks fed EFA-deficient diets.
***Lipids 22*, 637-642 (1987).**

Hydrogenation of vegetable and marine oils to increase plasticity and improve shelf life results in a decrease in polyunsaturated fatty acids (PUFA) and the formation of positional and geometric isomers, particularly of octadecenoic acid (1). As much as 20% of the fatty acids in hydrogenated vegetable oils are *trans* isomers of octadecenoic acid, while approximately 25% are *cis* isomers with the double bond located at the C4 to C16 positions (2,3).

Feed-grade blended fats make up nearly half of the 8 $\times 10^8$ kg of fats fed to food animals. In 1985, nearly 40% of the blended fats were restaurant greases (Rouse Marketing, personal communication). These fat sources contain large amounts of *cis/trans* positional isomers of 18:1 and lesser amounts of 18:2 isomers, which may be incorporated into animal products.

The composition of dietary lipids can influence not only the depot fat in adipose tissue (4), but also the phospholipids of intracellular organelles of various tissues (5). Many studies have shown that positional and geometric isomers of octadecenoic acid are readily absorbed and incorporated into tissue lipids of rats and humans (1,2,6,7). *Trans* isomers are incorporated into phospholipids (3,8) and may interfere with the biosynthesis of PUFA in rat liver microsomes by inhibiting Δ9, Δ6 and Δ5 desaturase enzymes (9,10). Certain *cis* isomers of octadecenoic acid are preferentially incorporated into phospholipids and may interfere with desaturation and elongation of fatty acids (2,3).

When fed in conjunction with essential fatty acid (EFA)-deficient diets, partially hydrogenated vegetable oils intensify the deficiency symptoms of poor growth and dermatitis in rats (10). In vitro studies on the inhibition of liver microsomal desaturases from EFA-deficient rats by positional and geometric isomers of octadecenoic acid show that the degree of inhibition is influenced by the position of the double bond (9,11).

Though many studies on the effects of hydrogenated oils on lipid metabolism in the presence and/or absence of EFA deficiency have been done in the rat, none have been found using the chicken. The present study was undertaken to determine the effects of feeding partially hydrogenated fats and/or diets deficient in EFA on the composition of lipids in liver subcellular organelles of young growing chicks.

MATERIALS AND METHODS

Four experimental diets were prepared from the basal diet described in Table 1. Each diet contained 50 g/kg of one of the following lipid sources: corn oil (CO), spent restaurant grease (SRG), partially hydrogenated soybean oil (HSBO) and a triglyceride mixture containing 30% triolein, 30% tripalmitin and 40% tristearin (OPS). SRG, obtained from a local restaurant, was composed of 80% prime tallow and 20% hydrogenated cottonseed oil. Further hydrogenation and isomerization was expected as a result of heating. HSBO (a margarine) contained a mixture of liquid soybean oil and partially hydrogenated soybean oil with added lecithin and mono- and diglycerides. Purified triglycerides were purchased from United States Biochemical Corp. (Cleveland, OH).

Day-old male broiler chicks (Hubbard strain) were randomly assigned to the four experimental diets. Each dietary treatment contained two replicate pens of eight chicks. The chicks were maintained in Petersime batteries and exposed to a cycle of 18 hr light and 6 hr dark for the duration of the 21-day experiment. Feed and water were provided ad libitum throughout the study. Total feed consumption and body weight gains were determined at the completion of the experiment for calculation of feed conversion (total feed/total gain).

On day 21, chicks were weighed and scored for perosis and dermatitis on a scale of 0 to 4 (12). Four chicks from

[d]Contains (in mg/kg of diet) $CoCl_2.6H_2O$, 5; $CuSO_4.5H_2O$, 60; $FeSO_4.7H_2O$, 500; KCl, 1500; K_2HPO_4, 6000; KIO_3, 6; $MgSO_4.7H_2O$, 6000; Na_2SeO_3, 0.43; ZnO, 90.

[e]Contains (per kg of diet) vitamin A, 4500 IU; vitamin D_3, 4500 ICU; vitamin E, 50 IU; vitamin K, 1.5 mg; thiamin, 15 mg; riboflavin, 15 mg; calcium pantothenate, 15 mg; niacin, 50 mg; pyridoxine, 6 mg; folic acid, 6 mg; vitamin B_{12}, 0.02 mg; biotin, 200 μg; choline, 1 g.

each experimental treatment (two per pen) were killed by cervical dislocation, and the livers were quickly removed. A 3-g sample of each liver was taken for subcellular fractionation and placed in a beaker containing ca. 10 ml chilled 0.25 M sucrose.

Livers were homogenized in the 0.25 M sucrose solution with a Kinematica Polytron (Luzern, Switzerland), and subcellular fractions were isolated by modifying the method of Mayne and Parker (13). The homogenate was centrifuged at 750 × g for 10 min to remove cellular debris and nuclei. The supernatant was centrifuged at 10,000 × g for 10 min to obtain a mitochondrial pellet, which was washed with 0.25 M sucrose, resuspended by homogenation and recovered after a second centrifugation at 10,000 × g. The supernatant containing cytosol and microsomes was centrifuged at 100,000 × g for 60 min to separate these components. All centrifugations were performed at 0 C, and samples were kept on ice between centrifugations. Mitochondrial and microsomal pellets, as well as samples of cytosol, were frozen (−20 C) until needed for fatty acid analysis.

Total lipids from subcellular fractions were extracted in chloroform/methanol (2:1, v/v) by the method of Bligh and Dyer (14). Methyl esters were prepared after saponification using boron trifluoride (15). The methyl esters were extracted in isooctane for chromatographic analysis using a HP 5890 gas chromatograph equipped with a flame ionization detector and a Nelson Analytical Data System (Hewlett Packard Co., Sunnyvale, CA). A DB225 (25% cyanopropylphenyl) fused silica megabore column (30 m × 0.53 mm ID) purchased from J & W Scientific Co. (Rancho Cordova, CA) was used with helium as a carrier gas at a flow rate of 3.4 ml/min. The oven temperature was maintained at 200 C for the first 15 min of the run and increased at a rate of 0.8 C per min to a final temperature of 218 C. Total analysis time per sample was 55 min. Both injector port and detector were set at 250 C.

Fatty acid standards for gas chromatography were purchased from Nu-Chek-Prep, (Elysian, MN). Proportions of fatty acids present in each sample were determined as area percent.

Fatty acid analysis was also done for each dietary lipid source, and the ratios of *cis* to *trans* isomers of 16:1 and 18:1 in SRG and HSBO were determined in triplicate by combined argentation (16) and gas chromatography. Silver nitrate-impregnated thin layer chromatography (TLC) plates were prepared by immersing precoated TLC plates (Silica Gel G) into a saturated methanolic solution of $AgNO_3$. Methylated samples of each lipid were applied, and the plates were developed twice in hexane/diethyl ether/glacial acetic acid (94:4:2, v/v/v). Methyl nonadecanoate was added as an internal standard to the recovered fractions, which were then analyzed by gas chromatography as described above.

Data were analyzed statistically by analysis of variance. When sample sizes were equal Tukey's post-priori test was used, and when sample sizes were unequal Bonferroni's multiple comparison post-priori test was employed (17). Variation between means was expressed as a pooled SEM for fatty acid data when group sample sizes were equal. A pooled SD was used when sample sizes were unequal.

RESULTS

The major fatty acids found in the four dietary lipids are given in Table 2. The triglycerides used in the OPS mixture were not pure; the triolein sample contained 69.0%

oleate (smaller amounts of 14:0, 16:0, 16:1 and 18:2) while the tripalmitin and tristearin samples were 99.7% 16:0 and 86.7% 18:0, respectively. Both the OPS and SRG diets were deficient in linoleic acid. The OPS diet provided 1.09 g linoleate/kg diet, and the SRG diet provided 1.82 g linoleate/kg diet. This is far below the 10 g/kg recommended by the National Academy of Science (18). In contrast, the HSBO and CO diets provided more than 15 g linoleic acid/kg diet.

Body weights at 21 days were significantly influenced by dietary fat source (Table 3). Chicks fed CO and HSBO were heavier ($p < 0.05$) than those fed OPS, while weights of chicks fed SRG were not different from those of chicks fed CO or OPS. The poorest feed conversion was observed in chicks fed OPS, and the best was seen in those fed CO. Perosis and dermatitis were observed in chicks from each treatment, but no significant effects due to EFA deficiency were noted.

The fatty acid profiles for microsomes, mitochondria and cytosol are presented in Tables 4–6. The DB225 megabore column used for chromatographic analysis of fatty acids in this experiment permitted baseline separation

of 18:2ω6 *cis* and *trans* isomers and near-baseline resolution of 18:1ω9 *cis* and *trans* isomers. However, the many positional isomers of 18:1 in SRG and HSBO could not be separated, and only one large nonsymmetrical peak and a small incompletely resolved peak after the major 18:1 peak were eluted. The areas of these two peaks were combined for statistical analysis. Although isomeric separation was incomplete, the shape of the 18:1 peaks found in liver subcellular components mimicked the shape of the 18:1 peaks found in the dietary fat source, suggesting that dietary 18:1 isomers were incorporated into liver cells. Unresolved positional isomers were present in both the *cis* and *trans* 18:1 fractions of SRG and HSBO separated by argentation chromatography.

Feeding EFA-deficient diets (SRG and OPS) led to a significant increase in the proportions of 18:1 and 20:2ω6 in microsomes (Table 4) and a decrease in the proportion of 18:2ω6, 18:3ω6 and 22:5ω6 when compared to the CO control. Chicks fed HSBO had increased proportions of 18:3ω3 and 20:5ω3 and decreased proportions of 20:4ω6 and 22:5ω6. Feeding a partially hydrogenated EFA-deficient diet (SRG) resulted in a microsomal fatty acid profile similar to that observed by feeding the unhydrogenated EFA-deficient diet (OPS).

Feeding an EFA-deficient diet led to a significant increase in the proportion of 18:1 and a significant decrease in the proportions of 18:0, 18:2ω6, 18:3ω6, 20:3ω9, 20:4ω6 and 22:5ω6 in mitochondria (Table 5). Feeding HSBO resulted in an increase in 18:1 and 20:5ω3 and a decrease in 20:3ω9, and 20:4ω6 and 22:5ω6. Chicks fed SRG had mitochondrial fatty acid profiles similar to those fed OPS.

Both linoleic acid and arachidonic acid were decreased in cytosol (Table 6) by feeding the EFA-deficient diet, and 18:3ω3 and 20:5ω3 were increased by feeding HSBO. No differences were seen in the cytosolic fatty acid profiles of chicks fed SRG and OPS.

DISCUSSION

The only overt sign of EFA deficiency in the chicks of this experiment after three weeks of experimental feeding was a significantly lower mean body weight in chicks fed OPS and SRG compared to that of chicks fed HSBO and CO. Chicks fed OPS had a poorer feed conversion than those fed other dietary lipids. This may be due to the highly saturated nature of the lipid source, as well as to the low levels of linoleic acid in the diet. Earlier investigators have reported that fatty acids from saturated fats such as lard and tallow are poorly absorbed by young growing chicks and turkey poults compared to fatty acids from vegetable oils (19,20).

The failure of chicks to develop severe EFA deficiency symptoms after 3 wk of feeding low linoleate diets is not surprising. Holman (21), in his review of EFA deficiency, discusses early studies in which day-old chicks grew normally for 6–8 wk on fat-free diets. Biochemical changes would be expected earlier, however, and changes in fatty acid profiles were observed herein.

EFA deficiency in rats and chicks is classically accompanied by decreased tissue levels of linoleic acid and arachidonic acid and by increased levels of de novo synthesized ω9-series fatty acids, oleic acid and its elongation product, 20:3ω9 (21,22). In the present work, feeding chicks the EFA-deficient OPS diet for 3 wk led to a significant reduction in 18:2ω6 and 20:4ω6 in all three liver subcellular fractions. Similarly, significant reductions in linoleic and arachidonic acids were seen in liver microsomes and mitochondria of chicks fed SRG. The lowered linoleic acid levels in cytosol were significant for SRG-fed chicks, but the arachidonic acid levels were not. The profiles of microsomal and mitochondrial lipids appeared to be more severely affected by feeding EFA-deficient diets than were the fatty acid profiles of cytosol lipids. Intermediates in the ω6 desaturation pathway were lowered in membrane lipids, as was the elongation product, 22:5ω6. The results from this experiment support the findings of Haeffner and Privett (23) that rats fed hydrogenated coconut oil (deficient in EFA) had decreased linoleic and arachidonic acid levels in mitochondrial phospholipids.

Increased levels of 20:3ω9 in tissue lipids have been used as a criteria for assessing EFA deficiency. This fatty acid is formed when the rate-limiting desaturation of 18:1ω9 is no longer inhibited by the presence of the more preferred substrates for the Δ6 desaturase, 18:3ω3 and 18:2ω6 (4). In the present experiment, however, levels of 20:3ω9 were depressed in chicks fed SRG, OPS and HSBO compared to the controls fed CO.

In rats, feeding certain hydrogenated fats can depress desaturation in the ω9 series. Thomassen et al. (1) reported that EFA deficiency in rats caused by feeding partially hydrogenated vegetable oil with virtually no linoleic acid was accompanied by elevated 20:3ω9 levels and a triene-to-tetraene ratio above 0.4. The elevated 20:3ω9 was less dramatic, however, when partially hydrogenated marine oils low in 18:2ω6 were fed. In a study by Hill et al. (10), the effect of EFA deficiency on triene-to-tetraene ratios also varied with dietary lipid source. Although levels of 20:3ω9 were elevated as a result of EFA deficiency, levels of 20:3ω9 were lower and precursor 20:2ω9 levels higher in liver phospholipids of rats fed partially hydrogenated soybean oil for 31 wk than in those fed hydrogenated coconut oil or low-fat corn oil diets. This effect was probably caused by impaired Δ5 desaturase activity by 18:1 isomers present in the partially hydrogenated soybean oil.

The source of dietary carbohydrate can also influence the response of experimental animals to the feeding of EFA-deficient diets. Trugnan et al. (24) reported that rats fed EFA-deficient diets containing hydrogenated coconut oil and sucrose developed the characteristic feature of EFA deficiency (reduced weight gain and decreased linoleic and arachidonic acid levels and increased 20:3ω9 levels in plasma phospholipids). When starch was fed in place of sucrose, however, the EFA deficiency symptoms were noticeably reduced.

Increased levels of 20:3ω9 in liver and heart phospholipids from EFA-deficient chicks fed diets containing isolated soy protein, corn starch and triolein for 3 wk have been demonstrated by Watkins (25). Possibly the types of dietary fat sources are responsible for the differing effects of EFA deficiency on ω9 desaturation in the present experiment. The fatty acid profile of each tissue is influenced in part by the dietary lipid source and by de novo synthesis of fatty acids. In addition, alteration of dietary fatty acids in liver microsomes by desaturation and elongation, rates of fatty acid oxidation and selective incorporation of certain fatty acids into specific lipid classes contribute to the tissue fatty acid profile (4).

A decrease in 20:4ω6 by isomers of 18:1 other than 18:1ω9 was reported in rats (11) and examined more closely by Lawson et al. (3) using concentrates of *cis* and *trans* isomers. *Trans* 18:1 isomers suppressed 20:4ω6 and 20:3ω9 levels and increased 18:2ω6 and 20:5ω3 levels in rat liver phosphatidylcholine and phosphatidylethanolamine. *Cis* 18:1 isomers suppressed 20:4ω6 levels in phosphatidylcholine, 20:5ω3 in phosphatidylcholine and phosphatidylethanolamine and 18:2ω6 in phosphatidylcholine, but increased levels of 20:4ω6 in phosphatidylethanolamine and 20:3ω9 in phosphatidylcholine and phosphatidylethanolamine. Mahfouz et al. (11) suggested that Δ6 desaturation of fatty acids was inhibited by 18:1 isomers in rats. Possibly the same mechanism is effective in chicks, since levels of 18:2ω6 were similar in liver fractions from chicks fed HSBO and CO, but levels of arachidonic acid were significantly lower in microsomes and mitochondria when HSBO was fed.

In the present experiment with chicks, feeding partially hydrogenated soybean oil also led to an increase in ω3 fatty acids. This increase may partially be due to the higher level of linolenic acid in the HSBO diet. (All other lipid sources in this experiment contained much lower levels of 18:3ω3).

In summary, the dietary lipids fed in this study had a significant effect on the fatty acid profiles of chick liver microsomes, mitochondria and cytosol. Feeding day-old chicks diets deficient in linoleate for 3 wk led to significant reductions in both linoleate and arachidonate. Feeding HSBO that had adequate levels of linoleate and linolenate also resulted in lowered arachidonate levels in liver fractions, suggesting that the 18:1 isomers present in the dietary lipid inhibited Δ6 desaturase activity. The effects of feeding a partially hydrogenated fat with low linoleate levels (SRG) were similar to the effects of feeding OPS. Thus, under the conditions of our experiment, the effects of feeding EFA-deficient diets and hydrogenated fats were not additive.

Further studies, to determine the effects of hydrogenated fats on linoleate metabolism after prolonged feeding in chickens are warranted. Such studies are important because blended fats containing *cis/trans* isomers of unsaturated fatty acids are used in poultry rations, and the expected accumulation of *cis/trans* isomers in poultry products would contribute to the total intake of these fatty acids in the diets of humans.

Response of Urinary Malondialdehyde to Factors that Stimulate Lipid Peroxidation In Vivo

S.N. Dhanakoti[1] and **H.H. Draper***
Department of Nutritional Sciences, University of Guelph, Guelph, Ontario, Canada N1G 2W1

Malondialdehyde (MDA) derivatives occur as normal constituents of rat and human urine. In a previous study, it was found that MDA excretion in rats is responsive to MDA intake and to certain factors that increase lipid peroxidation in vivo: vitamin E deficiency, iron administration and a high concentration of cod liver oil (CLO) fatty acids in the tissues. In the present study, the effect on MDA excretion of several additional dietary and endogenous factors was evaluated.

The composition of dietary fatty acids had a major influence on MDA excretion in fed animals, being highest for animals fed n-3 fatty acids (20:5 and 22:6) from CLO, intermediate for those fed n-6 (18:2) acids from corn oil (CO) and lowest for those fed saturated acids from hydrogenated coconut oil (HCO). Diet was the main source of urinary MDA in all groups. Fasting produced a marked increase in urinary MDA, which tended to be higher in rats previously fed CLO. Fasting MDA excretion was not affected by the level of CO in the diet (5, 10 or 15%), indicating that feeding n-6 acids does not increase lipid peroxidation in vivo. Adrenocorticotropic hormone and epinephrine administration increased urinary MDA, further indicating that lipolysis either releases fatty acid peroxides from the tissues or increases the susceptibility of mobilized fatty acids to peroxidation. A decrease in fasting MDA excretion was observed in rats previously fed a high level of antioxidants (vitamin E + BHT + vitamin C) vs a normal level of vitamin E. MDA excretion increased following adriamycin and CCl_4 administration. No increase was observed following short-term feeding of a choline-methionine–deficient diet, which has been reported to increase peroxidation of rat liver nuclear lipids.

This study provides further evidence that urinary MDA can serve as a useful indicator of lipid peroxidation in vivo when peroxidation of dietary lipids is precluded.

Lipids 22, 643–646 (1987).

Derivatives of malondialdehyde (MDA), a major carbonyl product of lipid peroxidation arising mainly from polyunsaturated fatty acids (PUFA), are normal constituents of rat and human urine. In a previous study (1), endogenous MDA excretion in the rat was found to increase in response to certain factors that enhance lipid peroxidation in vivo: vitamin E deficiency, iron nitrilotriacetate administration and a high PUFA intake from cod liver oil. In the present study, the effect of several additional factors on lipid peroxidation in vivo was evaluated using urinary MDA as an indicator: feeding saturated vs n-6 vs n-3 fatty acids; a high level of dietary antioxidants; administration of adrenocorticotropic hormone (ACTH), epinephrine (EP), adriamycin or CCl_4; and short-term choline-methionine deficiency.

METHODS

Experiment 1. The effect of feeding diets containing saturated vs n-6 (18:2) vs n-3 (20:5 and 22:6) fatty acids on lipid peroxidation in vivo was assessed in rats by the urinary MDA method. The composition of the diets is given elsewhere (1). The fat sources were as follows: 15% hydrogenated coconut oil (HCO); 5% corn oil (CO) + 10% HCO; 10% CO + 5% HCO; 15% CO; 5% CO + 5% HCO + 5% cod liver oil (CLO). All diets contained 30 IU vitamin E/kg as DL-α-tocopheryl acetate and were stored at 4 C. They were fed to five groups of eight male weanling Wistar rats (Woodlyn Laboratories, Guelph, Ontario). Body weights were determined weekly. After 10 wk, 24-hr urine samples were collected from fed rats and analyzed for total MDA by the high performance liquid chromatography (HPLC) method of Bird et al. (2) as modified for urine by Draper et al. (1). To determine the endogenous contribution to urinary MDA, the animals then were fed the PUFA-free 15% HCO diet for 48 hr, and urinary MDA was measured during the second 24-hr period. Finally, the animals were fasted for 48 hr, and MDA excretion was determined during the second 24 hr.

Experiment 2. After it was found in Experiment 1 that fasting increased MDA excretion, the effect of the lipolytic agents EP and ACTH on MDA excretion was investigated. These hormones were administered to groups of six adult male Wistar rats that had been fed a high-PUFA (10% CO + 5% CLO) diet for 4 wk. To eliminate the effect of dietary MDA on MDA excretion, the animals were fed a PUFA-free (15% HCO) diet for 48 hr, and basal MDA excretion was determined for the second 24 hr. Then they were injected intraperitoneally with saline (0.9%), ACTH (40 OU kg) or EP (1 mg/kg) and fed the 15% HCO diet for an additional 24 hr, during which time MDA excretion was again determined.

Blood samples were collected from the orbital sinus into tubes containing heparinized 0.9% saline (25 IU heparin/dl) prior to and 4 hr following administration of saline, ACTH or epinephrine. Samples also were collected from a group of six adult male rats (365 ± 10.5 g) fed Rodent Chow® prior to and following a 48-hr fast. Free fatty acids (FFA) in the plasma were determined by the method of Falholt et al. (3) as modified by Lee and coworkers (4).

Experiment 3. The effect of dietary antioxidants on urinary MDA was investigated. Diets containing n-6 (10% CO) or a mixture of n-6 and n-3 (10% CO + 5% CLO) fatty acids were fed for 4 and 6 wk, respectively, in conjunction with a mixture of antioxidants (300 IU DL-α-tocopheryl acetate/kg + 0.5% BHT + 0.5% vitamin C) or

Abbreviations: MDA, malondialdehyde; PUFA, polyunsaturated fatty acids; ACTH, adrenocorticotropic hormone; EP, epinephrine; HCO, hydrogenated corn oil; CO, corn oil; CLO, cod liver oil; HPLC, high performance liquid chromatography; FFA, free fatty acids; CMD, choline-methionine-deficient; EFA, essential fatty acids.

a normal level of vitamin E (30 IU DL-α-tocopheryl acetate/kg). Fat and antioxidant additions were made at the expense of cornstarch (1). Final 24-hr urine samples were collected in the fed state for MDA analysis. The 10% CO groups then were fasted for 48 hr, and endogenous MDA excretion during the final 24 hr was measured. The 10% CO + 5% CLO groups were fed a PUFA-free (15% HCO) diet for 48 hr, and MDA excretion was determined during the final 24 hr. They then were fasted for 48 hr, and fasting MDA excretion during the final 24 hr was again determined.

Experiment 4. The toxicity of CCl_4 has been attributed to peroxidation of hepatic lipids. Its effect on urinary MDA was investigated in two groups of eight adult male Wistar rats (~300 g) fed a PUFA-free (15% HCO) diet. MDA excretion during the 24 hr before treatment and during two 24-hr periods following intubation with CCl_4 (100 μl/100 g) or saline (0.9%) was determined. MDA excretion also was assessed in saline-treated rats given 8.0 g food (the amount consumed by the CCl_4-treated animals 0–24 hr following intubation) to test the possibility that the response to CCl_4 was affected by a depressed intake of food relative to that of the controls (21.0 g).

Experiment 5. Adriamycin (doxorubicin), an antitumor antibiotic (5,6), causes cardiac toxicity associated with lipid peroxidation (7). Experiment 5 was designed to determine whether this effect could be detected in terms of increased MDA excretion. Two groups of eight male Wistar rats (~425 g) were fed for 3 days a 5% HCO diet (Dyets Inc., Bethlehem, PA) containing no detectable MDA (<0.1 μg/g). On day 4, the animals were injected intraperitoneally with either saline (0.9%) or adriamycin hydrochloride (5 mg/kg) in saline. Food consumption and MDA excretion were monitored for 48 hr post-administration.

Experiment 6. Based on the appearance of diene conjugates absorbing at 232 nm in the liver nuclei of rats fed a choline-methionine–deficient (CMD) diet, Rushmore et al. (8) proposed that lipid peroxidation was involved in the subsequent development of a high incidence of hepatic tumors. Through the courtesy of Dr. A. K. Ghoshal (Dept. of Pathology, University of Toronto, Ontario), urine samples from CMD animals collected at the peak concentration of diene conjugates (48–72 hr) and from controls were obtained for MDA analysis.

Statistical analysis. The significance of differences in weight, food consumption and MDA excretion was determined using Student's t-test, except that in Experiment 1, differences in MDA excretion were evaluated using Duncan's multiple-range test. Significance was tested at the 5% and 1% levels of probability.

RESULTS AND DISCUSSION

PUFA intake and MDA excretion. Figure 1 illustrates the effects of feeding diets high in saturated, n-6 and n-3 fatty acids on MDA excretion. The composition of dietary fatty acids had a major influence on MDA excretion in fed rats, being highest for those fed n-3 acids from CLO, intermediate for those fed n-6 acids from CO and lowest for those fed saturated acids from HCO. There were no significant differences ($p > 0.05$) in MDA excretion between groups fed different levels of corn oil (5, 10 or 15%). Switching the CLO and CO groups to the PUFA-free 15% HCO diet resulted in a major decrease ($p < 0.01$) in MDA excretion and eliminated treatment differences. This observation indicates that, as reported previously (1), diet was the main source of urinary MDA in these groups. The rats fed the essential fatty acid (EFA)-deficient 15% HCO diet for 10 wk had a significantly ($p < 0.01$) lower body weight than the other groups (data not shown).

A 24-48 hr fast produced a marked increase ($p < 0.01$) in MDA excretion in all groups. This increase was highest in the rats previously fed CLO, but the difference was significant ($p < 0.01$) only with reference to those fed 15% CO or 15% HCO. A significant increase in fasting MDA excretion in animals fed a diet containing cod liver oil was seen in an earlier study (1). These increases presumably reflect an enhanced peroxidation of tissue lipids. Reddy et al. (9) observed that the adipose tissue of animals fed CLO had three times the fluorescence of tissue from animals fed corn oil. Iritani et al. (10) found that chemiluminescence emission associated with NADPH-dependent lipid peroxidation in liver microsomes was greater in rats fed 5% vs 0.5% CO but not 10% vs 5% CO.

There were no significant differences in fasting MDA excretion among groups fed different levels of corn oil. Lack of a dose response to CO intake may be due to the fact that the conversion of linoleate to arachidonic acid (the presumed main source of MDA from peroxidation of n-6 acids) does not increase in proportion to the level of linoleate in the diet. The more peroxidizable pentaenoic and hexaenoic acids of the n-3 series, on the other hand, are readily deposited in the tissues of animals fed CLO, though not extensively in adipose tissue (1). The results indicate that high intakes of oils containing dienoic n-6 acids do not enhance peroxidation of PUFA in vivo.

It is noteworthy that urinary MDA also increased in fasting rats fed the HCO diet. This increase, which was comparable to that of rats fed the CO diets, may have been due to peroxidation of 5,8,11-eicosatrienoic acid, which accumulates in plasma and tissue phospholipids in EFA deficiency.

Effect of ACTH and EP. After 4 wk, MDA excretion on the high-PUFA diet averaged 3.1–3.6 μg/24 hr ($p > 0.05$) (Table 1). These values decreased to 1.1–1.3 μg/24 hr on the PUFA-free diet. Small but significant ($p < 0.05$) increases in MDA excretion over that of the control group were observed during the 24 hr following ACTH or EP administration.

Plasma FFA levels were 36.5% and 57.7% above control values 4 hr following EP and ACTH administration, respectively (Table 2). In animals fasted for 48 hr, FFA levels increased by 78.0% (362 ± 4.8 vs 203 ± 2.2 μmol/dl). The smaller increments in MDA excretion observed

following ACTH or EP administration than those observed after fasting (Fig. 1) may have been due to a lesser lipolytic response.

The increase in MDA excretion following fasting or administration of lipolytic hormones may reflect a mobilization of fatty acid peroxides from the tissues. Alternatively, it is possible that mobilized PUFA are subject to peroxidation catalyzed by heme proteins or transition metals during transport in the serum. This question is worthy of further investigation.

Antioxidant effect. Feeding a high level of antioxidants was associated with reductions of 37% and 32% in fasting MDA excretion relative to that seen in controls fed a moderate level of vitamin E ($p < 0.01$) (Table 3). As the urine samples were collected 24–48 hr after the beginning of a fast, these reductions presumably reflect an inhibition of in vivo lipid peroxidation. This conclusion is supported by the fact that the reduction persisted in fasted animals after interim feeding of a peroxide-free diet. A similar effect was seen previously in fasted rats fed 100 IU or 30 IU vitamin E/Kg diet vs no antioxidant (1). Although the absolute decrease in MDA excretion associated with the high antioxidant intake was small, urinary MDA probably represents only a small fraction of the total MDA formed in vivo. ^{14}C-MDA administered orally to rats is extensively oxidized to $^{14}CO_2$, with only 10% of the radioactivity appearing in the urine (11). Ongoing experiments have indicated that urinary MDA consists mainly of lysine derivatives (unpublished results).

As observed previously (1), CLO markedly increased MDA excretion, an effect attributable mainly to enhanced peroxidation of dietary lipids (α-tocopherol was present as the acetate). Body weight gain was reduced in the high antioxidant group, probably as a result of the presence of BHT, which is known to depress growth at high concentrations. The elevation in urinary MDA associated with fasting was again evident in this experiment.

CCl_4 experiment. MDA excretion increased ($p < 0.01$) during the 24 hr following CCl_4 administration (Table 4), reflecting a stimulatory effect on in vivo lipid peroxidation. However, there was also a significant decrease in food intake by the CCl_4-treated rats (8.0 ± 0.9 g vs 21.0 ± 2.6 g) during the same period, raising the possiblity that the increase was due to inanition. Restricting the control rats to 8.0 g diet (which was eaten early in the 24-hr period) raised their MDA excretion to 2.4 ± 0.2 μg/24 hr ($p < 0.01$). This increase was significantly lower

†100 µl/100 g; 15% HCO diet.

($p < 0.01$) than that of the rats intubated with CCl_4 (3.8 ± 0.2 µg/24 hr). Hence, the increase in MDA excretion following the CCl_4 dose does not appear to have been due entirely to lipolysis arising from a coincident decrease in food consumption. Failure to observe an effect of CCl_4 on urinary MDA in a previous study (1) was probably due to a decrease in MDA intake from the diet (Rodent Chow®) by the CCl_4-treated animals. Thus, tests for lipid peroxidation in vivo using MDA excretion as a criterion should be carried out using an MDA-free diet.

Adriamycin experiment. A small but significant ($p < 0.05$) increase in urinary MDA was observed from 0 to 24 hr, but not from 24 to 48 hr, following adriamycin administration (Table 5). There was also a small reduction in food consumption following its administration (17.5 ± 1.2 g vs 15.9 ± 1.4 g). The tenuous increase in urinary MDA may be due to the organ specificity of this compound.

Effect of choline-methionine deficiency. There was no significant change in MDA excretion caused by short-term feeding of a CMD diet (4.0 ± 0.5 µg/24 hr in the CMD group vs 3.5 ± 0.8 µg/24 hr in controls). Lipid peroxidation caused by short-term feeding of the CMD diet is reportedly confined to hepatic nuclei (8); any increase in MDA production at this site, therefore, may have a negligible effect on total MDA excretion.

†Animals fed PUFA-free 15% HCO diet.

Forms of MDA in urine. Anion exchange chromatography of rat and human urine has been used to separate several discrete MDA derivatives. In addition to N-acetyl-ε-propenal lysine (12), a cyclized form of ε-propenal lysine, enaminals of the phospholipid bases serine and ethanolamine and, in some samples, a small amount of free MDA have been identified (Hadley, M., and Draper, H.H., unpublished results). Together, these compounds represent a large fraction of the total MDA in most urine samples. The identity of several minor MDA-yielding compounds is under investigation, including the possibility that there may be lipids in urine from which MDA is formed as an artifact during the procedure described for its estimation.

General conclusion. The results of this study provide further evidence that urinary MDA is useful as an indicator of in vivo lipid peroxidation when peroxidation of dietary lipids is precluded.

Effects of Diets Enriched in Eicosapentaenoic or Docosahexaenoic Acids on Prostanoid Metabolism in the Rat

Kevin D. Croft[a,*], **Lawrence J. Beilin**[a], **Frank M. Legge**[b] and **Robert Vandongen**[a]

To clarify the effects of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) on prostaglandin biosynthesis, diets supplemented with oils rich in one fatty acid or the other were fed to rats over a 4-wk period. Animals fed the Max EPA diet showed a significant decrease in plasma and tissue phospholipid arachidonic acid content. While plasma levels of DHA increased on a shark liver oil diet enriched in DHA, the liver and kidney phospholipid contents of DHA were not altered. In addiition, the DHA-enriched diet did not decrease the arachidonic acid content of either liver or kidney phospholipids. Whole blood thromboxane and vascular prostacyclin synthesis were decreased by 65% and 36%, respectively, in animals fed the Max EPA diet. No such decrease was seen in the rats fed DHA-enriched diets. We conclude from these results that in the rat DHA is not likely to have a significant effect on prostaglandin synthesis when given as a dietary supplement.
Lipids 22, 647–650 (1987).

Dietary fish oils are generally thought to have a cardiovascular protective effect, which is attributed mainly to their ability to modify prostaglandin and lipid synthesis (1–4). While fish oils invariably contain a mixture of fatty acids, including eicosapentaenoic acid (EPA, 20:5ω3) and docosahexaenoic acid (DHA, 22:6ω3), most biological activity has been ascribed to EPA. For example, dietary EPA can depress the production of thromboxane A_2 (TXA_2) by reducing platelet phospholipid arachidonic acid stores and by competitively inhibiting cyclooxygenase (5,6). However, at least one in vitro study has shown that DHA is also a strong inhibitor of prostaglandin biosynthesis (7). Von Schacky and Weber (8) supplemented the human diet separately with purified EPA and DHA, and although thromboxane formation was unaltered, DHA reduced platelet responsiveness, indicating that it may contribute to the antithrombotic effects of dietary fish oils.

We have carried out detailed studies on the effects of dietary fish oils on phospholipid fatty acid composition and prostaglandin synthesis in the rat (9,10) using commercially available cod liver oil and Max EPA, which are richer in EPA than in DHA. It is known that Australian fish species have a different fatty acid composition compared to Northern Hemisphere species commonly used in commercial oil production (11). A local fish liver oil was found to be highly enriched in DHA, with relatively small amounts of EPA and arachidonic acid, while the total ω3 fatty acid content was similar to Max EPA oil. To elucidate further the effectiveness of EPA and DHA as prostaglandin inhibitors, diets supplemented with oils enriched in one fatty acid or the other were fed to rats over a 4-wk period. Changes in plasma and tissue phospholipid fatty acid composition and prostanoid production were compared among Max EPA oil, a local shark liver oil and a control diet of coconut oil/3% safflower oil.

Abbreviations: EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid; TXA_2, thromboxane A_2; TXB_2, thromboxane B_2; RIA, radioimmunoassay.

MATERIALS AND METHODS

Animals and dietary treatment. Thirty male Sprague-Dawley rats (150–200 g) were randomly allocated to three groups of 10 and placed on a synthetic diet preparation. The synthetic diet consisted of (by weight) casein, 20%; macro-minerals, 2%; vitamin and trace mineral mix, 0.75%; cellulose, 7%; choline chloride, 0.25%; corn flour, 45%; sucrose, 15%; and fat, 10%. The dry components of the feed were prepared by Milne Stock Feed (Welshpool, Western Australia), and the oils were added in our laboratory before feed was baked into small biscuits. Fatty acid composition was not altered during the baking process, and fresh food was prepared each week. The fat component contributed 20% of the caloric content of the diet and was either Max EPA fish oil (R.P. Sherer Pty Ltd, Melbourne, Victoria, Australia), hydrogenated coconut oil containing 3% safflower oil, or a locally prepared shark liver oil. The major fatty acid composition of these oils (analyzed by gas chromatography) is outlined in Table 1. Body weights were measured weekly, and at the end of the 4-wk treatment period rats were placed in metabolic cages for 24-hr urine collection. Animals were anaesthetized with sodium pentobarbitone and killed. Approximately 10 ml of aortic blood was obtained together with samples of kidney and liver tissues and a strip of thoracic aorta.

Fatty acid analysis. Total lipids were extracted from plasma (100μl) with 1 ml of ether/methanol (5:1, v/v); 1% KCl solution (150 μl) was added to aid phase separation. Homogenized kidney and liver tissue were extracted with choloroform/methanol (2:1, v/v) and filtered. All extracts

were evaporated to dryness under nitrogen. All extracting solvents contained butylated hydroxy toluene as antioxidant. Total phospholipids were isolated from crude lipid extracts by thin layer chromatography (Silica Gel 60 F_{254}, Merck, Darmstadt, FRG) using a solvent system of hexane/ether/acetic acid/ methanol (170:40:4:4, v/v/v/v) (9). Analysis of acylated fatty acids in total lipids and phospholipids was carried out by gas chromatography of their corresponding methyl esters. Methyl esters were prepared by treatment of extracts suspended in ether (200 μl) with one drop of tetramethyl ammonium hydroxide solution (20% in methanol) at room temperature for 30 min. After settling, the upper layer was transferred to another vial and evaporated under nitrogen. The residue was redissolved in cyclohexane and analyzed using a Hewlett Packard 5890 gas chromatograph fitted with a 25-m methyl silicone capillary column (0.2 mm id), Hewlett Packard type 19091A-102, with hydrogen carier gas at 80 kPa. The oven was temperature-programmed as follows: 217 C for 14.5 min, 7 C per min to 252 C, then 25 C per minute to 340 C with a final hold of 3.5 min. Peaks were identified by comparison to authentic standards, and peak areas were calculated automatically using a Packard 604 recording data processor.

Serum thromboxane B_2 (TXB_2) analysis. Following collection, blood samples were allowed to clot by incubation for 1 hr at 37 C. Serum was removed after centrifugation and stored at −20 C. Samples were diluted 1:500 in radioimmunoassay (RIA) buffer prior to direct analysis for TXB_2 as previously described (12). The validity and reliability of these assays have been established in detail (13).

Aortic prostacyclin synthesis. The thoracic portion of the aorta was cleared of adhering tissue and washed in ice-cold saline. One cm sections were cut into rings and incubated in Krebs-Henseleit buffer at 37 C for 30 min. The aortic segments were then removed, blotted dry and weighed. The incubates were stored at −20 C for analysis of the stable prostacyclin hydrolysis product 6-keto $PGF_{1\alpha}$ by RIA (12,13).

Urine prostaglandin analysis. The volume of 24-hr urine collections was recorded, and samples were stored frozen at −20 C. PGE_2 and 6-keto $PGF_{a\alpha}$ were assayed in urine samples by RIA after organic extraction and thin layer chromatography as previously described (9).

Statistics. Results are expressed as the mean and standard error of the mean (SEM). One-way analysis of variance was used to test for significant differences between all dietary groups. Differences between any two dietary groups were established by modified t statistics using Fischer's least significance test.

RESULTS

All animals had a satisfactory weight gain over the 4-wk treatment period. Final weights for each of the groups were as follows: hydrogenated coconut oil containing 3% safflower oil, 223 ± 8 g; Max EPA oil, 246 ± 5 g; and shark liver oil, 250 ± 8 g.

Plasma and tissue fatty composition. The fatty acid composition of total plasma lipids of rats fed for 4 wk on the synthetic diets containing 10% (by weight) oil supplements is given in Table 2. Animals fed the Max EPA diet showed 36% lower (P < 0.01) 20:4 levels compared to the coconut oil control group. This lower 20:4 level was accompanied by a level more than three-fold higher of 20:5 and a slightly higher 22:6 level in plasma lipids. The animals fed shark oil showed a higher (P < 0.01) 20:4 content in plasma lipids together with a slightly higher level of 22:6 (P < 0.01). The 20:5 content of plasma lipids did not differ from those of the control group.

Results of the fatty acid analysis of liver phospholipids after the 4-wk feeding period are shown in Table 3. The most pronounced changes occurred in the rats fed Max EPA whose levels of 20:4 were lower by 33% (P < 0.001) and of 20:5 were six-fold higher. In contrast, animals on the shark oil diet showed 28% higher 20:4 and no change in 20:5. These changes were associated with small decreases in 18:0, 18:2 and 22:6 in the shark oil group compared to the coconut oil group. The fatty acid composition of kidney phospholipids (Table 4) showed similar trends to those observed for liver phospholipids. In particular, the Max EPA group showed lower 20:4 and a substantially higher 20:5 compared to the coconut oil control. However, in contrast to the results obtained in the liver, the rats fed shark oil had slightly lower 20:4 and a modest rise in 20:5 (P < 0.001) in kidney phospholipids. Again, 22:6 levels were not significantly higher on the shark oil diet,

HCO, hydrogenated coconut oil + 3% safflower oil; EPA, Max EPA oil; SLO, shark liver oil.

[a]Mean ± SEM, percent of total fatty acids, n = 10 for each group.

* and **, Significant differences ($P < 0.01$ and $P < 0.001$, respectively) between the HCO control and other dietary groups.

despite the large amounts of that fatty acid in shark liver oil. The 18:2 content of kidney phospholipids was lower on both of the fish oil diets compared to the coconut oil group ($P < 0.01$).

Prostaglandin synthesis. The whole blood production of TXB_2 (ng/ml serum) for each of the dietary groups is illustrated in Figure 1a. There was a 65% reduction ($P < 0.001$) in TXB_2 synthesis from animals fed the Max EPA diet compared to the coconut oil control group. The animals fed shark oil showed no significant difference in thromboxane production compared to the control group.

Prostacyclin production in incubated segments of aorta was assessed by measurement of the stable hydrolysis product 6-keto-$PGF_{1\alpha}$. The production of 6-keto-$PGF_{1\alpha}$ for each dietary group is illustrated in Figure 1b. These results show similar but less pronounced effects as those seen for serum thromboxane. The animals fed Max EPA were 36% lower ($P < 0.02$) in aortic prostacyclin production compared to the group fed coconut oil while production in the animals fed shark oil was not significantly different from controls.

There was no significant difference in urinary excretion of PGE_2 or 6-keto-$PGF_{1\alpha}$ among the dietary groups. The urinary excretions of PGE_2 and 6-keto-$PGF_{1\alpha}$, respectively, were as follows: coconut oil, 12.5 ± 1.8 and 14.1 ± 1.9 ng/24 hr; Max EPA, 12.1 ± 1.8 and 17.1 ± 1.6 ng/24 hr; shark oil, 12.4 ± 1.6 and 17.9 ± ng/24 hr. There was no significant differences in 24-hr urine volume among the dietary groups.

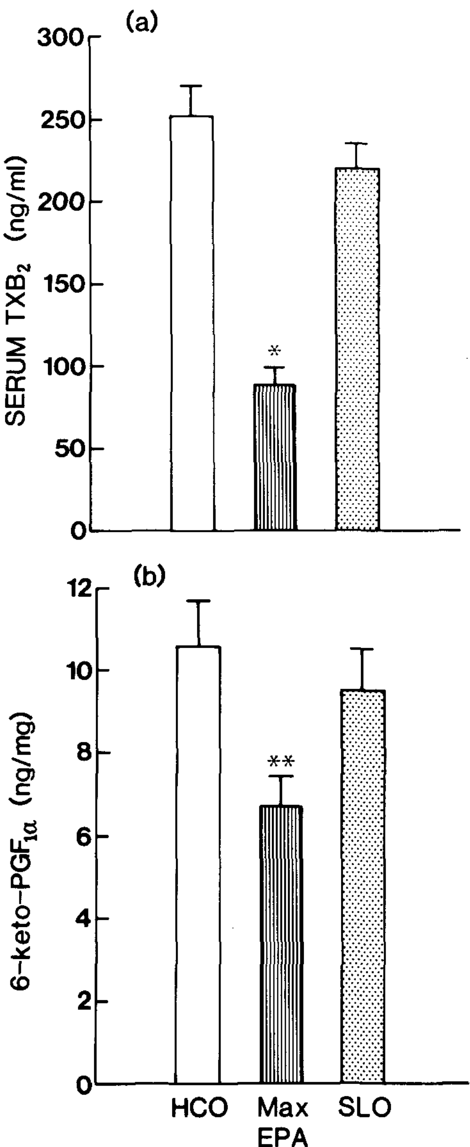

FIG. 1. The effects of dietary treatment with hydrogenated coconut oil containing 3% safflower oil (HCO), Max EPA fish oil (Max EPA) or shark liver oil (SLO) on (a) serum TXB_2 generation and (b) production of 6-keto-$PGF_{1\alpha}$ by incubated segments of aorta. *, $p < 0.001$ and **, $p < 0.02$ for differences between the HCO control groups and other dietary groups.

DISCUSSION

In this study, we have compared effects of dietary fish oils enriched with either EPA or DHA on tissue fatty acid composition and prostaglandin synthesis in the rat. We have found the dietary DHA is very poorly incorporated into tissue phospholipids and exerts a minimal influence on prostanoid synthesis.

The fatty acid composition of plasma lipids reflected the dietary fatty acid intake. Rats on the Max EPA diet showed higher levels of EPA and DHA and lower amounts of arachidonic acid. Those animals fed the shark oil diet showed a modest rise in DHA and arachidonic acid but no change in EPA compared to controls. Presumably the increased levels of arachidonic acid in plasma lipids are a result of the higher level (2.6%) of arachidonic acid in shark liver oil compared to Max EPA (< 1%) or the control diet.

In contrast to plasma lipids, DHA was not higher in either liver or kidney phospholipids from animals fed the shark oil diet. EPA was not increased in tissue phospholipids on this diet, while arachidonic acid was elevated in liver phospholipids but not in the kidney. These results are in contrast to other studies where rat platelet total phospholipids had a higher content of DHA when dietary DHA was increased from 0.8% to 1.6% of the total dietary

fatty acids (14). The lack of incorporation of DHA into tissue phospholipids is also in contrast to human studies where significant increases in platelet and leukocyte phospholipid DHA have been observed following diets enriched with DHA (8,15).

Rats fed the Max EPA diet showed a large rise in EPA content of both liver and renal phospholipids together with significantly lower arachidonic acid compared to the control group. These results are consistent with our previous studies (9,10) and those of others who fed fish oil diets to rats (16). The ability of EPA to be readily incorporated into tissue phospholipids at the expense of arachidonic acid is also indicated by its effectiveness at lowering prostanoid synthesis. Both whole blood thromboxane and vascular prostacyclin synthesis were lower in animals fed Max EPA. In previous experiments we have found that alterations in platelet phospholipid fatty acid composition after dietary Max EPA closely correlated with changes in plasma fatty acids and that these changes explain the observed effects on thromboxane production (10). No such decrease was seen in the rats fed shark oil which is not surprising in view of the lack of incorporation of DHA and EPA and the maintenance of arachidonic acid levels. The small but significant amount of arachidonic acid in the shark oil diet may compensate for the presence of EPA and DHA. This suggestion is supported by in vitro studies using human endothelial cells where DHA was incorporated into total phospholipids with a consequent reduction in arachidonic acid content; however, when cells were incubated with DHA and arachidonic acid together, the reduction in arachidonic acid was abolished and the uptake of DHA reduced (17).

Urinary excretion of PGE_2 and 6-keto-$PGF_{1\alpha}$ was not significantly different among the dietary groups. Although in previous experiments with large numbers of animals, 6-keto-$PGF_{1\alpha}$ excretion has been depressed by an EPA diet, results for PGE_2 have been less consistent (9,10). In man, urinary excretion of the major prostacyclin metabolites does not decrease on an EPA-enriched diet, although an increase in the 3-series prostanoids can be detected by gas chromatography–mass spectrometry (18). Our analytical procedure is unable to distinguish between the 2- and 3-series metabolites.

In vitro experiments using exogenous DHA indicate that this fatty acid is an inhibitor of prostanoid synthesis in ram seminal vesicles (7). This study shows, however, that in the rat DHA is not likely to have a significant effect on prostanoid synthesis when given as a dietary supplement due to its lack of incorporation into tissue phospholipids, particularly in the presence of small amounts of arachidonic acid. Even when DHA has been incorporated into platelet phospholipids, it is not released to any significant extent upon thrombin stimulation and can exert only minimal effects upon the arachidonic acid cascade (15). In a study similar to ours, Bruckner and coworkers (19) found that platelet DHA levels and serum TXB_2 were not altered in rats fed a DHA-enriched diet, while those fed an EPA-rich diet had significantly decreased TXB_2 levels. They conclude that EPA and not DHA is responsible for the alterations in platelet prostaglandin biosynthesis. Despite this, it cannot be ruled out that, at least in man, ingestion of DHA may influence platelet behavior by modifying plasma fatty acid composition (8).

ACKNOWLEDGMENTS

We would like to thank Peter Kailis for the shark oil and R.P. Sherer Pty Ltd. for the donation of Max EPA oil. We also thank Belinda Smith and Rhonda Plummer for their technical assistance. This work was supported by grants from the National Health and Medical Research Council of Australia, National Heart Foundation and the Royal Perth Hospital Research Foundation.

Lipid Composition of Cultured B16 Melanoma Cell Variants with Different Lung-colonizing Potential

L. Calorini, A. Fallani, D. Tombaccini, G. Mugnai and **S. Ruggieri***
Istituto di Patologia Generale, Università degli Studi di Firenze, Firenze, Italy

Lipid components influence several cell surface properties that are critical in different stages of the metastatic process. In this study, we examined whether the different lung-colonizing potential of B16-F1 and B16-F10 melanoma cells could be related to a characteristic lipid profile. The lipid analyses, carried out on the same cell cultures used for the assay of lung-colonizing potential, revealed characteristics in the lipid composition of both B16-F1 and B16-F10 melanoma cells that are common to other systems of malignant cells: a high level of 18:1 associated with low proportions of polyunsaturated fatty acids in phospholipids, accumulation of ether-linked lipids and absence of complex gangliosides. The two B16 melanoma variants differed significantly only with respect to ether-linked lipids, due to a higher level of alkyl-PC in B16-F10 than in B16-F1.
Lipids 22, 651–656 (1987).

The cell surface is known to be involved in the mechanism of metastatic diffusion of tumor cells (1). Indeed, it is through its cell surface that an invading malignant cell successfully interacts with a number of the host homeostatic mechanisms through several stages, ending with the occurrence of a secondary tumor at a distant site (2,3). Much information on biological and molecular changes of the cell surface of malignant cells has been accumulated over the last few years (4); data, however, are still lacking on which of these changes are relevant to the metastatic behavior of malignant cells. Those related to lipid structure (5,6) appear to be of particular importance. Specific lipid components might influence the metastatic potential of tumor cells through their effect on cell surface properties—permeability (7), adhesiveness (8), agglutinability (9), antigenicity (10), receptorial (11,12) or enzymatic (13) activity—that may be critical for metastastic diffusion.

The availability of tumor cell variants with different metastatic potential (14) has greatly improved our capacity to study the role of cell surface molecular characteristics in the metastatic process. From B16 melanoma, Fidler (15) selected B16-F1 cells, whose lung-colonizing potential is low, after one in vivo–in vitro cycle, and B16-F10 cells, with high lung-colonizing potential, after 10 in vivo–vitro cycles.

In the present study, we analyzed the various lipid components of F1 and F10 melanoma cells in order to investigate whether the different lung-colonizing potentials of the two variants may be correlated with a specific lipid pattern.

Some aspects of the lipid composition of F1 and F10 cells have recently been described by Schroeder and Gardiner (16), while Yogeeswaran et al. (17) and Raz et al. (18) have published data on their glycolipid structure.

MATERIALS AND METHODS

Cells and culture conditions. F1 and F10 variants of B16 melanoma were supplied by Dr. I. Fidler (Department of Cell Biology, University of Texas System Cancer Center, Houston). Upon arrival in our laboratory, the cells were cultured for a few passages and then frozen in liquid nitrogen.

For each experiment, cells were first thawed and then propagated for a few passages to obtain a sufficient number of cells to enable us to determine at the same time both their lung-colonizing potential and their various lipid components. Cells were seeded at 0.8×10^6 cells per dish (10-mm Falcon plastic culture dishes) and grown for 4 days at 37 C in antibiotic-free Eagle's minimal essential medium with a fourfold concentration of vitamins and essential amino acids (Flow Laboratories, Irvine, CA) supplemented with 10% fetal calf serum (Flow Labs) in a humidified atmosphere containing 5% CO_2. Cell cultures were passed at subconfluence by incubation at 37 C for 1 min with a 0.25% trypsin solution in phosphate-buffered saline (PBS). We monitored cultures periodically for mycoplasma contamination using Chen's fluorochrome test (19).

Determination of lung-colonizing potential. Cell cultures of F1 and F10 cells were harvested at the exponential growth phase by 1 min of trypsinization with 0.25% trypsin in PBS. Cells were washed by centrifugation followed by resuspension in PBS and then were counted by an automatic cell counter (Coulter Electronic, Luton, England). Only cells whose viability was greater than 95%, as demonstrated by Trypan blue exclusion test, were used. After adjusting cell concentration to 2.5×10^5/ml, 0.2 ml of single-cell suspensions was injected into the tail veins of six- to eight-week old C57B1/6 mice (Charles River Italia, Calco, Italy). Each assay was performed on 30 animals, which were killed 21 days after injection. Nodules on the lung surface were counted with the aid of a dissecting microscope. In three separate experiments, the mean number of lung nodules per animal inoculated with F1 and F10 cells was 3 (range 0–12) and 55 (range 15–136), respectively.

Lipid extraction and analysis. Cell cultures for lipid analyses were harvested by incubation at 37 C with a 0.5 mM EGTA solution in PBS. The EGTA-detached cells were washed twice by centrifugation followed by resuspension in PBS. Cells were counted and then sonicated with a Labsonic sonicator model 1510 (Braun, Melsungen, FRG). Total lipids were extracted from the sonicated cell

Abbreviations: PBS, phosphate-buffered saline; TLC, thin layer chromatography; GLC, gas liquid chromatography; FAME, fatty acid methyl esters; DPG, diphosphatidylglycerol; PE, phosphatidylethanolamine; PC, phosphatidylcholine; SP, sphingomyelin; PA, phosphatidic acid; PI, phosphatidylinositol; PS, phosphatidylserine; GL1, glucosyl-ceramide; GL2, lactosyl-ceramide; GL3, galactosyl-galactosyl-glucosyl-ceramide.

suspensions with chloroform/methanol (2:1, v/v) following the method of Folch et al. (20), and then were fractionated into neutral lipids and phospholipids by silicic acid column chromatography.

Neutral lipids were sequentially separated into cholesteryl esters, alkyldiacylglycerols, triacylglycerols, free fatty acids and free cholesterol by thin layer chromatography (TLC) on 0.25 mm Silica Gel H precoated plates (Merck, Darmstadt, FRG), using hexane/diethyl ether/acetic acid (85:15:1, v/v/v).

Cholesterol was determined in the total lipid extract and in the free and esterified cholesterol fractions by quantitative gas liquid chromatography (GLC) with coprostanol as an internal standard.

Triacylglycerols and free fatty acids were evaluated from quantitative GLC of their fatty acid methyl esters (FAME), which were obtained by acid-catalyzed methanolysis in the presence of an arachidic acid internal standard.

Alkyldiacylglycerols were converted into alkylglycerols by hydrogenolysis with sodium-bis(2-methoxy-ethoxy)aluminum hydride (Aldrich Chemical Co., Steinheim, FRG) in the presence of pentadecylglycerol as an internal standard (21) and were quantitatively assayed as isopropylidene derivatives by GLC.

Phospholipids in 1mg amounts were applied to 0.25 mm Silica Gel H precoated plates, activated at 110 C for 2 hr before use, and were chromatographed bi-dimensionally with chloroform/methanol/ammonia (95:45:11, v/v/v) followed by chloroform/methanol/acetic acid/water (90:40:12:2, v/v/v/v). Under these conditions, phospholipids were fractionated into diphosphatidylglycerol (DPG), phosphatidylethanolamine (PE), phosphatidylcholine (PC), sphingomyelin (SP) and phosphatidic acid (PA); phosphatidylinositol (PI) and phosphatidylserine (PS) were combined for analyses since they could not always be easily separated. After the plates were sprayed with 0.1% dichlorofluorescein in ethanol, the phospholipid fractions were localized under ultraviolet light and scraped into vials for phosphorus determination (22) after digestion with sulfuric acid/perchloric acid (3:2, v/v). PE and PC were submitted to ether-lipid analysis following Su and Schmid's procedure (21), in which the alkenyl-linked subfractions were converted into cyclic acetals in the presence of dimethoxytetradecane and the alkyl-linked subfractions were converted into alkylglycerols with pentadecylglycerol as its internal standard.

Glycolipids were determined radiometrically by measuring their radioactivity after exposing cells for 48 hr to growth media containing 1.0 μCi/ml of 3H-galactose (NEN Research Products, Dreieich, FRG). Neutral glycolipids and gangliosides were isolated from total lipids by Siakotos and Rouser's chromatographic procedure (23). Neutral glycolipids were then freed from the contaminating phospholipids and neutral lipids by acetylation followed by Florisil column chromatography according to Saito and Hakomori (24). Gangliosides and deacetylated neutral glycolipids were fractionated by TLC on high performance TLC plates (Merck) using chloroform/methanol/0.25% $CaCl_2$ (55:40:9, v/v/v) and chloroform/methanol/water (65:25:4, v/v/v), respectively. The labeled glycolipid fractions were revealed by fluorography and counted in scintillation vials. Glucosyl-ceramide (GL1), lactosyl-ceramide (GL2) and GM3 were identified by the carbohydrate group analysis, as we have previously described (25). GM2, GM1 and GD1a were identified by comparing their migration rates on TLC to those of authentic standards. The TLC of neutral glycolipids of F1 and F10 cells also revealed the presence of a more complex glycolipid, tentatively identified as galactosyl-galactosyl-glucosyl-ceramide (GL3) based on the similarity of its migration rate to that of an authentic standard. The oligosaccharide chain was not chemically characterized.

Gas chromatographic analyses. FAME were prepared from triacylglycerols, free fatty acids, cholesteryl esters and phospholipid classes by heating the sample at 80 C for 12 hr in a solution of 5% H_2SO_4 in methanol/benzene (25:1, v/v). FAME were extracted into hexane, concentrated under a stream of nitrogen and then analyzed by GLC in a Perkin Elmer Gas Chromatograph model 3920 equipped with hydrogen flame detectors. FAME were analyzed isothermally at 185 C on 6-ft glass columns packed with 10% EGSS-X on Gas-Chrom P 100–120 mesh (Supelco, Bellefonte, PA). FAME were identified by their retention times relative to those of standard methyl ester mixtures (Supelco).

The cyclic acetal derivatives of alkenyl groups and isopropylidene derivatives (26) of alkylglycerols were quantitatively analyzed at 195 C on 6-ft glass columns packed with 10% EGSS-X on Gas Chrom P 100/120 mesh.

Cholesterol was measured at 265 C on 6-ft glass columns packed with 3% OV 17 on Supelcoport 80/100 mesh (Supelco).

The methylglycoside products of the acid-catalyzed methanolysis of the glycolipids were analyzed as trimethylsilyl derivatives on 6-ft glass columns packed with 3% OV-17 on Supelcoport 80/100 mesh (Supelco) at a programmed temperature ranging from 120 C to 230 C (2 C/min).

Peak areas were measured with a Perkin-Elmer Sigma 10 integrator.

Statistical tests. Student's t-test was used to assess the statistical significance of the differences between F1 and F10 cells.

Lipid standards. We synthesized the standard of pentadecyl-glycerol (27). Dimethoxytetradecane, coprostanol and arachidic acid were supplied by Supelco.

RESULTS AND DISCUSSION

As shown in Table 1, the low metastatic F1 and the highly metastatic F10 melanoma cells contained comparable concentrations of total phospholipids and cholesterol, esterified cholesterol, triacylglycerols, alkyldiacylglycerols and free fatty acids. Schroeder and Gardiner, instead, reported a lower level of cholesterol in F10 than in F1 cells (16).

The two variants of B16 melanoma did not differ in their phospholipid composition (Table 2).

In both F1 and F10 cells, an appreciable proportion of PE was composed of alkenyl-linked molecules, while small percentages of alkyl-linked molecules were associated with PC (Table 3). This pattern is reminiscent of that found in different types of normal and malignant cells (29–41). Under our experimental conditions, alkyl-linked PE and alkenyl-linked PC were not detectable in

TABLE 1

Lipid Composition of B16-F1 and B16-F10 Melanoma Cell Lines[a]

Lipid Class	B16-F1	B16-F10
Total phospholipids[b]	49.6 ± 1.7	45.4 ± 2.4
Total cholesterol	6.8 ± 0.4	7.1 ± 0.7
Esterified cholesterol[c]	0.2 ± 0.1	0.2 ± 0.1
Triacylglycerols[d]	1.0 ± 0.1	1.1 ± 0.4
Alkyldiacylglycerols[e]	0.5 ± 0.2	0.6 ± 0.1
Free fatty acids	0.4 ± 0	0.4 ± 0

[a]Values, expressed as μg/10^{6}cells, are means ± SE of three separate experiments.

[b]As calculated by multiplying by 25 lipid phosphorus assayed on total lipids (22) after digestion with sulfuric acid/perchloric acid (3:2, v/v).

[c]Calculated from the gas chromatographic data of cholesteryl ester and free cholesterol thin layer chromatographic fractions and taking into account the value of total cholesterol in the total lipid extracts.

[d]Triacylglycerols (TG) were evaluated from the quantitative gas liquid chromatographic analysis of their fatty acid methyl esters using the following formula: (mol TG fatty acids/3) × molecular weight of TG. TG molecular weight was calculated on the basis of the fatty acid composition.

[e]Evaluated by the quantitative gas liquid chromatographic analysis of the isopropylidene derivatives of alkylglycerols using a 850 molecular weight as determined in the basis of the alkyl and acyl group composition.

TABLE 2

Phospholipid Composition of B16-F1 and B16-F10 Melanoma Cell Lines[a]

Phospholipid class	B16-F1	B16-F10
Diphosphatidylglycerol	5.1 ± 0.5	4.9 ± 0.4
Phosphatidylethanolamine	22.2 ± 0.8	23.4 ± 0.5
Phosphatidylcholine	54.9 ± 0.7	55.6 ± 1.6
Phosphatidylinositol + phosphatidylserine	11.3 ± 0.1	10.2 ± 1.0
Sphingomyelin	3.8 ± 0.2	3.9 ± 0.9
Phosphatidic acid	2.2 ± 0.1	1.7 ± 0.1

[a]Values, expressed as percentages of total phospholipid phosphorus (22), are means ± SE of three separate experiments.

either cell lines. The combined content of ether-linked lipids in F1 and F10 cells, calculated as a percentage of total lipids, yields values which are the lowest for the in vitro cell systems examined to date (39–41). Comparison of the ether-linked phospholipids of the two B16 melanoma variants revealed that F10 cells have a higher level of alkyl-PC than F1 cells, a difference analogous to that found by Friedberg et al. (42) between high- and low-metastatic mammary carcinomas.

Neutral glycolipids of F1 and F10 cells were composed primarily of glucosyl-ceramide and to a lesser extent of lactosyl-ceramide and of a fraction with a migration rate on TLC corresponding to that of a trihexosyl-ceramide standard (Table 4). GM3 accounts for 95% of total gangliosides of both F1 and F10 cells, the remainder being represented by GM2, GM1 and GD1a. GM3 was

TABLE 3

Percentages of Ether-linked Subfractions of Phosphatidylethanolamine (PE) and Phosphatidylcholine (PC) from B16-F1 and B16-F10 Melanona Cell Lines

	Percentage of total phospholipid class[a]	
Subfraction	B16-F1	B16-F10
Diacyl PE	87.0 ± 6.1	87.2 ± 4.9
Alkenyl-linked PE	13.0 ± 0.8	12.8 ± 1.3
Alkyl-linked PE	N.D.[b]	N.D.[b]
Diacyl PC	97.5 ± 8.9	95.3 ± 9.8
Alkenyl-linked PC	N.D.[b]	N.D.[b]
Alkyl-linked PC	2.5 ± 0.4	4.7 ± 0.6[c]

[a]Percentages of the various subfractions were calculated as previously described (41). Values are means ± SE of five separate experiments.

[b]N.D., not detectable under the analytical conditions used.

[c]Significantly different from B16-F1 at $P < 0.02$.

the only ganglioside in the study by Yogeeswaran et al. (17), while Raz et al. (18) found minor amounts of GM2 and GM1 together with GM3 in these cell lines. These discrepancies may be related to differences, even in the same transformed cells, in the expression of the block in ganglioside biosynthesis (11). The proportion of the various neutral glycolipids and gangliosides did not differ significantly between the two variants of melanoma cells.

The fatty acid compositions of the individual lipid classes from F1 and F10 cells are reported in Tables 5–7. In both cell lines, the fatty acid profile of CE and of TG was characterized by a high proportion of 18:1 followed by 16:0, while FFA were composed mainly of 16:0 followed by 18:1 (Table 5). F10 cells showed a higher level of 18:0 in TG and FFA than F1 cells.

In both F1 and F10 cells, the overall pattern of fatty acid profiles of the individual glycerophospholipids (Table 6) and of sphingomyelin (Table 7) was similar to that found in other types of cells grown in tissue culture (39,43–45). Moreover, the various glycerophospholipids of F1 and F10 cells showed elevated proportions of 18:1 and very low levels of 20:4, 22:5 and 22:6 fatty acids, a characteristic common to several systems of malignant cells (36,43–51). On the whole, the fatty acid compositions of the various glycerophospholipids and of sphingomyelin did not differ significantly for the two cell lines. This observation is at variance with Schroeder and Gardiner's finding of a lower content of C20 and C22 polyunsaturated fatty acids in the phospholipids of F10 than in those of F1 cells (16).

The alkyl chain composition of alkyl-linked PC was characterized in both F1 and F10 cells by a high proportion of 16:0 followed by 18:1, 18:0 and 16:1 (Table 8), a pattern comparable to that found in L-M cells (39) and in untransformed and SV40-transformed Balb/c 3T3 cells (41). The alkenyl chain profile of alkenyl-linked PE was similar to that of PC alkyl chains, although this latter had a lower level of 16:0. There were no significant differences in the alkenyl and alkyl chain compositions between F1 and F10 cells.

The following conclusions can be drawn from the results of the present investigation: (a) both F1 and F10 cells

TABLE 4

Neutral Glycolipid and Ganglioside Composition of B16-F1 and B16-F10 Melanoma Cell Lines[a]

	Neutral glycolipids[b]			Gangliosides[c]			
Cell line	GL1	GL2	GL3	GM3	GM2	GM1	GD1a
B16-F1	77.1 ± 8.6	15.2 ± 4.8	7.6 ± 4.0	95.1 ± 0.4	1.6 ± 0.1	1.5 ± 0.5	1.9 ± 0.8
B16-F10	87.7 ± 1.6	8.8 ± 0.9	3.3 ± 1.1	96.0 ± 1.3	0.9 ± 0.2	0.7 ± 0.3	2.3 ± 0.9

[a]Values are percentages of the total neutral glycolipid or ganglioside-associated radioactivity. "Total" refers to the sum of the radioactivities of individual glycolipids fractionated by thin layer chromatography. Each value represents the mean ± SE of three separate experiments.

[b]GL1, glucosyl-ceramide; GL2, lactosyl-ceramide; GL3, galactosyl-galactosyl-glucosyl-ceramide.

[c]Gangliosides are indicated according to the nomenclature of Svennerholm (28).

showed characteristics in their phospholipid fatty acid compositions, ether-linked lipid contents and glycolipid patterns that are common to several systems of transformed cells; (b) despite the differences in their lung-colonizing potential, the two B16 melanoma variants did not differ in terms of their major lipid components and phospholipid fatty acid profiles, a result that raises the issue of whether previously reported differences (16) in the cholesterol content and in the polyunsaturated fatty acid level of the two B16 melanoma variants might not be attributable to biological factors other than metastatic potential; (c) the high alkyl-PC level in F10 cells, which has also been found in high-metastatic mammary carcinoma cells (42), is the only lipid characteristic that can be related to a high metastatic potential.

[Received January 23, 1987]

[^{3}H]Cholesterol Transfer from Microemulsion Particles of Different Sizes to Human Fibroblasts

Stig Ekman
Department of Biochemistry and Pharmacy, Åbo Akademi, SF-20500 Turku, Finland

A new technique for preparing microemulsion particles of well-defined sizes and compositions is presented. Utilization of these microemulsions is advocated as lipoprotein models in studies of lipid transport and metabolism, rather than the currently used phospholipid-cholesterol vesicles. The emulsion particles consisted of egg phosphatidylcholine and cholesterol as surface lipids and cholesteryl oleate as core lipid. They were prepared by a combined injection and sonication technique and size-separated by a two-step procedure of gel filtration chromatography and density gradient centrifugation. By varying the ratios of core and surface material, particles covering a size range of 20–200 nm in diameter could be produced. The adequacy of these microemulsions as lipoprotein models was tested by studying the transfer of [^{3}H]cholesterol and [^{14}C]cholesterol oleate from the particles to cultured human fibroblasts. Up to a particle size of 100 nm, there was a slight increase of [^{3}H]cholesterol transfer. The transfer of [^{14}C]cholesteryl oleate was very slow, yet measurable. Studies of the exchangeability of cholesterol between the microemulsion core and surface phases indicated that all cholesterol can be transferred from microemulsions to cultured cells as a single pool.
Lipids 22, 657-663 (1987).

Surface transfer of free cholesterol between lipoproteins or lipoprotein-like structures and cellular plasma membranes has been the subject of intensive studies for many years (for reviews, see 1 and 2). This transfer or exchange process can both deliver and remove cellular cholesterol (3), and it has been suggested that it could play an important role in the regulation of cellular cholesterol content (4,5). Investigations of the flux of free cholesterol between a large variety of acceptor and donor structures, including liposomes (6–8), membranes (9–11), lipoproteins (12–14) and protein-lipid complexes (15), have shown a rapid exchange of cholesterol between these structures.

When studying the specific case of surface transfer from lipoproteins to cellular membranes, the situation gets more complex as protein effects have to be eliminated to produce pure transfer data. Specific receptor-mediated cell uptake via the low density lipoprotein (LDL) receptor has been abolished by using receptor-negative cells (16–18) or by modifying the protein part of the lipoprotein to prevent it from being recognized by the receptor (19–23). This, however, does not necessarily eliminate nonspecific protein-mediated uptake (24). To ensure abolishment of protein effects, donors that lack proteins should be used.

Abbreviations: egg PC, egg yolk phosphatidylcholine; LDL, low density lipoprotein; HDL, high density lipoprotein; VLDL, very low density lipoprotein.

The protein-lacking donors most extensively used in studies of surface transfer of cholesterol to cells are vesicles consisting of phospholipids and cholesterol. Vesicles are, however, essentially membrane models and therefore are less useful as lipoprotein models. Lipoproteins are composed of a surface monolayer of polar constituents (phospholipids, cholesterol and apoproteins) surrounding a hydrophobic core of nonpolar lipids, predominately cholesteryl esters and triglycerides (25). Thus microemulsions, i.e., particles with a central core of nonpolar lipids stabilized by a surface monolayer of polar lipids, appear to be a justifiable choice when looking for good protein-free lipoprotein models (26,27). In addition to the results obtainable with vesicles, microemulsions enable us also to examine how the transfer and metabolism of lipoprotein lipids are affected by the composition of the hydrophobic core and by the particle size (different ratios of core and surface lipids).

In this report, the preparation and characterization of well-defined and homogenous-sized microemulsion particles containing cholesteryl oleate as core lipid and cholesterol and egg yolk phosphatidylcholine (egg PC) as surface lipids are described. A size series of these microemulsions was prepared, and the relationship between the size of the microemulsion particles and the rate of cholesterol transfer to cultured cells was investigated.

MATERIALS AND METHODS

Cell culture. Human lung fibroblasts were used. The cells were cultured in Dulbecco's modified Eagle medium supplemented with 10% (v/v) newborn calf serum, 0.1 mM nonessential amino acid solution, 2 mM L-glutamine, 20 mM HEPES, 0.08% (w/v) sodium bicarbonate and 10 μg/ml of gentamicin in a humidifed atmosphere of 95% air and 5% CO_2. The fibroblasts were nontransformed and diploid and were used for experiments between the 8th and 15th passages.

Incubation medium. When it was observed that the microemulsions were unstable in ordinary cell culture media, possibly as a result of their high salt concentrations, a special incubation medium was composed. This medium contained only 1/10 of the amount of NaCl and 1/5 of the amount of KCl originally proposed by Eagle in basal media for cultivation of mammalian cells (28). The concentration of other salts, amino acids and vitamins was in accordance with Eagle's minimum essential medium (29), with the exception that the amount of sodium bicarbonate was 0.80 g/l and that this medium was supplemented with 15 mM HEPES, 10 μg/ml gentamicin and glucose to produce an osmolarity of 300 mOsmol/kg. The osmolarity was determined with a Osmomat 030 osmometer (Gonotec GmbH, Berlin, FRG).

Incubation procedures. For the experiments, cells were seeded in 50-mm diameter Petri dishes and grown to near confluency (200–300 μg cell protein/dish) in 5–7 days. On the day of the experiment, the growth medium was removed, the cell layer was washed once with 3 ml phosphate-buffered saline, and 2 ml incubation medium was added. After a 30-min preincubation at the incubation

temperatures (37 C or 4 C), the labeled microemulsion or LDL preparation was added. At the end of the incubation, the medium was collected and the cell layer was washed twice with cold phosphate-buffered saline containing 0.2% albumin and three times with phosphate-buffered saline without albumin. The cells were then detached by gentle scraping and sedimented by a low-speed centrifugation. The cell pellet was suspended and disrupted in 1 ml distilled H_2O by a short sonication. Aliquots of this suspension were taken for determinations of protein and radioactivity.

Preparation of microemulsions and [^{3}H]labeled LDL. The lipids used for preparation of microemulsions were egg PC, cholesterol and cholesteryl oleate. Stock solutions containing 10 mg/ml of these lipids were prepared in benzene and stored at −20 C. Trace amounts of [^{3}H]cholesterol and [^{14}C]cholesteryl oleate or 1-palmitoyl-2-[^{14}C]oleoyl-phosphatidylcholine were added to these solutions shortly before starting the preparation of microemulsion. Specific activities used were usually about 10,000 CPM/μg for cholesterol, 1,500 CPM/μg for cholesteryl oleate and 200 CPM/μg for egg lecithin.

When calculating the relative amounts of lipids needed to give microemulsion particles of specific sizes, it was assumed that the microemulsions were spherical droplets composed of two distinct phases: a hydrophobic core consisting mainly of cholesteryl oleate stabilized by a surface monolayer 2.0 nm thick (30) composed of PC and cholesterol. The somewhat different densities of the lipids — 1.016 g/ml for PC (31), 1.045 g/ml for cholesterol (32) and 0.96 g/ml for cholesteryl oleate (33) (at 23 C and 1 atm of pressure)—were also considered in these calculations. Since a constant amount of cholesterol (1 mg) and a constant molar ratio of egg lecithin and cholesterol (1:1) were used in the different preparations, it was essential to vary the amount of cholesteryl oleate according to the desired size of the microemulsion particles as indicated in Table 1.

Aliquots of the lipid stock solutions producing the appropriate amount of lipids were pipetted into glass vials. The solvent was evaporated under a stream of nitrogen, and the vials were placed in a vacuum desiccator overnight.

The lipid mixtures were resuspended in 400 μl ethanol/diethyl ether (2:1, v/v). Three hundred μl of this solution was slowly injected into 4 ml, 10 mM Tris/HCl buffer, pH 9.0, through the bottom of a sonication vessel thermostated at 55 C under simultaneous ultrasonic irradiation from an MSE sonifier equipped with a titanium probe (100 watts output). The apparatus used for the sonication is described in greater detail by Lundberg and Suominen (34). The sonication time was varied as follows depending on the type of microemulsion under preparation: 200 nm, 2 min; 150 nm, 5 min; 100 nm, 10 min; 50 nm, 20 min; 20 nm, 35 min.

The crude mixture of microemulsion particles thus obtained was separated according to size in two steps. The first step was a density gradient centrifugation using linear sucrose gradients in Tris buffer. The density of the microemulsion solution was raised using sucrose; 350-μl samples were layered under the gradients (3.5 ml), and centrifugation was performed in a Beckman SW 60 Ti rotor. The centrifugation force, duration and density gradient range differed for the different types of microemulsion, ranging from 10,000 g, 5 min and 0–10% (w/v) sucrose for 200-nm microemulsion particles to 95,000 g, 30 min and 0–30% when preparing 20-nm particles. At the end of the centrifugation, the bottoms of the tubes were punctured and 8-drop fractions were collected. The fractions containing lipids in the appropriate ratios were pooled for the second step of separation, gel filtration.

Ascending gel filtration chromatography was performed on a Sephacryl S-1000 Superfine column (1.6 × 32 cm) at 25 C and with a flow rate of 30 ml/hr using Tris buffer, pH 9.0, as eluent. The samples were applied in volumes of ~ 2 ml, and fractions of 1.45 ml were collected. The void volume V_o was determined using killed *Serratia marcescens* bacteria, and K_{av} was calculated from the equation $K_{av} = (V_e - V_o)/(V_t - V_o)$, where V_e is the volume of elution and V_t is the total bed volume.

LDL was isolated from fresh pooled human serum by preparative density gradient ultracentrifugation and labeled with [^{3}H]cholesterol using the exchange procedure described previously (18).

Electron microscopy. Microemulsion particles were negatively stained with 2% potassium phosphotungstate, pH 7.4, containing 200 μg/ml bacitracin on Formvar-coated copper grids. The grids were air-dried and examined in a Zeiss EM 109 electron microscope, calibrated with a grating replica.

Solubility. Twenty or 40 mg [^{3}H]cholesterol was added to 200 mg [^{14}C]cholesteryl oleate. This mixture was heated to 55 C and suspended in 3 ml of 10 mM Tris/HCl buffer, pH 9, in 4-ml ultracentrifugation tubes. The tubes were sealed under N_2 gas and incubated for four days under continuous shaking and repeated heating and cooling between 37 C and 55 C. The cholesterol-saturated cholesteryl oleate oil phase was flotated by ultracentrifugation (37 C, 100,000 g, 60 min) in a Beckman SW rotor, and the solubility of cholesterol was determined by radiochemical assay of the floating oil.

Analytical procedures. Cell and LDL protein were determined by the Lowry method as modified by Markwell et al. (35) and lipid phosphorus according to the method of Bartlett (36). Radioactivity was determined with a liquid scintillation counter (1210 Ultrobeta, LKB-Wallac, Turku, Finland) using Lumagel as scintillation fluid. To study the possible exchange of free cholesterol between the microemulsion core and surface phases, a modification of the cholesterol oxidase–phospholipase C method described by Moore et al. (37) was used. Briefly, microemulsion samples containing 10–20 μg free cholesterol were diluted to 1 ml with distilled H_2O, and 1 ml 50 mM potassium phosphate buffer, pH 7.7, containing 0.2 U phospholipase C and 1.3 mM $CaCl_2$ was added. This mixture was incubated at 37 C for 90 min. Then, 0.2 U cholesterol oxidase in 1 ml phosphate buffer was added, and the incubation was continued for 30 min. The incubation was stopped by adding 2 ml of cold methanol and the produced cholest-4-en-3-one was assayed spectrophotometrically at 240 nm against the reagent blank. The standard curve was constructed using 0–50 μg cholestenone in reagent solution. Total free cholesterol was assayed in the same way with the exception that 1% sodium taurocholate was added to the phosphate buffer to disrupt the microemulsion and solubilize free cholesterol. To determine the possible vesicle contamination of the microemulsion preparation, the 6-carboxyfluorescein method

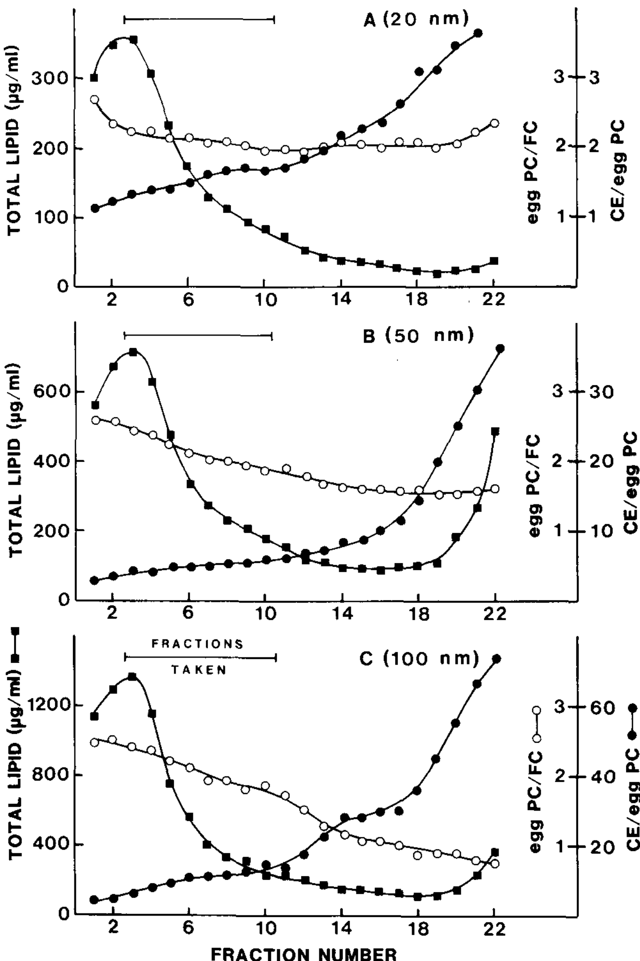

FIG. 1. Density gradient centrifugation of egg PC–cholesterol–cholesteryl oleate microemulsions. Preparation of particles: (A) 20 nm, (B) 50 nm and (C) 100 nm in diameter. Centrifugation was performed in a Beckman SW 60 Ti rotor. Sample volume was 0.35 ml and gradient volume 3.5 ml. Centrifugation conditions were (A) 30 min, 95,000 g, 0–30% (w/v) sucrose; (B) 15 min, 65,000 g, 0–20% (w/v) sucrose; (C) 5 min, 25,000 g, 0–15% (w/v) sucrose gradient. Fractions of 180 µl were collected; fractions taken for further experiments are indicated by horizontal bars. ■, Total amount of lipid in the fractions; ○, egg PC/free cholesterol (FC) weight ratio; ●, cholesteryl oleate (CE)/egg PC weight ratio.

of Weinstein et al. (38) as modified by Lundberg and Suominen (34) was utilized.

Materials. L-3-phosphatidylcholine, 1-palmitoyl-2-[1-^{14}C]oleoyl (57 mCi/mmol) and [7(n)-^{3}H]cholesterol (9.6 Ci/mmol) were purchased from Amersham, (Buckinghamshire, UK). [4-^{14}C]Cholesteryl oleate (59.4 mCi/mmol) was from New England Nuclear (Boston, MA). The radiochemical purities of cholesterol and cholesteryl oleate were found to be >98.5% by thin layer chromatography. Cholesterol and cholesteryl oleate were obtained from Merck (Darmstadt, FRG) and used after recrystallization from 1,2-dichlorethane (cholesterol) or acetone (cholesteryl oleate). Egg L-α phosphatidylcholine, phospholipase C (from *Clostridium perfringens*), and cholesterol oxidase (from *Pseudomonas*) were purchased from Sigma Chemical Co. (St. Louis, MO). Cell growth medium and supplements were obtained from Gibco Europe (Uxbridge, UK) and 4-cholesten-3-on from Fluka AG (Buchs, Switzerland). The Sephadex G-50 and Sephacryl S-1000 Superfine gel media were purchased from Pharmacia Fine Chemicals AB (Uppsala, Sweden), and the *Serratia marcescens* bacteria was a gift from the same firm, Lumagel was obtained from Lumac B.V. (Landgraaf, Holland).

RESULTS

Ultracentrifugation. The distributions of radiolabeled microemulsion particles in the centrifugation tubes after representative centrifugations are shown in Figure 1. Fraction 1 represents the bottom of the tube and fraction 22 the top. As the density of the microemulsion particles was less than unity because of their high content of cholesterol oleate, they had to be layered under the gradient and hence migrated upwards during the centrifugation. The largest (most cholesteryl oleate–rich) particles migrated fastest and the smallest (most dense) migrated slowest. Conditions were chosen to give only a minor migration of the peak of lipid material (see figure). A more effective centrifugation or a steeper gradient rapidly resulted in a creaming of most of the lipid material at the surface of the gradient with risk of coalescence of emulsion droplets. The fractions (indicated in figure) containing lipids in approximately correct ratios (Table 1) to give microemulsions of desired sizes were collected and subjected to gel filtration.

Gel filtration chromatography. Typical gel filtration patterns of preparations aimed at producing microemulsion particles 20 nm, 50 nm and 100 nm in diameter are illustrated in Figure 2. The column elution profile is quite symmetrical for the 20-nm preparation but less so for the 50-nm and 100-nm preparations. The figure also shows that the amount of egg PC relative to that of cholesterol is fairly high both in fractions near V_0 and V_t. This may be a result of the presence of egg PC–rich large multilamellar vesicles eluting near V_0 and small unilamellar vesicles eluting near V_t.

Gel filtration experiments with microemulsions where cholesteryl oleate and cholesterol were radiolabeled showed that the ratio of cholesteryl ester to free cholesterol was very high in fractions near V_0 (data not shown). This indicates the presence of large microemulsions with much core material in these fractions (in addition to the multilamellar liposomes). Regardless, the total amount of lipids in such less desirable lipid complexes was rather small. The major part of the lipids coeluted in the main peak, and the lipid composition throughout this peak elution region was rather homogeneous and in remarkably good agreement with the required (starting) composition (Table 1). Because only a few (2–3) of the peak fractions were collected for incubation experiments, a narrow distribution of microemulsion particle size could be expected. This was confirmed by negative stain electron microscopy showing circular structures (indicating spherical particles) of fairly uniform sizes. Counting 40 particles from a 20-nm preparation gave a size distribution of 23 ± 3 nm (mean ± SD), range 20–27 nm. K_{av} for the fractions taken for incubations (indicated in Fig. 2) were as follows: 20 nm preparation, 0.48; 50 nm, 0.33; 100 nm, 0.19; 150 nm, 0.13; 200 nm, 0.08. The presence of vesicles in a pooled 20-nm preparation was determined by the 6-carboxyfluorescein method and found to be less than 2%.

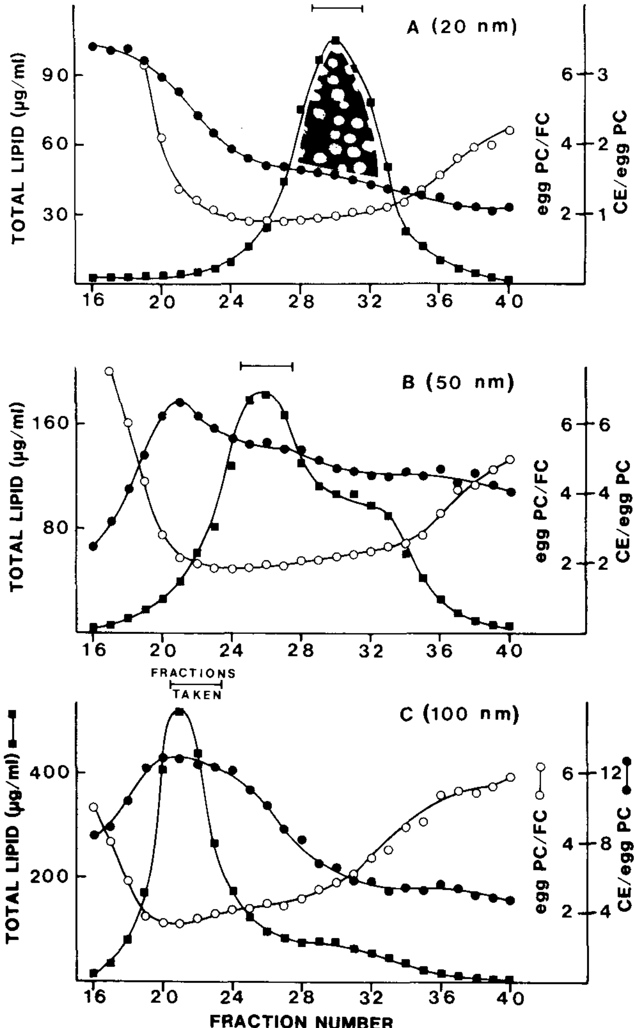

FIG. 2. Gel filtration chromatography of egg PC–cholesterol–cholesteryl oleate microemulsions. Preparation of particles:(A) 20 nm, (B) 50 nm and (C) 100 nm in diameter. After ultracentrifugation and concentration the samples were applied in volumes of ~ 2 ml to a column (1.6 × 32 cm) with Sephacryl S-1000 Superfine gel. The lipid material was eluted with Tris buffer, pH 9.0. Each collected fraction contained 1.45 ml. Fractions pooled for incubations with cells are indicated by horizontal bars. Inserted in (A) is a negative stain electron micrograph of a pooled sample. ■, Total amount of lipid in the fractions; ○, egg PC/free cholesterol (FC) weight ratio; ●, cholesteryl oleate (CE)/egg PC weight ratio.

Cell incubations. When initial incubations of human fibroblasts with microemulsions were performed, an unexpectedly great and rapid decrease of [^{3}H]cholesterol activity in the medium was observed. When this phenomenon was examined further, it appeared to occur also in the absence of cells. The [^{3}H]cholesterol that had disappeared from the medium was found firmly adsorbed to the walls and bottoms of the petri dishes (see figure). The obvious reason for this was a low microemulsion stability in this type of incubation medium (Dulbecco's modified Eagle medium). In an attempt to increase the stability of the microemulsions, an incubation medium with most of the sodium and potassium salts replaced by glucose was composed. In this medium, the microemulsion stability appeared to be satisfactory (Fig. 3B). Whether the increase in microemulsion stability was due to the decrease in salt concentration or the increase in glucose concentration was not further examined. This alteration of the incubation medium composition, however, raised a new question. Do fibroblasts cultured in such a sugar-rich medium deal with lipoproteins and lipoprotein models in the same way as fibroblasts growing under normal conditions? To examine this, an experiment was carried out in which the transfer of [^{3}H]cholesterol from LDL to fibroblasts growing in serum-free cell culture medium of ordinary composition (Dulbecco's MEM) was compared to transfer to fibroblasts cultured in the specially composed sugar-rich incubation medium. For the experiment [^{3}H]cholesterol LDL at a concentration of 25 µg LDL protein/ml medium was added to petri dishes containing 150–200 µg cell protein/dish. The amounts of transferred [^{3}H]cholesterol given as µg/mg cell protein were 3.6 ± 0.2 after 4.5 hr of incubation in Dulbecco's MEM and 3.7 ± 0.3 in the sugar-rich medium. After 9 hr of incubation the amounts were 5.3 ± 0.3 and 5.9 ± 0.5, respectively. (The values are means ± SD from five dish pairs [37 C − 4 C]). Thus the differences in the rates of [^{3}H]cholesterol transfer from the different media were not statistically significant.

Figure 4 compares the transfer of [^{3}H]cholesterol from microemulsion particles of different sizes to cultured human fibroblasts. The transfer rates have been corrected for passive cell surface adsorption by subtraction of transfer rates obtained at 4 C from those at 37 C. The rate of [^{3}H]cholesterol transfer increased with the diameter of the microemulsion particles in the range of 20 to 100 nm. For particles larger than 100 nm in diameter, no further increase in transfer rate was noted. (The curve for 150-nm particles was also determined, but being superimposable with the curves for 100-nm and 200-nm particles, it was not included in Figure 4 for the sake of clarity.)

To elucidate further the mechanism of the transfer process, an experiment with different-sized microemulsions doubly labeled with [^{3}H]cholesterol and [^{14}C]cholesteryl oleate was carried out. The transfer rates of the labeled lipids differed greatly. This shows that [^{3}H]cholesterol and [^{14}C]cholesteryl oleate were transferred separately and independently from the microemulsions to the cultured cells. The results in Table 2 also indicate that the transfer of [^{14}C]cholesteryl oleate is directly dependent on the concentration of this liquid in the incubation medium.

Localization and exchangeability of cholesterol in microemulsion. Because cholesterol is slightly soluble in cholesteryl esters (39–41), a certain proportion of the free cholesterol may be anchored in the hydrophobic core of the microemulsion inaccessible for exchange with cell cholesterol. To test this possibility, the solubility of cholesterol in cholesteryl oleate in the presence of an aqueous phase at 37 C was first determined. The solubility of cholesterol in the oily cholesteryl ester phase was 7.5 ± 0.5% by weight (mean ± SD, n = 4). This implies that a considerable proportion of the microemulsion cholesterol may be localized in the microemulsion core, although solubility in such a microsystem is, due to steric hindrance, not necessarily exactly equal to the solubility in the bulk system examined. Next an effort to establish the proportion of cholesterol that is located in or has access to the surface monolayer of the microemulsions was made. This

TABLE 1

Composition of Lipid Mixture Used for Preparation of Different-sized Microemulsion Particles

Required micro-emulsion particle diameter (nm)	Egg PC (mg)	Cholesterol (mg)	Cholesteryl oleate (mg)	Cholesteryl oleate/egg PC weight ratio	Egg PC/ cholesterol weight ratio
20	1.94	1.0	3.15	1.62	1.94
50	1.94	1.0	10.60	5.46	1.94
100	1.94	1.0	23.00	11.9	1.94
150	1.94	1.0	35.40	18.2	1.94
200	1.94	1.0	48.00	24.7	1.94

TABLE 2

Transfer of [^{3}H] Cholesterol and [^{14}C] Cholesteryl Oleate from Doubly Labeled Microemulsion Particles ca. 20 or 100 nm in diameter to Cultured Human Fibroblasts[a].

Size of ME (nm in ϕ)	Transfer of FC[b] (nmol/mg protein 5 hr.)	Transfer of CO[b] (nmol/mg protein 5 hr.)	CO/FC transfer ratio	CO/FC molar ratio in ME	Ratio of CO transfer (100 nm ME/20 nm ME)	Conc. ratio of CO in medium (= conc. ratio in 100 nm/20 nm ME)
20	1.16 ± 0.12	0.14 ± 0.04	0.12	1.85	$\frac{0.86}{0.12} = 7.2$	$\frac{14.1}{1.85} = 7.6$
100	1.47 ± 0.17	1.25 ± 0.27	0.86	14.1		

ME, microemulsion particle; FC, free cholesterol; CO, cholesteryl oleate.

[a]Cells at a concentration of 200 – 300 μg cell protein/petri dish were incubated in 2 ml incubation medium (see Materials and Methods) containing 5 μg (13 nmol) microemulsion-[^{3}H]cholesterol/ml for 5 hr at 37 C and 4 C.

[b]Calculated from the differences in cell-associated [^{3}H]cholesterol and [^{14}C] cholesteryl oleate radioactivity in cells cultured at 37 C and 4 C. Each transfer value represents the mean ± SD from four dish pairs.

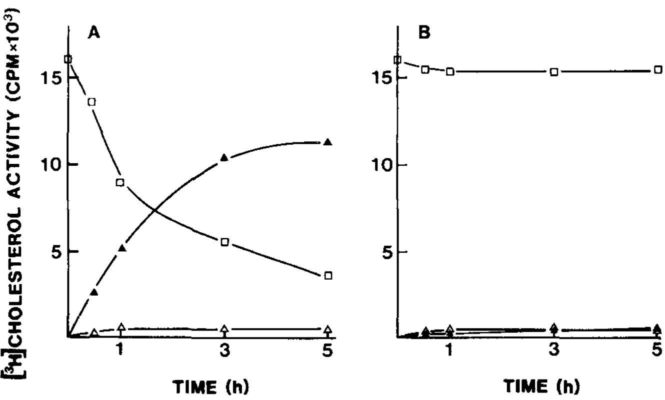

FIG. 3. The effect of incubation medium composition on the stability of microemulsions. Microemulsion particles ca. 100 nm in diameter containing 2 μg [^{3}H]cholesterol were incubated in 2 ml of cell culture medium. In (A) the medium was Dulbecco's modified Eagle medium; in (B) it was the incubation medium generally used in this investigation. This incubation medium was based on Eagle's minimum essential medium, where 9/10 of the NaCl and 4/5 of the KCl were replaced with glucose. Both media were supplemented as described in Materials and Methods. □, [^{3}H]cholesterol radioactivity (CPM) remaining in medium. ▲, [^{3}H]cholesterol activity that could be removed from the dishes by washing twice with 2.5 ml phosphate-buffered saline. ▲, [^{3}H]cholesterol activity that had to be extracted from the walls and bottoms of the dishes with 2.5 ml methanol/chloroform (2:1, v/v). Values are averages from two determinations.

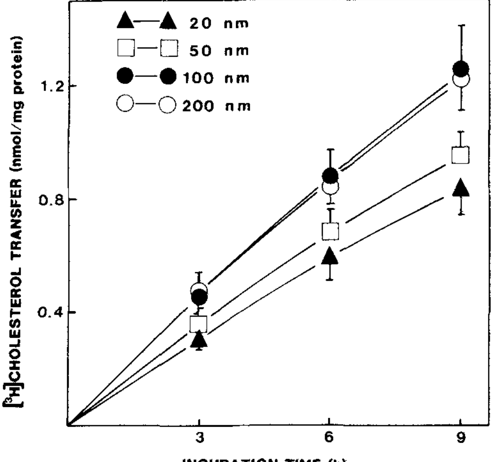

FIG. 4. The effect of microemulsion particle sizes on the transfer of [^{3}H]cholesterol from egg PC–cholesterol–cholesteryl oleate microemulsions to cultured human fibroblasts. Each petri dish contained 200–300 μg cell protein. The cells were incubated at 37 C and 4 C in 2 ml of incubation medium (see Materials and Methods) containing 1 μg (2.6 nmol) microemulsion-[^{3}H]cholesterol/ml. The amount of transferred [^{3}H]cholesterol is calculated from the difference in cell association of radiolabeled cholesterol at 37 C and at 4 C. Error bars represent SD for 6 determinations. Particles were ca. 200 nm (○), 100 nm (●), 50 nm (□), and 20 nm (▲) in diameter.

was done by measuring the susceptibility of cholesterol to oxidation with cholesterol oxidase after the phosphorylcholine head group had been cleaved off with phospholipase C. That phospholipase C action did not cause a disruption of the microemulsion particles was confirmed by the gel filtration elution profile of the microemulsion, which was unchanged after enzymatic treatment.

It was found that the amount of cholesterol oxidized in intact 100-nm microemulsion particles was the same as the amount oxidized in microemulsions disrupted in taurocholate. The values for "surface" cholesterol was 17 $\pm$ 2 μg/0.5 ml (mean $\pm$ SD, n = 5) and for total cholesterol was 18 $\pm$ 3 μg/0.5 ml (mean $\pm$ SD, n = 5). This indicates that the core pool of cholesterol in microemulsions can exchange with the surface pool and is thus available for surface transfer to acceptor structures.

DISCUSSION

These experiment were designed to prepare protein-free lipoprotein models (microemulsions) suited for studies of lipid transfer. For the preparation of microemulsions, a combination of ultrasonic irradiation and injection techniques was used. With such a combined technique two ways of varying the particle or droplet size are available: (i) The size of the particles will vary with the concentration of material in the injected solution. Lower concentrations produce smaller particles. (ii) The size will vary with the time and efficiency of the sonication. Longer and/or more effective sonication produces smaller particles.

The produced microemulsion particles were separated with respect to particle size in two steps: density gradient centrifugation and gel filtration chromatography. The polar surface lipids and hydrophobic core lipids remained associated during these fractionating procedures, which shows that real microemulsions had been produced. That the microemulsion particles in the different-sized preparations were fairly homogenous in size could be verified by electron microscopy. If the partition coefficients, K_{av}, for the fractions selected from the different preparations are plotted against the logarithms of the desired particle volumes, a linear relationship is obtained. This confirms that a size series of the desired type was produced. Chemical and radiochemical assay methods verified that the microemulsion particles had the required lipid compositions. When the results obtained by this combined technique are compared with results obtained utilizing only injection (27) or only sonication (26), it seems as if the combined method gave more homogenous particle sizes than sole injection technique and that the sonication time could be kept shorter than when using sonication technique alone.

The adequacy of these microemulsions as lipoprotein models in studies of physiological transfer processes was tested by incubating them with cultured human fibroblasts. Since different classes of lipoproteins vary considerably in size, an attempt to examine the size effect on transfer rates was made. In the utilization of these types of microemulsion preparations for incubation with cultured cells, a disadvantage that immediately became obvious was their low stability in the cell culture medium. This problem could be solved by decreasing the salt concentration in the medium while at the same time increasing the glucose concentration to maintain iso-osmolarity. This change in medium composition did not have any effect on the uptake of LDL in the cultured cells during an incubation period of 9 hr. It seems, therefore, reasonable that it will not affect the transfer rate of cholesterol either.

The transfer rates obtained in this experiment were 0.09–0.14 nmol cholesterol/mg protein and hour, at a concentration of 1 μg (2.6 nmol) cholesterol/ml incubation medium (Fig. 3). These rates are in good agreement with those previously obtained in this laboratory (23) for receptor-independent cholesterol transfer from HDL and LDL to human lung fibroblasts. The transfer rate of radiolabeled cholesterol from microemulsion preparations to cultured cells increased with the size of the emulsion particles in the range of 20–100 nm diameter. This agrees with results shown previously by Kovanen and Nikkilä (42), who determined relative transfer rates of free cholesterol from different lipoproteins to adipocytes. They found that the rate of exchange decreased with decreasing particle size. Contradictory results have been obtained for surface transfer of cholesterol between vesicles (8,43), showing faster transfer from small vesicles. This indicates that microemulsions may be more appropriate than vesicles as lipoprotein models in studies of lipid transfer. Support for this notion was found in recent studies (Ekman, S., and Lundberg, B., to be published in Biochim. Biophys. Acta) where the maximal [^{3}H]cholesterol transfer rates were about the same from LDL and microemulsions, but vesicles gave transfer approximately twice as fast.

The mechanism for the exchange process has been a matter of much debate. Results supporting both a mechanism involving collisions between the structures in question (1,44,45) and free diffusion of cholesterol through the aqueous phase (6,10,13) have been presented. The results in Table 2 support to some extent the aqueous diffusion mechanism insofar as they show that different components of the microemulsions are transferred to cells at different rates. The transfer rate for the more water-soluble cholesterol was much higher than that of the very unpolar cholesteryl oleate molecule. The results in Table 2 also show that the accumulated [^{3}H]cholesterol activity in the cultured cells was due neither to unspecific adherence of microemulsions to the cell surfaces nor to endocytosis of intact microemulsion particles. In these cases, the ratios of radiolabeled cholesterol and cholesteryl oleate recovered in or with the cells after the incubations would have been approximately the same as the ratios in the incubation medium. Some endocytosis naturally occurs in metabolically active fibroblasts. The fluid phase endocytosis in cultured fibroblasts at 37 C has been determined in this laboratory to ca. 190 nl per mg cell protein and hr (46). A comparison of this value with the transfer data in Table 2 shows that endocytosis may account for only ~ 1% of the cell accumulation of [^{3}H]cholesterol observed in this study.

This paper presents only the influence of microemulsion particle size on cholesterol transfer, but the influence of different core compositions has also been investigated and will be presented elsewhere (Ekman, S., and Lundberg, B., Biochim. Biophys. Acta, in press). Microemulsions of the present type have also been used in studies of factors affecting the lysis of the lipoprotein-like particles in lysosomes (47).

ACKNOWLEDGMENTS

I wish to thank Bo Lundberg and J. Peter Slotte for helpful discussions and suggestions, and Liisa Suominen for skillful assistance with the cell cultures. This work was supported by research grants from the Research Institute of the Åbo Akademi Foundation, and The Tor, Joe and Pentti Borg Foundation. These grants are gratefully acknowledged.

[Received December 23, 1986]

METHODS

Mass Spectra of the Picolinyl Ester Derivatives of Some Non-Methylene-Interrupted Octadecadienoic Acids

W.W. Christie*[,a], E.Y. Brechany[a], F.D. Gunstone[b], M.S.F. Lie Ken Jie[c] and R.T. Holman[d]
[a]The Hannah Research Institute, Ayr, Scotland KA6 5HL, [b]Chemistry Department, The University, St. Andrews, Scotland, [c]Chemistry Department, University of Hong Kong, Pokfulam Rd., Hong Kong and [d]The Hormel Institute, Austin, MN 55912.

The electron-impact mass spectra of the picolinyl ester derivatives of 5,12-, 6,12-, 7,12-, 8,12-, 6,10- and 6,11-octadecadienoic acids were obtained. There are features in each that are diagnostic of the position of the terminal double bond, although doubt could exist, with unknown compounds, about the position of the proximal double bond if authentic spectra were not available for comparison purposes. There appear to be features in the spectra of isomers with two and three methylene groups between double bonds that are of value for characterization purposes.
Lipids 22, 664–666 (1987).

One of the more convenient approaches to the location of double bonds in a fatty acid molecule consists in preparing a derivative such as the pyrrolidides (1) or picolinyl esters (2–4), because these give distinctive fragmentations that are generally characteristic of the double bond positions. These and alternative procedures for locating double bonds in unsaturated fatty acids have been reviewed comprehensively elsewhere (5,6).

The picolinyl ester derivatives are especially useful, because they give unambiguous spectra even for polyunsaturated fatty acids. Mass spectra of picolinyl esters have been used to good effect for the identification of unsaturated fatty acids in complex samples of natural origin (7–10). Recently (11) the electron-impact mass spectra of the picolinyl ester derivatives of the complete series of isomeric octadecenoates and methylene-interrupted octadecadienoates were described. Only when double bonds were at the extremities of the molecule were difficulties experienced in deducing the positions of the double bonds. In continuation of these studies, the mass spectra of picolinyl esters of some octadecadienoates with two or more methylene groups between the double bonds are described here. Fatty acids of this type are known to occur in the lipids of marine organisms, especially invertebrates (12,13).

MATERIALS AND METHODS

The all-*cis* 5,12-, 6,12-, 7,12-, 8,12-, 6,10- and 6,11-octadecadienotes were prepared by total synthesis (i.e., from low molecular weight precursors) (14). They were converted to the picolinyl ester derivatives by an improved procedure described elsewhere (9); in brief, the mixed anhydride of each fatty acid with trifluoroacetic acid was reacted with 3-(hydroxymethyl)-pyridine (10-fold molar excess) in the presence of 4-dimethylaminopyridine (1.2 molar proportion) as catalyst. The derivatives were submitted to gas chromatography–mass spectrometry (GC-MS) as described earlier (except that the upper temperature of the column was 10 C lower), i.e., a fused-silica capillary column (25 m × 0.2 mm i.d.), coated with a cross-linked (5% phenyl methyl) silicone (Hewlett

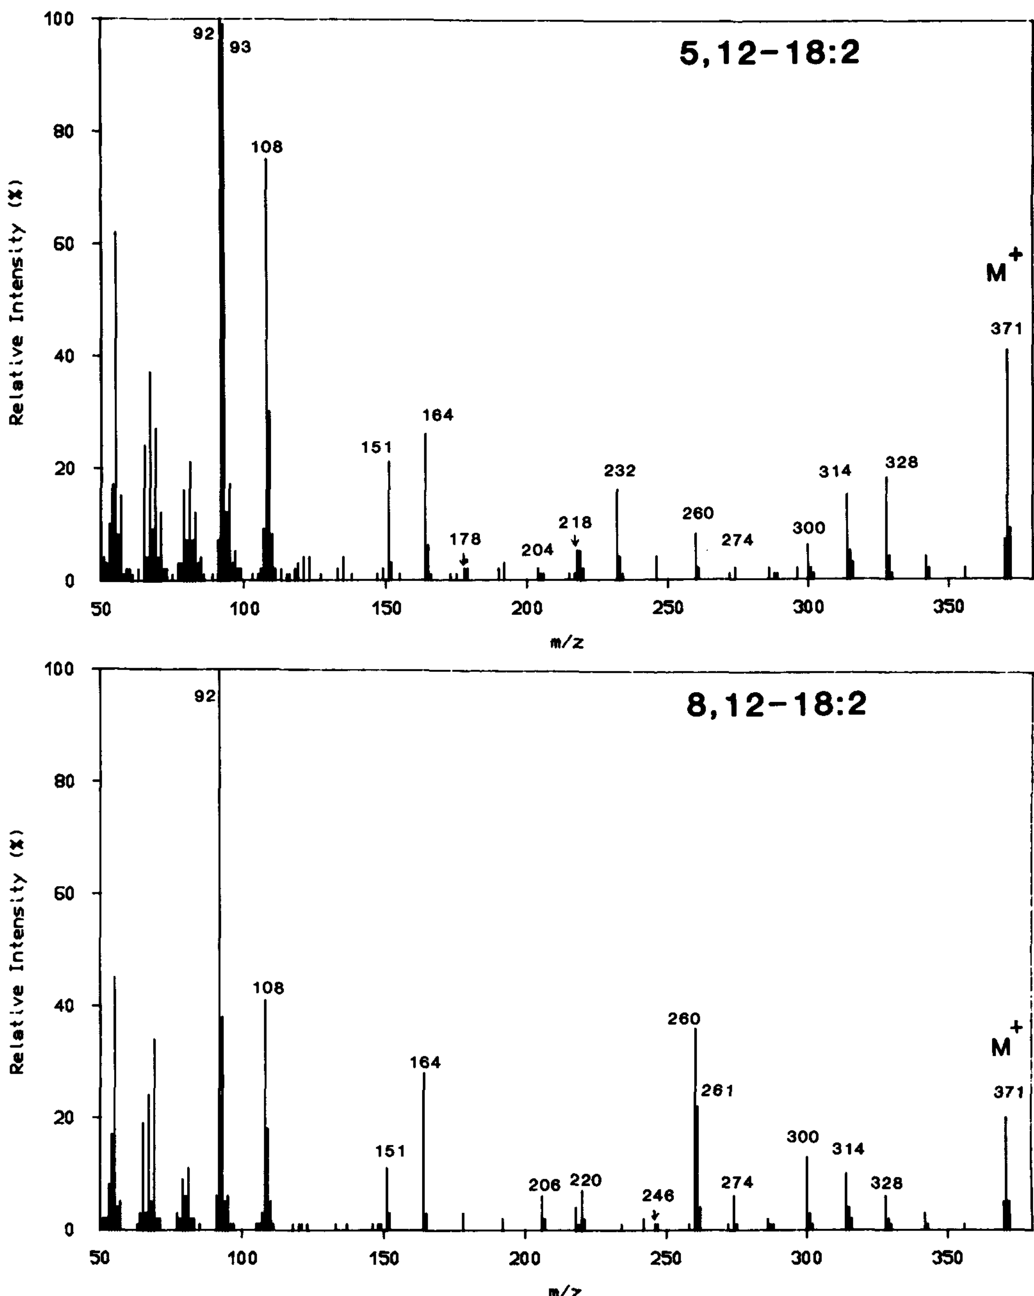

FIG. 1. The mass spectra of picolinyl 5,12-octadecadienoate (top) and picolinyl 8,12-octadecadienoate (bottom).

Packard Ltd., Wokingham, Berks), with helium as carrier gas, was temperature-programmed from 60 C to 220 C at 50 C/min then to 250 C at 1 C/min (7,9,10). The column outlet was connected directly into the source of a Hewlett Packard 5970 Mass Selective Detector, operated at an ionization energy of 70 eV.

RESULTS AND DISCUSSION

Each of the fatty acids was greater than 95% pure as judged from the total ion current trace of the picolinyl esters in the GC-MS experiment, and spectra were taken of material eluting at the centre of each chromatographic peak. The spectra of each of the isomeric picolinyl octadecadienoates are distinctive, and data for some of the ions of diagnostic value are listed in Table 1. The spectra of the picolinyl 5,12- and 8,12-octadecadienoates are illustrated in Figure 1 as examples.

Each isomer gives upon electron impact a prominent molecular ion (at m/z = 371) and abundant ions characteristic of picolinyl esters at m/z = 92 (the base ion in each, as for most picolinyl esters examined to date), 108, 151 and 164.

In the spectrum of the 5,12-isomer (Fig. 1, top), there are significant ions at m/z = 356 (M-CH_3), then with gaps of 14 atomic mass units (amu) separating the ions at m/z = 342, 328, 314 and 300, representing cleavage at successive methylene groups, followed by a gap of 26 amu

for the terminal double bond to m/z = 274. A feature of this kind has been found to be diagnostic for double bond positions in a large number of picolinyl esters (2,4–9). Continuing, there are further ions 14 amu apart at m/z = 260, 246, 232, 218 and 204, followed by another gap of 26 amu to 178 for the proximal double bond. Unfortunately, there are also ions present that could lead, if the structure were not known, to a suggestion that the double bond might be in position 6.

With the spectrum of the 6,12-isomer, the ions from m/z = 356 to 218 are present as in the previous isomer, so that the position of the terminal double bond is easily located. There are again ions characteristic of a double bond in position 6, although *a priori* it is possible to suggest that the proximal double bond is in position 7.

The distinctive feature of the spectrum of the 7,12-isomer (three methylene groups between the double bond) is a particularly abundant ion at m/z = 260 (72%), representing cleavage between carbons 10 and 11 (cf the 6,11-isomer, where there is a prominent ion at m/z = 246). Again the terminal double bond is easily identified, but without access to standards, the position of the proximal double bond might be less easy to determine.

The spectrum of the 8,12-isomer (two methylene groups between the double bonds) also has an abundant ion at m/z = 260, but in this instance as part of a doublet with an ion at m/z = 261 (Fig. 1, bottom). Similarly, the double bond in position 10 of the 6,10-isomer should prove easy to locate from the rules developed earlier, whereas a prominent doublet at m/z = 232/233 appears to confirm that this feature is characteristic of components with two methylene groups between the double bonds.

In summary, the position of the terminal double bond in picolinyl esters of dienes with two or more methylene groups between the double bonds should be easy to identify by employing the principles found to be of value for other unsaturated esters. On the other hand, the position of the proximal double bond could be misidentified as one carbon further from the carboxyl group than is in fact correct. On the other hand, access to spectra of authentic compounds will reduce the chance of error when unknowns are examined by this means. (Several fatty acids of this type have already been identified in the form of the picolinyl ester derivatives in the lipids of invertebrates from the Black Sea [Christie, W. W., Brechany, E. Y., and Stefanov, K., unpublished].) Although it may be misleading to draw general conclusions from only two examples of each, there appear to be features in the spectra of isomers with two and three methylene groups between the double bonds that may serve to remove any dubiety.

Isolation and Quantitation of Lectins From Vegetable Oils

David M. Klurfeld* and **David Kritchevsky**
The Wistar Institute, Philadelphia, Pennsylvania

The factor(s) responsible for the unexplained atherogenicity of peanut oil remain to be elucidated. To this end, we developed a technique to determine if lectin was present in the oil and to quantitate its concentration. This technique was applied to other vegetable oils including corn, soybean, and sunflower. Crude, unprocessed corn and soybean oils were also analyzed for lectin content. The crude oils contained from 858 to 2983 μg lectin per kg, while the refined oils contained 24 to 55 μg/kg of biologically active lectin. The identities of the isolated lectins were confirmed by electrophoresis on SDS-polyacrylamide gels. The biological significance of the presence of lectin in these oils remains to be determined.
Lipids 22, 667–668 (1987).

Peanut oil is more atherogenic than other vegetable oils when fed to laboratory animals as part of a cholesterol-rich or a cholesterol-free diet (1–3). In addition, the atherosclerotic lesions induced are fibromuscular rather than fatty, foam-cell lesions. Studies of alterations in lipid metabolism in animals fed peanut oil have revealed few, if any, significant differences that might account for the increased atherosclerosis observed in animals (4).

Lectins are proteins isolated in significant quantity from crops that provide edible oils. The proteins have potent biological effects mediated via high-affinity binding to specific carbohydrate residues. The presence of lectins in a variety of foods, such as vegetables, fruits, nuts and cereals, has been determined (5) but, to our knowledge, there are no reports of edible oils surveyed for lectin content.

The present investigation was undertaken to develop a technique to extract lectins from vegetable oils, to determine percentage recovery, to verify the identity of the lectins and to quantitate the isolated lectins. We have found lectins present in detectable amounts in processed oils, but these levels are only a few percent of the content found in unprocessed oils.

MATERIALS AND METHODS

The oils used were crude corn, crude soybean, two commercially available brands of processed soybean oil, one processed corn oil, one processed sunflowerseed oil, two processed peanut oils, two peanut oils from special cultivars and randomized (autointeresterified) peanut oil. The density of the oils was determined, and 500-g batches were mixed with 300 ml of petroleum ether in a separatory funnel. One hundred ml of 0.15 M phosphate-buffered saline (PBS) (pH 7.4) was added and mixed well. The phases were allowed to separate, and the aqueous phase was removed and refrigerated. This was repeated four times, and the PBS was pooled. The PBS extracts were concentrated at 4 C using an Amicon ultrafiltration chamber containing a 10,000 MW filter. Protein in the concentrated extracts was quantitated using the Bradford dye binding reagent (Bio-Rad Laboratories, Richmond, CA) (6).

Biological activity of the lectins was determined following the method of Lotan et al. (7), in which human erythrocytes were agglutinated by various concentrations of the PBS extracts. Samples were mixed in cuvettes and left undisturbed for 2.5 hr, and the optical density was measured at 620 nm. Peanut and soybean lectins, used as standards, were purchased from Sigma Chemical Co. (St. Louis, MO). For detection of peanut lectin, the erythrocytes were treated with neuraminidase to remove sialic acid residues (7).

The presence of lectins in oils was verified using 10% acrylamide gels containing sodium lauryl sulfate (8). Samples were electrophoresed under both reducing and nonreducing conditions at 6 mA/gel for 4 hr. Gels were fixed and stained with Coomasie Blue R-250.

Recovery efficiency was measured by dissolving peanut or soybean lectins in their respective oils at 1 mg/100 g by sonication in an ultrasonic bath. The oils were then subjected to the extraction procedure described above, and the biological activity was quantitated at multiple dilutions.

RESULTS

All of the oils tested contained detectable amounts of lectin-like activity. The dye-binding protein assay gave relatively high concentrations compared to the bioassay, suggesting the presence of other proteins as well as lectins (Table 1). One of the samples of processed soybean

TABLE 1

Quantitation of Total Protein and Lectin-like Activity in Crude and Processed Vegetable Oils (μg/kg)

Oil	Total protein	Lectin-like activity
Crude corn	9379	2983
Crude soybean	1926	858
Corn	190	24
Soybean	720	45
Sunflowerseed	849	44
Peanut[a]	580	55
Randomized peanut	204	35
Peanut[b]	120	30
Peanut[c]	154	26
Peanut[d]	206	28

[a]Grown in United States.

Abbreviations: PBS, phosphate-buffered saline.

oil contained Tween 80 and gave a very strong color for protein. It was determined that Tween 80 at concentrations as low as 0.0001% reacts in this assay. The other oils were without additives. Almost one-third of the protein in crude corn oil had lectin-like activity, but this was reduced by greater than 99% in the refined product. Analysis of the refined oils by colorimetric protein assay yielded values in the 200–850 μg/kg range, while the bioassay results for lectin gave results in the range of 24 to 45 μg/kg.

Recovery efficiency was determined to be 10%, with a range of replicate experiments from 9.4% to 10.1%. This figure represents recovery of biological activity, not merely extraction efficiency. Factors that may interfere with recovery of biological activity include addition of the solvent to the oils, which facilitated phase separation, or instability of the lectins during the extraction and concentration procedures.

Gel electrophoresis of the PBS extracts revealed bands in the samples from peanut, soybean and corn oils, which corresponded to published molecular weights of lectins from these plants (9–11). It is unclear why no protein bands were found upon electrophoresis of sunflowerseed oil, since the protein recovred by extraction was similar to that from the other oils.

DISCUSSION

The presence of lectins in vegetable oils was previously unsuspected and may have important biological consequences, since lectins are extremely potent compounds. For example, ricin D lectin derived from the castor bean is lethal in mice at 0.001 μg of nitrogen per g body weight; this is several hundred times more toxic than hydrogen cyanide (12). Therefore, the finding of microgram quantities of lectins in these oils may not be inconsequential in the intestine and other organs if they are absorbed from the gut. The presence of soy protein, but not lectin, in lecithin, margarine and oil has been reported (13).

Lectins from peanut, wheat germ and jack bean bind to rabbit aortic smooth muscle cells in vitro (14); several lectins bind to the endothelium of rat cerebral arterioles, but prior neuraminidase treatment is necessary to expose peanut lectin binding sites and accentuates soybean lectin binding sites (15). The lack of neuraminidase treatment may explain why peanut lectin does not consistently stain cellular structures in atherosclerotic arteries (16).

It is important to realize that lectins have specific affinities for sugar residues. Peanut lectin has specificity for D-galactose residues and preferentially for the α-D-Gal(1-03)-D-Gal NAc sequence, which is shared only by the lectin from the mushroom *Agaricus bisporus.* This sequence is expressed in GM_1 ganglioside found in myoblasts from rats and chicks (17,18). The presence of GM_1 on arterial smooth muscle cells may be a reason that peanut oil induces fibromuscular arterial lesions when fed in a hypercholesterolemic diet in contrast to other polyunsaturated fats that induce fatty lesions. This leads to the hypothesis that small amounts of peanut lectin, in the presence of hypercholesterolemia, could enhance proliferation of arterial smooth muscle cells. Lectins also bind to various cellular components of the immune system. Since macrophages are a major cell type in fatty streaks of experimental animals and humans (19,20), and these cells are scant in lesions induced by feeding peanut oil, the possibility exists that peanut lectin inhibits macrophage recruitment to the arterial wall during atherogenesis.

Among the peanut oils studied, the most atherogenic variety (1, unpublished results) contains the most lectin, and when it is randomized the lectin concentration is reduced by half. Randomization of peanut oil reduces its atherogenicity to that of corn oil (2). This suggests that the lectin content of peanut oil correlates with its atherogenic potential.

Although it is unlikely that lectins in the quantities found in these edible oils are of detriment in the human diet, it is possible that when the oils are fed as the sole fat source to experimental animals, the lectin content plays a role in some pathophysiologic effects. Further work is in progress in our laboratory to study the role of lectins in atherosclerosis.

ACKNOWLEDGMENTS

The authors thank Robert Manko for technical assistance. The oils from unique cultivars of peanut were supplied by Dr. R. E. Worthington of the Georgia Experimental Station and the crude oils were courtesy of Best Foods, CPC International. This work was supported in part by a grant from Best Foods, a grant (HL-03299) and Research Career Award (HL-00734) from the National Institutes of Health and funds from the Commonwealth of Pennsylvania.

Deconjugation of Bile Acids by Human Intestinal Bacteria Implanted in Germ-Free Rats

Toshiyuki Chikai[a], Hiroyuki Nakao[b] and Kiyohisa Uchida[a,*]
[a]Shionogi Research Laboratories, Fukushima-ku, Osaka, Japan, and [b]Shionogi Aburahi Laboratories, Shiga, Japan

Fecal bile acids in germ-free rats were analyzed after inoculation with *Bacteroides vulgatus, Bifidobacterium longum, Escherichia coli* or *Clostridium ramosum*. *B. vulgatus* preferentially deconjugated tauro-β-muricholic acid and *B. longum* taurocholic acid. *C. ramosum* deconjugated both bile acids, but *E. coli* deconjugated neither. 7α-Dehydroxylation of bile acids was negligible even after 18 days of inoculation, but a small amount of 7-oxo-bile acids, less than 5%, was formed. Fecal excretion of bile acids increased after inoculation with *B. vulgatus, B. longum* and *C. ramosum*, but not with *E. coli*.
***Lipids 22,* 669-671 (1987).**

Biotransformation of bile acids by intestinal bacteria includes deconjugation, desulfation, dehydroxylation, oxidation-reduction and epimerization (1-3). Of these, deconjugation activity is the most commonly observed (4), but it is not yet known whether the reaction is common to different bile acids. The present paper reports that deconjugation activity differs not only with the strain of bacteria but also with the structure of the bile acid.

MATERIALS AND METHODS

Germ-free Wistar male rats (20-37 wk old) bred in our laboratory were housed under germ-free conditions and inoculated orally with four organisms, *Bacteroides vulgatus, Bifidobacterium longum, Escherichia coli* and *Clostridium ramosum,* originally isolated from normal human feces, in which these organisms represented the predominant strain of each group. Each organism was cultured for 72 hr at 37 C in GAM semifluid media (Nissui Co., Tokyo, Japan); after thorough mixing, a 1-ml aliquot was administered to each rat.

All rats were fed a commercially available chow diet (Oriental CMF diet, Oriental Kobo Co., Tokyo, Japan) sterilized by radiation. Feces from each rat were collected at 2-day intervals, and a portion was utilized to determine bacterial concentrations (5). The remaining feces were dired to a constant weight and utilized for bile acid analysis.

Feces were ground, and a portion (usually 1 g) was extracted three times with 20 ml of absolute ethanol for 1 hr at 90 C (6,7). The extract was filtered and evaporated to dryness under a stream of nitrogen. The residue was dissolved in 10 ml of 90% ethanol, and a portion of this solution (usually 1 ml) was subjected to PHP-LH-20 column chromatography to separate bile acids into their free and three conjugate forms—glycine conjugates, taurine conjugates and sulfates (8). The conjugate fractions were hydrolyzed by solvolysis and/or alkaline hydrolysis, and the bile acids in the hydrolysates were extracted with diethylether after acidification with hydrochloric acid solution. The bile acids were methylated with freshly prepared diazomethane and then trifluoroacethylated with trifluoroacetic anhydride. The bile acid derivatives were quantified by gas liquid chromatography utilizing a Shimadzu gas chromatograph Model GC-7A (Shimadzu Co., Kyoto, Japan) equipped with a flame ionization detector. A glass column (1.6 m × 3 mm i.d.) packed with 1.5% QF-1 or 1.5% AN-600 on 80-100 mesh Gas Chrom Q was used. The operation temperatures were 235 C and 210 C for the 1.5% QF-1 and 1.5% AN-600 columns, respectively, and 290 C for the detector (6,7).

RESULTS

Table 1 shows fecal bacterial concentrations in gnotobiote rats examined on days 7 and 14 after inoculation. The number was around 10^{10} in all groups. The total amounts of fecal bile acids excreted in a day and the percentages of free forms and conjugates are given in Table 2. All the bile acids in germ-free rats were conjugated with taurine, and neither glycine conjugates nor sulfates were detected. *B. vulgatus, B. longum* and *C. ramosum* formed free bile acids to some extent, but *E. coli* did not.

The fecal bile acid composition is given in Table 3. Major bile acids in germ-free rats were cholic and β-muricholic acids; they comprised about 90% of the total bile acids. Chenodeoxycholic acid was present at about 5%. In gnotobiote rats, the values for cholic and β-muricholic acids were not changed markedly, but some oxo-bile acids, such as 3α,12α-dihydroxy-7-oxo- and 3α-hydroxy-7-oxo-5β-cholanoic acids, were detected in amounts of less than 6-7%. The total amounts of bile acids in feces increased in rats inoculated with *B. vulgatus, B. longum* and *C. ramosum,* but not in those with *E. coli.*

Table 4 shows the percentages of the free forms of each cholic acid and β-muricholic acid in the feces collected before (day 0) and after inoculation of bacteria on days 3-4, days 9-10 and days 17-18. *B. vulgatus* formed only 3.8% free cholic acid on days 3-4, but markedly deconjugated tauro-β-muricholic acid, giving a value of 91.7%. These values were almost the same in the other determinations on days 9-10 and days 17-18, though they did

vary somewhat. On the contrary, *B. longum* mostly deconjugated taurocholic acid and a little tauro-β-muricholic acid. *C. ramosum* deconjugated both bile acids, but *E. coli* deconjugated neither.

DISCUSSION

Deconjugation activity for conjugated bile acids is found in many species of intestinal bacteria (2,3). Among them, Bacteroides, Streptococcus, Lactobacillus, Eubacterium and some aerobic bacteria deconjugate both taurine and glycine conjugates of bile acids (9–11), but Kobashi et al. (12) demonstrated that *Peptostreptococcus intermedius* deconjugated taurocholic acid, while *Lactobacillus brevis* and *Streptococcus faecalis* II-136 deconjugated glycocholic acid predominantly in vitro. They isolated enzymes that hydrolyzed taurine- or glycine-conjugated bile acids specifically from these bacteria.

The present experiment demonstrated that both *B. vulgatus* and *B. longum* deconjugated taurine-conjugated bile acids, but the former deconjugated tauro-β-muricholic acid in preference to taurocholic acid while the latter deconjugated taurocholic acid preferentially. In addition, *C. ramosum* deconjugated both bile acids, but *E. coli* deconjugated neither. Although it is not known whether these bacteria contain enzymes that hydrolyze tauro-β-muricholic acid or taurocholic acid specifically, these taurine-conjugated bile acids are deconjugated by different intestinal bacteria in vivo, at least in rats.

The total amounts of bile acids in feces increased in rats inoculated with bacteria having the ability to deconjugate bile acids. The fecal bile acid excretion of germ-free rats is lower than (almost half) that of conventional rats (13), due to lack of biotransformation of bile acids by intestinal microflora. Although Kellogg et al. (14) concluded that only deconjugation does not cause an increase in fecal excretion of bile acids, our data suggest that it does increase fecal excretion. We speculate that free bile acids are excreted more rapidly than the conjugates, and adhesion of free bile acids to bacteria or dietary fibers would be a cause for larger excretion of bile acids. We also observed that the cecum was bigger in germ-free rats than in conventional rats, and the size was decreased in rats monoinfected with *B. vulgatus, B. longum* or *C. ramosum* but not with *E. coli.* Although absorption of bile acids from the cecum is considered to be less effective than that from the small intestine, the cecum may play a role in bile acid absorption to some extent in germ-free or *E. coli* gnotobiote rats.

ACKNOWLEDGMENTS

We thank Dr. Y. Benno of the Institute of Physical and Chemical Research for furnishing the organisms used in the study. The help of Miss M. Katayama in preparing the manuscript is appreciated.

[Received January 12, 1987]

Phosphocholine Phosphatase and Alkaline Phosphatase Are Different Enzymes in Hamster Heart

Grant M. Hatch and **Patrick C. Choy***
Department of Biochemistry, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, Canada R3E OW3

The CDP-choline pathway is the major pathway for the synthesis of phosphatidylcholine in the hamster heart. The formation of phosphocholine from choline was regarded as the first committed reaction in this pathway. We demonstrated earlier that the phosphocholine pool in the heart was substantially less than that found in other tissues, and we observed that a substantial amount of the phosphocholine was hydrolyzed back to choline by a phosphatase. This phosphatase was located in the microsomal fraction of the heart, and unlike alkaline phosphatase, it was not inhibited by amino acids. The pH optima and heat sensitivity of phosphocholine phosphatase were also found to differ from alkaline phosphatase. Phosphocholine did not inhibit the hydrolysis of p-nitrophenylphosphate, but a "mixed type" inhibition of the hydrolysis of phosphocholine was observed in the presence of p-nitrophenylphosphate. Our data support the hypothesis that these two activities originate from separate and distinct enzymes, and we postulate that the cardiac phosphocholine phosphatase may play a role in the regulation of the phosphocholine pool size in the hamster heart.
Lipids 22, 672-676 (1987).

Phosphatidylcholine is the major phospholipid in mammalian tissues, and its biosynthetic pathway via CDP-choline was elucidated by Kennedy (1). In hamster heart the majority of phosphatidylcholine biosynthesis proceeds via the CDP-choline pathway (2). Choline is actively taken up by the hamster heart and is rapidly phosphorylated to phosphocholine by choline kinase (2,3). Phosphocholine is converted to CDP-choline by CTP:phosphocholine cytidylyltransferase, the rate-limiting enzyme of the CDP-choline pathway (2,4). CDP-choline is condensed with 1,2-diacylglycerol to form phosphatidylcholine (2,4).

In rat liver, the formation of phosphocholine appears to be the first committed step for the formation of phosphatidylcholine (5). The reaction catalyzed by choline kinase is essentially irreversible, and a relatively large and constant pool of phosphocholine is maintained (5). Moreover, pulse-chase studies in rat liver have clearly demonstrated that CDP-choline is the obligatory product of phosphocholine (6). In the hamster heart, the reaction catalyzed by choline kinase is also irreversible, but the phosphocholine pool is much lower than that found in the liver (2,3). Our earlier work suggests that some of the phosphocholine formed in the heart may be hydrolyzed back to choline by a yet undefined phosphatase (2).

*To whom correspondence should be addressed at Department of Biochemistry, Faculty of Medicine, University of Manitoba, 770 Bannatyne Ave., Winnipeg, Manitoba, Canada, R3E OW3.

Due to the relatively small pool size of phosphocholine in the hamster heart, alteration of this pool may play a regulatory role in phosphatidylcholine biosynthesis. Hence, the control of phosphocholine hydrolysis by a phosphatase, in addition to the phosphorylation reaction catalyzed by choline kinase, may be important in the maintenance of the phosphocholine pool in the heart. In this study, we provide strong evidence that the hydrolysis of phosphocholine is catalyzed by a specific phosphatase that is different from the cardiac alkaline phosphatase.

MATERIALS AND METHODS

Phosphocholine, p-nitrophenyl-phosphate and alanine were purchased from Sigma Chemical Co. (St. Louis, MO). [Methyl-^{3}H]choline was obtained from New England Nuclear (Boston, MA). AG1-X8 anion exchange resin was purchased from Bio-Rad. Aqueous counting scintillant was obtained from Amersham (Ontario, Canada). Phospho[methyl-^{3}H]choline was synthesized enzymatically from [methyl-^{3}H]choline by the procedure of Paddon and Vance (7). All other biochemicals were of analytical grade and were purchased from Fisher Scientific Chemical Co. (Winnipeg, Manitoba).

Male Syrian golden hamsters of 100 ± 15 g were used throughout the study. The hamsters were maintained on Purina hamster chow and tap water, ad libitum, in a temperature- and light-controlled room.

Hamster hearts were homogenized in 10% 0.25 M sucrose, 10 mM Tris-HCl, 1 mM EDTA, pH 7.4. Subcellular fractions were prepared from the homogenate as described previously (8). In brief, the homogenate was centrifuged at 1,000 × g for 10 min, and the supernatant was centrifuged at 12,500 × g for 15 min. The pellet, designated as mitochondrial fraction, was washed with buffer A, recentrifuged and resuspended in buffer B. The supernatant was centrifuged at 100,000 × g for 60 min. The resultant pellet, designated as microsomal fraction, was washed with buffer A, recentrifuged and resuspended in buffer B. Buffer A contained 0.15 M Tris-HCl, pH 8.0, and buffer B contained 0.25 M sucrose, 10 mM Tris-HCl, pH 7.4. The purities of the mitochondrial and microsomal fractions were analyzed by marker enzymes. The mitochondrial fraction was contaminated with 10% of microsomal material and the microsomal fraction contained 5% mitochondrial particles (8). Protein was determined by the method of Lowry et al. (9).

Alkaline phosphatase activity was determined by a modified procedure of Cox and Griffin (10). The assay mixture contained 0.4 M Tris-HCl, pH 10, 1 mM $MgCl_2$, 10 mM p-nitrophenyl-phosphate and 10 µl of the microsomal fraction in a total volume of 0.5 ml. The reaction mixture was incubated at 37 C for 30 min, and the reaction was terminated by addition of 1 ml 0.25 N NaOH. The amount of p-nitrophenol formed was determined by absorbance at 410 nm, with the aid of p-nitrophenol standards. The reaction mixture without the addition of microsomal fraction was used as control.

Phosphocholine phosphatase activity was determined by the formation of labeled choline from labeled phosphocholine (7). The reaction mixture contained 0.1 M Tris-HCl (pH 9.0), 10 mM $MgCl_2$, 10 mM phospho-[methyl-^3H]choline and 30 μl microsomal fraction in a total volume of 0.1 ml. The reaction mixture was incubated at 37 C for 30 min, and the reaction was terminated by boiling the tubes for 2 min. The reaction mixture without the addition of microsomes was used as control. After the termination of the reaction, 1 ml of water was added to the assay mixture, and the entire mixture was applied to a AG1-X8 anion exchange column (1.0 ml bed volume). Choline in the reaction mixture was washed from the column with 10 ml of water, and the radioactivity in a 2-ml aliquot of the eluant was determined. Radioactivity in the sample was determined by liquid scintillation counting using channels' ratio calibration method.

Results in this study are depicted as mean ± S.D. (number of experiments). A two-tailed Students' t-test was used for determination of significance. The level of significance was defined as $P < 0.05$. Results of kinetic inhibition of phosphocholine phosphatase and alkaline phosphatase are depicted as the mean of two separate experiments. Kinetic data were depicted on the basis of least squares analysis of data points.

RESULTS

The majority of alkaline phosphatase (68%) and phosphocholine phosphatase (72%) activities were found to be located in the microsomal fraction of the hamster heart, with the remainder in the mitochondrial fraction. As previously indicated (11), the pH optimum for microsomal alkaline phosphatase was found to be between 9.75 and 10.25, depending on the substrate concentration. In the presence of 10 mM p-nitrophenyl phosphate, the enzyme depicted a pH optimum of 10.0 (Fig. 1). The pH optimum for phosphocholine phosphatase was 9.0 and remained unchanged at different substrate concentrations (Fig. 1).

To discern the possible difference between these two activities in the hamster heart, the effects of L-phenylalanine and L-alanine on alkaline phosphatase and phosphocholine phosphatase activities were investigated. L-Phenylalanine (10–25 mM) inhibited both activities, but a higher degree of inhibition was obtained with alkaline phosphatase than that of phosphocholine phosphatase (Table 1). L-Alanine at 25 and 50 mM caused significant inhibition of alkaline phosphatase activity, but did not inhibit phosphocholine phosphatase (Table 2). The nature of inhibition of alkaline phosphatase by L-alanine was further investigated. The activities of the enzyme at different substrate levels in the absence and presence of 25 and 50 mM L-alanine were determined, and the results are depicted in a double-reciprocal plot. The kinetic studies revealed that the inhibition by L-alanine was essentially uncompetitive (Fig. 2).

The possibility of the two activities sharing the same catalytic site was studied by a kinetic approach. In the presence of phosphocholine (1–50 mM), alkaline phosphatase activities were not affected (Table 3). However, the presence of p-nitrophenylphosphate (1–50 mM) caused significant inhibition of phosphocholine phosphatase activities (Table 3). In the presence of 0.1 and 0.2 mM p-nitrophenylphosphate, a "mixed-type" of inhibition on phosphocholine phosphatase activity was observed (Fig. 3).

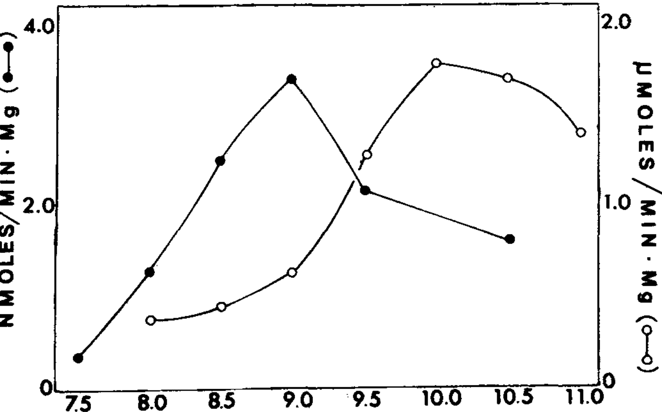

FIG. 1. The pH profiles of phosphocholine phosphatase and alkaline phosphatase. The pH profiles of phosphocholine phosphatase (●) and alkaline phosphatase (○) were determined in the presence of 10 mM concentration of phospho-[Me-^{3}H]-choline and p-nitrophenyl-phosphate, respectively. The points represent the mean values obtained from two separate sets of experiments, each of which was assayed in duplicate.

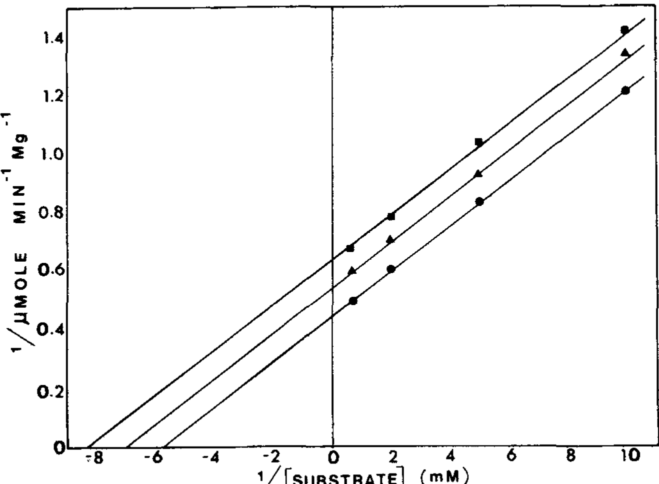

FIG. 2. The inhibition of alkaline phosphatase activity by L-alanine. The hydrolysis of p-nitrophenyl-phosphate in the absence (●) and the presence of 25 mM (▲) and 50 mM (■) L-alanine were determined. The assays were performed as described in Materials and Methods, and 10 μl of microsomal preparation (0.02 mg protein) was used in each assay. The points represent the mean values obtained from two separate sets of experiments, each of which was assayed in duplicate. The lines depicted were obtained from least squares analysis. The correlation coefficient was 0.99 for each line.

The effect of temperature on the activities of alkaline phosphatase and phosphocholine phosphatase in hamster heart microsomes was studied. Microsomal preparations were incubated at 55 C for different time periods, and the enzyme activities were subsequently determined. As shown in Figure 4, treatment at 55 C caused a differential loss of activities between these two enzymes. Incubation of the microsomal preparation for 5 min caused a 30% loss of phosphocholine phosphatase activity, whereas a 10% loss of alkaline phosphatase activity was observed.

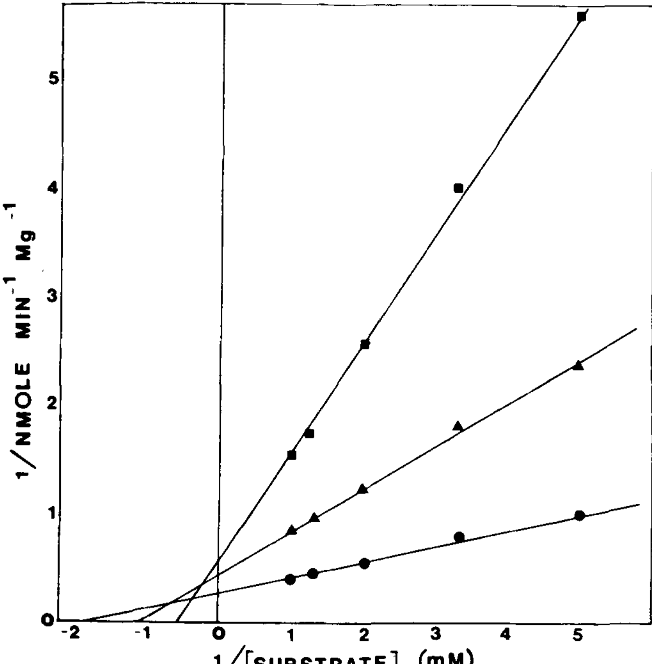

FIG. 3. The inhibition of phosphocholine phosphatase activity by p-nitrophenyl-phosphate. The hydrolysis of phospho-[Me-^{3}H]choline was determined in the absence (●) and presence of 0.1 mM (▲) and 0.2 mM (■) p-nitrophenyl-phosphate. The assays were performed as described in Materials and Methods, and 30 μl of microsomal preparation (0.06 mg protein) was used in each assay. The points represent the mean values obtained from two separate sets of experiments, each of which was assayed in duplicate. The lines depicted were obtained from least squares analysis, and the correlation coefficient was 0.99 for each line.

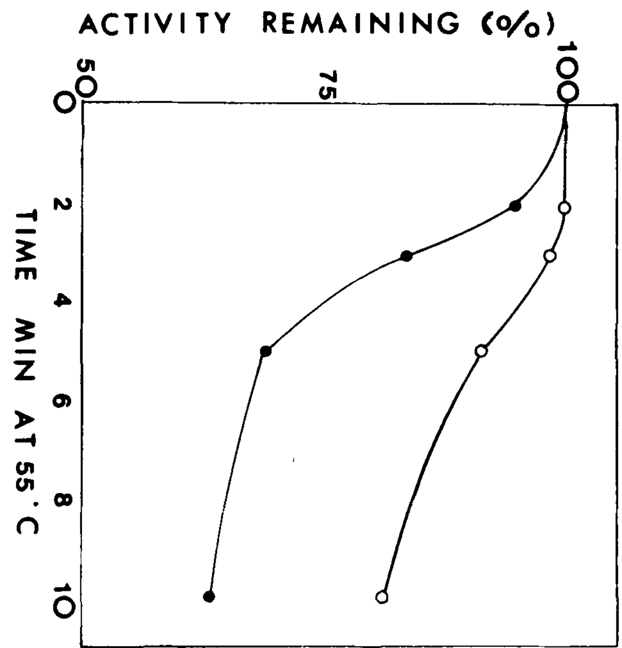

FIG. 4. The effect of incubation at 55 C on phosphocholine phosphatase and alkaline phosphatase activities. Microsomal preparations were incubated at 55 C for 0–10 min. The ability of the incubated microsomal preparation to hydrolyze p-nitrophenyl-phosphate (○) and phospho-[Me-^{3}H]choline (●) was determined. The assay conditions were as described in Figs. 2 and 3. The points represent the mean value of two separate sets of experiments, each of which was assayed in duplicate.

DISCUSSION

The objective of this study was to examine whether phosphocholine phosphatase and alkaline phosphatase are the same enzyme in hamster heart and to determine whether these two activities were subjected to the same metabolic regulation. It is clear from our study that the two activities in the hamster heart microsomes are modulated differently in vitro. The difference in pH profiles and responses to heat treatment and to various inhibitors all suggest that the two activities originate from two separate and distinct enzymes.

Alkaline phosphatase from mammalian sources exists in three distinct categories: the placenta type, the intes-

tinal type and the liver-bone-kidney type (11). They are different from each other by their responses to uncompetitive inhibition by specific amino acids, heat stability and pH optima at specific substrate concentrations. Previous studies have clearly demonstrated that the cardiac alkaline phosphatase belongs to the liver-bone-kidney type (12,13). It has also been reported that the liver-bone-kidney type in the heart may exist in multiple molecular forms, and these forms may have different properties (11–13). Hence, it can be argued that the observed differences between phosphocholine phosphatase and alkaline phosphatase in this study may result from a broad specificity of one specific form of cardiac alkaline phosphatase. However, this argument is not supported by the kinetic data of phosphocholine phosphatase in the presence of p-nitrophenylphosphate. Further evidence against this supposition was obtained from the inhibition studies of alkaline phosphatase by phosphocholine.

Since the conversion of phosphocholine to CDP-choline is the rate-limiting step in the CDP-choline pathway (2,14), the maintenance of the phosphocholine pool is important to facilitate the rate-limiting role of the CTP:phosphocholine cytidylyltransferase. In the hamster heart, the observed turnover of phosphocholine by dephosphorylation (2) implies that phosphocholine phosphatase may play a significant role in the control of phosphatidylcholine biosynthesis via the regulation of the phosphocholine pool. If phosphocholine phosphatase indeed contributes to the regulation of phosphatidylcholine biosynthesis, its modulation and metabolism should be distinct from the alkaline phosphatase. Our study reveals that, unlike alkaline phosphatase (15), phosphocholine phosphatase in the heart may not be subjected to modulation by alanine and other amino acids (Hatch, G.M. and Choy, P.C., unpublished results). The ability to hydrolyze phosphocholine in vitro had also been reported in the liver (16), intestinal cells (17) and HeLa cells (7), but such reaction was postulated to be of limited importance in the regulation of phosphocholine pool or phosphatidylcholine biosynthesis in these tissues (7). However, the pool of phosphocholine in the heart (0.24 mM) is much lower than that found in the liver (1.3 mM) or HeLa cells (1.8 mM) (14). In the heart, the diminished pool size of phosphocholine implies that the metabolism of this important metabolite of the CDP-choline pathway may be regulated differently. At present, the rationale for a relatively small pool of phosphocholine pool in the heart is not explained. It is also not clear if the small phosphocholine pool in the heart can be attributed to the functional role of the cardiac phosphocholine phosphatase. In view of the fact that the apparent Km (0.56 mM) of the enzyme for phosphocholine (Fig. 3) is much greater than the pool of phosphocholine in the heart, it is possible that one of the major functions of the cardiac phosphocholine phosphatase is to prevent the accumulation of a large phosphocholine pool.

The Activity and Properties of a Hepatic Acid Cholesteryl Ester Hydrolase Obtained from Rats of Different Age Groups

Mitsuo Tanaka*, **Toshihiro Iio** and **Toshikazu Tabata**
Showa College of Pharmaceutical Sciences, 1-8, Tsurumaki-5-Chome, Setagaya-Ku, Tokyo, Japan

The activity of lysosomal acid cholesteryl ester hydrolase (acid CEH, EC 3.1.1.13) in rat liver was determined at 3, 5, 7, 10 and 20 wk following birth. The levels of acid CEH activity showed a marked decrease as rats grew older, whereas those of other lysosomal marker enzymes, such as acid phosphatase, β-glucuronidase and cathepsin B and D, showed only a slight decrease. On the other hand, acid CEH activity was detected in all subcellular fractions obtained from rat liver, but the enzyme activity in these fractions did not show the age-related decrease observed in the lysosomal fraction. The results presented here suggest that the marked alteration of lysosomal acid CEH activity that accompanies aging may be related to its possible involvement in the regulation of cholesterol concentration in rat liver.
Lipids 22, 677–679 (1987).

It is well known that hepatic lysosomal acid cholesteryl ester hydrolase (acid CEH) plays an important role in the metabolism of exogenous cholesteryl esters introduced into cells as lipoproteins (1). The activity of the enzyme is lowered under several conditions, such as fasting (2), Wolman's disease (3), thyroidectomy (4) and Triton WR-1339 treatment (5). It has also been reported that acid CEH activity may be an important factor in the accumulation of cholesteryl esters such as that occurring in atherosclerosis (6).

We have recently shown that acid CEH activity varies according to a diurnal rhythm (2). In addition, we have found that a cytosolic protein in rat liver has an inhibitory effect on lysosomal acid CEH activity (7). However, the mechanisms involved in the regulation of lysosomal acid CEH are as yet unknown.

On the other hand, age-related changes in the activities of HMG-CoA reductase (8) and 7α-hydroxylase (9) and in the absorption (10) and turnover (11) levels during cholesterol metabolism have been reported. In the present experiment, we studied the relationship between aging and changes in lysosomal acid CEH activity in rat liver.

MATERIALS AND METHODS

Chemicals and radiochemicals. Cholesteryl [1-^{14}C]oleate (sp act 58.6 mCi/mmol) was purchased from New England Nuclear Corp. (Boston, MA). Phenolphthalein glucuronide, phenylphosphate, hemoglobin and α-N-benzoyl-DL-arginine-2-naphthylamide hydrochloride (BANA) were purchased from Sigma Chemical Co. (St. Louis, MO).

Animals. Male Sprague-Dawley rats were purchased from Japan Clea Corp. (Tokyo). Rats were housed under controlled lighting (lights on from 06:00 to 18:00) and were given food and water ad libitum.

Preparation of subcellular fractions. For the preparation of subcellular fractions from rat liver, the method of Brecher et al. (12) was employed. Rats were killed by decapitation, and livers were perfused with ice-cold 1.15% KCl solution at 4 C. The tissues were homogenized in 8 vol of ice-cold 0.25 M sucrose/1 mM EDTA/0.01 M Tris-HCl buffer (pH 7.5). The homogenate was centrifuged at 1,000 × g for 10 min, and the resulting supernatant was centrifuged at 3,300 × g for 20 min. The 3,300 × g supernatant solution was then centrifuged at 12,000 × g for 35 min. The resulting pellet was rehomogenized in 0.25 M sucrose solution and recentrifuged at 12,000 × g for 20 min. The original 12,000 × g supernatant solution was recentrifuged at 105,000 × g for 60 min.

Acid cholesteryl ester hydrolase assay. The activity of acid CEH was measured by the method of Brecher et al. (12). Preparation of the substrate was performed as described previously (7).

Assay of lysosomal marker enzymes. Cathepsin D was assayed by the method of Hirado et al. (13), and the amount of reaction products was assayed by the method of Lowry et al. (14). Cathepsin B was assayed by the method of Lenney et al. (15), using BANA as the substrate. β-Glucuronidase was assayed using phenolphthalein glucuronide as the substrate. Phenolphthalein liberated from the substrate was measured by the method of Gianetto et al. (16). Acid phosphatase was measured using phenylphosphate as the substrate essentially as described previously (17). Protein concentration was assayed by the method of Lowry et al. (14).

RESULTS AND DISCUSSION

Changes in the activity of lysosomal acid CEH in rat liver were studied over a period extending from 3 to 20 wk after birth. The acid CEH activity showed a gradual reduction as rats grew older, that is, the activity in lysosomes from 20-wk-old rats was decreased to about one-half of the level in 3-wk-rats (Fig. 1).

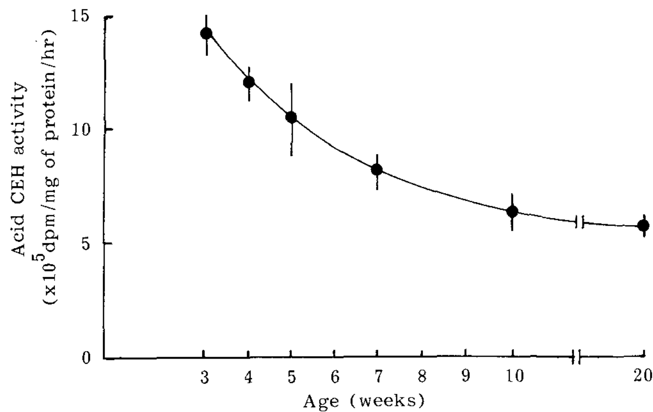

FIG. 1. Acid cholesteryl ester hydrolase (acid CEH) activity during liver development. Standard assay conditions were used as described in Materials and Methods. Values are given as mean ± SEM of six rats.

*To whom correspondence should be addressed.
Abbreviations: CEH, cholesteryl ester hydrolase; BANA, α-N-benzoyl-DL-arginine-2-naphthylamide hydrochloride.

On the other hand, the levels of other lysosomal marker enzymes, such as acid phosphatase, β-glucuronidase and cathepsin B and D, showed little change as rats grew older, and their activities in 20-wk-old rats were about 101%, 86%, 91% and 93%, respectively, of those of 3-wk-old-rats.

It is generally accepted that acid CEH is found in all subcellular fractions from rat liver and that the major proportion of the enzyme activity appears to be associated with lysosomes. We therefore compared the age-related changes occurring in acid CEH activity in various subcellular fractions obtained from both 3- and 20-wk-old rats (Fig. 2). The distribution profile of acid CEH in 3-wk-old rats was similar to that obtained from 20-wk-old rats except for an age-dependent decrease in acid CEH activity observed in the lysosomal fraction. These results suggest that the decrease in acid CEH activity as rats grew older is markedly dependent upon the lysosomal fraction in rat liver and that lysosomal acid CEH may be related to the regulation of cholesteryl ester hydrolysis in liver cells.

Brooks et al. (18) recently reported that the activity of acid triacylglycerol lipase from rat lung was significantly low in the fetus, but increased at birth, and later showed a decline in adulthood. In terms of such an age-related decrease of acid lipolysis in rats, our present results seem to be similar to data on the properties of acid triacylglycerol lipase from rat lung.

It is generally known that the levels of biosynthesis (19) and biodegradation of cholesterol (9,11) are reduced with aging. However, Kritchevsky et al. (20) have reported that the lipolytic activity of rat aorta increases with aging and that the phenomenon may be part of a protective mechanism against the accumulation of cholesteryl esters with aging. In contrast, Brown et al. (1) have reported that the intracellular enzymes located in lysosomes may play a role in regulation of the serum cholesterol level. In our investigations in changes as rats grew older, it is noteworthy that the levels of acid CEH activity were markedly decreased as rats grew older, whereas those of other lysosomal marker enzymes were unaffected by different age groups. This finding suggests that an age-dependent increase in serum and liver cholesterol levels may be partly related to the observed decrease of lysosomal acid CEH activity as rats grew older. In order to confirm this possibility, however, further studies will be required.

On the other hand, several authors have reported that changes in lysosomal acid CEH activity in atherosclerosis could be caused by alterations in the lipid composition and other properties of the substrate vehicle or by substrate dilution at the interface (12,21), that is, enzyme-substrate interaction might be important for the hydrolytic activity of acid CEH. Accordingly, the kinetic parameters of lysosomal acid CEH, given in Figure 3 as Lineweaver-Burk plots, showed apparent Km values of 10 μM and 9.1 μM and Vmax values of 0.33 nmol and 0.16 nmol in 3- and 20-wk-old rats, respectively. Our results thus showed that the affinity of acid CEH, as indicated by the similarity in the apparent Km, did not change as rats grew older. Moreover, protein synthesis is decreased in old animals, as shown by Von Hahn (22) and Mainwaring (23). Furthermore, Yamamoto and Yamamura (10) have reported that decreased protein synthesis in aging animals may cause decreased formation of enzymes involved in lipid synthesis. From these reports, our result suggests that the age-dependent decrease in acid CEH activity may be due to a reduced capacity for de novo enzyme synthesis with aging.

[Received March 18, 1987]

ERRATUM

In the paper "Partial Purification and Characterization of Free and Immobilized Lipases from *Mucor miehei*" by Birgitte Huge-Jensen, Donna Rubano Galluzzo and Robert G. Jensen, Vol. 22, No. 8, pp. 559–565, there were two typographical errors, one giving an incorrect temperature and the second omitting part of a figure legend.

In the Materials and Methods section, the sentence starting on line 10, page 560, should have read:

(b) Step 2: hydrophobic interaction chromatography. A solution (50 ml) containing 2% of the DEAE Sepharose purified powder in 0.2 M ammonium acetate, pH 4.7, was stirred for 30 min at 30 C.

The legend for Fig. 8 should have read:

FIG. 8. Tandem-crossed immunoelectrophoresis, stained with Coomassie Brilliant Blue. Arrows indicate lipases, detected as described in Fig. 2. Applied antibodies as in Fig. 2. (a) Well 1, 5 μg of conA-Sepharose purified lipase A preparation. (b) Well 2, 4.4 μg of phenyl-Sepharose purified lipase B preparation..

An International Conference on

Diet, Lipids and Cancer
Metabolism—Membranes—Mechanisms
May 22-26, 1988

Yulara Resort (via Ayers Rock)
Northern Territory, Australia

The views, and counterviews, of specialists from a wide range of disciplines —epidemiology, physiology, endocrinology, biochemistry, metabolism, membranology—will refocus attention on the role of nutrition in the prevention, management and treatment of human cancer. Full participation, by a maximum of 300 registrants, will be actively encouraged through a wide range of presentation styles—lectures, discussions, debates, posters.

Sponsored by:

Monohydroperoxides of Linoleic Acid in Endoplasmic Lipids of Rats Exposed to Tetrachloromethane

Hartmut Frank*, Manfred Wiegand, Manfred Strecker and Dietmar Thiel
Institut fuer Toxikologie der Universitaet Tuebingen, Wilhelmstrasse 56, D-7400 Tuebingen 1, Federal Republic of Germany

An accurate method for the quantitative determination of hydroperoxy and hydroxy fatty acids in liver microsomes is presented which involves the use of ^{18}O-labeled internal standards. The method is employed for the determination of hydroperoxides in rat liver microsomes after aerobic incubation with Fe^{2+}/ADP and in microsomes from animals exposed to 75 mg tetrachloromethane/kg body weight. The amounts found after artificial microsomal "lipid peroxidation" are almost two orders of magnitude larger than those in microsomes from tetrachloromethane-exposed animals.
Lipids 22, 689-697 (1987).

The radical-initiated oxidative degradation of polyunsaturated fatty acids of membrane lipids, commonly referred to as "lipid peroxidation," has been suggested as the underlying mechanism in the toxicity of various xenobiotics such as tetrachloromethane (1), acetaminophen, adriamycin, alcohol, nitrogen oxides, ozone (2), cadmium (3) and 2,3,7,8-tetrachlorodibenzodioxin (4). It has also been discussed as being involved in atherosclerosis (2), hemolytic anemia (5), the pathogenicity of zinc deficiency (6), cancerogenesis and aging (2).

Lipid peroxidation is viewed as the biochemical counterpart to autoxidation of fats. The latter is a process characterized by formation of unpleasant flavors and leads to drying of fats and oils via autocatalytic oxidative degradation and polymerization of polyunsaturated fatty acids (7). More detailed investigations of the reactions and structures involved have recently been initiated (8,9).

The suggestion that lipid peroxidation participates in a pathogenic process is usually based upon the presence of substances in membrane lipids forming with thiobarbituric acid a chromophore with an extinction maximum of 535 nm (10). Other phenomena associated with lipid peroxidation are an increase in the extinction of lipids at 235 nm (11), formation of fluorescent products of undefined structure (12), loss of polyunsaturated fatty acids (13) and expiration of alkanes by animals exposed to lipoperoxidative xenobiotics or conditions (14). Further methods to monitor lipid peroxidation are electron-spin resonance spectroscopy (15) or spectrophotometric detection of chemiluminescence (16). These reflect various side reactions or side products that are usually observed when polyunsaturated fatty acids are subjected to oxidation. Their correlation to pathophysiological derangements is not surprising when lipid membranes are damaged.

Aerobic microsomal incubations usually serve as in vitro models for lipid peroxidation. Such a model can be regarded as a valid analog when similarity in quantitative terms to the effects elicited by an assumed lipoperoxidative xenobiotic in vivo is found. Tetrachloromethane is regarded as a prime example for such a chemical. Indeed, small amounts of alkanes are invariably exhaled by animals exposed to this compound. However, other parameters of lipid peroxidation are often not correlated (17,18).

Formation of fatty acid hydroperoxides is the primary stage in reaction schemes invoked in lipid peroxidation. The purpose of the present work is the identification and quantitative determination of hydroperoxides in microsomal lipids of CCl_4-intoxicated animals. Hydroperoxides decompose rapidly during work-up. Therefore, for quantitative determination they are usually reduced to the corresponding hydroxy derivatives (19,20). This, on the other hand, hampers the individual determination of hydroperoxides and hydroxides. Liquid chromatographic analysis in principle does not require reduction (21,22) but is not sufficiently selective and sensitive to allow the reliable determination of hydroperoxides in complex biological matrices (23-25).

We used gas chromatography and mass spectrometry (GC/MS) with suitable ^{18}O-labeled internal standards. This allows differentiation between hydroperoxy and hydroxy fatty acids and their quantitative determination in vivo. Hydroperoxides in microsomes from a typical in vitro lipid peroxidation experiment and in microsomes from rats exposed to tetrachloromethane have been determined.

MATERIALS AND METHODS

Chemicals. Chemicals were obtained from suppliers as indicated: adenosine 5'-diphosphate disodium salt (ADP), isocitrate dehydrogenase 2U/mg and nicotinamide adenine dinucleotide phosphate (NADP) from Boehringer-Mannheim (Mannheim, FRG); 18-oxygen from MSD, (Montreal, Ontario); hydroxy octadecanoic acid from Nu-Chek-Prep (Copenhagen, Denmark); D,L-isocitric acid sodium salt dihydrate, phospholipase A_2 (*Naja naja,* 553 U/mg) and soybean lipoxygenase I (EC 1.13.1.13.) from Sigma Chemical (St. Louis, MO); platinum IV oxide from Ventron (Karlsruhe, FRG); trimethylchlorosilane from Pierce (Rotterdam, The Netherlands); and acetic acid, *bis*-trimethylsilyl-acetamide, calcium chloride dihydrate, citric acid monohydrate, diethylether, ethylenediamine tetraacetic acid, hexane, iron (II) sulfate heptahydrate, isopropanol, linoleic acid, magnesium chloride hexahydrate, methanol, phenobarbital sodium, potassium chloride, potassium hydroxide, pyridine, saccharose, silica gel Si-60, sodium borohydride, anhydrous sodium sulfate, disodium tetraborate decahydrate, toluene, triphenylphosphine and *tris*-hydroxymethyl-amino methane from Merck (Darmstadt, FRG).

In vitro experiments: pretreatment of animals and preparation of microsomes. Male Sprague-Dawley rats weighing 300-400 g were purchased from Ivanovas (Kisslegg, FRG). Before the experiments, they were kept for 1 wk at a constant day-night cycle of 24 hr for acclimatization, with free access to food (Altromin, Lage, FRG) and water.

*To whom correspondence should be addressed.
Abbreviations: GC/MS, gas chromatography/mass spectroscopy; ADP, adenosine 5'-diphosphate disodium salt; NADP, nicotinamide adenine dinucleotide phosphate; PTFE, polytetrafluoroethylene; HPLC, high performance liquid chromatography.

For induction of drug-metabolizing enzymes, the animals received one intraperitoneal injection of 80 mg phenobarbital/kg body weight dissolved in 1 ml distilled water and for the following 5 days 0.1% phenobarbital in the drinking water. After starvation for 24 hr, they were killed by decapitation. The livers were removed, cut into small pieces, rinsed twice with cold saline and homogenized in Tris/KCl buffer (Tris/HCl, pH 7.4, 50 mmol/l; KCl, 120 mmol/l) containing 250 mmol/l saccharose and 1 mmol/l EDTA-sodium salt. Microsomes were prepared by fractionated centrifugation (26). The pellet was suspended in Tris/KCl buffer, and the microsomes were sedimented again and resuspended to a protein concentration of 10 mg/ml. The following experiments were performed immediately afterwards.

Protein determination. Protein was determined according to Peterson's method (27). A calibration curve was constructed with bovine serum albumin. Cytochrome P-450 was determined according to Omura and Sato (28), with aliquots diluted to a concentration of 2 mg microsomal protein/ml.

Aerobic incubation of microsomes with Fe^{2+}/ADP. Microsomal suspension, 0.8 ml, corresponding to 8 mg microsomal protein was incubated at 37 C for 5 min in the presence of 0.4 ml sodium isocitrate solution (80 mmol/l), 0.8 units isocitrate dehydrogenase, 1.6 ml Tris/KCl buffer (pH 7.4, as above) and 0.4 ml magnesium chloride solution (33 mmol/l). After addition of 0.4 ml of a solution of NADP (10 mmol/l in Tris/KCl buffer) and 0.4 ml of a mixture of $FeSO_4$ (0.2 mmol/l) and ADP (20 mmol/l), the microsomes were incubated for another 15 min. The reaction is stopped by adding 1 ml sodium-EDTA (50 mmol/l) and cooling to 0 C. Aliquots of 1 ml are removed for quantitative determination of hydroperoxy- and hydroxy-octadecadienoic acid as described below.

Exposure of rats to tetrachloromethane. The rats received a dose of 75 mg/kg tetrachloromethane by inhalation (29). After 6 hr, the animals were killed and microsomes were prepared.

Preparation of isotope-substituted standards: [$^{18}O_2$]hydroperoxyoctadecadienoic acid. The equipment used is shown in Figure 1. The volume of the reaction vessel was 150 ml. The two standard ground joints were equipped with screw-cap adapters (a,b) with silicone-rubber seals laminated with polytetrafluoroethylene (PTFE). A pointed glass rod of 6 mm diameter (c) and the [$^{18}O_2$] gas ampoule were inserted as shown. The adapter *(e), fused directly to* the vessel, was closed with a PTFE-laminated silicon septum. A dropping funnel (g), 250 ml volume, was connected with polyethylene tubing (4 mm id) to the stop-cock (f) of the incubation vessel. Linoleic acid (0.8 mmol) was suspended by sonication for 5 min in 120 ml borate buffer (125 mmol/l, pH 9), filled into the dropping funnel and purged with a stream of argon for 30 min.

Both stop-cocks (f and h) were opened and the vessel was gently filled, the adapter (b) being lifted to let the air escape. The stop-cock (h) of the dropping funnel was closed, and the funnel was rinsed with 20 ml borate buffer. After replacement of oxygen for argon, the stop-cock was opened again, and the buffer was transferred to the vessel as described before. This was repeated. Any residual air entrapped in adapter (b) was removed by turning the vessel; slight tapping let the air escape via the dropping funnel. The funnel was filled again with

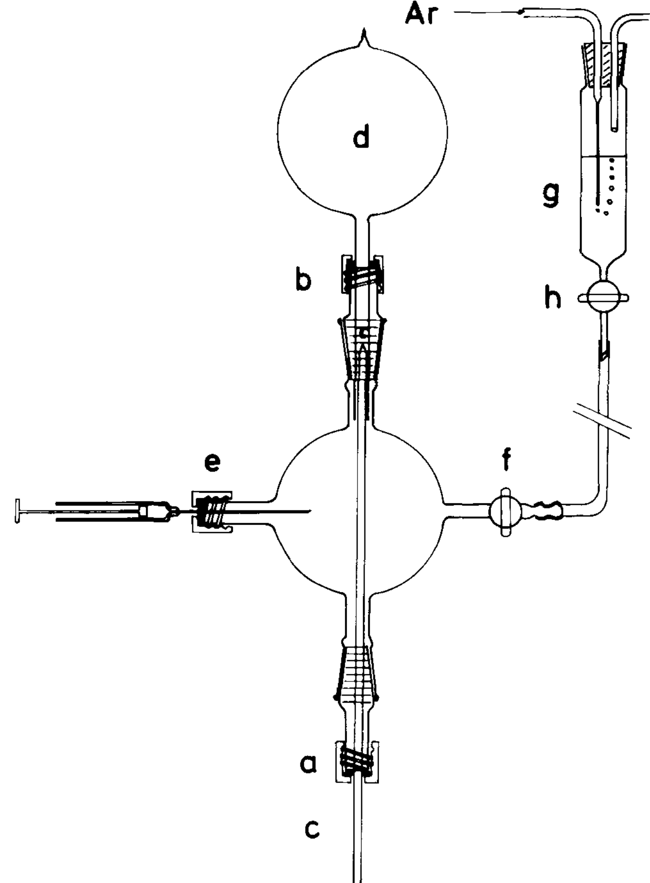

FIG. 1. Vessel for preparation of 13-[$^{18}O_2$]hydroperoxy 9,11-octadecadienoic acid by lipoxygenase-catalyzed oxygenation of linoleic acid with $^{18}O_2$. Description see experimental part.

borate buffer corresponding to the volume of the [$^{18}O_2$] ampoule; both stop-cocks were then left open. Soybean lipoxygenase I (2 mg in 50 μl borate buffer) was injected through the adapter (e). The seal of the ampoule was broken by pushing the glass rod in; the rod was pulled back, and the suspension of linoleic acid and the oxygen gas were equally distributed between vessel and ampoule by turning and shaking the whole apparatus. Every 15 *min, 2 mg* lipoxygenase were added and each time the contents were thoroughly mixed. The progress of the reaction was checked by UV analysis at 235 nm. The reaction was complete after about 90 min. Aqueous citric acid (3%, 20 ml) was used to fill the dropping funnel and 60 ml was injected through the septum (e). Argon was introduced through a needle inserted into the septum. During this procedure the vessel was positioned as shown in Figure 1, with the ampoule pulled back as far as possible. Argon was admitted to make up for the volume of consumed oxygen. The ampoule could then be resealed to save most of the residual $^{18}O_2$, however diluted.

The reaction mixture was extracted three times with 50 ml of ether. The combined extracts were dried over anhydrous sodium sulfate, concentrated on a rotary evaporator to about 10 ml and transferred to a silica gel column (200 mm × 8 mm, Si-60). The hydroperoxide was eluted with toluene/methanol/acetic acid (98.7:1:0.3,

v/v/v). The fractions with elution volumes between 100 and 130 ml were combined, diluted with methanol and concentrated under reduced pressure at a temperature of 15 C. Toluene and acetic acid were removed by repeated azeotropic distillation with methanol. The [$^{18}O_2$]hydroperoxy octadecadienoic acid was stored in methanolic solution at −18 C. A small aliquot was reduced, derivatized and analyzed by GC/MS as described below, showing an isotopic purity of 91% and an isomeric composition of 95% 13-isomer and 5% 9-isomer. The yield, based upon UV analysis, was 32%.

[^{18}O]Hydroxy octadecadienoic acid. [^{18}O]Hydroxy octadecadienoic acid was prepared by reduction of [$^{18}O_2$]hydroperoxide (30). Sodium borohydride was preferred over other reducing agents; triphenylphosphine oxide, for instance, was more difficult to remove during chromatographic purification.

Hydroxy octadecanoic [$^2H_3$]methyl esters. Hydroxy octadecanoic acid, obtained from a commercial supplier and containing all isomers hydroxylated between the 6- and 15-positions, was esterified by heating to 110 C with hydrogen chloride (3 mol/l) in [$^2H_4$]methanol. After 30 min, excess reagent was evaporated under a stream of nitrogen, the residue was dried in vacuo over potassium hydroxide and dissolved in hexane/isopropanol (99.75:0.25, v/v). The isomers were separated by micropreparative high performance liquid chromatography (HPLC) (31) on a silica gel column (25 cm × 0.4 mm, Lichrosorb Si 60, 10 μm, Merck) with hexane/isopropanol (99.75:0.25, v/v) as mobile phase at a flow rate of 1.5 ml/min. Fractions containing the 9-, 10-, 12- and 13-hydroxy octadecanoic [$^2H_3$]methyl esters were collected. The relative and absolute amounts were determined by gas chromatography on a glass capillary (25 m × 0.25 mm) deactivated by silanization (32) and coated with OV-101, film thickness 0.1 μm, and UV analysis at 206 nm.

Quantitative determination of 13-hydroperoxy and 13-hydroxy 9,11-octadecadienoic acid: sample preparation and derivatization. For determination of 13-hydroperoxy and 13-hydroxy 9,11-octadecadienoic acid formed upon aerobic incubation of microsomes with Fe^{2+}/ADP, 3 μg of [$^{18}O_2$]hydroperoxy octadecadienoic acid/mg microsomal protein were added as internal standard. When samples from untreated animals or from animals exposed to tetrachloromethane were analyzed, 50 ng/mg protein was added to microsomes and 10 ng/mg protein to liver homogenate. For determination of 13-hydroxy 9,11-octadecadienoic acid, [^{18}O]hydroxy octadecadienoic acid served as internal standard.

Triphenylphosphine, 200 μg in 10 ml ether per mg protein, was added, and the mixture was stirred at 0 C; reduction was omitted when hydroxy acid alone was to be determined. After 1 hr, the ether was evaporated, the residue was dissolved in 15 ml chloroform/methanol (2:1, v/v) and the solution was filtered through a glass-fiber filter (No. 6, Schleicher and Schuell, FRG). The volume was reduced to 0.5 ml on a rotary evaporator, and the concentrated extract was transferred to a culture tube (10 cm × 1 cm). Phospholipase A_2—20 μg in 1 ml borate buffer, 125 mmol/l, pH 9.0, containing 0.1 mg calcium chloride—was added and the mixture was shaken vigorously. After 90 min, it was adjusted to pH 5 with aqueous citric acid (3%) and the ether layer was transferred to another culture tube and brought to dryness under a stream of nitrogen. The residue was dissolved in 1 ml ether/methanol (2:1, v/v), and diazomethane was bubbled into the solution for 5 min. After 30 min at room temperature, the sample was brought to dryness and the residue dissolved in 25 μl of *bis*-trimethylsilyltrifluoroacetamide, 25 μl pyridine and 10 μl trimethylchlorosilane. The sample was ready for GC/MS after 20 min at room temperature.

Determination of positional isomers. For determination of the isomeric composition, the extracted lipids were reduced with triphenylphosphine and treated with phospholipase A_2. PtO_2-catalyzed hydrogenation yielded the corresponding hydroxy octadecanoic acid isomers, which were esterified with diazomethane. The 9-, 10-, 12- and 13-isomers of hydroxy octadecanoic [$^2H_3$]methyl ester were added as internal standards in amounts as expected to be present in the sample. After trimethylsilylation, the samples are analyzed by GC/MS.

GC/MS. The instrument is a Finnigan 4021 with an Incos data system. For GC, aliquots containing 1–50 ng hydroxy fatty acid derivatives were injected onto a silanized glass capillary coated with OV-101. The injector temperature was 280 C; the silanized glass insert of the injection port was replaced after every five injections. Injections were done in the splitless mode at an initial oven temperature of 60 C. Half a minute later, the split valve was opened and the following temperature program was started: 0.5 min isothermal, 40 C/min to 180 C, 4 C/min to 300 C. The carrier gas was helium with an inlet pressure of 100 kPa. The GC/MS interface was a silanized fused-silica capillary (40 cm × 0.1 mm). The interface temperature was 300 C.

For MS, the ion source temperature was 290 C, ionizing voltage was 35 eV, scan speed from m/z 50 to 550 was one second and secondary electron multiplier voltage was 1.6 kV. When analyzing in vitro samples, the mass spectrometer was scanned over the total mass range and reconstructed mass fragmentograms were generated; for in vivo samples, multiple ion detection was preferred.

RESULTS AND DISCUSSION

Tetrachloromethane is thought to cause lipid peroxidation by hydrogen abstraction from polyunsaturated fatty acids. This is initiated by trichloromethyl radicals that are formed via cytochrome P-450-dependent reduction (33,34). For other xenobiotics, generation of hydroxyl radicals has been invoked (35). The next stage in this hypothetical sequence is addition of oxygen to yield peroxy radicals and, by abstraction of hydrogen atoms from other polyunsaturated fatty acids, monohydroperoxides.

Monohydroperoxides of linoleic and arachidonic acid are detectable in rat liver microsomes after aerobic incubation with Fe^{2+}/ADP (20). Hydroperoxides derived from linoleic acid are present in highest concentrations; the 9-, 10-, 12- and 13-isomers have been found. Those of arachidonic and docosahexaenoic acid are present in much smaller amounts. It is likely that the latter undergo secondary reactions faster than the linoleic acid derivatives due to their greater number of double bonds. We therefore concentrated upon determination of the linoleic acid derivatives.

The method used for determination of 13-hydroperoxy and 13-hydroxy 9,11-octadecadienoic acid in microsomal lipids after in vitro and in vivo experiments involves

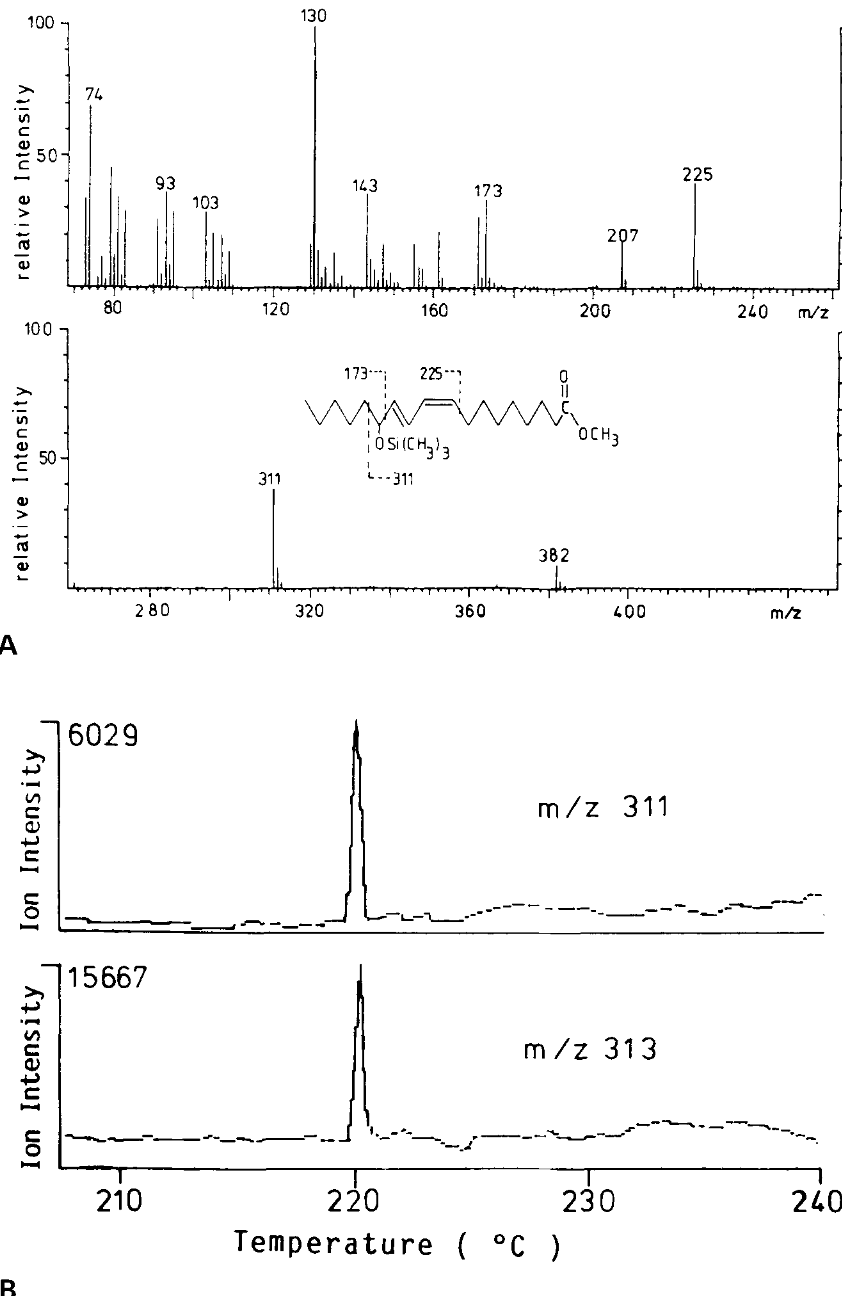

FIG. 2. (a) Mass spectrum of 13-trimethylsiloxy 9,11-octadecadienoic methyl ester; (b) selected ion-current profiles of m/z 311 and m/z 313 (internal standard) in microsomes from a control animal.

internal standardization with [$^{18}O_2$]hydroperoxy 9,11-octadecadienoic acid, reduction to the corresponding hydroxy fatty acid and derivatization to yield 13-trimethylsiloxy 9,11-octadecadienoic acid methyl ester. The samples are analyzed by gas chromatography and mass spectrometry monitoring the abundant α-fragments, m/z 311 and 225 for the endogenous hydroperoxide and m/z 313 and 227 for the ^{18}O-labeled standard (Fig. 2). It is important to verify the respective retention times with authentic standards, as several oxygen-containing derivatives of arachidonic or docosahexaenoic acid yield ions with the same masses. The quantity of 13-hydroperoxy plus 13-hydroxy 9,11-octadecadienoic acid is calculated from the ratios of the peak areas of the ion chromatograms of m/z 311 vs 313 and 225 vs 227, taking the percentages of isotopic and isomeric purity of the internal standard into account.

Isotopic dilution analysis with two different internal standards, i.e., [$^{18}O_2$]hydroperoxy and [^{18}O]hydroxy fatty acid, allows differential analysis for hydroperoxy and hydroxy fatty acids. The sum of hydroperoxy and hydroxy fatty acids is determined with [$^{18}O_2$]hydroperoxy

fatty acid as internal standard. A second aliquot with [^{18}O]hydroxy fatty acid as internal standard serves for determination of hydroxy fatty acid alone. The difference between both represents hydroperoxy fatty acid.

Internal standards labeled with ^{18}O in the hydroperoxy moiety have been used to study the rearrangement of linoleic acid hydroperoxides (36). Hydroperoxy fatty acids ^{18}O-labeled in the carboxyl group (37) are not suitable, since the internal standard should not only serve for correction of volumetric errors and as reference for calculation of response factors, but also for compensation of chemical losses. Also, ^{18}O-labeling of the carboxyl group is difficult to achieve with high isotopic yield, and under our conditions of sample pretreatment and derivatization, exchange of oxygen took place.

Nonspecific formation of hydroxy fatty acids from hydroperoxides may falsify the results from samples not reduced with triphenylphosphine. Hydroperoxides may nonspecifically form hydroxy acids, e.g., via reactions as proposed by Russel (38). Its significance was investigated by adding increasing amounts of synthetic nonlabeled 13-hydroperoxy 9,11-octadecadienoic acid to aliquots of a microsomal sample. Nonspecific conversion of about 5% of added hydroperoxide to the corresponding hydroxide took place. This was accounted for when endogenous hydroxy fatty acids were determined in nonreduced samples.

The accuracy of the method was tested with liver homogenate from untreated Sprague-Dawley rats. In a first series of analyses (Table 1, series a), increasing amounts of 13-[$^{18}O_2$]hydroperoxy 9,11-octadecadienoic acid were added. The precision of determination was about ±15%, sufficient to monitor the trends in the following in vitro and in vivo experiments. In a second series (Table 1, series b), reduction of the samples with triphenylphosphine was omitted to determine 13-hydroxy 9,11-octadecadienoic acid alone; the quantity found was not different from the values obtained in series a, showing that all of linoleic acid oxidized in position 13 was present as hydroxide. Its level in microsomes from untreated animals was in the range of 10 to 14 pmol/mg protein. Whether this was an in vivo constituent or an artifact formed during preparation cannot be decided.

In one series (not shown), samples were spiked with synthetic nonlabeled 13-hydroperoxide and kept at 0 C

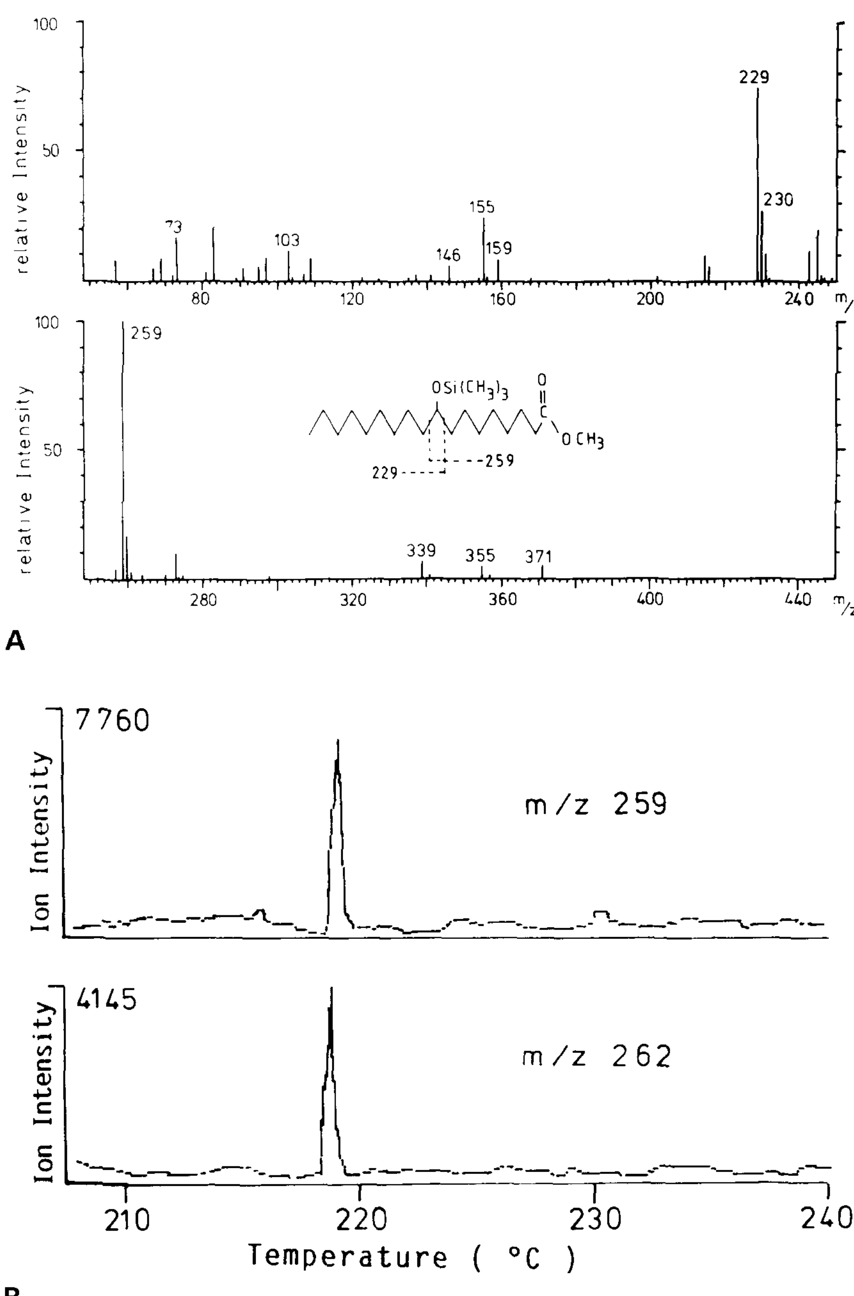

FIG. 3. (a) Mass spectrum of 9-trimethylsiloxy octadecanoic methyl ester; (b) selected ion-current profiles of a sample from an aerobic microsomal incubation with Fe^{2+}/ADP; m/z 259 = endogenous 9-hydroxy octadecanoic methyl ester; m/z 262 = $^{2}H_3$-labeled internal standard.

for 1 hr before the ^{18}O-labeled internal standard was added. In this case, only 24% of the spiked amount was recovered, showing the importance of rapid work-up.

The amounts of 13-hydroperoxy and 13-hydroxy 9,11-octadecadienoic acid found after 15 min of aerobic incubation of microsomes with Fe^{2+}/ADP are shown in Table 2. Hydroperoxide was formed in large amounts; apparently, some of it was reduced to the hydroxide.

For determination of the relative amounts of the isomers of oxidized octadecadienoic acid, they were hydrogenated to the hydroxy octadecanoic acid isomers. The 9-, 10-, 12- and 13-hydroxy octadecanoic [$^{2}H_3$]methyl esters were added as internal standards. Quantitative determination was done by GC/MS monitoring the C-terminal α-fragments (Fig. 3, Table 3). The isomeric composition after aerobic incubation of microsomes with Fe^{2+}/ADP is shown in the last column of Table 3. The relative values are in good agreement with previous results (20). The 9-isomer predominated, in contrast to the even isomer distribution after homogeneous autoxidation (31). The reason for this peculiar pattern is unknown. Small amounts of 10- and 12-isomers were found, which are probably

TABLE 3

Fragment Ions in the EI Mass Spectra of 9-, 10-, 12- and 13-Trimethylsiloxy octadecanoic Methyl Esters, Resulting from Cleavage of the Bond of the Trimethylsiloxy-carbon Proximal (α_ω) or Distal (α_c) to the Carboxyl Terminal. In the second column (α_c) the lower number of each row corresponds to the $[^2H_3]$-methyl ester. The last column shows the relative percentage of each isomer found after aerobic incubation of microsomes with Fe^{2+}/ADP (n = 4).

Isomer	α_ω (m/z)	α_c (m/z)	Relative amount in % (mean ± S.D.)
9	229 (75)	259 262 (100)	56 ± 2
10	215 (100)	273 276 (85)	5 ± 2
12	187 (100)	301 304 (30)	5 ± 2
13	173 (100)	315 318 (60)	33 ± 3

Relative abundances indicated in parentheses.

"ene" reaction products of singlet oxygen. No hydroxy octadecanoic acids other than the 9-, 10-, 12- and 13-isomers were detected.

The absolute values determined previously without internal standardization have been about 10-fold lower (20). Obviously, when the decomposition of hydroperoxides during sample preparation is not accounted for, reliable quantitative determination is not feasible.

The amounts of 13-hydroperoxy and 13-hydroxy 9,11-octadecadienoic acid in liver homogenate and microsomes from untreated rats and animals exposed to tetrachloromethane are shown in Table 4. The sum of 13-hydroperoxide and 13-hydroxide found in liver homogenate or microsomes of control animals was similar to the contents in 13-hydroxide. Consequently, only very little can be present as hydroperoxide. Treatment of rats with 75 mg tetrachloromethane/kg body weight, which causes massive centrilobular necrosis (39), entailed a small, insignificant increase of the sum of hydroperoxide and hydroxide in the homogenate. In microsomes, a significant increase of the sum of hydroperoxide and hydroxide was found, but not of hydroxide alone. 13-Hydroperoxy 9,11-octadecadienoic acid was increased by about 140 pmol/mg microsomal protein, which is considerably less than after a typical microsomal lipid peroxidation in vitro.

In comparison to the values reported for hydroxy-eicosatetraenoic acid isomers, which have been obtained without internal standardization, and not differentiating between hydroperoxy and hydroxy derivatives (40), the standard deviations for hydroxy-octadecadienoic acid isomers were considerably larger between individual animals, in spite of the small relative standard deviation of the analytical method (15%). In contrast to hydroxy-eicosatetraenoic acid (40), no significant increase of oxidized octadecadienoic acid was found in liver homogenate from rats treated with tetrachloromethane. It is not known whether this may be due to the much larger dose of tetrachloromethane administered in that study (3.2 g/kg). However, the effective dose is difficult to assess when the animals are kept in open cages, as most of it is exhaled unchanged (41).

The low levels of hydroperoxides found after tetrachloromethane exposure in vivo suggest that either formation of oxidized fatty acids was slow or their detoxification efficient. Preliminary experiments showed that the amounts of oxidized linoleic acid increased during exposure to tetrachloromethane in the course of several hours. Apparently, not only the extent but also the rate of oxidation is different between aerobic microsomal incubations and tetrachloromethane exposure in vivo. While in the former case the critical reactions took place within a quarter of an hour, metabolism of tetrachloromethane in vivo and the consecutive fatty acid oxidation proceeded within several hours.

Admittedly, additional aspects must be addressed before definite conclusions can be drawn. Thus, it must be considered that the liver tissue is damaged by tetrachloromethane in a focal pattern, and that the procedures employed for isolation of microsomes do not discriminate between affected and nonaffected regions. Also, the labeled fatty acid hydroperoxides employed as internal standards may differ in their chemical and biochemical properties from phospholipid hydroperoxides. Therefore, the absolute values determined by the method presented here may still deviate from the true values. Nevertheless, for a comparative study as undertaken here, only relative values are needed.

TABLE 4

13-Hydroperoxy 9,11-octadecadienoic Acid and 13-Hydroxy 9,11-octadecadienoic Acid in Liver Homogenate and Microsomes from Untreated and Tetrachloromethane-exposed Male Sprague-Dawley Rats (means ± S.D., n = 3)

	13-Hydroperoxide + hydroxide (pmol/mg protein)	13-Hydroxide (pmol/mg protein)
Controls		
Homogenate	19 ± 7	20 ± 7
Microsomes	87 ± 28	102 ± 33
CCl_4-treated		
Homogenate	27 ± 10	17 ± 9
Microsomes	230 ± 40	118 ± 17

Microsomal lipid peroxidation, induced by hydrogen peroxide-producing enzymes (42) in the presence of iron and oxygen in high concentrations, does not parallel the formation of oxidized fatty acids elicited in vivo by tetrachloromethane. This must be viewed in context with other evidence. Several cellular defense lines can prevent lipoperoxidative damage to membranes, which may explain why in vivo the levels of hydroperoxides are low. Enzymes scavenging reactive oxygen species and other protective mechanisms are operative in vivo. It is known that oxygen-modified fatty acid residues in phospholipids are rapidly excised by phospholipases (43) and/or are reduced to hydroxy fatty acids (44,45). Glutathione-dependent processes and various antioxidants afford further protection against oxidative damage (46,47).

It is likely that autoxidation proceeds relatively rapidly when all these mechanisms are absent, as is typical for aerobic microsomal incubations. However, the complex question about involvement or significance of lipid peroxidation in pathogenicity in vivo is not a qualitative one, but rather needs to be answered in quantitative terms. From this point of view, it is questionable whether in vitro experiments involving massive oxidative breakdown of polyunsaturated fatty acids, sometimes under addition of nonbiological hydroperoxides and performed in the absence of all cellular defense systems that are usually operative, may yield useful information for understanding the processes involved in vivo. The significance of lipid peroxidation must be reconsidered, and a clearer definition of the term is necessary. Further development of suitable analytical methods is required to clarify whether it is more than an in vitro phenomenon.

The results lend little support to the view that peroxidative processes are causally related to tetrachloromethane toxicity. Other effects such as covalent modification and cross-linking of polyunsaturated fatty acids (48) and the ensuing inactivation of anabolic enzymes of the endoplasmic reticulum are probably more significant as primary lesions (49).

Lipid Composition of *Bacillus megaterium* Spores and Spore Membranes

M. Nikolopoulou and J.C. Vary*
Department of Biological Chemistry, University of Illinois at Chicago, Chicago, IL 60612

***Bacillus megaterium* QM B1551 spore lipids were extracted by an improved technique, and the phospholipid and fatty acid compositions were determined. Phospholipids accounted for 65% of the total fatty acids; the neutral lipid fraction contained 15% and the remaining fatty acids were in the interphase, aqueous phase and pellet from the lipid extraction. Each phospholipid had similar fatty acid compositions as did the delipidated pellet. However, the aqueous phase and, to some extent, the interphase had unique fatty acid compositions. Also, fatty acids were found acylated to proteins, which was observed by electrophoresis of delipidated proteins from spores grown in [1-^{14}C]palmitate. Therefore, spores contain unique non-phosphatide fatty acid components that can now be analyzed.**
Lipids 22, 698-703 (1987).

Bacilli are relatively unique in containing a large proportion of branched chain fatty acids (1). We and others have determined the fatty acid and phospholipid composition of *Bacillus megaterium* QM B1551 spores (2-4). Curiously, about 50% of the spore fatty acids have been reported to be in a non-phosphatide fraction (3). In an attempt to better define the lipid composition of spores, we have found that previous measurements have significantly underestimated both the fatty acid and phospholipid contents. In addition, we found previously unreported fatty acids, another phospholipid and diacylglycerols. We attribute these new findings to better lipid extractions and improved chromatographic procedures.

These data are important because they provided the basis for our identification of a unique class of phospholipids associated with protein in spore membranes (Nikolopoulou, M., and Vary, J.C., in preparation), the occurrence of spore proteins with covalently bound fatty acids (reported here) and the presence of diacylglycerol that stimulates a protein kinase for protein phosphorylation during sporulation (unpublished).

MATERIALS AND METHODS

Materials. Organic solvents were ACS grade or better from Fisher Scientific (Chicago, IL). Fatty acid standards were from Supelco Inc. (Bellefonte, PA). Silica Gel H was from E.M. Reagents (EM Laboratories, Cincinnati, OH), and other chemicals were from Sigma Chemical Co. (St. Louis, MO) or CalBiochem (La Jolla, CA). Radioactive precursors were from ICN Biomedicals (Irvine, CA).

Preparation of spores and homogenates. Spores of *B. megaterium* QM B1551 were grown in supplemented nutrient broth, washed and extracted with SDS-DTT to make them lysozyme-sensitive (5,6). Spore homogenates and membranes were prepared by lysis and sonication as previously described (7,8). In some cases, spores were grown with [1-^{14}C]palmitate (sp act 58 mCi/mmol), which was added to late exponential phase cells at a final concentration of 10 μCi/ml. All references to spore weights are on a dry weight basis.

Lipids were extracted from disrupted spores by two methods. In method A, spores were extracted with SPS as described by Bligh and Dyer (9) and were modified (2). In method B, spores were incubated in SPS at room temperature for 1 hr with periodic vortexing. The suspension was centrifuged at 6,000 × g for 10 min, and the pellet was extracted four more times with 10 min of incubation in SPS and vigorous vortexing. The combined supernatant fractions were separated into aqueous and organic solvent phases as described (2). The lower organic phase was collected, and the aqueous phase extracted four more times with fresh lower phase. The organic fractions were combined, washed once with 20% volume of fresh upper phase, dried under N_2 and resuspended in $CHCl_3$/methanol (2:1, v/v). The aqueous phase was centrifuged once at 6,000 × g for 5 min, and the supernatant fraction was separated from the white interphase. Finally, the interphase was dissolved in $CHCl_3$/methanol (2:1, v/v).

Phospholipids were separated by TLC on Silica Gel H plates that were prerun in methanol and activated at 110 C for 30 min. The solvent was chloroform/methanol/acetic acid/H_2O (60:20:8:0.5, v/v/v/v), and spots were visualized by I_2 vapor, molybdate spray or autoradiography on Kodak X-Omat AR film. Quantitation was by scraping and phosphate assay (10) or by measuring radioactivity (5).

To determine the fatty acid composition of different lipid fractions, 2 ml of 4% sulfuric acid in methanol and 50 nmol of nonadecanoic acid were added, and the samples were transesterified for 60 min at 70 C. Upon cooling, 1.0 ml of H_2O was added, and the methyl esters were extracted with 2 ml of petroleum ether. Total spore fatty acids were determined by direct transesterification of intact spores (20 mg) in 2.0 ml of 4% sulfuric acid in methanol. Strong acid is known to completely disrupt spores, called "acid popping" (11,12), making all fractions of the spore accessible to methylation. To separate the fatty acid methyl esters from any contaminants, the petroleum ether extract was applied on activated Silica Gel H plates and chromatographed in hexane/diethyl ether/acetic acid (70:30:1, v/v/v). After development, the area corresponding to standard methyl esters (R_f = 0.7) was scraped and eluted with petroleum ether. The petroleum ether extract was dried with a stream of N_2, and the methyl ester residue was dissolved in 20-30 μl of distilled CS_2 and analyzed by GLC.

Methyl esters were separated on a Varian model 3700 chromatograph equipped with a 2 m × 2 mm id stainless steel column packed with GP 10% DEGS-PS on 80/100 Supelcoport. The column oven was programmed to maintain 135 C for 10 min, then to increase to 160 C at 3 C/min and finally to maintain at 160 C for 10 min. The

Abbreviations: DTT, dithiothreitol; GLC, gas liquid chromatography; SDS-DTT, sodium dodecylsulfate-dithiothreitol; SPS, single phase solvent; TLC, thin layer chromatography.

injection port and the detector were at 200 C and 250 C, respectively. The carrier gas was N_2 at a flow rate of 30 ml/min.

Quantitation of the fatty acids in each sample was achieved by comparing the peak areas relative to the standard nonadecanoic acid with the aid of an integrator. The fatty acid methyl esters were identified by comparing their equivalent chain length with standards and were confirmed by mass spectrometry on a Finnigan 4510 spectrometer equipped with a 30 m × 0.25 mm id fused silica capillary column coated with SP-2330. The spectrometer was operated with electron multiplier at 70 kV, emission current −0.25 mA and an electron energy of 70 eV. The carrier gas was helium at a pressure of 22 psi.

In all cases, blanks (no sample) were run through the same extraction procedures and analyzed by GLC, as were all solvents. The experiments reported here had blanks close to background, and all values were corrected for the blanks. Also, all glassware used for lipid analyses was rinsed with methanol. By using these precautions and methylation procedures, we discovered an artifact in our previously published fatty acid compositions (4). The diethyl ether used previously contained an antioxidant, butylated hydroxytoluene, which appeared as n-C14 by retention time in GLC. Therefore, the values for fatty acids reported here represent a correction and, as noted above, the identity of each fatty acid was confirmed by mass spectrometry.

Electrophoresis. The disrupted spores were delipidated as described above and electrophoresed in 13% polyacrylamide gels by the method of O'Farrell (13), except no dithiothreitol (DTT) was added unless indicated. After staining and destaining, the gels were enhanced and subjected to fluorography. Hydroxylamine treatment of delipidated protein before or after electrophoresis was performed exactly as described previously (14).

RESULTS AND DISCUSSION

Fatty acid content. The total fatty acid content of *B. megaterium* spores was determined by direct transesterification of intact spores. For one batch of spores, 44.4 µmol of fatty acids/g of spores was found, and this same batch was used for all of the studies described below. Other spore batches had different values, with an average of 48 ± 10 µmol/g of spores (± standard deviation, n = 5), which was higher than the value of 39 that we calculated from previous results (3). However, we wish to note that the absolute values are probably not significant and direct comparisons between the fatty acid contents of different spore batches should not be made. Not only were different spore batches variable, but different lots of nutrient broth produced spores with different total fatty acid contents. Finally, it may be noted that SDS-DTT "coat-stripped" spores were used in all studies, but when nonstripped spores were used, the fatty acid content was 53 ± 6 µmol/g of spore (± standard deviation, n = 3), which shows that within experimental error, SDS-DTT extracted and nonextracted spores had the same fatty acid content. This last observation agrees with our previous results on the similarity of phospholipid content between extracted and nonextracted spores, suggesting that it is unlikely that these spores contain an intact functional outer membrane (7), which would have been removed by SDS-DTT.

Lipid extraction. To investigate the lipids, we mechanically disrupted the *B. megaterium* spores and extracted the lipids by method A of Bligh and Dyer, which has been routinely used (2,4,7,15) for analysis of bacillus lipids. Only 68% of the total spore fatty acids were in the organic phase of the lipid extract (Table 1), and the remainder was distributed in other fractions. Method B recovered an additional 5.2 µmol of fatty acid in the organic phase of the lipid extract, which came mainly from the pellet, since the interphase and aqueous phase remained about the same. Further extractions of the delipidated pellets failed to recover any significant additional amounts of fatty acid (<1%). Note that the sum of the fatty acid contents of the various lipid fractions was the same as found by transesterification of whole spores.

Similarly, from spore homogenates, methods A and B extracted 11 ± 1 and 14 ± 2 µmol of phospholipid phosphate/g of spore (± standard deviation, n = 4), respectively. Several other methods of extraction were tested exactly as described by Cohen et al. (16), Folch and Lees (17) and Rose and Oklander (18), and all gave values that ranged from 10 to 13 µmol of phospholipid phosphate/g of spore.

Fatty acids. The fatty acid composition of each fraction in Table 1 was determined by GLC, and the identity of each fatty acid was assigned by retention time and confirmed by mass spectrometry (Table 2). For total spore fatty acids, the major species were i-C14, i-C15 and a-C15, which represented almost 80% of all species. The C18 species were previously not reported because C17 or C18 was used as an internal standard (3,4); in a separate experiment, we determined that spores had no C19 fatty acids, which is why we used that as our internal standard.

When the lipids were extracted from spore homogenates, the fatty acid composition of the organic phase was similar to that of the whole spores, except for more i-C16 and less i-C15 and a-C15 in the former. However, the interphase was enriched for all C16 and C18 species, and the aqueous phase was enriched for i-C16 and i-C18. The delipidated pellet was similar (within experimental error) to the whole spores and probably represents unbroken spores.

TABLE 1

Fatty Acid Content of Spore Homogenate Lipid Extract[a]

	Extractable fatty acids/g of spore			
	Method A		Method B	
Fraction	µmol	%	µmol	%
Organic phase	30.0	68	35.2	80
Interphase	3.5	8	2.6	6
Aqueous phase	4.0	9	3.5	8
Delipidated pellet	6.8	15	2.7	6
Total	44.3	100	44.0	100

[a]The fatty acid content of single phase solvent-extracted spore homogenates was determined as described in the text. Values are from one batch of spores which, by direct transesterification of whole spores, contained 44.4 µmol of fatty acid/g of spore.

TABLE 2

Fatty Acid Composition of the Spore Fractions[a]

Fatty acid	Whole spores	Organic phase	Interphase	Aqueous phase	Delipidated pellet
i-C14	17.3 ± 0.4	19.9 ± 2.0	19.7 ± 4.5	11.8 ± 2.8	14.1 ± 1.1
n-C14	1.9 ± 0.7	1.7 ± 0.4	3.1 ± 2.2	1.2 ± 0.7	1.7 ± 0.3
i-C15	26.1 ± 0.5	21.8 ± 1.3	14.4 ± 2.0	12.4 ± 2.3	24.3 ± 2.7
a-C15	35.2 ± 0.5	29.7 ± 1.6	19.1 ± 2.9	14.9 ± 3.2	32.7 ± 3.5
n-C15	1.9 ± 0.2	1.4 ± 0.2	1.1 ± 1.1	0.9 ± 0.6	1.5 ± 0.3
i-C16	4.0 ± 0.3	10.2 ± 0.5	13.2 ± 2.3	32.5 ± 4.9	4.3 ± 0.3
n-C16	4.0 ± 1.6	3.9 ± 0.4	8.4 ± 1.9	5.5 ± 1.3	5.4 ± 1.1
i-C17	1.2 ± 0.8	2.0 ± 0.1	—[b]	2.4 ± 2.0	3.1 ± 1.7
a-C17	3.4 ± 0.6	2.7 ± 1.3	—	1.1 ± 0.8	3.1 ± 0.5
i-C18	1.3 ± 0.5	3.5 ± 0.6	9.5 ± 0.8	15.2 ± 2.0	3.7 ± 2.5
n-C18	1.8 ± 0.7	2.1 ± 1.2	6.6 ± 1.3	1.3 ± 0.7	2.7 ± 1.1
n-C18:1	1.9 ± 0.6	1.1 ± 0.3	5.0 ± 1.6	0.9 ± 0.4	3.4 ± 0.3

[a]The fatty acid composition of each fraction from Table 1 was determined as described in the text. Values are mol % representing the mean ± standard deviations, n = 4.
[b]Not detectable.

TABLE 3

Phospholipid Composition[a]

Phospholipid	Homogenate	Membranes
Phosphatidylglycerol	36.7 ± 2.7	42.1 ± 3.5
Diphosphatidylglycerol	26.8 ± 2.8	20.2 ± 1.1
Phosphatidylethanolamine	17.2 ± 2.6	16.5 ± 1.0
Glucosaminylphosphatidylglycerol	14.5 ± 0.6	14.9 ± 0.9
X (unidentified phospholipid)	4.7 ± 1.0	6.3 ± 2.3

[a]Spore homogenates or membranes were extracted by method B, and the organic phases were separated by thin layer chromatography as described in the text. Values are mol % representing the mean ± standard deviations, n = 4 for homogenates and n = 3 for membranes.

Phospholipids. The organic phases of the lipid extract from spore homogenates and, for comparison, spore membranes were separated by TLC and quantitated by phosphate assays. The results (Table 3) show a distribution similar to previous data (2,3) with the exception of an additional minor phospholipid "X" that has not been identified. This phospholipid X was not seen by previous investigators because their TLC solvent system did not separate X from diphosphatidylglycerol (DPG). The possibility of any other unknown phospholipids was investigated by two-dimensional TLC of lipid extracts from $^{32}PO_4$-grown spores as previously described (19). In addition to the five spots reported here, there were some barely detectable spots representing common phospholipid metabolic intermediates like phosphatidic acid and CDP-diacylglycerol, but these represented less than 1% of the total. There was no radioactivity where phosphatidylserine or inositol phospholipids would migrate, and we could have detected them at the level of <1% (data not shown). Therefore, all of the lipid phosphate could be accounted for as phospholipid.

Fatty acid composition of phospholipids. The fatty acid composition of each phospholipid class was determined for both homogenates and purified membranes (Table 4). The phospholipids in the homogenate and purified membranes had very similar fatty acid compositions, and the different phospholipids were also similar to each other in fatty acid composition. In all cases, the phospholipids were rich in i-C14, i-C15 and a-C15 like whole spores, and most variations were within experimental error with the exception of a few, e.g., i-C15. There were no phospholipids with unique fatty acid compositions. All fatty acids were linked to the glycerol moieties by ester bonds, since no plasmalogens were detected when assayed by the methods of Owens (20) (data not shown).

Neutral lipids. When lipid extracts (method B) were separated by TLC in hexane/diethyl ether/acetic acid (70:30:1, v/v/v), the phospholipids remained at the origin while free fatty acids and diacylglycerol had approximate R_f values of 0.3 and 0.5, respectively, corresponding to the R_f values of commercial standards. Similar results were found with benzene/diethyl ether/ethanol/acetic acid (50:40:20:0.2, v/v/v/v) as a TLC solvent. The diacylglycerol spot contained two subspecies of 1,2-diacylglycerol and 1,3-diacylglycerol that were not completely resolved and were, therefore, treated as one component. No spots corresponding to monoacylglycerol, triacylglycerol, cholesterol or cholesteryl esters were observed. The fatty acid

TABLE 5

Phospholipids and Neutral Lipids in Spore Homogenates and Membranes[a]

	Phospholipids	Diacylglycerol[b]	Free fatty acid
Homogenate	80.9 ± 5.3	15.0 ± 4.4	4.2 ± 1.8
Membranes	83.2 ± 5.5	12.6 ± 2.8	4.3 ± 2.8

[a]Lipids were extracted from spore homogenates and membranes, separated by thin layer chromatography, transesterified and the fatty acids were measured by gas liquid chromatography as described in the text. Values are fatty acid mol % representing the mean ± standard deviation, n = 3 in each case.
[b]Diacylglycerol contained both 1,2-diacylglycerol and 1,3-diacylglycerol species.

contents of the neutral lipid fractions and phospholipids from both homogenates and membranes are shown in Table 5. The bulk of the fatty acids were in phospholipids as expected with a small amount of free fatty acids, but the amounts of diacylglycerols were surprisingly high. Such high levels of diacylglycerol could result from improper handling that allowed considerable phospholipid degradation.

We know spores contain a Ca^{++}-dependent phospholipase C activity (unpublished), which could produce diacylglycerol. However, we think that these neutral fractions may be more important than merely sample degradation for the following reasons. First, the amounts of diacylglycerols were similar in homogenates and purified membranes, but preparation times for those fractions are quite different: 20 min and 18 hr, respectively. Second, the addition of 1 mM EDTA during the entire isolation procedure did not alter the results. Third, in addition to 1,2-diacylglycerol, which could be the product of phospholipase C, 1,3-diacylglycerol was also present in almost equal amounts. The fatty compositions of both the 1,3-diacylglycerol and free fatty acids were significantly different from the 1,2-diacylglycerol and phospholipids (the latter two were similar to each other). Therefore, it is likely that 1,3-diacylglycerol and free fatty acids represent unique lipid fractions (unpublished). However, for the

purposes of this report, we have now accounted for all of the spore fatty acids; from the results in Tables 1 and 5 about 65% of the total spore fatty acids were in phospholipid, 15% in neutral lipids containing diacylglycerols and free fatty acids and the remaining 20% in other fractions in Table 1. In these other fractions, there were at least two classes of substances that contained fatty acids. One was a unique pool of phospholipids high in i-C14, i-C16 and i-C18 that was resistant to lipid solvent extraction (Nikolopoulou, M., and Vary, J.C., in preparation), which accounted for almost half of the fatty acids in the delipidated pellet. Another class was proteins with acylated fatty acids as described below.

Acylation of proteins with fatty acids. When delipidated spore membranes were separated by SDS-PAGE, phospholipids were found in the molecular weight positions between 6 and 15 kDa, but no phospholipids were found above 15 kDa (Nikolopoulou, M., and Vary, J.C., in preparation). However, the protein above 15 kDa did contain fatty acids that were found after eluting the proteins from the gel followed by dialysis, transesterification and GLC analysis. Most of the fatty acids (>50%) were n-C14, n-C16 and n-C18, but the amounts were too low to accurately quantitate. To determine what proteins contained fatty acids, spores were grown in [1-^{14}C]palmitate (10 μCi/ml). With spores grown in [^{14}C]palmitate, delipidated proteins were prepared and separated by SDS-PAGE followed by autoradiography (Fig. 1). Panel A, lane 1, shows several bands that were radioactive, suggesting that proteins might have palmitate attached, and lane 2 was the same except the proteins were boiled in sample buffer containing DTT before electrophoresis. Since the banding patterns were the same, the fatty acids were not attached by thioester bonds such as through a glycerol moiety. Shown in panel B, lanes 1, 2 and 3, are a control and the results of treating the delipidated membrane proteins with hyroxylamine by published methods (14). Almost all of the bands were gone, or at least significantly reduced, after NH_2OH at pH 10, suggesting that the palmitate was in ester linkage to suggesting that the palmitate was in ester linkage to proteins and very little in amide or ether linkage. None of the above treatments changed the Coomassie blue staining patterns of the gel. Direct transesterification of delipidated membrane proteins completely eliminated all radioactivity (which was soluble in $CHC1_3/CH_3OH$) and shows that the radioactively labeled bands were not a result of metabolism of palmitate to amino acids. These data are the first to show direct acylation of fatty acids to proteins in bacilli. As in eukaryotes, the function of these post-translational modifications is unknown, but the hydrophobic fatty acids could serve as membrane anchors or even regulate catalytic activity.

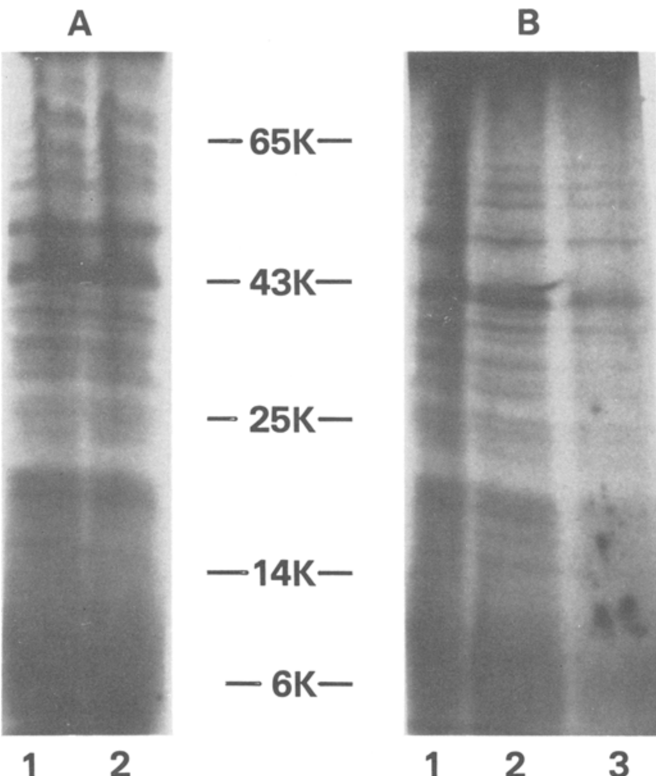

FIG. 1. Fatty acylated spore proteins. Spore were grown with [1-^{14}C]palmitate and disrupted, and the homogenate was delipidated by method B. The delipidated proteins (200 μg) were separated by SDS-PAGE followed by autoradiography. Panel A, prior to electrophoresis, samples were boiled without dithiothreitol (DTT) (lane 1) or with 1 mM DTT (lane 2); panel B, samples were treated with H_2O (lane 1), 1 M NH_2OH at pH 7 (lane 2) or 1 M NH_2OH at pH 10 (lane 3) as described (14), followed by electrophoresis and autoradiography as described in the text.

In summary, we have accounted for the fatty acids previously reported to be >50% in non-phosphatide fractions (3). By improved lipid extraction, 65% of the fatty acids were in phospholipids and 15% in neutral lipids. The remainder were in the aqueous phase (6%) and interphase (8%) of the lipid extraction and 6% was in the delipidated pellet. The phospholipids were quantitated and analyzed for fatty acid composition, and no phospholipid contained a unique composition. Finally, fatty acids were also found in the delipidated pellet that were acylated to proteins.

[Received October 30, 1986]

Abnormal Metabolism of Polyunsaturated Fatty Acids and Phospholipids in Diabetic Glomeruli

Tetsuto Kanzaki*, **Yo Ishikawa, Nobuhiro Morisaki, Kohji Shirai, Yasushi Saito** and **Sho Yoshida**
Second Department of Internal Medicine, School of Medicine, Chiba University, 1-8-1 Inohana, Chiba City, 280, Japan

Studies were done on changes in phospholipid content and fatty acid composition of phospholipids and on the role of the acylation pathway in synthesis of phospholipids in the development of abnormal fatty acid composition in the glomeruli of rats 2 and 10 mo after induction of diabetes with streptozotocin. The proportions of individual phospholipids in the glomeruli of rats were not changed 2 mo after induction of diabetes, but the proportion of phosphatidylethanolamine (PE) decreased and that of sphingomyelin increased 10 mo after induction of diabetes. In contrast, in liver the proportion of PE was increased and that of phosphatidylcholine was decreased. These results showed that changes of individual phospholipids in glomeruli were time-dependent and tissue-specific. Two mo after induction of diabetes, the main change in the phospholipid fatty acid composition of diabetic glomeruli was a decrease in arachidonic acid (AA); the main change in serum free fatty acids (FFA) was an increase in linoleic acid (LA) and a decrease in AA. Ten mo after induction of diabetes, the main changes in the phospholipid fatty acid composition of glomeruli were an increase in LA and a decrease in AA; the main change of the serum FFA composition was a decrease in AA. Thus, the fatty acid composition of glomerular phospholipids was not directly correlated to that of the serum in diabetic rats. Acyl-CoA synthetase and acyltransferase activities increased in diabetic glomeruli with either AA or LA as substrate, but activity toward LA increased more at 2 mo after induction of diabetes. Acyl-CoA synthetase activity increased in diabetic glomeruli with LA as substrate, but that did not change with AA as substrate at 10 mo after induction of diabetes. Furthermore, acyltransferase activity decreased in diabetic glomeruli with AA as substrate, although that did not change with LA as substrate at 10 mo after induction of diabetes.
Lipids 22, 704–710 (1987).

The content of arachidonic acid (AA) in phospholipids of the serum and several tissues is reported to decrease, but linoleic acid (LA) increases in experimental diabetes mellitus (1-6). Holman et al. (3) reported that one cause of these changes was a decrease in insulin-dependent desaturase activity for polyunsaturated fatty acids (PUFA). However, factors in individual tissues may also be important in changes of these fatty acid levels, because heart, liver, skin, testis, aorta and kidney may differ from each other and from serum (3,4). These findings indicate that glomerular metabolism of PUFA is important for development of an abnormal fatty acid composition in experimental diabetes mellitus.

Serum PUFA such as AA are incorporated into tissue phospholipids mainly through Lands' pathway in the liver (7). This pathway consists of 2 steps: first, activation of free fatty acids (FFA) to acyl-CoAs by acyl-CoA synthetase and then incorporation of the acyl-CoAs into phospholipids by acyl-CoA:1-acylglycerophospholipid (lysoPL) acyltransferase. In this work, we investigated whether Lands' pathway contributes to changes in fatty acid contents of glomeruli in experimental diabetes mellitus.

The proportion of phosphatidylethanolamine (PE) is reported to be increased with a decrease in that of phosphatidylcholine (PC) in the liver of diabetic rats (8). These changes were attributed to decreased methylation of PE to PC (9). But Clark et al. (5) reported that the contents of PE and PC are not changed in renal cortex, renal plasma membranes or glomeruli of diabetic rats. These data on changes in the composition in the glomeruli and the liver were obtained in the early stage of diabetes mellitus, when diabetic nephropathy was still not clear (10,11) (3-6 wk after the streptozotocin injection). Thickening of the glomerular mesangial matrix was seen 6 mo after induction of diabetes mellitus (12). Thus, there may be two stages of metabolism. The second aim of this work was to compare metabolism in an advanced stage of diabetic nephropathy with that in the early stage. In this work, we compared the metabolism of fatty acids and phospholipids in rats 2 mo and 10 mo after induction of diabetes mellitus. The results indicated the importance of tissue metabolism and the time dependence in development of the abnormalities seen in diabetic glomeruli.

MATERIALS AND METHODS

Chemicals. LA and AA were obtained from Nu-Chek-Prep (Elysian, MN). 1-Acylglycerophosphorylethanolamine (lysoPE) was obtained from Serdary Research Laboratories (Ontario, Canada). Adenosine triphosphate (ATP) and coenzyme A (CoA-SH) were from Sigma Chemical Co. (St. Louis, MO). Glutathione and Triton X-100 were from Wako Pure Chemical Industries Ltd. (Tokyo). [1-^{14}C]LA (52.6 mCi/mmol) and [1-^{14}C]AA (52.0 mCi/mmol) were from New England Nuclear (Boston, MA).

Induction of diabetes. Male Wistar rats, 2 mo old, weighing about 250 g, were given an injection through a tail vein of streptozotocin (60 mg/kg) in saline and were maintained on standard chow (Oriental Cobo Co., Tokyo) for 2 or 10 mo. Control rats were given standard chow for the same period.

Preparation of glomeruli. Kidneys were quickly removed from anesthetized rats and washed with ice-cold saline, and glomeruli were prepared by the method of Wakashin et al. (13).

Preparation of enzyme solution. Glomeruli from two kidneys were homogenized with 2 ml of ice-cold 0.25 M sucrose-5 mM Tris-HCl buffer (pH 7.4) in a teflon-glass homogenizer (10 strokes). The homogenate was centrifuged

Abbreviations: AA, arachidonic acid; LA, linoleic acid; PUFA, polyunsaturated fatty acids; FFA, free fatty acids; lysoPL, 1-acylglycerophospholipid; PE, phosphatidylethanolamine; PC, phosphatidylcholine; lysoPE, 1-acylglycerophosphorylethanolamine; ATP, adenosine triphosphate; CoA-SH, coenzyme A; TLC, thin layer chromatography; PI, phosphatidylinositol; PS, phosphatidylserine; Sph, sphingomyelin; PA, palmitic acid; OA, oleic acid; SA, stearic acid.

at 800 × g for 5 min, and the supernatant was used for enzyme assay.

Measurement of acyl-CoA synthetase activity. Acyl-CoA synthetase activity was assayed as described previously (14). The characterization of this enzyme in glomeruli has been reported elsewhere (15).

Measurement of lysoPE acyltransferase activity. LysoPE acyltransferase activity was measured by a slight modification of the method of Kramer and Deykin (16). The mixture for assay of lysoPE acyltransferase contained 20 mM ATP, 200 μM CoA-SH, 50 mM $MgCl_2$, 150 mM Tris-HCl buffer (pH 7.4), 250 μM lysoPE, 200 μM FFA, 0.1 μCi [1-^{14}C]FFA and 0.1-0.3 mg protein of glomerular enzyme solution in a final volume of 0.25 ml. The reaction mixture was incubated for 45 min at 37 C. The reaction was stopped by addition of 4 ml of Folch's solution (chloroform/methanol, 2:1, v/v). Lipid was extracted by the method of Folch et al. (17) and PE was separated by thin layer chromatography (TLC, Merck, Darmstadt, FRG) (18). Radioactivity of PE was counted, and acyltransferase activity was calculated from the specific activity. Enzyme activity increased linearly with the amount of enzyme protein up to 800 μg and with the incubation period for up to 90 min.

Fatty acid compositions of serum FFA and glomerular phospholipids. Serum FFA was separated by TLC (first with isopropylether/acetic acid, 96:4, v/v; second with petroleum ether/diethylether/acetic acid, 90:10:1, v/v/v) (18). Glomerular lipids were extracted by the method of Folch et al., and then phospholipid was separated by unicil column chromatography. In some experiments, phospholipids were isolated by TLC (chloroform/methanol/petroleum ether/acetic acid/boric acid, 80:60:40:20:3.6, v/v/v/v/w)(19). This method does not resolve phosphatidylinositol (PI) from phosphatidylserine (PS).

The extracts were then evaporated under N_2 gas. Methylation of serum FFA was achieved by incubating the extracts with 0.2 ml of boron trifluoride methanol complex for 2 min at 100 C, and the methylated fatty acids were extracted with 2 ml of hexane. Hydrolysis of phospholipids and methylation of the fatty acids of glomeruli were achieved by incubating the extracts with 1 ml of 0.6 N NaOH in 100% methanol for 30 min at room temperature. After incubation, the mixture was neutralized with 6 N HCl, and the methylated fatty acids were extracted with 2 ml of hexane.

The fatty acid composition of serum FFA and glomerular phospholipids was analyzed by gas chromatography in a GC 7-A model apparatus (Shimadzu Co., Kyoto) equipped with a 2 m × 2 mm id glass column packed with 15% DEGS and with a flame ionization detector. The column temperature was 190 C. Nitrogen was used as carrier gas, and the flow rate was 50 ml/min. Peaks were identified by comparison with standards (Nu-Chek-Prep). The peak area was calculated electronically with a computing integrator (Chromatopac CRIA; Shimadzu Co., Kyoto). The values reported in Tables 3, 4 and 5 are mean area %.

Lipid analysis of glomeruli and liver. Before lipids were extracted, cholesterol acetate was added as an internal standard. Then lipids were extracted by the method of Folch et al. and analyzed with TLC and a flame ionization detector (20,21) using an Iatroscan TH-10 TLC/flame ionization analyzer (Diatron, Tokyo). Lipids were separated with the solvent system of hexane/ether/formic acid (54:5:0.05, v/v/v) for neutral lipids and chloroform/methanol/water (60:2:2, v/v/v) for phospholipid subfractions.

Measurement of protein. Protein was measured by the method of Lowry et al. (22).

Statistics. The significance of differences in mean values was evaluated by Student's t-test.

RESULTS

Animal conditions (Table 1). The body weights of diabetic rats were markedly less than those of controls 2 and 10 mo after injection of streptozotocin. The kidney weights of diabetic rats were not significantly different from those of controls.

The serum glucose levels of diabetic rats were markedly increased 2 and 10 mo after injection of streptozotocin. However, the glucose levels were higher after 2 mo than after 10 mo. The total cholesterol levels of diabetic rats were significantly higher after 2 mo, but lower after 10 mo than those of controls. The mean triglyceride levels of

diabetic rats were also higher after 2 mo and lower after 10 mo than those of controls. The serum lipid levels of controls were slightly, but significantly, higher after 10 mo than after 2 mo.

Lipid contents of glomeruli from control and diabetic rats (Table 2). The major lipids of glomeruli were free cholesterol and phospholipids. There were no significant differences in their contents (μg/mg glomerular protein) in control and diabetic rats after either 2 or 10 mo. The relative amounts of PC and PI plus PS were also similar in normal and diabetic rats at both times. In diabetic rats after 10 mo, the relative amount of PE was significantly decreased and that of sphingomyelin (Sph) was significantly increased, although these changes were not clear after 2 mo. Serum lipids were not correlated with tissue lipids (Table 1). The contents of free cholesterol and phospholipids on the basis of glomerular protein were lower after 10 mo than after 2 mo.

Serum FFA in diabetic rats (Table 3). Serum FFA were analyzed to see whether their composition reflected that in the glomeruli. The main saturated FFA in the serum was palmitic acid (PA), the main monoene was oleic acid (OA) and the main PUFA were LA and AA (Table 3, control). Diabetic rat serum contained more LA but less AA than controls at either 2 or 10 mo, but the increase in LA and the decrease in AA were most profound at 2 mo and the decrease in AA was most prominent at 10 mo. A slight increase in docosahexaenoic acid was observed at both times.

Control animals showed age-dependent changes in serum

FFA. AA content increased almost three-fold between 2 and 10 mo, while LA and PA content decreased to a lesser degree.

Fatty acid composition of glomerular phospholipids from diabetic rats (*Table 4*). The main saturated fatty acids were PA and stearic acid (SA), the main monoene was OA and the main polyenes were LA and AA. The relative amounts of fatty acids in glomerular phospholipids were different from those in serum FFA. Diabetes lowered AA and increased LA in glomeruli at 2 or 10 mo. No age-dependent changes in free fatty acids in glomeruli were observed in controls.

Fatty acid composition of individual phospholipids of glomeruli from diabetic rats after 10 mo (*Table 5*). The fatty acid composition of individual phospholipids was analyzed to determine in which subfraction these changes occurred. LA was mainly present in PC and AA mainly in PE. In diabetes mellitus, LA was increased in PC, and the mean level of LA in PE was also increased slightly, but not significantly. AA decreased only in PE and did not change significantly in other fractions. PA was significantly decreased in PC and PE. There was no significant difference in the contents of PI + PS in control and diabetic glomeruli.

Acyl-CoA synthetase and lysoPE acyltransferase activities of glomeruli from diabetic rats. As changes of both LA and AA were observed in PE, the pathway for synthesis of PE from FFA was investigated. LA and AA were used as substrates because the contents of both in PE changed. In diabetic rats at 2 mo, the acyl-CoA synthetase

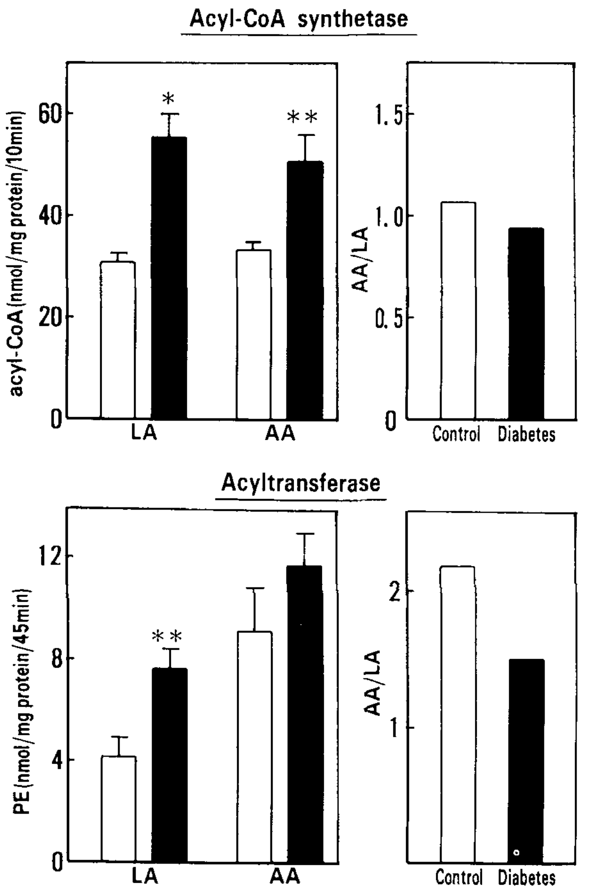

FIG. 1. Acyl-CoA synthetase and lysoPE acyltransferase activities of glomeruli from control and diabetic rats at 2 mo. Results are shown as means ± SEM for five animals. activities with LA and AA as substrates were significantly higher than those in control rats, but the ratio of arachidonyl-CoA synthesis/linoleyl-CoA synthesis was not significantly different in control and diabetic rats (Fig. 1). In diabetic rats after 10 mo, the acyl-CoA synthetase activity with LA as substrate was significantly increased but that with AA as substrate was not changed, and so the ratio of arachidonyl-CoA synthesis/linoleyl-CoA synthesis was decreased (1.04 vs 0.70) (Fig. 2). In diabetic rats after 2 mo, lysoPE acyltransferase activity with LA as substrate was increased significantly, but that with AA as substrate was increased only slightly; consequently the ratio of PE synthesis from AA/PE synthesis from LA was decreased (2.17 vs 1.51) (Fig. 1). In diabetic rats after 10 mo, lysoPE acyltransferase activity with LA as substrate was not changed but that with AA as substrate was decreased significantly, and so the ratio of PE synthesis from AA/PE synthesis from LA was decreased (2.17 vs 1.47) (Fig. 2).

Phospholipid content of the liver of diabetic rats after 10 months (Fig. 3). Liver phospholipids 10 months after induction of diabetes were examined to determine whether changes in glomeruli are tissue-specific. The proportion of PE was increased with reciprocal decrease in the proportion of PC in the liver of diabetic rats after 10 mo.

DISCUSSION

We found that the proportions of individual phospholipids in the glomeruli of diabetic rats were not changed after 2 mo, in agreement with Clark et al. (5), but that the proportion of PE was decreased and that of Sph was increased reciprocally after 10 mo (Table 2). Therefore, the changes of individual phospholipids in the glomeruli of diabetic rats were time-dependent. Fass and Carter (8) reported that PE increases in rat liver 3 wk after induction of diabetes. We observed an increase in PE and a decrease in PC in livers of 10-mo diabetics. These results indicate that changes of individual phospholipids in glomeruli were tissue-specific. The enzyme methylating PE to form PC is thought to be present in the liver and to show reduced activity in diabetes mellitus (9). It is unknown whether this enzyme exists in glomeruli and whether the methylation pathway is important for synthesis of PC in glomeruli. Our results suggest that this pathway is not so important for the synthesis of PC in the glomeruli as in the liver. The reason that the proportion of PE decreased and that of Sph increased in the glomeruli in the later stage of diabetes is not clear. The

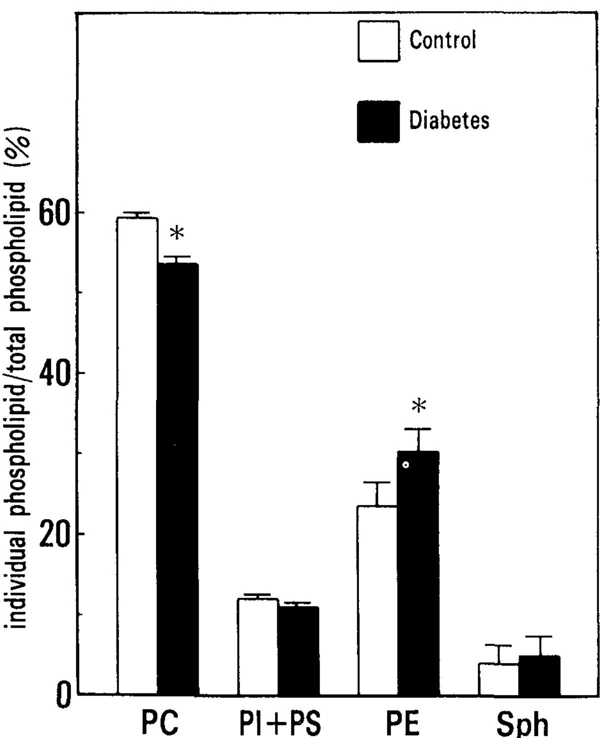

FIG. 3. Phospholipid content of the liver of diabetic rats after 10 mo. Results are means ± SEM for five rats. The asterisks above the bar indicate significant differences from the control value: *, $p < 0.05$. diabetic state might (i) inhibit de novo PE synthesis and (ii) either stimulate Sph synthesis or inhibit sphingomyelinase, or both. However, the precise effects of diabetes mellitus on these pathways are not known. Another possibility is that Sph-rich and PE-poor cell populations increased in the glomeruli of diabetic rats. Glomeruli prepared by the method used in this work could contain endothelial, mesangial and epithelial cells. Mesangial cells may proliferate in the diabetic state (23).

The fatty acid composition of phospholipids depends on the balance of their synthesis and degradation. The deacylation-reacylation cycle is especially important for PUFA (7). In this work, we examined the synthetic pathway (acylation). Our results showed that in diabetes mellitus there was an imbalance of utilization of PUFA in the acyl-CoA synthetase-lysoPE acyltransferase system: incorporation of LA into PE was preferential to that of AA in diabetic glomeruli both at 2 and 10 mo (Figs. 1 and 2). Our results indicate that this abnormal metabolism could contribute to the abnormal fatty acid composition of phospholipids in both early and late stages of diabetes mellitus. An AA-specific acyl-CoA synthetase was reported to be present in platelets (24), and its presence explains the high and selective incorporation of AA into phospholipids in platelets in spite of the low serum AA concentration. However, we could not detect an AA-specific acyl-CoA synthetase in glomeruli (15), and Clark et al. reported that acyl-CoA synthetase activities have little difference between LA and AA as substrates in normal or diabetic renal homogenates (25). On the contrary, the Michaelis coefficient (Km) of acyl-CoA synthetase for LA was lower and maximum velocity (Vmax) was higher than those for AA (Km for LA, 12.8 μM; Km for AA, 19.3 μM; Vmax for LA, 152 nmol/mg protein/10 min; Vmax for AA, 115 nmol/mg protein/10 min) (15). Thus, LA is a better substrate than AA for glomerular acyl-CoA synthetase. This and the imbalance in the acyl-CoA synthetase-lysoPE:acyltransferase system in the diabetic state indicate that glomeruli cannot counteract the abnormal FFA composition in diabetic serum at the level of uptake of FFA into the tissue and in fact may make it worse.

The mechanism of the imbalance in PE synthesis is not clear. In preliminary experiments, we found that the PE and Sph contents affect the enzyme activities in different ways with different substrate fatty acids. Possibly microenvironments of the enzyme and substrates may be important; we are now examining this possibility.

The changes observed in the phospholipids of diabetic glomeruli could affect either membrane functions or eicosanoid metabolism. The decrease in the proportion of PE, the increase in that of Sph and the decrease in double bonds of fatty acids in phospholipids could all result in decreased fluidity of glomerular cell membranes (5,26,27). Mead (28) reported that membrane proteins are easily released from membranes in these conditions, with consequent decrease in integrity of the membranes.

AA released from phospholipids was reported to be metabolized through the cyclooxygenase and lipooxygenase pathways in glomeruli (29-31). The syntheses of prostaglandins are affected not only by enzymes such as phospholipase and cyclooxygenase, but also by the AA content of phospholipids (32). Although several roles of prostaglandins in glomeruli, such as inhibition of platelet aggregation in glomerulonephritis (33) and regulation of angiotensin metabolism (34), have been proposed, little is known about the roles of these metabolites in formation of diabetic nephropathy. Rogers and Larkins (35) reported that the productions of PGI_2 and PGE_2 from endogenous AA were not decreased in the glomeruli of diabetic rats after 5 wk, in spite of a decrease in AA in phospholipids (5). It is not known whether PG synthesis decreases in the late stage. The decrease in AA in diabetic glomeruli was mainly in that of PE at 10 mo (Table 5). The origin of AA is not known; if PC is the main source of AA, no changes of PG may occur, but if PE is the main source of AA, then PG production may decrease. The glomeruli used in this work could contain various cell populations, such as endothelial, mesangial and epithelial cells. If AA in phospholipids and the release of AA from phospholipids were decreased in endothelial cells, the production of PGI_2 should decrease, thus facilitating thrombus formation (36). Further investigations are needed to correlate our data with results on diabetic nephropathy.

[Received December 5, 1986]

Enteral Absorption in Man of Eicosapentaenoic Acid in Different Chemical Forms

S. El Boustani,[a] C. Colette[b], L. Monnier[b], B. Descomps[a,*], A. Crastes de Paulet[a] and F. Mendy[c]

[a]Laboratoire de Biochimie A, Institut de Biologie, Montpellier, France, [b]Service des Maladies Métaboliques, Hôpital Lapeyronie, Montpellier, France, and [c]Laboratoires SOPHARGA, Puteaux, France

After administering the equivalent of 1 g of eicosapentaenoic acid (EPA) in four different chemical forms, the kinetics of EPA incorporation into plasma triglycerides (TG) were compared by gas liquid chromatography on a capillary column following separation of the lipid fraction by thin layer chromatography.

EPA incorporation into plasma TG was markedly smaller and later when EPA was administered as an ethyl ester rather than as EPA free fatty acid, EPA arginine salt or 1,3-dioctanoyl-2-eicosapentaenoyl glycerol (2-EPA). Our results and the data in the literature are compatible with the hypothesis that 2-EPA is absorbed with minimum hydrolysis and escapes random distribution between the other positions of the glycerol molecule during the absorption process.

Lipids 22, 711–714 (1987).

Dietary fat modification is now considered to be an effective tool for modifying the phospholipid fatty acid composition of cell membranes, especially in blood platelets. The effect of dietary manipulation and the metabolism of polyunsaturated fatty acids (PUFA) have been extensively studied in the aim of influencing the physiological responses mediated by the oxygenated metabolites of the eicosapolyenoic acid cascade.

Several studies have been devoted to the action and metabolism of eicosapentaenoic acid (EPA) in animals or in man, especially its antithrombotic effect (1-7). Owing to the greater stability of esterified PUFA vs free fatty acids, and to the potential toxicity of methanol released by methyl ester hydrolysis, many of the studies concerning dietary manipulation with EPA have used the ethyl ester of this acid, as in a recent study by Tamura et al. (8). However, some data in the literature raise questions about the relative difficulty of its hydrolysis by pancreatic lipase (9-11); this difficulty could result in some impairment of its subsequent intestinal absorption.

For this reason, we compared in this study the kinetics of EPA incorporation into plasma triglycerides (TG) in man after ingestion of four chemical forms of EPA: ethyl ester, free fatty acid, arginine salt and triglyceride (1,3-dioctanoyl-2-eicosapentaenoyl glycerol [2-EPA]). The kinetics of this incorporation after EPA ethyl ester ingestion differed strikingly from the kinetics following ingestion of the three other forms.

MATERIALS AND METHODS

Reagents. Free fatty acid, arginine salt, ethyl ester of EPA and 2-EPA of pure analytical grade were generously provided by Roussel-Uclaf Laboratories (Romainville, France).

The purity of the chemical forms was checked by gas chromatography-mass spectrometry; when useful, this was completed by NMR spectroscopy.

Organic solvents, hexane (Uvasol), chloroform, methanol, inorganic compounds and 2′,7′-dichlorofluorescein were from E. Merck (Darmstadt, FRG). The lipid and fatty acid standards were from Fluka (Buchs, Switzerland) or Sigma Chemical Co. (St. Louis, MO).

Experimental protocol. Eight normal volunteers, 25-29 years of age, were given the equivalent of 1 g of EPA per os at 8 a.m. after an overnight fast; immediately afterward they ate a light lipid-free breakfast. Under the same conditions, four of the subjects received the four chemical forms of EPA, each form taken at subsequent 1-wk intervals. The other four received only two forms, the free fatty acid and 2-EPA.

Blood samples (7 ml on ethylene diamine tetraacetate) were taken 0, 1, 2, 3, 4, 5, 6, 9, 12 and 24 hr after EPA ingestion. At 6 and 12 hr the samples were taken just before meals of low lipid content, and at 0 and 24 hr after an overnight fast.

Analytical methods. Plasma lipids were extracted by chloroform/methanol according to the method of Folch et al. (12). The lipid classes were separated by thin layer chromatography on Kieselgel 60 F 254 (Merck) using hexane/diethyl ether/acetic acid (80:20:1, v/v/v) as the developer. The lipid fractions were detected under UV light after spraying the plates with 2′,7′-dichlorofluorescein. The TG fraction was scraped from the plates and transesterification was performed for 30 min at 80 C in methanol/sulfuric acid (19:1, v/v) without extraction from the gel. The methyl esters extracted with hexane were analyzed by gas liquid chromatography using a Fractovap 2900 (Erba Science) chromatograph, FFAP capillary columns (25 m × 0.32 mm) and a flame ionization detector at 250 C. The injection temperature was 230 C, and the oven

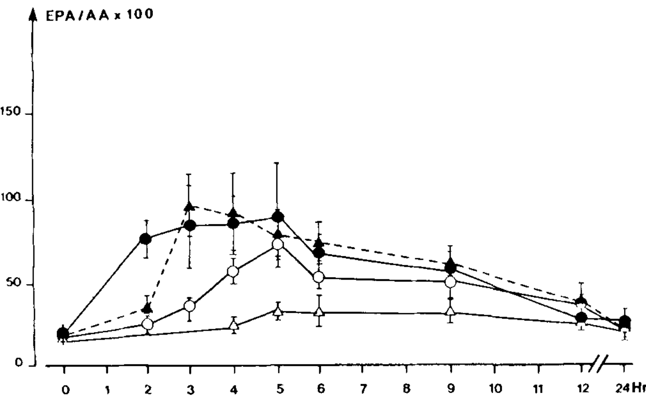

Fig. 1. EPA/AA × 100 ratio variation in plasma TG; mean value (± SEM) after ingestion of 1 g of EPA in the form of 2-EPA (○) free EPA (▲), arginine EP (•) and ethyl EP (△).

Abbreviations: PUFA, polyunsaturated fatty acids; AA, arachidonic acid; EPA, eicosapentaenoic acid; 2-EPA, 1,3-dioctanoyl-2-eicosapentaenoyl glycerol; EP, eicosapentaenoate; TG, triglyceride.

was programmed to increase the temperature 10 C/min from 50 C to 150 C, and then 2 C/min from 150 C to 200 C. The esters were identified by their retention times with respect to pure fatty acid standards. The relative proportions of EPA and arachidonic acid (AA) were evaluated using a digital integrator (I.C.A.P-5 or Spectra-physics).

RESULTS

After 1 g EPA was ingested, its absorption was followed by substantial incorporation into plasma TG characterized by a rise in the ratio of EPA to AA in the plasma lipid fraction. The different absorption rates of EPA as given in the four different chemical forms were estimated from the corresponding variations of the ratio of EPA to AA in plasma TG.

Figure 1 compares the variation of the mean values of the ratio of EPA to AA in plasma TG after ingestion of the four different chemical forms. There is a striking difference among the kinetics observed after administration of EPA as ethyl ester and the three other chemical forms. When administered as ethyl ester, the rise of EPA in plasma TG was about three times less and occurred at least 3 hr later than with the three other chemical forms. The difference between EPA ethyl ester and the other forms is statistically significant ($p < 0.05$ at 5 and 6 hr), as is the increase in EPA/AA after ethyl ester ingestion ($p < 0.05$ at 5, 6 and 9 hr. vs control at 0 hr).

Tables 1-4 detail the individual variations of the ratio of EPA to AA in plasma TG after ingestion of the four different chemical forms of EPA.

After ingestion of an amount of the TG 2-EPA equivalent to 1 g of EPA, the ratio of EPA to AA increased in all eight subjects (Table 1). The maximum (3 to 10 times the basal value) was observed 4 or 5 hr after ingestion of TG. The maximum of the mean values (four to five times the mean basal value) was observed between 4 and 5 hr.

When the subjects were given 1 g of free EPA (Table 2), the increase in the ratio of EPA to AA was rapid; the maximum occurred at 3 hr and reached 5 to 12 times the initial value (mean value 5.5).

The variation of the ratio of EPA to AA after ingestion of an equivalent of 1 g of EPA as arginine salt was similar to that of 2-EPA; the maximum of the mean value is five times the basal value and occurred at 5 hr.

After ingestion of the ethyl ester of EPA, the ratio of EPA to AA in plasma TG rose slowly, and the maximum of the mean value was only two times higher than the basal value and was delayed until 9 hr.

DISCUSSION

The percentage of AA in plasma TG can be considered constant over the 24-hr period studied here, since this fatty acid was not supplied by food during this period. Under these conditions, the kinetics of EPA absorption can be estimated from the variation of the ratio of EPA to AA in plasma TG. This method has been used successfully by others (13). Our results show significant modifications of the ratio of EPA to AA in plasma TG after ingestion of the equivalent of 1 g of EPA in different chemical forms.

In spite of several individual variations, common characteristics clearly appeared, e.g., there was a 5- to 12-fold rise in the ratio of EPA to AA in 19 of the 20 experiments in which EPA was ingested as TG (2-EPA), free fatty acid and arginine salt. However, after ingestion of EPA ethyl ester, the ratio of EPA to AA increased only 1.5- to 3-fold over the basal value. This indicates that EPA was less incorporated into plasma TG after ingestion of the ethyl ester than after ingestion of the three other forms, but it does not imply that EPA ethyl ester is an ineffective therapeutic agent. The rise in the EPA/AA ratio is statistically significant at 5, 6 and 9 hr vs control at 0 hr. EPA ethyl ester has, in fact, been shown to be able to modify platelet function. The results obtained here with EPA ethyl ester are in agreement with data in the literature (14), e.g., a twofold rise above the basal level was obtained by Nagakawa et al. (5) even after repeated administration and by Tamura et al. (14) even after administration of a higher dose (3.5 g/day).

EPA was less readily incorporated into plasma TG after ingestion of ethyl ester than after ingestion of the TG (2 EPA), free fatty acid or arginine salt. The difference could result from impairments at the EPA ethyl ester hydrolysis step, at the EPA absorption step or from interference with some unknown process involved in the PUFA absorption mechanism. EPA is well absorbed when given as free fatty acid or arginine salt. The difference is possibly the result of poor hydrolysis of EPA ethyl ester by pancreatic lipase and a subsequent decrease in the incorporation of EPA ethyl ester into the mixed micelle. This resistance could result from both the EPA and the ethyl components of the molecule. An unusual resistance of the ethyl esters was in fact reported in 1958, i.e., the hydrolysis of ethyl oleate was found to be less than the hydrolysis of triolein (9), and the hydrolysis of ethyl esters was generally less than the hydrolysis of the homologous methyl esters (10,11). EPA structure is also involved in the relatively low susceptibility of EPA esters to hydrolysis by pancreatic lipase. Hydrolysis of eicosapentaenoyl or docosahexaenoyl glycerides is less than hydrolysis of oleyl glycerides (15,16) even when these fatty acids are situated at positions 1 and 3 on the triglyceride molecule, which are known to be the preferential sites of pancreatic lipase action (17). This resistance has been related to the proximity of the first double bond to the carboxyl group (17,18). Although the EPA glyceryl or docosahexaenoyl glycerol esters are resistant to hydrolysis by *pancreatic* lipase even at positions 1 and 3, the n-3 docosapentaenoyl glycerol is not (19). In the last compound, five methylene groups separate the ester function from the nearest double bond vs only two or three in the other molecules. Thus, $\Delta 4$ and $\Delta 5$ polyunsaturated fatty acids such as docosahexaenoic, eicosapentaenoic (and probably arachidonic) acids are scarcely released from their glyceride combinations by pancreatic lipase. On the other hand, $\Delta 7$ fatty acids such as n-3 docosapentaenoic acid are readily released by this enzyme and more easily available for further metabolism. A steric hindrance by the ω methyl group has also been suggested (16,19) to be the cause for the resistance of esters of the other fatty acids.

If such a resistance to the digestive enzymatic process impairs EPA ethyl ester hydrolysis, the same must hold for 2-EPA, especially when the ester bond is at position 2, which is resistant to pancreatic lipase. However, in all of the subjects studied, EPA incorporation into plasma TG was much greater after ingestion of 2-EPA than of ethyl ester. It is possible that the absorption of the ethyl ester takes place without prior enzymatic hydrolysis. This hypothesis is now under investigation.

Sterol and Phospholipid Acyl Chain Alterations in *Saccharomyces cerevisiae* Secretion Mutants as a Function of Temperature Stress

Christopher Low and **Leo W. Parks***
Department of Microbiology, North Carolina State University, Raleigh, NC

Analyses of free sterol, steryl ester and fatty acid components from yeast secretion mutants indicated that free and esterified sterol remained relatively constant over a growth range of 24 C to 34 C. The saturated fatty acid components (16:0 and 18:0) increased while the unsaturated fatty acids (16:1 and 18:1) decreased as the growth temperature increased. In secretory mutants, fatty acid composition changes are more pronounced than in the wild-type strain. A shift toward increased saturated and decreased unsaturated fatty acid was observed when cells were subjected to a 2-hr temperature upshift to 37 C. Steady-state fluorescence anisotropy data indicated that modifications to the lipid component of yeast plasma membrane produced lipid thermotropic transitions that were 3 C to 6 C higher in yeast cells subjected to thermal stress.
Lipids 22, 715–720 (1987).

The yeast *Saccharomyces cerevisiae* synthesizes and incorporates ergosterol and a mixture of phospholipids (sphingolipids, cardiolipin [CL], phosphatidylserine [PS], phosphatidylethanolamine [PE], phosphatidylcholine [PC] and phosphatidylinositol [PI] into membranes (1). The membrane lipid composition in this yeast has been shown to be dependent upon temperature, carbon source and lipid precursor supplement (1). By using a yeast sterol auxotroph, we have demonstrated coordinated regulation of fatty acid and phospholipid composition of the yeast plasma membrane (2) as a function of exogenous sterol. Maintenance of membrane integrity and stability under adverse environmental stress has been attributed to the presence of sterols in the plasma membrane (1,3). The stability of membranes during interactions with other membranes is important to the understanding of the mechanisms of membrane adhesion, fusion, cell division and detachment (4).

A body of evidence suggests a common eukaryotic protein secretory pathway that is mediated by membrane-bound structures (5,6). The isolation of temperature-sensitive secretory (sec) yeast mutants has shown that synthesis and secretion of extracellular and periplasmic protein are tightly coupled and appears to follow the typical eukaryotic secretory pathway (7–9). Yeast secretion mutants are conditionally restricted in expansion of plasma membrane. Restriction of plasma membrane expansion cannot be attributed to a cessation of phospholipid synthesis or altered phospholipid headgroup composition (10). Since the principal functional role for sterols in the plasma membrane appears to be structural, it seemed appropriate to determine whether any differences in sterol metabolism as a function of temperature stress mediated the defect in membrane formation.

MATERIALS AND METHODS

Strains and medium. The strains used in this study (Table 1) were derived from the wild-type strains X2180-1A and X2180-1B (7–9,11). The cells were grown on medium containing 0.67% yeast nitrogen base and 2% dextrose (YNBD); growth was followed turbidimetrically using a Klett-Summerson photoelectric colorimeter equipped with a green filter. Lipid extracts from wild-type and mutant yeasts cultured without shifting to the restrictive temperature (37 C) were compared to extracts from cells that had been incubated for 2 hr at the restrictive temperature. Based on differences in the sterol patterns found in these strains, a representative set of strains displaying the appropriate organelle phenotype (vesicle, Golgi, endoplasmic reticulum and no organelle accumulation) (8) upon temperature upshift was chosen for further analysis.

TABLE 1

Strain List

Strains	Genotype and organelle accumulated[a]
X2180-1A	a, *CUP1, SUC2, mal, gal2,* secretion wild-type, temperature-sensitive wild-type and parental for HMSF strains

Abbreviations: CL, cardiolipin; PS, phosphatidylserine; PE, phosphatidylethanolamine; PC, phosphatidylcholine; PI, phosphatidylinositol; YNBD, medium containing 0.67% nitrogen base and 2% dextrose; DMSO, dimethylsulfoxide; TLC, thin layer chromatography; GLC, gas liquid chromatography; DPH, 1,6-diphenyl-1,3,5-hexatriene; FS, free sterol; SE, steryl ester.

Growth conditions. In temperature upshift experiments, cultures of X2180-1A, HMSF134, HMSF154, HMSF169 and HMSF190 were grown at 24 C to mid-log (100 Klett units) and the cultures divided in half. One-half of each culture was reincubated at 24 C and the other half at 37 C for 2 hr. For the 37 C-incubated cultures, a New Brunswick gyrotory water-bath shaker (Model G76) (water bath preset to 37 C) was used. Thermal equilibrium between the yeast culture medium and the water bath was reached within 15 min of placing the cultures in this water bath. At the end of 2 hr, yeast cells from the 24 C and 37–39 C cultures and from stationary phase cells cultured at 24 C were harvested and quantified by dry weight for lipid analyses and by wet weight for plasma membrane preparations. Temperature profile experiments from 26–40 C were carried out using a gradient incubator (Scientific Industries). The cells were cultured to stationary phase on YNBD over a temperature range of 26–40 C, and duplicate 10-ml samples were harvested for lipid analyses.

Lipid analyses. For lipid analysis, the cells were lyophilized and then either steamed in the presence of dimethylsulfoxide (DMSO) or subjected to alkaline saponification (12). In all cases, total cellular lipids were extracted using the procedure of Parks et al. (12). The thin layer chromatography (TLC) solvent system of Skipski and Barclay (13) was used to separate the extracted lipid components. The free sterols and sterol from steryl esters (saponified with 6% KOH in methanol, 2 hr, 80 C, and hexane extracted) were quantitated by gas liquid chromatography (GLC) [Applied Science Labs (Deerfield, IL), 3% SE-30, 235 C, N_2 carrier gas flow rate of 20 ml min^{-1}] (12). Phospholipids were extracted from TLC plates with chloroform/methanol (1:1, v/v) and rechromatographed using a two-dimensional TLC system (14). The fatty acid components of each phospholipid species were converted to their methyl ester equivalents (15,16) and then separated by GLC (Supelco 10% DEGS, 175 C, N_2 carrier gas flow rate of 20 ml min^{-1}).

Fluorescence anisotropy. For steady state fluorescence anisotropy studies, plasma membranes from yeast cultures were prepared using the *Oerskovia xanthineolytica* lyticase enzyme as described by Bottema et al. (17). Steady-state fluorescence anisotropy changes were measured with an SLM instrument series 8000 spectrofluorimeter using the lipophilic probe 1,6-diphenyl-1,3,5-hexatriene (DPH) (18). The steady-state polarization was calculated from the equation $P = (R - 1)/(R + 1)$, and by substitution of $R = I_{\parallel}/I_{\perp}$ into $r_s = (I_{\parallel} - I_{\perp})/(I_{\parallel} + 2I_{\perp})$ the steady-state fluorescence anisotropy was determined. Here, $I_{\parallel}$ and $I_{\perp}$ are the intensities of parallel and perpendicular polarized light, respectively. At each temperature point, triplicate measurements of the total photon counts were taken (>2 × 10^5 photons counted per data point measurement for statistical relevance). Temperature was determined within ±0.5 C and absorbance (460 nm) was less than 0.40 for all samples that contained DPH at a concentration of 1 μM in 10 mM Tris, 1 mM EDTA buffer, at pH 6.8. A linear least squares fit was used in determining the fluorescence anisotropy plot discontinuities.

Materials. DPH was purchased from Sigma Chemical Co. (St. Louis, MO). Solvents were from Fisher Scientific (Springfield, NJ) and were redistilled prior to use. Culture media and supplies were from Difco (Detroit, MI). A Varian 2700, a Hewlett-Packard 5890A gas-liquid chromatograph and a Beckman model 332 gradient liquid chromatograph were coupled to an IBM CS-9000 laboratory instruments computer and used for all GLC and high performance liquid chromatography (HPLC) analyses.

RESULTS

Screening of secretion mutants for altered sterol metabolism. Growth experiments (Fig. 1) showed that temperature sensitivity was detectable in the mutants after 2 hr of incubation at 37 C. The strains were inoculated into fresh medium and allowed to grow at 24 C until they reached 100 Klett units. At that time, each culture was shifted to 37 C for 2 hr, and the temperature was returned to 24 C. All of the mutants showed growth rate reductions following temperature upshift. By conducting the temperature downshift (37 C to 24 C), we were able to determine that these cells did not recover from thermal stress by returning to the original log phase growth rate in the same batch culture.

In one strain (HMSF134), it was noted that intracellular free sterol (FS) and steryl ester (SE) levels were comparable to that found in the wild-type (X2180-1A) when this strain was grown to stationary phase at 24 C. Intracellular SE (detected by GLC sterol analysis of the saponified SE fraction) did not accumulate under conditions of a temperature upshift as did the other representative strains, as evidenced by the high FS to SE ratio (FS/SE) (Table 2). Other secretion mutants, like the wild-type, began to accumulate SE after temperature upshift to 37 C. There were no large interstrain differences in total sterol between wild-type and the secretion mutant strains tested when cultured under the same temperature regimen (Table 3). For cells grown to stationary phase, the range of total sterol was 0.4 to 0.6 μg 10^8 $cells^{-1}$ (Table 3). A two- to fivefold increase in total sterol content was found in strains X2180-1A, HMSF154, HMSF169 and HMSF190 cultured to midexponential phase without temperature upshift compared to total sterol values for conditions of temperature upshift (37 C)

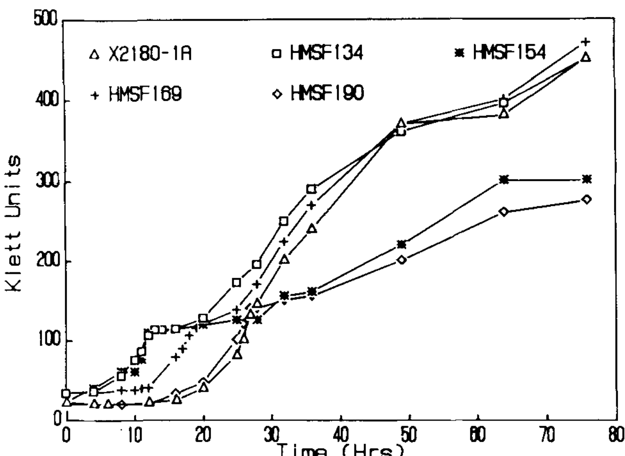

FIG. 1. Dual temperature shift growth of secretion mutants. Cells were cultured on yeast nitrogen base with dextrose to 100 KLett units at 24 C, then shifted to 37 C for 2 hr. The time period of the temperature upshift for each strain starts at 100 Klett units.

(Table 3). In cells subjected to temperature upshift, the total sterol content ranged from 0.4 to 0.9 μg 10^8 cells^{-1}, an amount not significantly different from cells grown to stationary phase (Table 3).

When sterols were compared by cell number (μg sterol 10^8 cells), the data for HMSF134 showed FS/SE ratios of 9 and 12 in mid-log temperature-upshifted and non-temperature-shifted cultures, respectively (Table 2). Cells quantitated by dry weight showed FS/SE ratios of 10 and 12.5 when cultured under the same conditions (data not shown). The FS/SE ratios (mid-log, temperature upshifted) for X2180-1A, HMSF154, HMSF169 and HMSF190 ranged from 0.7 to 3.0 and were at least threefold lower than that for HMSF134 (Table 2). Similar values of FS/SE were obtained when dry weight determinations were used, 0.6 to 2.7 for all tested strains except HMSF134, which had an FS/SE ratio of 10 (data not shown).

Temperature profile of secretion mutant lipids. Analysis of the FS and SE by GLC revealed that when these strains were cultured between 26–34 C, the cells had measurable levels of SE and FS (Table 4). The maximum values for free sterol (2.8, 1.0, 0.9, 1.1 and 0.8 μg mg^{-1} dry wt) occurred between 30 C and 34 C and were for X2180-1A, HMSF134, HMSF154, HMSF169 and HMSF190, respectively. The FS/SE ratio for HMSF134

Each strain was incubated in individual cultures over the temperature range of 26–40 C and harvested at 24 hr into stationary phase. Above the strain-specific restrictive temperature, these strains did not grow (nd). In the case of X2180-1A, free sterol was measured for the entire range of 26–40 C; however, steryl ester was not detected by GLC above 36 C (nde).

[a]nd: Not determined—cells did not grow at these temperatures.

[b]nde: No detectable ester.

observed under these conditions ranged from 1.0 to 0.9 for growth between 26 and 34 C, respectively. Analysis of total fatty acids from cells cultured to stationary (no temperature shift), mid-log (no temperature shift) and mid-log (with subsequent temperature shift) did not reveal any significant interstrain differences (data not shown), Comparative analyses of the fatty acids from cultures grown to stationary phase at different temperatures showed modifications to saturated and unsaturated fatty acid components (Figs. 2A-D). As the temperature increased (Figs. 2A and B), the content of 16:0 (except for HMSF190) and 18:0 (except in the wild-type) increased until a growth temperature just less than the restrictive temperature was reached. When the temperature was restrictive, there was a two- to threefold increase in the amount of 16:0 in the secretion mutant and wild-type (grew at 40 C) strains (Figs. 2A and B). For the 18:0 component, the increase was not as pronounced except for HMSF134. The 16:1 and 18:1 (except HMSF190) components decreased as the growth temperature increased, and when a growth temperature just below the restrictive temperature was reached, there was a large decrease in the amount of 16:1 and 18:1 (Figs. 2C and D). In each case, the sensitivity of the secretory mutants to temperature upshift was more pronounced than the wild-type.

Effect of temperature on secretion mutant plasma membranes. Analysis of the steady-state fluorescence anisotropy for plasma membrane preparations showed that in each strain—X2180-1A (wild-type parental), HMSF134, HMSF154, HMSF169 and HMSF190—there was a discontinuity in the plots for strains not subjected to a temperature upshift (Fig. 3). However, under conditions of temperature upshift, HMSF134 plasma membrane preparations showed no discontinuity, while the plots for X2180-1A, HMSF154, HMSF169 and HMSF190 displayed a discontinuity similar to that for non-temperature-upshifted cells (Fig. 4). In each case, except for HMSF134, the temperature at which the discontinuity in the fluorescence anisotropy plot appears is at a high temperature (3-6 C) for plasma membrane isolated from temperature-upshifted cells compared to plasma membrane from cells cultured at 24 C. The temperature at which these discontinuities appear (33-36 C in non-

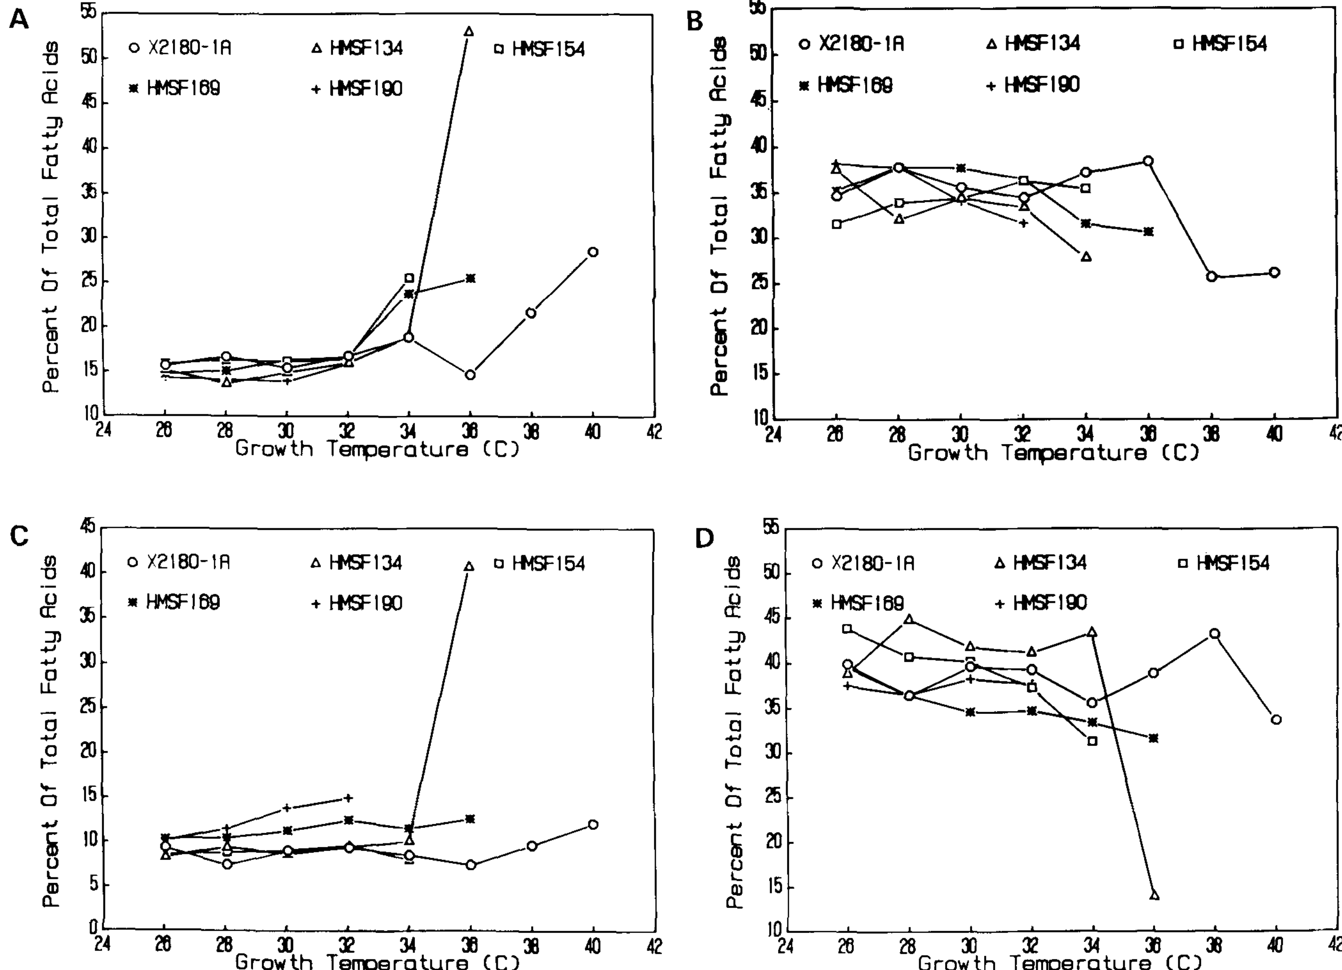

FIG. 2. Fatty acids in secretion mutants and the parental wild-type. Individual cultures were grown to stationary phase on yeast nitrogen base with dextrose over a temperature range of 26-40 C using a temperature gradient incubator. In Table 4, the temperatures above which these strains did not grow are indicated. For each long chain fatty acid species, the percent of the total long chain fatty acids is plotted (16:0, A; 18:0, B; 16:1, C; and 18:1, D).

temperature-shifted cells, and 36–42 C in temperature-upshifted cells) is above the optimal growth temperature range of 28–32 C for *S. cerevisiae*.

DISCUSSION

In yeast cells wild-type for ergosterol and sterol biosynthesis but conditionally defective for secretion properties, no large increase or decrease in total sterol content was observed in cells cultured to stationary phase (Table 3). There was, however, an increase followed by a decrease in intracellular FS and SE mg^{-1} dry wt (Table 4) as the growth temperature increased to 32 C. The observation that these maxima for FS and SE content occur at different temperatures in different strains may indicate a strain-related specificity for optimal lipid content as a function of growth temperature. Ramirez et al. have shown that under conditions of temperature stress, the yeast secretion mutants do not appreciably alter the phospholipid head group composition (10). Instead, we found that these yeasts modify the fatty acids attached to the membrane phospholipids. These changes in fatty acids reflect the increased sensitivity of the secretory mutants to thermal stress. The predominant changes appeared to be the fatty acids (Figs. 2A–D). The saturated fatty acids (16:0 and 18:0) increased while the unsaturated fatty acids either decreased (16:1) or remained unchanged (18:1). However, analyses of total fatty acids by chain length and unsturation showed larger fluctuations at a temperature just below the restrictive temperature in each different class of secretion mutant as well as the wild-type (X2180-1A). This may reflect cellular loss of regulatory function for membrane composition at that particular temperature. Based on the data presented here, modifying the fatty acid chain length and unsaturation appears to be the preferred method of maintaining plasma membrane integrity for growth at different temperatures when the sterol structure is fixed (yeasts wild-type for sterol synthesize only ergosterol as a normal end product). Comparing the total fatty acids (data not shown) with the sterol analyses (Table 4) indicated that the secretion mutants tested do not have an altered sterol biosynthetic metabolism that produces the membrane synthesis defect (cessation of membrane growth). Conceptually, this means that even when the yeast secretion mutants are conditionally blocked from new plasma membrane synthesis, they still produce lipid components that can potentially modify the plasma membrane for growth under temperature stress. These new plasma membrane precursors are not incorporated into existing plasma membrane when thermal stress is applied and the cell membrane ceases to grow. Therefore, when the plasma membrane preparations from temperature-stressed cells were examined, they reflected an increase in the temperature at which the discontinuity occurred. This is due to the inherent mixing of the existing plasma membrane and potential new membrane lipid components. This also would occur in the non-temperature-shifted cells, but since these cells were not temperature-stressed, the potential new membrane lipid components would not contain subunits optimal for growth at a higher temperature and would thus have a fluorescence anisotropy discontinuity at a lower temperature (Fig. 3).

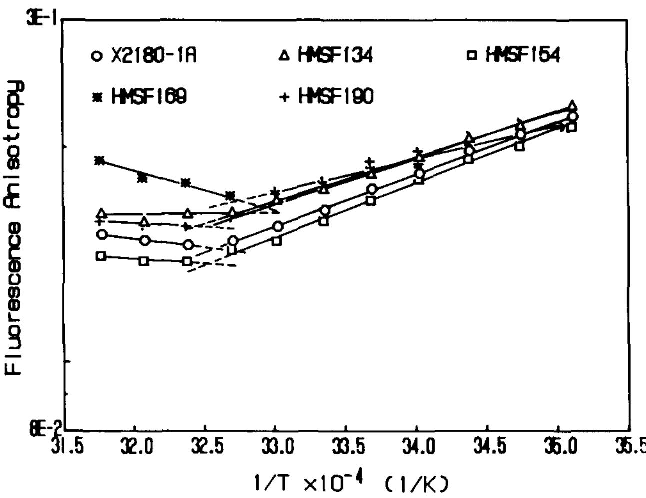

FIG. 3. Fluorescence anisotropy of plasma membrane from secretion mutants (24 C). Plasma membranes were isolated from secretion mutants cultured at 24 C to mid-log phase. The wildtype (X2180-1A) is shown for comparison over the range of 12 to 42 C.

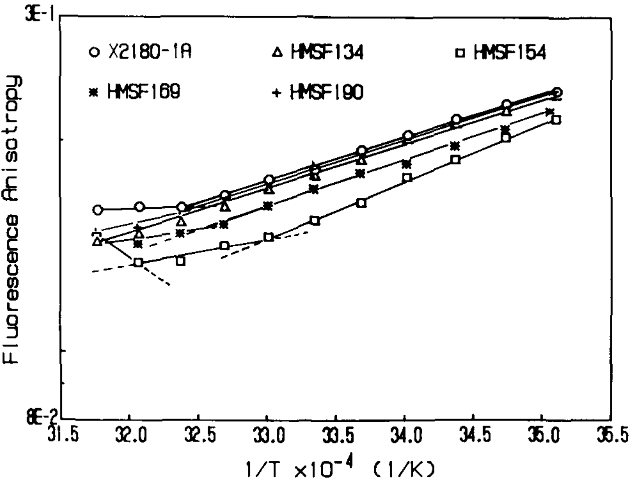

FIG. 4. Fluorescence anisotropy of plasma membrane from secretion mutants (37 C). Plasma membranes were isolated from secretion mutants cultured at 24 C to mid-log phase, then temperature upshifted to 37 C for 2 hr before harvesting. The wild-type (X2180-1A) is shown for comparison over the range of 12 to 42 C. For HMSF134, HMSF154, HMSF169 and HMSF190, the data points nearest the ordinal axis are almost coincident.

In the fluorescence anisotropy plot (Fig. 4), no discontinuity for HMSF134 was observed when the plasma membrane sample was from temperature-stressed cells, while in HMSF134 which had not been temperature-stressed, there was an observed discontinuity. The fact that no discontinuity was observed may be due to maintenance of a large FS pool rather than shunting FS into SE during temperature stress in this HMSF134 (Table 2). The vesicle membranes accumulated in HMSF134 may be enriched in FS that is not shunted into SE. Sterol enrichment of vesicle membrane (nascent plasma membrane at the permissive temperature) may produce larger fluctuations in fatty acid species to compensate for FS enrichment of nascent membrane. Inherent in the plasma

membrane preparation procedure is mixing of pre-existing and nascent (vesicle) plasma membrane. This mixing may produce a modified plasma membrane in which we observe the straight line plot for HMSF134. The mixing of pre-existing and nascent membrane is actually an advantage because it gives an overall distinction between pre-existing plasma membrane and nascent membrane optimized for growth at the permissive temperature, compared to preexisting plasma membrane (optimized for growth at 24 C) mixed with nascent plasma membrane optimized for the restrictive temperature. HMSF134, like the other strains tested, modifies the fatty acid content of its set of phospholipids (Fig. 2A–D). During a temperature upshift, the altered fatty acid composition and additional FS available may be sufficient to prevent loss of membrane integrity measured as a discontinuity in the fluorescence anisotropy plot. The observed discontinuities in the fluorescence anisotropy plots (Figs. 3 and 4) were determined by a least squares fit of the appropriate data points so that the calculated goodness of fit value (r) was >0.99.

Cyclic Fatty Esters: Hydroperoxides from Autoxidation of Methyl 9-(6-Propyl-3-Cyclohexenyl)-(Z)8-Nonenoate

Richard A. Awl*, **Edwin N. Frankel** and **David Weisleder**
Northern Regional Research Center, Agricultural Research Service, U.S. Department of Agriculture, 1815 North University, Peoria, IL 61604

Autoxidation of the cyclic fatty acid ester, methyl 9-(6-propyl-3-cyclohexenyl)-(Z)8-nonenoate (I) was investigated to characterize the hydroperoxide isomers formed and to provide basic information on their chemistry, detection and effect on the quality of polyunsaturated cooking oils. Oxidation at 60 C with 1% hydroperoxide initiator produced a monohydroperoxide fraction containing five positional isomers (7-, 11-, 12-, 13- and 14-OOH), resolved by high performance liquid chromatography, as their allylic hydroxy esters. Their structures were established by ^{1}H- and ^{13}C-NMR spectroscopy and by capillary gas chromatography–mass spectrometry (GC-MS) as trimethylsilyl ether derivatives. Two additional isomers (8- and 9-OOH) were detected by GC-MS in only trace (<1%) quantities. Capillary GC resolved some geometric and stereoisomers, as well as positional isomers. Compared to photosensitized oxidation, two additional positional isomers (11- and 14-OOH) were produced by autoxidation. More stereoisomers were formed, and oxidation of the ring double bond was favored 8:1 over that of the side chain. This selectivity may be attributed to greater steric hindrance for oxygen attack at the side-chain double bond. A free radical mechanism is proposed to explain the greater isomeric complexity of the hydroperoxide products compared to photosensitized oxidation.
Lipids 22, 721–730 (1987).

Research on the autoxidation of fats is of worldwide interest because of nutritional, safety, storage and other economic problems resulting from the oxidative deterioration of fats, particularly those high in polyunsaturated fatty acids. Current understanding of the chemistry of autoxidation of fats has been reviewed recently in detail (1,2). When unsaturated fatty acids in vegetable oils undergo thermal oxidation in air, the primary oxidation products, monohydroperoxides, are formed relatively rapidly, and then react further to yield a variety of polar, secondary oxidation products, including dimers, polymers, volatile and nonvolatile degradation products (3,4).

One aspect of lipid research that has not received much attention is the oxidation of cyclic fatty acids (CFA). Methods are still needed to detect and characterize specific CFA and their reaction products. Previously, we synthesized and characterized a homologous series of CFA of known structures expected in heat-abused fats (5). We later prepared and characterized methyl 9-(6-propyl-3-cyclohexenyl)-(Z)8-nonenoate (I) and its hydrogenated derivatives (6), selected triglycerides (7) and primary photosensitized oxidation products (8). In this paper we report the isolation and characterization of the hydroperoxides formed by free radical autoxidation of the cyclic ester I.

MATERIALS AND METHODS

The preparation of cyclic fatty acid methyl ester (CFAME) I, the spectroscopic, nuclear magnetic resonance (NMR) and the chromatographic methods were essentially the same as described previously (8), except for the conditions for high performance liquid chromatography (HPLC), capillary GC, and GC-MS described below. Where necessary the NMR techniques of correlated spectroscopy (COSY) and selective homonuclear decoupling spectra were used to confirm structural assignments. COSY is a two-dimensional NMR technique used to acquire, in a single spectrum, information on those protons that are mutually coupled (9).

Autoxidation of I. CFAME I (2.0 g) was oxidized by heating isothermally at 60 or 80 C in a test tube with oxygen bubbling at a moderate rate from a capillary inlet tube. To initiate the autoxidation at 60 C it was necessary to add 1% of a hydroperoxide fraction previously isolated from the oxidation of CFAME at 80 C. Samples were analyzed periodically by thin layer chromatography (TLC) to follow oxidation. Autoxidized I was then fractionated by silicic acid chromatography (8), and the monohydroperoxides were further separated by preparative HPLC (10).

Silicic acid chromatography and HPLC of allylic hydroxy esters. The allylic hydroxy derivatives, produced by isolating the hydroperoxide fraction by silicic acid chromatography and reducing with $NaBH_4$, were separated by HPLC under the following conditions: Zorbax Sil preparative column (25 × 2.12 cm, i.d.; 6 μ silica); mobile phase, hexane/CH_2Cl_2/CH_3CN 5:3:0.25 by volume; flow, 4.0 ml/min at 1800 psi; infrared detector; sample injections, ca. 50–60 μl neat. Further separations were achieved by successive HPLC with Partisil M9 preparative column (100 × 0.94 cm, i.d.; 10 μ silica); mobile phase, hexane/CH_2Cl_2/EtOAc, 7:4:1 by vol; flow, 3.0 ml/min at 1100 psi; refractive index detector; sample injection, 16 mg/60 μl CH_2Cl_2. Further separations by HPLC were obtained by changing the mobile phase composition to 7:5:2, by reducing the flow to 1.5 ml/min and by using a Zorbax Sil analytical column (25 × 0.46 cm, i.d.; 5 μ particle size); mobile phase, hexane/CH_2Cl_2/EtOAc 7:4:1; flow, 2.0 ml/min at 600 psi; refractive index detector.

Capillary GC and GC-MS. Capillary GC was performed with a Perkin Elmer Sigma 3B gas chromatograph. Operating conditions were as follows: fused silica column (30 m × 0.24 mm i.d.) of SP2330 (0.2 μm film); linear gas velocity (He), 22.1 cm/sec; split ratio, 80/1; injector, 225 C; detector, 225 C. Column was heated isothermally at 170 C for 22 min and programmed at 10 C/min to 250 C. For GC-MS, a Finnigan MAT 1020/OWA system was used,

RESULTS

Hydroperoxidation. When cyclic ester I was exposed to oxygen at 40 C, no oxidation was observed after 120 hr (see Table 1). At 60 C, oxidation produced only traces of hydroperoxides after 150 hr. However, in the presence of 1% hydroperoxide mixture isolated chromatographically from I as an initiator, autoxidation at 60 C resulted in 30% oxidation products after 80 hr. At 80 C, 18% oxidation occurred after 24 hr and 75% oxidation after 48 hr.

Hydroperoxides expected by the free radical autoxidation of cyclic ester I are shown in Figure 1. The 7-, 11-, 12-, 13- and 14-hydroperoxides were identified in significant amounts (normalized values: 4.2 to 38%) and the 8- and 9-hydroperoxides in minor amounts (0.4 to 1.9%). As in previous papers (5–8), we designate "*cis*" and "*trans*" for the relative geometry of the ring substituents (Δ10,15) of diene I or its derivatives, and "Z" and "E" for the relative geometry of substituents at double bonds of the side chain. Because diene I is initially a mixture of *cis* and *trans* isomers (ca. 25% and 75%, respectively), all hydroperoxides except the 8-OOH isomer consist of both *cis* and *trans* isomers. Because the 8-OOH isomer has a double bond between C-9 and C-10, there can no longer be any *cis/trans* relationship between substituents at C-10 and C-15. The allylic hydroxy esters formed by reducing

the hydroperoxides with $NaBH_4$ are designated as the 7-, 8-, 9-, 11-, 12-, 13- and 14-OH isomers. The saturated trimethylsilyl ether (TMS) derivatives formed by catalytic hydrogenation and silylation of the hydroperoxides or allylic hydroxy esters are designated as 7-, 8-, 9-, 11-, 12-, 13- and 14-TMS, respectively.

High performance liquid chromatography. The hydroperoxide fraction obtained by silicic acid chromatography of autoxidized cyclic ester I, proved to be a complex mixture of isomeric products that was too difficult to separate directly by HPLC. The HPLC separation was improved by reducing the hydroperoxides with $NaBH_4$ (Fig. 2). Major fractions 6–13 were shown by ^1H NMR to consist mainly of allylic hydroxy esters. Minor fractions 1–5 were mixtures of other components. Fractions 8 and 13 were further separated by HPLC under slightly different conditions (Figs. 3A and 4A). Fraction 8-2 was separated by HPLC into two more fractions, 8-2-1 and 8-2-2 (Fig. 3B), shown to consist of pure isomers by ^1H NMR. Fraction 13 (Fig. 3) was similarly resolved into additional components 13-1 and 13-2. Fraction 13-2 was resolved further into fractions 13-2-1, and 13-2-2 (Fig. 4), and they were characterized by ^1H and ^{13}C NMR, GC-MS, and capillary GC.

Nuclear magnetic resonance. Hydroperoxide components in main HPLC fractions (Figs. 2–4) were assigned one of the structures in Figure 1 (Tables 2 and 3) on the basis of ^1H, ^{13}C and distortionless-enhancement-by-polarization-transfer (DEPT) NMR spectra (see Tables 2 and 3). DEPT is a useful, time-saving technique for editing ^{13}C spectra into separate spectra for CH_3, CH_2 and CH groups (9). The ^{13}C NMR spectra provided additional information to identify specific isomers in Figure 1 with individual HPLC fractions. NMR spectra of the 7-, 9-, 12- and 13-OOH stereoisomers (Fig. 1) and their 9-, 12- and 13-OH allylic derivatives agreed with those reported previously (8). There was no evidence for any 8-OH or the 10-OH isomer in our NMR spectra of the major HPLC fractions 6–13.

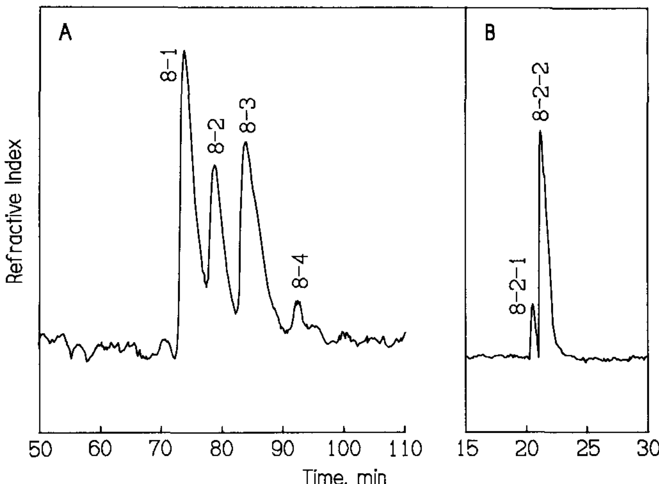

FIG. 3. Separation of $NaBH_4$-reduced hydroperoxides of fraction 8 (Fig. 2) by successive high performance liquid chromatography (HPLC). (A) Preparative column: 100 × 0.94 cm, i.d.; Partisil M9, 10 μ; mobile phase, hexane/CH_2Cl_2/EtOAc, 7:4:1, by vol; flow, 3.0 ml/min at 1100 psi. (B) Separation of fraction 8-2 by HPLC: mobile phase, hexane/CH_2Cl_2/EtOAc, 7:5:2 by vol as mobile phase; flow, 1.5 ml/min.

Values expressed as ppm. NMR, nuclear magnetic resonance; HPLC, high performance liquid chromatography.

[a]See Figures 2–4.

[b]See Figure 1.

[c]Multipliciaties as follows: q, quartet; t, triplet; d, doublet; s, singlet. Resonances common to all samples were: δ174.3 ± 0.1(s) for C-1, δ34.1 ± 0.1(t) for C-2, δ24.8 ± 0.2(t) for C-3, δ14.4 ± 0.1(q) for C-18 and δ51.5 ± 0.1(q) for OCH_3. Resonances varied between isomers over a small range for C-4, δ28.6–29.7(t); C-5, δ25.0–29.4(t); C-16, δ29.5–35.5(t); and C-17, δ19.6–21.2(t).

[d]These assignments may be reversed.

[e]These assignments may be reversed.

Fractions 7 and 11 were shown to have a hydroxyl group at C-7 position, because coupling was observed between the proton on the hydroxyl-bearing carbon and the olefinic protons on carbons 8 and 9 (Table 2). For fraction 8-3, a hydroxyl group in the C-11 position was shown by 2D COSY and selective homonuclear decoupling experiments. The proton on the hydroxyl-bearing carbon was shown to be coupled to H-10, which in turn is coupled to H-9 and H-15 (see Table 2). Components of fractions 6, 8-1 and 8-2-2 were found to have the hydroxyl substituent on C-14. H-14 was coupled to the olefinic protons in the cyclohexene ring but not to H-10 (Table 2).

Slight variations in the proton chemical shifts for the same positional isomers in HPLC fractions of different retention volumes were considered as good evidence of stereoisomerism. For example, the H-10 shifts for the 14-OH isomer varied, from δ2.53 in fraction 6, δ2.50 in fraction 8-1 and δ2.91 in fraction 8-2-2 (Table 2), presumably due to the *cis* and *trans* configuration of side chains. Likewise, for the 13-OH stereoisomers of fractions 10, 12 and 13-1, the H-10 shifts were at δ2.67, δ3.09 and δ3.05, respectively. However, no variation of H-10 shifts (or H-12 or H-13) was observed between 7-OH stereoisomers of fractions 7 and 11, apparently because the OH substituent is relatively less influenced by configurational and conformational differences of the cyclohexene moiety in the 7-OH isomer than in the 11-, 12-, 13- and 14-OH isomers. A comparison of the chemical shifts for carbons as well as protons showed that fractions 10 and 12 (Table 2) correspond to the same 13-OH stereoisomers as previously obtained by photosensitized oxidation of I (8). However, fraction 13-1 corresponds to a different 13-OH stereoisomer. Also, when the 12-OH stereoisomer of fraction 9 (Table 2) was compared with the 12-OH stereoisomer isolated from photosensitized oxidation (8), no differences in these chemical shifts or coupling constants were detected, indicating that the same 12-OH stereoisomer was present in both sources.

Because all of the olefinic protons listed in Table 2 exhibited a vicinal coupling constant of less than 12 Hz, all isomers isolated and identified here by NMR have only Z-double bonds. However, the 7-OH isomer isolated previously from the photosensitized oxidation of I contained an E-double bond at C-8, as evidenced by its coupling constant $J_{7,8}$ = 15.5 Hz (8).

The ^{13}C NMR data (Table 3) were consistent with the ^{1}H NMR data (Table 2) in supporting the structures for the hydroperoxide components, based on previously established assignments (8). Multiplicities of signals were determined by DEPT experiments, and the expected resonances for the side chain propyl and methyl ester groups were observed. Although resonances attributed to C4-6 and C-17 varied between isomers, they were not especially helpful in distinguishing between isomers. Variations in shifts of C-15 and C-16 were due to either *cis* or *trans* ring substitutions. ^{13}C NMR assignments for the olefinic, methinyl and hydroxyl-bearing carbons (C-7 to C-14; Table 3) were most helpful in determining positional isomers. Slight variations in the chemical shifts of C7-14 were observed between stereoisomers in spectra of HPLC fractions 10, 12 and 13-1. Fraction 10 had the same ^{13}C chemical shifts as the previously reported 13-OH stereoisomer (8).

GC-MS characterizations. Characteristic MS and interpretations of the electron-impact (EI) MS fragmentations for the positional isomers 7-, 8-, 9-, 12- and 13-TMS were reported in our previous investigation of the photooxidation of cyclic ester I (8). The 11- and 14-TMS isomers were characterized by MS because they are derived from unique hydroperoxides of the autoxidation of I (Fig. 1). The cyclohexanol cleavage mechanism was previously invoked to explain the fragmentation of isomers 13-TMS

FIG. 5. Proposed electron impact-mass spectrometry fragmentations for hydrogenated trimethylsilyl ether derivatives of: (A) 11- and 14-OOH isomers and (B) 10-OOH isomer (Fig. 1).

and 12-TMS, giving the characteristic masses of the 13-TMS (m/z = 171) and 12-TMS (m/z = 299) isomers for selected ion monitoring (11). However, the cyclohexanol cleavage of isomeric 11-, 14- and 10-TMS derivatives produces only common mass fragments (Fig. 5). The favored mass fragment m/z 129 predicted by this cleavage mechanism was also relatively abundant in the EI-MS spectra of the other positional isomers, 7-, 8-, 9-, 12- and 13-TMS. Any other characteristic mass fragments were either too weak to detect or absent in the EI-MS of HPLC fractions 6, 8-2, 8-3 and 8-4, composed of either 11- or 14-TMS (Table 4). Likewise, on the basis of the cyclohexanol cleavage mechanism (Fig. 5B), EI-MS of 10-TMS isomer was not expected to yield a characteristic mass useful for mass chromatography, because the favored mass fragment m/z = 299 is also produced by isomer 12-TMS (8). The allylic 10-OH isomer was not detected by NMR in any reduced HPLC fractions isolated from either photooxidation (8) or autoxidation products of I.

The hydroperoxide components of fractions 6, 8-2-2 and 8-4 (Figs. 2–4) were all shown to have essentially the same skeletal structure by MS. Fraction 6 gave the following representative mass fragments (after hydrogenation and silylation), m/z (rel int): M-15, 369 (2.0); M-31, 353 (1.9); 341 (2.3); 337 (7.5); M-90, 294 (24); 252 (9.0); 171 (4.6); 159 (7.8); 151 (11.5); 138 (17.3); 129 (50); B, 73 (100); 43 (27). These results together with NMR spectra show that these fractions contain methyl 14-hydroxy-9(2-propylcyclohexyl) nonanoate (as 14-TMS). Similarly, EI-MS of fraction 8-3 gave the following representative fragments (after hydrogenation and silylation), m/z (rel int): M-15, 369 (1.7); M-31, 353 (0.9); 341 (4.2); M-90, 294 (19.2); 285 (0.9); 251 (7.4); 171 (9.3); 159 (7.1); 151 (4.1); 143 (8); 137 (13.4); 129 (46.3); 81 (44.1); B, 73 (100); 43 (26.5). These data together with NMR spectra are consistent with the methyl 11-hydroxy-9-(2-propylcyclohexyl)nonanoate (as 11-TMS), derived from the 11-OOH isomer.

Hydroperoxides present in the minor HPLC fractions 1–5 (Fig. 2) could be identified by GC-MS and capillary GC retention. GC-MS showed that ca. 81% of fraction 1 was unreacted I (Table 4). About 44% of fraction 2 consisted of 8-TMS isomers, but >50% could not be identified. Approximately 30% of fraction 4 was due to 13-TMS isomers and 16% to 12-TMS isomers. Fractions 3 and 5 were not identified. The 9-TMS derivative was only detected in fractions 2 and 5 and represented only ca. 2–3% and ca. 4%, respectively.

Capillary GC. Different positional isomers have geometric or stereoisomers with identical or nearly identical relative retentions (Table 4). These relative retentions may be shifted slightly by variations in the sample size or composition, and this type of evidence alone cannot be relied upon to positively identify positional isomers, especially when particular stereoisomers of different positional isomers showed differences of only 0.02 units or less in relative retentions. Therefore, confirmation of their identity by mass chromatography was required.

The isomeric composition of the isolated hydroperoxide fraction was determined quantitatively by capillary GC of the saturated TMS derivatives (Table 5, Fig. 6). About 19% unidentified material eluted after the TMS

[b]Fraction isolated by silicic acid chromatography (10).

[c]Methyl 9-(6-propyl-3-cyclohexenyl)-(Z)8-nonenoate oxidized at 60 C for 80 hr (see Table 1). *Trans* and *cis* refer to ring substituents at C-10 and C-15.

[d]Identity as hydroperoxide precursor or diene I isomers, based on previous GC-MS, mass chromatography and nuclear magnetic resonance correlations.

[e]Normalized after excluding I (*cis* and *trans*). u = Unresolved peak.

[f]Retention time (t_r) = 10.00 min.

[g]Tentative assignments, based on previous relative retentions (Table 4).

derivatives. Capillary GC analyses indicated that initially the major portion (ca. 57%) consisted of 26.3% 13-OOH and 30.6% 12-OOH. A smaller portion (23% or less) consisted of 3.4% 11-OOH, 11.6% 14-OOH, 7.2% 7-OOH and 1.5% 8-OOH. Only a trace (ca. 0.3%) of 9-OOH was identified in the primary oxidation fraction. Thus, unlike photooxidation at 0 C (8), autoxidation of I at 60 C favored the formation of hydroperoxides from the ring double bond by a ratio of 8:1 over the side-chain double bond of I.

When the HPLC fractions containing allylic OH esters were hydrogenated, saturated isomers of I (defined as IS) were formed. The *trans* and *cis* saturated isomers of rel retention 1.00 and 1.08, respectively, were detected by capillary GC and GC-MS (Table 4). The occurrence of these geometric isomers is attributed to catalytic hydrogenolysis of the allylic hydroxy esters followed by their hydrogenation (12). Because the IS isomers were formed by hydrogenation only, they were not present in the initial HPLC fractions analyzed by NMR. However, the fortuitous formation of *cis* and *trans* IS isomers in the hydrogenated fractions allowed us to calculate the relative retention times of the corresponding TMS isomers. Geometric TMS isomers were tentatively assigned, therefore, on the basis of the respective ratio of the IS peaks. For example, in fraction 6, GC showed 39.9% *trans* IS but only 2.1% *cis* IS with only one major peak (47.7%) corresponding to *trans* 14-TMS (R_r = 1.37). Therefore, the tentative assignment of *trans* and *cis* 13-TMS isomers with characteristic m/z = 171 (8) was made on the basis of the observed ratio of the respective IS isomers.

DISCUSSION

Cyclic fatty acids are generally considered to be formed in only trace amounts in heated fats. However, recent analyses revealed monomeric CFA at levels ranging from 0.1% to 0.5% in commercial frying oils in the U.S. (13). Therefore, little or no oxidation of CFA might be expected in the presence of the usual amounts of linoleate and linolenate in vegetable oils. Concentrated mixtures of CFA isolated from severely thermally abused oils were found to be toxic when fed experimentally to animals in high doses (14–18). However, because these feeding studies were generally conducted only with mixtures of CFA, those chemical structures responsible for the observed toxicity have not yet been determined (17–19).

In the photosensitized oxidation of diene I, concerted addition of singlet oxygen and double bond migration produced the (E)7-, 8-, (E)9-, 12- and 13-hydroperoxide (OOH) isomers (14). The 7-, 10-, 11- and 14-OOH isomers may be formed from the 8-, 9-, 12- and 13-OOH by allylic rearrangement (8). However, by free radical autoxidation, the 7-, 10-, 11- and 14-OOH positional isomers (see Fig. 1) are expected to be formed as primary products directly from I. All positional isomers of the hydroperoxides of Figure 1 have three stereocenters and 2^3 possible stereoisomers, except the 8-OOH and 10-OOH isomers. The latter have only two stereocenters and 2^2 possible stereoisomers. Many of these stereoisomers were partially resolved by capillary GC. The hydroperoxide mixtures characterized in this study are more complex than the hydroperoxides from photosensitized oxidation of cyclic ester I (8), because positional, geometric (E-,Z- and Z-,Z-) and stereoisomers are formed in unequal proportions. The autoxidation of I produced the 11- and 14-OOH isomers not previously found in photosensitized oxidation (8). The presence of these new hydroperoxide isomers supports the free-radical mechanism shown in Figure 1.

The different distribution of hydroperoxide isomers summarized in Figure 1 can be attributed to steric hindrance from the side chains of the cyclohexene in I. Oxygen attack at the end carbons of the allylic free

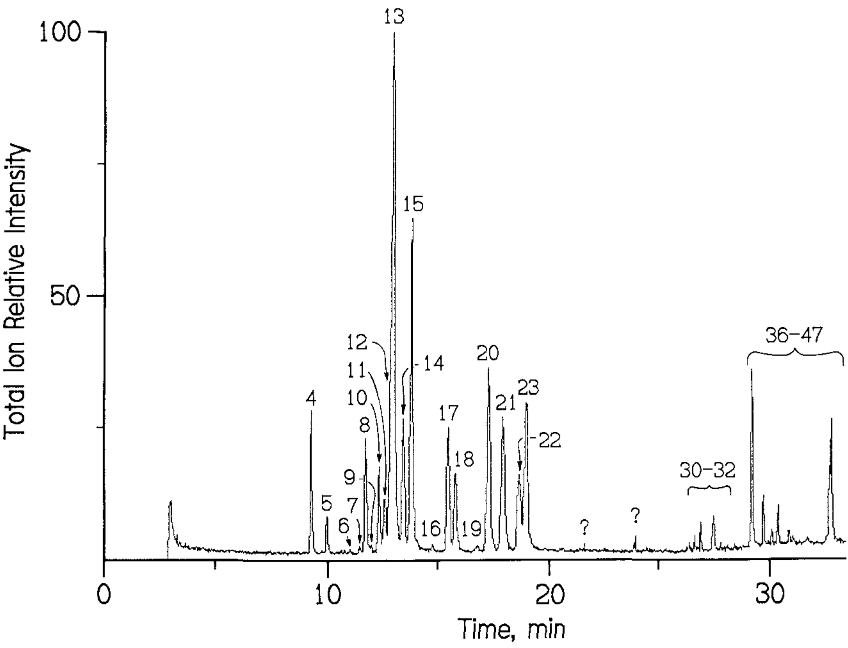

FIG. 6. Capillary gas chromatography-mass spectrometry fragmentations for hydrogenated trimethylsilyl ether derivatives of: (A) 11- and 14-OOH isomers and (B) 10-OOH isomer (Fig. 1).

FIG. 7. Alternate free radical cyclization mechanism.

radicals is hindered in varying degrees by the ester and propyl side chains. Formation of the 12- and 13-OOH isomers is most favored, because the 12- and 13-carbons are farthest from the side chains and least hindered. The longer and bulkier ester side chain exerts more steric hindrance at an adjacent carbon than the shorter propyl group. Therefore, the 14-OOH isomer is formed in larger amount than the 11-OOH isomer. Likewise, because carbon-7 is more accessible than carbon-9, more 7-OOH isomer is formed than 9-OOH isomer. The 9- and 10-carbons appear least accessible to oxygen attack. The 9-OOH isomer is formed in only trace amounts, and the absence of 10-OOH isomer can be explained by the inaccessibility of the trisubstituted carbon-10 to oxygen

attack. The intermediate allylic radical B may not be formed because of this steric hindrance.

An alternative mechanism to explain the absence of the 10-OOH isomer and the relatively low concentration of the 11-OOH isomer may involve the homo-allylic double bond leading to 1,3-cyclization of their peroxyl radicals (Fig. 7). This type of cyclization was proposed for the formation of bicycloendoperoxides from polyunsaturated fatty acids containing three or more double bonds (20). Similar five-membered hydroperoxy epidioxides were identified in autoxidized methyl linolenate (10,21,22). These secondary oxidation products are formed by cyclization of the 12- and 13-hydroperoxyl radicals of linolenate. This reaction accounts for the concentrations of the internal 12- and 13-hydroperoxide isomers being lower than the external 9- and 16-OOH isomers, a well-known characteristic of linolenate autoxidation (1,2). However, the cyclization mechanism of Figure 7 needs to be substantiated by further characterization of the secondary oxidation products of I.

The present work reports the successful application of high resolution NMR and mass spectrometry to the characterization of hydroperoxides formed from the autoxidation of a CFA that contains a center of unsaturation both in a six-membered ring and in a chain substituent. By this approach, the relative oxidative susceptibility of each type of double bond was determined.

Our results also indicate that pure ester I or its CFA would undergo autoxidation even at 60 C if initiated by other hydroperoxides, to generate a complex mixture of isomeric cyclic hydroperoxides. This hydroperoxide mixture may readily undergo secondary oxidations to form condensation and decomposition products. This information should aid other investigators in analyzing, identifying and isolating CFA hydroperoxides in heated fats and in evaluating their effects on the quality and nutritional deterioration of polyunsaturated fats.

[Received April 14, 1987]

Characterization of Phospholipase A_2 from Rabbit Lung Microsomes[1]

Octávio M.O. Filgueiras[a] and **Fred Possmayer**[a,b,*]
Departments of [a]Obstetrics and Gynecology and [b]Biochemistry, University of Western Ontario, London, Ontario, Canada

A phospholipase A_2 activity associated with the microsomal fraction of rabbit lung homogenates was studied. The enzyme showed specificity for the *sn*-2 ester bond of phosphatidylcholine, had an alkaline pH optimum and required Ca^{2+} for activity. Other divalent cations were unable to support hydrolysis. In the absence of detergents, exogenous phosphatidylethanolamine was deacylated at a rate sevenfold higher than phosphatidylcholine. The activity toward both substrates could be enhanced by sodium deoxycholate or, more effectively, by sodium taurodeoxycholate. Phosphatidylethanolamine required higher detergent/phospholipid molar ratios than phosphatidylcholine. Under these conditions, the preference for the former substrate over the latter was nearly abolished. The zwitterionic detergent 3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate (CHAPS) and the nonionic detergent Triton X-100 were either ineffective (phosphatidylcholine) or inhibitory (phosphatidylethanolamine). Addition of KCl produced opposite effects on the activity depending on the bile salt used to disperse the substrate. The phospholipase A_2 activity was inhibited by *p*-bromophenacyl bromide but remained unaffected after treatment with diisopropylfluorophosphate or NaF. N-Ethylmaleimide, but not other thiol reagents, partially inhibited the activity.
Lipids 22, 731–735 (1987).

Phospholipase A_2 (EC 3.1.1.4) catalyzes the hydrolytic removal of a fatty acyl chain from the *sn*-2 position of phospholipids. While secretory phospholipases A_2 such as those from the venoms of serpents and arthropods and from pancreatic juice have been studied in great detail (1), much less is known about their intracellular counterparts, including their exact physiological function(s) (2). A distinctive characteristic of the latter group of phospholipases is their relatively low activity under the experimental conditions habitually used (1,2).

The presence of phospholipases in lung tissue is well documented. Following the initial observations made with whole homogenates (3-6), Otha et al. (7) described a Ca^{2+}-independent phospholipase A_2 in rat lung high-speed supernatant that was inhibited by fluoride and by sodium deoxycholate. A second Ca^{2+}-independent activity, specific for 1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (platelet-activating factor), was later reported in lung cytosol (8). Recently these two phospholipases have been separated not only from each other but also from yet a third cytosolic, Ca^{2+}-dependent phospholipase A_2 (9). Garcia and coworkers showed that while rat lung mitochondria and microsomes both contained phospholipase A_2 (10), no activity was associated with the lamellar bodies (11). These findings were confirmed for microsomes and lamellar bodies from rat lung by Longmore et al. (12). However, lamellar bodies from rabbit lungs were reported to express phospholipases A_1 and A_2 (13). In lung homogenates from rabbits and dogs, phospholipase A_2 was demonstrated in nearly all subcellular fractions (14).

We decided to study phospholipase A_2 in lung microsomes because of the generally accepted involvement of these membranes in phospholipid biosynthesis (15,16) and the reported absence of appreciable phospholipase A_1 in lung microsomal preparations (10,12,17). In the present work, we confirm the specificity of the enzyme[2] for the *sn*-2 position of phosphatidylcholine and describe the optimal conditions for its assay with exogenous substrates as well as the effects of detergents, salt, inhibitors and divalent cations.

MATERIALS AND METHODS

Materials. Water was deionized through a Milli-Q Reagent Water System (Millipore, Mississauga, ON, Canada). Radioactive substrates were from NEN (DuPont, Montreal, PQ, Canada). Phosphatidylethanolamine, obtained from egg phosphatidylcholine by transphosphatidylation, and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine were from Avanti Polar Lipids (Birmingham, AL). Dipalmitoylphosphatidylcholine, sodium deoxycholate, sodium taurodeoxycholate, diisopropylfluorophosphate and *p*-hydroxymercuribenzoate were from Sigma Chemical Co. (St. Louis, MO). *p*-Bromophenacyl bromide was from Aldrich (Milwaukee, WI). 3-[(3-cholamidopropyldimethylammonio]-1-propanesulfonate (CHAPS) and Triton X-100 were purchased, respectively, from Boehringer Mannheim (Dorval, PQ, Canada) and J.T. Baker (Phillipsburg, NJ). LK6D thin-layer plates were from Whatman (Clifton, NJ). All other reagents were from BDH (Toronto, ON, Canada).

Isolation of microsomes. Pregnant New Zealand White does of 24 days gestation whose fetuses were used in other experiments were killed by intravenous injection of pentobarbital, and their lungs were excised. After being washed the lungs were briefly disrupted in a Waring blender and homogenized in a Potter-Elvehjem tube in 0.25 M sucrose, 1 mM EDTA, 10 mM Tris-HCl (pH 7.4) to yield a 10% (w/v) homogenate. After centrifugation at 1,000 × g for 5 min, the resulting supernatant was centrifuged at 20,000 × g for 20 min. The supernatant obtained from the latter centrifugation was then subjected to centrifugation at

Abbreviation: CHAPS, 3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate.

[2]The word "enzyme" is used throughout for the sake of simplicity. Especially because lung microsomal preparations result from a heterogeneous population of cells, the possibility exists that such preparations contain different proteins with phospholipase A_2 activity.

105,000 × g for 1 hr. The resulting pellet (henceforth referred to as microsomes) was then gently resuspended in the same buffer at an approximate protein concentration of 10 mg/ml, immediately frozen and kept at -80 C until use.

Phospholipase A_2 assay. Unless indicated otherwise in figure legends, the standard incubation mixtures (final volume 0.2 ml), made up in 100 mM Tris-HCl (pH 8.5), contained 20 nmol of EDTA, 2 μmol of $CaCl_2$, 1.5 μmol of sodium taurodeoxycholate and 1.6 μmol of 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-phosphocholine (specific radioactivity 300–400 dpm/ nmol). In some cases, 1.6 μmol of a mixture of 1-palmitoyl-2-[1-^{14}C]arachidonoyl-*sn*-glycero-3-phosphoethanolamine and unlabeled phosphatidylethanolamine (see *Materials*) to give a specific radioactivity of 300-400 dpm/ nmol was used under conditions described in the figure legends. The reaction was started by the addition of 80 μg of microsomal protein (corresponding to ca. 65 nmol of membrane phospholipid) and incubated at 37 C. After 1 hr, the volume was adjusted to 0.5 ml with water, and the mixture was subjected to a modified Dole extraction, essentially as described by van den Bosch and Aarsman (18). Blanks without microsomes were always included, and the results were corrected for the background radioactivity thus extracted (less than 0.05% of the total radioactivity of the assay mixture even when detergents were present).

Except for the positional specificity of the enzyme (Fig. 2), which was determined only once in duplicate, the results are representative of at least two similar experiments carried out with different microsomal preparations. In all cases, each data point is the average of duplicate determinations whose average deviation from the mean was less than 8%.

Analytical techniques. Protein was determined by the method of Lowry et al. (19) using bovine serum albumin as standard.

RESULTS

The optimal conditions for lung microsomal phospholipase A_2 activity toward exogenous phosphatidylcholine were determined by studying the influence of pH, time and the concentrations of $CaCl_2$, sodium deoxycholate and phosphatidylcholine. The activity was optimal at pH 8.5, linear with protein concentration until at least 0.6 mg/ml and linear with incubation time for at least 80 min (not shown). The deacylation was dependent on the presence of Ca^{2+} (optimal concentration 10 mM, not shown). Other divalent cations were either totally ineffective or replaced Ca^{2+} to a very limited extent (Table 1). When using phosphatidylcholine as substrate, the activity was barely detectable in the absence of sodium deoxycholate (Fig. 1A). The optimal deoxycholate concentration depended on the concentration of substrate (not shown) and, in general, nearly equimolar amounts of bile salt and phosphatidylcholine were required. Concentrations of substrate around and below the critical micellar concentration of deoxycholate (20) required a proportionally higher amount of detergent, presumably reflecting the inability of the bile salt to stimulate hydrolysis at levels incompatible with micelle formation (note also the lag phase in Fig. 1B). Using optimal deoxycholate/phosphatidylcholine molar ratios, saturation kinetics could be obtained (not shown). However, the observation that deoxycholate precipitates with Ca^{2+} prompted us to look for a detergent compatible with that cofactor. Since the precipitation mentioned above and noted previously by others (21) is due to the free carboxylic group (22), a bile acid conjugated with an amino sulfonic acid was an obvious alternative to deoxycholate. Therefore, sodium taurodeoxycholate was chosen and its ability to stimulate phospholipase A_2 was compared with that of its nonconjugated counterpart. In addition, since the charge of substrate dispersions is known to be an important factor for the

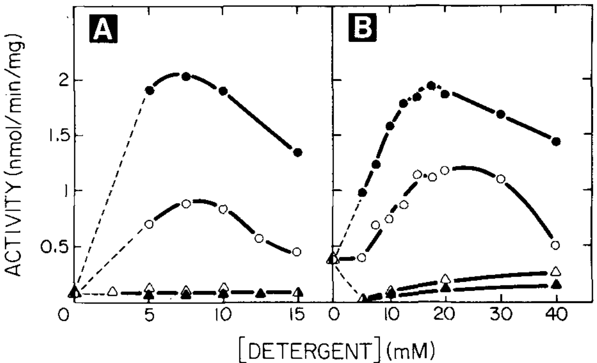

FIG. 1. Effects of different detergents on lung microsomal phospholipase A_2 activity. Except for the detergent used—sodium deoxycholate (○), sodium taurodeoxycholate (●), CHAPS (△) or Triton X-100 (▲)—at the indicated concentrations, standard incubation mixtures were carried out either with phosphatidylcholine (A) or phosphatidylethanolamine (B). For Triton X-100, an average M_r = 646 Da was used.

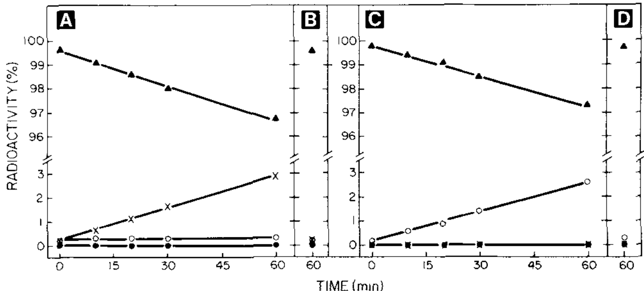

FIG. 2. Distribution of radioactivity after incubation of two differently labeled phosphatidylcholines with rabbit lung microsomes. Standard incubation mixtures were used except for the substrate, which was either 1-palmitoyl-2-[1-^{14}C]palmitoyl-*sn*-glycero-3-phosphocholine (A, B) or 1,2-dipalmitoyl-*sn*-glycero-3-phospho[*Me*-^{14}C] choline (C, D). Panels B and D represent blank incubations without microsomes. At the indicated times, the mixtures were adjusted to 1 ml with 19 mM H_2SO_4 and extracted (24). After evaporation under N_2, the chloroform-methanol phases were analyzed by thin-layer chromatography (25), and the areas corresponding to phosphatidylcholine (▲), lysophosphatidylcholine (○) and fatty acids (×) were scraped and counted for radioactivity. The water-methanol phases were evaporated overnight at 60 C and counted for radioactivity (●). Results are expressed as percentage of the total radioactivity recovered.

TABLE 1

Effect of Different Divalent Cations on Phospholipase A_2 Activity from Lung Microsomes

Cation	Activity (%)
Ca^{2+}	100
Cd^{2+}	10
Sr^{2+}	8
Mn^{2+}	7
Mg^{2+}	6
Ba^{2+}	4
Co^{2+}	2
Ni^{2+}	2
Cu^{2+}	2

Standard incubation conditions were used with phosphatidylcholine as substrate, except that divalent cations (as chlorides) were added to give final concentrations of 10 mM. Data are expressed as percentage of the activity obtained with $CaCl_2$ (1.8 nmol/min/mg) after correction for background hydrolysis in the absence of added ions (21 pmol/min/mg).

activity of a number of lipolytic enzymes (23), some incubations were performed with the zwitterionic bile salt analogue CHAPS or with the nonionic detergent Triton X-100. Parallel experiments were conducted with phosphatidylcholine (Fig. 1A) and phosphatidylethanolamine (Fig. 1B) as exogenous substrates. For ease of comparison, all the incubations depicted in Figure 1 were done with the same microsomal preparation. It is clear that in the absence of detergent, phosphatidylethanolamine was hydrolyzed at least sevenfold faster than phosphatidylcholine. In keeping with the results previously obtained with phosphatidylcholine (Fig. 1A), the addition of sodium deoxycholate increased the enzymatic specific activity toward phosphatidylethanolamine (Fig. 1B). However, the optimal bile salt concentration was considerably higher for this substrate (note the different scales for detergent concentration in panels A and B, Fig. 1). Regarding the stimulation of activity toward phosphatidylcholine and phosphatidylethanolamine, it is interesting to note that the addition of sodium deoxycholate to mixtures of $CaCl_2$ and substrate produced macroscopic changes that were much more dramatic in the case of phosphatidylethanolamine. This occurred even at the lower detergent levels (5-15 mM) and resulted in the separation of large aggregates (presumably containing phosphatidylethanolamine, Ca^{2+} and deoxycholate) from an optically clear liquid phase.

Optimal concentrations of taurodeoxycholate stimulated the activity to about twice the levels obtained with optimal concentrations of deoxycholate (Fig. 1). Again, phosphatidylethanolamine required relatively higher detergent concentrations.

On the other hand, addition of either CHAPS or Triton X-100 failed to change the very low activities obtained with exogenous phosphatidylcholine in the absence of any detergent (Fig. 1A), and both detergents inhibited the deacylation of phosphatidylethanolamine, particularly at concentrations of 5-10 mM (Fig. 1B).

The specificity of the deacylating activity regarding the two acyl chains of the substrate was investigated by carrying out two similar incubations, one using phosphatidylcholine radiolabeled in the *sn*-2 acyl chain and the other using a choline-labeled substrate, and analyzing the distribution of radioactivity at various time intervals. The specificity of the microsomal phospholipase toward the *sn*-2 acyl chain of the substrate can be concluded from the absence of any measurable phospholipase A_1 (Fig. 2A) and any phospholipase B (or a combination of a phospholipase A_1 and a lysophospholipase) (Fig. 2C). These findings were corroborated in a more quantitative manner by the stoichiometry of the reaction: calculations based on the slopes of the regression lines depicted in Figure 2A showed that palmitate became unesterified at a rate comparable to that of phosphatidylcholine hydrolysis (0.76 and 0.72 nmol/min, respectively). Similarly, for the choline-labeled substrate (Fig. 2C), the rate of phosphatidylcholine degradation equaled that of lysophosphatidylcholine formation (0.66 nmol/min).

Since at some stage in its purification the microsomal phospholipase A_2 will likely require the use of salt, we investigated the effect of KCl on the activity. Again, phosphatidylcholine (Fig. 3A) or phosphatidylethanolamine (Fig. 3B) were used as substrates and optimal concentrations of deoxycholate or taurodeoxycholate were employed in each case (cf. Fig. 1). Phosphatidylethanolamine was also used in the absence of any detergent. As shown in Figure 3, the KCl effects were qualitatively independent of the substrate used but strongly dependent on whether the assay system contained deoxycholate (activation) or taurodeoxycholate (inhibition).

The influence of several compounds on lung microsomal phospholipase A_2 activity is indicated in Table 2. In keeping with the Ca^{2+} dependency mentioned

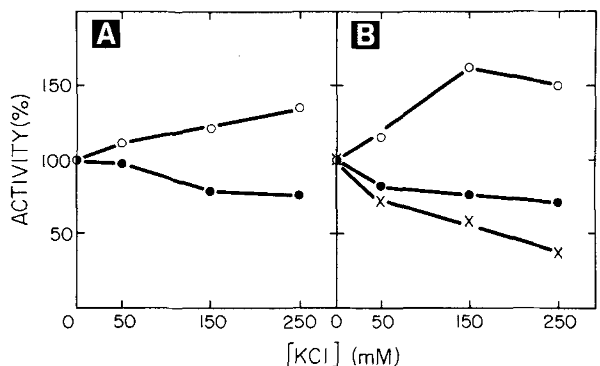

FIG. 3. Effects of KCl on lung microsomal phospholipase A_2 activity. The enzymatic activities were determined in the presence of the indicated KCl concentrations with standard incubation mixtures containing phosphatidylcholine (A) and 7.5 mM sodium deoxycholate (○) or 7.5 mM sodium taurodeoxycholate (●); or phosphatidylethanolamine (B) and 17.5 mM sodium deoxycholate (○), 17.5 mM sodium taurodeoxycholate (●) or no detergent (×). Phospholipase A_2 activity is expressed as percentage of the activity obtained for each detergent/phospholipid combination without KCl.

TABLE 2

Influence of Various Reagents on Phospholipase A_2 Activity from Lung Microsomes

Reagent in preincubation	Concentration during preincubation (mM)	Residual activity (%)
None	—	100
EDTA	40	3
p-Bromophenacyl bromide	0.4	8
	4	2
N-Ethylmaleimide	8	65
Iodoacetamide	8	84
p-Hydroxymercuribenzoate	8×10^{-3}	97
	8	82
NaF	8	95
Diisopropylfluorophosphate	8	90

Microsomes (80 μg protein) were preincubated at 37 C in the presence of the indicated reagents (total volume 123 μl). After 30 min, the tubes were placed in ice, and phosphatidylcholine, EDTA and taurodeoxycholate were added to give standard assay concentrations (see Materials and Methods). The assay of residual phospholipase A_2 activity was initiated by addition of $CaCl_2$ (final concentration 10 mM) and incubation at 37 C (total volume 0.2 ml). Results are expressed as percent activity relative to that of microsomes preincubated with buffer alone (3 nmol/min/mg).

above, an excess of EDTA resulted in an almost complete loss of activity. While virtually no activity could be recovered after preincubation of microsomes with the alkylating reagent *p*-bromophenacyl bromide, no marked inhibitory effects were obtained with diisopropylfluorophosphate or fluoride. Among the thiol reagents tested, only N-ethylmaleimide reduced the activity to a considerable extent.

DISCUSSION

The optimal pH and Ca^{2+} levels required by phospholipase A_2 from rabbit lung microsomes are similar to those reported for the microsomal enzyme from rat lung assayed with either exogenous (10) or endogenous (12) substrates. However the results obtained with divalent cations (Table 1) contrast with reports indicating that some of these ions, particularly Sr^{2+} and Mg^{2+}, can partially support other Ca^{2+}-dependent phospholipases (26–28).

In agreement with previous evidence obtained from rat lung microsomes (12), microsomal preparations obtained from rabbit lung also failed to significantly deacylate exogenous phosphatidylcholine (Fig. 1A). However, hydrolysis could be greatly stimulated by the addition of sodium deoxycholate (Fig. 1A and Ref. 17). In a search for a Ca^{2+}-compatible detergent, we found that replacement of deoxycholate with taurodeoxycholate resulted in a roughly twofold stimulation of the activity (Fig. 1). Interestingly, the optimal Ca^{2+} concentration did not change when taurodeoxycholate replaced deoxycholate (not shown). The importance of the detergent's negative charge in bile salt stimulation of the microsomal phospholipase is suggested by the failure of CHAPS to stimulate the activity (Fig. 1). This detergent is a zwitterionic bile salt analogue whose resemblance to bile salts extends to its membrane-solubilizing properties (29). Therefore, regarding its preference for negatively charged substrate-water interfaces, this enzyme is more similar to pancreatic than to snake venom phospholipases A_2 (30–33). This view is further strengthened by the experiments depicted in Figure 1 with Triton X-100, a nonionic detergent commonly employed in the assay of snake venom phospholipases A_2 (34).

The apparent preference of the pulmonary microsomal phospholipase for phosphatidylethanolamine over phosphatidylcholine in the absence of detergents (Fig. 1) has also been observed with a number of other membrane-bound phospholipases (35 and references therein). As recently shown for rat liver mitochondria, this preference does not reflect true enzyme specificity but rather the ability of phosphatidylethanolamine to achieve a more extensive association with the enzyme-containing membranes (35). As a corollary, it follows that there should be no difference in the rates of deacylation of these substrates when a preassociation of the substrate with enzyme-containing membranes is prevented, for example, by solubilization. Comparable enzymatic activities toward both substrates can indeed be obtained at optimal bile salt concentrations (Fig. 1), indicating that an interpretation similar to that derived for mitochondrial phospholipase (35) might be appropriate for the apparent specificity of the lung microsomal enzyme in the absence of detergents.

The experiments conducted with KCl (Fig. 3) illustrate how the addition of simple ions can cause opposite effects on phospholipase A_2 activity, simply by replacing a conjugated bile salt with its unconjugated counterpart. These results emphasize the need for caution when drawing general conclusions from lipolytic reactions conducted in the presence of detergents (2).

The data obtained with *p*-bromophenacyl bromide and with diisopropylfluorophosphate (Table 2) suggest the importance of a histidine rather than a serine

residue at the active site of the enzyme from lung microsomes and make it comparable, in this regard, to most of the phospholipases A_2 studied so far (1). In agreement with the view that this class of enzymes lacks free sulfhydryl groups (1), most of the thiol reagents tested were unable to appreciably inhibit the activity (Table 2). The reason why N-ethylmaleimide partially inhibited the enzyme is not clear at present but, in view of the fact that *p*-bromophenacyl bromide can react with sulfhydryl groups (36,37), the possibility remains that free sulfhydryls are critical for this enzyme's activity. Obviously, the clarification of this and other questions must await the eventual purification of the enzyme.

ACKNOWLEDGMENTS

The authors would like to thank M. Ormseth and M. Quirie for providing the rabbit lungs. This work was supported by the Canadian MRC (F.P.) and the Canadian Lung Association (O.M.O.F.).

Suckling mice were injected daily from birth for 10 days with potent preparations of mouse interferon α/β. Interferon treatment resulted in a markedly lower concentration of polyunsaturated fatty acids (20:4ω6 and 22:6ω3) in the two principal liver phospholipids, phosphatidylcholine and phosphatidylethanolamine, than in livers of control-treated mice. This effect appeared to correlate with a low level of synthesis of polyunsaturated phospholipids in the livers of interferon-treated mice. Thus, in control mice, synthesis of species of polyunsaturated phospholipids increased markedly in the first 10 days of life, whereas in 10-day-old interferon-treated mice, the level of synthesis of species of polyunsaturated phospholipids was comparable to that in newborn mice. In parallel, a marked increase in the diacylglycerol content without change of its renewal was observed in the livers of interferon-treated mice. We suggest that interferon treatment results in an inhibition of one of the processes that leads to activation of the enzymatic systems responsible for the synthesis of species of polyunsaturated phosphatidylcholine and phosphatidylethanolamine in the liver of suckling mice. It seems likely that these results are related to the inhibition of liver cell maturation and the marked cell necrosis that are observed in interferon-treated suckling mice.
Lipids 22, 736–743 (1987).

Administration of potent preparations of interferon α/β to suckling mice in the first week of life results in inhibition of growth, diffuse liver cell necrosis and death (1). Recently we showed that this interferon treatment resulted in a marked increase in liver triglycerides and a decrease in the level of some hepatic phospholipids (2). Whereas the percentage of liver phospholipids (PL) (relative to liver protein) increased in the first week of life for normal suckling mice, it decreased in the livers of interferon-treated mice (2). These biochemical modifications, not observed in adult mice (2), were accompanied by the appearance of abnormal tubular aggregates arising from the endoplasmic reticulum of hepatocytes (3,4), suggesting important alterations in the lipid-protein interactions at the level of these membranes (5).

There have been several reports indicating that, in vitro, interferon induced changes in the fatty acid composition of PL in cells. Thus, Chandrabose et al. (6) observed that mouse interferon induced a decrease in the unsaturated fatty acid content of all the major PL in mouse sarcoma cells, and Apostolov and Barker (7,8) showed that human interferon reduced the C18 unsaturated fatty acid content of human fibroblasts and bovine kidney cells. These changes may contribute to the observed increased rigidity of the plasma membrane lipid bilayer of some interferon-treated cells (9). The results presented herein indicate that in vivo, interferon induces similar biochemical modifications in suckling mice as a result of alterations in the metabolism of the polyunsaturated molecular species of liver PL.

MATERIAL AND METHODS

Mice. Litters of Swiss mice were obtained from the pathogen-free colony at the Institut Recherches Scientifiques sur le Cancer, Villejuif, France.

Interferon preparation. Mouse interferon α/β was prepared from suspension cultures of mouse sarcoma C243 cells inoculated with Newcastle disease virus (NDV). The methods of production and purification have previously been described (10). Interferon was assayed by inhibition of cytopathic effect of vesicular stomatitis virus on L cells in monolayer culture (0.2 ml/well) in Falcon microplates. Units in the text are expressed as international mouse reference units. The specific activity of this purified interferon was ca. 2×10^7 units/mg protein. Control preparations consisted of supernatant from cultures of C243 cells prepared in exactly the same way as interferon except that the interferon inducer, NDV, was omitted.

Experimental plan. Half of the mice in each litter were marked and injected subcutaneously in the intercapsular region daily from birth to the sixth or tenth day with 0.05 ml of purified mouse interferon having a titer of 3.2×10^6/ml or with the control preparation. Mice were killed on the sixth or the tenth day. After mice were killed , the livers were weighed; a piece was removed for histologic examination and the remaining tissue was weighed, ground with a blender in 10 ml of chloroform/methanol (1:1,v/v) and stored at -80 C. The lipid extraction was performed according to Folch et al. (11).

Separation of neutral lipids and total PL for analysis of fatty acids. Lipids were chromatographed on a silica gel (Mallinckrodt, Paris KY) column. After the column was washed with hexane/isopropyl ether (90:10, v/v), triacylglycerols were eluted by hexane/isopropyl ether (70:30, v/v), diacylglycerois and all nonphosphorus-containing lipids by isopropyl ether/methanol (95:5, v/v) and PL by methanol (93-95% recovery). Aliquots of triacylglycerol and 1,2-diacylglycerol fractions were purified by thin layer chromatography (TLC) on silica gel G 60 precoated plates (Merck, Darmstadt, FRG) in heptane/isopropyl ether acetic acid (60:40:4 v/v/v) solvent system (12). The 1,2-diacylglycerol and triacylglycerol spots, detected under UV light after spraying with primuline reagent

(13), were scraped into screw-capped tubes. A known amount of 17:0 fatty acid was added as a tracer to each fraction, and transesterification by methanolic-HCl was performed as previously described (14).

Fatty methyl esters were analyzed using a gas liquid chromatograph (Packard 428, Downers Grove, IL) with a 10% SP 2330 on 100/120 chromosorb WAW column of 9′ 1/16″ SS operated isothermally at 190 C. Results are expressed as percent of total fatty acids by means of a coupled integrator (Packard instrument).

The amount of fatty acid in each of the samples was calculated by comparing the surface of each of the peaks to the surface of the peak of 17:0 on the same chromatogram.

Analysis of fatty acids in phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS) and phosphatidylinositol (PI). PL from the fraction previously purified by column were separated by TLC using chloroform/methanol/acetic acid/water (60:30:7:3, v/v/v/v) as developing solvent (15). PC, PE, PS and PI spots visualized under UV light after spraying with primuline were scraped into screw-capped tubes, and methyl esters of fatty acids were prepared as described above.

In vivo measurement of PL biosynthesis in the liver of suckling mice. Suckling mice were killed 5,20,45 or 60 min after injection of 150 μCi of [2-^{3}H] glycerol per 5 g of mouse. Livers were homogenized in 20 vol of chloroform/methanol (1:1, v/v) and the protein precipitate, separated from the organic phase by centrifugation, was reextracted by two other extractions with this solvent mixture. The pooled organic phases were adjusted to 2:1 chloroform/methanol and subsequently washed as previously described (14,16). Total lipid phosphorus and lipid radioactivity was determined on aliquots of lipids extracted from liver.

Neutral lipids were resolved by TLC on silica gel G 60 precoated plates in monodimension with heptane/isopropyl ether/acetic acid (60:40:4, v/v/v). Lipids were detected under UV light with primuline reagent, or standards were chromatographed in parallel and stained with vanillin/sulfuric acid spray reagent.

PL were separated by two-dimensional TLC on 10 × 10 cm silica gel precoated plates using solvents previously described (17). The spots on the chromatogram were visualized with the phosphorus-specific spray reagent of Dittmer and Lester (18).

Visualized spots were scraped into a counting vial, and 3 ml of ethanol/water (1:1, v/v) and 8 ml of Picofluor-30 (Packard) were successively added (19). After mixing, each vial was counted in a Tricarb spectrometer (Packard). The counting efficiency was determined by the external-standard channel ratio, and the results are expressed in dpm.

Proteins in the delipidized precipitate were determined by the method of Lowry et al. (20) after dissolving in 1 N NaOH.

Triacylglycerols were determined by enzymatic method (21) on aliquots of total lipid and triacylglycerol chromatographic fraction dissolved in a minimum volume of propanol. The proportions of 1,2-diacylglycerols in neutral lipids were determined in the corresponding fraction of column chromatography by the same enzymatic method after separation of

[a]The results expressed as the percentage of total fatty acids are means ± SM.
[b]Number in parentheses indicates the number of mice. Newborn and 10-day-old mice came from the same litters, whereas 6-day-old mice came from a second experiment at a different time of year.
[c]U.I., the unsaturation index, is the sum of the percentage multiplied by the number of double bonds for each fatty acid in the mixture.

the 1,2-diacylglycerols in parallel with a known amount of purified diacylglycerols by TLC as described above. The amount of diacylglycerols on the plate was calculated from the corrected OD obtained with the standard spot of diacylglycerols on the same plate.

Separation of molecular species of radioactive PC and PE. PC and PE were purified from the PL fraction by preparative TLC on 20 × 20 cm plates coated with silica gel N, HR (Macheray-Nagel, Düren, FRG) containing 1% sodium carbonate in chloroform/methanol/acetic acid/water (60:30:7:3, v/v/v/v) (15). PC and PE, localized by fluorescence after plates were sprayed with primuline, were eluted from gel by extraction with a mixture of chloroform/methanol/ acetic acid/ water (50:39:1:10, v/v/v/v) (22). The different molecular species of PC and PE were separated by chromatography on 5 × 10 cm silica gel G 60 precoated plates impregnated with silver nitrate (23,24). In brief, the plates were immersed for 30 min in a solution of 50 g of silver nitrate dissolved in 50 ml of water, then dried for 10 min at 110 C and activated for 8 min at 170 C before use. Each purified PL (about 2 mg) was spotted on each plate, and chromatography was performed in a chloroform/methanol/ water solvent system (60: 40:7.5. v/v/v) for PC and (70:40:10, v/v/v) for PE. After drying, the four major separated fractions were identified by the reagent of Dittmer and Lester, scraped into counting vials and counted as described above.

RESULTS

Effect of interferon on the fatty acid composition of phospholipids in the livers of suckling mice (Table 1). Palmitic (16:0), stearic (18:0), oleic (18:1), linoleic (18:2ω6), eicosatetraenoic (20:4ω6) and docosahexaenoic (22:6ω3) acids are the major fatty acids in the liver PL of suckling mice (Table 1). In the first 10 days of life, the proportion of polyunsaturated fatty acids in liver PL increased (43.7% at birth to 47.5% for 10-day-old mice). This overall increase in polyunsaturated acids in PL was not observed in interferon-treated suckling mice. Thus, the percentage of 20:4ω6 and 22:6ω3 in PL increased by 15% for control mice (compared to newborn mice) and either decreased for interferon-treated mice at 10 days or showed the same value as for newborn mice. The percentage of oleic acid declined with age for control mice, but for interferon-treated mice it stayed at the same level as for newborn mice. It is interesting to note that the polyunsaturated fatty acid index of interferon-treated 10-day-old mice was closer to that of newborn mice than it was to control 10-day-old suckling mice.

Effect of interferon on the fatty acid composition of the major liver PL of suckling mice (Table 2). In PC, there was a clear-cut decrease in the percentage of eicosatetraenoic (20:4ω6) and docosahexaenoic (22:6ω3) acids and an increase in the percentage of palmitoleic (16:1), oleic (18:1), linoleic (18:2ω6) and eicosapentaenoic (20:5ω3) acids in interferon-treated

[a]The results are given in percentage of total fatty acids recovered and are expressed as means ± SE. Four pools of two livers were analyzed: each determination was done in duplicate. Minor fatty acids as 12:0, 14:0, 14:1, 15:0, 17:0, 20:0, 20:1, 22:1 and 24:0 are not included in the table, but for the determination of total fatty acids all identified acids were included.
[b]U.I., the unsaturation index, is the sum of the percentage multiplied by the number of double bonds for each fatty acid in the mixture.
ND, Not detected.

mice. The unsaturation index decreased from 176 for control mice to 144 for interferon-treated mice.

PE contains the highest percentage of unsaturated fatty acids of liver PL. Interferon treatment resulted in a decrease in palmitoleic, eiocosatetraenoic and docosahexaenoic acids, accompanied by an increase in the percent of oleic, linoleic and linolenic in ω3 (18:3ω3) fatty acids. The overall unsaturation index decreased from 248 for control mice to 227 for interferon-treated mice.

No change in the unsaturation index was observed in the fractions PS and PI.

Effect of interferon on the amount of fatty acids in the livers of suckling mice. The results presented above give only an imperfect picture of the extent of the biochemical changes due to interferon treatment, as in the first 10 days of life the liver weight increases from 83 mg at birth to 208 mg (10 days) for control mice and 260 mg for interferon-treated mice, and the amount of liver lipids increases from 3.1 mg/liver at birth to 9.8 mg for control mice and 25 mg for interferon-treated mice (2). For this reason, we have quantitated fatty acids in the liver PL using an internal standard of 17:0. Thus, per liver, the total amount of palmitic acid (16:0) doubled, and oleic (18:1) and linoleic (18:2ω6) acids tripled or quadrupled in interferon-treated mice (Table 3). However, in the two groups of mice, the levels of polyunsaturated fatty acids in C20 and C22 were virtually equal; only the sum of unsaturated fatty acids in ω6 was increased in interferon-treated mice as a result of the marked increase in linoleic acid (18:2ω6).

In contrast, there was a marked decrease in the amount per liver of fatty acid present in the liver PL (i.e., 8.8μmol per liver for control mice to 5.2 μmol for interferon-treated mice). Palmitoleic (16:1), oleic (18:1), linolenic (18:3ω6 and 18:3ω3) and docosatrienoic (22:3) acids present in PL decreased ca. 20%; palmitic (16:0), stearic (18:0), eicosatrienoic (20:3) and eicosapentaenoic (20:5) acids decreased 40%; eicosatetraenoic (20:4ω6) and docosahexaenoic (22:6ω3) decreased more than 50%. Only docosapentaenoic acid (22:5ω3) increased by 8%.

It can be seen, therefore, that the polyunsaturated fatty acids in PL were the most affected by interferon treatment. (For control mice, polyunsaturated fatty acids in phospholipids represent 4.3 μmol per liver, whereas they only constitute 2.3 μmol for interferon-treated mice).

Effect of interferon on biosynthesis of lipids in the livers of suckling mice: kinetics of incorporation of 1(3)-^{3}H glycerol. Five min after injection of radioactive glycerol, 50% of the lipid radioactivity was present in triacylglycerides. The level of radioactivity in triacylglycerides then decreased for 8-day-old control mice, whereas it increased for interferon-treated mice (Fig. 1). The radioactivity in diacylglycerides was greater in interferon-treated mice than in control mice and decreased in parallel with time in both groups (Fig. 1). The radioactivity in PL increased in parallel for both groups, although the amount in interferon-treated mice was about half that of control mice (Fig. 1). Although there was a marked decrease in the PL content of the liver in interferon-treated suckling mice (2.1

[a]The amount in μmol/liver of each fatty acid is mean± SM and is determined by comparison with an internal standard of 17:0 fatty acid introduced in the lipids at the time of transesterification (see Materials and Methods). Calculations take into account the surface of the peaks of fatty acids with that of standard on the same chromatogram. Number in parentheses indicates the number of mice. Values statistically different between control and IFN-treated:*, $p < 0.05$; **, $p < 0.01$.
ND, not detected.

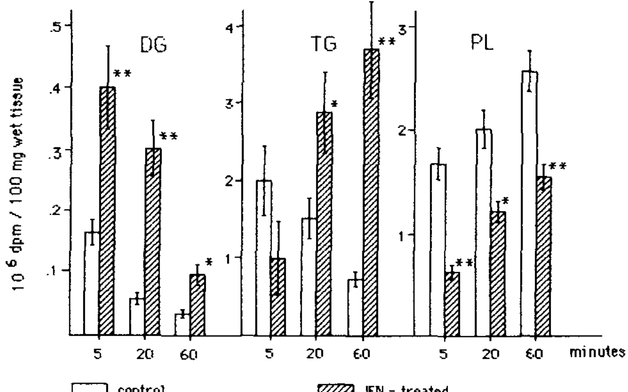

FIG. 1. Effect of interferon treatment on the kinetics of 1(3)-^{3}H-glycerol incorporation into the diacylglycerols (DG), triacylglycerols (TG) and phospholipids (PL) of the livers of suckling mice. Each value was the mean ± SM of dpm/100 mg of wet tissue. Values statistically different between control and IFN-treated; *, $p < 0.05$; **, $p < 0.01$.

± 0.2% of wet tissue compared with 3.6 ± 0.3% in control mice), the specific radioactivity of PL was comparable between the 2 groups and increased regularly between 5 and 60 min (for control mice, 450 ± 60 dpm/μg of PL [5 min] to 560 ± 40 dpm/μg [20 min] and 710 ± 50 [60 min], whereas for interferon-treated mice, the values were 290 ± 80 [5 min], 570 ± 50 [20 min] and 740 ± 40 [60 min]). There was no significant difference in the distribution of radioactivity in the different species of PL.

Comparison of PL synthesis in the livers of newborn and 10-day-old control and interferon-treated mice. Incorporation of ^{3}H-glycerol in liver PL was determined 45 min after injection of the tracer. As can be seen in Table 4, the amount of radioactivity per 100 mg liver protein doubles or triples in control mice between birth and 10 days, whereas the levels in interferon-treated mice are comparable to those found in newborn mice.

Distribution of radiolabel among the different molecular species of PC and PE (Table 5). For 10-day-old control mice, the radiolabel in PC was found almost equally distributed in the low unsaturated (i.e., monoenoic and dienoic) and polyunsaturated (i.e., tetraenoic and hexaenoic) species. In contrast, in 10-day-old interferon-treated mice, only 37% of the radioactivity was found in the polyunsaturated species, as was also found in newborn mice.

For PE, in 10-day-old control mice, the major part (82%) of the radioactivity was found in the polyunsaturated species. Interferon treatment resulted in a decrease in this percentage to 66%, which was similar to the percent of radioactivity in newborn mice.

In summary, interferon treatment affected preferentially the synthesis of molecular species of PC and PE containing mostly polyunsaturated fatty acids.

Effect of interferon on the composition and metabolism of 1,2-diacylglycerols and triacylglycerols. As interferon treatment of suckling mice resulted in an abnormal accumulation of 1(3)-^{3}H-glycerol in 1,2-diacylglycerols and as these compounds are common intermediates for triacylglycerol and phospholipid biosynthesis, we determined the concentration and the specific radioactivity of 1,2-diacylglycerols and their fatty acid composition. Interferon treatment increased the concentration of 1,2-diacylglycerols about four- to fivefold in the liver (from 0.4 ± 0.3 μmol/g of wet tissue in control mice to 2.1 ± 1.0 μmol/g in interferon-treated mice), although their average specific radioactivity remained almost equivalent (1787 ± 291 dpm/μg of diacylglycerols for control mice and 1591 ± 230 dpm/μg for interferon-treated mice). Moreover, there was only a significant decrease of 18:1

TABLE 4

Radioactivity Incorporated in the Liver Phospholipids of Newborn Mice and 10-Day-Old Control and Interferon-Treated Mice*

		10-Day-old mice	
	Newborn (8)	Control (6)	IFN-treated (6)
LPC	1,013 ± 150[a]	2,112 ± 276	563 ± 172[a]

PA	613 ± 51[i]	1,198 ± 134[j]	976 ± 207[i,j]
TG	160,066 ± 21,735[k]	231,116 ± 20,358[k]	294,982 ± 59,655[k]

*Values are means ± SE of dpm/100 mg of liver proteins. The radioactivity in each phospholipid was measured 45 min after injection of 150 μCi of 1(3)-^{3}H-glycerol/5 g of mouse. Each chromatogram of labeled lipids was done in duplicate and the radioactivity was determined in each of the chromatograms. Number of parentheses indicates the number of mice per group. Values with a common superscript are not significantly different. LPC, lysophosphatidylcholine; PA, phosphatidic acid; SPH, sphingomyelin; DPG, diphosphatidylglycerol; TG, triacylglycerols.

(from 32.5 to 26.3%) and a nonsignificant increase of 20:4 and 22:6 in the diacylglycerols (DG) of interferon-treated mice (Table 6).

These variations cannot explain, therefore, the interferon-induced decrease in the proportion of polyunsaturated fatty acids in liver PL. The same arguments hold for the triacylglycerols, whose concentration was increased five- to sixfold by interferon treatment (2) and where only a significant increase of 18:1 was observed in the fatty acid composition between the two groups (Table 6).

DISCUSSION

The experimental results presented herein emphasize the very marked effects of interferon on lipid metabolism in the livers of suckling mice. It seems, therefore, that the interferon-induced alterations at the level of neutral lipids and PL do not have the same origin. Thus, we have previously observed, on one hand, a retention of newly formed triacylglycerols in the liver without any modification of their fatty acid composition and, on the other hand, a decrease in the total

TABLE 5

Distribution of the 1(3)-^{3}H-Glycerol Among Molecular Species of Liver Phosphatidylcholine (PC) and Phosphatidylethanolamine (PE) in Newborn Mice and 10-Day-Old Control and Interferon-Treated Mice[a]

	PC			PE		
		10-Day-old			10-Day-old	
Molecular Species[b]	Newborn	Control (6)[c]	IFN-treated (6)	Newborn	Control (6)	IFN-treated (6)
Monoenoic	30	18 ± 1	28 ± 3*	17	8 ± 1	16 ± 2*
Dienoic	32	31 ± 4	35 ± 3	16	10 ± 1	19 ± 2*
Tetraenoic	21	23 ± 3	19 ± 2	31	35 ± 4	29 ± 3

[a]Results are expressed as dpm percentage of the total dpm recovered from the four fractions separated on the chromatogram.
[b]Each molecular species is defined by its most unsaturated fatty acid.
[c]Number in parentheses indicates number of determinations. The distribution of 1(3)-^{3}H-glycerol among PC and PE of different degrees of saturation at each time-interval was analyzed by argentation TLC. In 10-day-old suckling mice, the distribution of radiolabel did not change with time during the experimental period, and the results were the means ± SM of analyses 5, 20 and 60 min after injection of labeled glycerol (six pools of lipids from two animals). At birth, PC and PE were analyzed 45 min after label injection (two pools of lipids from three animals each).
*Value statistically different between control and IFN-treated, $p < 0.01$.

amount of PL (2). This latter effect was most pronounced for those PL containing polyunsaturated fatty acids in C20 and C22, which correlated with a decrease in the incorporation of 2-^{3}H-glycerol into polyunsaturated species of PL (this publication). At the same time, the concentration of precursors (1,2-diacylglycerols) increases markedly without significant modifications in their renewal or in their composition in polyunsaturated fatty acids. Our present results may best be discussed relative to the pronounced metabolic changes that occur in the liver of normal animals during the postnatal period.

Pollak and Harsas (25) observed an increase in the polyunsaturated fatty acids arachidonic (20:4ω6) and docosahexaenoic (22:6ω3) and a decrease in the proportion of oleic acid (18:1) in the PL of liver mitochondria in 3-day-old rats as compared to newborn. Ogino et al. (26) showed that in suckling rats the polyunsaturated species of liver choline glycerophospholipids increased rapidly during the first days of life, in contrast to the decrease in the monoenoic species. We noted similar changes in the liver PL of control suckling mice in our experiments: an increase in arachidonic (20:4ω6) and docosahexaenoic (22:6ω3) acids and a decrease in oleic acid (Tables 1 and 2). These physiological changes in the degree of unsaturation of liver PL fatty acids in the course of development in the first few days of life was markedly affected by daily administration of interferon. Thus, by the sixth to eighth day of life, interferon treatment resulted in a pronounced decrease in the percentage of polyunsaturated fatty acids in liver PL compared to control mice. In fact, the composition of PL fatty acids of these 6- or 10-day-old interferon-treated suckling mice remains similar to that of newborn mice.

The decrease in the polyunsaturated fatty acids in PL in the livers of interferon-treated mice appeared to be a specific effect and did not stem from a general decrease in the availability of polyunsaturated fatty acids. Thus, when one compares the ratio of fatty acid content of liver PL to the total amount of liver fatty acids, it was apparent that, for each fatty acid examined, this ratio was much lower for interferon-treated suckling mice than for control mice (Table 3). Furthermore, the decrease in 18:1 and the accumulation of the 20:4 and 22:6 species in DG appears to be the result of the decreased incorporation of polyunsaturated fatty acids in the PL of interferon-treated mice.

The second major effect of interferon on liver lipid metabolism concerned the amount of liver PL (2). In the neonatal period of several different animal species, selective changes occur in the activity and concentration of microsomal enzymes for the synthesis of liver PL and triacylglycerols (27-31). As shown in Table 4, interferon treatment inhibited the physiological increase in the synthesis of liver PL. When the activity was expressed per 100 mg of protein, the value in 10-day-old control mice was double that of newborn or interferon-treated mice. This effect of interferon on PL synthesis was especially marked for PC and PE. Induction of the synthesis of diacylglycerol-choline-phosphotransferase and diacylglycerol-ethanolamine-phosphotransferase occurs in rats during the first days of life (27,31,32). This increase in the activity of the PC and PE synthesis is probably accompanied by a change in the specificity of the enzymes toward the different molecular species of diacylglycerol (33). In this regard, it has recently been reported that there is a significant increase in the production of liver microsomal PC, with an increasingly higher proportion of unsaturated fatty acids in the perinatal period (26, 34,35). In parallel, there is also an increase in the activity of the PC synthesis by N-methylation of PE (27), a metabolic pathway that produces molecular species with a high content of polyunsaturated fatty acids (22,36,37).

It is also possible that interferon treatment resulted in an inhibition of the reacylation of lysophospholipids formed by hepatic phospholipases (38-40). In fact, the microsomal lysophospholipid acyltransferases, which can remodel PL by transferring fatty acids on C2 of the glycerol of lysophospholipids, show considerable activity toward polyunsaturated acyl-CoA (38-42).

The results in Table 5 suggest that interferon treatment of suckling mice inhibits this change in the molecular specificity of the biosynthetic enzymes. For example, the inhibitory effect of interferon is especially evident in the molecular species of PC and PE, having the greatest percentage of polyunsaturated fatty acids in C20 and C22. The liver content of these molecular species is about half as much in 10-day-old interferon-treated mice (1.66 μmol per liver) as in 10-day-old control mice (3.28 μmol) (Table 4). The inhibition of the synthesis of polyunsaturated PL in interferon-treated mice can be related to the ultrastructural observations of Moss et al. (3,4), who showed that interferon treatment of suckling mice resulted in the rapid appearance of characteristic tubular aggregates associated with the granular endoplasmic reticulum. In the postnatal period, there is also a rapid development and increase in the endoplasmic reticulum, which is the principal site of PL synthesis in hepatocytes (25,43,44). One may suggest that interferon alters the normal development of the endoplasmic reticulum, which would then limit the growth of enzymatic systems necessary for the synthesis of PL, or that interferon inhibits the synthesis of those enzymes necessary for PL synthesis, which, in turn, would limit the construction of new membranes essential for the developing endoplasmic reticulum (32).

Lastly, interferon treatment results in a very marked increase in liver diacylglycerol level. The diacylglycerol accumulation in response to hormonal stimulation has been shown using a variety of cells and hormones (45-47). Diacylglycerol serves as a substrate for lipases or as a precursor in PL and triacylglycerol synthesis. But it can also act as a second messenger and can regulate protein kinase C activity (47-48). The increase in the hepatic diacyglycerol concentration in interferon-treated suckling mice may alter the metabolic response of the liver to different hormonal stimuli in the postnatal period (49). Indeed, Wolfman and Macara (50) have recently observed that the ras-transformed fibroblasts possess elevated diacylglycerol levels and have decreased sensitivity to phorbol ester activation of protein kinase C.

In Daudi cells, which had been prelabeled with [2-$_3$H]-glycerol, Yap et al. (51,52) have observed a very early and transient two- to threefold increase in the concentration of radiolabel in DG of interferon-treated cells. Interferon in concentration exceeding 2 IU/ml

inhibits the division of cells, and the degree of inhibition corresponds closely to the size of the increase in diacylglycerol label (52). In newborn mice, interferon treatment does not result in an inhibition of liver growth (2), and the specific radioactivity of liver DG after injection of (1,3-^{3}H)-glycerol appeared identical between the two groups of mice. In fact, in vivo, the increase in the concentration of DG reflects a more complex action of interferon on the metabolism of lipids in the liver. Interferon probably alters in the newborn mouse the hepatic pathways responsible for formation and utilization of DG.

This ensemble of results, especially the decrease in liver polyunsaturated PL and increase in DG would appear to have consequences for the maturation of hepatocytes in suckling mice. In many respects, the hepatocytes of 10-day-old interferon-treated suckling mice resembled newborn mice biochemically (rather than control 10-day-old littermates). On the other hand, the fact that interferon interferes with the synthesis of certain polyunsaturated species of PL in the liver (especially certain species of polyenoic PC and PE) of suckling mice may lead to a decrease in the general availability of polyunsaturated species of these PL indispensable for the development of other tissues (35,53). This decrease in polyunsaturated fatty acids availability may be related to other interferon-induced lesions, which only become manifest later in life (54-56).

[Received February 23, 1987]

New Findings in the Fatty Acid Composition of Individual Platelet Phospholipids in Man after Dietary Fish Oil Supplementation

Trevor A. Mori*, **James P. Codde**, **Robert Vandongen** and **Lawrence J. Beilin**
Department of Medicine, University of Western Australia, Royal Perth Hospital, Perth, Western Australia 6000

Nine healthy male volunteers were given 15 Max EPA fish oil capsules providing 2.67 g of eicosapentaenoic acid (EPA, 20:5ω3) and 1.72 g of docosahexaenoic acid (DHA, 22:6ω3) daily for 3 wk. Measurements were taken at baseline, at the end of the fish-oil period, and at 2 and 6 wk postsupplementation. The effect of fish oil on plasma lipids and the fatty acid composition of individual platelet phospholipids was studied. In general, the proportions of 20:5ω3 and 22:6ω3 in platelet phosphoglycerides were substantially increased mainly at the expense of arachidonic acid (AA, 20:4ω6). A large and significant increase in the relative EPA content of phosphatidylcholine (PC) ($P < 0.001$) and phosphatidylethanolamine (PE) ($P < 0.001$) was noted at the end of the 3 wk supplementation. We have also shown for the first time a small but significant ($P < 0.001$) incorporation of EPA in phosphatidylserine (PS). Incorporation of DHA was also detected in PC, PE and PS, whereas the relative AA content of these phospholipids was significantly reduced. Fish oil supplementation led to a significant increase of 22:5ω3 in PS and decreases of 20:3ω6 in PC and 22:4ω6 in PE. Postsupplementation measurements showed a gradual return of all fatty acids to baseline levels. The fatty acid composition of the phosphatidylinositol (PI) fraction remained unchanged throughout the trial period. We conclude that in humans ω3 fatty acids are incorporated into platelet membrane phospholipid subclasses with a high degree of specificity.
Lipids 22, 744–750 (1987).

Both arachidonic acid (AA) and eicosapentaenoic acid (EPA) are substrates for the cyclooxygenase and lipoxygenase enzymes and thus are precursors of eicosanoids, which have a broad spectrum of biological activities and have been implicated in the pathogenesis of atherothrombotic and inflammatory processes (1–3). However, the eicosanoids derived from AA and EPA differ significantly in biological activity. Whereas thromboxane A_3 (TXA_3) is less proaggregatory than thromboxane A_2 (TXA_2) (4,5) and leukotriene B_5 (LTB_5) is less active as a chemotactic compound than leukotriene B_4 (LTB_4) (6–8), prostaglandin I_3 (PGI_3) is as potent as prostaglandin I_2 (PGI_2) as an antiaggregatory agent (4,9). Consequently, a shift of prostanoid formation from the 2- to the 3-series may change the TXA/PGI balance (10) favorably (1).

A number of studies in humans in which a diet has been supplemented with ω3 fatty acids given as either fish meal, fish oil concentrate or purified ω3 fatty acids (11–14) have shown a favorable pattern on blood and platelet lipids (15–17), reduced platelet aggregability (17–18), a prolonged bleeding time (18) and a reduced blood pressure response to pressor hormones (18). Furthermore, dietary EPA is transformed to PGI_3 (9), while TXB_3, the stable metabolite of platelet-derived TXA_3, has been observed in platelets (19).

In order to elucidate further the mode of action of the ω3 fatty acids on platelet reactivity, previous investigators have examined the fatty acid composition of platelet membrane phospholipids (11,14,20–23). These analyses have been confined largely to determining changes in fatty acid composition of total phospholipids or changes in the relative content of AA and EPA. While these are considered the principal fatty acids, there has been a tendency to overemphasize EPA and disregard the possible effects of other ω3 polyunsaturated fatty acids (PUFA) present in fish diets that could also be incorporated into membrane phospholipids and modify subsequent eicosanoid metabolism. For this reason we examined the total fatty acid composition of individual platelet phospholipids of wider range of ω3 PUFA in human subjects taking dietary fish oil supplements.

MATERIALS AND METHODS

Study design. Nine healthy male volunteers, 20 to 45 years of age, who were nonsmokers were asked to withhold all drugs known to interfere with eicosanoid formation or lipid metabolism during the study period of 10 weeks. Two baseline measurements on separate days were taken during the first week, and volunteers were then instructed to take five Max EPA capsules three times daily with meals for 3 wk. This supplement is equivalent to a daily intake of 2.67 g EPA and 1.72 g docosahexalaoic acid (DHA). Further measurements were made at the end of the fish-oil period, as well as 2 and 6 wk postsupplementation.

Materials. One g of Max EPA capsules (PR Scherer Pty Ltd., Melbourne, Australia) contained EPA (17.82%) and DHA (11.49%) as verified by gas liquid chromatography (GLC) (see Table 1). The vitamin A and E content of the Max EPA was measured by Dr. D. S. Petterson using high performance liquid chromatography and tocol as an internal standard. Cholesterol content was determined by Dr. F. Legge utilizing GLC and cycloartenol as an internal standard. Both analyses were carried out at the Western Australian Department of Agriculture. The spary reagent 8-hydroxy-1,3,6-pyrenetrisulfonic acid trisodium salt was purchased from Eastman Kodak Co. (Rochester, NY); 14% boron trifluoride in methanol was from BDH Chemical Ltd; authentic standard fatty acid methyl

Total ω3	4.90 g/day
Vitamin A	1380 μg/day
Vitamin E	7890 μg/day
Cholesterol	57 mg/day

esters and phospholipids were from Sigma Chemical Co. (St. Louis, MO). Thin layer chromatography (TLC) was carried out on silica gel 60 F_{254}, precoated aluminum sheets (Merck Art. 5554). GLC was performed on a Packard Model 437 Gas Chromatograph equipped with a Packard Model 604 Recording Data Processor.

Platelet preparation and lipid extraction. Blood (20 ml) from unfasted volunteers was obtained by venipuncture and collected into EDTA (1 mg/ml), then briefly shaken and centrifuged at 110 × g for 15 min at room temperature. Platelet pellets were prepared at room temperature as follows: platelet-rich plasma was removed and centrifuged at 1000 × g for 15 min, and the platelet-poor plasma was frozen (-20 C) until analysis. The platelet plug was resuspended in EDTA/NaCl buffer (pH 7) and recentrifuged. Washed platelets were extracted with $CHCl_3/CH_3OH$ (2:1v/v, 5 ml) containing 50 mg/l of the antioxidant butylated hydroxytoluene, the sample was centrifuged at 1000 × g for 5 min, and the organic phase was evaporated under vacuum yielding a crude lipid extract.

TLC and fatty acid analysis. Phospholipid subclasses were separated from total lipid extracts by TLC using a solvent system of ethyl acetate/N-propanol/chloroform/methanol/0.25% aqueous KCl (25:25:25:13 :9,v/v/v/v/v) (24). TLC plates were sprayed with the reagent 8-hydroxy-1,3,6-pyrenetrisulfonic acid trisodium salt (25) (10 mg/100 ml methanol), allowed to dry for several minutes and visualized under UV light (254 nm and 366 nm). The zones containing phosphatidyl ethanolamine (PE), -inositol (PI), -serine (PS) and -choline (PC), as determined by comparison with authentic standards, were scraped off, and fatty acid methyl esters were prepared by treatment of samples with 14% boron trifluoride in methanol at 100 C for 30 min (26). After dilution with water, methyl esters were extracted with hexane, dried under N_2 and then dissolved in hexane (5 μl) for GLC analysis. The methyl esters were separated on a BP 20 vitreous silica column (0.53 mm × 12 m) (Scientific Glass Engineering, Melbourne, Australia), temperature-programmed from 180 C to 220 C at 5 C/min with hydrogen as carrier gas and a split ratio of 50:1. Peaks were identified by comparison with a known standard mixture of fatty acid methyl esters. The amounts of individual fatty acids were calculated as relative percentage with the evaluated fatty acids set as 100%.

Plasma lipids. Lipids from platelet-poor plasma frozen at -20 C were assayed as follows: cholesterol and triglyceride were determined enzymatically on an Abbott ABA-100 analyzer using reagents from Abbott and standardized with serum-based calibrators, the values of which were traceable to the Centers for Disease Control (Atlanta, GA). The coefficients of variation were 1.5 and 2.0%, respectively. Plasma high density lipoprotien (HDL) cholesterol was assayed on a heparin-manganese chloride supernatant (27) (final manganese concentration 0.091 mol/l) with addition of 4 mM EDTA to the Abbott cholesterol reagent (28). HDL subfractions, HDL_2-C and HDL_3-C, were measured by the double precipitation method of Gidez et al. (29) (final dextran sulphate concentration 0.13%). Statistics calculated on 42 separate runs using a subject's aliquoted frozen (-70 C) plasma were as follows: mean total HDL cholesterol, 1.61 mmol/l with standard deviation 0.057 mmol/l and coefficient of variation 3.53%; mean HDL_3 cholesterol, 0.734 mmol/l with standard deviation 0.063 mmol/l and coefficient of variation 8.63%; and mean HDL_2 cholesterol 0.874 mmol/l, standard deviation 0.057 mmol/l and coefficient of variation 6.53%. Low density lipoprotein cholesterol (LDL-C) was calculated from the Friedewald formula (30).

Statistics. Results are expressed as the mean and standard error of the mean (SEM). One-way analysis of variance (ANOVA) using repeated measures was used to test for variations between visits for individual fatty acids. Differences between any two visits within a particular fatty acid were established by the Newman-Keuls test.

RESULTS

The fatty acid composition of the Max EPA capsules is shown in Table 1. The amounts of ω3 fatty acids,

vitamins A and E, and cholesterol provided by the fish oil are shown in Table 2. With respect to the ω3 fatty acids, the major contributors were 20:5 (17.82% of the total fatty acids by weight) and 22:6 (11.49%), with minor contributions from 18:3 (0.62%) and 22:5 (2.78%). Vitamin E is added to the capsules as an antioxidant.

The fatty acids shown in each of the phospholipids (Tables 3-6) were those observed within the detectable limit of the gas chromatograph and clearly demonstrate a variation in the fatty acid distribution in phospholipid subclasses. All comparisons within fatty acids are relative to the second baseline visit, which in all cases did not differ statistically from the first.

In general, after 3 wk of taking the oil, the proportions of 20:5ω3 and 22:6ω3 were substantially increased in platelet phosphoglycerides, mainly at the expense of ω6 polyunsaturated fatty acids, and in particular 20:4ω6 (Tables 3-5). The one exception was PI, which showed no significant changes in any of the fatty acids during the trial period (Table 6).

At the end of the supplement, the PS fraction showed significant increases in the levels of 20:5ω3 and 22:6ω3, which together constitute about 30% of the capsule content by weight (Table 3). In addition, a significant increase in 22:5ω3 and a fall in 20:4ω6 ($P < 0.05$) were observed. The levels of 20:4ω6, 20:5ω3, 22:5ω3 and

[c]Visits 4 and 5, measurements taken 2 and 6 wk postsupplementation.

22:6ω3 all showed a return to basal levels within 2 wk of ceasing supplementation, although that of 22:6ω3 remained significantly higher compared with baseline values.

The platelet PE fraction showed a significant fall in 20:4ω6 ($P < 0.001$) at the end of the supplementation period and a gradual return to pretreatment levels 2 wk after the supplement had been withdrawn (Table 4). In a similar way, the level of the chain elongation product of 20:4ω6 (22:4ω6) fell significantly during the intervention period, gradually rising afterward, although remaining lower at 2 and 6 wk. The relative proportions of the ω3 fatty acids 20:5, 22:5 and 22:6 all increased during the supplement. The largest increase was in 20:5ω3 ($P < 0.001$) and to a lesser extent 22:6ω3. The level of 22:5ω3 was also slightly increased, but this was not significant. Both 20:5ω3 and 22:6ω3 remained high ($P < 0.001$ and $P < 0.01$, respectively) 2 wk after Max EPA but had reached basal levels after 6 wk.

Analysis of the PC fraction showed a five fold increase in 20:5ω3 and a two fold rise in 22:6ω3 (Table 5). Both fatty acids remained significantly high 2 wk after oil supplementation and that of 20:5ω3 was still high after 6 wk. A small but statistically insignificant rise in 22:5ω3 was observed during the supplementation period. The levels of the two ω6 fatty acids, 20:3 and 20:4, were both lowered significantly during fish oil supplementation. That of 20:3ω6 had returned to baseline within 2 wk of ending the supplement, while that of 20:4ω6 had reached basal levels by the sixth week. It is significant to note that the fatty acid

HDL_3 cholesterol (mmol/l)	0.44 ± 0.04	0.38± 0.04	0.59 ± 0.04
LDL cholesterol (mmol/l)	3.46 ± 0.36	3.65 ± 0.35	3.33 ± 0.39

Values are mean ± SEM. ANOVA between visits: no significant difference. HDL, high density lipoprotein; LDL, low density lipoprotein.
[a]Visit 2, baseline measurement.
[b]Visit 3, at the end of the 3-wk supplementation period.
[c]Visit 5, 6 wk postsupplementation.

20:3ω6 is the immediate precursor of 20:4ω6. The proportion of 22:4ω6 was not significantly altered during the trial.

Plasma cholesterol, triglycerides and lipoproteins were not significantly altered by the fish oil (Table 7).

DISCUSSION

It has been suggested that the low incidence of cardiovascular disease in Eskimos may be related to their diet, which consists mainly of marine fish (11-13, 31,32). Subsequent evidence indicates that this may be due to the high intake of polyunsaturated fatty acids of the ω3 series and, in particular, EPA and DHA, both of which constitute a large proportion of the fish oil. The diet may consequently lead to a synthesis of the 3-series prostanoids replacing the platelet-reactive prostanoids of the 2-series (1,17). The resultant shift in balance of proaggregatory to antiaggregatory prostanoids would then lead to a reduced thrombotic tendency.

Recent attention has thus turned to supplementation of Western diets with fish oils to elucidate their effect on blood lipids, platelet function and eicosanoid production (11-13, reviews), factors which are implicated in the pathogenesis of cardiovascular disease. However, in many cases, different fish containing varying types and amounts of fatty acids have been used, making comparisons of results between studies difficult. Although fish oil is a readily available source of EPA, significant amounts of DHA and other fatty acids are present, so it is not possible to attribute all the effects observed to EPA alone. In particular, DHA had been shown in vitro (33,34) and more recently in vivo (22) to inhibit platelet aggregation. Since platelet reactivity may be dependent on the fatty acid composition of its membrane, a number of studies have examined changes in fatty acid content following dietary fish oil supplementation (11,14, 20-23). Many of these studies have been limited, reporting either changes in fatty acid composition of total platelet phospholipids or changes in the relative content of several of the major fatty acids. The principal problems have been the time required and the difficulty in cleanly separating the major phospholipid subclasses. In a recent study in which volunteers supplemented their diet with 25 ml/day of cod liver oil for 5 mo, individual phospholipids were separated. However, of the long chain fatty acids, only EPA and DHA from the ω3 series and AA from the ω6 series were reported (20). Similarly, a previous study had reported total fatty acid composition of PE and PC only. Whereas PS and PI were isolated as one fraction (23). To our knowledge, a detailed analysis of total fatty acid composition of *all* the individual phospholipid subclasses has not been undertaken, warranting this investigation in normal human subjects taking moderate amounts of Max EPA fish oil for 3 wk.

In the present trail, we have been able to obtain complete separation of PE, PC, PS and PI by utilizing one-dimensional TLC and subsequently visualizing the bands with the aid of a reagent that is highly UV-active (see Materials and Methods). The method used is less time-consuming than the often favored two-dimensional TLC; it also is very sensitive and leads to reproducible separation of all phospholipid subclasses.

In platelet PE and PC, EPA increased from control values of 1.20% (PE) and 0.85% (PC) to 7.5% (PE) and 4.33% (PC) during fish oil administration (Tables 4 and 5). At the same time, the levels of DHA also rose from 4.12% to 5.65% in PE and from 1.57% to 3.01% in PC, while both PE and PC showed significant falls in AA content. These findings within PE and PC agree with previous observations (20-23). Interestingly, the level of 22:4ω6 fell significantly in PE from 4.77% to 2.31% for the same period, suggesting a decreased synthesis from its immediate precursor, AA. In light of the fall in AA, the result is not unexpected. Post-oil supplementation measurements show a gradual rise in 22:4ω6 in PE with a significant difference persisting at 6 wk (visit 5), while AA showed a more rapid return to basal levels.

These results may reflect a gradual reactivation of

the enzymes involved in the chain elongation of 20:4ω6 to 22:4ω6. The proportion of 22:4ω6 in PC was, however, considerably lower and not affected by the fish oil, which may indicate a preferential incorporation of this fatty acid into PE. A similar fall in 22:4ω6 has been observed in both PE and PC after 6 wk of dietary supplementation with cod liver oil (23). The proportion of 20:3ω6, the immediate precursor of AA, fell from 2.05% to 1.05% ($P < 0.01$) in PC during the fish oil intake. This may indicate a reduction in its synthesis from 18:2ω6 and may have contributed to the fall in AA in PC. It is interesting to note the significant rise ($P < 0.01$) in the level of oleic acid (18:1ω9) in both PE and PC 6 wk after the cessation of the supplement. However, it is doubtful whether this can be attributed to the fish oil; it may merely reflect a change of diet by several of the participants after ceasing the supplement.

The PS fraction provided some interesting and novel results (Table 3). The increase in 20:5ω3 ($P < 0.001$) and 22:5ω3 ($P < 0.01$), with a concomitant reduction in 20:4ω6, has not previously been reported and may be important in our understanding of the mode by which fatty acid incorporation occurs. All three fatty acids showed a rapid return, and within 2 wk of ending the supplement they were not different from baseline. The increase in the proportion of 22:5ω3 in PS was large considering the small amount of this fatty acid provided by Max EPA; this would suggest that a portion of the EPA in the diet is chain-elongated to 22:5ω3 and subsequently preferentially incorporated into the PS fraction. Small but insignificant rises in the level of 22:5ω3 were also noted in PE and PC. These results are in contrast with a recent study in which 6 g/day of purified EPA given for 6 days resulted in minimal changes in 22:5ω3 in the first 24 hr, which is expected if it is synthesized from EPA, before rising significantly in PE and PC only (22). The study also suggests that dietary EPA was not metabolized to DHA, indicating that the increase in DHA that we have observed in PS, PE and PC is directly obtained from Max EPA. In another study, a significant decrease in 22:5ω3 was observed in a combined fraction of PS + PI after administering dietary cod liver oil (23). The investigators were, however, unable to confirm which phospholipid had contributed to the fall in 22:5ω3. The significance of the small quantity of 22:5ω3 in PS remains to be elucidated.

None of the other fatty acids examined in the phospholipid subclasses were altered by the fish oil during our trial. We were unable to confirm a previous finding of a significant reduction in the 18:2ω6 content of PE after 4 wk of Max EPA (21).

In accordance with previous investigations, there were no appreciable changes in the fatty acid composition of PI during fish oil supplementation (Table 6) (11,13,20-22). This failure to incorporate EPA, even when the fatty acid is provided in purified and high doses, reflects a tightly controlled system (22). The suggestion that the phospholipid fatty acid composition of blood cells is predetermined during their formative stages (17,20,22) would certainly be compatible with the observation for PI, but not for PE, PC or PS. A second regulatory mechanism proposed involves a "fine tuning" of the fatty acid compositions, and this does appear to operate in the three latter phospholipids (20). It is worth noting that both neutral lipids and the polar lipids of marine fish are rich in ω3 PUFA, with a ratio of ω3/ω6 PUFA of 10-15:1 (35). It has been shown recently that the composition of PI from marine fish is very similar to that in terrestrial mammals, whereas the other phospholipids contain large amounts of ω3 PUFA obtained from the diet (35). These observations would support the proposal that fatty acid composition of PI is strictly controlled and not responsive to dietary manipulation. The apparent inability to obtain incorporation into PI during fish oil supplementation may be of importance, as this phospholipid is thought to be a major source of AA, which is the substrate for both the cyclooxygenase and lipoxygenase enzymes.

It is clear that in vivo the mechanisms that regulate the fatty acid composition in different platelet phospholipid subclasses differ from those that operate in vitro. In the latter, it has been repeatedly shown that radiolabeled EPA and DHA are rapidly and significantly incorporated into all phospholipid subclasses, including PI, and this is independent of the presence of labeled AA (20,34,36-38).

The most consistent effect of fish oils on blood lipids has been a fall in triglycerides (11,14). Furthermore, in a trial in which men consumed varying amounts of Max EPA for 3 wk periods, plasma triglycerides fell proportionally to the supplemental dosage (39). The effect of dietary fish oils on the plasma total cholesterol levels appears to depend on both the kind of dietary treatment provided and the quantity consumed (11,14). Significant changes were observed only in feeding trials that used very high doses of fish oil and Max EPA, resulting in lower total cholesterol (11, 14,39). Changes in HDL cholesterol concentration have not been frequently observed. An increase in HDL cholesterol was found only after a 20 g/day Max EPA supplementation for 3 wk (39). Variable changes in LDL cholesterol have been observed after supplementation with fish oils.

In conclusion, we have shown that fish oil supplements cause marked changes in the fatty acid composition of PE and PC but not in the PI fractions observations that agree with previous findings (11,14, 20-22). We have also noted, for the first time, that EPA incorporation may occur into the PS fraction. Our findings reinforce the hypothesis that in vivo fatty acid incorporation into platelet membrane phospholipid subclasses occurs with a high degree of specificity, which may reflect the operation of tightly regulated control mechanisms (17,20,22). At this stage, the importance of these observations is uncertain, but it has been suggested that it may by necessary to modify fatty acid composition of specific lipid pools within the platelet membrane in order to alter eicosanoid production (38). The extent to which the membrane composition must be altered in order to affect function also remains unknown. However, in view of the current results, the changes in a wider range of fatty acids within individual phospholipids need to be considered in interpreting the molecular and functional effects of dietary fish oil.

ACKNOWLEDGMENTS

This work was supported by grants from the Diabetes Research Foundation of Western Australia and the Raine Centre for Cardiovascular Studies and by a project grant from the National Health and Medical Research Council of Australia. We also thank Miss Margaret Baron-Hay for analysis of the plasma lipids.

METHODS

Rapid Isolation of Microsomes for Studies of Lipid Peroxidation

Phillip W. Albro*, **Jean T. Corbett** and **Joanna L. Schroeder**
Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, P.O. Box 12233, Research Triangle Park, NC 27709

Conventional isolation of microsomes by high-speed centrifugation from isotonic sucrose requires exposure to air for several hours, leading to the formation of low levels of lipid peroxidation products. Sucrose interferes in protein and malondialdehyde assays and provides no protection against lipid peroxidation during workup. A new procedure for the purification of microsomes from rat liver substitutes mannitol (a hydroxyl radical scavenger) for sucrose and takes advantage of the properties of morpholinopropane sulfonic acid (MOPS) buffer and triethylenetetramine to provide protection against lipid peroxidation during the rapid (less than one hour) workup and subsequent low-temperature storage. The microsomal fractions prepared by the proposed method are free of detectable mitochondrial contamination and at least as pure overall as those prepared by the conventional method, but they have higher glucose-6-phosphatase and laurate hydroxylase activities and significantly less malondialdehyde than conventional microsomes at the time isolation is complete. Laurate hydroxylase activity is more stable during frozen storage in mannitol medium. The kinetics of lipid peroxidation in vitro are quite different for microsomes prepared by the two methods.
Lipids 22, 751–756 (1987).

The difficulties associated with quantitative monitoring of lipid peroxidation in vivo generally preclude studies of the chemical mechanisms involved (1,2). One of the most widely used model biological systems in which such studies have been performed is a suspension of hepatic microsomes, with peroxidation of the membrane lipids supported either nonenzymatically in the presence of ascorbate or enzymatically in the presence of NADPH. Some form of chelated iron is usually supplied as an accelerator of the process, and a variety of products may be measured to follow the course of the complex sequence of reactions involved. The overall process may be indicated by disappearance of polyunsaturated fatty acids or by production of conjugated double bonds, lipid peroxides or hydroperoxides, volatile hydrocarbons, carbonyls or compounds that react with thiobarbituric acid (TBA) to yield a red pigment. Under appropriate conditions (3), the TBA assay may be specific for the quantitative measurement of malondialdehyde (MDA).

A previous publication from this laboratory has emphasized the importance of zero-time controls in studies of lipid peroxidation in microsomes (3). We have always observed lipid peroxidation products to some extent in microsomes prepared by conventional high-speed centrifugation, prior to their incubation. "Conventional" microsomes generally require several hours for isolation and washing, during which time they are exposed to oxygen in the air for at least the first half of the isolation and are in the presence of whatever metal ions may be present in the tissue homogenate. Chelators and/or antioxidants can be included in the homogenate but may be difficult to remove when the microsomes are subsequently to be studied.

We have tended to prepare liver homogenates in 0.25 M sucrose, since many of the products of lipid peroxidation are rapidly metabolized by mitochondria, and we have been unable to prepare microsomes adequately free of mitochondria if ionic media were used in the homogenization. Unfortunately, sucrose can interfere with the TBA assay under some conditions (3) and clearly, in itself, provides no protection against lipid peroxidation during the isolation of the microsomes. The present study was performed in order to develop a more rapid, protective method of microsome isolation yielding a product suitable for studies of lipid peroxidation in vitro.

MATERIALS AND METHODS

Inorganic chemicals used in this study were from Fisher Scientific Co. (Raleigh, NC). Organic chemicals were from Aldrich Chemical Co. (Milwaukee, WI), and biologicals were from Sigma Chemical Co. (St. Louis, MO).

Absorption spectra were scanned using a Beckman DU-7 spectrophotometer with a 0.5-nm slit. Gas chromatography of fatty acid methyl esters (made by transesterification of lipid extracts with boron trifluoride-methanol, ref. 4) was done on a Varian 1200 gas chromatograph using EGSS-X and SE-52 packed columns and an Adalab data system for peak area measurements. Components were identified by correspondence of retention indices with those of known standards from Applied Science Labs. (State College, PA).

Protein in suspensions of microsomes was measured by a modification of the method of Lowry et al. (5) as described previously (6). Cytochrome P-450 was estimated by the method of Omura and Sato (7). Enzymes glucose-6-phosphatase, acid phosphatase, cytochrome C oxidase, 5′-nucleotidase, urate oxidase and laurate hydroxylase were assayed by published methods (8–13). Total microsomal lipid was determined on a weight basis following extraction and washing by the method of Folch et al. as described previously (3). RNA was determined as described by Schneider (14), phospholipid by Bartlett's method (15) and total cholesterol by a ferric chloride method (16). Production of MDA and other thiobarbiturate-reactive substances was monitored as described previously (3). H_2O_2 was monitored by a peroxidase-scopoletin assay (2).

Microsomal suspensions were incubated with NADPH, ferrous sulfate and ADP to promote lipid peroxidation as described elsewhere (3). Controls included incubation mixtures to which trichloroacetic acid (TCA) was added before NADPH (zero-time controls), mixtures lacking

Abbreviations: TBA, thiobarbituric acid; MDA, malondialdehyde; TCA, trichloroacetic acid; MOPS, morpholinopropane sulfonic acid; TET, triethylenetetramine hydrochloride.

NADPH and mixtures lacking microsomes. Measurements included fatty acid compositions of the incubation mixtures, TBA reactivity (3), conjugated double bonds (17) and lipid hydroperoxides (thiocyanate method, ref. 18).

For electron microscopy, microsomal pellets were held in Fowler's fixative at 4 C overnight, rinsed at 4 C overnight in 0.2 M phosphate pH 7.4, postfixed in 1% osmium tetroxide in the same buffer, dehydrated in graded ethanol and embedded in Epon. Thin sections (60-90 nm) were cut using a Sorvall MT-1 ultramicrotome and were stained with 5% uranyl acetate/2.7% lead citrate.

Micrographs were taken using a Phillips model 400 electron microscope.

PREPARATION OF MICROSOMES

Conventional high-speed method. One-g portions of diced liver from male CD rats (Charles River, ca. 200 g body weight, fasted overnight prior to death) were homogenized in four volumes of freshly prepared 0.25 M sucrose using a Teflon-glass homogenizer driven by a Wheaton Instruments #903475 stirring motor at gradually increasing speed up to full (five strokes total). The homogenates were centrifuged at 12,000 × g for 10 min in a Sorvall SS34 rotor (4 C), after which the supernates were centrifuged at 100,000 × g for 1 hr in a Ti-60 rotor. The microsomal pellets were resuspended in fresh 0.25 M sucrose and repelleted as above. The final pellets were resuspended in 0.25 M sucrose to 10 mg of protein per ml and were either assayed immediately or were quick-frozen with liquid nitrogen for storage at −70 C.

New method. Four solutions were prepared: wash solution—0.25 M mannitol; homogenizing medium—0.25 M mannitol containing 0.025 M morpholinopropane sulfonic acid (MOPS) buffer pH 7.4 and 0.2 mM triethylenetetramine hydrochloride (TET); dilutant—0.0125 M mannitol containing 0.1 mM TET, 8 mM calcium chloride, pH 7.5; and storage medium—0.25 M mannitol containing 0.025 M MOPS pH 7.4, freshly bubbled with helium to deaerate.

All media were used ice-cold. One-g portions of liver were diced in wash solution, drained and homogenized as for the conventional method, but in the homogenizing medium described. After centrifugation at 12,000 × g for 10 min, the supernate was filtered through a loose plug of glass wool to remove floating fat and again centrifuged at 12,000 × g for 10 min. This supernate was diluted with four volumes of dilutant, stirred with a glass rod for 30 sec and centrifuged for 10 min at 1000 × g (4 C). The pellet was suspended in 2.5 ml of storage medium with gentle stirring to disperse clumps and was either assayed immediately or frozen with liquid nitrogen for storage at −70 C.

RESULTS

Electron micrographs of the preparations of microsomes are shown in Figure 1. The high-speed microsomes are more tightly packed and contain a large number of free ribosomes. The low-speed microsomes are much less tightly packed, but all of the visible ribosomes are either bound to membrane vesicles or clumped together. The micrographs closely resemble those published by Kamath and Rubin (19) and by Baker et al. (20). We have not seen intact mitochondria in either type of preparation.

Composition of and enzyme activity associated with freshly prepared microsomes are summarized in Table 1. All quantitative data in the tables represent triplicate determinations on each of at least three independent preparations of microsomes by each preparative method. In all cases, comparisons are between microsomes prepared by the two methods at the same time from portions of liver from the same rat and are based on two-tailed t-tests with df = 5.

The yield of protein was lower by the new method than by the conventional high-speed method. The ratio of RNA to protein was higher by the new method, but the difference reflected the lower amount of protein. Phospholipid was lower by the new method, but the difference was not statistically significant because of a high standard deviation for conventional microsomes. The ratio of cholesterol to phospholipid was similar for the two methods, as was the concentration of cytochrome P-450.

Acid phosphatase, taken as indicative of contamination by lysosomes, was identical for the two methods. 5'-Nucleotidase, a small amount of which is always found even in the most highly purified microsomes, but which is generally taken as indicative of the amount of contamination by fragments of the plasma membrane, was significantly higher ($P < 0.05$) in the high-speed microsomes. Levels of urate oxidase, a marker for peroxisomes, were quite variable from one preparation to another. The mean was higher for microsomes prepared by the new method, but the difference was not statistically significant. Cytochrome C oxidase, a mitochondrial marker, was extremely low in both preparations.

Highly significant differences ($P < 0.01$) were seen in mean levels of two rather fragile microsomal enzymes, glucose-6-phosphatase and laurate hydroxylase, with the activities being higher in the microsomes prepared by the new method. The differences in glucose-6-phosphatase were much less when microsomes that had been stored at −70 C were compared (Table 2). Laurate hydroxylase was more stable in frozen "new-method" microsomes than in conventional microsomes.

Glucose-6-phosphatase	0.122 ± 0.010[b]	0.127 ± 0.00[a]
Laurate hydroxylase	0.95 ± 0.022[a]	1.37 ± 0.11[b,c]

[a]A 12% decrease on freezing (same units as Table 1).
[b]No decrease on freezing.
[c]$p < 0.05$, new vs conventional.

Fatty acid compositions of the microsomes prepared by the two methods are summarized in Table 3. The differences cannot be accounted for solely on the basis of differences in peroxidative loss of polyunsaturates and probably reflect differences in the amounts of contamination by other subcellular membranes.

Absorption spectra of zero-time control TBA assays applied to both types of freshly isolated microsomes and read against reagent blanks containing neither sucrose nor mannitol are shown in Figure 2. The background produced by sucrose is obvious, although there is no "peak" at 532 nm as would be produced by MDA (21). In

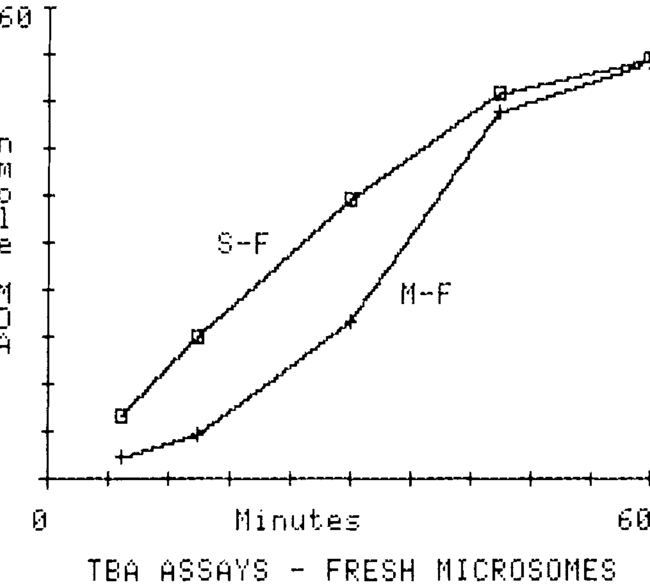

FIG. 3. Time course of production of malondialdehyde by microsomes (1 mg protein/ml) in 25 mM Tris/HCl (pH 7.4) with 100 mM KCl, 330 μM Fe SO_4, 1 mM ADP and 1.85 mM NADPH at 37 C under air on a rotary shaker. S-F, fresh microsomes from sucrose method; M-F, fresh microsomes from mannitol method.

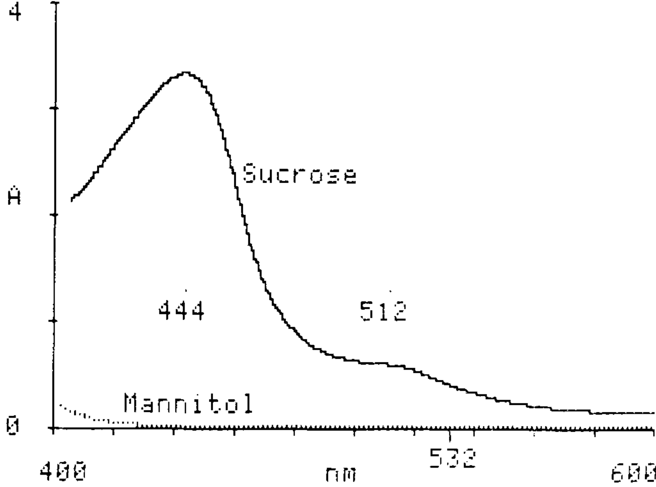

FIG. 2. Visible absorption spectra of TBA reaction products from unincubated microsomes in Tris buffer (zero controls—see text) scanned against procedure blanks lacking microsomes and microsome-suspending media. Upper curve (solid), conventional microsomes (sucrose); lower curve (dotted), microsomes prepared by the proposed method (mannitol).

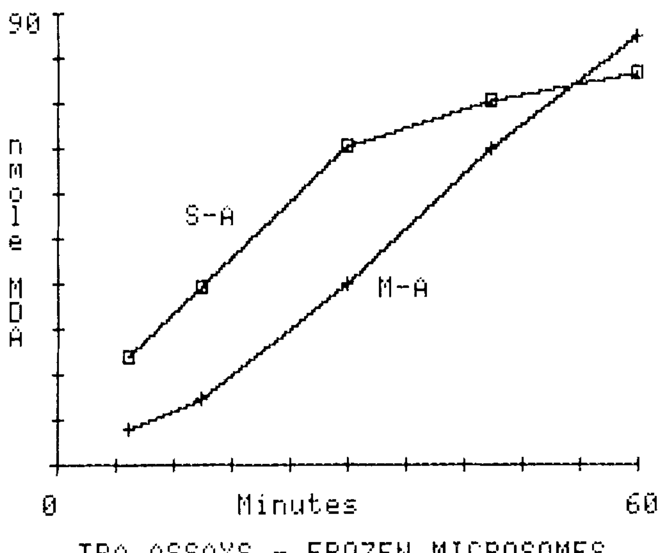

FIG. 4. Time course of production of malondialdehyde by microsomes under the same conditions as Fig. 3 except that the microsomes had been stored at −70 C for two weeks prior to incubation. S-A, "aged" microsomes from sucrose method; M-A, "aged" microsomes from mannitol method.

contrast, microsomes prepared by the new method show no interfering background. Once again, this shows the importance of reading TBA-assay test samples against a zero-time control when sucrose is present (3).

Figure 3 shows the time course of MDA production when microsomes prepared by the two methods were incubated in Tris buffer with NADPH, ferrous sulfate and ADP (3). The colorimetric assay used is relatively specific for MDA rather than its precursors (3). While both types of microsomes eventually produced the same amount of MDA, the "conventional" microsomes gave an initial burst of MDA followed by a parabolic pattern of release. Microsomes prepared by the new method gave a sigmoidal pattern, although there was no true lag. These contrasting patterns were also seen when microsomes that had been stored at −70 C for one month were similarly incubated (Fig. 4).

TABLE 4

Lipid Peroxidation Products in Unincubated Microsomes[a]

Oxidation product	nmol/mg protein	
	Conventional method	New method

Malondialdehyde (MDA)	0.39 ± 0.061	0.07 ± 0.004[b]
Labile MDA precursors	18.7 ± 0.98	21.8 ± 2.56

[a]Means of triplicate determinations on each of three independent preparations of each type. Microsomes frozen prior to assay, but not incubated.

[b]$p < 0.001$ (two-tailed t-test). Other comparisons not statistically significant.

To determine whether these differences in kinetics were due to differences in levels of preexisting MDA precursors, unincubated (frozen) microsomes were assayed for TBA reactivity both by relatively MDA-specific and nonspecific techniques (3), for the presence of conjugated double bonds in the extracted lipids (17) and for total lipid peroxides/hydroperoxides (18). Solvents used for lipid extraction contained 0.001% butylated hydroxy toluene as antioxidant, and solid EDTA was added to the microsomal suspensions prior to extraction. Results are summarized in Table 4. Microsomes stored in sucrose contained over five times as much preformed MDA as microsomes stored in mannitol and slightly more lipid hydroperoxide. Compounds that could decompose to form MDA were slightly higher in microsomes prepared by the new method. Conjugated double bonds were not readily quantified, since there was no obvious source of microsomal lipid known to be free from such products to use in obtaining a difference spectrum (17). However, the absorbance at 234 nm was not conspicuously different for lipids from the two types of preparations. It was established that even deliberately adding excess TET to the assay mixtures did not interfere with either the TBA assay or the hydroperoxide assay (not shown). Neither sucrose nor mannitol "storage media" had detectable (>0.3 nmol/ml) hydrogen peroxide levels even after storage for 6 mo at 4 C.

A preliminary nonlinear regression analysis (geometric, parabolic, hyperbolic, probit, second-through-fourth order polynomial and inverse transform) of the data in Figures 3 and 4 indicated that while the data for the conventional microsomes could be well fit by a ($y = 1/\text{nmol MDA}$; $x = 1/\text{time}$) transformation, giving correlation coefficients of 0.9966 and 0.9971 for Figures 3 and 4, respectively, the data for microsomes prepared by the new method were better fit by a third-order polynomial (correlation coefficients of 0.9977 and 0.9999, respectively). In the latter case, the second-order term dominated the relationship. The physical correlates of these preliminary observations need to be investigated in the future.

DISCUSSION

The low-speed centrifugation method for preparation of microsomes is adapted from the sucrose-based method of kamath and rubin (19), differing primarily in the composition of the media used. Each mannitol-based solution has an osmotic strength matching that of the corresponding sucrose solution. Mannitol was chosen because (a) unlike sucrose, it does not interfere with the TBA assay or most protein assays; (b) it is a well-known inhibitor of hydroxyl-radical-mediated reactions; and (c) it has been used in the past for subcellular fractionation (although mainly for nonmammalian "microsomes" and mitochondria, e.g., refs. 22, 23).

TET was included in the homogenizing medium because it is an effective chelator of trace metals, has been shown to prevent the formation of hydrogen peroxide during the autooxidation of sulfhydryl compounds (24) and does not interfere with the TBA or lipid hydroperoxide assays (unpublished observations). MOPS buffer was used to prevent the alkaline decomposition of mannitol and because, unlike the more commonly used Tris buffer, it does not partition into the lipid extract and is not itself an antioxidant.

Microsomes can be prepared by the proposed method in about an hour, while several hours are necessary in the conventional method. The rapidly prepared microsomes are at least as pure as the conventional ones, judging by the data in Table 1 and, if used fresh, have a higher level of the peroxidation-sensitive enzyme glucose-6-phosphatase (25). The labile enzyme laurate hydroxylase is preserved better during frozen storage of microsomes prepared by the proposed method than during the storage of conventional microsomes in 0.25 M sucrose.

The enzyme levels in Table 1 for microsomes prepared in mannitol would be consistent with less than 0.1% contamination by mitochondria (26), up to 3.2% lysosomes (27), 1.3% peroxisomes (28) and as much as 5.7% plasma membrane fragments (29). The last estimate is probably high, since microsomes are themselves thought to contain some 5′-nucleotidase (30).

Incubation of the microsomes in the presence of NADPH, ferrous sulfate and ADP gives, after 1 hr, about the same amount of MDA for both types of preparations. However, the time course of the process is quite different in the two. Since MDA production occurs at the end of a sequence of steps involving the incorporation of oxygen into a fatty acid chain at at least two points, one would expect the rate of MDA release to increase as intermediates in the process accumulate. This is what is observed for microsomes prepared by the proposed method. In contrast, MDA release from conventional microsomes was initially very fast, slowing continuously throughout the course of the incubation.

The differences in MDA release patterns cannot be explained by any difference in the content of polyunsaturated fatty acids, since that was similar in both. The content of preformed oxidation products, except for MDA itself, was similar in both. The total amount of MDA released in one hour was only about 5% of the amount of NADPH provided, and the microsomes prepared by the new method were still releasing MDA at close to their maximum rate. Even had the microsomal suspending medium contained as much TET as the homogenizing medium, there would have been a 33-fold excess of ferrous sulfate present during the incubation. Since the suspending medium did not contain TET, the excess of ferrous ion must have been much greater than 33-fold.

Among the possible causes for the difference in MDA-release kinetics are (a) the microsomes prepared by the new method would have had weakly bound metal ions effectively "extracted" by the TET in the homogenizing medium, while those ions would have remained in the conventional microsomes; (b) the conventional microsomes may have contained peroxidation intermediates differing in kind, if not in amount, from those present in the other preparation; (c) the physical difference in the preparatons, with many free ribosomes in the conventional prep and only adsorbed ribosomes in the mannitol-based prep may have influenced the transfer of products. The fact that the cause for the difference in kinetics cannot be given an obvious explanation supports the suggestion that microsomes prepared by the proposed method may be useful in studies of the mechanistic aspect of lipid peroxidation.

A second advantage of the proposed method is clear from Figure 2. Avoiding sucrose eliminates the correctable but high background in the TBA assay, making it possible to more accurately measure low levels of peroxidation products. Even trace levels of MDA may be considered significant, since the mitochondrial contamination of these preparations is so low that MDA metabolism will be insignificant.

ACKNOWLEDGMENTS

The authors express their appreciation to Fred Talley and his support staff for the electron micrographs and to Carolyn Milford for typing the manuscript.

The Differential Effect of Polymyxin B_1 on Guinea Pig Lung Mitochondrial and Microsomal Glycerophosphate Acyltransferase

Salil K. Das[a,*] and **Dipak Haldar**[b]
[a]Department of Biochemistry, Meharry Medical College, Nashville, TN 37208, and [b]Department of Biological Sciences, St. John's University, New York, NY 11439

The activities of guinea pig lung mitochondrial and microsomal glycerophosphate acyltransferase differed in sensitivity to polymyxin B_1. At an antibiotic concentration of 1 mg/ml, the mitochondrial enzyme activity was stimulated twofold, but the microsomal enzyme activity was completely inhibited. Furthermore, the mitochondrial enzyme activity was stimulated by polymyxin B_1 without the addition of exogenous acyl-CoA. Additional experiments ruled out the possibility of polymyxin B_1 acting as a substrate for the mitochondrial acyltransferase. These results suggest either that the polymyxin B_1 sensitivity of mitochondrial and microsomal glycerophosphate acyltransferase is different or that their accessibility to substrates is different because the two isoenzymes are located differently in the different phospholipid microenvironment of the membranes.
Lipids 22, 757-759 (1987).

We have previously demonstrated a biomodal distribution of glycerophosphate acyltransferase activity in guinea pig lung and suggested that this enzyme might play an important role in lung development (1). Recent studies with liver and lung have indicated that a portion of this enzyme is exposed on the cytosolic side of the endoplasmic reticulum (2,3), whereas in mitochondria the enzyme spans the transverse plane of the outer membrane (4-8). Our results (1) indicated that lung mitochondrial and microsomal glycerophosphate acyltransferase have different functional characteristics. For example, while the microsomal enzyme activity was inhibited by N-ethylmaleimide, trypsin and acetone, the mitochondrial enzyme activity was either unaffected or stimulated. The exact mechanisms for this differential response are unclear. However, it is possible that particular locations of the enzymes in the respective membranes in relation to exposure to cytosolic environment may be responsible for this phenomenon. To substantiate this hypothesis, we searched for a probe with a strong binding affinity toward biological membranes. It is expected that such a binding would alter the activity of an enzyme depending on whether it is located in the outer or inner surface of the membrane. For this purpose, we used polymyxin B_1, a cyclic polypeptide containing one 8- to 9-carbon fatty acid residue, as a probe. Polymyxin B_1 is known to have a strong bactericidal activity due to its binding to the plasma membrane. It causes swelling of the outer leaf of the outer membrane and thereby disturbs the normal organization of the membrane and alters its permeability characteristics (9).

MATERIALS AND METHODS

Male guinea pigs (Hartley strain) of 300-g body weight were used. Their lungs were removed and washed with cold saline and with 0.25 M sucrose and were hand-homogenized in 0.25 M sucrose/0.01 M Tris, pH 7.4 (5 ml/g lung) with a Potter Elvehjem homogenizer. The homogenate was centrifuged at 1,000 × g for 10 min. The supernatant fluid was centrifuged at 20,000 × g for 20 min. The pellet was resuspended in a sucrose-Tris buffer and resedimented at 6,500 × g. The sediment (6,500 × g) was washed three times with sucrose-Tris buffer. It was finally resuspended in the same medium and used as mitochondrial preparation. The 20,000 × g supernatant fluid was centrifuged at 105,000 × g for 60 min to sediment the microsomes. The microsomal pellets were washed two times and resuspended in sucrose-Tris buffer. Protein was estimated according to Lowry et al. (10). Mitochondrial and microsomal cross-contaminations were evaluated by measuring marker enzymes, such as NADPH cytochrome c reductase and succinic dehydrogenase (11), as well as N-ethylmaleimide sensitivity of the subcellular glycerophosphate acyltransferase as described previously (1). Glycerophosphate acyltransferase assays were performed in a total volume of 0.5 ml as described in previous studies (1). All assays contained an optimal concentration of palmitoyl- or oleoyl-CoA (72 μM for mitochondria and 144 μM for microsomes), 1.5 mM *sn*-[2-^{3}H]glycerol 3-phosphate with a specific radioactivity of 10×10^3 cpm per nmol and ca. 0.1 mg subcellular protein. Polymyxin B_1 was purchased from Sigma Chemical Co. (St. Louis, MO) and added at 0.1, 0.2, 0.4, 1.0 and 2.0 mg/ml to the reaction mixture. The reaction was initiated by the addition of a subcellular fraction and terminated after 3 min by the addition of 1 ml of 1-butanol. An aliquot (0.7 ml) of the washed butanol extract was taken in a scintillation vial, evaporated under nitrogen and mixed with aquasol (5 ml) and counted in a Beckman LS-355 scintillation counter.

RESULTS AND DISCUSSION

The mitochondrial preparation had high succinic dehydrogenase (23.88 ± 8.56 nmol/min/mg; 5 determinations) and low NADPH cytochrome c reductase activity (12.37 ± 1.10 nmol/min/mg protein, 5 determinations). The microsomal preparation, by contrast, had high NADPH cytochrome c reductase (47.37 ± 1.10 nmol cytochrome c reduced/min/mg) and little succinic dehydrogenase activity (2.65 ± 1.55 nmol formazan/min/mg). Furthermore, at NEM concentration of 8.0 mM, the microsomal glycerophosphate acyltransferase activity was inhibited by 90%, whereas the mitochondrial activity was completely resistant. Thus, the mitochondrial and microsomal preparations were reasonably pure.

As shown in Figure 1, the treatment with polymyxin B_1 provides another method by which lung mitochondrial and microsomal glycerophosphate acyltransferase could be distinguished. In the presence of palmitoyl-CoA as the donor, polymyxin B_1 (1.0 mg/ml) caused nearly 150% stimulation of the mitochondrial enzyme activity while almost completely inhibiting the corresponding microsomal enzyme. Qualitatively similar differential effect of polymyxin B_1 was observed when oleoyl-CoA was used instead of palmitoyl-CoA as the acyl donor. The inhibitory action of polymyxin B_1 on microsomal enzyme was maximal within 1 min of incubation. Polymyxin B_1 has also been shown to have similar differential effects on mitochondrial and microsomal glycerophosphate acyltransferase in rat liver (5).

Thin layer chromatographic analysis of acylation products (lysophosphatidic acid and phosphatidic acid) using a solvent system, diisobutyl ketone/acetic acid/water (40:25:5, v/v/v), indicated that the polymyxin B_1 addition to the incubation medium of mitochondrial fraction did not alter the percent composition of the mono- (47.6%) and diacylated (52.4%) products. It should be noted that the condition used for the assay of glycerol 3-phosphate acylation were such that there was linearity with time and with the amount of protein. Because the ratio of the amount of lysophosphatidic acid and phosphatidic acid did not change in the presence of polymyxin B_1, the increased acylation of glycerol 3-phosphate by polymyxin B_1 is probably due to the stimulation of both acylation steps.

The difference in polymyxin B_1 sensitivity between the mitochondrial and microsomal glycerophosphate acyltransferase might be due to differences in the phospholipid microenvironment of the membranes or the orientation of the enzymes within the respective membrane. It is interesting to note that in the absence of an exogeneously added acyl donor, the endogenous mitochondrial enzyme activity (0.4 nmol/min/mg) was stimulated approximately 17-fold by polymyxin B_1 (1 mg/ml), whereas the endogenous microsomal enzyme activity remained unaffected by the antibiotic (Table 1). This observation indicates that polymyxin B_1 might partly act as a substrate for the mitochondrial enzyme, especially because the stimulation of the mitochondrial acyltransferase due to the addition of polymyxin B_1 (17-fold) was even more than that due to the addition of palmityl-CoA (threefold). Alternatively, the antibiotic interacts with the phospholipid bilayer of the mitochondrial outer membrane and perturbs the phospholipid microenvironment of the acyltransferase.

In order to investigate whether polymyxin B_1 may partly act as a substrate for the mitochondrial enzyme, the mitochondrial fraction was incubated with 72 μM-[palmitoyl-1-^{14}C]palmitoyl CoA (40 mCi/mmol), and varied concentrations of polymyxin B_1 (0.1, 0.2, 0.4, 0.6, 1.0 and 2.0 mg/ml) and glycerophosphate acyltransferase activities were determined. Polymyxin B_1 addition to the incubation medium caused a stimulation on the incorporation of radiolabeled substrate into phospholipids (Table 2). This observation suggests that polymyxin B_1 is not used as a substrate, but rather stimulates the accessibility of the mitochondrial glycerophosphate acyltransferase to exogenous palmitoyl CoA or to endogenous acyl donors.

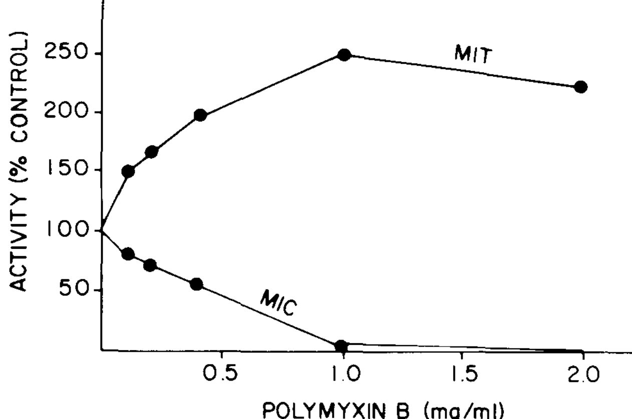

FIG. 1. Differential action of polymyxin B_1 on mitochondrial and microsomal glycerophosphate acyltransferase. The reaction was initiated by addition of the subcellular fraction to the incubation mixture. Palmitoyl-CoA was used as the acyl donor at 72 μM concentration for the mitochondria and 144 μM for the microsomes. Polymyxin B_1 was added as indicated. The specific activities of the subcellular fractions in the absence of polymyxin B_1 were 1.3 ± 0.1 and 2.9 ± 0.3 nmol/min/mg protein for mitochondria and microsomes, respectively.

TABLE 1

Effect of Polymyxin B_1 on Guinea Pig Lung Mitochondrial and Microsomal Glycerophosphate Acyltransferase Activity

	Enzyme activity (nmol glycerol 3-phosphate incorporated/min/mg protein)	
Additions to incubation medium	Mitochondria	Microsomes
None	0.40 ± 0.01	0.60 ± 0.01
Palmitoyl CoA	1.31 ± 0.10	2.91 ± 0.31
Polymyxin B_1	6.82 ± 0.82	0.71 ± 0.01
Palmitoyl CoA + polymyxin B_1	7.61 ± 0.51	0.62 ± 0.02

Assay conditions for glycerophosphate acyltransferase are described under Materials and Methods. Palmitoyl-CoA at concentrations of 72 μM for mitochondria and 144 μM for microsomes was used as the acyl donor. Polymyxin B_1 at a concentration of 1 mg/ml was used for both mitochondrial and microsomal fractions. Each value is the mean ± S.D. of 5 experiments.

TABLE 2

Effect of Polymyxin B_1 on Guinea Pig Lung Mitochondrial and Microsomal Glycerophosphate Acyltransferase Activity

Addition of polymyxin to incubation medium (mg/ml)	Enzyme activity (nmol palmitoyl CoA incorporated/min/mg protein)
None	1.8 ± 0.3
0.1	2.9 ± 0.3
0.2	4.6 ± 0.6
0.4	6.2 ± 0.4
0.6	7.3 ± 0.6
1.0	8.2 ± 0.7
2.0	6.9 ± 0.5

Assay conditions for glycerophosphate acyltransferase are described under Materials and Methods. [Palmitoyl-1-^{14}C]palmitoyl CoA (40 mCi/mmol) at a concentration of the 72 μM was used as substrate. Each value is the mean ± S.D. of 3 experiments.

As glycerophosphate acyltransferase is a membrane-bound enzyme, its activity is regulated by different phospholipid species (12). If polymyxin B_1 binds with the phospholipids of the outer side of the mitochondrial outer membrane, these phospholipid molecules, which take part in modulating the mitochondrial glycerophosphate acyltransferase activity, will be affected. We have recently shown that in lung (6), mitochondrial enzyme is stimulated twofold in the presence of a proteolytic enzyme such as trypsin. As the mitochondrial outer membrane is impermeable to trypsin, this stimulation could be regualted from the cytosolic side of the mitochondrial outer membrane. Indeed, these results and results with liver mitochondria (8) indicate that the mitochondrial glycerophosphate acyltransferase is a transmembrane protein. Currently, we are studying the effects of polymyxin B_1 on glycerol phosphate acylation and monoamine oxidase activity in lung mitochondrial outer membrane preparations.

In an isoionic medium, the mitochondrial enzyme might not be exposed to the aqueous environment outside the mitochondria (5), but a portion of the enzyme could still be present imbedded in the phospholipid layer of the outer side of the mitochondrial outer membrane. It is this portion that is involved in the manifestation of the stimulatory action of polymxin B_1 on mitochondrial glycerophosphate acyltransferase.

A Facile Synthesis and Carbon-13 Nuclear Magnetic Resonance Spectral Properties of 7-Ketocholesteryl Benzoate

Edward J. Parish*, Tsao-Yi Wei and **Peter Livant**
Department of Chemistry, Auburn University, Auburn, AL 36849

This paper presents a modified method of the selective allylic oxidation of cholesteryl benzoate. Pyridinium chlorochromate, in refluxing benzene, has been found to be an effective and convenient reagent for the efficient oxidation of cholesteryl benzoate to 7-ketocholesteryl benzoate in high yield. Also included herein are the carbon-13 nuclear magnetic resonance spectral properties of 7-ketocholesteryl benzoate and cholesteryl benzoate.
Lipids 22, 760–763 (1987).

Among the most frequently encountered oxidation products of cholesterol are those with an oxygen function at C-7 (1,2). Many of these oxidized derivatives may be formed enzymically from cholesterol or may be the result of autoxidation. These compounds have been found in animal tissues and foodstuffs (2) and are known to be inhibitors of mammalian sterol biosynthesis (3–6) and cell replication (7–9).

As a result of our continuing studies on sterol biosynthesis, we have developed a simplified method for the synthesis of 7-ketocholesteryl benzoate, 2, a key intermediate in the synthesis of 7-oxygenated sterols. The method reported herein is applicable to both small- and large-scale preparations and represents an improvement in convenience and yield over previously reported procedures.

Carbon-13 nuclear magnetic resonance (^{13}C NMR) spectral studies can provide far more information concerning the structure of steroids than proton (^{1}H) NMR studies, since most of the carbons exhibit separately resolved signals that may be assigned to specific carbon atoms with a high degree of confidence (10). As an extension of our synthetic studies, we have completed the unambiguous ^{13}C NMR assignments for carbon atoms in 7-ketocholesteryl benzoate, 2, and cholesteryl benzoate, 1.

1 R_1 = H, R_2 = H   2 R_1 = R_2 = O

SCHEME 1. Steroid structures of *1* and *2* and ring numbering system.

EXPERIMENTAL METHODS

General methods. Melting points were determined with an Electrothermal capillary apparatus and are uncorrected. Infrared (IR) spectra (KBr pellet) were recorded on a Perkin-Elmer Model 580 spectrometer. ^{1}H NMR and ^{13}C NMR spectra (deuterated chloroform solvent) were obtained with a Bruker AM-400 spectrometer operating at a frequency of 400.179 MHz for ^{1}H and 100.619 MHz for ^{13}C using tetramethylsilane as an internal standard. Proton spectra were obtained using 16K data points and a sweep width of 10 ppm, while parameters for carbon spectra were 32K and 250 ppm, respectively. Distortionless enhancement polarization transfer (DEPT) experiments (11,12) were conducted at $\theta = 135°$, which corresponds to a pulse width of 21.4 sec. Carbon-hydrogen (C–H) correlation (13,14) was conducted using 2K data points in the F2 dimension and 512 data points in the F1 dimension. The F1 data was zero-filled to 1K, and exponential line broadening (2 Hz in F2 and 0.25 Hz in F1) was included before Fourier transformation. Proton chemical shifts for the C-18 and C-19 angular methyl resonances were calculated by the method of Zurcher (15). Mass spectral (MS) analysis was conducted on a VG-7070E magnetic sector mass spectrometer at 70 eV (source temperature was 150 C) using a solid probe, and the results are presented in terms of relative intensity (percentage of the base peak) along with probable mode of origin. Gas liquid chromatographic (GLC) analysis was performed on a Hewlett-Packard (HP) gas chromatograph (5710 A) equipped with a 25-M glass capillary column coated with DB-5 and a flame ionization detector. Thin layer chromatography (TLC) was carried out on plates of Silica Gel G (Analtech, Newark, DE) with the components visualized after being sprayed with molybdic acid (16). Solvent systems for TLC analysis were SS-1, toluene, SS-2, 10% ether in hexane and SS-3, 10% ethyl acetate in hexane. Column chromatography employed silica gel (60–200 mesh) on columns that were 100 cm × 1.5 cm. Cholesteryl benzoate was prepared in 89% yield by treatment of purified commercial cholesterol (98% pure by GLC analysis) with benzoyl chloride in pyridine (mp 148.5–150 C, lit. [17] mp 147 C). Commercial cholesterol (Sigma Chemical Co., St. Louis, MO) was purified by multiple recrystallizations from acetone-water. A sample of authentic 7-ketocholesteryl benzoate was prepared by the procedure of Salmond et al. (18). Pyridinium chlorochromate (PCC) was obtained from the Aldrich Chemical Co. (Milwaukee, WI).

General oxidation procedures. Cholesteryl benzoate (4.91 g, 0.01 mol) was dissolved in benzene (250 ml) containing molecular sieves (0.5 g, type 3A). Pyridinium chlorochromate (PCC, 64.67 g, 0.30 mol) was added, and the stirred reaction mixture was gently refluxed under

Abbreviations: ^{13}C NMR, carbon-13 nuclear magnetic resonance; ^{1}H NMR, proton nuclear magnetic resonance; IR, infrared; DEPT, distortionless enhancement polarization transfer; MS, mass spectra; GLC, gas liquid chromatography; HP, Hewlett-Packard; TLC, thin layer chromatography; PCC, pyridinium chlorochromate; DMF, N,N-dimethylformamide; DMSO, dimethylsulfoxide.

a nitrogen atmosphere for 24 hr. The benzene solution was decanted, and the remaining contents of the reaction flask were washed several times with ether. The combined extracts were washed with a saturated NaCl solution, dried over anhydrous magnesium sulfate and evaporated to dryness under reduced pressure. TLC analysis (SS-1) indicated the presence of a single component of ca. 95% purity. The residue was subjected to column chromatography using a solvent gradient of ether in toluene. The purified material was recrystallized from acetone-water to yield 7-ketocholesteryl benzoate (4.39 g, 87%): mp 158–159.5 C, lit. (17) 159 C; IR ν_{max} 1735, 1685, 1670, 1245, 1039 cm^{-1}; ^1H NMR: 0.69 (S, 3H, C−18−CH_3), 1.25 (S, 3H, C−19−CH_3), 4.93 (m, 1H, C−3−H), 5.73 (m, 1H, C−6−H), 7.73 (m, 5H, benzoate); ^{13}C NMR: (Table 1); MS, m/e (rel int): 504 (M, 4%), 382 (M-benzoic acid, 7%), 367 (M−CH_3−benzoic acid, 2.8%), 121 (benzoyloxy, 5%), 105 (benzoyl, 100%). GLC analysis indicated a single major component of 98% purity, and TLC analysis indicated a single component in three solvent systems (SS-1, SS-2 and SS-3). Both analyses showed identical chromatographic mobility with an authentic compound.

RESULTS AND DISCUSSION

The allylic oxidation of Δ^5-steroids was initially accomplished by chromic acid reagents with only limited success (19). For example, the allylic oxidation of **1** with sodium chromate in acetic acid/acetic anhydride gave **2** in an optimum yield of 38% (18).

Synthetically useful changes in the properties and reactivity of chromium (VI) reagents have been brought about by the formation of amine complexes. The Collins reagent is formed by the complexation of chromium trioxide with pyridine (20,21). Using this reagent, the allylic oxidation of **1** gave a 68% yield of **2** (17), and in a related study, using very anhydrous conditions, cholesteryl acetate was oxidized to 7-ketocholesteryl acetate in 72% yield (22). Similar complexes have been formed using chromium trioxide and pyrazole (23), 3,5-dimethylpyrazole (18) and benzotriazole (24) and have been shown to oxidize **1** to **2** in 70–76% yields. These reactions require the preparation of the reagent complex before each reaction.

Commercially available PCC has recently become widely used in organic synthesis for the oxidation of

primary and secondary alcohols to carbonyl compounds (25). This reagent, in methylene chloride containing pyridine (26), other aromatic amines (27), pyrazole (28), 3,5-dimethylpyrazole (29) and benzotriazole (24), was reported to effect the selective oxidation of the allylic hydroxyl function of a number of steroidal alcohols. At room temperature, PCC in methylene chloride was found to be an ineffective reagent for allylic oxidation (18). In contrast to these latter results, we have achieved moderate success using PCC in refluxing methylene chloride for allylic and benzylic oxidations (30). PCC, in dimethylsulfoxide, has also been used for the oxidation of β-ionone to the corresponding diketone (31).

In the present study, we have found that PCC, in refluxing benzene, can affect the high yield (87%) oxidation of 2 to 1. This conversion was accomplished with a 1:30 ratio of reagent (PCC) when 1–10 g of 2 were oxidized. Oxidations of 2 conducted on quantities of less than 1 g were successfully performed using smaller quantities of reagent (1:25) with similar yields, thus demonstrating the ability of the described method to be useful for both large- and small-scale preparations. This efficient procedure represents a significant improvement in both yield and convenience compared to other reported methods for the allylic oxidation of 1 and 2.

Using the reaction conditions described herein, additional studies were conducted using other solvents with 1 and PCC. Under these conditions, refluxing acetone, pyridine, N,N-dimethylformamide (DMF) and dimethylsulfoxide (DMSO) at 100 C yielded 2 in 2%, 0%, 18% and 77% yield, respectively. In a previous study, we found the use of refluxing methylene chloride as solvent yielded 54% of 2 from 1 (30).

As an extension of our synthetic studies, we have completed the unambiguous ^{13}C NMR assignments for carbon atoms in 7-ketocholesteryl benzoate, 2, and cholesteryl benzoate, 1 (Table 1, Fig. 1). The previously reported ^{13}C spectrum of cholesteryl acetate (10,32) was used to assign resonances due to carbons 16–18 and 20–27. Carbons of the benzoate group were assigned using standard spectra of benzoate esters (33). A DEPT (11,12) experiment separated the remaining carbon resonances into two groups, secondary (down) and primary or tertiary (up). An additional C—H correlation experiment (13,14) provided data to unambiguously assign the peaks at 45.4, 49.8 and 50.0 ppm to carbons 8, 9 and 14, respectively.

Evaluation of the C—H correlation spectrum indicated that the carbon peaks at 45.4, 49.8 and 50.0 correlated with proton (^{1}H) multiplets at 2.25, 1.55 and 1.35 ppm, respectively.

The assignment of 45.4 ppm at carbon 8 was straightforward, since the proton multiplet at 2.25 ppm is adjacent to the carbonyl function at carbon 7 and is characteristically shifted to a downfield position (deshielded) (34). The assignment of 49.8 ppm as carbon 14 and 50.0 as carbon 9 was based on the observation that the C-14 proton is closer to the ketone function at carbon 7 and is, therefore, more deshielded than the C-8 proton (1.55 ppm vs 1.35 ppm). It is also interesting to note (based on the C—H correlation spectrum) that the protons on C-15 appear at 1.22 and 2.42 ppm. The proton shifted downfield to 2.42 ppm is the proton that, upon

inspection of models, is seen to be quite close to the carbonyl at carbon 7.

From the results presented in Table 1, the introduction of the ketone function at carbon 7, 2, causes several major changes, notably at carbons 7, 8 and 14 and at the olefinic carbons 5 and 6. By the use of the DEPT and C—H correlation techniques, the assignments of the carbons in 1 and 2 were conveniently made in a timely manner. The results obtained were in favorable agreement with the salient carbon assignments for cholesteryl acetate and 7-ketocholesteryl acetate made using earlier ^{13}C NMR techniques (10,32).

Immunocytochemical Localization of Lingual Lipase in Serous Cells of the Developing Rat Tongue

Ingram M. Roberts[a,*], **Lucien E. Nochomovitz**[a], **Ronald Jaffe**[b], **Selma I. Hanel**[a], **Magaly Rojas**[a] and **R.A. Agostini Jr.**[b]

[a]Departments of Medicine and Pathology, George Washington University Medical Center, George Washington University School of Medicine, Washington, DC 20037 and [b]Department of Pathology, Children's Hospital, University of Pittsburgh School of Medicine, Pittsburgh, PA 15260

The ontogeny of the rat lingual serous and mucous glands was explored by light and electron immune microscopy using the peroxidase-antiperoxidase and streptavidin-gold techniques. Tissues from fetal and neonatal rats from day 18 of gestation through 4 wk after birth were fixed and embedded in paraffin or Epon for light and transmission electron microscopy, respectively. Electron microscopy revealed that the only cells containing lingual lipase were the developing serous cells; secretory granules containing lingual lipase of varying degrees of maturity were seen. Mucous cells did not show immunospecific staining in rats of any age. The neonatal "mixed" lingual glands secrete lingual lipase from serous components immediately after birth to aid in fat digestion.
Lipids 22, 764-766 (1987).

Lingual lipase is an important enzyme in gastric fat digestion in man and other animals (1-5). We have recently demonstrated by immunocytochemical methods using a polyclonal monospecific antibody to lingual lipase that the enzyme is found primarily in the serous von Ebner glands located beneath the circumvallate papilla of the tongue in adult rats (5). Serous demilune cells of the lingual mucous glands also contain lingual lipase. However, the mucous cells of adult rats do not contain this enzyme (5). The aim of this study was to explore the ontogeny of rat lingual lipase, using immunocytochemical techniques to determine at what stage of development and in what specific cell type this enzyme first appears.

MATERIALS AND METHODS

Lingual lipase was purified from adult male Sprague Dawley rats, and polyclonal antibodies were raised in female New Zealand rabbits as previously described (5).

Chemicals. Octylglucoside was purchased from Sigma Chemical Co. (St. Louis, MO). Sephacryl S-200, polybuffer 74 and PBE 94 were products of Pharmacia Fine Chemicals (Piscataway, NJ). Buffers were composed of ACS-grade chemicals (Fisher Scientific Co., Pittsburgh, PA). Other chemicals were of the highest purity available.

Immunocytochemical localization of rat lingual lipase light microscopy. The method for light immunomicroscopy was as previously described (5) except that tissues were immersed in 10% alcoholic formalin/95% alcohol (1:9, v/v) and fixed overnight. The specimens were processed on an Autotechnicon and embedded in Tissue Prep (paraffin and synthetic polymer, Fisher Scientific). Tissue from day-1 postpartum rats was obtained prior to the initiation of suckling.

Sections were cut at 4-5 μm, hydrated through xylene and 95% alcohol to water. Endogenous tissue peroxidases were depleted with 1% hydrogen peroxide in methanol for 30 min. Immunospecific staining was not observed when sections were stained with pre-immune serum or second antibody (goat antirabbit IgG) in the absence of primary antibody (rabbit antilipase).

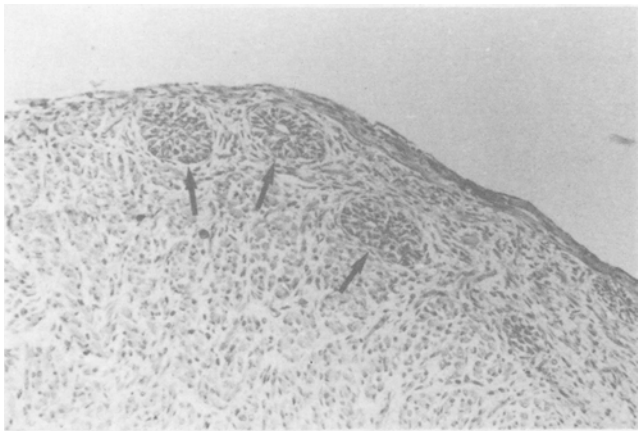

FIG. 1. Immature glands (arrows), day 18 of gestation. There is no immunospecific staining for lingual lipase at this time. (40×, hematoxylin and eosin).

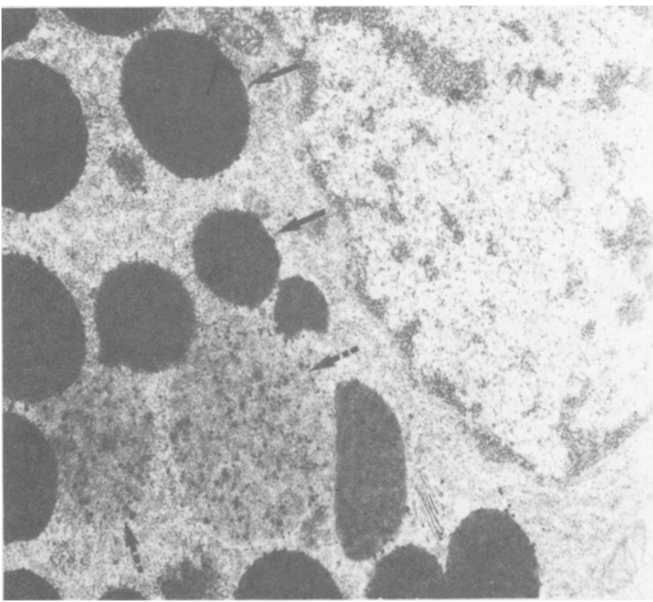

FIG. 2. Day 1 after birth. Gold particles are restricted to the serous granular cells. There is gold found in association with mature (compact; solid arrows) and immature (light fuzzy; dashed arrows) secretory granules. The granules exhibit varying density. (27,000×, streptavidin-gold).

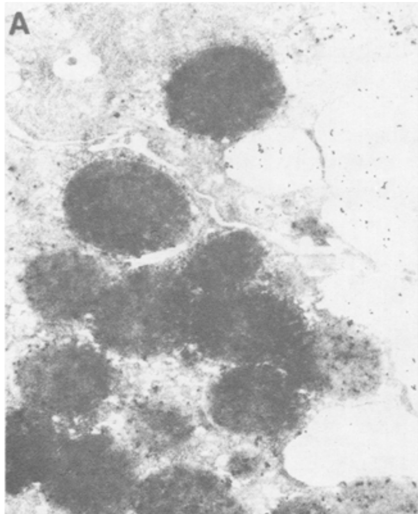
*To whom correspondence should be addressed at Division of Gastroenterology, George Washington University Medical Center, 2150 Pennsylvania Ave. N.W., Rm. 603, Washington, DC 20037.



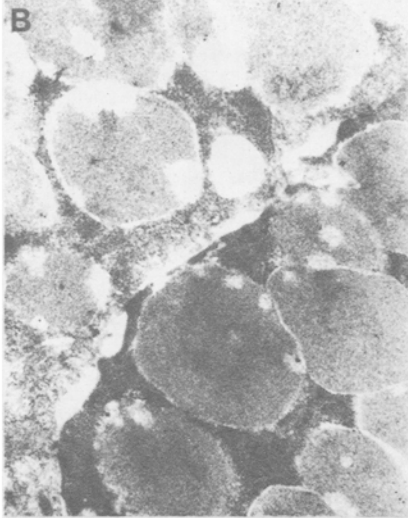


FIG. 3. Day 1 after birth. (a) Serous cells demonstrate gold in association with all granules. Exocytosis of lingual lipase is evident by the presence of gold in the ductular lumen (27,000×, streptavidin-gold). (b) Mucous cells from "mixed" glands. Note the absence of specific immunostaining for lingual lipase by the streptavidin-gold technique (27,000 ×, streptavidin-gold).

Additional sectons were stained for mucin by the mucicarmine method and for glycoprotein by the periodic acid-Schiff (PAS) method (6).

Electron microscopy. The method for electron microscopy was as previously described (5) except that sections of rat tongue containing lingual serous and mucous glands were immersed in 1% glutaraldehyde at 4 C for only 1 hr, followed by washing in 0.2 M phosphate buffer with 10% sucrose for 48 hr. Tissues were postfixed, dehydrated, embedded and stained for electron microscopy using the biotin-streptavidin technique (ABC) previously described (5). Immunospecific staining was not seen with pre-immune serum, second antibody or streptavidin-gold in the absence of rabbit antilipase (first antibody).

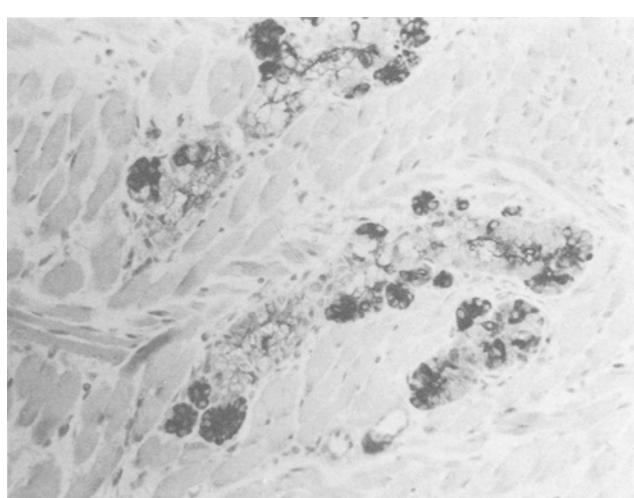

FIG. 4. Day 3 after birth. "Mixed" serous and mucous glands. Note the intense immunospecific staining for lingual lipase in the serous cells (100×, peroxidase-diaminobenzidine).

RESULTS

Primitive cellular cords appeared in the subepithelial stroma of the dorsum of the posterior tongue for the first time on the 18th day of gestation (Fig. 1). The cords showed no stainable mucin, glycogen or lingual lipase. In addition, lingual lipase was not detectable on day 19. Some primitive glands between days 20 and 21 appeared to stain positively for the presence of mucin and lingual lipase. On day 22 of gestation (prepartum), all glands contained stainable lingual lipase (peroxidase-antiperoxidase method, PAP), mucin and glycogen and were easily recognized on light microscopy. By the first postpartum day, three cell types were identified by electron microscopy in these "mixed" glands: (a) undifferentiated cells without cytoplasmic specialization; (b) serous cells with dark, apical cytoplasmic granules; and (c) mucous cells with characteristic mucous granules. The serous cells contained cytoplasmic secretory granules of varying degrees of maturity (Fig. 2). Immune electron microscopy showed lingual lipase in all serous granules, and there was lipase detectable in the glandular lumens (Fig. 3a). Neither the undifferentiated nor the mucous cells had evidence of lingual lipase (Fig. 3b). By the third postpartum day, there were fewer undifferentiated cells in the mixed glands, and mucous cells were the predominant cell type. The serous cells of the mixed glands contained larger granules and there were more gold particles per granule than in the day 1 specimens. At this stage, also, exclusively serous acini accompanied the mixed glands, i.e., reminiscent of the adult rat tongue (5). The serous glands contained glycogen, but did not stain positively for mucin. Both the serous and mixed glands demonstrated stainable lipase by light microscopy (Fig. 4). However, by the

fourteenth postpartum day, the mixed glands had developed a predominantly mucous adult appearance with only occasional lipase-containing demilune cell. The serous glands also then showed the branching ducts and multiplicity of acini of the adult rat tongue.

DISCUSSION

We have shown that, in the adult rat, lingual lipase appears to be confined to the serous von Ebner glands and demilune cells of the lingual mucous glands (5). Other investigators have shown that there is abundant lipolytic activity present in the tongue of the newborn rat (1-4) and have histologically studied the ontogeny of the lingual mucous and serous glands (1). We have demonstrated that rat lingual lipase is immunocytochemically clearly detectable in all mixed glands as early as the 20th to 22nd gestational days. It is difficult, however, using light microscopy to identify the precise cell that contains the enzyme because the entire gland stains for mucin and glycogen. Using immune electron microscopy, we have shown for the first time that only the serous cells of these developing glands contain lingual lipase. We have confirmed the findings of other investigators that these mixed glands appear prior to the development of the serous glands (1). A source of lipase is extremely important to the neonatal rat, as the process of suckling begins immediately after birth. We have noted that the mixed glands become progressively mucous in nature until they obtain their adult appearance by postpartum day 14. Lingual lipase secreted by mixed glands begins the process of neonatal fat digestion until the serous glands fully develop and assume a dominant role in secretion of the enzyme. The mixed glands differentiate into almost exclusively mucous glands, in which the demilune cells alone contain lingual lipase.

Isoprenoid Fatty Acids From Marine Sponges. Are Sponges Selective?

Nestor M. Carballeira*, **Lilliam Maldonado** and **Beatriz Porras**
Department of Chemistry, University of Puerto Rico, Rio Piedras, Puerto Rico 00931

The burrowing sponges *Anthosigmella varians* and *Spheciospongia vesparium* were found to be rich in the isoprenoid phospholipid fatty acid 4,8,12-trimethyltridecanoic (5.2% and 23%, respectively, of the total fatty acid composition), while the burrowing sponge *Chondrilla nucula* and the demosponge *Agelas dispar* contained the acid 3,7,11,15-tetramethylhexadecanoic (13.8% and 8.6%, respectively, of the total phospholipid fatty acid composition). No other isoprenoid fatty acid was found, and the two acids described in this work did not occur concomitantly in the same sponge.
Lipids 22, 767–769 (1987).

Isoprenoid fatty acids have been of special interest during recent years, in particular for the petroleum industry and the field of geochemistry (1). Speculation about the possible conversion of marine lipids to petroleums, initiated by the discovery of pristanic and phytanic acids in a California petroleum (2) and in recent and ancient sediments, initiated interest in the geological fate of these acids as possible biomarkers for the search of petroleum (1). Two important isoprenoid fatty acids have been isolated from both terrestrial and marine sources, namely the 4,8,12-trimethyltridecanoic and the 3,7,11,15-tetramethylhexadecanoic (phytanic) acids. The latter has been found in fish and marine mammal oils (3); in sheep, ox, and butterfat (2); in patients with Refsum's syndrome (4); and in halophilic bacteria (5). The 4,8,12-trimethyltridecanoic acid has been detected in herring, seal oil, sheep fat and geological samples (2). However, to the best of our knowledge, no definite study of isoprenoid fatty acids from marine sponges has been performed, albeit that some have been isolated from a few sponges. For example, the 3,7,11,15-tetramethylhexadecanoic acid (phytanic) was reported to be a 3% constituent of the total phospholipid fatty acids of the marine sponge *Aplysina fistularis* by Walkup et al, (6). On the other hand, the marine sponge *Petrosia ficiformis* was reported to contain 4% of 4,8,12-trimethyltridecanoic acid (7) but no phytanic acid. Therefore, it seems that some marine sponges are specific for phytanic acid while others are specific for the 4,8,12-trimethyltridecanoic acid; many do not possess any isoprenoid fatty acids at all. We therefore decided to scrutinize several sponges for isoprenoid phospholipid fatty acids, and herein we report the results of our investigation.

The marine sponges in this study are *Agelas dispar, Anthosigmella varians, Spheciospongia vesparium* and *Chondrilla nucula*. The latter three sponges are bona fide burrowing sponges; these are among the most interesting since they burrow into shells, rocks and corals (8). *A. varians* is one of the most variable demosponges in shape and size. *A. varians* and corals have similar habitat requirements and usually are encountered in a competitive interaction for substrate dominance. This competitive interaction results in the overgrowth and death of the coral (9). Another common West Indian sponge, *C. nucula*, can overgrow large tracts of the corals *Porites furcata* and entire colonies of *Siderastrea siderea* and *Diploria clivosa* (9). *A. dispar*, on the other hand, is not considered to be a burrowing sponge but is a common Caribbean sponge that has not received particular attention. Interesting was the finding by Cullen and Devlin (10) of a novel quaternary 9-methyladenine in this sponge. However, to the best of our knowledge, no study of the lipids of *A. dispar* has been carried out. Interesting for us were the phospholipid fatty acids of *A. dispar*, since phospholipid fatty acids from marine sponges have been shown to possess an unusual 5,9-unsaturation (11).

EXPERIMENTAL METHODS

A. dispar, A. varians, C. nucula and *S. vesparium* were collected near La Parguera, Puerto Rico, during April 1986. The sponges were washed in sea water, carefully cleaned of all nonsponge debris and cut into small pieces. Immediate extraction with chloroform/methanol (1:1, v/v) yielded the total lipids. The neutral lipids, glycolipids and phospholipids were separated by column chromatography on ammonium hydroxide-treated silicic acid (100–200 mesh) using the procedure of Privett et al. (12). The fatty acyl components of the phospholipids were obtained as their methyl esters by reaction of the phospholipids with methanolic hydrogen chloride (13) followed by purification on column chromatography eluting with hexane/ether (9:1, v/v). The resulting methyl esters were analyzed by gas chromatography-mass spectrometry (GC-MS) using a Hewlett Packard 5995 A Gas chromatograph-mass spectrometer equipped with a 30 m × 0.32 mm fused silica column coated with SE-54. For the location of double bonds, N-acylpyrrolidide derivatives were prepared by direct treatment of the methyl esters with pyrrolidine/acetic acid (10:1, v/v) in a capped vial (1 hr at 100 C) followed by ethereal extraction from the acidified solution and purification by preparative layer chromatography (PLC). Hydrogenations were carried out in 10 ml of absolute methanol and catalytic amounts of platinum oxide (PtO_2). Mass spectrometry results are available upon request. The mass spectra of the isoprenoid fatty acids are presented below.

RESULTS

Our results are shown in Table 1, where the fatty acid composition of the four sponges is presented. We can see that the sponges *A. varians* and *S. vesparium* are specific for the 4,8,12-trimethyltridecanoic acid, while the sponges *A. dispar* and *C. nucula* contain the 3,7,11,15-tetramethylhexadecanoic acid. To the best of our knowledge, no other isoprenoid fatty acid has been detected in a marine sponge. Moreover, the two isoprenoid fatty acids mentioned above do not occur concomitantly in the same sponge, i.e., the sponge has either the 4,8,12-trimethyltridecanoic acid or the 3,7,11,15-tetramethylhexadecanoic acid, but not both at the same time. Most sponges do not have isoprenoid fatty acids. We can also see from the table that principal fatty acids common to all sponges are hexadecanoic (11–34%), octadecanoic (3–17%) and behenic (1–13%). In most of these sponges, even phospholipid fatty acids (saturated and unsaturated) were the predominant ones. The most striking example was the case of *A.varians*, where even phospholipid fatty acids accounted for more than 90% of the total mixture. In general, branched fatty acids (anteiso and iso) were not abundant but odd fatty acids (saturated and unsaturated) were even less abundant. In *A. varians*, we could not detect any odd fatty acids. Isoprenoid fatty acids were present in the three burrowing sponges that we have analyzed in this work. The most striking result was observed in the sponge *S. vesparium*, where the isoprenoid fatty acid 4,8,12-trimethyltridecanoic accounted for more than 23% of the total mixture. No other sponge has been reported, to the best of our knowledge, that contains more isoprenoid fatty acids than *S. vesparium.*

Major acids from *A. dispar* were palmitic (16:0), phytanic (20:0), docosanoic (20:0) and behenic (22:0). The latter acids accounted for more than 43% of the total mixture. Three interesting unsaturated very long chain fatty acids were encountered in the *A. dispar* that we collected. These were the 5,9-tetracosadienoic (24:2), the 5,9-pentacosadienoic (25:2) and the 5,9-hexacosadienoic (26:2) acids, which accounted for 10% of the total mixture. The 5,9-unsaturation is typical of marine sponges (6,7), but it is very rare to find three consecutive acids with the 5,9-unsaturation together in the same sponge. The phospholipid mixture was shown by thin layer chromatography (TLC) to be phosphatidylcholine (PC), phosphatidylserin (PS) and phosphatidylethanolamine (PE). For the characterization of the fatty acids, capillary GC combined with

MS was used. The fatty acid methyl esters (FAME) of the 5,9 very long chain fatty acids had equivalent chain lengths (ECL) values typical of dienoic acids; for example, the 5,9-hexacosadienoic acid had a ECL of 25.42. ECL clearly expresses where a FAME elutes with respect to the series of straight chain saturated methyl esters in a temperature-programmed run. Furthermore, upon catalytic hydrogenation (PtO_2), the dienoic acids were converted to their respective saturated acids, thus excluding the possibility of any branching. To exactly locate the double bonds, pyrrolidide derivatives of the fatty acid methyl esters were then prepared, revealing a peak at m/e 180. The latter peak is typical when two double bonds are located at the 5-and 9-positions, resulting from allylic cleavage (6). Also, comparison with authentic samples from other sponges confirmed our results (6,7). Interesting to us was the presence of a FAME with an ECL value of 17.58, just between the heptadecanoic and octadecanoic acids in the FAME mixture of *A. dispar*. The mass spectrum of the methyl ester of this acid revealed a M^+= 326 corresponding to a 20:0 acid. To explain the capillary GC retention time with the MS results, multiple methyl branching should be proposed. In fact, the latter acid was inert upon catalytic hydrogenation (PtO_2), thus excluding the possibility of any unsaturation. Furthermore, the mass spectrum of the methyl ester of this acid revealed a base peak at m/e 101 (100%) and peaks at m/e 171 (15%) and m/e 241 (2%), immediately suggesting it to be the methyl ester of the known 3,7,11,15-tetramethylhexadecanoic (phytanic) acid. A GC-MS comparison with an authentic sample confirmed the results.

DISCUSSION

Isoprenoid fatty acids found to date in marine sponges are the 4,8,12-trimethyltridecanoic and the 3,7,11,15-tetramethylhexadecanoic. There is no report to date, to the best of our knowledge, of other isoprenoid fatty acids. These acids could be of geological significance since the phytanic acid, for example, could be transformed (or has been sometime in the past) to phytane and could be part of marine sediments. In other words, these acids can be potential biomarkers (1).

In analogy to Refsum's syndrome (4), the accumulation of these isoprenoid fatty acids could be due to a deficiency of α—oxidase activity. Because of a methyl substituent at carbon 3, for example, phytanic acid cannot be β-oxidized but it can undergo α-oxidation to pristanic acid. A deficiency of α-oxidation prevents the metabolism of phytanic acid and thus may result in its accumulation in the sponge.

The origin of these isoprenoid fatty acids is also worthy of investigation. They could arise from the phytol portion of chlorophyll (14) since, for phytanic acid, that has been shown to be the case. These isoprenoid fatty acids could also be of planktonic origin or they could arise from halophilic bacteria, which are known to contain such acids (15). Still another possibility is for the sponge to be synthesizing the acids from isoprene units, since these sponges seem to be selective for one acid or the other. A symbiotic relationship between the sponge and bacteria may also be taking place. A more interesting problem seems to be the specificity displayed by these sponges. Why are these sponges specific for the 4,8,12-trimethyltridecanoic acid while others are specific for the 3,7,11,15-tetramethylhexadecanoic acid? To answer the latter question as well as to generalize the specificity displayed by the sponges in this work, a number of additional sponges will have to be analyzed for the presence of these branched acids. Work is in progress towards these ends.

ACKNOWLEDGMENT

Thomas R. Tosteson and Vance Vicente from La Parguera, Puerto Rico, did the collection and classification of the sponge. Dr. O. Rosario assisted in the mass spectrometry. Financial support was provided by the University of Puerto Rico, FIPI (Grant No. 86-100-12-88.0) and NIH-MBRS (Grant No. 5 S06 RR 08 102-14).

[Received April 23, 1987]

An International Conference on

Diet, Lipids and Cancer
Metabolism—Membranes—Mechanisms
May 22-26, 1988

Yulara Resort (via Ayers Rock)
Northern Territory, Australia

The views, and counterviews, of specialists from a wide range of disciplines —epidemiology, physiology, endocrinology, biochemistry, metabolism, membranology—will refocus attention on the role of nutrition in the prevention, management and treatment of human cancer. Full participation, by a maximum of 300 registrants, will be actively encouraged through a wide range of presentation styles—lectures, discussions, debates, posters.

Sponsored by:
Australian Biochemical Society
Australian Cancer Society
American Oil Chemists' Society
Japanese Oil Chemists' Society
International Union of Biochemistry

Ether Lipids in Oncology–Welcoming Address

Otto Westphal
Max-Planck-Institut für Immunbiologie, Freiburg, Germany

Ladies and Gentlemen,

It is an honor for me to welcome you who have come from all over the world to the First International Symposium on Ether Lipids in Oncology. As one who witnessed the development of the subject over the last 20 to 25 years, allow me a short historical sketch.

In 1960, Armour & Co. in Chicago took a patent (1) for the production of stable fat emulsions that can be administered intravenously as a parenteral high-caloric nutrient for clinical use. For the dispersion of the fat particles, soybean lecithin was recommended. But such lecithin mixtures, in contact with air, rather soon acquired pyrogenic properties. The underlying mechanism was explained by autoxidation of (conjugated) fatty acid double bonds in certain lecithin molecules. Autoxidation and occurrence of undesired pyrogenicity could be prevented by partial catalytic hydrogenation. Because hydroxy- (or peroxy-) lecithins could be suspected to be the cause of pyrogenic activity and because we at the Max-Planck-Institut in Freiburg were very interested in structurally defined pyrogens for the initiation of artificial fever (2-4), we decided to attempt the synthesis of such hydroxy-lecithins and to test them for possible pyrogenic activity.

At that time, in 1960, a young and ambitious student of chemistry, Hansjörg Eibl, contacted me to ask for a diploma and doctor thesis. He agreed to enter the field of lecithin synthesis, starting with dioleoyl lecithin and planning the preparation of higher unsaturated lecithins (5). However, rather soon we were driven into other, even more interesting aspects of that field. Eibl continued his training and interest in organic chemistry and biochemistry of phospholipids, joined the groups of van Deenen in Utrecht and Lands in Ann Arbor and made phospholipids his "grand passion" (6).

At that time, in 1960, a group of investigators around the late Prof. Herbert Fischer at our Institute in Freiburg had found that complement-fixing immune reactions are accompanied by a significant overproduction of lysolecithin due to stimulation of phospholipase A activity (7). The authors suggested that lysolecithin might be the biologically active, common initiator of complement activation (8,9). Fischer, together with Paul Gerhard Munder, then found that very small amounts of exogenous lysolecithin strongly enhanced the phagocytic activity of peritoneal macrophages in vitro and in vivo (10). This finding prompted a general survey on the possible role of lysolecithins in immune reactions.

Somewhat later, stimulated by Munder and Fischer's finding, our chemical group proposed the synthesis of structurally defined lysolecithins and especially lysolecithin analogs that might differ physicochemically and, thus also biologically from the natural prototype (11-15).

Interestingly, we soon discovered that no total organic synthesis of lysolecithins had hitherto been described. Van Deenen and coworkers had applied combinations of organic-preparative and enzymatic methods and arrived at optically active preparations. All commercially available preparations were manufactured from natural lecithin mixtures by phospholipase action.

From about 1965-68, Arnold, Eibl and Weltzien synthesized a rather comprehensive series of racemic and optically active glycero- and other phospholipids (11-15), some in radiolabeled form, which more or less resembled natural lysolecithins. Eibl developed plenty of imagination and new ideas on how to synthesize hitherto unknown compounds. Special emphasis was placed on ether-analogs (13-15) because of their higher metabolic stability and longer half-life. In 1967, Weltzien and Arnold synthesized the 1-*O*-octadecyl-2-*O*-methyl-glycero-3-phosphocholine (13), abbreviated ET_{18}-OCH_3, which turned out to become the model of the new ether lipid antitumor drugs.

Many of the highly purified lysolecithin analogs were given to Fischer and Munder for biological screening in vivo and in vitro. These studies started in 1967-68, years ago, and it was P. G. Munder who did most of the work on lysolecithin analogs as a new class of immunomodulators (16). Munder and his coworkers were also the first to observe the selective destruction of various tumor cells by lysolecithin analogs (17-20). Klibansky and de Vries (21) had observed selective sensitivity of human leukemic cells towards natural lysolecithin. With the many analogs at hand, Munder was able to define certain structural requirements for optimal antitumor activity, first summarized and submitted for publication in June 1976 (16).

Glycerolipids with a long-chain alkyl substituent instead of an ester group, in the 1-position of glycerol have been known for about half a century. They occur in nature, especially in fish and higher animals (see, for example, ref. 22). Thus, ether lysolecithins in principal are natural products.

I think it is fair to say that the many studies on the action of lysolecithin analogs on tumors that followed are based on those first and fundamental observations by Munder and his coworkers. Early in the studies, it became apparent that the C_{18}-ethers in position 1 of glycerol, such as ET_{18}-OCH_3 and ET_{18}-OH, were quite efficient antitumor agents (16-19). The 2-*O*-methyl derivative is now being widely used as a model type compound of this series, as will become obvious in the course of this symposium.

In the meantime, Eibl succeeded in simplifying and economizing the chemical synthesis as well as in the large-scale preparation of lysolecithin analogs, such as ET_{18}-OCH_3 and others (23).

Of considerable importance was the finding by Munder that some of the active ether compounds, such as ET_{18}-OCH_3, would be fully active when given orally (20); this greatly facilitated the start-up of clinical trials.

In our efforts to understand the mechanism of the antitumor activity of ether lipids, we all felt most stimulated by the research work of Fred Snyder's group in Oak Ridge, starting in the late '60s, on the 1-*O*-alkyl cleavage enzyme and its mode of action (24). The Snyder group showed the enzyme system to be present in many normal tissues but absent or of very low activity in neoplastic cells. This suggested a possible explanation for the accumulation of ether lipids in tumor tissues with concomitant disturbance of their membrane metabolism. Munder

and others, at that stage arrived at the proposal that two main activities of one and the same ether lipid may combine favorably to the final antitumor effect, namely ether lipid-activated macrophages would act, directly or indirectly, on ether lipid-intoxicated tumor cells (20).

Another stimulus was the announcement by Hanahan and coworkers (San Antonio) in 1979, and by others, of the purification and structural analysis of the platelet-activating factor (PAF). PAF, being a 2-*O*-acetyl-1-*O*-alkyl-ether lipid (25), is of course chemically very similar to some of the known synthetic tumoricidal ether lipids. This certainly widened general interest in the biology of ether lipids.

I would like to express my great pleasure and our satisfaction that leading and pioneering scientists in the field of ether lipids have come here together. I welcome you all and ask you to kindly allow me not to mention many names, though I would like to welcome you as members of a kind of rather young, and therefore eager and energetic, scientific family dispersed all over the world, from the US, over Europe, including Israel, to the Far East and Japan. We are also pleased, Dr. Brachwitz, that both Germanys are represented here. We are all motivated by our work in an apparently narrow field of interest. But, as we shall see, it is in reality a vast field with important, and necessary, contributions from physical chemistry, organic chemistry and biochemistry to physiology, pharmacology and biomedical research and with prospects that we, at present, can only envisage.

You know, and you will discuss, biological activities of ether lipids other than their very tumoricidal potencies. The focus on antitumor activities is certainly wise. Yet, we may be allowed to also point to other exciting biological functions of ether lipids, and one may later find such activities to be biologically interlinked or interdependent. We will have three stimulating days, and we will have ample opportunity to make new friends and renew old friendships, also outside the formal sessions.

Thanks to the organizers of this symposium, to Unger as the scientific secretary, and to the distinguished members of the Organizing Committee. Many thanks also to those institutions who have sponsored our meeting! I herewith open our Symposium.

REVIEW

Biosynthesis and Biotransformation of Ether Lipids[1]

Helmut K. Mangold* and **Nikolaus Weber**
Federal Center for Lipid Research, Institute for Biochemistry and Technology, H.P. Kaufmann-Institute, Piusallee 68, D-4400 Münster, Federal Republic of Germany

Some naturally occurring as well as synthetic ether lipids are biologically active. In certain cases, the effects of these substances are enhanced, in others, they are inhibited by compounds that were isolated from natural sources or prepared by chemical synthesis. The biotransformation of natural or "unnatural" ether lipids in microorganisms, plant or animal tissue also can lead to substances that elicit biological effects. The production of such compounds through various biotechnological techniques is a field wide open for future exploration. In addition to animal cell cultures, plant cell cultures may become useful tools in biomedical studies concerned with ether lipids.
Lipids 22, 789-799 (1987).

Naturally occurring ether lipids (alkoxylipids), once considered to be "dead ends" of lipid metabolism, have been found to be intimately involved in a variety of physiological reactions (1-4). Biologically active ether lipids include compounds containing an alkyl or a 1-alkenyl moiety. The platelet activating factor, for example, a powerful lipid mediator, is a phospholipid containing an alkyl moiety (5,6), whereas, the fecapentaenes, potent mutagens, are polyunsaturated 1-*O*-(1-alkenyl)glycerols (7).

In recent years, numerous synthetic ether lipids that do not occur in nature have been prepared to find therapeutic agents such as agonists and antagonists of natural lipid mediators (8,9) and compounds that can be of value in the therapy of cancer patients (10-13).

The results of some recent studies indicate that certain biological effects are due to products that are derived, in living systems, from both natural and synthetic "unnatural" ether lipids. The biotransformations that ether lipids undergo in animal and plant cells, therefore, are of great current interest.

The present review describes briefly a few biologically active lipids containing alkyl or 1-alkenyl moieties and, in more detail, various reactions in animal and plant cells involving both natural ether lipids and those having "unnatural" structures.

NATURALLY OCCURRING ETHER LIPIDS

Neutral and ionic lipids containing an alkyl or 1-alkenyl moiety bound to glycerol at position 1 are ubiquitous though, as a rule, minor constituents of animal cells (14-16) but not of plant cells (17). All of these natural products are chiral compounds; their alkyl and 1-alkenyl moieties usually are saturated and monounsaturated and have chains predominantly of 16, 18 and 20 carbon atoms.

Neutral ether lipids include 1-*O*-alkyl-2.3-diacyl-*sn*-glycerols, 1-*O*-(1-alkenyl)-2,3-diacyl-*sn*-glycerols (neutral plasmalogens) and a variety of ether glycolipids such as 3-*O*-alkyl-2-acyl-1-*β*-D-galactopyranosyl-*sn*-glycerols (2,4,18). Ionic ether lipids are the 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines, the 1-*O*-(1-alkenyl)-2-acyl-*sn*-glycero-3-phosphocholines (choline plasmalogens), and the corresponding glycerophosphoethanolamines and glycerophosphoserines (2,4,16).

In addition to ether lipids with a single alkyl moiety, hearts of some mammalian species contain extremely small proportions of phospholipids derived from 1,2-di-*O*-alkylglycerols (19,20). And, besides alkyl and 1-alkenyl ethers of glycerol, traces of ether lipids having a diol backbone occur in nature; these diol lipids also include neutral and ionic compounds (21). Alkyl ethers (22) and 1-alkenyl ethers (23) of cholesterol are found in mammalian heart tissues. In contrast, disteryl ethers that occur in refined edible fats and oils are not natural products. These compounds are formed from sterols of plant and animal origin during the bleaching process (24,25). They are not absorbed in the gastro-intestinal tract, and their

consumption does not lead to ill effects (26). It remains to be mentioned that very small amounts of 1-*S*-alkylglycerols, i.e. thio analogues of the common 1-*O*-alkylglycerols, occur in some mammalian hearts (27).

In the past, numerous reports described biological effects of ether lipids such as bacteriostatic actions, hemopoietic effects and inhibition of tumor growth (28). As a rule, these effects were obtained solely with substances isolated from animal tissues. Synthetic compounds, however, were inactive. It thus appeared reasonable to presume that the actions observed were due to impurities in the naturally occurring ether lipids.

In the last few years, several biologically active ether lipids were isolated from animal tissues. Their structures were determined, and the effects obtained with these natural compounds could be verified using structurally identical preparations that were obtained by chemical synthesis.

The results of recent studies show that naturally occurring 1-*O*-alkyl-*sn*-glycerols differing in chain length or degree of unsaturation as well as "unnatural" synthetic alkylglycerols and other ether lipids possess different biological properties. A racemic mixture of dodecylglycerol, for example, shows strong bacteriostatic effects (29). In addition, *rac*-1-*O*-dodecylglycerol induces an efficient stimulation of mouse peritoneal macrophages for ingestion. This process may be of advantage for immunological therapy (30). A homologous compound, 1-*O*-tridecyl-*sn*-glycerol, which occurs in a marine sponge, displays toxicity to goldfish, whereas its enantiomer shows no toxicity at similar concentrations (31).

The best-known naturally occurring ether lipids are the 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholines—platelet activating factor (PAF, PAFacether, AGEPC). This potent lipid mediator is a mixture of compounds having predominantly saturated alkyl moieties with 16 and 18 carbon atoms (32,33). The biological effects of PAF are summarized in several recent articles (34–37) and two books (5,38). It is striking that 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines having alkyl chains of less than 16 or more than 18 carbon atoms and those having acyl chains with more than three carbon atoms are much less active than PAF itself. And, it is remarkable that both configurational and positional isomers of PAF do not exhibit the strong biological activities of the naturally occurring substance (39). A renal lipid showing an antihypertensive effect, a substance whose structure had remained unknown for over 25 years, proved to be identical with PAF (40). Lyso-PAF, i.e. 1-*O*-alkyl-*sn*-glycero-3-phosphocholines, exhibits cancerostatic properties (11,41).

Rather unusual compounds are moenomycin A, an antibiotic containing a long-chain 2-*O*-alkyl-*sn*-glycero-3-phosphoric acid component (42), and the 1(3)-2-diacylglycero-3(1)-*O*-4′-(*N,N,N*-trimethyl)homoserines (43), ether lipids occurring in some lower eucaryotes and cryptogamic plants (44). In this context, an ether lipid having a methacrylic acid moiety bound to position 1 of glycerol (45) and a series of polyether macrolides, the halichondrins, are to be mentioned (46). The former compound is present in some brown algae occurring in Japanese waters and the halichondrins are constituents of sponges found in the same habitat. One of the latter substances, halichondrin B, exhibits potent antitumor activity.

In the early 1980s, two groups of workers described the isolation of strongly mutagenic lipids from human feces (47–50). They characterized these substances as polyunsaturated 1-*O*-(1-alkenyl) glycerols (47,48); the general structure of the fecapentaenes is shown below.

These ether lipids are potentially important factors in the etiology of cancer of the colon (7). Very recently, an acetylenic 1-alkenylglycerol, raspailyne A, was isolated from a sponge found off the coast of Brittany (51). It is believed that this unusual ether lipid exhibits herbicidal and antifungal activities.

"Darmstoff," a mixture of long-chain cyclic acetals of glycero-3-phosphoric acid, is a potent stimulator of gastrointestinal smooth muscle which may be a hypotensive agent (10). Long-chain cyclic acetals of glycerol (52) and the corresponding phosphorylated compounds (53) have been synthesized.

"UNNATURAL" ETHER LIPIDS

Compounds that have not been found yet in nature are ether lipids having alkyl or 1-alkenyl chains of less than 12 carbon atoms and those with alkyl or 1-alkenyl moieties resembling the common polyunsaturated acyl moieties with at least 18 carbon atoms. Both saturated normal-chain and branched-chain 1-*O*-alkylglycerols have been prepared by chemical synthesis (54,55). 3-*O*-alkyl-*sn*-glycerols, the enantiomers of the naturally occurring compounds, and racemic mixtures of various ether lipids have been synthesized (56,57). Unsaturated, including polyunsaturated alkylglycerols (57) and 1,2-di-*O*-alkylglycerols (58,59) have been prepared as well.

Synthetic compounds include the symmetrical 2-*O*-alkylglycerols, 1.3-di-*O*-alkylglycerols and more complex ether lipids derived therefrom. Syntheses of neutral and ionic ether lipids with a 2-*O*-alkylglycerol (Cegla, G., and Mangold, H. K., unpublished data) or a 1,3-di-*O*-alkylglycerol backbone have been described (60). These substances have found wide use in biochemical and biomedical studies (28,61). Procedures for the synthesis of 1,2,3-tri-*O*-alkylglycerols have been worked out (58,62). The latter compounds have not been detected in nature. They are isosteric to the triacylglycerols, the common "fats," but are neither hydrolyzed enzymatically nor absorbed by the gastrointestinal tract intact. For these reasons, radioactively labeled trialkylglycerols serve as model substances in studies of intestinal fat absorption (61).

Numerous glycerophospholipids (63) and glyceroglycolipids (64) containing alkyl or 1-alkenyl moieties have been prepared.

In the past few years, intensive efforts have been devoted to the development of ether lipids that function as receptor antagonists of PAF; typical examples are shown below.

Much research work has been done also on the synthesis of ether lipids that exhibit antitumor activity, such as the 1-*O*-alkylglycerophosphocholines (11), 1-*O*-alkyl-2-*O*-methylglycerophosphocholines (e.g. ET-18-OCH_3) (65,66) and a cyclic analog of the latter (SRI 68-834) (67). A series of conjugates of lipids and 1-β-D-arabinofuranosylcytosine has been described that exhibit antineoplastic activity (68,69). In addition, a thioether lipid (BM 41.440) has been shown to be a highly active cancerostatic agent (70,71).

BIOSYNTHESIS AND BIOTRANSFORMATION OF ETHER LIPIDS IN THE ANIMAL CELL

The steps involved in the biosynthesis of ether lipids are well known: the long alkyl and 1-alkenyl chains are derived from long-chain fatty acids by reduction of their CoA derivatives to alcohols, probably via aldehydes. The ether bond is formed by the reaction of these alcohols with acyldihydroxyacetonephosphates. Reduction of the resulting alkyldihydroxyacetonephosphates leads to alkylglycerophosphates, which are acylated to alkylacylglycerophosphates. From these, various neutral and ionic ether lipids are derived by following the Kennedy pathway. 1-Alkenyl moieties are formed by dehydrogenation of the alkyl moieties of alkylacylglycerophosphoethanolamines, but not the dehydrogenation of alkylacylglycerophosphocholines (72–75).

This pathway is based on metabolic studies with radioactively labeled palmitic and stearic acids and the corresponding aldehydes, alcohols and alkylglycerols. It shows that the alkyl- and 1-alkenyl moieties of ether lipids are derived from long-chain fatty acids as follows:

Fatty acid → Aldehyde → Alcohol → Alkyl ether → 1-Alkenyl ether

It is striking that the alkyl and the 1-alkenyl moieties found in the ether lipids of animal cells are exclusively saturated and monounsaturated although the acyl moieties of these lipids contain large proportions of polyunsaturated chains. Feeding of polyunsaturated fatty acids or aldehydes to rats does not lead to the formation of ether lipids containing polyunsaturated alkyl and 1-alkenyl chains. After feeding rats polyunsaturated alcohols, however, polyunsaturated alkyl and 1-alkenyl moieties can be found in the ionic ether lipids of the animals' intestinal mucosa. Similarly, feeding animals polyunsaturated 1-*O*-alkylglycerols leads to ionic ether lipids having polyunsaturated alkyl and 1-alkenyl chains. The lack of polyunsaturated alkyl and 1-alkenyl moieties in lipids of normal animal tissues is obviously due to the fact that polyunsaturated fatty acids are not reduced to aldehydes and that the latter are not reduced to alcohols (76).

In the gastro-intestinal tract, large proportions of dietary 1-*O*-alkylglycerols are cleaved at the ether bond, whereby the alkyl moieties give rise to the corresponding fatty acids (77–80). The remainder is incorporated into 1-*O*-alkyl-2,3-diacyl-*sn*-glycerols as well as 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines and 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphoethanolamines (79–81). However, 3-*O*-alkyl-*sn*-glycerols are not extensively acylated (81). The formation of neutral and ionic ether lipids proceeds through a stereospecific phosphate transfer from ATP to position 3 of 1-*O*-alkyl-*sn*-glycerol (82); the resulting 1-*O*-alkyl-*sn*-glycero-3-phosphate undergoes the reactions of the Kennedy pathway. 2-*O*-Alkylglycerols are also cleaved, though to a much smaller extent (84,85). The acylation of 2-*O*-alkylglycerols to 2-*O*-alkyl-1,3-diacyl-*sn*-glycerols proceeds at a slower rate than that of 1-*O*-alkylglycerols (82–84). 2-*O*-alkyl-1-acyl-*sn*-glycero-3-phosphocholines and 2-*O*-alkyl-1-acyl-*sn*-glycero-3-phosphoethanolamines are formed in small proportions (85). Ether lysophospholipids such as 1-*O*-alkyl-*sn*-glycero-3-phosphocholines and 1-*O*-alkyl-*sn*-glycero-3-phosphoethanolamines are rapidly acylated in the intestinal mucosa (86). Dietary alkylacylglycerophospholipids are hydrolyzed at the acyl ester bonds and the resulting lyso compounds are reacylated in the mucosa (86). As mentioned above, considerable proportions of 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphoethanolamines are desaturated to 1-*O*-(1-alkenyl)-2-acyl-*sn*-glycero-3-phosphoethanolamines, whereas 1-*O*-

SCHEME 1. Biosynthesis of ether lipids in the animal cell.

alkyl-2-acyl-*sn*-glycero-3-phosphocholines are not converted to the corresponding plasmalogens (86,87).

Dietary 1,2-di-*O*-alkylglycerols are acylated more efficiently in the digestive tract than their symmetrical isomers (88). 1,2-Di-*O*-alkylglycerophospholipids are poorly absorbed (88); dialkylglycerophosphocholines inhibit the absorption of sterols by the mucosa (89), whereas the absorption of fatty acids and bile acids is not affected (90).

Ether lipids are only minor constituents of human food and animal feed (28,91). They are certainly not the main source of the neutral and ionic ether lipids found in the intestinal mucosa and other mammalian tissues (92). Obviously, the major portion of ether lipids is synthesized in the organism as described in several recent review articles (72–75).

The precursors of the fecapentaenes are still unknown; they are likely to be rather complex compounds (50).

The metabolic interrelationship between various ether lipids and ester lipids is of great interest. Long-chain alcohols are located at the branch point in the biosynthesis of alkyl and 1-alkenyl moieties of ether lipids as well as the alkyl and acyl moieties of waxes and other ester lipids. Therefore, the competing pathways leading to the formation of alkyl, 1-alkenyl and acyl moieties in the lipids of mammalian tissues can be assessed by following the distribution of intravenously administered long-chain alcohols from the blood to various organs of an animal. The results of such a study in the rat revealed that oxidation of the long-chain alcohol and incorporation of the resulting fatty acid in a wide variety of lipids are by far the most prominent reactions (93). Acylation of the long-chain alcohol occurs especially in the liver, which appears to be the major site of biosynthesis of wax esters. Incorporation of the long-chain alcohols into ether lipids occurs in all tissues studied, but most prominently in the heart. The biosynthesis of ether lipids continues to increase for 24 hr in all tissues except the intestine. This finding attests to the remarkable metabolic stability of ether lipids.

The results of experiments aimed at determining the relative metabolic stability of various diradylglycerophospholipids in Ehrlich ascites cells of tumor-bearing mice show that the alkylacylglycerophospholipids have a faster turnover rate than the 1-alkenylacylglycerophospholipids (94,95). Moreover, highly unsaturated molecular species of alkylacylglycerophospholipids and 1-alkenylacylglycerophospholipids exhibit higher turnover rates than those having only one or two double bonds. It is evident that ether glycerophospholipids are intimately involved in the metabolism of arachidonic acid and other highly unsaturated fatty acids that serve as precursors of various icosanoids (96).

Minor proportions of 1-*O*-alkyl-2,3-diacyl-*sn*-glycerols and 1-*O*-(1-alkenyl)-2,3-diacyl-*sn*-glycerols are found in perinephric fat, bone marrow, the aorta and other healthy human tissues (97,98). In perinephric fat and subcutaneous adipose tissue, these two classes of neutral ether lipids occur at levels of about 0.3%, each (98,99). The content of neutral and ionic ether lipids in the human aorta is less (100); it increases, though, with age and with severity of atherosclerosis (101,102). Both transplantable and spontaneous animal tumors contain much larger proportions of neutral ether lipids and also elevated levels of ionic ether lipids, particularly plasmalogens (102,103). As a rule, the level of alkyldiacylglycerols in human tumors is about 10 times higher than in healthy tissues; it ranges from 1 to 5% (104,105). The proportions of ether lipids increase with tumor growth (106,107). Tissue remote from a tumor contains normal levels of alkyldiacylglycerols, whereas areas surrounding the tumor may exhibit fairly high levels due to protrusions of neoplastic cells (108).

Healthy tissues that have a low level of ether lipids, such as the liver, contain an enzyme that catalyzes the oxidative cleavage of the ether bond in alkylglycerols (109) as well as in ether lipids having a hydroxy group in position 2 and a hydroxy or a phosphorylcholine or phosphorylethanolamine moiety in position 3 of the glycerol backbone (110). In comparison to healthy tissues, tumors show low levels of such etherase activity (111). This difference in ether cleaving activity and differences in the levels of phospholipases C and D in healthy and neoplastic cells may be the basis for a successful cancer therapy by means of certain ether lipids (112,113).

Much work has been devoted to the characterization of tumor lipids (oncolipids) (105–107). Attempts have been made to develop diagnostic procedures based on the ether lipid contents of blood and other tissues. The validity of results obtained by photodensitometry of charred fractions on thin-layer chromatograms has been questioned (114). Better methods for the quantitative analysis of ether lipids in total lipid extracts have been developed in recent years (114–117). Nevertheless, it is not certain whether determination of ether lipid levels in tissues will be of use in the diagnosis of cancer.

It should be possible to give labeled precursors of ether lipids to cancer patients in order to permit the scintigraphic detection of neoplastic tissue because of its elevated ether lipid content. A long-chain alcohol such as (*Z*)-9-octadecenol is not suitable for this purpose as large proportions of the precursor are oxidized to the corresponding fatty acid, which is incorporated into ether lipids and ester lipids (118). Alcohols with less than 16 carbon atoms may be better suited as tumor cells incorporate these medium-chain precursors preferentially into both alkyl and 1-alkenyl moieties of ether lipids if a mixture of alcohols differing in chain lengths is administered to ascites cells (119).

It appears that the interrelation of the metabolic reactions involved in the regulation of the levels of ether lipids in the cell still has to be clarified. There is hope that tests for tumor-specific compounds in blood will permit an early diagnosis of occult primary neoplasias. The search for such tumor markers is gaining momentum (120). In this connection, a screening method based on water-suppressed proton nuclear magnetic resonance spectroscopy of plasma is of great interest (121).

Animal cell cultures are useful tools in studying the biosynthesis and biotransformation of ether lipids (61, 122–124). In general, the pathways found in animals for the biosynthesis and the metabolism of ether lipids are also operational in cultured cells that have been derived from normal and neoplastic tissues (125–127). Consequently, neutral and ionic ether lipids, predominantly alkyldiacylglycerols, alkylacylglycerophosphocholines and 1-alkenylacylglycerophosphoethanolamines, are found in normal and neoplastic cells in culture (127,128). High proportions of neutral ether lipids, which are known to be characteristic constituents of cancer cells (61,72),

occur also in normal tracheal cells when grown in culture (128).

Elevated levels of ether lipids, particularly alkyldiacylglycerols, are correlated in transformed cell lines with high rates of glycolysis. This also is obvious from the relationship between the enhanced rate of glucose uptake and metabolism and the high levels of alkyldiacylglycerols that were observed in rat squamous carcinoma cells in culture (126,129).

Oncogenically transformed fibroblast cells of mice were found to contain elevated levels of neutral lipids including alkyldiacylglycerols (130,131) and to incorporate high proportions of radioactivity into these ether lipids when incubated with labeled hexadecanol (132). Moreover, it is evident that a close relationship exists between the lipid composition of these fibroblast cells and their tumorigenicity. Thus, the cells containing the highest level of alkyldiacylglycerols produce more tumors, and the number of cells that are required for the induction of neoplasia is far less than of cell lines with low levels of ether lipids (130,133).

In addition, fibroblast cells containing high proportions of ether lipids show resistance to cell membrane fusion induced by polyethyleneglycol (130,131,133). In this context, it is interesting to note that the cellular resistance to vinblastine found in cultured leukemic lymphocytes is closely correlated with increasing proportions of alkylacylglycerophosphocholines and 1-alkenylacylglycerophosphoethanolamines as well as a concomitant decrease in diacylglycerophosphocholines and diacylglycerophosphoethanolamines (134).

Incubation of some normal and neoplastic cells in culture with 1-*O*-alkylglycerols leads to both neutral and ionic ether lipids (Fig. 1), whereas 2-*O*-alkylglycerols are incorporated preferentially into neutral ether lipids (85, 135,136). Enrichment of ionic ether lipids in cell membranes by supplementation of cell cultures with alkylglycerols may be helpful for investigating their biochemical and biophysical effects and their influence on cellular resistance (134). Furthermore, neoplastic cells in culture are useful models for studying antitumor properties of synthetic alkyllysoglycerophospholipids (12,137–139).

The Zellweger syndrome involves a defect in the biosynthesis of ether lipids (140). Methods for the biochemical diagnosis of this disease are based on the application of radioactively labeled precursors of ether lipids in human tissues (141) and fibroblast cultures (142,143).

BIOTRANSFORMATION OF ETHER LIPIDS IN THE PLANT CELL

It appears that most plant cells are devoid of ether lipids; however, a few exceptions to the rule are known (17,144). Plants are provided with an enzyme system that reduces the CoA derivatives of long-chain fatty acids to aldehydes and the latter to alcohols (145). In plants, such long-chain alcohols are acylated to wax esters (146), but ether lipids are not formed. Plants are capable, however, of incorporating exogenous alkylglycerols into more complex ether lipids (147) and converting 1,2-di-*O*-alkyl-3-*O*-β-D-galactopyranosyl-*sn*-glycerol, a synthetic ether analog of monogalactosyldiacylglycerol, to the 6-*O*-acyl derivative (148).

When long-chain fatty acids such as stearic, oleic and linoleic acids are added to heterotrophic or photomixotrophic plant cell cultures, these acids are incorporated into the cells' diacylglycerophosphocholines and other ionic ester lipids (149,150). The corresponding 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines, 1-*O*-(1-alkenyl)-2-acyl-*sn*-glycero-3-phosphocholines and other ionic ether lipids are not formed (150). It appears that in plant cell cultures neither saturated and monounsaturated fatty acids nor polyunsaturated ones are reduced to long-chain aldehydes and alcohols.

When long-chain alcohols are incubated with plant cells in culture under aerobic conditions, these alcohols are largely oxidized to the corresponding fatty acids. Under nearly anaerobic conditions, wax esters are produced in fairly large proportions (151). Ether lipids are neither formed under aerobic nor under anaerobic conditions. Obviously, plant cells in culture are neither provided with enzymes that could reduce the CoA derivatives of long-chain fatty acids (to alcohols) nor provided with those capable of catalyzing the formation of ether bonds by the reaction of alcohols with acyldihydroxyacetonephosphates. These findings and the presence of an ether-cleaving enzyme explain why plant cells in culture are devoid of ether lipids (152).

In photomixotrophic cell suspension cultures of rape, 1-*O*-alkylglycerols can serve as precursors of more complex ether lipids (152–154). When such cultures are incubated with *rac*-1-*O*-alkylglycerols, fair proportions of

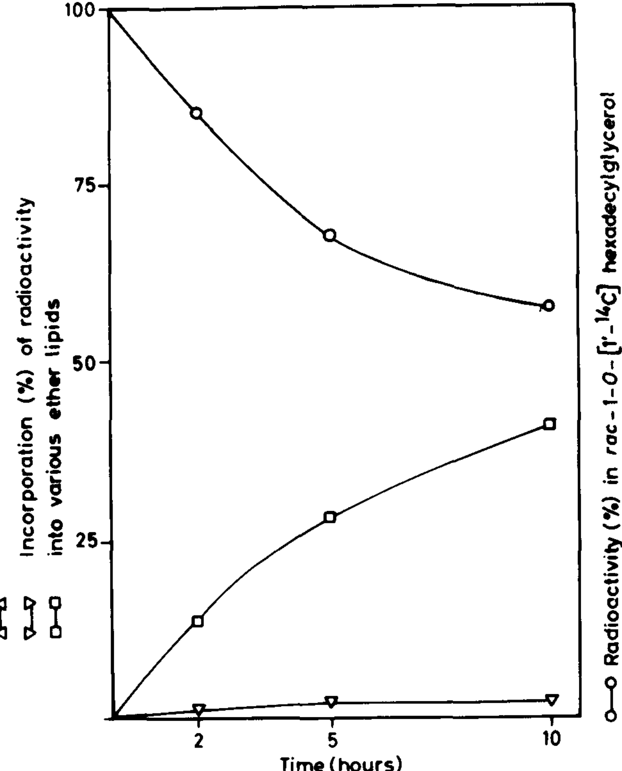

FIG. 1. Incorporation of *rac*-1-*O*-[1'-^{14}C]hexadecylglycerol into ether lipids of Ehrlich ascites cells in culture (○—○, *rac*-1-*O*-[1'-^{14}C]hexadecylglycerol, substrate; △—△, alkyldiacylglycerols; □—□, glycerophospholipids) (135).

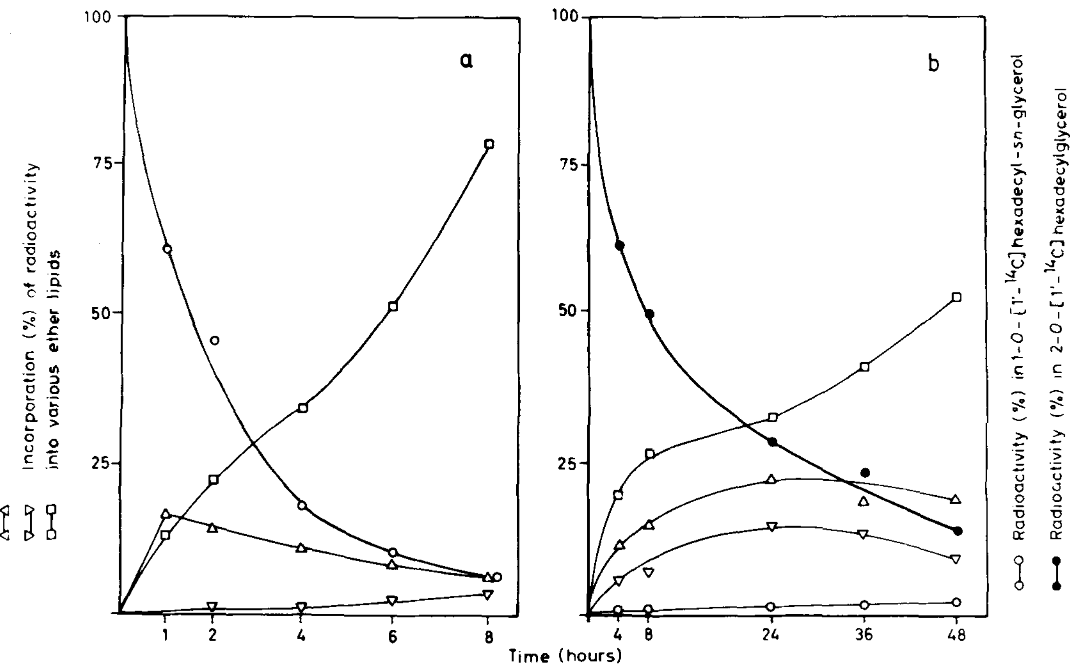

FIG. 2. Incorporation of radioactive alkylglycerols into ether lipids of photomixotrophic rape cells in suspension culture. (a) Incorporation of 1-*O*-[1'-^{14}C]hexadecyl-*sn*-glycerol (substrate) ○—○; (b) incorporation of 2-*O*-[1'-^{14}C]hexadecyl-*sn*-glycerol (substrate) ●—●; △—△, alkylacylglycerols; ▽—▽, alkyldiacylglycerols; □—□, alkylacylglycerophosphocholines (156,157).

1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines, 1-*O*-alkyl-2-acyl-*sn*-glycerols and *x*-1-*O*-alkyl-3-acylglycerols are formed. Better yields are obtained by incubating photomixotrophic rape cells with 1-*O*-alkyl-*sn*-glycerols. The synthetic enantiomers, i.e. 3-*O*-alkyl-*sn*-glycerols, are not incorporated into ionic ether lipids.

The biotransformation of various 1-*O*-alkyl-*sn*-glycerols into alkylacylglycerophosphocholines is dependent on both the chain length and the degree of unsaturation of their alkyl chains: 1-*O*-Tetradecyl-*sn*-glycerol is incorporated more efficiently than 1-*O*-hexadecyl-*sn*-glycerol and the latter more efficiently than 1-*O*-octadecyl-*sn*-glycerol. Monounsaturated and polyunsaturated 1-*O*-alkylglycerols are better substrates than saturated compounds having the same chain length.

It is certainly of interest that plant cell cultures can also acylate, phosphorylate and aminate the prechiral 2-*O*-alkylglycerols to yield chiral 2-*O*-alkyl-1-acyl-*sn*-glycero-3-phosphocholines (154).

The enzymes involved in the biosynthesis of molecular species of 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines, of 2-*O*-alkyl-1-acyl-*sn*-glycero-3-phosphocholines and of 1,2-diacyl-*sn*-glycero-3-phosphocholines show similar specificities with regard to chain lengths and degree of unsaturation of the alkyl and the acyl moieties. The different alkylacylglycerophosphocholines formed in plant cell cultures are capable of replacing up to one-half of the physiological membrane lipids, i.e. diacylglycerophosphocholines, without changing the total amount of diradylglycerophosphocholines as compared to untreated cells (155). Thus, the CDP phosphocholine:diacylglycerol phosphotransferase in plants does not appear to have an absolute specificity for diacylglycerols, but also it will accept 1-*O*-alkyl-2-acyl-*sn*-glycerols and 2-*O*-alkyl-1-acyl-*sn*-glycerols as substrates.

In addition, minor proportions of neutral ether lipids such as 1-*O*-alkyl-2-acylglycerols, 1-*O*-alkyl-3-acylglycerols and 1-*O*-alkyl-2,3-diacylglycerols are synthesized by plant cells from exogenous 1-*O*-alkylglycerols (156), whereas 2-*O*-alkylglycerols are incorporated into 2-*O*-alkyl-1(3)-acylglycerols and 2-*O*-alkyl-1,3-diacylglycerols in significant quantitites (Fig. 2) (157). Similar results are obtained with cultured liver cells (85) and Ehrlich ascites cells using 1-*O*-alkylglycerols or 2-*O*-alkylglycerols as substrates (Fig. 1) (135).

In contrast to animal cells, plant cells do not dehydrogenate alkyl moieties to 1-alkenyl moieties (148,154). Yet, if added to plant cell cultures, 1-*O*-(1-alkenyl)glycerols are incorporated, though in poor yields, into ionic ether lipids (154).

It would be very helpful if a biotechnological process could be developed for the production of chiral 1-*O*-alkyl-2-*O*-methyl-*sn*-glycero-3-phosphocholines. Attempts to prepare such compounds by adding 1-*O*-alkyl-2-*O*-methylglycerols to plant cell cultures so far have failed.

The 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines formed in plant cell cultures from exogenous 1-*O*-alkylglycerols can be subjected to alkaline hydrolysis to yield the corresponding lyso compounds, 1-*O*-alkyl-*sn*-glycero-3-phosphocholines, which are of interest as cancerostatic agents. Acetylation of the latter affords 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholines, PAF, in high yields (156). The biological activity of PAF obtained by this semisynthetic procedure is at least as high as that of synthetic preparations.

Similarly, 2-*O*-alkyl-*sn*-glycero-3-phosphocholines and 2-*O*-alkyl-1-acetyl-*sn*-glycero-3-phosphocholines can be

obtained from 2-*O*-alkylglycerols using the biosynthetic capacity of plant cell cultures (157). These chiral ether lipids are rather difficult to prepare by chemical synthesis.

The method described is recommended especially for the preparation of radioactively labeled chiral ether lipids. The specific radioactivities of the precursors are not diminished in the final products because there are no endogenous ether lipids that would lead to isotope dilution.

Little is known regarding the effects exogenous ether lipids can exert on plant cells. Reportedly, 1-*O*-(*Z*)-9'-octadecenyl-*sn*-glycerol, selachyl alcohol, promotes the growth of pea stem sections (158); PAF strongly stimulates ATP dependent H^+ transport in microsomes of hypocotyls (159) and the activity of microsomal 1,3-β-D-glucan synthase (160).

DISCUSSION

The rather small differences between the structures of ether lipids and ester lipids are reflected in pronounced diversities in the physical properties of liposomes formed by these substances and of membranes containing them (161). Ether lipids are more stable against chemical and enzymatic attack than ester lipids (54,55), but they are more susceptible to autoxidation (162).

The physical and chemical characteristics distinguishing the ether lipids from the structurally related ester lipids can be of use in biomedical research, clinical diagnosis and therapy. For example, cholesteryl alkyl ethers and retinyl alkyl ethers can serve as models of ester lipids in studies of lipoprotein metabolism (163). Trialkylglycerols labeled with ^3H or ^{14}C as well as a ^{75}Se-analog are used in the diagnosis of chronic pancreatitis and other disorders of fat absorption in man (61). The incapsulation of drugs into liposomes formed by ionic ether lipids and the intravenous administration of these vesicles holds great promise in cancer therapy (164).

It is striking that various biological effects of ether lipids are restricted to one or just a few molecular species of a given class of compounds such as the 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholines (35-38). The enormous specificity of individual compounds and the mechanisms of their biological effects remain to be clarified.

Biotransformations of ether lipids and catabolic events may play a role in the action of these substances in biological systems. It is of great interest that biotransformations of alkylglycerols and the enzymatic cleavage of the ether bond, reactions that occur in animal cells, also proceed in plant cells (Figs. 1 and 2). It thus is possible to prepare complex ether lipids including chiral compounds, from simple precursors using plant cells that do not contain endogenous ether lipids. For the same reason, it is much easier to investigate the biotransformation of natural or synthetic ether lipids in plant cell cultures than in animal cell cultures. Thus, plant cell cultures may become useful tools in biomedical studies on ether lipids.

It should be remembered that microorganisms in extreme environments contain complex ether lipids whose structures differ from those in animal cells. Halophilic bacteria, for example, lack significant proportions of ester lipids, their membrane lipids being derived from 2.3-di-*O*-phytanyl-*sn*-glycerol (165,166). Thermophilic bacteria, on the other hand, are characterized by a range of complex phospholipids and glycolipids whose structures are based on dialkyldiglycerol tetraethers and a variety of ether lipid cores (167,168). Methanogenic bacteria contain diglycosyl derivatives of dibiphytanyl tetraether and the corresponding glycerophosphoglycolipids (169). The alternative membrane lipids of certain bacteria are not necessarily the result of environmental adaptation, "but rather a consequence of evolution from a common archaebacterial ancestor" (170)—a provocative and ingenious thought, indeed!

The isolation and identification of archaebacterial lipids, their modification by chemical reactions or biotransformation, and the assessment of the biological effects of natural and synthetic compounds containing ether bonds are of great interest.

The Degradation of Platelet-Activating Factor and Related Lipids: Susceptibility to Phospholipases C and D[1]

Rebecca W. Wilcox, Robert L. Wykle, Jeffery D. Schmitt and Larry W. Daniel*
Department of Biochemistry, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103

1-*O*-Octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine ($ET\text{-}18\text{-}OCH_3$) is an ether-linked lipid that exhibits selective cytotoxicity toward several types of tumor cells and is relatively inactive toward normal cells under the same conditions of treatment. The mechanism of this selective cytotoxicity is unknown. We conducted studies to determine whether this compound is metabolized by phospholipases C and D and, if so, whether sensitive and resistant cells differ in their ability to degrade $ET\text{-}18\text{-}OCH_3$ by these enzymes. We have examined the metabolism of the L-isomer of $ET\text{-}18\text{-}OCH_3$, 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine (L-$ET\text{-}18\text{-}OCH_3$), by lysophospholipase D of rat liver microsomes and by a phospholipase D from the marine bacterium *Vibrio damsela*. The metabolism of L-$ET\text{-}18\text{-}OCH_3$ was also examined in cell culture using Madin-Darby canine kidney cells, human promyelocytic leukemia cells and human myelocytic leukemia cells. In these studies, L-$ET\text{-}18\text{-}OCH_3$ and related 1-*O*-alkyl-linked phosphocholine analogs radiolabeled with ^3H in the 1-*O*-alkyl chain were used.

L-$ET\text{-}18\text{-}OCH_3$ was not hydrolyzed by lysophospholipase D from rat liver microsomes under conditions where cleavage of 1-*O*-alkyl-2-lyso-*sn*-glycero-3-phosphocholine was observed. However, phospholipase D from the marine bacterium *V. damsela* readily hydrolyzed L-$ET\text{-}18\text{-}OCH_3$ to 1-*O*-[^3H]octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphate, demonstrating that L-$ET\text{-}18\text{-}OCH_3$ can be degraded by a phospholipase D. Platelet-activating factor (PAF) and lyso-PAF were also substrates for the bacterial phospholipase D.

When intact cells were incubated with radiolabeled L-$ET\text{-}18\text{-}OCH_3$, a product was formed that was identified as 1-*O*-[^3H]octadecyl-2-*O*-methyl-*sn*-glycerol. There are two mechanisms that could account for the appearance of this product. The first involves cleavage of the compound by a phospholipase C, resulting in direct release of the diglyceride. The second possible mechanism involves cleavage by a phospholipase D to form the phosphatidic acid analog with subsequent hydrolysis to the diglyceride by a phosphohydrolase. Preliminary data support the phospholipase C–type mechanism. Regardless of which mechanism operates in intact cells, the metabolic degradation of L-$ET\text{-}18\text{-}OCH_3$ does not appear to be a significant factor in the selective cytotoxicity of this antitumor agent.

Lipids 22, 800–807 (1987).

Abbreviations: GPC, glycero-3-phosphocholine; $ET\text{-}18\text{-}OCH_3$, 1-*O*-octadecyl-2-*O*-methyl-*rac*-GPC; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-GPC; lyso-PAF, 1-*O*-hexadecyl-*sn*-GPC; TLC, thin layer chromatography; MDCK, Madin-Darby canine kidney; HL60, human promyelocytic leukemia; K562, human myelocytic leukemia; PBS, phosphate-buffered saline; BSA, bovine serum albumin; ID_{50}, the concentration of compound resulting in 50% loss of viability of cells treated 48 hr.

1-*O*-Octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (GPC) ($ET\text{-}18\text{-}OCH_3$) is an antitumor agent that is selectively cytotoxic to several types of neoplastic cells and is characterized by its relative inactivity toward normal cells (1). Of the three cell lines used in this study, HL60 cells appear to be most sensitive to $ET\text{-}18\text{-}OCH_3$, while MDCK and K562 cells are relatively resistant. It has been suggested that the selective cytotoxicity of the drug results from its accumulation in neoplastic cells containing a low activity of the alkyl cleavage enzyme (2–5). According to this hypothesis, normal cells and some types of neoplastic cells were suggested to be resistant to ether lipids due to a higher activity of the alkyl cleavage enzyme, which might prevent accumulation of the alkyl lysophospholipid analogs, thus averting cell death. However, recent studies indicate that the specific activity of the alkyl cleavage enzyme in both sensitive and resistant cells is of the same order of magnitude, suggesting that this enzyme is not responsible for the selectivity of $ET\text{-}18\text{-}OCH_3$ (6).

In the present study, we have examined alternative mechanisms of $ET\text{-}18\text{-}OCH_3$ hydrolysis that involve phospholipases C and D. Cleavage by a phospholipase C should result in the formation of a diglyceride and a phosphobase. Cleavage by a phospholipase D produces phosphatidic acid and a base. The existence of mammalian phospholipase C that degrades phosphatidylcholine has been demonstrated in Madin-Darby canine kidney (MDCK) cells (7), 3T3-L1 cells (preadipocytic), human promyelocytic leukemia (HL60) cells (8), canine myocardium (9) and HeLa cells (10). A mammalian lysophospholipase D enzyme specific for phosphocholine- and phosphoethanolamine-linked glycerolipids that contain an alkyl linkage at the *sn*-1 position and a free hydroxyl moiety at the *sn*-2 position has also been documented (11–13). We have here examined the possible involvement of phospholipases in the mechanism of action of $ET\text{-}18\text{-}OCH_3$. Lysophospholipase D, phospholipase D and phospholipase C were examined for their possible role in $ET\text{-}18\text{-}OCH_3$ hydrolysis.

Previous studies on the biological effects of $ET\text{-}18\text{-}OCH_3$ have used mixtures of the D- and L-isomers; however, we have prepared the stereochemical homolog of naturally occurring phospholipids, 1-*O*-[^3H]octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine (L-$ET\text{-}18\text{-}OCH_3$), for use in studies on $ET\text{-}18\text{-}OCH_3$ metabolism.

MATERIALS AND METHODS

Cells. MDCK cells and cell culture reagents were purchased from Flow Laboratories (Rockville, MD). HL60 and human myelocytic leukemia (K562) cells were obtained from American Type Culture Collection (Rockville, MD). Liver microsomes were prepared using a Sprague-Dawley rat.

Reagents. Bovine serum albumin (BSA) and Tris-HCl were obtained from Sigma Chemical Co. (St. Louis, MO). $MgCl_2$ was purchased from Fisher Scientific Co. (Fair

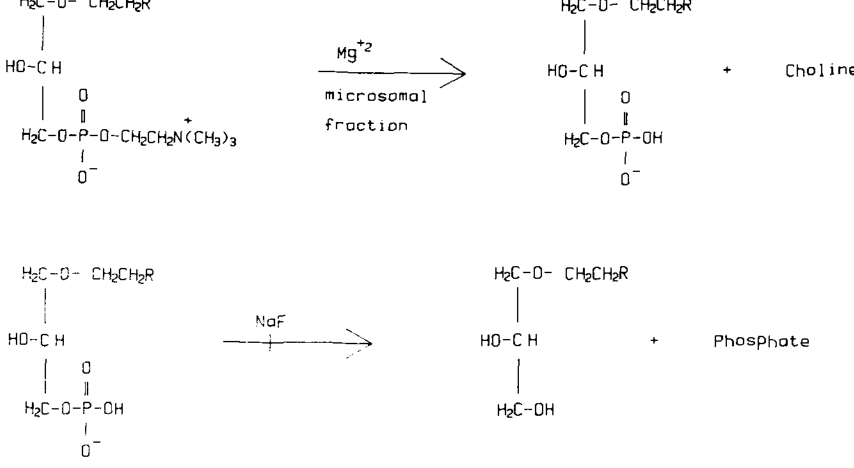

FIG. 1. Lysophospholipase D pathway. In this pathway, the initial product is 1-*O*-alkyl-2-lyso-*sn*-glycero-3-phosphate, which is rapidly converted by a phosphohydrolase in the microsomes to 1-*O*-alkyl-glycerol. The phosphohydrolase can be inhibited by NaF, resulting in the accumulation of 1-*O*-alkyl-*sn*-glycero-3-phosphate. R = $-(CH_2)_{13}CH_3$ or a similar long chain moiety.

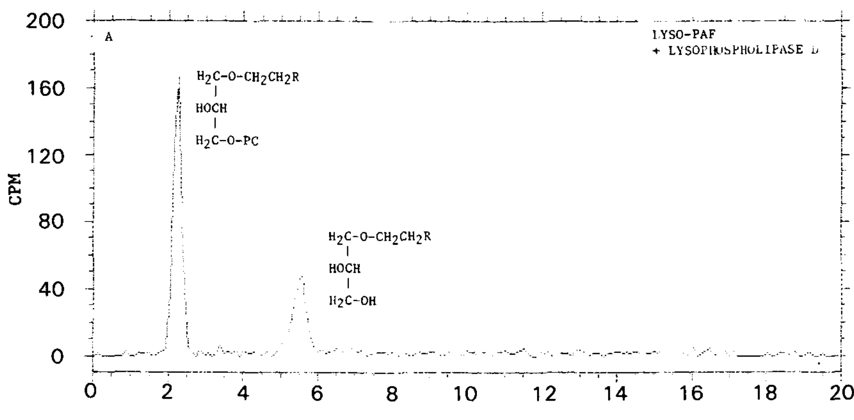
Lawn, NJ). Dulbecco's phosphate-buffered saline (PBS) was from Gibco Laboratories (Chagrin Falls, OH), and p-bromophenacyl bromide was from Aldrich Chemical Co. (Milwaukee, WI).

Lipids. 1-*O*-Octadecyl-2-*O*-methyl-*rac*-GPC (ET-18-OCH_3) was a gift from Dr. Wolfgang Berdel, Technical University of Munich (Munich, FRG). 1-*O*-Hexadecyl-*sn*-GPC was purchased from R. Berchtold, Biochemical Laboratory (Bern, Switzerland). 1-*O*-[9,10-^{3}H]Hexadecyl-*sn*-GPC (lyso-PAF) (56 Ci/mmol) and 1-*O*-[9,10-^{3}H]hexadecyl-2-acetyl-*sn*-GPC (PAF) (56 Ci/mmol) were synthesized as described earlier (14). 1-*O*-Hexadecyl-2-*O*-methyl-*sn*-glycerol was a gift from Jeff Surles, University of North Carolina-Chapel Hill, (Chapel Hill, NC). 1-*O*-Octadecenyl-2-*O*-methyl-*sn*-GPC was synthesized by adding a phosphocholine moiety to 1-*O*-octadecenyl-2-*O*-methyl-*sn*-glycerol according to the method of Brockerhoff and Ayengar (16). The synthesis of 1-*O*-octadecenyl-2-*O*-methyl-*sn*-glycerol paralleled the synthesis of 1-*O*-alkyl-2-*O*-ethyl-*sn*-glycerol reported previously (15), substituting selachyl alcohol (1-*O*-octadecenyl-*sn*-glycerol; Western Chemical Industries Ltd., Vancouver, Canada) for chimyl alcohol and methyl methanesulfonate for ethyl methanesulfonate. The 1-*O*-octadecenyl-2-*O*-methyl-*sn*-GPC was tritiated catalytically using palladium (10%) on charcoal to yield 1-*O*-[9,10-^{3}H]octadecyl-2-*O*-methyl-*sn*-GPC (56 Ci/mol).

Lysophospholipase D assay. The lysophospholipase D assays were performed using rat liver microsomes as described by Wykle and Schremmer (11). Protein determinations were made using the method of Bradford (Biorad, Richmond, CA) with BSA as a standard (17). The substrates tested were 1-*O*-[^{3}H]octadecyl-2-*O*-methyl-*sn*-GPC and 1-*O*-[^{3}H]hexadecyl-*sn*-GPC. p-Bromophenacyl bromide, which did not block lysophospholipase D activity, was added to prevent *sn*-2 acylation of the lyso compound (13). The reactions were terminated by lipid extraction using an acidified Bligh and Dyer (18) procedure in which the methanol contained 2% acetic acid. After extraction, the lipids were analyzed by thin layer chromatography (TLC). Following chromatography, the resolved

FIG. 2. Substrate specificity of lysophospholipase D. Of the compounds tested, only those containing ether-linked groups at the *sn*-1 position are hydrolyzed. In addition, the 2-hydroxy group must be unesterified. PC, phosphocholine; PE, phosphoethanolamine; R = $-(CH_2)_{13}CH_3$ or a similar long chain moiety.



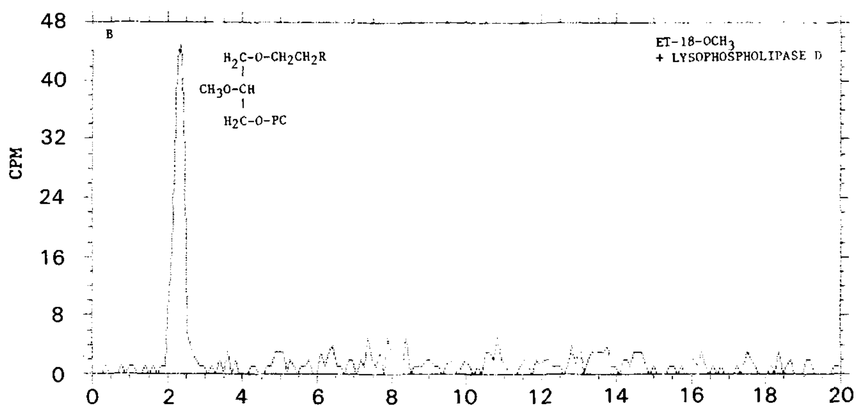


FIG. 3. Relative susceptibility of 1-*O*-[^{3}H]alkyl-2-lyso-*sn*-GPC (lyso-PAF) and 1-*O*-[^{3}H]alkyl-2-*O*-methyl-*sn*-GPC (L-ET-18-OCH_3) to rat liver lysophospholipase D. Lyso-PAF was hydrolyzed by the enzyme under the experimental conditions; L-ET-18-OCH_3 was not. Each 3-ml incubation mixture contained $MgCl_2$ (5 mM), Tris-HCl buffer (0.1 M, pH 7.1), rat liver microsomes (0.5 mg protein), p-bromophenacyl bromide (0.13 M) added directly in 20 μl acetone, and a combination of the respective unlabeled substrates (17 nmol) and radiolabeled substrates (300,000 dpm; 2 pmol) added in 20 μl ethanol. Each incubation was shaken at 37 C for 10 min, and the reactions were terminated by extraction. The lipids were then dried under N_2, resuspended in chloroform/methanol (9:1, v/v) and separated on layers of Silica Gel 60 by developing in ethyl ether/water (100:0.5, v/v) or in chloroform/methanol/glacial acetic acid/water (50:25:8:3, v/v/v/v). The samples depicted in this figure were chromatographed in the solvent system ethyl ether/water (100:0.5, v/v). The major peaks are identified by the adjacent structures, based on migration with standards. In Figures 3–5, radioactivity was measured using a Bioscan radiochromatogram imaging system and is expressed as counts per minute. The abscissa represents distance in cm on the thin layer chromatography plate. Scans of the entire sample lane are shown. Origin, 1–2 cm; solvent front, 18–20 cm.

lipids were visualized by exposing the plates to iodine vapors; radiolabeled products were located using a radiochromatogram imaging system (Bioscan Inc., Washington, DC) (Fig. 3). Regions containing radiolabeled lipid were then scraped and counted using a Packard liquid scintillation counter. Further details of the experimental procedures are given in the figure legends.

Bacterial phospholipase D assay. The phospholipase D enzyme isolated from the marine bacterium *Vibrio damsela* was a gift from A. S. Kreger (Bowman Gray School of Medicine, Winston-Salem, NC). This enzyme preparation was from the stage-4 purification pool with a specific activity of 2 × 10^6 hemolytic units/mg protein and a concentration of 1.47 mg protein/ml (19). Details of incubations are given in the legends of Figures 4 and 5. Substrates tested were 1-*O*-[^{3}H]octadecyl-2-*O*-methyl-*sn*-GPC (1.5 × 10^6 dpm, 12 pmol), 1-*O*-[^{3}H]hexadecyl-*sn*-GPC (6.2 × 10^5 dpm, 5 pmol), 1-*O*-[^{3}H]hexadecyl-2-acyl-*sn*-GPC (9 × 10^5 dpm, 7 pmol) and 1-*O*-[^{3}H]hexadecyl-2-acetyl-*sn*-GPC (1.0 × 10^6 dpm, 8 pmol).

Incubations of ET-18-OCH_3 with intact cells. MDCK cells were cultured as a monolayer in Dulbecco's modification of Eagle's medium supplemented with 10% (v/v) fetal bovine serum, 100 units of penicillin/ml, 100 μg of streptomycin/ml, 0.22% Na_2HCO_3 and 2 mM L-glutamine. HL60 and K562 cells were cultured in suspension in RPMI 1640 medium with the same supplements. For these experiments, the cells were pelleted, resuspended in medium containing radiolabeled L-ET-18-OCH_3 and cultured in 35-mm petri dishes during the 48-hr time course (Fig. 6). The concentration of L-ET-18-OCH_3 (24 nM) in these experiments was 100-fold less than the

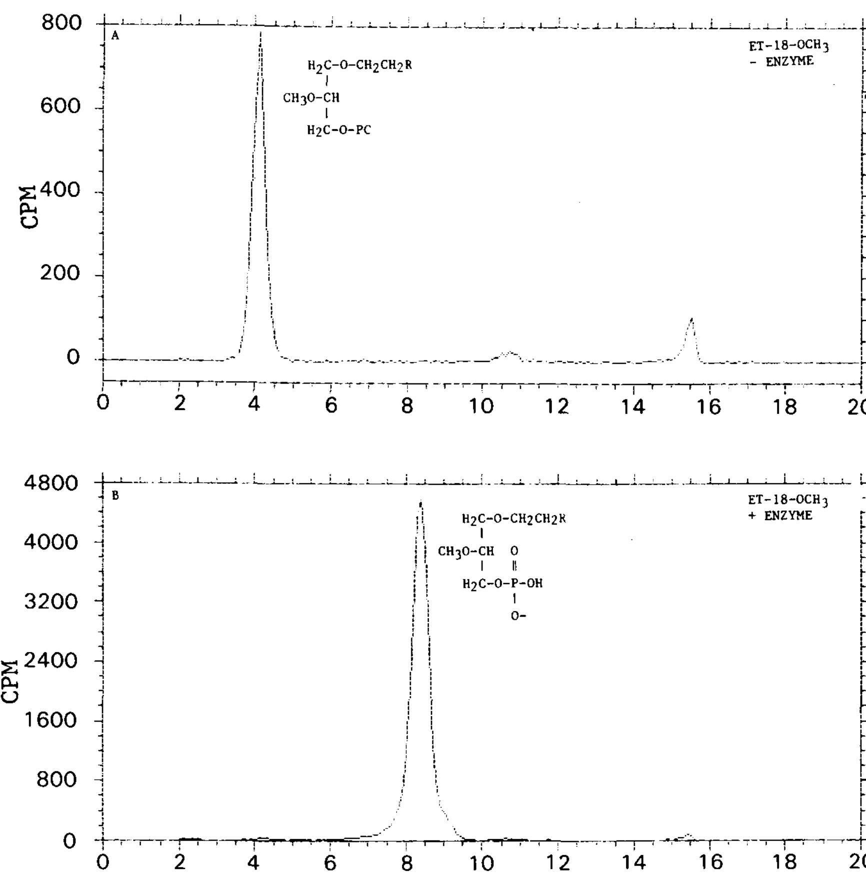

FIG. 4. Hydrolysis of 1-*O*-[^{3}H]octadecyl-2-*O*-methyl-*sn*-GPC to 1-*O*-[^{3}H]octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphate by phospholipase D isolated from the bacterium *Vibrio damsela*. Each incubation mixture in a final volume of 1 ml phosphate-buffered saline was shaken for 30 min at 37 C and contained 1-*O*-[^{3}H]octadecyl-2-*O*-methyl-*sn*-GPC (1.5 $\times$ 10^6 dpm, 12 pmol) dried under N_2 and sonicated in 400 μl PBS and (A) no enzyme or (B) 29.4 μg enzyme. The reactions were terminated by lipid extraction as described in Materials and Methods for lysophospholipase D assays. Samples were analyzed by thin layer chromatography using the solvent system chloroform/methanol/glacial acetic acid/water (50:25:8:3, v/v/v/v).

ID_{50} (the concentration of compound resulting in 50% loss of viability of cells treated 48 hr) of the sensitive HL60 cell line. After each incubation period, the cells and fluids (medium) were extracted separately using an acidified Bligh and Dyer (18) procedure in which the methanol contained 2% acetic acid. Lipids were analyzed by TLC using solvent systems described below.

RESULTS AND DISCUSSION

Hydrolysis of L-ET-18-OCH_3 by lysophospholipase D. Lysophospholipase D has been shown to hydrolyze 1-*O*-alkyl-linked choline- or ethanolamine-containing phosphoglycerides but not the corresponding 1-*O*-acyl compounds (13) (Figs. 1 and 2). The enzyme is found in a number of tissues, requires Mg^{+2} for activity and does not act on substrates esterified at the *sn*-2 position (11,12). The cellular role of this novel enzyme is unknown. In the present study, when radiolabeled 1-*O*-hexadecyl-*sn*-GPC (lyso-PAF) was incubated with rat liver microsomes in the presence of Mg^{+2}, the substrate was hydrolyzed to 1-*O*-hexadecyl-*sn*-glycerol (Fig. 3A) as reported by Wykle and Schremmer (11). It was also reported that PAF could be cleaved by lysophospholipase D if the acetate group was first removed by an acyl hydrolase present in the microsomes to form the lyso compound (13).

To establish that the enzyme under study was the Mg^{+2} requiring lysophospholipase D described by Wykle and Schremmer (11), the ion requirements of the enzyme were investigated. When the microsomal enzyme preparation was treated with 10 mM EDTA without the addition of Mg^{+2}, 1-*O*-hexadecyl-*sn*-GPC was not hydrolyzed to 1-*O*-hexadecyl-*sn*-glycerol (data not shown). This confirmed that the enzyme being assayed was the lysophospholipase D described earlier.

We tested whether L-ET-18-OCH_3 could be hydrolyzed directly by lysophospholipase D. When radiolabeled L-ET-18-OCH_3 was incubated with rat liver microsomes in the presence of Mg^{+2}, hydrolysis did not occur (Fig. 3B). These findings are in agreement with earlier observations that a free hydroxy group is required at the *sn*-2 position (11–13). Unless a mechanism is available to remove the 2-*O*-methyl group, lysophospholipase D does not appear to play a role in the metabolism of L-ET-18-OCH_3.

Hydrolysis of L-ET-18-OCH_3 by a bacterial phospholipase D. Several phosphocholine-containing lipids were

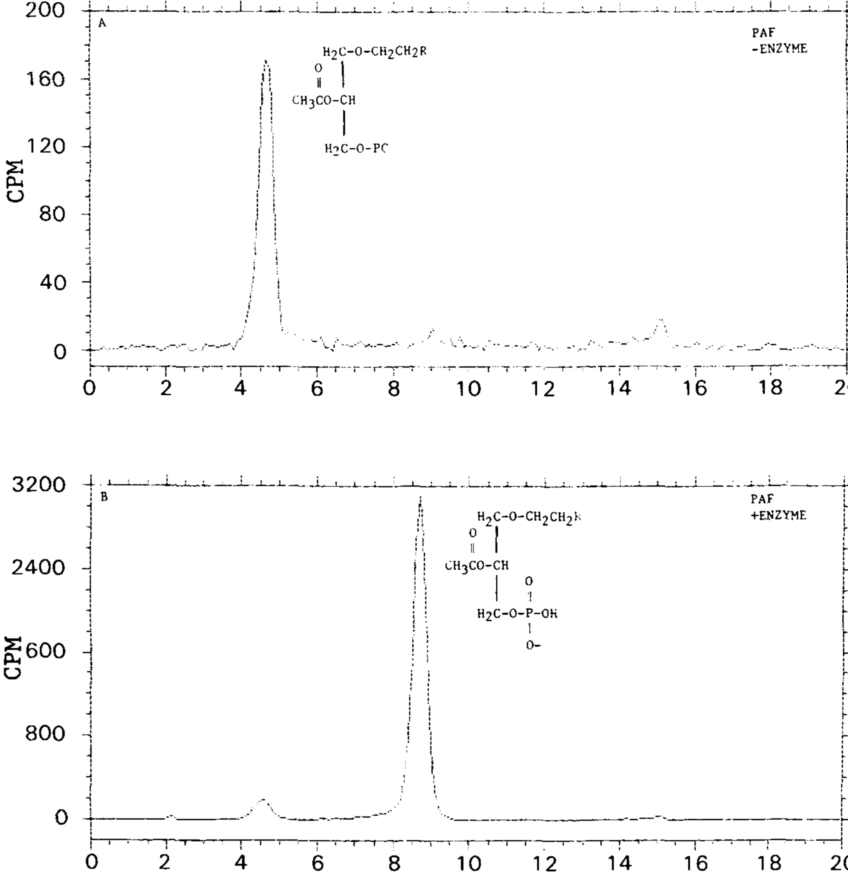

FIG. 5. Hydrolysis of 1-*O*-[3H]hexadecyl-2-*O*-acetyl-*sn*-GPC (platelet-activating factor) to 1-*O*-[3H]hexadecyl-2-*O*-acetyl-*sn*-glycero-3-phosphate by bacterial phospholipase D. The incubation mixture in a final volume of 1 ml contained 1-*O*-[3H]hexadecyl-2-acetyl-*sn*-GPC (1.0×10^6 dpm, 8 pmol) added as described in Figure 4. Incubation times and other conditions as well as methods for analysis of the products were the same as described in Figure 4.

tested as substrates for phospholipase D isolated from the bacterium *Vibrio damsela* (19). Figure 4 shows the degradation of L-ET-18-OCH_3 to 1-*O*-[3H]octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphate by this enzyme. This demonstrated that L-ET-18-OCH_3 is susceptible to metabolism by a phospholipase D and provided a standard for the reaction product of phospholipase D cleavage. Figure 5 shows the degradation of 1-*O*-[3H]hexadecyl-2-acetyl-*sn*-GPC (PAF) to 1-*O*-[3H]hexadecyl-2-acetyl-*sn*-glycero-3-phosphate. Other substrates tested were 1-*O*-[3H]hexadecyl-2-acyl-*sn*-GPC and 1-*O*-[3H]hexadecyl-*sn*-GPC (lyso-PAF). These compounds were also hydrolyzed to the corresponding phosphatidic acid by the bacterial phospholipase D (data not shown).

Hydrolysis of L-ET-18-OCH_3 in intact cells. Figure 6 shows the loss of radiolabeled L-ET-18-OCH_3 from the medium and uptake by MDCK, HL60 and K562 cells. The data points represent relative amounts of label since conditions for recovery were not optimal in these studies. Loss of label due to desaturation at position 9,10 cannot be ruled out. We have not explored this possibility. We have ascribed the loss of label to adsorption to the petri dishes due to the high radiospecific activity of the [3H]L-ET-18-OCH_3 employed (56 Ci/mmol); similar low recoveries are observed in studies using ^{3}H PAF of high radiospecific activity. The concentration of [3H]L-ET-18-OCH_3 used in these studies was 24 nM, whereas the ID_{50} has been reported as 2.5 μM (20). Figure 7 shows the appearance of the hydrolysis product from each cell line. This product, which appeared in both cell and fluid extracts, was identified by TLC as the diglyceride 1-*O*-[3H]octadecyl-2-*O*-methyl-*sn*-glycerol. In two neutral lipid TLC systems, hexane/ethyl ether/formic acid (90:60:4, v/v/v) and ethyl ether/water (100:0.5, v/v), the hydrolysis product migrated (Rf = 0.5 in the ethyl ether/water [100:0.5, v/v] solvent system) with authentic 1-*O*-hexadecyl-2-*O*-methyl-*sn*-glycerol. A TLC zonal scan of products isolated from HL60 fluids after incubation with [3H]ET-18-OCH_3 for 48 hr showed the radiolabeled hydrolysis product in zones 16–21 (Fig. 8). The 1-*O*-hexadecyl-2-*O*-methyl-*sn*-glycerol standard was visualized by iodine staining or by charring the standard lanes. The Rf value of the hydrolysis product in the ethyl ether/water (100:0.5, v/v) solvent system increased after acetylation to 1-*O*-alkyl-2-*O*-methyl-3-acetylglycerol (data not shown). This demonstrated the presence of a free hydroxyl moiety in the radiolabeled hydrolysis product.

No evidence for 1-*O*-alkyl cleavage enzyme products was obtained. Alkyl cleavage activity should have resulted in the appearance of labeled fatty aldehyde and

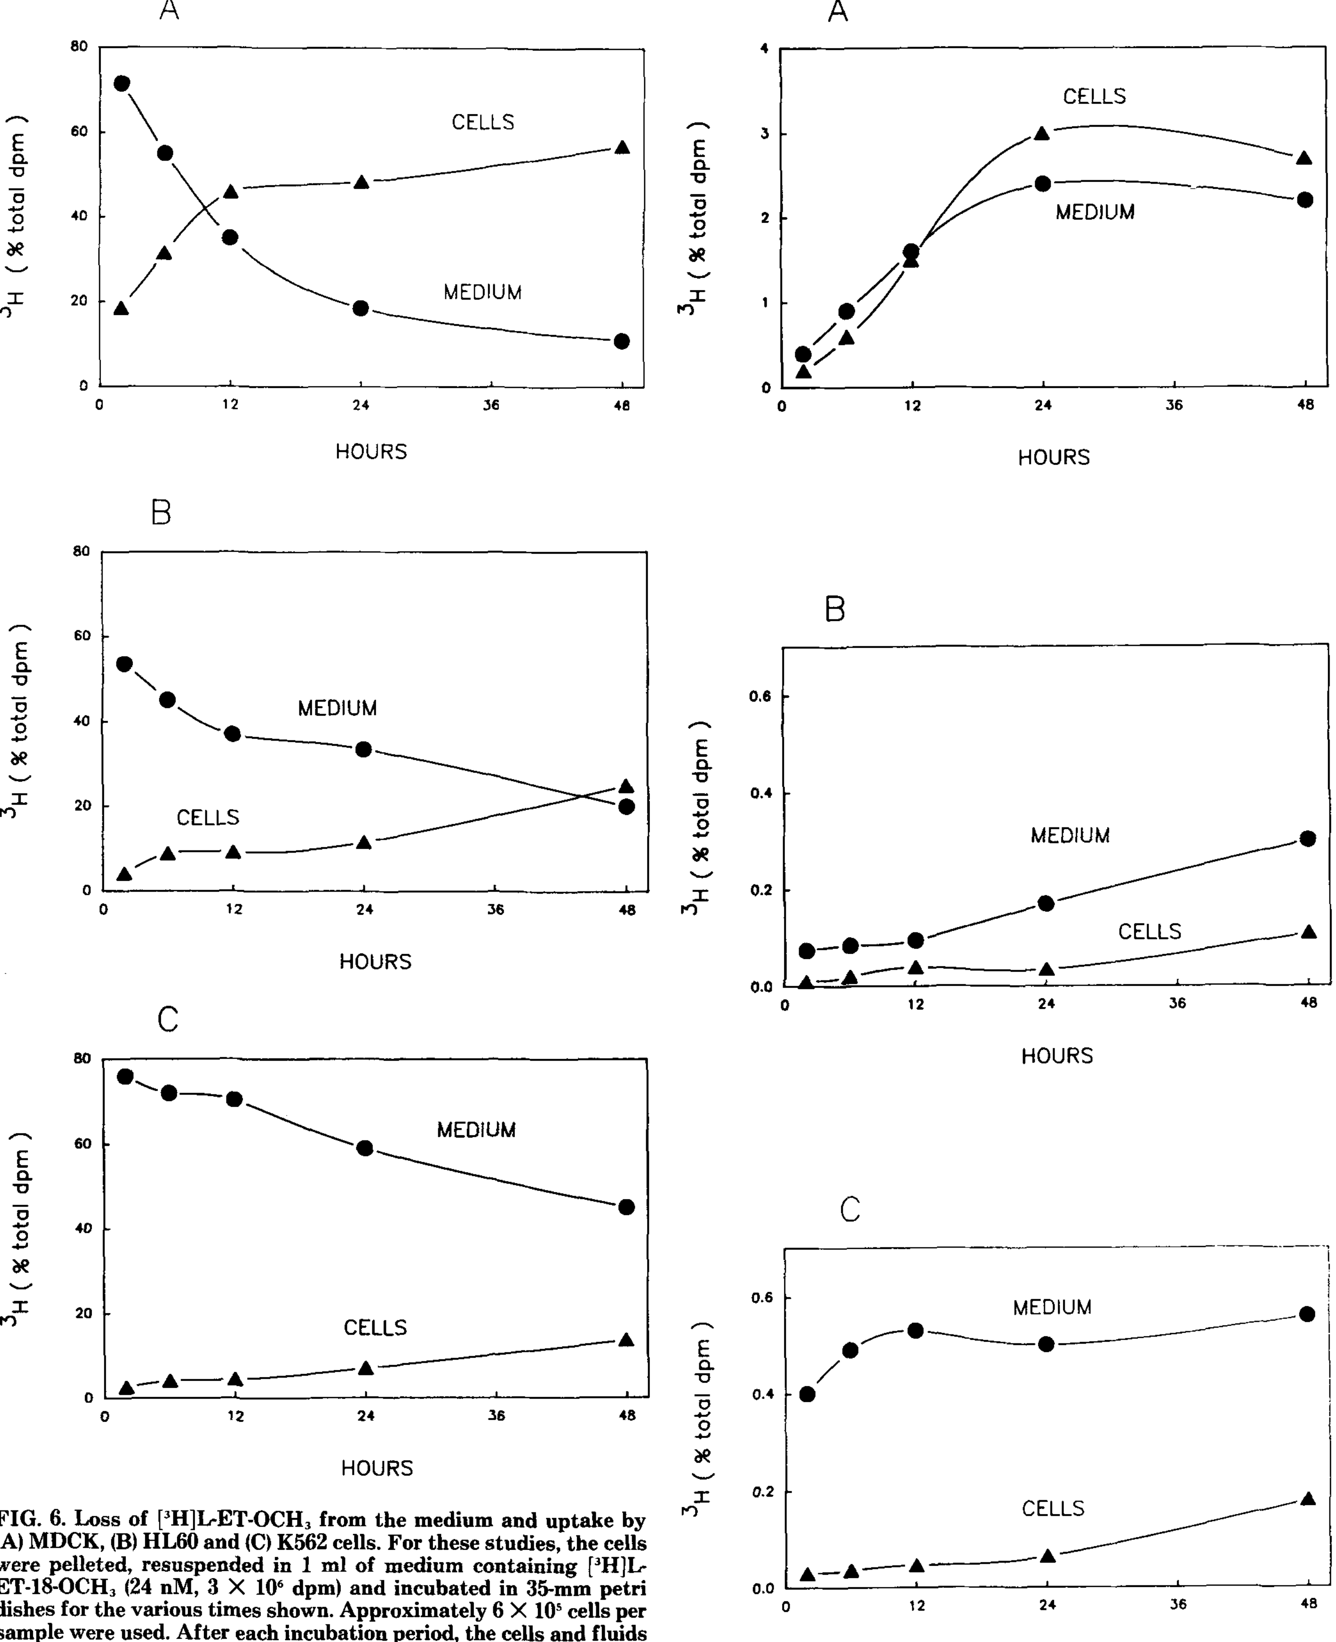

FIG. 6. Loss of [^{3}H]L-ET-OCH_3 from the medium and uptake by (A) MDCK, (B) HL60 and (C) K562 cells. For these studies, the cells were pelleted, resuspended in 1 ml of medium containing [^{3}H]L-ET-18-OCH_3 (24 nM, 3×10^6 dpm) and incubated in 35-mm petri dishes for the various times shown. Approximately 6×10^5 cells per sample were used. After each incubation period, the cells and fluids (medium) were extracted and analyzed by thin layer chromatography. The neutral lipid solvent systems used were hexane/ethyl ether/formic acid (90:60:4, v/v/v) or ethyl ether/water (100:0.5, v/v). The basic phospholipid solvent system used was chloroform/methanol/ammonium hydroxide (65:35:8, v/v/v). Values are percentage of total [^{3}H]ET-18-OCH_3 (dpm) added to each sample that was recovered in the cell extract (▲) or fluid extract (●).

FIG. 7. The formation of 1-*O*-[^{3}H]alkyl-2-*O*-methylglycerol by (A) MDCK, (B) HL60 and (C) K562 cells after incubation with [^{3}H]L-ET-18-OCH_3. These are *the same samples* as in Figure 6. Values are percentage of total dpm added to the sample that were recovered as radiolabeled diglyceride in the cell extract (▲) or fluid extract (●).

fatty acid, which would be expected to incorporate into various cellular lipids. Hoffman and Snyder (6) recently compared alkyl cleavage enzyme activity in cells that demonstrate different sensitivities to ET-18-OCH_3. In contrast to previous studies by other investigators, they found that microsomal preparations from sensitive (HL60) and resistant (K562, MDCK) cells did not differ significantly in alkyl cleavage enzyme activity. They also reported the appearance of the metabolic products 1-*O*-alkyl-2-methoxyglycerol and 1-*O*-alkylglycerol after incubation of HL60, K562 and MDCK cells for 24 hr with 0.5 μM ET-18-OCH_3.

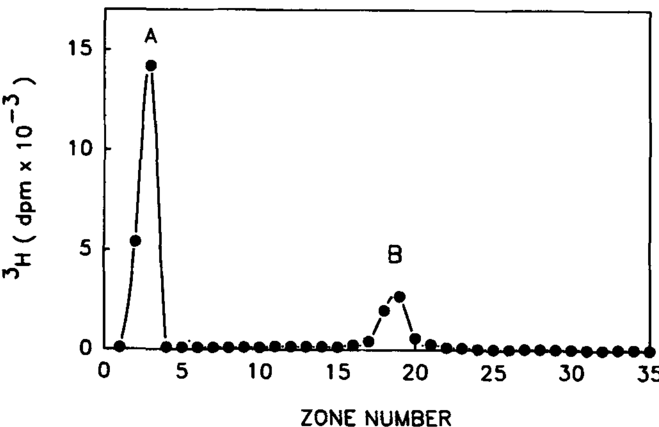

FIG. 8. Zonal scan of a thin layer chromatogram showing the migration of [^{3}H]L-ET-18-OCH_3 and the radiolabeled hydrolysis product, both isolated from HL60 fluids after incubation with [^{3}H]L-ET-18-OCH_3 for 48 hr. The labeled product at zones 16–21 migrated with authentic 1-*O*-hexadecyl-2-*O*-methyl-*sn*-glycerol standard. Each zone division represents a 5-mm region of the thin layer chromatographic sample lane. The origin was at zone 3; the solvent front corresponded to zone 35. (A) [^{3}H]L-ET-18-OCH_3; (B) diglyceride (1-*O*-hexadecyl-2-*O*-methyl-*sn*-glycerol).

The appearance of a radiolabeled diglyceride metabolite suggested a phospholipase C–type mechanism of hydrolysis of ET-18-OCH_3 in whole cells. However, it was also important to consider an alternative mechanism in which a phospholipase D enzyme coupled with a phosphohydrolase could result in the appearance of a diglyceride product. The second mechanism is analogous to that of lysophospholipase D in rat liver microsomes mentioned above. Figure 9 shows the reaction scheme for each of the possible mechanisms of ET-18-OCH_3 hydrolysis.

A basic phospholipid TLC solvent system (chloroform/methanol/ammonium hydroxide [65:35:8, v/v/v]) capable of resolving phosphatidic acid from other components was used to determine if the metabolite 1-*O*-[^{3}H]octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphate was present; none was detected. This evidence supports a phospholipase C–type mechanism of hydrolysis (Fig. 9A), but further experiments must be conducted to clarify this mechanism.

These studies demonstrate that ET-18-OCH_3 is very poorly metabolized by all the cell lines tested. In addition, the liver lysophospholipase does not act on the compound. Based on earlier findings and those reported here, ET-18-OCH_3 is not a substrate for the alkyl cleavage enzyme. The pattern of uptake of ET-18-OCH_3 and release

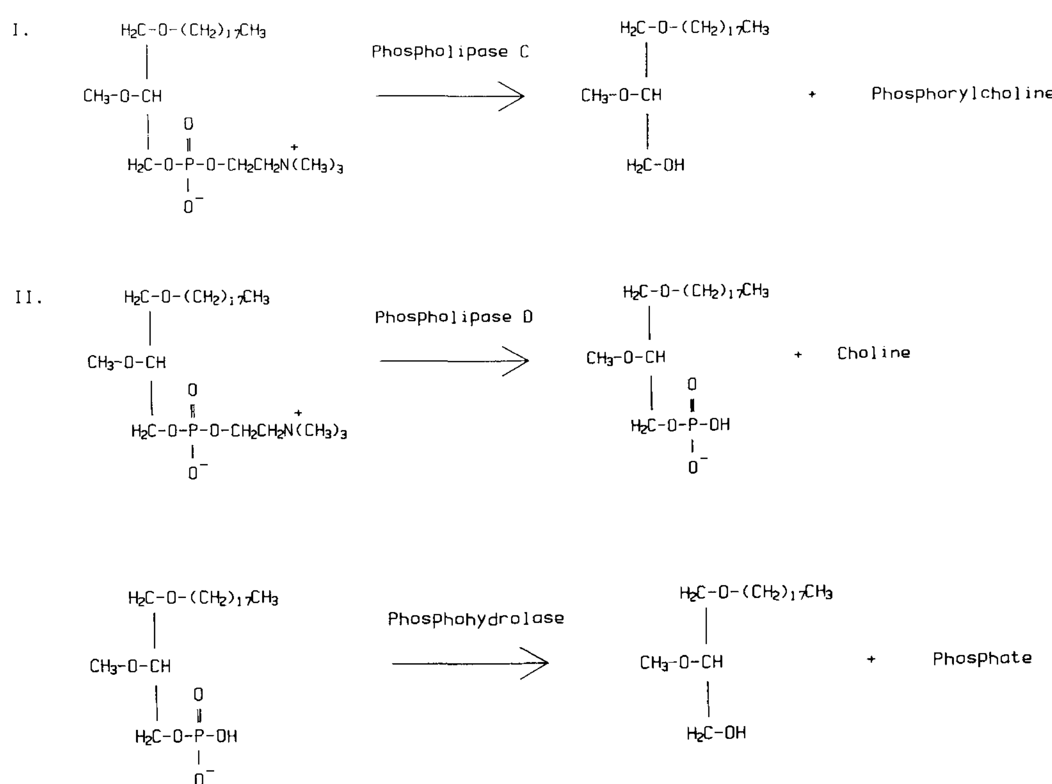

FIG. 9. Two possible pathways explaining the appearance of a radiolabeled diglyceride after incubation of cells with [^{3}H]L-ET-18-OCH_3.

of diglyceride product varied among the cell lines tested. However, these data did not suggest a correlation between cytotoxicity of ET-18-OCH_3 and metabolic degradation of this compound. The selective cytotoxicity of ET-18-OCH_3 toward tumor cells does not appear to be attributable to differences in the catabolism of the compound in normal versus neoplastic cells.

Enzymatic Acylation of Ether and Ester Lysophospholipids in Rat Liver Microsomes[1]

W. Neumüller[a], E.A.M. Fleer[a], C. Unger[b] and H. Eibl[a,*]

[a]Max-Planck-Institut für biophysikalische Chemie, Göttingen, Federal Republic of Germany, and [b]Klinikum der Universitat Göttingen, Göttingen, Federal Republic of Germany

The acylation of lysophospholipids by rat liver acyltransferases was studied. A comparison between ester and ether lysophospholipids as substrates revealed large differences in substrate properties. For instance, oleic acid from oleoyl-CoA and arachidonic acid from arachidonoyl-CoA were not incorporated into 1-*O*-octadecyl-*sn*-glycero-3-phosphocholine under experimental conditions that allowed an optimal transfer of oleic acid and arachidonic acid to 1-*O*-palmitoyl-*sn*-glycero-3-phosphocholine. However, we observed an acyl-CoA-independent transfer of arachidonic acid from 1-*O*-stearoyl-2-*O*-arachidonoyl-*sn*-glycero-3-phosphoinositol to 1-*O*-octadecyl-*sn*-glycero-3-phosphocholine.

Lipids 22, 808–812 (1987).

Acyltransferases are important enzymes for the biosynthesis of phospholipids. They catalyze the stepwise acylation of glycerophosphate (de novo synthesis) (1,2) and also are involved in the acylation of ester lysophospholipids, which are generated in natural membranes by the action of phospholipases A_1 and A_2 (3,4).

The metabolic fate of ether lysophospholipids receives increasing attention because these compounds show antineoplastic activity (5-9). Ether lysophospholipids are more toxic in cell cultures than the respective ester analogs (10). This may reflect differences in the substrate properties of ether lysophospholipids in comparison to ester lysophospholipids. However, little information exists on the substrate behavior of ether lysophospholipids for phospholipid–metabolizing enzymes.

Two possible mechanisms of acylation of lysophospholipids are considered here. First, ether lysophospholipids are reported to be acylated by acyltransferases that normally acylate ester lysophospholipids (11–14). On the other hand, specific acylation of ether lysophospholipids by CoA-dependent and CoA-independent transferases has been reported (15–18). These transferases esterify 1-*O*-octadecyl-*sn*-glycero-3-phosphocholine by transferring an arachidonoyl residue from the 2-position of diacylphospholipids to the 2-position of the ether lysophospholipid. Both reactions, acylation and transacylation, yield identical products. In this study, we set out to determine which is the dominant pathway in the acylation of 1-*O*-octadecyl-*sn*-glycero-3-phosphocholine.

EXPERIMENTAL

Materials. Lysophosphatidylinositol, lysophosphatidylserine, and 5,5′-dithiobis-2-nitrobenzoic acid (DTNB) were obtained from Sigma (Munich, FRG); 1-*O*-stearoyl-2-*O*-[^{14}C]arachidonoyl-*sn*-glycero-3-phosphoinositol, 1-*O*-[^{3}H]-octadecyl-*sn*-glycero-3-phosphocholine, 1-*O*-[1-^{14}C]palmitoyl-*sn*-glycero-3-phosphocholine and [1-^{14}C]oleoyl-CoA were purchased from Amersham Buchler (Braunschweig, FRG). Lysophosphatidylcholine, lysophosphatidic acid and lysophosphatidylethanolamine were synthesized in our laboratory as described before (19,20). Oleoyl-CoA and arachidonoyl-CoA were prepared according to Reitz et al. (21). Other chemicals were of analytical or higher grade and used without further purification.

Methods. Rat liver microsomes were prepared according to Yawetz et al. (22). The microsomes were suspended in an aqueous solution of 4 M NaCl, 0.1 M Tris/HCl (pH 7.4) to yield a protein concentration of 20 mg/ml. The suspension was sonicated in a Branson microtip B 15 for 5 min (energy stage 4) using the pulse mode with 20% pulse time. After dilution with an equal volume of water, the suspension was centrifuged at 100,000 × g for 60 min in a Beckman ultracentrifuge (L5-65 B). About 80% of the acylation activity was found concentrated in a fluffy-layer fraction. Pellet and supernatant showed each about 10% acylation activity. The fluffy layer was used as an enzyme source for the acylation studies.

During acylation of lysophospholipids with acyl-CoA, free CoA is formed. The amount of CoA can be measured using DTNB as a thiol-specific reagent (23). The acylation assays were performed at 37 C in a buffer system of 100 mM Tris/HCl (pH 7.4), containing 0.2 mM DTNB and 0.15 mg/ml microsomal protein. The amount of CoA formed was monitored via DTNB at 412 nm in a Hitachi spectrophotometer 150-20. The substrate concentration was 30 nmol/ml for lyso-PA and 170 nmol/ml for the other lysophospholipids. In order to measure the hydrolysis of acyl-CoA by acyl-CoA hydrolases, 2-desoxy-lysolecithin (DLPC), which cannot be acylated, was used instead of lysophospholipid. The rate from this reaction was considered to be the blank rate and was subtracted from the rate of the acylation reaction in the presence of substrates.

In the radioactive assays, DTNB was omitted from the incubation mixture. Either 170 nmol (20 nCi) 1-*O*-[^{14}C]-palmitoyl-*sn*-glycero-3-phosphocholine or 170 nmol (1 μCi) 1-*O*-[^{3}H]octadecyl-*sn*-glycero-3-phosphocholine was incubated with 50 nmol (1 μCi) [1-^{14}C]oleoyl-CoA and 0.15 mg microsomal protein in 1 ml 0.1 M Tris/HCl buffer (pH 7.4). The reaction was stopped after the indicated time periods by adding 100 μl formic acid. After freeze-drying, the lipids were extracted from the reaction mixture with chloroform and were separated by thin layer chromatography (TLC) on silica gel plates (Silica Gel 60, 20 × 20 cm, Merck, Darmstadt, FRG) in a solvent system of chloroform/methanol/acetic acid/water (100:60:20:5 by vol).

TABLE 1

Acylation Rates of 1-O-Palmitoyl-*sn*-glycero-3-phosphocholine/ phosphate with Oleoyl-CoA at Different DTNB Concentrations

DTNB (nmol/ml)	Specific activity (nmol/min/mg)		
	Lyso-PC*	Lyso-PA*	DLPC
1000	111	211	12
800	111	211	13
600	119	215	14
400	125	223	16
200	134	233	18
100	134	233	20

The acylation reactions were measured at 412 nm with 1-O-palmitoyl-*sn*-glycero-3-phosphocholine/phosphate (lyso-PC/PA) as substrates. The acyl-CoA hydrolase activity was monitored with DLPC. The DTNB concentration ranged from 1 μmol to 0.2 μmol/ml in a 100 mM Tris/HCl buffer (pH 7.4) at 37 C. The protein concentration was 0.15 mg, and the reaction was started with 20 nmol oleoyl-CoA. All acylation rates (*) are corrected for hydrolase rates.

TABLE 2

Acylation of Lysophospholipids with Oleoyl- and Arachidonoyl-CoA

Lyso-PL	Specific activity (nmol/min/mg)	
	18:1	20:4
Lyso-PC	125	130
Alkyl lyso-PC	<5	<5
Lyso-PA	240	34
Lyso-PS	53	85
Lyso-PI	53	117
Lyso-PE	36	32

In an incubation volume of 1 ml 100 mM Tris/HCl (pH 7.4), 0.15 mg microsomal protein was incubated with 170 nmol alkyl lyso-PC, lyso-PC, lyso-PE, lyso-PS, lyso-PI or 30 nmol of the respective lyso-PA at 37 C. The incubation mixture contained 0.2 mM DTNB. The acylation was monitored at 412 nm by following the formation of CoA from acyl-CoA with DTNB. All data are corrected for the hydrolase reaction (18 nmol/min/mg).

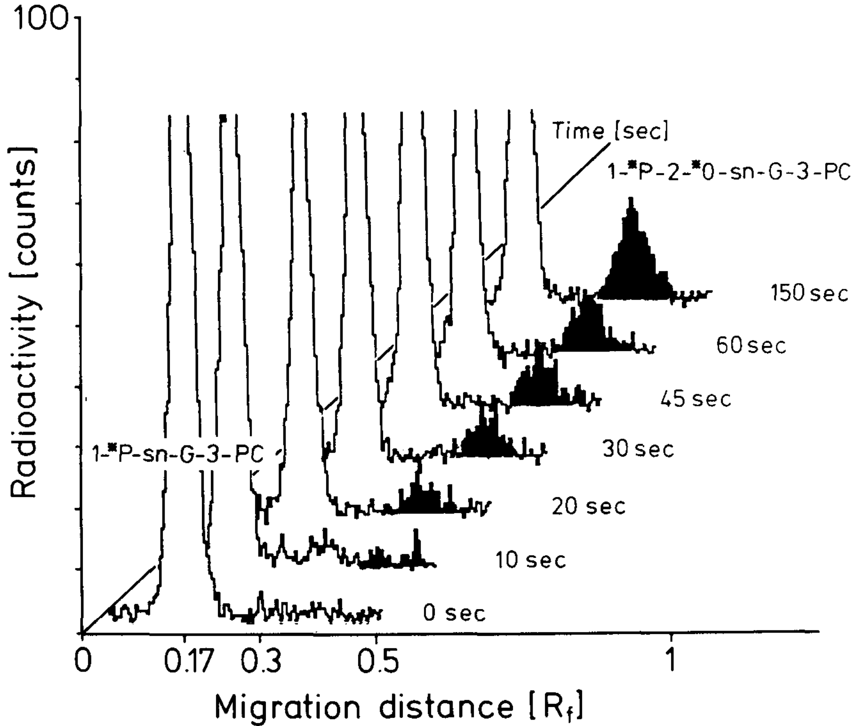

FIG. 1. Acylation of 1-O-[1-^{14}C]palmitoyl-lysolecithin with [1-^{14}C]oleoyl-coenzyme A. Microsomal protein (0.15 mg) was incubated with 170 nmol 1-O-[1-^{14}C]palmitoyl-*sn*-glycero-3-phosphocholine (1-*P-*sn*-G-3-PC) and 50 nmol [1-^{14}C]oleoyl-CoA for 0, 10, 20, 30, 45, 60 and 150 sec in an incubation volume of 1 ml. The reacylation reaction was stopped with formic acid. After freeze-drying, the lipids were extracted from the reaction mixture with chloroform and were separated by TLC on silica gel plates in a solvent system of chloroform/methanol/acetic acid/water (100:60:20:5 by vol). After drying, the plates were scanned in a Berthold linear analyzer LB 2842. The radioactive reaction product was identified as 1-O-palmitoyl-2-O-oleoyl-*sn*-glycero-3-phosphocholine (1-*P-2-*O-*sn*-G-3-PC).

After drying, the plates were scanned in a Berthold linear analyzer LB 2842 with data system LB 500. The acylation products were identified by their R_f-values and by comparison with reference substances that were run on the same plate.

For transacylation, 1-O-[^{3}H]octadecyl-*sn*-glycero-3-phosphocholine (10 nmol, 7 μCi) was incubated with 8 nmol (1 μCi) 1-O-stearoyl-2-O-[1-^{14}C]arachidonoyl-phosphoinositol and 0.15 mg microsomal protein in 1 ml 100 mM Tris/HCl-buffer (pH 7.4). After 60 min, the

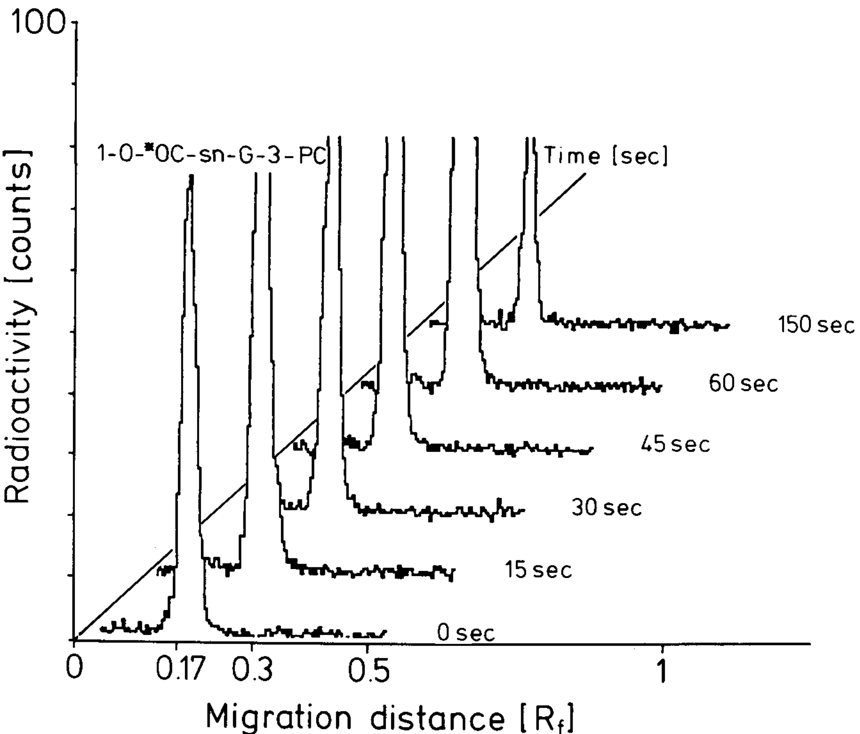

FIG. 2. Acylation of 1-*O*-[^{3}H]octadecyl-lysolecithin with [1-^{14}C]oleoyl-CoA. Microsomal protein (0.15 mg) was incubated with 170 nmol 1-*O*-[^{3}H]octadecyl-*sn*-glycero-3-phosphocholine (1-O-*Oc-*sn*-G-3-PC) and 50 nmol [1-^{14}C]oleoyl-CoA for 0, 15, 30, 45, 60 and 150 sec in an incubation volume of 1 ml. The reaction was stopped by formic acid, and the lipids were extracted and identified as described in Figure 1. No products were formed in the indicated time period. In addition, we performed incubations for longer time periods. Even after 5 and 10 min, no product formation was detected. Therefore, the specific rate of the reaction, if any, is less than 60 pmol/mg protein/hr. This demonstrates that acyl-CoA-dependent acyltransferases cannot acylate ether lysophospholipids.

reaction was stopped with 100 µl of 60% formic acid. Extraction of lipids was performed as described for the acylation assay.

RESULTS AND DISCUSSION

Lysophospholipids have been described as potent antineoplastic agents (24–28). Therefore, it is important to understand the metabolic fate of these molecules in the living cell. In this study, we compare the properties of ester and ether lysophospholipids as substrates for acyltransferases, which catalyze the synthesis of phospholipids. These acyltransferases are important enzymes for detoxification of lysophospholipids. They have been described first by Lands (3) as acyl-CoA-dependent enzymes in rat liver and are mainly localized in membranes of the endoplasmatic reticulum, as shown by Eibl et al. (29). Their acyl-CoA requirement was applied to develop a spectrophotometric assay with DTNB as the sensitive indicator for the appearance of sulfhydryl groups (4). Since amounts of 1 µmol DTNB per incubation volume of 1 ml already inhibited the enzyme reaction, we used smaller amounts of DTNB and obtained satisfactory results with only 0.2 µmol DTNB (see Table 1). The inhibitory effect of DTNB was more pronounced for the substrate combination lyso-PC/oleoyl-CoA, which showed a decrease in specific activity of about 20%, than for the combination lyso-PA/oleoyl-CoA, which showed a drop of only 11%. The effect on the hydrolase activity was large, and the decrease of specific activity amounted to about 50%, however, on a much lower level of total activity as for the transfer rates.

The results obtained in the optimized spectrophotometric assay are summarized in Table 2. High incorporation rates for oleic acid are observed with lyso-PC and lyso-PA as fatty acid acceptors. The rates are lower for lyso-PE and the respective lyso-PS and lyso-PI. The acylation rates for arachidonoyl-CoA with the different lysophospholipids are quite similar in comparison to the incorporation of oleic acid. The specific rate is high for lyso-PC and the rates are low for lyso-PE and lyso-PS. However, there is a large difference in the acylation rates for lyso-PA (de novo synthesis) and lyso-PI (deacylation-reacylation cycle). For lyso-PA, incorporation of oleic acid is high and acylation with arachidonic acid is very low; vice versa for lyso-PI as substrate: the incorporation of oleic acid is low and the acylation with arachidonic acid compares with the high rates measured for the incorporation into lyso-PC. This is in agreement with the generally accepted finding that biosynthetically formed phosphatidic acid is low in arachidonic acid and that phosphatidylinositol is relatively high in it. No detectable transfer was observed with alkyl lyso-PC (<5 nmol/min/mg protein), which may explain the higher toxicity of this

compound in different cell lines in comparison to the ester analog.

The spectrophotometric test is not sensitive enough to measure very low incorporation rates (<5 nmol/min/mg protein). Since the DTNB-test reports the appearance of free sulfhydryl groups, it measures the sum of two enzyme activities: the acyltransfer and the hydrolase reaction. If acyltransfer and hydrolase rates are in the same magnitude order, the calculated acyltransfer rates become unreliable. In this case, a direct measurement of the products formed in the current reaction is necessary; this requires radiolabeled substrates.

In the first set of experiments, shown in Figure 1, the acyltransfer rate for 1-*O*-[^{14}C]palmitoyl-*sn*-glycero-3-phosphocholine/[^{14}C]oleoyl-CoA was determined by following the formation of 1-*O*-[^{14}C]palmitoyl-2-*O*-[^{14}C]oleoyl-*sn*-glycero-3-phosphocholine (Fig. 1). The specific activity for this reaction was 172 nmol/min/mg protein, which is much higher than 134 nmol/min/mg protein, the rate observed in the optimized spectrophotometric assay. It again demonstrates that even low concentrations of DTNB interfere with the acylation reaction. While the spectrophotometric assay does allow comparison of acyltransferase activities, absolute rates of enzyme activity need to be determined in the absence of DTNB.

In the second set of the radioactive incubations, we used 1-*O*-[^{3}H]octadecyl-*sn*-glycero-3-phosphocholine/[^{14}C]-oleoyl-CoA as substrates. No product was formed in the indicated time period (Fig. 2). The sensitivity of the test does allow the identification of 100 dpm (0.5 cpm), which corresponds to 1 pmol product. Since we were not able to detect any product after 10 min of incubation (data not shown), the rate of acylation, if any, is less than 60 pmol/mg/hr. This indicates that an exchange of an ester for an ether group in lysolecithin results in what seems a complete loss of substrate properties for the acyl-CoA-dependent acyltransferases from rat liver microsomes. So, 1-acyl lysolecithins are substrates for the acyltransferases, whereas 1-alkyl lysolecithins are not.

In recent publications by Kramer et al. (17,30), it was described that an acyl-CoA-independent pathway for the acylation of ether lysophospholipids exists in human platelets. It requires 1,2-diacyl-*sn*-glycero-3-phospholipids as a cofactor. We searched for a similar reaction in rat liver. Using 1-*O*-[^{3}H]octadecyl-*sn*-glycero-3-phosphocholine as an acyl acceptor and 1-*O*-stearoyl-2-*O*-[^{14}C]arachidonoyl-*sn*-glycero-3-phosphoinositol as acyl-donor in incubations with rat liver microsomes, we observed the formation of 1-*O*-[^{3}H]-octadecyl-2-*O*-[^{14}C]arachidonoyl-*sn*-glycero-3-phosphocholine (Fig. 3). This product contains both labels, ^{3}H and ^{14}C, in a ratio of 1:1 on a molecular basis. A rate of 42 nmol/mg protein/hr was calculated for the CoA-independent transacylation reaction. This rate is much higher than the estimated maximum rate for the acyl-CoA-dependent acyltransferase reaction (60 pmol/mg protein/hr, based on the sensitivity limit of the test). Therefore, we conclude that the acyl-CoA-independent transfer reaction is the dominant pathway for the acylation of ether lysolecithins in rat liver.

From these experimental results of the acylation of ester and ether lysophospholipids, we conclude that two independent pathways of acylation exist in rat liver. The first route depends on acyl-CoA as cosubstrate and is dominant for ester lysophospholipids; the second route

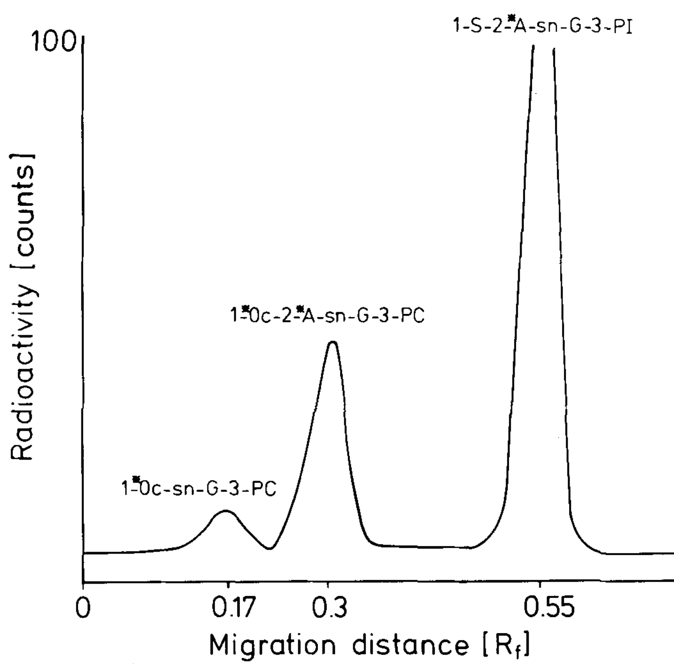

FIG. 3. Acylation of 1-*O*-[^{3}H]octadecyl-lysolecithin with 1-*O*-stearoyl-2-*O*-[1-^{14}C]arachidonoyl-*sn*-glycero-3-phosphoinositol as a fatty acid donor (transacylation). 1-*O*-Stearoyl-2-*O*-[1-^{14}C]arachidonoyl-*sn*-glycero-3-phosphoinositol (1-S-2-*A-*sn*-G-3-PI) (8 nmol) and 1-*O*-[^{3}H]octadecyl-*sn*-glycero-3-phosphocholine (1-*Oc-*sn*-G-3-PC) (10 nmol) were incubated with 0.15 mg microsomal protein in an incubation volume of 1 ml. After 60 min, the reaction was stopped with formic acid, and the lipids were extracted and identified as described in Figure 1. The radioactive reaction product was identified as 1-*O*-octadecyl-2-*O*-arachidonoyl-phosphocholine (1-*Oc-2-*A-*sn*-G-3-PC). Counts in the figure represents both ^{14}C- and ^{3}H-activity after 10 min. The product of the reaction in the middle peak contains ^{14}C and ^{3}H activity. This peak's area was collected, and ^{14}C- and ^{3}H-activities were measured separately in a Zinser III Liquid Counter. The ratio of ^{14}C/^{3}H was close to 1, as expected. Control runs with both starting materials did not show radioactivity in the area of the enzyme reaction product.

is independent from acyl-CoA and uses diacyl phospholipids as a fatty acid source. This pathway is dominant for the acylation of ether lysophospholipids with arachidonic acid.

[Received July 16, 1987]

Increased Membrane Permeability for an Antitumoral Alkyl Lysophospholipid in Sensitive Tumor Cells[1]

Joachim Storch* and **Paul G. Munder**
Max-Planck-Institut fuer Immunbiologie, 7800 Freiburg, Stuebeweg 51, Federal Republic of Germany

We have investigated cellular sensitivity to the antitumoral alkyl lysophospholipid (ALP) 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine ($ET\text{-}18\text{-}OCH_3$) in vitro. The permeation of this lipid into the cell was not influenced by metabolic inhibitors of ATP biosynthesis. $ET\text{-}18\text{-}OCH_3$ uptake was not saturable within sublytic concentrations, but could be inhibited in part by cytochalasin B (CB) and dipyridamole. The activation energy of the CB-sensitive uptake process was increased up to threefold compared to CB-insensitive uptake. $ET\text{-}18\text{-}OCH_3$ influx and equilibrium binding of $ET\text{-}18\text{-}OCH_3$ were decreased in a fibrosarcoma cell variant (MethA) selected for $ET\text{-}18\text{-}OCH_3$ resistance. The resistant MethA cells were also less sensitive to cytolysis by lysophosphatidylcholine and other ALP. After 72 hr, the resistant MethA cells had metabolized only 11.8% more of the absorbed $ET\text{-}18\text{-}OCH_3$ than sensitive MethA cells. However, they tolerated at least a 30-fold concentration of this ALP. The uptake mechanism, which could be inhibited by CB, was less active in resistant MethA cells and several other ALP-resistant cell lines. The concentration of CB, required for maximal uptake inhibition, was increased more than four times in the ALP-sensitive tumor cell lines. CB-specific $ET\text{-}18\text{-}OCH_3$ uptake was also enhanced after virus transformation of 3T3 fibroblasts by SV 40. Dipyridamole retarded the $ET\text{-}18\text{-}OCH_3$-mediated cell destruction.
Lipids 22, **813–819 (1987).**

Alkyl lysophospholipids (ALP) are stable ether or thioether analogues of 2-lysophosphatidylcholine (2-LPC), which is present in 3–12% of the total phospholipids in cellular membranes and plasma (1). ALP cannot enter the deacylation-acylation cycle of cellular phospholipids (2) because a lysophospholipase cannot split the alkyl bond, and acylation is blocked in most of these compounds by a stable substitution of position *sn*-2 of the glycerol backbone.

Among many biological effects, ALP inhibit growth and metastasis of different syngeneic tumors in the mouse (for review, see ref. 3). Moreover, the results of a clinical phase I study suggest that ALP might be useful in human cancer therapy (4). The antineoplastic activity is probably caused by the generation of tumoricidal macrophages (5) and a direct progressive destruction of tumor cells, whereas nontransformed cells are less affected (5–7). Some evidence has been reported (6–10) suggesting that sensitive cells take up more ALP or fail to split the ether bond because of the lack of a glyceryl-ether cleaving enzyme (E.C. 1.14.16.5). One of the most potent ether analogues of lysolecithin that we tested was the 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine ($ET\text{-}18\text{-}OCH_3$). Here we report on cellular metabolism and cellular uptake mechanism of this compound in sensitive and resistant cell lines.

MATERIALS AND METHODS

Alkyl lysophospholipids. 1-*O*-hexadecyl-*sn*-glycero-3-phosphocholine (L-ET-16-OH), 3-*O*-hexadecyl-*sn*-glycero-1-phosphocholine (D-ET-16-OH) and 1-*O*-octadecyl-9′-enyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine were purchased from R. Berchtold (Biochemical Laboratory, Bern, Switzerland).

1-*O*-octa-[9,10(n)-^{3}H]decyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine ($ET\text{-}18\text{-}OCH_3$) was obtained by catalytic reduction of 1-*O*-octadecyl-9′-enyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine with tritium gas (Amersham Radiochemical Center, Buckinghamshire, U.K.). The specific activity was 3.53 Ci/mmol. Unlabeled $ET\text{-}18\text{-}OCH_3$ was purchased from Medmark Chemicals (Gruenwald, Muenchen, FRG).

Other chemicals. Cytochalasin B (CB), cytochalasin E (CE), dipyridamole (DP), papaverine and bovine serum albumin (BSA) were purchased from Sigma Chemical (St. Louis, MO). Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS) and sodium pyruvate were purchased from Gibco (Karlsruhe, FRG). FBS was used after inactivation for 1 hr at 50 C. 2-LPC was purchased from Roth (Karlsruhe, FRG).

Cells and cell culture. The cell lines listed in Table 1 were cultivated with DMEM plus 10% fetal bovine serum (FBS; v/v), 1 mM sodium pyruvate, 5×10^{-5} M β-mercaptoethanol, 50 units penicillin and 50 μg streptomycin per ml at 37 C in a humidified 10% CO_2 atmosphere. All cells were used in the log phase of growth. Viability, tested by trypan blue dye exclusion, was never below 90%.

(BALB/c $\times$ C57BL)F_1 bone marrow–derived macrophages (MO) were cultivated in Teflon bags, as previously described (6). The cultures usually reached confluence after 12 days. The drug-resistant fibrosarcoma cells were

Abbreviations: ALP, alkyl lysophospholipids; 2-LPC, lysophosphatidylcholine (1-acyl-*sn*-glycero-3-phosphocholine); $ET\text{-}18\text{-}OCH_3$, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine; D-ET-16-OH, 3-*O*-hexadecyl-*sn*-glycero-1-phosphocholine; L-ET-16-OH, 1-*O*-hexadecyl-*sn*-glycero-3-phosphocholine; CB, cytochalasin B; CE, cytochalasin E; DP, dipyridamole; FBS, fetal bovine serum; BSA, bovine serum albumin; DMEM, Dulbecco's modified Eagle's medium; DMSO, dimethyl sulfoxide; MO, macrophage; PBS, phosphate-buffered saline.

derived from surviving cells of cultures, which had been propagated in the presence of 6 μg ET-18-OCH_3/ml. These cells were further selected by cultivation with succeeding 10, 20 and 30 μg/ml of ET-18-OCH_3. Before use, resistant fibrosarcoma variant (rMethA) cells were propagated for several days in culture medium without this ALP and washed repeatedly. This did not alter the induced resistance to ET-18-OCH_3. 3T3 Fibroblasts were used in a nonconfluent state (3–4 × 10^5 cells per cm^2). For absorption studies, 3T3, SV40-3T3 and L929s fibroblasts were harvested by treatment with a 0.25% solution of trypsin (Boehringer, Mannheim, FRG) for 10 min. Trypsin was inactivated by FBS, and cells were washed twice before use. This procedure had no influence on ET-18-OCH_3-uptake.

Lipid extraction and lipid analysis were performed as previously described (6). In brief, lipids were extracted as described by Ways and Hanahan (18), separated on silica-coated thin layer plates using chloroform/methanol/H_2O (60:40:10, v/v/v) as solvent. The separated compounds were detected by iodine vapor and scraped off into scintillation vials. One ml of H_2O was added, and the vials were shaken for 24 hr to obtain a very fine suspension. The samples were measured in a scintillation counter after adding 12 ml of Bioflur (New England Nuclear, Boston, MA).

Binding of ET-18-OCH_3 to serum components. For separation of lipoproteins, we used a previously described method (19) with a few modifications. FBS was brought to a density of 1.21 g/cm^3 by addition of solid NaBr. The samples were allowed to equilibrate for 15 min at 37 C in the presence of ^{3}H-labeled ET-18-OCH_3 (5 μg/ml). Each 1.25 ml of the samples was pipetted into a 11 × 60 mm polyallomer centrifuge tube (Beckman Instruments, Palo Alto, CA). A discontinuous gradient was formed by carefully layering 1 ml of NaBr solution with a density of 1.063 g/cm^3 above the serum, followed by 1 ml with a density of 1.019 g/cm^3 and finally 1 ml with a density of 1.006 g/cm^3. To minimize mixing, salt solutions were allowed to gravity-feed down the side of the tubes through a glass capillary. Six samples were centrifuged at 20 C for 24 hr at 400,000 × g in an SW-56 rotor (Beckman). Each 0.25 ml of the samples was succeedingly measured by liquid scintillation counting after the addition of 12 ml Bioflur.

Absorption and inhibitor studies. CB, CE and DP were stored in a stock solution with dimethyl sulfoxide (DMSO) at −20 C. If not otherwise indicated, 10^6 cells were preincubated for 1 hr with 1 ml of DMEM containing 10% FBS, 0.5% DMSO and the inhibitor. We incubated the samples at 37 C in a humidified 10% CO_2 atmosphere for another 2 hr with labeled ET-18-OCH_3 (1 μg/ml). Absorption was stopped by addition of 10 ml of an ice-cold, phosphate-buffered NaCl-solution (0.9%, pH 7.2; phosphate buffered saline [PBS]). Samples were immediately centrifuged and washed twice with 10 ml of chilled PBS. No significant loss of absorbed ET-18-OCH_3 occurred by this procedure, since transport activity was minimal at this temperature. A portion of the cell suspension was resolved in Bioflur (New England Nuclear) and assayed for liquid scintillation counting.

When the temperature dependence of ET-18-OCH_3 uptake was determined, cells were incubated with 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid–buffered DMEM containing 10% FBS in a thermostated water bath. After the temperature had equilibrated, absorption of ET-18-OCH_3 (2 μg/ml) within 1 hr was measured as described above. When the membrane translocation of ET-18-OCH_3 was determined, we used the previously described albumin-extraction method (20). Therefore, cells were washed twice with 10 ml chilled PBS containing 1% fatty acid-free BSA.

Assays for the cytotoxicity of ET-18-OCH_3. 5 × 10^5 Cells/ml DMEM plus 10% FBS were cultivated with the indicated concentration of ET-18-OCH_3 for 24 hr. Cells were washed once, and ^{3}H-thymidine incorporation was measured as described (6). When the influence of DP on ET-18-OCH_3 cytotoxicity was studied, cells were preincubated without ET-18-OCH_3 for 4 hr in the presence or absence of DP, which was added in an ethanol solution. The final ethanol concentration was 0.05%. MethA cells (5 × 10^4/ml) were incubated for 72 hr and washed twice before ^{3}H-thymidine incorporation was measured.

Since mature bone marrow MO do not incorporate thymidine, the number of viable cells was determined with a culture counter after 72 hr of incubation. Therefore, 2 × 10^6 cells were placed into culture dishes with a hydrophilic Teflon membrane (Petriperm, Heraeus, FRG). The final volume was 5 ml (DMEM plus 10% FBS). Under these conditions, viable cells remained attached on the surface of the dishes, whereas damaged cells detached and could be removed by washing the monolayers once with PBS. The number of nonadherent but not trypan blue–stained cells was always below 8% of control cultures. The adherent cells were then harvested with a rubber policeman. When ALP-induced cytolysis in the absence of FBS was determined, 10^6 cells/ml were incubated with 7.5 μg ALP (2-LPC) per ml of DMEM for 30 min in a 10% CO_2 atmosphere at 37 C. The percent of trypan blue–dyed cells was immediately determined by counting 200 to 300 cells with a haematocytometer.

If not otherwise indicated, all experiments were done in triplicate and standard deviations were below 10%.

RESULTS

Selective cytotoxicity and cellular metabolism of ET-18-OCH_3. Already after 24 hr of incubation, differences in ET-18-OCH_3 resistance are revealed (Fig. 1). 3T3 and L929s fibroblasts were less sensitive, but 48 hr later only the 3T3 cells survived a concentration of 20 μg/ml ET-18-OCH_3, and ^{3}H-thymidine incorporation remained at 80% of control. This value decreased to less than 10% of control with L929s fibroblasts after 72 hr. Abels., P815, SV40-3T3 and MethA were the most sensitive tumor cell lines. Bone marrow–derived MO were only moderately resistant against ET-18-OCH_3 (see Fig. 7). In contrast, rMethA could be cultivated continuously in the presence of 30 μg/ml ET-18-OCH_3 with a doubling time of 20–24 hr.

The metabolism of ET-18-OCH_3 was low in all cell lines studied. After 12 hr of incubation, between 88.9 and 94.6% of the absorbed compound was unchanged. Even after 72 hr, only 8.4% in MethA and 20.2% in rMethA were metabolized. On thin layer chromatography, the ET-18-OCH_3 metabolites migrated with oleic acid, neutral lipids, phosphatidylethanolamine and phosphatidylcholine. We did not further analyze these metabolites. At present, it is not completely clear whether ALP

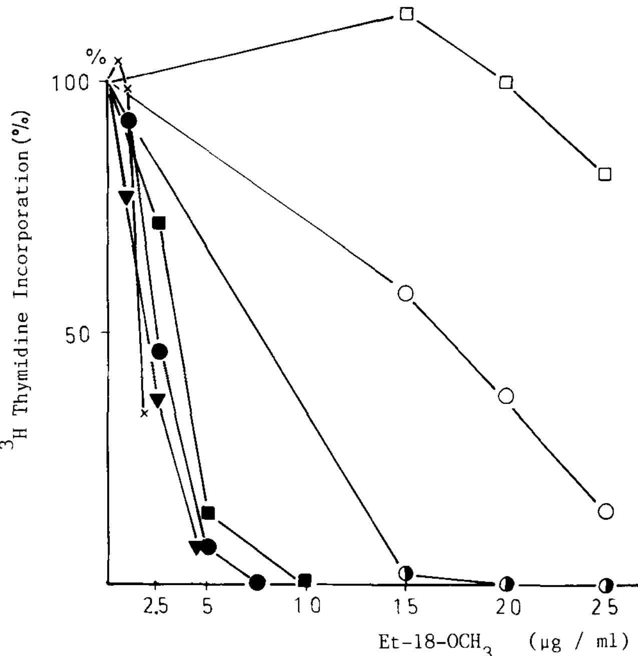

FIG. 1. ET-18-OCH$_3$-induced growth inhibition. 5 × 10^5 Cells/ml DMEM plus 10% FBS were cultivated for 24 hr with the indicated concentration of ET-18-OCH$_3$. Cells were washed once and ^{3}H-thymidine incorporation within 4 hr was determined. Mean of 4 separate determinations; SD ⩽ 15%. □, 3T3; ○, L929s; ◑, YAC; ■, SV40-3T3; ●, MethA; ▼, P815; x, Abels.

cytotoxicity is primarily due to direct lysis by the accumulated compound itself or to secondary toxic effects induced by ALP, like a disturbance of lipid metabolism (6). Table 2 shows that drug resistance in rMethA was accompanied by increased cell membrane stability to cytolysis by different ALP and 2-LPC.

Uptake and equilibrium binding of ET-18-OCH$_3$. Figure 2 shows the time course of ET-18-OCH$_3$-uptake in the presence or absence of FBS (10% v/v). Within the first 2 hr, the rate of uptake was enhanced about twofold in the sensitive cells. It should be noted that rMethA cells had been cultivated several days without ET-18-OCH$_3$ and washed repeatedly. Since ET-18-OCH$_3$ uptake was reduced in both cell variants in the presence of serum, we examined the binding of ET-18-OCH$_3$ to serum components. After density gradient separation of FBS, more than 90% of the added ET-18-OCH$_3$ was bound to a serum fraction with a density >1.21 g/cm^3, which has been previously identified as albumin (21). This indicates that ET-18-OCH$_3$ has the same high affinity binding to serum albumin as also described for natural LPC (21). In the presence of serum, the uptake rate was about linear with respect to time up to 4 hr (Fig. 2), and further studies were done within this period.

After 2 hr of incubation and two saline washes, only 10.3% of the MethA-bound ET-18-OCH$_3$ could be extracted by two washes with a chilled solution of 1% BSA in PBS. It has been demonstrated previously (20) that albumin washing removes the LPC from the outer cell membrane monolayer because albumin binds LPC with high affinity. Since ET-18-OCH$_3$ had the same high affinity to albumin like LPC, the albumin-unextractable ET-18-OCH$_3$ in MethA cells was probably inaccessible to albumin and was therefore not located on the cell surface. This finding is supported by the observation that equilibrium establishment between albumin-bound and cell surface-bound LPC is rapidly achieved, at least before 2 hr (20). In contrast, membrane translocation of LPC (20) or cellular uptake of ET-18-OCH$_3$ in the presence of serum (Fig. 2) is a comparatively slow process, i.e., the equilibrium time for cellular ALP uptake is 20–24 hr. Albumin-unextractable ET-18-OCH$_3$ uptake (influx) was increased 2.7 times in sensitive MethA. After equilibrium

TABLE 2

ALP-Induced Cytolysis in MethA and Drug-Resistant Mutant Cells (rMethA)

Compound	Increase in trypan blue-dyed cells (% of total cell number) MethA	rMethA
2-LPC	23 (±6)	5 (±1)
D-ET-16-OH	87 (±4)	29 (±6)
L-ET-16-OH	70 (±2)	8 (±2)
ET-18-OCH$_3$	57 (±3)	31 (±3)

10^6 Cells/ml were incubated for 30 min at 37 C in the presence of 7.5 µg/ml compounds in the absence of fetal bovine serum. Two hundred to 300 cells were counted for determinations of the percent of trypan-blue dyed cells. Mean of three separate experiments (± SD).

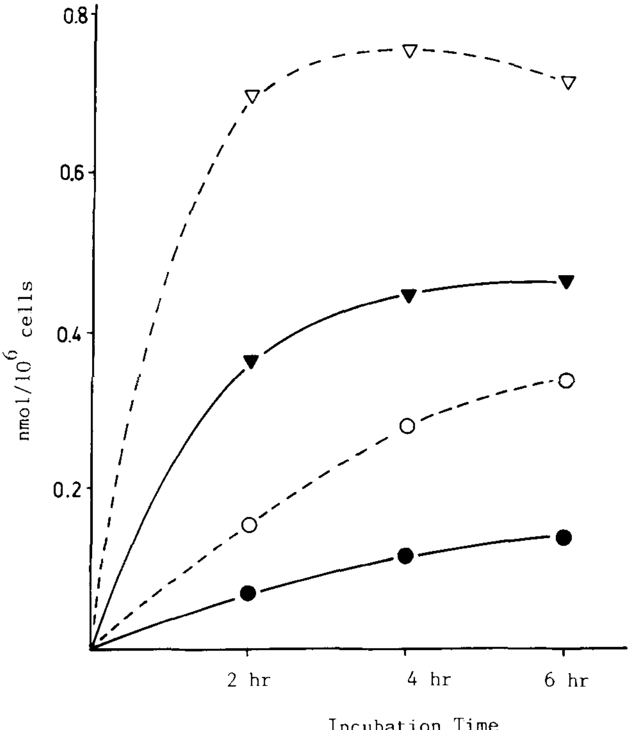

FIG. 2. Time course of ET-18-OCH$_3$ absorption in the presence and absence of FBS. 10^6 Cells/ml were incubated at 37 C with 1 µg/ml ET-18-OCH$_3$ in the presence or absence of 10% (v/v) FBS. Absorption was measured as described in Materials and Methods. ○, MethA plus FBS; ▽, MethA without FBS; ●, rMethA plus FBS; ▼, rMethA without FBS.

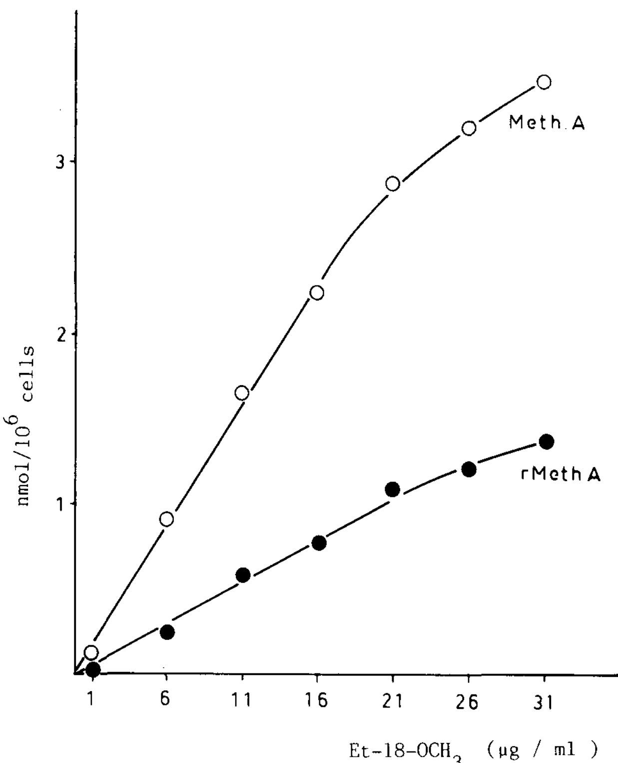

FIG. 3. Concentration dependence of ET-18-OCH_3-uptake in MethA and rMethA cells. 10^6 Cells/ml DMEM/10% FBS were incubated with the indicated concentration of ET-18-OCH_3 for 2.5 hr. Absorption was measured as described in Materials and Methods.

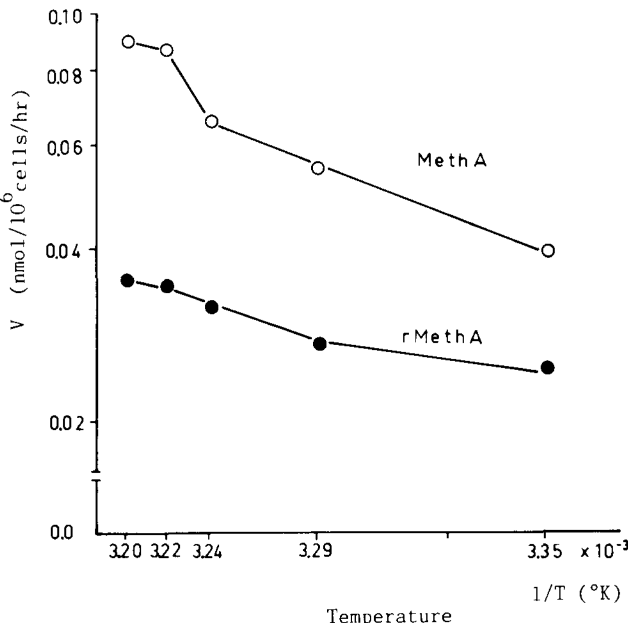

FIG. 4. Arrhenius plots for the uptake of ET-18-OCH_3 by normal and resistant MethA cells. 0.5 × 10^6 Cells/ml DMEM/10% FBS were incubated at the indicated temperature for 1 hr with 2 μg/ml ET-18-OCH_3. Uptake was determined as described in Materials and Methods. Mean of 3 experiments, SD ≤ 5%.

establishment, sensitive MethA cells bound 3–4 times as much of the drug as did the resistant mutant cells, indicating that, besides enhanced influx, the number of cellular binding sites was also increased in the sensitive cells.

Temperature and concentration dependence of ET-18-OCH_3-uptake. Figure 3 shows that uptake of ET-18-OCH_3 is about linear with respect to extracellular concentration up to 20 μg/ml. Only a slight saturation was visible above this concentration in MethA and rMethA.

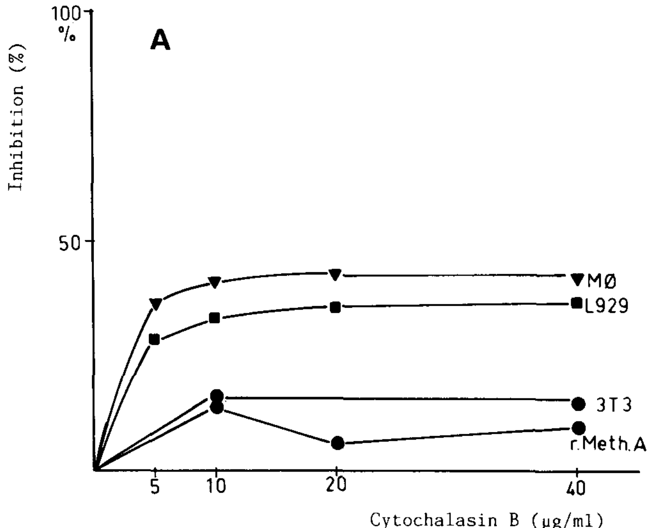
Figure 4 shows the temperature dependence of ET-18-OCH_3 uptake. The decrease in absorption rate at low temperature is probably caused by a decrease in lipid fluidity. The Arrhenius plots for MethA and rMethA reveal differences in the activation energy, which is about three times increased in the sensitive cells between 3.22 × 10^{-3} K (37 C) and 3.24 × 10^{-3} K (35 C) and below 3.29 × 10^{-3} K (31 C). At 0–4 C, both cell variants bound the same low amount of ET-18-OCH_3, which came close to 20% with respect to MethA at 37 C. In this case, 80% of the cell-bound ET-18-OCH_3 was extracted by albumin washing and was therefore mostly located on the cell surface.

This blocking of ET-18-OCH_3 transport into the cell is in agreement with the blocking of LPC transport at 0 C (20). Our results can be explained by two different uptake mechanisms in MethA and rMethA cells. In support of this, significant discontinuities in the Arrhenius plot are only seen with MethA cells at 3.24 × 10^{-3} K (37 C) and 3.22 × 10^{-3} K (35 C). A different membrane protein-lipid interaction must have influenced ET-18-OCH_3 uptake in these sensitive cells, and it could reflect a lipid-phase transition or a phase separation of membrane proteins involved in ALP transport.

Inhibitor studies. When we incubated the cells with 10^{-2} M NaN_3 plus 5 × 10^{-2} M 2-deoxyglucose or with 10^{-2} M NaF plus 10^{-2} M NaN_3, ET-18-OCH_3 uptake was inhibited for less than 10% in MethA and rMethA. Similar effects were seen with macrophages and L929s fibroblasts. It has been demonstrated previously that the cellular ATP level drops rapidly after this treatment, and endocytosis is also blocked (22). Therefore, the ET-18-OCH_3 uptake in our studies did not occur via endocytosis, and it depended apparently not on cellular energy.

Many nonsaturable transport processes are inhibited by DP, CB and papaverine (23). ET-18-OCH_3 uptake into sensitive MethA cells could also be inhibited by these compounds, but uptake into rMethA was hardly affected. Both cell variants had about the same uptake rates in the presence of 40 μg/ml CB (Table 3).

Figures 5A and 5B show the influence of CB concentration on the inhibition of ET-18-OCH_3 uptake. In 3T3, MO, L929s and rMethA, maximal inhibition occurred at 5–10 μg/ml CB. In contrast, with Abels., P815, YAC, SV-40-3T3 and MethA, more than 40 μg/ml CB was necessary to complete uptake inhibition (Fig. 5B). Figure 5C shows the inhibition of ET-18-OCH_3 uptake by DP (this drug had a limited solubility of about 20 μg/ml under our incubation conditions, pH 7.4). DP was as effective as CB. Papaverine also acted as an inhibitor, but CE had hardly any effect (results not shown). The inhibition of ET-18-OCH_3 uptake by CB did not change at a molar ratio of ET-18-OCH_3 to CB between 0.1 and 3.1. This indicates that uptake inhibition was not caused by the formation of an ET-18-OCH_3–CB complex and that CB is no competitive inhibitor of ET-18-OCH_3 uptake. Table 3 shows the amount of ET-18-OCH_3 absorbed in the presence



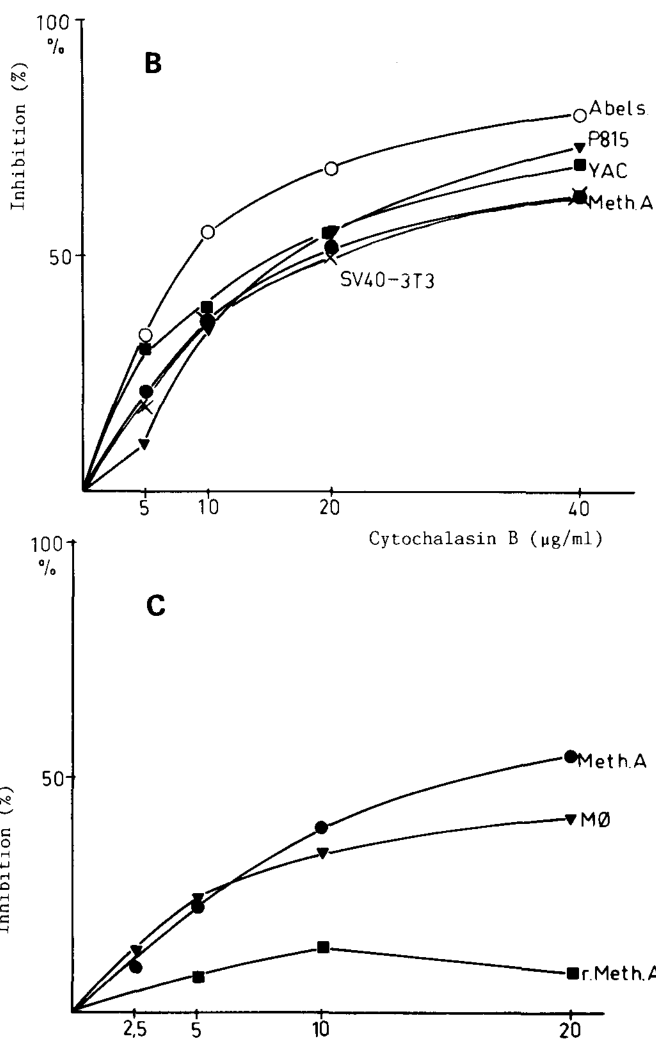


FIG. 5. Inhibition of ET-18-OCH_3-uptake by CB and DP. 10^6 Cells/ml DMEM/10% FBS were first incubated for 1 hr with the indicated concentration of the inhibitor. Then ET-18-OCH_3 was added and uptake determined after another 2 hr, as described in Materials and Methods. A shows the more resistant cell lines, where inhibition was complete at about 10 µg/ml CB. B shows the sensitive cell lines, where maximal inhibition was not achieved even with 40 µg/ml CB. C shows the inhibition of ET-18-OCH_3-uptake by dipyridamole.

TABLE 3

Uptake of ET-18-OCH_3 in the Presence or Absence of Cytochalasin B (40 µg/ml)

	ET-18-OCH_3 (pmol/10^6 cells)		
Cell line	−Cytochalasin B	+Cytochalasin B	Cytochalasin B-specific uptake
MO	129 ± 5	75 ± 2	54
MethA	158 ± 3	77 ± 1	≥81
rMethA	83 ± 3	76 ± 2	7
3T3	109 ± 1	94 ± 8	15
SV40-3T3	146 ± 9	53 ± 4	≥93
L929s	72 ± 4	46 ± 0.7	26
Abels.	116 ± 4	23 ± 0.7	≥93
P815	222 ± 4	60 ± 2	≥162
YAC	82 ± 3	25 ± 1	≥57

10^6 Cells/ml DMEM/10% FBS were incubated for 2 hr in the presence or absence of 40 µg/ml cytochalasin B (CB), which was added in a DMSO solution (final DMSO concentration in all samples 0.5%). Uptake of ET-18-OCH_3 was determined as described in Materials and Methods. CB-specific ET-18-OCH_3 uptake was calculated from the difference of both values if inhibition seemed complete at 5–10 µg/ml CB (see also Figs. 5A and 5B). If maximal inhibition was not achieved at 40 µg/ml CB, it is indicated that CB-specific uptake is even higher. Mean of three separate determinations ± SD.

or absence of 40 µg/ml CB. From these data, the CB-dependent ET-18-OCH_3-uptake was calculated. Only the CB-inhibitable (=CB-specific) uptake was decreased in the resistant variant of MethA. The most sensitive cell lines (Abels., MethA, P815 and SV40-3T3) showed the highest activities of this CB-dependent ALP transport system.

Influence of DP on cytotoxicity of ET-18-OCH_3. The lower activity of a CB-specific transport system was a characteristic of ET-18-OCH_3 resistance. Thus it should be possible to render cells more resistant to ET-18-OCH_3 by inhibition of this uptake process.

This was demonstrated by addition of 5–10 µg/ml DP together with ET-18-OCH_3 to the cell cultures. Figures 6 and 7 show that DP protected MethA and MO in a concentration-dependent manner. Cell destruction of MO was retarded to a greater extent. We had assured ourselves that the number of living cells correlated to ^3H-thymidine incorporation under these conditions.

DISCUSSION

It was shown in this study that various cell lines exhibit a very different sensitivity to the antitumoral ALP ET-18-OCH_3 in vitro. A highly drug-resistant variant of a methylcholanthren-induced fibrosarcoma cell line (MethA) was isolated. We used these cells to study the mechanism of ALP resistance. In accordance with Hoffman et al. (24), we found that metabolism of ET-18-OCH_3 was negligible, but cellular drug concentration after equilibrium binding was 3–4 times decreased in the resistant cells. Our results indicate that this was caused by a lower influx together with a decreased number of cellular binding sites. Since cell mass of MethA and rMethA was equal, ET-18-OCH_3 was probably not equally distributed over the cell but stored in distinct cellular structures. Another indication for a nonhomogenous

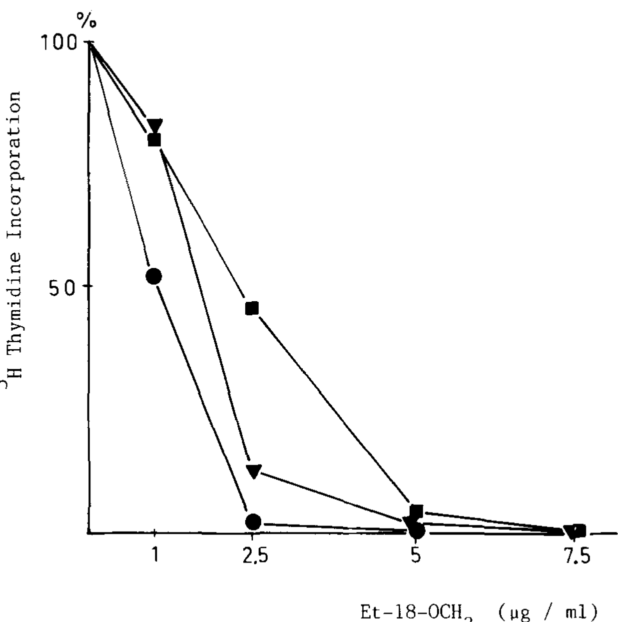

FIG. 6. Influence of DP on the ET-18-OCH$_3$-mediated cytotoxicity for MethA cells. 5 × 10^5 Cells/ml DMEM/10% FBS were incubated with the indicated concentration of ET-18-OCH$_3$ for 72 hr. Since DP had to be added in an ethanol solution, all samples were adjusted to the final ethanol concentration of 0.05%. Before the determination of ^{3}H-thymidine incorporation, cells were washed twice. Mean of 2–3 independent experiments, done with triplicate cultures, SD ⩽ 10%. ●, Control; ▼, 5 µg/ml DP; ■, 10 µg/ml DP.

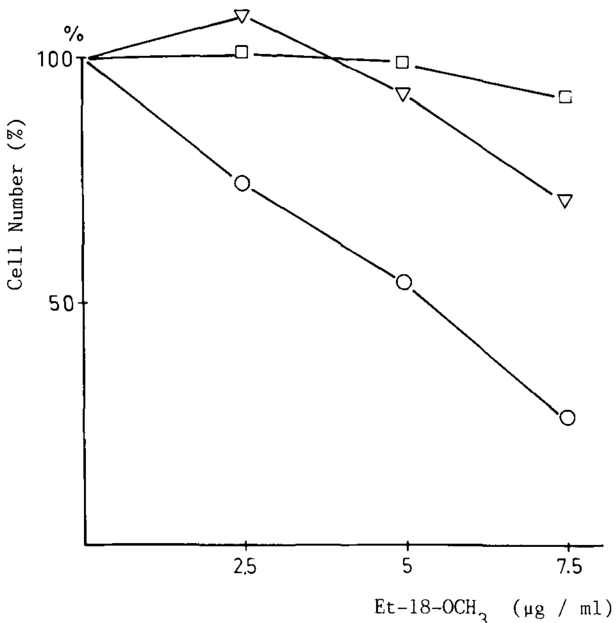

FIG. 7. Influence of DP on the ET-18-OCH$_3$-mediated cytotoxicity for bone marrow-derived macrophages. 2 × 10^6 Cells/5 ml DMEM/10% FBS were cultivated for 72 hr. DP was added in an ethanol solution (final ethanol concentration in all samples was 0.05%). The number of living cells was determined as described in Materials and Methods. Each point is the mean of two independent experiments done with triplicate cultures, SD ⩽ 15%. ○, Control; ▽, 5 µg/ml DP; □, 10 µg/ml DP.

distribution of ALP was recently described (24). The resistant mutant cells also showed a substantially lower sensitivity to direct lysis by different lysophospholipids. These findings suggest that ALP-binding sites within the cell membrane could also be responsible for ALP-induced cell lysis. Moreover, the clustering or an increased number of ALP-binding sites could explain the selectivity of ALP-induced inhibition of membrane-bound enzymes in some tumor cells (6,25,26). Local accumulation of ALP within the cell membrane could also increase the permeability for ions like Ca (27) and thereby cause tumor growth inhibition. Uptake of ET-18-OCH$_3$ was not saturable within sublytic concentrations of the drug and, moreover, not influenced by inhibitors of ATP biosynthesis. Because of the cytolytic activities of the ALP (28), however, it cannot be excluded that uptake saturation would appear at higher concentrations. Our results with a previously published albumin extraction method (20) strongly suggest that ET-18-OCH$_3$ permeated across the cell membrane. Interestingly, CB inhibited this translocation specifically. It has been suggested that CB and other membrane-active compounds like DP, papaverine and so on may interact with hydrophobic regions of integral membrane proteins (29), because CB was not bound to membrane lipids (30) and had no influence on membrane lipid fluidity (31). Integral membrane proteins can act as specific transport sites by disturbing the order of the lipid bilayer. The different activation energy of normal and CB-inhibitable ET-18-OCH$_3$ uptake is probably a further indication for specialized membrane structures of ALP transport. CB could bind directly or in close proximity to ALP flip-sites and could sterically hinder the permeation of the drug. The lower sensitivity of several cell lines to the cytotoxicity of ET-18-OCH$_3$ corresponded to the decrease in CB-specific ET-18-OCH$_3$-uptake, but not to the overall ET-18-OCH$_3$-uptake (compare Fig. 1 to Table 3). We propose the hypothesis that ALP is transported across the lipid bilayer by a CB-specific integral membrane protein, which could also have an increased affinity to ALP. In the ALP-sensitive tumor cell lines—MethA, YAC, Abels. and P815—a higher concentration of CB was necessary to achieve maximal uptake inhibition. This was also observed after virus transformation of 3T3 fibroblasts. Since equilibrium binding studies have shown that SV40-3T3 and 3T3 cells have the same number of CB-binding sites per cell (31), ALP transport sites were probably only dislocated from CB-binding sites in SV40-3T3. This could be true for the other transformed cell lines.

The inhibition of ET-18-OCH$_3$-uptake by DP or CB showed similar characteristics. We could demonstrate that a partial inactivation of the transport system by DP rendered the cell more resistant to ET-18-OCH$_3$ cytotoxicity. Since DP is rather nontoxic, it could be used to protect a cell against ET-18-OCH$_3$, when damage is unfavorable. Moreover, it could be of advantage that MO are apparently protected to a greater extent than tumor cells like MethA. Maybe this is the result of a more effective inhibition of ALP-uptake into MO by DP (Fig. 5C). It should be noted that macrophages are important for the antitumoral activity of ALP in vivo (5).

A possible therapeutical value of the combined application of ALP and DP is now under study in experimental tumors in mice and rats.

Tumor cells grown in the presence of 1-*O*-alkyl-2-*O*-methylglycero-3-phosphocholine (AMG-PC) accumulated this ether lipid in their membranes. Depending on the cell type and the dose of the compound, up to 17% of the total phospholipids of the purified plasma membranes consisted of authentic AMG-PC. Extensive incorporation of the agent resulted in a decrease in plasma membrane fluidity and inhibition of tumor cell invasiveness in embryonic chick heart fragments. The extent of AMG-PC incorporation and fluidity change was not strictly correlated with the degree to which tumor cell invasion was inhibited.
Lipids 22, 820–823 (1987).

1-*O*-Alkyl-2-*O*-methylglycero-3-phosphocholine (AMG-PC) has been shown to inhibit specifically tumor cell growth and metastasis and is being tested as an anticancer drug in clinical trials (1). The mechanism of this drug's action is still unknown. In a previous report, we suggested a drug-induced alteration in membrane fluidity is possibly involved in the inhibition of tumor cell invasion in vitro (2). Here we have extended these investigations to four tumor cell lines, each of which differs in the degree of sensitivity to AMG-PC with respect to inhibition of cell growth and invasion. Incorporation of the drug was quantitated in subcellular fractions (an effort not previously undertaken) and was compared with the changes observed in membrane fluidity in these fractions. These dose-dependent alterations in the composition and structural order of membrane lipids were considered in relation to the degree of inhibition of tumor cell invasion in vitro.

MATERIALS AND METHODS

Cells and drug. MO_4 cells are virally transformed C_3H Mouse-fibroblastic cells that are invasive in vitro (2) and produce invasive and metastasizing fibrosarcomas in syngeneic mice (3). LLC-H61 is a highly metastatic subclone of the Lewis lung carcinoma cell line (4). The tumorigenic R1C cell line was established from baby rat kidney cells by transfection with a genomic fragment (map coordinates 0–16%) of the oncogenic adenovirus type 12 (5). Each of these adherently growing cell lines was cultured in Dulbecco's modified Eagle's medium (Flow Labs Ltd., Irvine, United Kingdom). HL-60 human promyeloid leukemia cells (6) were cultured in suspension in RPMI 1640 medium. The media were supplemented with 10% fetal calf serum and antibiotics (penicillin, 100 IU/ml; streptomycin, 50 μg/ml). The drug AMG-PC (racemic 1-*O*-octadecyl-2-*O*-methylglycero-3-phosphocholine; ET-18-OCH_3, provided by W.E. Berdel, Technical University, Munich, Federal Republic of Germany) was dissolved in the culture media and added to the cell cultures 48 hr before harvesting the cells for the experiments.

Subcellular fractions. Cells were broken by pumping single-cell suspensions in Hanks' solution (Oxoid, London, United Kingdom) through an air-driven cell disruptor (Stansted Fluid Power Limited, Stansted, Essex, United Kingdom; model AO612, Disrupting Valve 516), using an air pressure of 45 lb/in^2 and a cell density of 5.10^7 cells/ml (7). A crude nuclear fraction was obtained by centrifugation twice at 1000×g for 10 min, with intermittent washing. Plasma membranes were purified from (1.95–945).10^4 g.min pellets, utilizing a discontinuous sucrose gradient, as described in detail (8). The purity of the plasma membrane preparations was ascertained routinely by electron microscopy and by marker assays, as described (8).

Lipid analysis. Lipids were extracted from the subcellular fractions with chloroform/methanol (2:1, v/v) followed by partition according to the method of Folch et al. (9). Phospholipids were separated by thin layer chromatography on precoated silica gel plates (E. Merck, Darmstadt, Federal Republic of Germany) using chloroform/methanol/0.5 M ammonia (50:65:9, v/v/v; two runs). AMG-PC and other phospholipids were quantitated by phosphate analysis (10).

In these experiments, we have also determined the amount of authentic AMG-PC accumulated in the two subcellular fractions (Table 2). The relative uptake of AMG-PC by the cells, as quantitated in these fractions, generally reflected the dose supplied in the culture medium. A high mol % of AMG-PC in the plasma membranes (MO_4, exp. 1; LLC-H61, exp. 2) was associated with an increase in the P_{DPH} value (Table 1). This was not the case in the nuclear fractions, a finding we do not clearly understand. This different effect of AMG-PC on the fluidity of plasma membranes and nuclei may relate to the different lipid composition of these two organelles, plasma membranes being typically enriched in cholesterol and sphingomyelin (ordering lipids; ref. 12). Alternatively, AMG-PC may have a metabolic effect, acting differently on the lipid composition (fluidity) of plasma and nuclear membranes. When expressed in mol % of the total phospholipids, the purified plasma membranes contained twice as much AMG-PC as the nuclei. When expressed as a ratio of AMG-PC to endogenous phosphatidylcholine, this factor was 3 to 4. This relative enrichment of AMG-PC in the plasma membranes may be even higher, when one considers a possible contamination of the nuclear fraction with plasma membranes.

In Table 3, the data are summarized and compared

with the inhibitory effect of the incorporated AMG-PC on the invasiveness of the tumor cells in embryonic chick heart fragments, as shown in detail before (2). The validity of this invasion assay is well established (2,12,13); we present the results here only in a simplified semiquantitative notation (Table 3). The experimental results allow us to draw the following conclusions: First, accumulation of AMG-PC in the cellular membranes under conditions where cell growth was only minimally affected generally led to inhibition of tumor cell invasion. However, the degree of inhibition for a given cell type (MO_4) was not strictly correlated with the amount of AMG-PC incorporated. For LLC-H61 cells, the least sensitive to the cytotoxic action of AMG-PC, even massive incorporation of the agent (at 30 μg/ml) still allowed a small degree of invasion. Clearly, the inhibitory effect of AMG-PC depends on the cell type. Second, the extent of the AMG-PC–induced alterations in fluidity

TABLE 3

Summary of Data Relating Accumulation of AMG-PG from Culture Medium into Tumor Cellular Membranes with Alterations in Membrane Fluidity and Inhibition of Tumor Cell Invasiveness In Vitro

[c]Semiquantitative analysis of invasion into chick heart tissue, graded according to Bracke et al. (14). –, No invasion (grades I and II); +, invasion less than 50% (grade III), + +, invasion more than 50% (grade IV). For details see Materials and Methods.

of the plasma membranes or in the cell nuclear fractions was not correlated with the degree of inhibition of invasion of the various tumor cells.

Although this study shows that no direct causal relationship exists among the amount of AMG-PC accumulated in tumor cell membranes, the consequent alterations in membrane fluidity and the extent of inhibition of tumor cell invasiveness, these membrane structural alterations nevertheless may contribute to the biological mechanisms of AMG-PC action, in which other factors may play a more dominant role (16,17).

Estimation of membrane fluidity. 1,6-Diphenyl-1,3,5-hexatriene (DPH; Koch-Light Labs, Colnbrook, United Kingdom) was used as a fluorescent probe for measuring the steady-state fluorescence polarization (P_{DPH}, at 25 C) with Elscint apparatus, model MV-1A (Elscint Ltd., Haifa, Israel) (8). P_{DPH} values mainly reflect the orientational constraint of the motions of the probe, and they are quantitatively related to order parameters in the membrane lipids (11). High P_{DPH} values represent high structural order or low membrane fluidity, and vice versa. The quantitative contributions of the individual membrane lipid components to the P_{DPH} value have been described in detail (12).

Invasion assay. The capacity of tumor cells to invade normal tissue was assayed in confrontations between test cell aggregates (diameter 0.2 mm) and precultured fragments of 9-day-old embryonic chick heart (diameter 0.4 mm) on top of a semisolid agar medium, as described in detail elsewhere (2,13). The degree of cell interaction was classified as described previously (14): grades I and II (confronting cells found at the periphery of or intermixed with the outer fibroblastic layer of the heart fragment, respectively) were combined to indicate the absence of invasion (denoted as –); grade III, when confronting cells replaced the cardiac muscle to less than 50% (denoted as +); and grade IV, when confronting cells replaced the cardiac muscle to more than 50% (denoted as + +). Grades III and IV meet the criteria of invasion in vivo.

RESULTS AND DISCUSSION

Four types of tumor cells were grown in the presence of the agent AMG-PC. The doses added to the culture media were adapted to individual cell lines according to the degree of cytotoxicity. For instance, for HL-60 cells the drug was already quite toxic at 1 μg/ml, whereas growth of LLC-H61 cells was not inhibited in the presence of a dose as high as 30 μg/ml. In all cases, the highest concentration of AMG-PC used permitted cell growth to densities of at least 75% of those observed for controls. Under these conditions, we have determined the drug-induced alterations in the structural order of membrane lipids (i.e., reciprocal of membrane fluidity; ref. 11) by steady-state fluorescence polarization using the probe DPH (Table 1). The measurements were performed in intact cells, in purified plasma membranes and in a crude nuclear fraction. No comparison should be made between the absolute P_{DPH} values of different experiments, because it is known that small differences in culture conditions (e.g., cell density, serum, time after subculturing) may already affect the data (reviewed in ref. 15). For instance, a different degree of triglyceride accumulation in cells may lead to differences in P_{DPH} values. When compared to the appropriate controls within individual experiments, the P_{DPH} values in the intact cells were in most, but not all, cases decreased in a drug dose–dependent fashion, in agreement with previous results on MO_4 cells (2). In the latter report (2), this decrease in P_{DPH} was tentatively attributed to the cellular membranes rather than triglyceride accumulation in the cytoplasm. Surprisingly, however, the present results (Table 1) demonstrate that the P_{DPH} values in the purified plasma membranes were not decreased, but rather increased in some cases (R1C; MO_4, exp. 1; LLC-H61, exp. 2),

especially at the higher doses of AMG-PC. This was why we measured other subcellular fractions, notably a nuclear one. Here we found a decrease in P_{DPH} for two cell types, HL-60 and LLC-H61. We have confirmed that this decrease indeed pertained to the structural order of the lipids of this fraction; liposomes prepared from the extracted lipids of the nuclear fractions showed a similar difference in P_{DPH} value (data not shown).

A Continuous Assay for O-Alkylglycerol Monooxygenase (E.C. 1.14.16.5)[1]

Jochem Koetting[a,*], Clemens Unger[b] and Hansjoerg Eibl[a]
[a]Max-Planck-Institut fuer biophysikalische Chemie, Am Fassberg, D-3400 Goettingen, Federal Republic of Germany, and [b]Zentrum Innere Medizin, Abt. Haematologie/Onkologie Robert-Koch-Str. 40, D-3400 Goettingen, Federal Republic of Germany

The antitumor activity of alkyl lysophospholipids has raised some questions concerning the degradation of O-alkyl bonds in naturally occurring ether lipids. In this report, we describe the first continuous assay for O-alkylglycerol monooxygenase (AGMO), the only enzyme known to cleave the O-alkyl bond in saturated ether lipids and ether phospholipids. AGMO activity was monitored at 340 nm by coupling the NADH redox reaction to the tetrahydropteridine cofactor of the rat liver microsomal enzyme. Turnover rates as low as 0.6 nmol/min could be measured. Using radiolabeled substrates, the products were identified with a TLC-Linear-Analyzer. The only interference with this assay can arise from other reducing agents, e.g. dithiothreitol. The assay was used to develop protocols for the solubilization of AGMO from membrane preparations in the presence of detergents.
Lipids 22, 824–830 (1987).

The antitumor activity of alkyl lysophospholipids (ALP) has been ascribed to their ability to stimulate macrophages (1) and to their cytotoxicity (2–4). One of the possible explanations for the cytotoxicity is that the tumor cells cannot degrade and therefore they accumulate (5) these lytic compounds because they lack a key enzyme (6). It is likely that the enzyme(s) cleaving O-alkyl bonds are not present in these cells (6,7). The only enzyme known to cleave the O-alkyl bond in ether lipids and ether phospholipids is O-alkylglycerol monooxygenase (AGMO, E.C. 1.14.16.5). This tetrahydropteridine (PtH_4)-dependent enzyme first was described in rat liver microsomes (8) and in tumor cells AGMO activity could not be detected or was present only at low levels (7). To facilitate more detailed investigations on the role of AGMO, we have developed a continuous spectroscopic assay.

MATERIALS AND METHODS

Enzymes and coenzymes. Dihydropteridine reductase (E.C. 1.6.99.7), *DL*-6-methyl-5,6,7,8-tetrahydropterine ($MPtH_4$) and *DL*-6,7-dimethyl-5,6,7,8-tetrahydropterine ($DMPtH_4$) were purchased from Sigma, Munich; NADH was purchased from Boehringer Mannheim, FRG.

Substrates. 1-O-[15′,16′-^{3}H]Hexadecyl-*rac*-glycerol (27 µCi/µmol, 1-[^{3}H]H-G), 3-O-hexadecyl-*sn*-glycero-1-phosphocholine (3H-*sn*-G-1PC) and 1-O-hexadecyl-*sn*-glycero-3-phosphocholine (1H-*sn*-G-3PC) were synthesized in our laboratory according to Eibl (9–11). Radiolabeled lyso-platelet-activating factor (1-O-[^{3}H]octadecylglycero-3-phosphocholine) was purchased from Amersham Buchler, Braunschweig, FRG. The tritiated substrates were dissolved in 0.1 M Tris/HCl buffer (pH 8.8) at a concentration of 10 mM. 1-[^{3}H]H-G was solubilized with 7 mg/ml tetradecylphosphocholine, which also was synthesized in our laboratory. The concentration of 3H-*sn*-G-1PC or 1H-*sn*-G-3PC was 10 mM in buffer.

Detergents. All detergents were purchased in the highest available quality from Serva, Heidelberg, FRG.

Microsomal AGMO preparation. Male rats (Wistar strain) with a body weight of 200–300 g were anesthesized with ether, decapitated, and the liver was removed. After washing with 0.9% NaCl (w/v) solution, the liver (about 7 g per animal) was cut into small pieces and homogenized with three strokes in an Elvehjem-Potter homogenizer with a teflon piston (400 rpm). For each gram of tissue, 1 ml of 0.25 M sucrose in 0.05 M Tris/HCl buffer (pH 7.6) was used. All procedures were carried out at 4 C. Microsomes were prepared by a two-step centrifugation using the method of Yawetz et al. (12). The microsomal pellet was resuspended in a 0.05 M Tris/HCl buffer (pH 8.8) that contained 20% glycerol (w/v) at a protein concentration of about 20 mg/ml.

Protein was determined according to the method of Peterson (13) with BSA as standard.

AGMO assay: spectrophotometric. A typical assay system consisted of the following compounds, which were incubated in the sample and reference cuvettes in a temperature-controlled (37 C) cell-holder of a double-beam spectrophotometer (Hitachi 150/20): 50 µl AGMO preparation (about 1 mg protein), 20 µl NADH solution (10 µmol/ml), 2.5 µg dihydropteridine reductase (5 µl) and 500 nmol alkyl lysophospholipid or 50–500 nmol alkylglycerol. Tris/HCl buffer (0.1 M, pH 8.8) was used to make up 1 ml. Sample and reference cuvettes then were adjusted at 340 nm, and optical stability was checked for 30 sec. The reaction was initiated by addition of 10 µl $MPtH_4$ (0.2 µmol) in the sample cuvette. The decrease in absorbance at 340 nm was followed for 1 min (ΔA_R). The control reaction was set up with an identical incubation mixture except lacking substrate in both cuvettes. A control without substrate in both cuvettes is necessary to detect the amount of the NADH/NAD^+-side reactions (Fig. 1, step 2) and eliminate the contribution of the autoxidation of $MPtH_4$ (step 3). The change in absorbance within one min after addition of $MPtH_4$ is ΔA_C. AGMO activity was calculated from the difference, $\Delta A = \Delta A_R - \Delta A_C$, using an absorbance coefficient $\varepsilon_{340} = 6.22\ mM^{-1}cm^{-1}$.

AGMO assay: radiolabeled substrates. The products of the spectroscopic AGMO assay with 50–100 nmol 1-[^{3}H]H-G (1.35 – 2.7 µCi per incubation) were identified

Abbreviations: AGMO, O-alkylglycerol monooxygenase; ALP, alkyl lysophospholipids; BSA, bovine serum albumine; DTT, dithiothreitol; 1-[^{3}H]H-G, 1-O-[^{3}H]hexadecylglycerol; 3H-*sn*-G-1PC, 3-O-hexadecyl-*sn*-glycero-1-phosphocholine; 1H-*sn*-G-3PC, 1-O-hexadecyl-*sn*-glycero-3-phosphocholine; PtH_4, *D,L*-5,6,7,8-tetrahydropterine; $DMPtH_4$, *D,L*-6,7-dimethyl-PtH_4; $MPtH_4$, *D,L*-6-methyl-PtH_4; PtH_2, dihydropteridine, q-, quinoid isomer or 7,8-isomere, see Fig. 4; $DMPtH_2$, $MPtH_2$, 6,7-dimethyl- or 6-methyl-derivate, respectively, of PtH_2; TLC, thin layer chromatography.

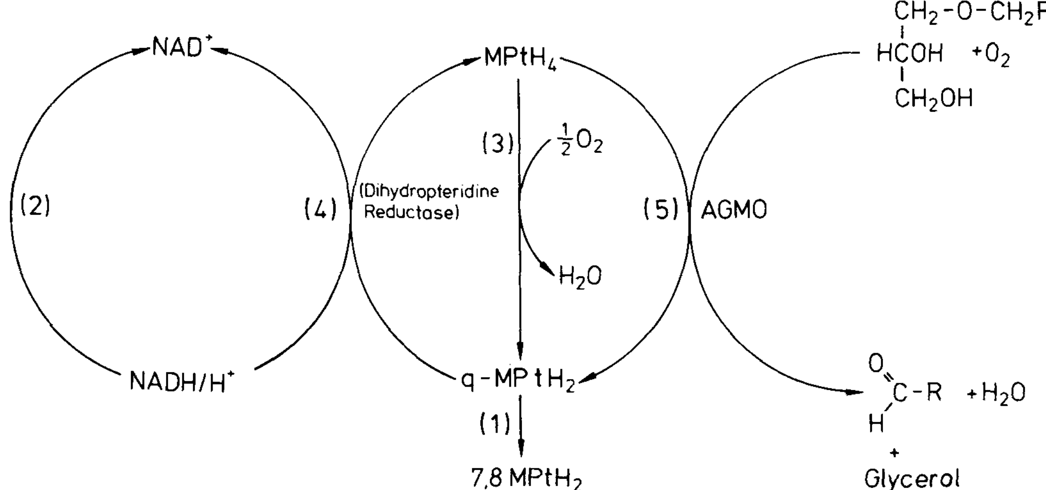

FIG. 1. Reactions in the coupled AGMO assay. The AGMO-catalyzed cleavage of the *O*-alkyl bond is shown with an alkylglycerol and oxygen as substrates and 6-methyl tetrahydropterine ($MPtH_4$) as cofactor (5). The cofactor is converted to a quinoid 6-methyl-dihydropterine (q-$MPtH_2$), which can tautomerize in a side reaction to the 7,8-isomer (1). The quinoid tautomere is regenerated to $MPtH_4$ by reductase and using NADH/H+ as cofactor (4). The resulting decrease of NADH is continuously followed at 340 nm. Side reactions and autoxidation of NADH and $MPtH_4$ are summarized under (2) and (3).

by using radiolabeled substrates. The enzyme reaction was stopped by adding 100 μl undiluted formic acid to both photometer cuvettes after the 1 min incubation. The solutions were freeze-dried in small tubes (1.5 ml), and the residue from each tube was extracted with 200 μl $CHCl_3$. Aliquots were separated on Kieselgel 60 TLC plates (Merck Darmstadt, FRG) and developed in hexane/diethylether/acetic acid (60:40:1). The radioactive products were localized and quantified on the plates with a Berthold TLC linear analyzer (Wildbad FRG; 14). Qualitative identification was performed by comparing the R_f-values with reference substances on the same TLC plate.

RESULTS

The principle of the assay is shown in Figure 1. The cleavage of the *O*-alkyl bond by the enzyme (step 5) is coupled with the oxidation of its cofactor, 6-methyl-5,6,7,8-tetrahydropterine ($MPtH_4$). We found that it is possible to use the regeneration of $MPtH_4$ by oxidation of NADH (step 4) for a continuous spectrophotometric enzyme assay. The coupled AGMO assay system described here involves several reaction steps, which we have examined in detail. The effect of the assay conditions on these reactions is described below. The data given in the tables and figures are means of three to 10 measurements with a standard deviation of ±5%.

Characterization of the products and comparison with other assay systems. Cleavage of the *O*-alkyl bond in ether phospholipids by AGMO can be demonstrated directly under the conditions used for spectrophotometric assay. As shown in Figure 2, the rate of appearance of the various radiolabeled products of oxidation of the substrate 1-[^{3}H]H-G was identified and quantified by TLC. With the mobile phase used, reaction products (hexadecanol R_f = 0.24, hexadecanoic acid R_f = 0.35, hexadecanal R_f = 0.63) were well separated from the substrate (R_f = 0.04). The appearance of products generated with time also was analyzed. After 0.5 min, hexadecanal was the main product, while hexadecanoic acid was present at the same amount with small traces of hexadecanol after one min (data not shown).

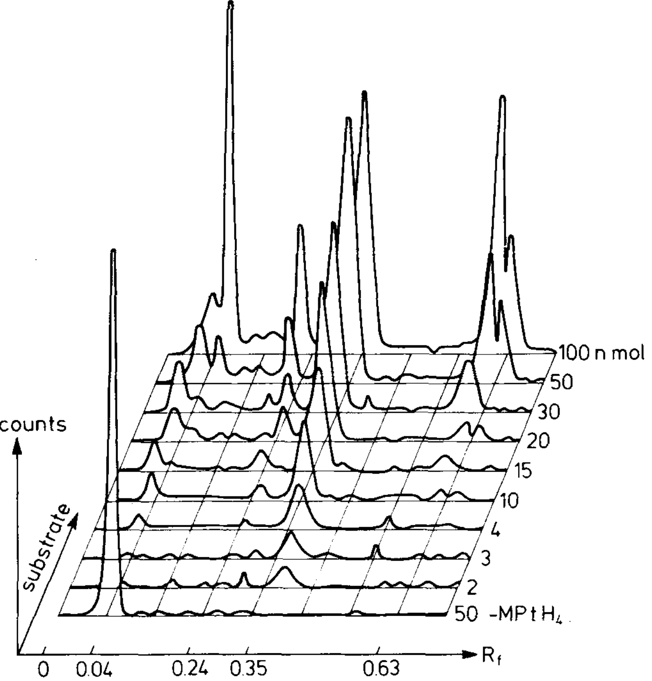

FIG. 2. Identification of products after AGMO action (1 min) with increasing concentrations of 1-[11′,12′-^{3}H]hexadecylglycerol as substrate. The products were analyzed with a linear analyzer on TLC plates and identified by their R_f values. The substrate (R_f = 0.04) was incubated with 1 mg protein of a microsomal AGMO. The products identified after one min were hexadecanol (R_f = 0.24), palmitic acid (R_f = 0.35) and hexadecanal (R_f = 0.63).

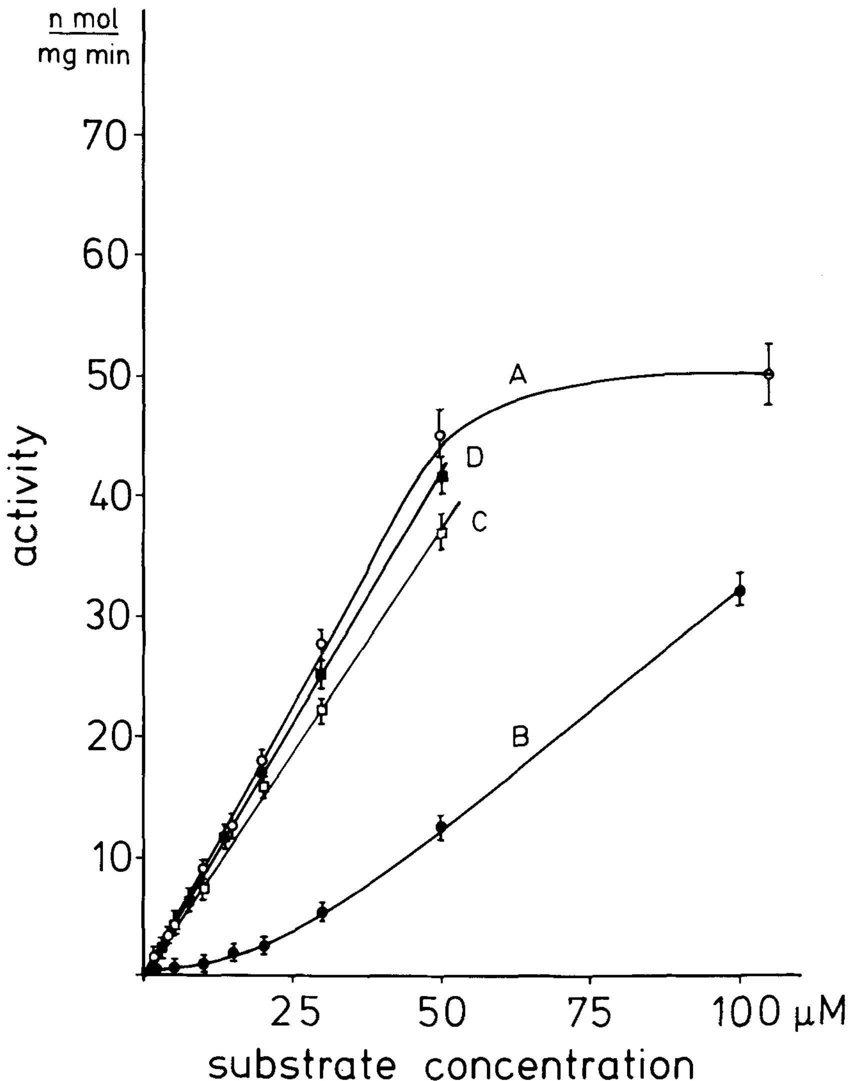

FIG. 3. True enzymatic activity within a standard deviation of 5% (curve A) is recorded only when in addition to the amount of aldehyde, generated as quantified by TLC (curve B) fatty acid and fatty alcohol are added. Curve A is measured with the spectrophotometric assay. Curve C represents the generated amounts of fatty aldehyde and fatty acid; curve D depicts the summarized amounts of fatty aldehyde, acid and fatty alcohol as calculated. As AGMO preparation, 1 mg of microsomal protein was used with 1-[11′, 12′-^{3}H]hexadecylglycerol as substrate. Incubation time for the spectrophotometric and for the radiolabeled assay was one min.

The radioactive products formed at various 1-[^{3}H]H-G concentrations during the one min incubation period are shown in Figure 2. Without the coenzyme, only the substrate is present in the incubation mixture. With increasing amounts of substrate, palmitic acid is the main product; hexadecanal (R_f = 0.63) is an intermediate that is spontaneously oxidized to hexadecanoic acid. Under the assay conditions, the aldehyde also can be reduced to hexadecanol by NADH.

Evaluation of each single product formed from 1-[^{3}H]H-G as substrate and comparison with the spectrophotometric assay are shown in Figure 3. Curve A shows the activity measured by absorbance change. In curve B, the amount of generated fatty aldehyde is shown. However, true AGMO activity data can be performed through product analysis. This was accomplished by adding the amounts of generated acid (calculated addition to the aldehyde: curve C), generated alcohol and aldehyde (curve D).

In order to compare the present continuous AGMO assay with the phosphate assay (15) and the assay conditions used by Soodsma et al. (16), microsomal enzymic activity was measured in parallel. With 1-*O*-[^{3}H]octadecyl-G-3PC as substrate, the following AGMO activities (nmol/mg min) were obtained: 7.4 ± 0.4 (this publication); 7.04 (16) and 7.1 (15). Regardless of the detection method, the AGMO activities of a microsomal enzyme preparation are the same within expected tolerance.

Choice of the cofactor. The PtH_4 cofactor is oxidized to PtH_2, and PtH_4 rapidly is regenerated by reductase using NADH/H^+ as cofactor (Fig. 1, step 4). The PtH_4 cofactor is very sensitive to autoxidation (Fig. 1, step 3); the product (PtH_2) occurs in two isomeric forms, quinioid-

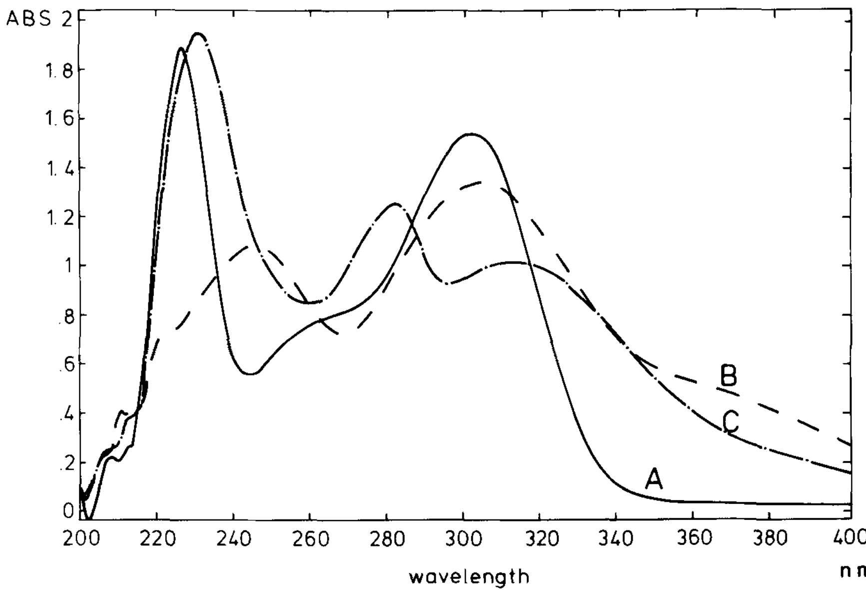

FIG. 4. UV-vis spectra of *D,L*-6-methyl-5,6,7,8-tetra-hydropterine ($MPtH_4$) (A), of quinoide *D,L*-6-methyl-dihydropterine (B) and of 7,8-*D,L*-methyl-dihydropterine (C). The spectra were recorded with a Hewlett-Packard 8451A diode array spectrophotometer. A total volume of 1 ml 0.1 M Tris/HCl buffer (pH 8.8) contained 0.2 μmol $MPtH_4$ (A). Curve B was recorded immediately after addition of 10 μg peroxidase (E.C. 1.11.1.7, Boehringer Mannheim, FRG) and 0.2 μmol H_2O_2. Spectrum C was recorded after 10 min.

TABLE 1

Relationship between AGMO[a] Activity and Tetrahydropteridine Structure Measured with the Spectrophotometric (A) and Radiolabeled (B) Assay

		Specific activity (nmol/mg min)			
	Assay:	A		B	
Substrate	Coenzyme:	$MPtH_4$	$DMPtH_4$	$MPtH_4$	$DMPtH_4$
3-*O*-Hexadecyl-*sn*-glycero-1-PC		4.9	1.3	—	—
1-*O*-[11′,12′-³H]Hexadecylglycerol		13.5	3.1	12.9	12.9

[a]A microsomal AGMO preparation was used, and 1 mg protein was incubated for each test. Substrate concentration was 0.5 mM for 3-*O*-hexadecyl-*sn*-glycero-1-PC and 50 μM for 1-*O*-[11′,12′-³H]hexadecylglycerol.

(q-) and 7,8-PtH_2. At 340 nm, the absorbance spectra of q-$MPtH_2$ and 7,8-$MPtH_2$ show an isobestic point (Fig. 4). Due to the higher instability of $DMPtH_4$, comparable spectra of this cofactor were not recorded.

To study the influence of structural variations in tetrahydropteridines on their cofactor properties in the continuous assay, $MPtH_4$ and $DMPtH_4$ were used in both the photometric and the radiolabeled test. 3H-*sn*-G-1PC and 1-[³H]H-G served as substrates. The results summarized in Table 1 show there is no difference in AGMO activity with both of these cofactors in the radiolabeled assay. With the spectrophotometric test, the true enzymic activity is measured only when $MPtH_4$ is used as cofactor but not with $DMPtH_4$.

Effect of reducing agents and dihydropteridine reductase. Reducing agents, such as dithiothreitol (DTT), interfere with the spectrophotometric assay because of their competition with the NADH-dependent reduction of q-$MPtH_2$ (Fig. 1, step 4). For example, addition of 1 mM DTT decreases the kinetically measurable AGMO activity to 58%, while there is no change in the detectable substrate turnover using the radiolabeled assay.

Presence of the dihydropteridine reductase (E.C. 1.6.99.7) has no significant effect on AGMO activity measured with the kinetic or radiolabeled assay because q-$MPtH_2$ is reduced spontaneously by NADH. We routinely add dihydropteridine reductase, although it is not necessary for these experiments.

Effect of detergents. To show the effect of detergents towards AGMO activity, rat liver microsomes were incubated with various concentrations of detergents as described in Table 2. AGMO is hardly affected by detergents such as digitonin and is inactivated by about 50% by Triton X-100 (Table 2). Centrifugation of the

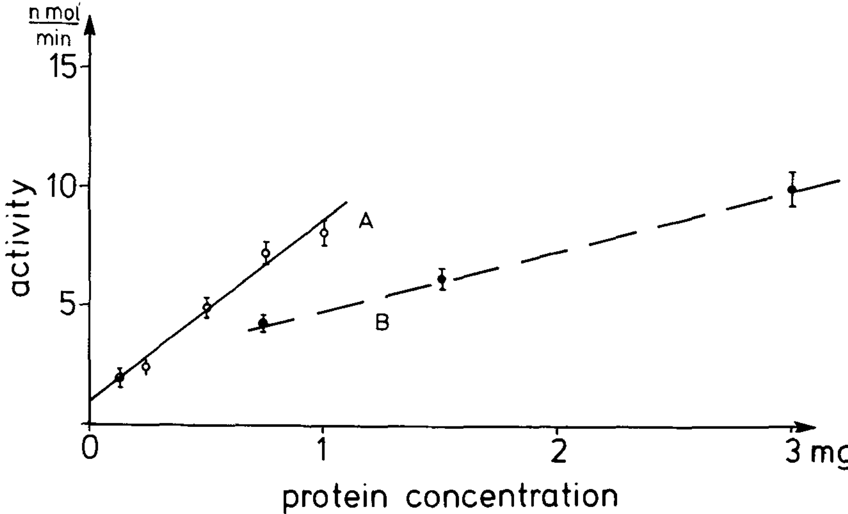

FIG. 5. Relationship between substrate cleavage and protein concentration of the AGMO preparation for a microsomal (A) and a digitonin-solubilized sample (B). As substrate, 3-*O*-hexadecyl-*sn*-glycero-1-phosphocholine (0.5 mM) was used. AGMO activity was estimated with the new continuous assay and values were calculated from the initial rate of one min incubations.

TABLE 2

Effect of Different Detergents on AGMO Activity

Detergent	Conc. (%, w/v)	AGMO activity (%) Incubation	AGMO activity (%) Supernatant
None	—	100	3
Octylglucoside	0.8	54	10
Triton X-100	0.08	50	4
	0.16	46	17
Digitonin	0.50	100	0
	1.5	98	76
Nacholate	0.3	66	0
Nadesoxycholate	0.05	63	7

Rat liver microsomes (AGMO activity 7.4 nmol/mg min = 100%, substrate: 3H-*sn*-G1PC) were incubated with the given detergent concentrations in 0.05 M Tris/HCl buffer (pH 8.8) on ice for 15 min. AGMO activity was measured again; the mixture then was centrifuged for one hr at 200,000 × g in a Beckman ultracentrifuge. AGMO activity was estimated in the supernatant as described in Materials and Methods.

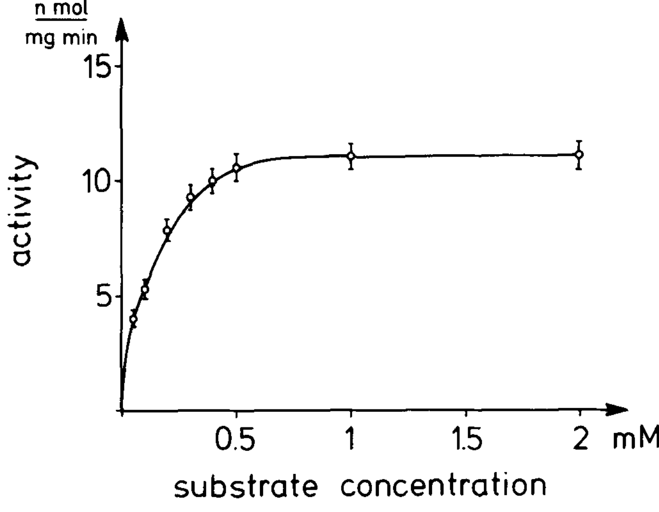

FIG. 6. Relationship between AGMO activity and 3-*O*-hexadecyl-*sn*-glycero-1-phosphocholine concentration. A microsomal AGMO preparation (1 mg) was used in the spectrophotometric assay; enzymic activity was calculated from the initial rate of one min incubations.

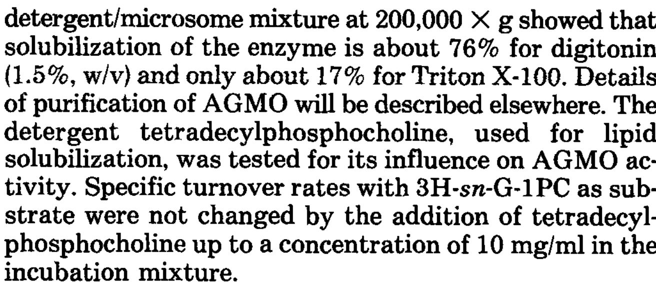

detergent/microsome mixture at 200,000 × g showed that solubilization of the enzyme is about 76% for digitonin (1.5%, w/v) and only about 17% for Triton X-100. Details of purification of AGMO will be described elsewhere. The detergent tetradecylphosphocholine, used for lipid solubilization, was tested for its influence on AGMO activity. Specific turnover rates with 3H-*sn*-G-1PC as substrate were not changed by the addition of tetradecylphosphocholine up to a concentration of 10 mg/ml in the incubation mixture.

Linearity with protein concentration. The initial rate of cleavage of the alkyl bond is linear with protein concentration (Fig. 5) for the microsomal AGMO preparation (curve A). Higher (>1 mg/ml) concentration of microsomal preparations could not be measured because of light-scattering effects. With AGMO solubilized in digitonin (1.5%, w/v), the linearity of the activity could be shown in the range of 0.75 mg to 3 mg protein. The lowest amount of AGMO activity that could be detected was 0.6 nmol/min, corresponding to 34 μg protein of rat liver microsomes in 1 ml.

Dependence on the substrate concentration and the substrate specificity of AGMO. Dependence of the reaction rate on the substrate concentration is shown in Figure 6. The initial rate of AGMO activity shows saturation at a concentration of 0.5 mM 3H-*sn*-G-1PC. The curved shape and the saturation concentration agree with

TABLE 3

Substrate Specificity of AGMO[a] Determined with the Spectrophotometric Assay

Substrate	Specific activity (nmol/mg min)
3-*O*-Hexadecyl-*sn*-glycero-1-PC	4.9
1-*O*-Hexadecyl-*sn*-glycero-3-PC	4.1
1-*O*-[^{3}H]Octadecylglycero-3-PC	3.2
1-*O*-[11′,12′-^{3}H]Hexadecylglycerol	9.4

[a]A microsomal AGMO preparation was used; 1 mg protein was incubated for each test. Substrate concentraton was 0.5 mM for alkyl lysophospholipids and 50 μM for 1-*O*-[11′,12′-3H]hexadecylglycerol.

results of earlier studies (15,17). The saturation concentration for alkylglycerols is between 0.05 and 0.5 mM, depending on chain length.

The specific activity of AGMO for several substrate analogs is summarized in Table 3. 3H-*sn*-G-1PC (100%) is a slightly better substrate than the naturally configurated 1H-*sn*-G-3PC (83%). Also, hexadecyl ether lipids are better substrates than octadecyl ethers. In general, long chain alkylglycerols are better substrates than ALP (Table 3, see also ref. 18).

DISCUSSION

The present assay offers some obvious advantages over those proposed earlier (15,16,19,20). The specific activity in the microsomal fraction and the dependence on the substrate concentration are in accord with those observed by others. The advantages of the new AGMO assay developed here are:

- It is fast, simple and sensitive.
- The assay is continuous, and initial rates can be measured by using reasonably small samples of the enzyme and the substrate.
- There are no structural restrictions for substrate specificity studies like a radiolabel or phosphate group in the molecule.
- No substrate/product separations are necessary.
- The high sensitivity of the assay enables, after a few preparation steps, detection of AGMO in different cell and tissue samples.

The variability of products formed during enzymatic hydrolysis observed by other authors (8,16,17,21,22) could be due to autoxidation of the primary product. The cleavage products in the presence of nucleotides has been established before (16). In accordance, our TLC analysis shows that fatty alcohol, aldehyde and acid were formed. Under the incubation conditions of the spectroscopic assay, NADH is a strong reducing agent for PtH_2. Therefore, PtH_2 produced during *O*-alkyl cleavage immediately generates NAD^+, which may spontaneously oxidize the aldehyde to acid. The suggestion of Pfleger et al. (21) that fatty aldehyde is an intermediate product whose fate in the incubation medium is dependent on other agents present is valid.

As shown in Table 1, it is more advantageous to use $MPtH_4$ than $DMPtH_4$ as a cofactor for AGMO in the continuous assay. This is because the rate of isomerization (Fig. 1, step 1) of $DMPtH_2$ is sensitive to the buffering ions (23), and the tautomerization of q-$DMPtH_2$ is twice as fast as that of q-$MPtH_2$ (23). In addition, q-$MPtH_2$ is reduced quantitatively by NADH to $MPtH_4$, while q-$MPtH_2$ is reduced only 25% to $DMPtH_4$ (Table 1). This explains the observation of Tietz et al. (8) that $MPtH_4$ has significantly better cofactor properties than $DMPtH_4$ in the presence of reduced nucleotides. Van der Heiden and Brink (24) raised some objections against the use of NADH detection at 340 nm in the presence of $MPtH_4$ because they observed a shift of the absorbance maximum of NADH to a longer wavelength. Also, they described that the nonenzymatic oxidation of NADH with q-$MPtH_2$ is not linear with time. Under the AGMO assay conditions described here (using the initial phase of the enzymic reaction), these difficulties were resolved and measurement of the initial rate of the enzyme reaction was possible.

The present assay was employed to monitor the purification of AGMO. As shown in Table 2, the use of digitonin to solubilize AGMO from microsomal membranes is more effective than Triton X-100, as described by Ishibashi and Imai (22). When comparing specific activity with 1-[^{3}H]H-G as substrate, one must consider that activities used by the authors are given for an incubation time of 30 min. Compared to specific activity of 0.54 nmol/mg min (normalized from the 30 min time points) as reported by these authors, our solubilized microsomal AGMO preparations have an average specific activity of 10.8 nmol/mg min. We will report the purification of the enzyme in detail elsewhere.

Substrate Specificity of *O*-Alkylglycerol Monooxygenase (E.C. 1.14.16.5), Solubilized from Rat Liver Microsomes[1]

Jochem Kötting*[,a], Clemens Unger[b] and Hansjörg Eibl[a]
[a]Max-Planck-Institut für biophysikal. Chemie Am Fassberg, D-3400 Goettingen, Federal Republic of Germany, and [b]Zentrum Innere Medizin, Abt. Haematologie/Onkologie, Robert-Koch-Str. 40, D-3400 Goettingen, Federal Republic of Germany

Synthetic alkyl lysophospholipids (ALP) show antineoplastic activity. In the present discussion, the cytotoxicity of ALP is attributed to their accumulation in tumor cells. Some neoplastic cell species, in contrast to normal cells, cannot metabolize ALP because of a lack of *O*-alkylglycerol monooxygenase (AGMO) activity. To understand the metabolic fate of ether lipids and ether-linked phospholipids, AGMO substrate specificity studies were undertaken. Thirty-five different natural and synthetic ether lipids and their metabolites (including a thioether) were tested as substrates for AGMO. The study revealed that the potent cytostatic substance, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine is not a substrate for AGMO. Therefore, its selective toxicity to tumor cells cannot be based on the differences in direct detoxification of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine by AGMO in normal and malignant cells. However, 1-*O*-octadeyl-2-*O*-methyl-*rac*-glycerol, which can be formed by phospholipase C hydrolysis, is a good substrate for AGMO.
Lipids 22, 831–835 (1987).

The antitumor activity of synthetic alkyl lysophospholipids and lysophospholipid analogs (ALP) has been ascribed to a direct cytotoxic effect (1–4). This direct effect and the cause of ALP selectivity against tumor cells still is not clearly understood (5,6). As originally shown by Snyder and Wood (7,8), various tumors of animal and human origin have high levels of ether lipids. It has been proposed that this enrichment of ether lipids in some tumor cell species is due to the lack of ether lipid-degrading enzyme activity (9). Such an enzyme is alkylglycerol monooxygenase (AGMO), which originally was discovered in rat liver microsomes (10). Indeed, it has been shown that many tumor tissues are low in AGMO levels (11). Therefore, ALP could accumulate in tumor cells, leading to disturbance of lipid metabolism (12). AGMO is the only known enzyme to cleave the *O*-alkylbond in saturated ether lipids according to the reaction scheme below (10), using tetrahydropteridine (PtH_4) derivatives as a cofactor. Fatty aldehyde and glycerol or glycerophosphocholine are the primary cleavage products in this reaction (Fig. 1).

Although several investigations on AGMO have been carried out in the past (3,10,13–17), there still is lacking clear-cut information on the substrate specificity of an enriched AGMO preparation from rat liver. To obtain more information on the metabolism of natural (e.g. PAF) and synthetic ALP, we have undertaken a detailed study of the general structural requirements of AGMO substrates. For this, we developed a new assay for AGMO that uses the $NADH/NAD^+$ redox reaction to measure continuously the decrease of the tetrahydropteridine cofactor. A detailed report on this assay is published in this issue (18). With this continuous assay, we were able to measure the substrate properties of a large variety of ether lipids that were synthesized in our laboratory without the need for a radioactive label or for a phosphate group in the molecule; these are prerequisites for the use of other assay methods for AGMO activity (14,17). In addition, the kinetic analysis of *O*-alkyl cleavage reaction is performed easily with this spectrophotometric assay. AGMO substrate specificity was measured with a microsomal enzyme preparation and the digitonin–solubilized enzyme from rat liver (18).

EXPERIMENTAL

Ether lipids. All lipids were synthesized in our laboratory according to Eibl (19–21). The substrates were dissolved in 0.1 M Tris/HCl buffer (pH 8.8) in the concentrations given in the tables. Compounds that were difficult to dissolve in buffer were solubilized with 1-lauroyl-propanediol-1,3-PC (7 mg/ml) or tetradecyl-PC (7 mg/ml)

containing buffer. Lysoplasmalogens were isolated according to the procedures of Warner and Lands (22) and Pugh et al. (23) from bovine heart; they were purified by silica gel chromatography and characterized by TLC.

Other chemicals. All other chemicals purchased were the highest available quality and used without further purification.

Preparation of O-alkylglycerol monooxygenase. Rat liver microsome preparation and solubilization of AGMO with the use of digitonin has been described before (18).

Enzymatic assay. Turnover rates and specific AGMO activities were estimated with the coupled spectrophotometric assay at 37 C in 0.1 M Tris/HCl buffer (pH 8.8) with the cofactor *D,L*-6-methyl-5,6,7,8-tetrahydropterine (0.5 mM) as described elsewhere (18). In each assay, 0.8 mg protein of a microsomal AGMO preparation or 1.5 mg protein of a digitonin (1.5%, w/v) solubilized AGMO sample was added to the reaction mixtures in a total volume of 1 ml. By variation, optimal substrate concentrations were estimated for each compound and given in the tables. Absorbance change was read on a Hitachi 150-20 double-beam spectrophotometer for two min, and AGMO activity was calculated from the initial rate.

Protein estimation. Protein concentration was determined according to the method of Peterson (24) with bovine serum albumin as standard.

TABLE 1

O-Alkylglycerol Monooxygenase (AGMO) Activity Solubilized by Digitonin from Rat Liver Microsomes with Mono-*O*-alkylglycerols and 1-*S*-Octadecylglycerol as Substrates

Substrate (-*rac*-glycerol)	Conc.[c] (mM)	AGMO activity (nmol/min/mg)	(%)[d]
1-*O*-propyl-	0.5–90	0	0
1-*O*-pentyl-	1–90	0	0
1-*O*-hexyl-	50	6.2	94
1-*O*-heptyl-	15	3.6	54

[a]Substrate was solubilized with 1-lauroyl-propanediol-1,3-PC (7 mg/ml).
[b]Substrate was solubilized with tetradecyl-PC (7 mg/ml).
[c]Optimal substrate concentration for the highest AGMO activity is given.
[d]3-*O*-Hexadecyl-*sn*-glycero-3-phoscholine is set to 100%.

RESULTS

The specificity of AGMO for various substrates was measured with membrane-bound as well as with digitonin-solubilized AGMO enzymes. Specific AGMO activity with 3-*O*-hexadecyl-*sn*-glycero-1-PC was 4.9 nmol/mg/min for microsomes and 6.6 nmol/mg/min for the digitonin extract, and the values were defined as 100% activity. This compound was chosen as a standard because it is easily water-soluble, forming micelles without addition of detergents. Also, it was the best ether phospholipid substrate for AGMO. The data given in the Tables 1–4 are means of three to 10 measurements with a standard deviation ±5%.

The substrate behavior of 1-*O*-alkylglycerols with the digitonin–solubilized enzyme is summarized in Table 1. In view of their substrate properties, *O*-alkylglycerols can be divided into three groups: first, the monomeric soluble short chain alkylglycerols (propyl- and pentyl-residues), which are not cleaved by AGMO; and second, the ether compounds with a C_6 to C_9 alkyl residue. These hexyl- to nonyl-*O*-glycerols are substrates for AGMO with activities depending on their maximal nonaggregated concentrations. The third group, the long chain *O*-alkylglycerols (C_{14} to C_{18}), are very good substrates; the hexadecyl residue is the optimal chain length (192%). The large differences in the optimal substrate concentrations for AGMO activity resulted from the different critical micellar concentrations of each compound (short-chain and long-chain alkyl ethers).

Lauroylpropanediol-1,3-PC and tetradecyl-PC, used as detergents for lipid solubilization, were tested for their influence on AGMO activity. Specific turnover rates of 3-*O*-hexadecyl-*sn*-glycero-3-PC were not changed by addition of these lipids to an incubation mixture of up to 10 mg/ml of each compound.

Thioethers, for instance, 1-*S*-octadecylglycerol, also are cleaved by AGMO. The rate is lower than for the corresponding ethers.

Investigations on the influence of the monomeric solubility of the ether glycerides on their substrate properties towards AGMO were conducted using ether lipids with *D*-mannitol instead of glycerol. For instance, 1-*O*-octyl-*D*-mannitol is easily water–soluble, and this variance in the structure of the polyhydroxy backbone leads to a dramatic loss of AGMO activity (only 4%) compared to that of the 1-*O*-octylglycerol.

The substrate properties of di-*O*-alkylglycerols are summarized in Table 2. 1-*O*-Hexadecyl-3-*O*-methyl-*rac*-glycerol is the best AGMO substrate tested. However, with increasing length of the second alkyl chain, AGMO activity diminishes. As compared to the standard, the rate of hydrolysis for 1-*O*-hexadecyl-3-*O*-octyl-*rac*-glycerol is only 17%, whereas 1-*O*-tetradecyl-2-*O*-octadecyl-*rac*-glycerol does not serve as a substrate at all.

To test whether the high turnover rates of the short chain 1-*O*-hexadecyl-3-*O*-alkyl-*rac*-glycerols are due to an additive cleavage of the second ether bond, we synthesized different *O*-alkyl-palmitoyl-glycerols with alkyl chains from C_2 to C_5. None of these compounds, for instance 1-palmitoyl-3-*O*-allyl-*rac*-glycerol, is an AGMO substrate, indicating that alkyl residues shorter than C_5 are not cleaved by AGMO. Therefore, it is tempting to speculate that there is no additive cleavage of the second *O*-alkyl bond in short-chain 1-*O*-hexadecyl-3-*O*-alkyl-*rac*-glycerols.

The presence of an ester bond at the glycerol vicinal to the ether bond is a negative factor for AGMO activity,

TABLE 2

O-Alkylglycerol Monooxygenase (AGMO) Activity Solubilized by Digitonin from Rat Liver Microsomes with Di-O-alkylglycerols, Acylalkylglycerols and Derivatives as Substrates

Substrate (*rac*-glycerol)	Conc.[c] (mM)	AGMO activity (nmol/min/mg)	AGMO activity (%)[d]

[d]3-*O*-Hexadecyl-*sn*-glycero-3-phosphocholine is set to 100%.

TABLE 3

O-Alkylglycerol Monooxygenase (AGMO) Activity Solubilized by Digitonin from Rat Liver Microsomes with Alkyl-(lyso-)phospholipids as Substrates

Substrate (phosphocholine)	Conc.[a] (mM)	AGMO activity (nmol/min/mg)	AGMO activity (%)
1-*O*-hexadecyl-*sn*-glycero-3-	0.5	5.5	83
3-*O*-hexadecyl-*sn*-glycero-1-	0.5	6.6	100
1-*O*-octadecyl-*sn*-glycero-3-	0.5	4.3	65
1-*O*-hexadecyl-propanediol (1,3)-	0.5	5.7	86
1-*O*-hexadecyl-propanediol(1,2)-	0.5	3.6	54
1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-	1	1.5	22
1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-	0.1–2	0	0
1-*O*-hexadecyl-*sn*-glycero-phospho-*N,N,N*-trimethyl-hexanolamin	0.5	3.7	56

[a]Optimal substrate concentration for the highest AGMO activity is given.

as shown with 1-*O*-hexadecyl-2-acetyl-*rac*-glycerol. In comparison to 1-*O*-allyl-2-*O*-octadecyl-glycerol (91%) or 1-*O*-octadecyl-2-*O*-methyl-glycerol (100%), this compound is still a sufficient substrate for AGMO (75%).

The distance between alkyl chains on the glycerol molecule (1,2 vs 1,3, e.g. 1-*O*-allyl-3-*O*-hexadecyl-*rac*-glycerol 214%, compared with 1-*O*-allyl-2-*O*-octadecyl-*rac*-glycerol 91%) significantly influences AGMO activity. 1-*O*-Allyl-2-*O*-octadecylglycerol still is a good substrate (91%) even when one considers that in general, cleavage of a C_{18} residue occurs 1.7 times slower than the cleavage of a C_{16} chain (1-*O*-hexadecylglycerol compared to 1-*O*-octadedcylglycerol in Table 1).

Some of the ether phospholipids whose properties as AGMO substrates were investigated are listed in Table 3. Comparison of the activities of AGMO on 1-*O*-hexadecyl-*sn*-glycero-3-PC and 3-*O*-hexadecyl-*sn*-glycero-1-PC revealed that the structure with PC in the *sn*-1 position is a slightly better substrate. This is surprising, since naturally occurring phospholipids normally have the opposite configuration. AGMO again cleaves the octadecyl chain at lower rates than the hexadecyl chain, for instance, with activities of 65% for 1-*O*-octadecyl-*sn*-glycero-3-PC vs 83% for 1-*O*-hexadecyl-*sn*-glycero-3-PC. Absence of the hydroxygroup in the ALP (1-*O*-hexadecyl-propanediol-1,3-PC, 86%) does not change the substrate behavior significantly. In contrast, the close vicinity of PC to the alkyl ether bond (1-*O*-hexadecyl-propanediol-1,2-PC, 54%) has a negative influence on the substrate property.

Although the biologically important compound PAF (1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-PC) is a poor AGMO substrate, it still can be degraded. However, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-PC cannot.

Structural variations in the PC residue of ALP influence AGMO activity markedly: it decreases from 83% for 1-*O*-hexadecyl-*sn*-glycero-3-PC to 56% for 1-*O*-hexadecyl-*sn*-glycero-3-phospho-*N,N,N*-trimethylhexanolamine.

Unsaturated alkyl ether groups behave in different ways as substrates for AGMO, depending on the position of the double bond in the alkyl chain as shown in Table 4. Substitution of octadecyl by octadecen-(9,10)-yl has no significant effect on AGMO activity, as can be seen from the comparison of 1-*O*-oleyl-*rac*-glycerol and 1-*O*-oleyl-2-*O*-methyl-*rac*-glycerol (Table 4) with the octadecyl compounds 1-*O*-octadecyl-*rac*-glycerol (Table 1) and 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycerol (Table 2), respectively. However, lysoplasmalogen, with unsaturation in the α,β-position, is not a substrate for AGMO. This is consistent with the proposed mechanism of the cleavage of the *O*-alkylbond via a hemiacetal by Tietz et al. (10). However, a slight shift of the double bond to the β-position will result in substrate properties. 1-*O*-(*cis*)-2′-hexadecenylglycerol has a rate of 124%, which is lower than the 192% that is determined for 1-*O*-hexadecylglycerol. A hemiacetal cannot be formed when the double

TABLE 4

O-Alkylglycerol Monooxygenase (AGMO) Activity Solubilized by Digitonin from Rat Liver Microsomes with Substrates Containing Unsaturated Alkyl Chains

Substrate	Conc.[c] (mM)	AGMO activity (nmol/min/mg)	(%)[d]
1-*O*-oleyl-*rac*-glycerol[a]	1	7.7	116

1-*O*-oleyl-2-acetyl-*rac*-glycerol[a]	1	8.8	134
lysoplasmalogen	2–200	0	0
1-*O*-(*cis*)-2′-hexadecenyl-glycerol[b]	0.5	8.2	124

[a]Substrate was solubilized with 1-lauroyl-propanediol-1,3-PC (7 mg/ml).

[b]Substrate was solubilized with tetradecyl-PC (7 mg/ml).

[c]Optimal substrate concentration for the highest AGMO activity is given.

[d]3-*O*-Hexadecyl-*sn*-glycero-3-phosphocholine is set to 100%.

bond is in α,β position to the *O*-alkylbond. Therefore, the metabolism of the *O*-alkylbond in plasmalogens by plasmalogenases and the cleavage of the saturated ether bond are two totally separate pathways.

DISCUSSION

Since phospholipids form aggregates in aqueous solutions (2), the enzymatic activities of lipid-metabolizing enzymes could be related to the lipid superstructures and surface properties (25,26). A study of AGMO activity toward short- and middle-chain alkyl glycerols showed that these compounds are substrates only in a very small range of concentration. So, it is not surprising that e.g. 1-*O*-octylglycerol was not described as a substrate for AGMO in a previous study (10). As is shown in detail elsewhere (27), AGMO is a membrane-bound enzyme. This fact makes the development of model kinetics of the substrate behavior difficult, and normal kinetic analyses are not valid (28). However, microsomal fractions show the same AGMO specificity as solubilized and enriched enzyme samples do (data not shown). In addition, with 1-*O*-hexadecyl-*rac*-glycero-3-PC and 1-*O*-hexadecylglycerol as substrates, the saturation of substrate concentration are in accord with data from other investigations (15,17).

The poor solubility of the long-chain *O*-alkylglycerols (C_{12} to C_{18}) in water raises several difficulties in the assay system, such as low substrate concentration and turbidity. Several methods for overcoming these problems have been used by others (10,13–16,29–31) based on using alcohols to dissolve the substrates. As one can observe in a cuvette, addition of an alcoholic solution or of substrate to the aqueous assay system immediately leads to precipitation of the substrate. A powerful help is using the phospholipid analogs such as 1-lauroyl-propanediol-1,3-PC and tetradecyl-PC as detergents, resulting in a clear solution of the substrates. Within the concentration range used, these compounds had no effect on AGMO activity. Using these detergents is an additional reason why our microsomal AGMO activities with substrates like 1-*O*-hexadecylglycerol are higher than those reported by others (10,14–16).

While PAF shows only poor substrate property (22%, Table 3), the lyso-compound 1-*O*-hexadecyl-*sn*-glycero-3-PC (Lyso-PAF) is a good substrate (83%, Table 3). Lyso-PAF is generated by acetyl hydrolase (E.C. 3.1.1.48) (32) removing the acetyl residue from the *sn*-2 position. This is the biological-important pathway in PAF metabolism. In addition, phospholipase C (E.C. 3.1.4.3) acts on PAF with very high turnover rates (33). The product, 1-*O*-hexadecyl-2-acetyl-glycerol, is an intermediate in PAF biosynthesis (34) and also is a good substrate for AGMO (75%, Table 2). Therefore, in contrast to Lee et al. (31) and in accord with Hoffman et al. (35), the hydrolysis of *sn*-2 position is not a necessary condition for the action of AGMO. In addition, the initial rate of cleavage was linear with time. This does not indicate any substrate conversion other than alkyl cleavage activity.

Starting from 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-PC, described as a potent cytotoxic agent (1), an analog cascade of enzymatic reactions can be constructed. With two different assay systems (17,18,27), it is now shown in disagreement to earlier discussion (3,5) that 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-PC is not a substrate for AGMO (Table 3). However, after removing PC through phospholipase C or a phosphocholine transferase (6), 1-*O*-octadecyl-2-*O*-methylglycerol could be generated. This compound is, like Lyso-PAF, an excellent substrate (100%, Table 2) for AGMO. To what extent ALP(-analogs) antitumor drugs can be generated selectively through competition of metabolizing enzymes is under study in our laboratory. Therefore, the simple explanation for the toxicity and selectivity of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-PC, based on the difference of AGMO content in normal and malignant cells, is not correct. This also was shown in other studies (35,36) comparing AGMO activity levels in different cell types with the sensitivity of these cells to an ALP treatment.

To recapitulate, general conclusions seem to emerge about the substrate specificity from the studies reported in this paper. The position of the ether bond to be cleaved in the glycerol backbone is not important. One steric unhindered position in the glycerol (-derivative) must be present. The substrate requires an aliphatic chain longer than C_6. In di-*O*-alkylglycerols, only one chain should be longer than C_5. In mixed acylalkylglycerols, the alkyl chain to be cleaved must be longer than the acyl residue. The alkyl chain may contain double bonds but not in α,β position relative to the ether bond. The rate of the *O*-alkyl cleavage is dependent on structural variations in the polar region of ether lysophospholipids. Thioether lipids are also cleaved by AGMO.

[Received February 5, 1987]

Differential Effects of Ether Lipids on the Activity and Secretion of Interleukin-1 and Interleukin-2[1]

Reinhard Andreesen*,[2] and **Veronika Giese**
Medizinische Klinik I der Universität Freiburg i. Breisgau, Freiburg, Federal Republic of Germany

Alkyl lysophospholipids (ALP) are synthetic analogues of lysophosphatidylcholine and represent a new generation of antitumor drugs currently being tested in phase-I trials in patients with cancer. The present study reports the differential modulation of human immunocompetent cells in vitro by ALP. Serum-bound ALP effectively blocked the response of growth factor–dependent cells to interleukin-2 (IL-2), inhibited the cellular production and release of IL-2 and suppressed the comitogenic effect of interleukin-1 (IL-1) on mouse thymocytes. In contrast, ALP-primed, monocyte-derived macrophages (MO) lost their ability to release IL-1 in response to stimuli like lipopolysaccharides (LPS) during terminal maturation from monocytes. Supernatants from ALP-primed, LPS-induced MO possessed costimulatory as well as direct mitogenic activity. Neither ALP alone nor ALP-conditioned MO supernatants stimulated mouse thymocytes. Priming of MO by ET-18-OH, an ALP molecule not substituted in the *sn*-2 position, occurred at concentrations 4- to 16-fold higher than the most active compounds ET-18-OCH$_3$ and the thioether analogue BM 41.440. ALP also primed MO for subsequent activation of tumor cytotoxicity by LPS and interferon-gamma.

IL-1 has multiple biological activities in common with ALP, and it may mediate antitumor activity and other ALP effects in vivo. The ability of ALP to induce differential immunomodulation, as demonstrated in this study, may make ALP worthy of study for the therapy of both autoimmune and neoplastic disease.
Lipids 22, 836–841 (1987).

Synthetic alkyl analogues of natural 2-lysophosphatidylcholine (LPC) are a new class of antitumor agents currently being tested in phase-I trials in patients with tumors (1). In animal models, demonstration of a tumor-therapeutic activity requires both a low tumor burden and long-term application of rather small doses. In addition, ALP are anticarcinogenic (2) and protect from radiation damage (3). Despite well-documented in vivo effects, their underlying mechanisms of action are still unclear. Activation of macrophages to cytotoxicity (4), induction of cell differentiation (5), inhibition of tumor cell invasion (6) and a direct destructive effect on cells selective for neoplastic cells (1–9) have all been proposed. We previously reported on the interference of alkyl lysophospholipids (ALP) with normal lymphocyte transformation (10), and we now present data proving a differential effect of ALP on the production and biological activity of interleukin-1 (IL-1) and interleukin-2 (IL-2). The current study demonstrates that ALP-primed human monocyte-derived macrophages (MO) respond to subsequent stimuli with the release of large quantities of IL-1-like activity. ALP simultaneously inhibit lymphocyte production of IL-2 and lymphocyte responses to both IL-1 and IL-2.

MATERIALS AND METHODS

Lysophospholipids. Natural 2-LPC was purchased from Sigma Chemical Co. (St. Louis, MO) and *rac*-1-octadecyl-2-methoxy-*sn*-glycero-3-phosphocholine (ET-18-OCH$_3$) from Medmark Chemicals (Grünwald b. München, FRG). *Rac*-1-octadecyl-*sn*-glycero-3-phosphocholine (ET-18-OH) was provided by H. U. Weltzien (Max Planck Institut, Freiburg, FRG); *rac*-1-mercapto-hexadecyl-2-methoxymethyl-*sn*-glycero-3-phosphocholine (BM 41.440) was a gift from W. Pahlke (C. F. Boehringer Mannheim GmbH, Mannheim, FRG).

Cells. Peripheral blood leukocytes were separated from buffy coat preparations of healthy blood donors by density gradient centrifugation on Ficoll-Hypaque. Monocytes were isolated from other mononuclear cells (MNC) by adherence to plastic petri dishes (60 min at 5×10^6 MNC per ml RPMI1640 supplemented with 5×10^{-5} M 2-mercaptoethanol, antibiotics and 15% fetal calf serum [FCS]), cultured overnight in RPMI1640 plus 10% human AB-group serum and recovered by vigorous pipetting at 4 C. Monocytes were greater than 90% pure as estimated by cytochemistry and antigen analysis (11). They were cultured in suspension at 3×10^5/ml RPMI1640 plus 10% AB-serum on hydrophobic Teflon foils for various time periods (12) and subjected to further experimentation at their sequential stages of differentiation. MO phenotype was determined to judge the stage of maturation (11), which was completed after 10 days in culture, after which the cells were termed mature monocyte-derived MO (TMO).

MLA144 cells (a T-cell line of gibbon origin, ref. 13) were provided by H. Rabin (National Cancer Institute, Frederick, MD), maintained in RPMI1640 plus 10% FCS and subcultured every 3–4 days.

Activation of monocyte MO and production of supernatants. Monocyte MO were cultured at 5×10^4 per 0.2 ml RPMI1640 plus 30% FCS for 24 hr with and without ALP. The medium was then replaced with fresh RPMI1640 plus 30% FCS, the cells were incubated for 30 min, and 10 μg/ml lipopolysaccharides (LPS, Salmonella abortus equi M6; donated by Dr. Galanos, Max Planck Institut, Freiburg, FRG) was added in RPMI1640 plus 10% FCS. Supernatants were collected after 24 hr, centrifuged at 200 g for 10 min and stored at 4 C.

Thymocyte proliferation assay (IL-1). Thymocytes prepared from 3- to 4-week-old C3H/HeJ mice (Bonholtgard, 868 Ry, Denmark) were cultured in triplicate at 5×10^6 cells/ml RPMI1640 plus 10% FCS with and without 1:200 diluted phytohemagglutinin (PHA) (Gibco, Grand Island, NY) in a final volume of 0.2 ml in flat-bottomed 96-well microplates containing 1:4 dilutions of test

Abbreviations: ALP, alkyl lysophospholipids; IL-1 and IL-2, interleukin-1 and -2; MO, macrophages; MNC, mononuclear cells; TMO, mature macrophages; LPS, lipopolysaccharides; PHA, phytohemagglutinin.

supernatants. The cultures were incubated for three days before they were pulsed for 6 hr with 0.2 μCi ^{3}H-thymidine (sp act 28 Ci/mmol; Amersham and Buchler, Braunschweig, FRG) and subsequently harvested. IL-1 activity is expressed as counts/min (cpm). In some experiments, thymocytes were cultured with ALP alone or with and without ALP in the presence of recombinant human interleukin-1-alpha (Hoffman-LaRoche, Nutley, NJ) at a 1:7,500 dilution.

Bioassay for interleukin-2. IL-2-dependent mouse cells (HT-2, gift from Dr. Larrick, Cetus Co., Emeryville, FL) were passaged three times a week in an IL-2-containing medium conditioned for 48 hr by human blood MNC stimulated with 1:50 diluted PHA, 2 μg/ml concanavalin A and irradiated allogeneic lymphoblastoid cells in a ratio of 1:1. HT-2 cells were taken for the IL-2 assay after two days of last passaging, washed twice in serum-free medium and cultured with the 1:2 diluted test supernatants for 24 hr before the 6-hr ^{3}H-thymidine incorporation was measured.

Tumor-cytostasis assay (14). Monocyte-derived TMO were seeded at 5 × 10^4/0.2 ml RPMI1640 plus 30% FCS and cultured for 24 hr with or without 16 μg/ml ET-18-OCH$_3$. MO were then incubated twice with fresh complete medium for 30 min each time and subsequently cultured with serum-free RPMI1640 (containing 0.1 mg/ml lactalbuminhydrolysate, 0.2 mg/ml fetuin and 0.15 U/ml swine insulin) in the presence of LPS or recombinant human interferon-gamma (rIFNg, Biogen, Geneva, Switzerland) for 24 hr. MO monolayers were then rinsed twice with warm serum-free medium before 10^4 U937 cells (K. Nielsson, Uppsala, Sweden) were added. After coincubation of MO and targets for another 48 hr, the cultures were pipetted to bring target cells into suspension, 0.1 ml aliquots were transferred to a new microplate and ^{3}H-thymidine uptake was measured with a 6-hr pulse. Activation indices were calculated by dividing cpm values of target cells after coincubation with control MO vs cpm values of target cells after coculture with activated MO.

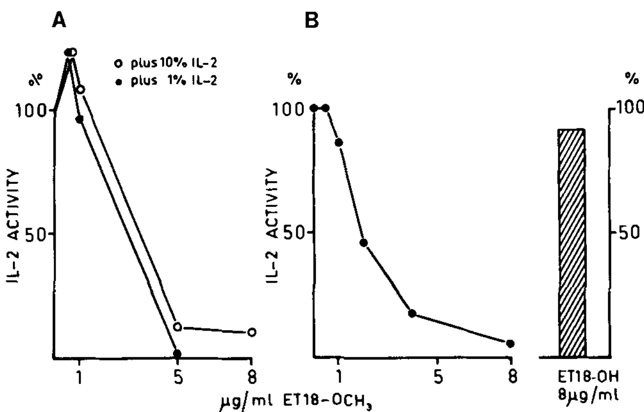

FIG. 1. Inhibition of (A) response to and (B) activity of interleukin-2 (IL-2) by alkyl lysophospholipids (ALP). HT-2 cells were cultured with IL-2 standard preparations in the presence of ET-18-OCH$_3$. After 24 hr, the 6-hr thymidine uptake was measured; results are expressed as percentage of control cultures without ET-18-OCH$_3$ (part A). In part B, MLA144 cells were cultured with ET-18-OCH$_3$ or ET-18-OH for 24 hr; fresh medium was added and supernatant collected after another 24-hr culture period. IL-2 activity was assessed therein as described above and is expressed as percentage of control supernatants from cells cultured without ALP, mean of triplicate values, S.D. less than 15%.

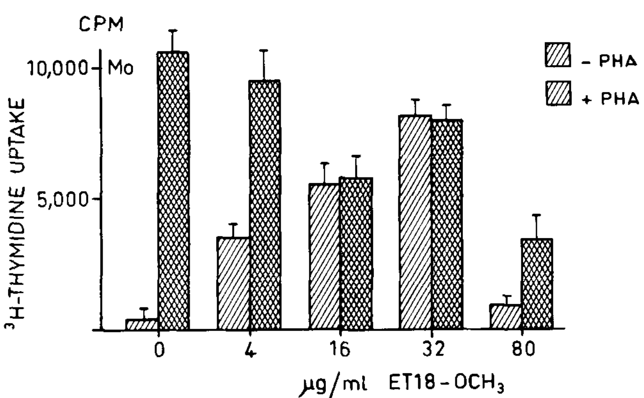

FIG. 2. Inhibition of the comitogenic (interleukin-1-like) and generation of a mitogenic activity in lipopolysaccharides stimulated blood monocytes after preculture with alkyl lysophospholipids (ALP). Blood monocytes were separated by adherence, cultured overnight and incubated with ALP for 24 hr. Then the medium was changed, cells were rinsed twice and 10 μg/ml LPS was added for another 24 hr before supernatants were collected and tested for their ability to be directly stimulatory to mouse thymocytes or indirectly in the presence of PHA. Results are given as counts/min, mean of triplicate values.

RESULTS

Based on our earlier findings that ALP interfere with normal lymphocyte transformation and inhibit growth of activated lymphoblasts (10), we started an investigation into the immunomodulatory effects of ALP in vitro by looking at the response of IL-2-dependent cells in the presence of ALP. As shown in Figure 1A, ET-18-OCH$_3$ inhibited IL-2 response of HT-2 cells at concentrations above 2 μg/ml, whereas lower doses had a minor, reproducible stimulatory effect. The production of IL-2 was also inhibited within a similar dose range of ET-18-OCH$_3$ (Fig. 1B). Both effects were seen only with those analogues of 2-LPC that are modified in *sn*-1 and *sn*-2, whereas the ether analogue ET-18-OH had no effect. In the presence of ALP, the response of normal lymphoblasts to IL-2-containing supernatants is suppressed similarly, as is the release of IL-2 (data not shown).

Peripheral blood monocytes respond to activation by LPS with the release of the lymphocyte-activating factor termed IL-1 (15). We measured IL-1 in MO supernatant by its ability to act on C3H/HeJ mouse thymocytes either directly or in the presence of the mitogen PHA. If monocytes were first incubated for 24 hr with ET-18-OCH$_3$, they responded to subsequent LPS stimulation with the release of decreasing amounts of costimulatory activity (Fig. 2). However, a dose-dependent increase of a direct mitogenic activity was found in LPS-stimulated, ALP-preincubated monocyte supernatant.

When blood monocytes are cultured on hydrophobic Teflon foils in the presence of human AB-group serum, they differentiate into mature MO-type cells (for details, see refs. 11 and 12). During this in vitro maturation, they rapidly lose their ability to respond to LPS stimulation with IL-1 release (Fig. 3), as has been shown by others using different culture systems (16). However, if these

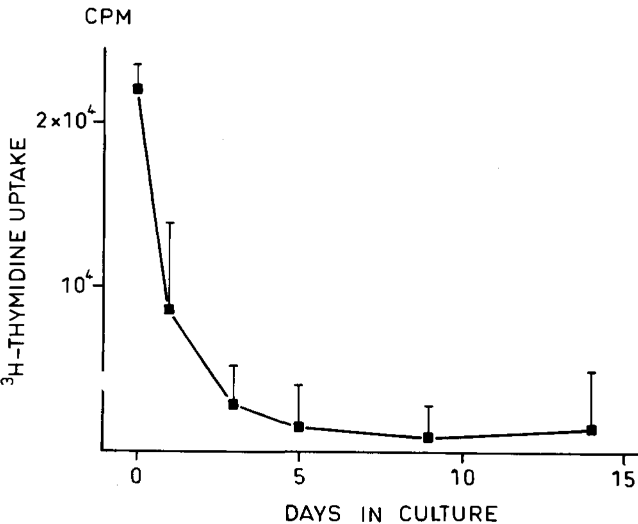

FIG. 3. Release of interleukin-1 (IL-1) activity by human monocytes/macrophages at different stages of in vitro maturation. Monocytes as well as monocyte-derived macrophages obtained after various days in culture were cultured with 10 μg/ml lipopolysaccharides for 24 hr. Thereafter, supernatants were tested for IL-1-like activity on mouse thymocytes. Data are mean of triplicates from three separate experiments.

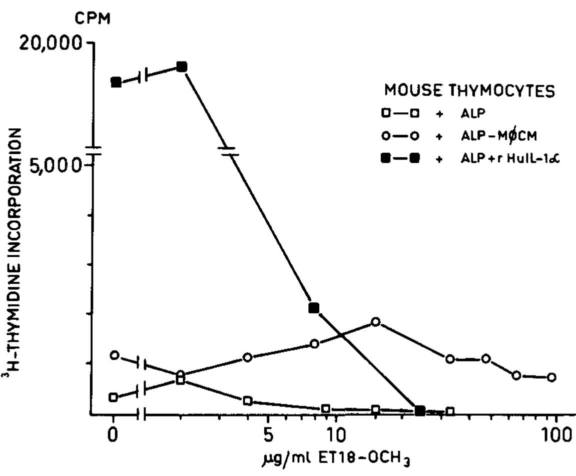

FIG. 5. Effect of alkyl lysophospholipids (ALP) and ALP-conditioned macrophage (MO) supernatants on mouse thymocytes and the comitogenicity of interleukin-1 (IL-1). Mouse thymocytes were cultured with suboptimal PHA concentrations with ALP and ALP-conditioned MO supernatants, respectively, either alone or in the presence of recombinant human IL-1-alpha at a dilution of 1:7,500 for 3 days before thymidine uptake was measured. Data are expressed as cpm, mean of triplicate values, S.D. less than 15%.

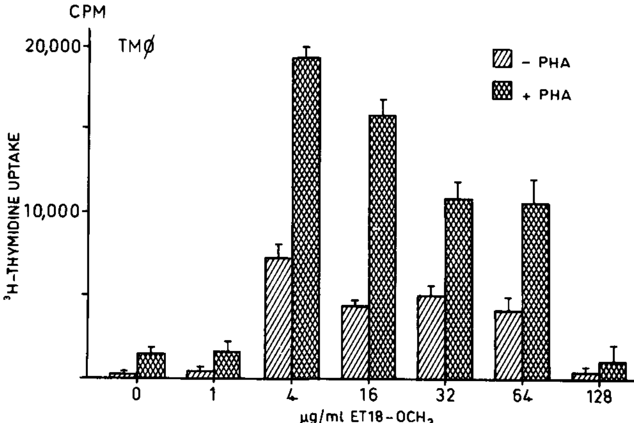

FIG. 4. Generation of interleukin-1 (IL-1)-like activity in lipopolysaccharide (LPS)-stimulated monocyte-derived macrophages (MO) after induction with alkyl lysophospholipids. Teflon culture-derived mature MO were incubated with various concentrations of ET-18-OCH$_3$ for 24 hr and rinsed twice with fresh medium before 10 μg/ml lipopolysaccharides were added. After another 24-hr culture period, supernatants were collected and tested. For further details, see legend to Fig. 2.

monocyte-derived TMO were first cultured with ALP for 24 hr, they retain their ability to mount an effective response to LPS stimulation and secreted high amounts of IL-1-like material in relation to the ALP concentrations used (Fig. 4). Again, the MO supernatant transformed thymocytes directly but also effectively potentiated the mitogenicity of suboptimal PHA concentrations. This dose-dependent "priming" activity of ALP on TMO is still seen at concentrations in the near-toxic range: only about 50% of the MO exclude trypan blue after a 24-hr culture with 64 μg/ml ALP (data not shown).

TMO cultured with ALP alone without a subsequent second stimulus did not release any IL-like material. In addition, ALP itself had no stimulatory effect in the comitogenic assay. In contrast, ALP effectively blocked the thymocyte response to recombinant IL-1-alpha (Fig. 5).

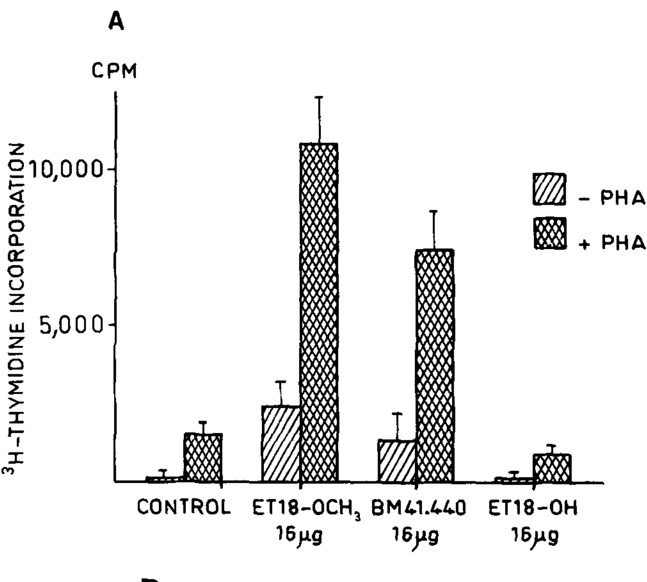
Other ether analogues of 2-LPC also preactivated TMO when modified in both the *sn*-1 and *sn*-2 positions (like the thioether analogue BM 41.440, Fig. 6A). However, ET-18-OH is as effective in priming MO as the most active analogue ET-18-OCH$_3$, although requiring a 4- to 16-fold higher concentration (Fig. 6B).

TMO maintained their state of primed activity for about 24 hr after removal of the ALP. In Figure 7, results of a typical experiment are shown where TMO were cultured for 24 hr with or without 16 μg/ml ET-18-OCH$_3$, and at various times after removal of the ALP were recultured in serum-free medium stimulated with LPS.

As IL-1 secretion is only one parameter indicative of an activated state of MO, we also evaluated the activity of ALP-primed TMO as tumor-cytotoxic effector cells. As shown in Figure 8, pretreatment of ALP augmented the response of TMO to activation for tumor cytotoxicity. As demonstrated, other MO activators like interferon-gamma can also act as the second stimulus, thus establishing the preactivated state of ALP-primed MO. In these experiments, ALP alone did not activate MO for tumor cytotoxicity (data not shown).

DISCUSSION

Synthetic ALP were the first reported molecularly defined lipid mediators that possess immunomodulatory as well as other biological activities (17). A decade later, the description of the ALP structure of platelet-activating factor (PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphatidylcholine) defined a new class of naturally occurring ether lipids with hormone-like activity (18–20).



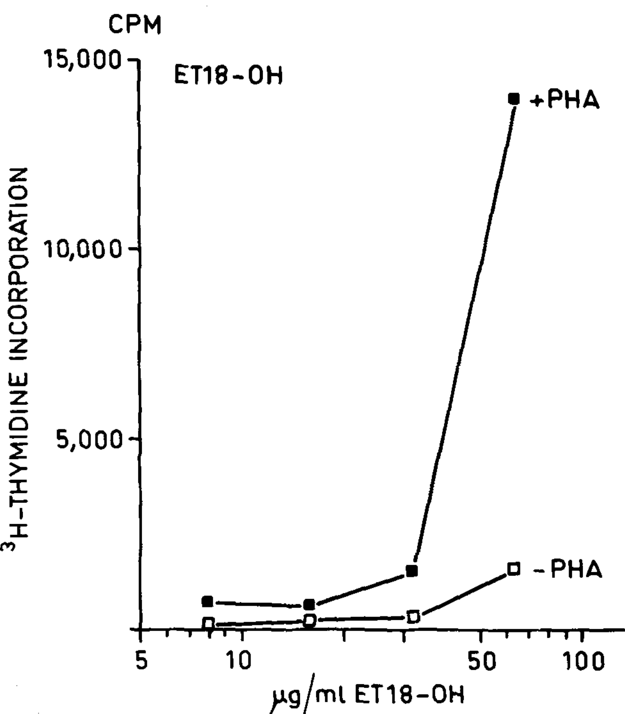


FIG. 6. Priming of monocyte-derived macrophages (MO) by alkyl lysophospholipids (ALP): dependence on the molecular structure of the ALP. Teflon culture-derived mature MO were incubated 24 hr with various ALP compounds at 16 µg/ml (A) and with ET-18-OH at increasing concentrations (B) before lipopolysaccharides were added. Supernatants were collected after 24 hr and tested on mouse thymocytes. Data are indicated in part A and are mean of triplicates for part B; S.D. less than 15%.

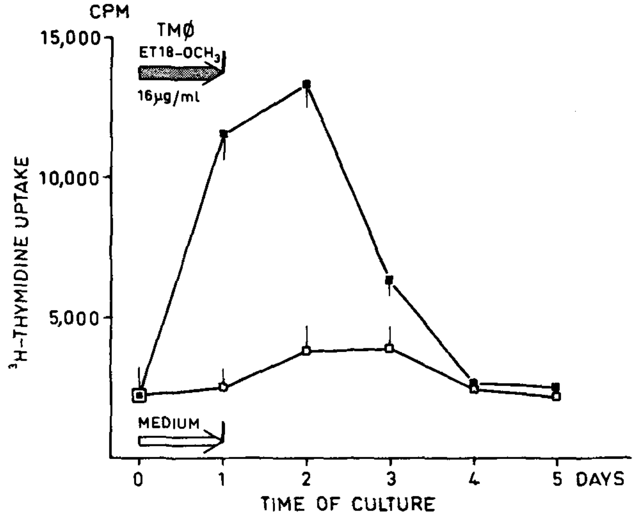

FIG. 7. Duration of the alkyl lysophospholipid (ALP)-induced state of primed activity in monocyte-derived macrophages (MO). Teflon culture-derived mature MO were incubated with medium alone or with 16 µg/ml ET-18-OCH₃. Lipopolysaccharide was then added at 10 µg/ml for 24 hr either directly thereafter or following cultivation of the MO in serum-free RPMI1640 for various time periods. For further details, see legend to Fig. 2.

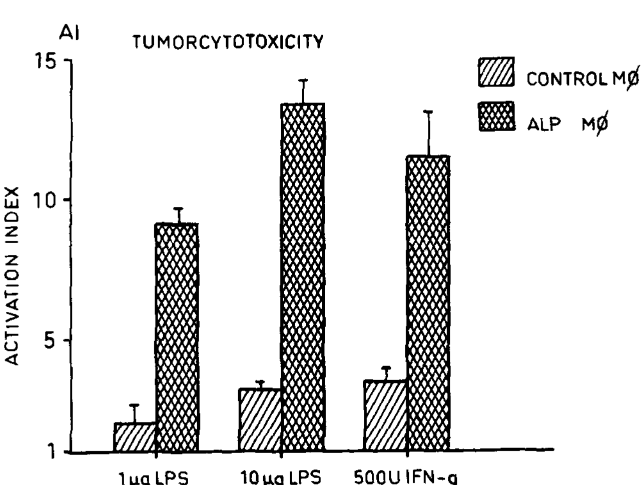

FIG. 8. Enhancement of tumor-cytotoxic effector cell activation by lipopolysaccharides (LPS) and interferon-gamma after precultivation of macrophages (MO) with alkyl lysophospholipids (ALP). Mature MO (TMO) were sequentially cultured in microplates with 16 µg/ml ET-18-OCH₃ for 24 hr and LPS or interferon-gamma (also 24 hr) before U937 tumor cells were added and cocultured with the mature MO (TMO) for 48 hr. Thereafter, the microcultures were pipetted, and ^{3}H-thymidine uptake into 0.1 ml aliquots was measured in a separate microplate. Results are expressed as activation indices calculated by dividing cpm of tumor cells after coculture with control TMO vs cpm of tumor cells after coculture with activated TMO, mean of triplicate values.

The results of the present study provide evidence for a novel function of ether lipids, i.e., the differential manipulation of immune responses in vitro. ALP inhibited lymphocyte response to IL-2 and rIL-1-alpha and suppressed the production of IL-2 in competent cells. These effects may be related to our recent discovery that mitogen-stimulated lymphoblasts not only ceased to grow but rapidly died in the presence of ALP. Small resting lymphocytes are unaffected by ALP (10), while the activation of lymphocytes by a variety of stimuli is supressed by ALP (10). In contrast, ALP render monocyte-derived MO responsive to subsequent activating stimuli. Only ALP-"primed" MO, but not untreated control MO, could be stimulated by LPS to release high amounts of

a lymphocyte-activating factor activity. In addition to its costimulatory effect, this factor was also directly mitogenic in the mouse thymocyte assay. As purified and recombinant human IL-1 preparations do not activate lymphocytes directly (21), the activity found in the ALP-primed, LPS-stimulated MO supernatant should be termed "IL-1-like material," which must contain more than the single "mature" polypeptide (17,500 mol wt), defined to be the extracellular secreted form of IL-1 (22). Biological activity has been described also for small peptide fragments (23), and an intracellular, nonsecreted precursor molecule with a higher molecular weight (31,000 mol wt) has been shown to be directly mitogenic (24). ALP primed MO at concentrations in the toxic range. It is thus possible that intracellular IL-1 precursors were released and were, in part, responsible for the observed effect of ALP-primed MO. High performance liquid chromatography experiments are in progress to further elucidate the molecular nature of this IL-like activity.

No IL-1-like material was induced by ALP alone. The molecular mechanism by which ALP induce MO preactivation is not understood. Possible explanations may be linked to the ALP-induced inhibition of key phospholipid—metabolizing enzymes (25), which provide arachidonic acid for the biogenesis of leukotrienes and prostaglandins. Interestingly, indomethacin, which like ALP inhibits arachidonic acid metabolism, also enhanced IL-1 production (26). There may well also be an interaction between lipid and peptide mediator synthesis (27).

ALP represent a new generation of potent antitumor drugs (1). However, the clinical tumor-therapeutic potential of ALP is, to say the least, incompletely understood. Apart from a direct cytotoxic effect on malignant cells (7-9) and the inhibition of tumor cell invasion (6), these compounds induce various subtle changes in cell biology (e.g., activation of cytotoxic effector cell function [4] and induction of cellular differentiation [5]). ALP are also highly active adjuvants (17) in both in vivo and in vitro cell cooperation systems (28). ALP also protect animals from radiation damage by mechanisms as yet unexplained (3).

Multiple biological activities have also been ascribed to IL-1 (21). Some striking similarities exist between the effects of ALP and IL-1 in vitro and after administration in vivo; for example, IL-1 also is cytostatic for tumor cells in vitro (29,30), is a radioprotector (31), activates MO for cytotoxicity (32) and induces monophasic fever (21) and chills, which we observed in two tumor patients after high-dose intravenous application of ALP (personal observation). IL-1 secretion from mature tissue MO in synergism with other activating signals present in the microenvironment may be a mediator for many of the effects observed after ALP administration in vivo. In addition, the effects of ALP on IL-1-producing cells other than monocyte MO (15) need to be evaluated.

ALP preactivate MO not only for IL-1 release but also for other effector cell functions of activated cells (e.g., tumor cytotoxicity, prostaglandin E_2 secretion (Andreesen and Steinhauer [manuscript in preparation]) and probably others still to be looked at.

In conclusion, the study demonstrates a new activity of ALP. This "immunomodulatory" activity may be an important aspect of its tumor-therapeutic role and also its interaction with immunocompetent cells. The differential action of ALP on the immune system (summarized in Fig. 9) with MO activation and suppression of lymphocyte function could indicate a potential for beneficial effects of ALP in autoimmune diseases and in the acquired immunodeficiency syndrome (AIDS).

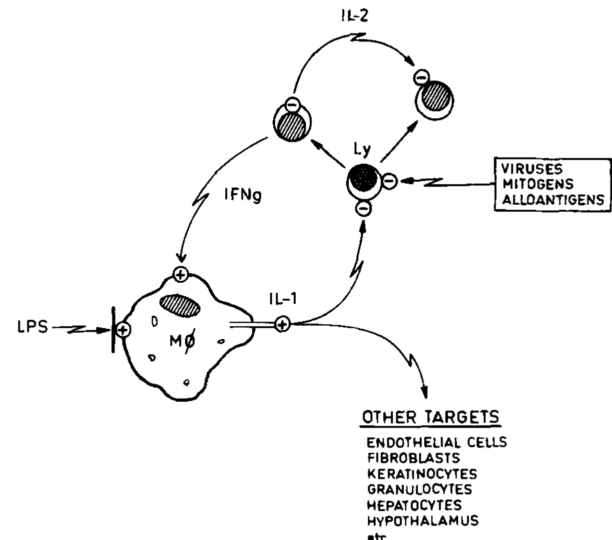

FIG. 9. Differential effects of alkyl lysophospholipids (ALP) on human immunocompetent cells in vitro. ALP restore the capacity of mature macrophages (MO) to respond to lipopolysaccharides (LPS) with the release of interleukin-1 (IL-1)-like activity and also augment activation of MO cytotoxicity by interferon-gamma and LPS. ALP inhibit lymphocyte response to IL-1, interleukin-2 (IL-2) and in general transforming stimuli. ALP, in addition, block IL-2 synthesis. IL-1 seems to be directed to other, non-lymphocyte, targets.

ACKNOWLEDGMENT

We gratefully acknowledge the excellent technical work of Barbara Wohlhüter and Annegret Schulz and thank Wulf Pahlke (Boehringer Mannheim GmbH) for cooperation. In our search for the mechanisms by which the drug 1-*O*-alkyl-2-*O*-methylglycero-3-phosphocholine (AMG-PC) inhibits tumor growth and metastasis, we have detected a metabolite, 1-*O*-alkyl-2-*O*-methylglycerol (AMG), in membranes of MO_4 mouse fibrosarcoma cells grown in the presence of the drug. Synthetic AMG inhibited the activation of highly purified human protein kinase C by diacylglycerol in the presence of phosphatidylserine. Furthermore, AMG also inhibited the receptor-specific binding of ^{3}H-phorbol-12,13-dibutyrate to human HL-60 promyeloid leukemia cells in a dose-dependent fashion. AMG-PC was not effective or much less so in these assays. We suggest that interaction of the metabolite AMG with protein kinase C may inhibit stimulus-response coupling in tumor cells and may thus potentially contribute to the mechanism by which AMG-PC exerts its anticancer activities.

Lipids 22, 842–846 (1987).

The drug 1-*O*-alkyl-2-*O*-methylglycero-3-phosphocholine (AMG-PC) has been shown to specifically inhibit the growth of tumor cells in vitro and in vivo, to inhibit tumor cell invasion and metastasis and to enhance the tumoricidal capacity of macrophages (reviewed in ref. 1). The mechanisms involved in these actions are unknown. Besides the possibility that accumulation of the drug as such in cellular membranes (2) may alter their structure and functioning, possible metabolic products of the drug should also be considered. Since AMG-PC is not a substrate for the alkyl cleavage enzyme (3), possible metabolites may only be formed via enzymatic cleavage of the phosphate bond.

In the present report, we show that the metabolite 1-*O*-alkyl-2-*O*-methylglycerol (AMG) is detectable in membranes of tumor cells grown in the presence of AMG-PC. Given the structural analogy of this metabolite to 1,2-diacylglycerol, a natural activator of protein kinase C (PKC) (4), we have investigated the possibility that AMG interacts with this key enzyme in cell signal transduction. First, we demonstrate that AMG inhibits the diacylglycerol-stimulated activity of a highly purified preparation of human PKC. Second, we show that AMG inhibits the binding of a biologically active phorbol ester to its receptor (PKC) on human HL-60 cells.

MATERIALS AND METHODS

Chemicals. The AMG-PC analogs racemic 1-*O*-octadecyl- and 1-*O*-hexadecyl-2-*O*-methylglycero-3-phosphocholine as well as 1-*O*-hexadecyl-2-*O*-methyl-*rac*-glycerol (AMG) were purchased from Bachem AG (Bubendorf, Switzerland). 1,2-Dioctanoyl-*sn*-glycerol (diC_8) was obtained from Avanti Polar Lipids (Birmingham, AL). Phosphatidylserine (PS; from bovine brain), 1,2-dioleoyl-*rac*-glycerol (diolein), leupeptin, phenylmethylsulphonyl fluoride (PMSF), soybean trypsin inhibitor, aprotinin, histone IIIS (from calf thymus) and adenosine 5′-triphosphate (ATP) were obtained from Sigma Chemical (St. Louis, MO). ^{32}P-ATP (3 Ci/μmol) and ^{3}H-phorbol-12,13-dibutyrate (PDBu, 12.5 Ci/mmol) were from New England Nuclear (Boston, MA), and cholesterol and ethylene-glycol-bis(beta-aminoethylether)-N,N,N′,N′-tetraacetic acid (EGTA) from BDH (Poole, U.K.). All chemicals were of analytical grade.

Cells. MO_4 cells are virally transformed C_3H mouse fibroblastic cells that are invasive in vitro (5) and produce invasive and metastasizing fibrosarcomas in syngeneic mice (6). They were cultured in minimum Eagle's medium (Rega I; Gibco Europe, Paisley, U.K.) supplemented with 10% fetal calf serum and 0.05% glutamine. Cells were also grown in the presence of AMG-PC (octadecyl-type, 7 μg/ml culture medium), added 48 hr prior to membrane lipid analysis. The concentration of the drug used permitted growth to about 80% of that of control cells (5). Human HL-60 promyeloid leukemia cells (7) were maintained as a suspension culture in RPMI 1640 medium, supplemented with 20% fetal calf serum.

AMG detection in membranes. A crude membrane fraction from MO_4 cells was prepared by centrifugation of the low-speed supernatant of a cell homogenate at 105,000 × g for 1.5 hr, as described before (8). Lipids were extracted with chloroform/methanol (2:1, v/v) followed by partition according to Folch et al. (9) and were separated by thin layer chromatography (TLC) on precoated silica gel plates (Merck, Darmstadt, FRG) using hexane/ether/acetic acid (60:40:1.6, v/v). The spot corresponding to AMG was scratched off, extracted and trimethylsilylated with a mixture of pyridine-hexamethyldisilazane-trimethylchlorosilane (12:5:2, v/v/v; obtained from Pierce Chemical Co., Rockford, IL) for 2 hr at room temperature and analyzed by gas liquid chromatography according to Myher and Kuksis (10), using a 25 m CP-Sil 58 column. AMG was also enzymatically prepared from AMG-PC (octadecyl-type) using phospholipase C (20 U/ml) from *Clostridium perfringens* (obtained from Sigma) in 10 mM $CaCl_2$, 0.1 mM $ZnCl_2$, 20 mM Tris-HCl (pH 7.4) at 37 C for 15 hr. The AMG formed (in low yield) was separated from AMG-PC by TLC and trimethylsilylated

Abbreviations: AMG-PC, 1-*O*-alkyl-2-*O*-methylglycero-3-phosphocholine; AMG, 1-*O*-alkyl-2-*O*-methylglycerol; PKC, protein kinase C; diC_8, 1,2-dioctanoyl-*sn*-glycerol; PS, phosphatidylserine; PMSF, phenylmethylsulfonyl fluoride; ATP, adenosine 5′-triphosphate; PDBu, ^{3}H-phorbol-12,13-dibutyrate; EGTA, ethylene-glycol-bis(beta-aminoethylether)-N,N,N′,N′-tetraacetic acid; TLC, thin layer chromatography.

as described above. The AMG thus prepared and that isolated from MO_4 cell membranes were identical, as unambiguously shown in Figure 1. AMG was quantitated by the detector response, using a known amount of heptadecanoic acid methyl ester as a reference.

Phorbol ester receptor assay. Binding of ^{3}H-PDBu to HL-60 cells in the presence or absence of inhibitors, supplied in dimethyl sulfoxide (0.5% final content), was performed by the method of Goodwin and Weinberg (11) in polypropylene tubes, using 5–10 × 10^5 cells and 20 nM ^{3}H-PDBu per assay (0.2 ml), unless otherwise stated. AMG and ^{3}H-PDBu were added simultaneously. Following incubation at room temperature for 30 min, excess cold assay buffer was added, and free and receptor-bound ^{3}H-PDBu were immediately separated by filtration through glass-fiber filters (Whatman GS/A). The filters were washed rapidly with excess buffer and prepared for liquid scintillation counting. The results are presented as specific binding, that is, the difference between ^{3}H-PDBu bound in the presence and absence of 20 μM unlabeled PDBu.

Purification of protein kinase C. Human PKC was isolated from a platelet/lymphocyte fraction of 50 buffy coats of donor blood. The purification procedure follows essentially the methods of Kikkawa et al. (12) and Girard et al. (13) and will be described in detail elsewhere. In brief, buffy coats were centrifuged (1300 × g, 8 min, 20 C) to remove granulocytes and erythrocytes. The rest of the procedure was performed at 0–4 C. Platelets and lymphocytes were spun down at 1700 × g (45 min) and taken up in 5 vol homogenization buffer containing 0.25 M sucrose, 10 mM EGTA, 2 mM EDTA and protease inhibitors (leupeptin, trypsin inhibitor, PMSF and aprotinin). Cells were broken in a Omni homogenizer (Sorvall) and the 100,000 × g supernatant of the cell homogenate underwent three chromatographic steps: DEAE cellulose, Phenyl sepharose CL-4B and affinity column chromatography using phosphatidylserine and cholesterol in the column matrix (13). PKC was eluted from the affinity column with 10 ml of 5 mM Tris-HCl (pH 7.5), 0.2 M NaCl, 5 mM 2-mercaptoethanol, 2 mM EGTA in a yield of about 50 μg protein. The PKC preparation thus obtained was 7,500-fold purified relative to the cytosolic fraction and showed one single band of 81 kD (see Fig. 2) upon SDS-polyacrylamide gel electrophoresis (14). The enzyme was stored in 40% sucrose at −70 C until use.

Enzyme assays. The activity of PKC in the presence or absence of stimulatory/inhibitory lipids was determined essentially according to Kikkawa et al. (15). The assays were performed in a 2 mM Ca^{2+}-EGTA buffer (16) yielding 10 μM free Ca^{2+} or in 2 mM EGTA. The reaction mixtures (60 μl final volume) furthermore contained 10 mM Mg^{2+}, 20 mM Tris-HCl (pH 7.5), 200 μg/ml histone IIIS, 20 μM leupeptin, 10 μM ^{32}P-ATP (0.5–1 μCi per assay) and PKC (10 μl preparation). Lipids were present in amounts indicated in the footnote of Table 1 and the legend of Figure 2. They were added as liposomes (10-μl samples), prepared by sonication for 1 min in a Branson Sonifier equipped with a standard probe (50 W). Incubations were started by addition of ATP and performed for 5 min at 30 C. The reaction was stopped by precipitation on Whatman paper filters (3 Chr) in cold 10% trichloroacetic acid plus 10 mM K_2HPO_4. The filters were extensively washed and prepared for liquid scintillation counting.

RESULTS AND DISCUSSION

In a previous study (5), it was demonstrated that the anticancer drug AMG-PC inhibits the invasion of MO_4 fibrosarcoma cells into normal embryonic chick heart tissue, under conditions where growth of the tumor cells in tissue culture was only minimally affected. In the companion article (2), we have shown that under these conditions AMG-PC is accumulated in the tumor cell membranes, predominantly in the plasma membrane: MO_4 cells grown in the presence of 5–10 μg/ml AMG-PC for 48 hr incorporated the drug to about 10% of the total phospholipids (measured in purified plasma membranes). Figure 1 shows

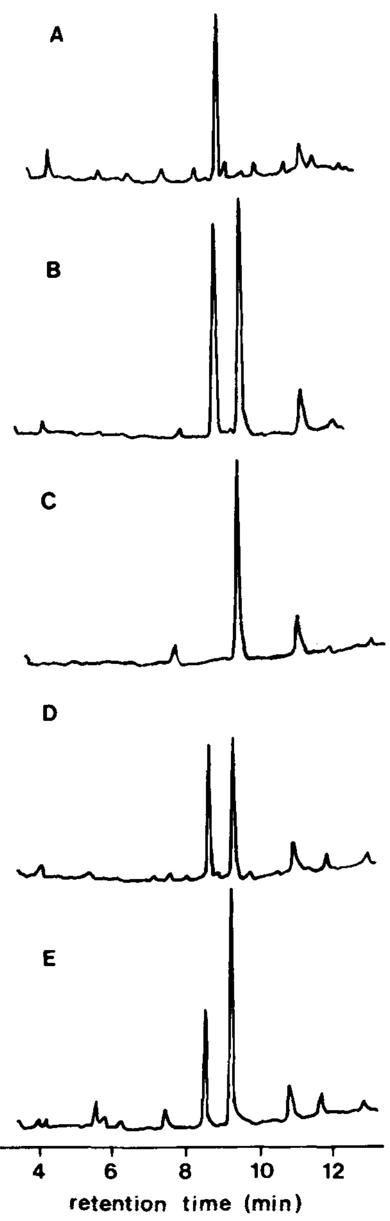

FIG. 1. Detection of 1-*O*-octadecyl-2-*O*-methylglycerol (AMG) in membranes from MO_4 cells grown in the presence of 1-*O*-octadecyl-2-*O*-methylglycero-3-phosphocholine (AMG-PC). Gas liquid chromatography of trimethylsilyl derivatives. The first peak, at a retention of 8.7 min, was not identified. (A) Control cells; (B) cells grown with AMG-PC; (C) AMG prepared from AMG-PC (octadecyl-type) using phospholipase C from *Cl. perfringens*; (D) C added to A; (E) C added to B.

that the incorporated drug was partly metabolized to AMG, presumably by a phospholipase C-like enzyme that is able to split off or exchange the phosphocholine moiety. The gas chromatogram (Fig. 1B), pertaining to cells grown with AMG-PC, shows two main peaks (retention times 8.7 and 9.3 min), the first of which is an unidentified compound that was also found in the control cells (Fig. 1A), while the second peak was identified as AMG. The amount of AMG detected in the membrane preparation corresponded roughly to 1 μg (or 3 nmol) per 10^8 cells. It should be noted that this is a steady-state value. Nothing is known about any possible further metabolism of AMG, such as conversion to a phosphatidic acid analogue or degradation by an alkyl cleavage enzyme (3).

Many cellular activities, including proliferation, differentiation and secretion in endocrine and exocrine systems, depend on transmembrane stimulus-response coupling that may be mediated by PKC (4). Although not yet established, it is not unlikely that this key enzyme in signal transduction is also involved in the mechanism of (tumor) cell adhesion and invasion, possibly through specific phosphorylation of cytoskeleton-associated proteins (4). PKC is thought to be physiologically activated by diacylglycerol derived from receptor-mediated phosphatidylinositol hydrolysis and is the receptor for biologically active phorbol esters, such as PDBu (4). In the following experiments, we have studied the interaction of AMG-PC and AMG with PKC, in both an enzymatic assay and a PDBu-receptor assay.

We have purified human PKC to apparent homogeneity (Fig. 2, right) and used this preparation to study the lipid dependency of the enzyme in the presence of 10 μM Ca^{2+} and in submicromolar Ca^{2+} (excess EGTA) (Table 1). In agreement with literature data (4,15,17), PS was found to be necessary to achieve substantial activation. At submicromolar free Ca^{2+}, like under physiological conditions in the resting cell, only diacylglycerol (diolein) is able to activate PKC in the presence of PS (six- to eightfold stimulation, relative to the basal level with PS only). Diolein alone had no effect (not shown here). At 10 μM Ca^{2+}, the PS-dependent basal activity is much higher, and diolein is not able to increase this activity any further (exp. 2) or more than 30% (exp. 1). Neither AMG-PC nor AMG activate PKC by themselves or in the presence of PS. Rather, they inhibit the basal activities in the presence of PS some 10–20%. The largest inhibitory effect of AMG was found specifically on the diacylglycerol stimulation of the enzyme, precisely the activity that is physiologically relevant and that is generated in the cell upon receptor stimulation. This inhibitory effect of AMG, shown in Figure 2, was dose-dependent and was present in excess EGTA as well as in 10 μM Ca^{2+} (the latter being relevant only in experiment 1, where diolein was indeed stimulating the PS-dependent activity of the enzyme; see Table 1). We have no clear explanation for the variability generally found in the degree of diolein stimulation of the PS-dependent enzyme activity among individual experiments. In contrast to AMG, AMG-PC does not have a significant effect on the diolein-stimulated PKC activity (Fig. 2). As noted above, the drug only inhibits the basal PS-dependent activities somewhat, confirming to a certain extent results of Helfman et al. (18). These authors, however, used only a very crude PKC preparation, unphysiologically high Ca^{2+} concentrations and no diacylglycerol.

TABLE 1

Lipids Dependency of the Activity of Purified Human Protein Kinase C (PKC) toward Histone as a Substrate

	PKC activity (pmol ^{32}P incorporated per min per 10 μl PKC preparation)[a]

[b]PS, diolein, AMG and AMG-PC: 100, 5, 13.3 and 20 μg/ml assay mixture, respectively.

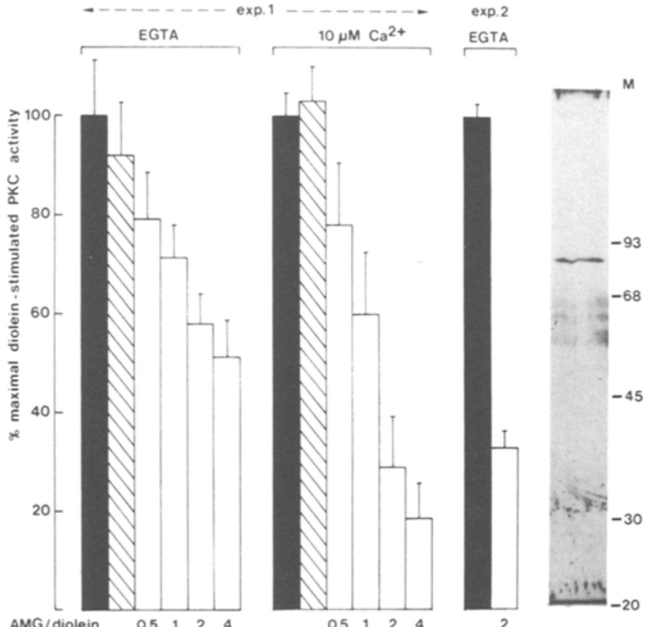

FIG. 2. Effect of 1-*O*-hexadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (AMG-PC) and 1-*O*-hexadecyl-2-*O*-methyl-*rac*-glycerol (AMG) on the diacylglycerol-stimulated, phosphatidylserine (PS)-dependent activity of purified human protein kinase C (PKC) (basal PS-dependent activity, given in Table 1, subtracted) in the presence of 2 mM EGTA or 10 μM Ca^{2+}, as indicated. Solid columns, controls (100%), containing only PS and diolein, 100 and 5 μg/ml assay mixture, respectively; hatched columns, AMG-PC added in a ratio (w/w) AMG-PC/diolein = 2; open columns, AMG added in the ratios (w/w) indicated. Data are means of triplicate values, with SD as indicated. Experiments 1 and 2 correspond to those indicated in Table 1. Right panel: polyacrylamide gel showing the purity of the PKC preparation (from human lymphocytes/platelets) used in the present experiments. The silver-stained gel shows one band at 81 kD. Positions of authentic marker proteins (M) are indicated.

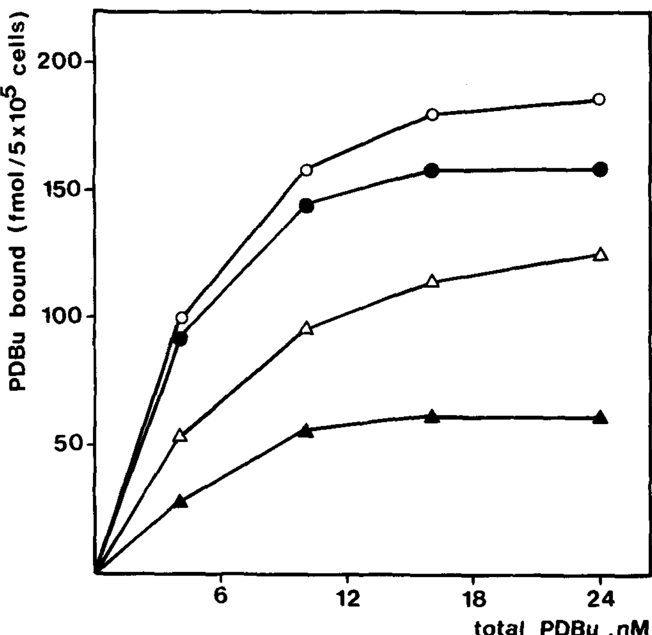

FIG. 3. Binding of ^{3}H-phorbol-12,13-dibutyrate (^{3}H-PDBu) to intact HL-60 cells in the presence of various concentrations of 1-*O*-hexadecyl-2-*O*-methyl-*rac*-glycerol (AMG) as a function of the total ^{3}H-PDBu concentration in the medium. ○, Control cells, without AMG; ●, 25 μM; △, 100 μM; ▲, 200 μM AMG. A representative experiment is shown where data points are means of triplicates (SD < 10%).

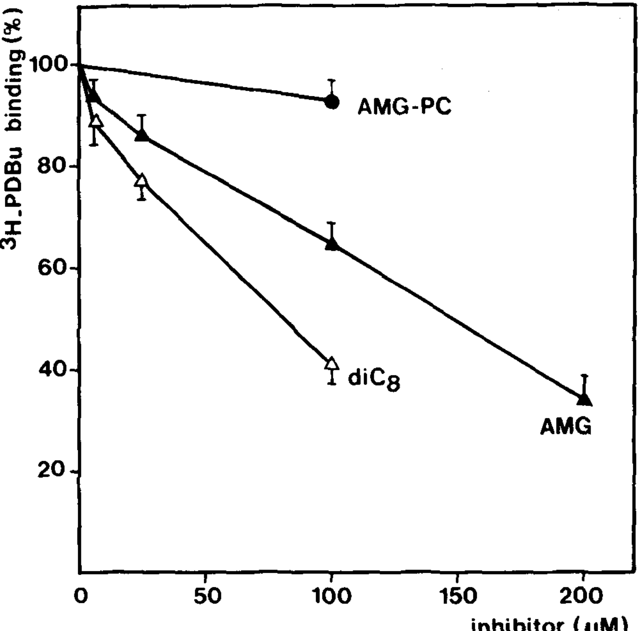

FIG. 4. Inhibition of ^{3}H-phorbol-12,13-dibutyrate (^{3}H-PDBu) binding to intact HL-60 cells by various concentrations of 1-*O*-hexadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (AMG-PC) (●), 1-*O*-hexadecyl-2-*O*-methyl-*rac*-glycerol (AMG) (▲), 1,2-dioctanoyl-*sn*-glycerol (diC_8) (△), in the presence of 20 nM ^{3}H-PDBu. Data points are means of triplicates, with SD as indicated.

A substantial inhibition of the diacylglycerol-stimulated PKC activity, as we have found with AMG, should also be demonstrable in more complicated biological systems, such as PKC-mediated differentiation of HL-60 cells. As a first approach, we have studied in this cell system the effect of AMG on the specific binding of a biologically active phorbol ester, ^{3}H-PDBu, to its receptor (PKC). As shown in Figure 3, this binding is indeed inhibited by AMG in a dose-dependent fashion. At 20 nM PDBu, about 70% inhibition was reached with 200 μM AMG. Under these conditions, we also determined the inhibitory capacity of AMG-PC and diC_8, a membrane-permeable synthetic diacylglycerol, known to be a potent activator of PKC (19,20). Figure 4 shows that ^{3}H-PDBu binding is only minimally inhibited by AMG-PC, whereas diC_8 inhibits this binding twice as much as does AMG. However, if one takes into account that generally only the 1,2-*sn*-enantiomers of diacylglycerol (analogs) are biologically active (17,20) and that AMG is racemic, the inhibitory capacities of AMG and diC_8 may be the same. The concentration in the medium at which these compounds inhibit PDBu binding may seem high, but is, of course, dependent on their extent of incorporation (partitioning) into the apolar region of the cell membrane. This degree of uptake in the membrane is as yet unknown, but may likely be very low. As noted, we have found a steady-state content of about 1 μg (3 nmol) AMG per 10^8 MO_4 cells cultured in the presence of a dose of AMG-PC that only minimally inhibited cell growth. This cellular content of AMG is of the same order of magnitude as the amount of diacylglycerol generated in other cell types upon receptor stimulation (21). This notion together with the data on AMG inhibition of the diacylglycerol-stimulated PKC activity (Fig. 2) could indicate that the formation of AMG from AMG-PC in the cell membrane is physiologically relevant.

In conclusion, the anticancer drug AMG-PC accumulating in tumor cell membranes has a relatively small inhibitory effect on the enzymatic and phorbol ester receptor activities of PKC. However, its metabolite, AMG, detectable in the membranes of tumor cells grown in the presence of the drug, has much larger effects. It inhibits dose-dependently both the binding of PDBu to its receptor and the diacylglycerol-stimulated activity of PKC. The latter effect of AMG on this key enzyme in transmembrane signalling may potentially contribute to the mechanism by which AMG-PC exerts its anticancer activities. Whether this is indeed of physiological relevance remains to be further investigated.

ACKNOWLEDGMENTS

We thank Dr. Hidde L. Ploegh for stimulating discussions and for reading this manuscript. Liesbeth Pastoors and Gea Meijerink are thanked for technical and secretarial assistance, respectively.

[a]Oncologic Center-Vrije Universiteit Brussel, Cancer Research Unit, Brussels, Belgium, [b]Laboratory of Experimental Cancerology, Department of Radiotherapy and Nuclear Medicine, University Hospital, Gent, Belgium, [c]Division of Cell Biology, The Netherlands Cancer Institute, Antoni Van Leeuwenhoekhuis, Amsterdam, The Netherlands, and [d]Division of Hematology and Oncology, Department of Medicine, Technical University Munich, Munchen, Federal Republic of Germany

The antiinvasive activity on MO_4 mouse cells of the following lipid derivatives was tested in vitro: an alkyl-lysophospholipid derivative (ET-18-OCH_3), a thioether-phospholipid derivative (BM 41.440), an alkyl-linked lipoidal amine (CP-46,665) and a naturally occurring ester-linked phospholipid (2-LPC). In this test, BM 41.440 had the same antiinvasive potency as ET-18-OCH_3, whereas CP-46,665 and 2-LPC had no effect on invasion. Comparison of the antiinvasive effect of ET-18-OCH_3 on three types of cells showed the following ranking: 12R1C-RK rat kidney adenovirus type 12 transfected cells > MO_4 mouse cells > LLC-H61 Lewis lung carcinoma cells. This ranking was not reflected in ET-18-OCH_3-induced changes of cell surface exposed glycopeptides derived from the three types of cells metabolically labeled with radioactive fucose. The present and previous experiments suggested that changes in invasion caused by lipid derivatives depended upon relative cell surface fucosyl-glycopeptide alterations in both the invasive cells and the normal tissue.

Lipids 22, 847–850 (1987).

The alkyl-lysophospholipid ET-18-OCH_3 has been shown to inhibit metastasis of Lewis lung carcinoma (1). Experiments in vitro with malignant mouse MO_4 cells suggested an antiinvasive activity of ET-18-OCH_3 at concentrations that permitted growth and directional migration of these cells (2). We have examined whether the antiinvasive effect of ET-18-OCH_3 on MO_4 cells was shared by other lipid derivatives, namely, a thioether-lysophospholipid, BM 41.440; an alkyl-linked lipoidal amine, CP-46,665; and a naturally occurring ester-linked phospholipid derivative, 2-LPC. We also examined whether two other malignant cell types, the LLC-H61 Lewis lung carcinoma subline (3) and the 12RIC-RK rat kidney adenovirus type 12 transfectant (4), were sensitive to the antiinvasive activity of ET-18-OCH_3. Since alterations of invasion in vitro had been ascribed to changes in cell surface glycopeptides (5), we compared the effect of ET-18-OCH_3 on invasion with that on the gel filtration profiles of cell surface fucosyl-glycopeptides from the three cell types.

MATERIALS AND METHODS

Cell lines. MO_4 cells (obtained through M. De Brabander, Janssen Pharmaceutica Research Laboratories, Beerse, Belgium) are immortalized fetal C3H mouse cells transformed by Kirsten murine sarcoma virus (6); they produced invasive and metastatic sarcomas after transplantation into syngeneic mice (7).

12R1C-RK cells (obtained through L. Smets, The Netherlands Cancer Institute, Amsterdam, The Netherlands) are baby WAG RIJ rat kidney cells, which after transfection with a genomic fragment of the oncogenic adenovirus type-12 DNA (left 0 to 16%) gave rise to tumors in nude mice (4).

LLC-H61 cells (obtained from G. Vaes, Institute of Cellular and Molecular Pathology, Brussels, Belgium) were derived from a highly metastatic subclone of a C57B1/6 mouse Lewis lung carcinoma cell line (3).

LLC-H61 cells and 12R1C-RK cells were maintained in Dulbecco's Modification of Eagle's Medium (DMEM, Flow Laboratories, Irvine, Scotland), MO_4 cells in Minimum Essential Medium Eagle (modified) with Earle's salts and nonessential amino acids (EMEM, Flow), both supplemented with 10% (v/v) fetal bovine serum, 0.05% (w/v) L-glutamine, 250 IU/ml penicillin and 100 μg/ml streptomycin (hereafter called culture medium).

Drugs. The following lipid derivatives were dissolved to concentrations between 1 and 30 μg/ml in the culture medium described with the cell lines: 2-lysophosphatidylcholine (2-LPC; F. Roth, Karlsruhe, FRG); *rac*-1-*O*-octadecyl-2-*O*-methylglycero-3-phosphocholine (ET-18-OCH_3; Medmark Chemicals, Muenchen-Gruenwald, FRG); *rac*-1-hexadecyl-mercapto-2-methoxymethyl-3-propyl-phosphoric-acid-monocholin-ester (BM 41,440; Boehringer Mannheim, Mannheim, FRG); 1-2-decycloxy-3-(4,4 amino-methyl, phenylpiperidine) (CP-46,665; Pfizer Central Research, Groton, CT). The structure of these drugs has been described (8,9).

Assay for invasion. Spheroids of MO_4 or 12R1C-RK cells (0.2 mm in diameter) or clusters of LLC-H61 cells were confronted with precultured fragments of 9-day-old embryonic chick heart (PHF) (0.4 mm in diameter) in individual cultures on a Gyrotory® shaker (10). The specificity and the relevance of this assay have been reviewed (11). Drugs were added at the onset of the culture. Confronting pairs were fixed after 4 days in Bouin Hollande's solution for embedding in paraffin and complete serial sectioning into 8-μm-thick sections. Consecutive sections were stained with hematoxylin and eosin or with an antiserum against embryonic chick heart (12). Histological analysis of invasion was based on occupation and degeneration of the PHF and scored on criteria

Abbreviation: PHF, precultured embryonic chick heart fragment.

described earlier (13) and slightly modified: grades I and II, absence of invasion; grades II-III, a few single cells were inside the PHF without evidence of degeneration; grade III, invasion in less than half of the PHF; grade IV, invasion in more than half of the PHF.

Isolation and analysis of cell surface glycopeptides. Changes in the fucosyl-glycopeptides of the cell membrane were monitored by incubating the cells for 16 hr at 37 C in culture medium supplemented with either L-[6-^{3}H]fucose (1μCi/ml, 60 Ci/mmol) or L-[1-^{14}C]fucose (0.5 μCi/ml, 60 mCi/mmol), both purchased from the Radiochemical Center Amersham (Buckinghamshire, UK). The glycopeptides were isolated from the surface of the cell with the help of proteolytic enzymes as described (14) and dialyzed against bidistilled water. Gel filtration was performed on Bio-Gel P-10:Sephadex G-50 (2:1, w/w) columns, eluted with 0.1 M Tris-HCl buffer (pH 8.0) containing sodium dodecyl sulphate (0.1%; w/v), EDTA (0.01%, w/v) and 2-mercaptoethanol (0.1%, v/v). Cell surface glycopeptides from treated and untreated cells were investigated by cochromatography.

RESULTS AND DISCUSSION

Effect of lipid derivatives on invasion. Invasion of MO_4 cells, 12R1C-RK cells or LLC-H61 cells into PHF was

Asterisks indicate matched experiments. Roman figures are grades of invasion after 4 days, as described in Materials and Methods; number of cultures in parentheses. n.d., No data.

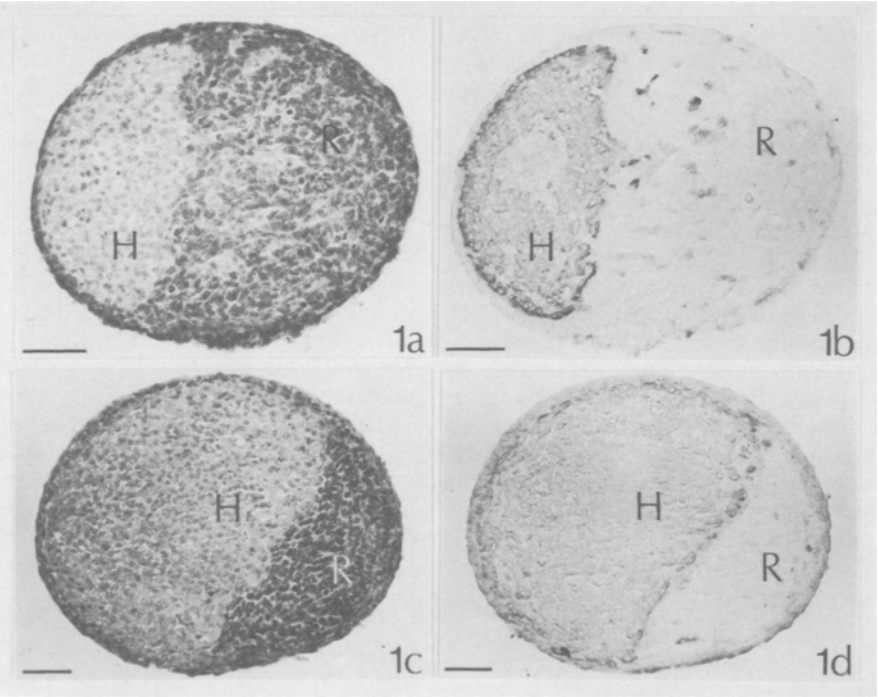

FIG. 1. Photomicrographs of sections from confronting cultures of 12R1C-RK cells (R) and embryonic chick heart (H) without (1a and 1b) and with 3 µg/ml ET-18-OCH$_3$ (1c and 1d). Fixation after 4 days; staining with hematoxylin-eosin (1a and 1c) and with antiserum against chick heart (1b and 1d). Scale bars = 50 µm.

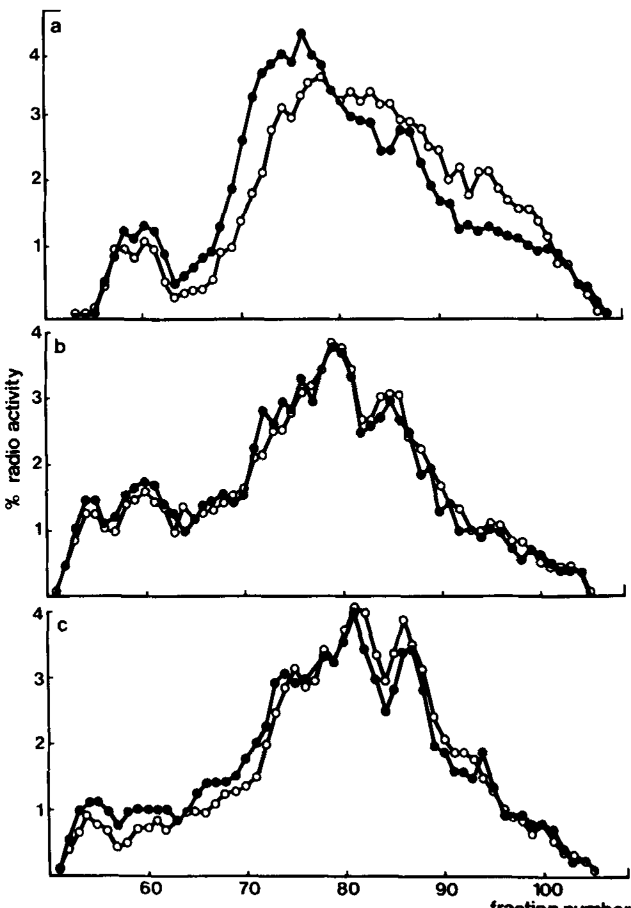

FIG. 2. Gel filtration profiles of surface glycopeptides derived from untreated (open symbols) and ET-18-OCH_3-treated (closed symbols) MO_4 (a), 12R1C-RK (b) and LLC-H61 (c) cells metabolically labeled with [^{3}H]fucose or with [^{14}H]fucose; cochromatography on Bio-Gel P-10:Sephadex G-50 columns.

obvious in all control cultures (Table 1), as described earlier (10,15). For MO_4 cells, ET-18-OCH_3 and BM 41.440 were antiinvasive in this assay; BM 41.440 had the same potency as ET-18-OCH_3, since both inhibited invasion at a concentration of 10 μg/ml. At this concentration, CP-46,665 had no effect on the invasion of MO_4 cells (Table 1). The differential antiinvasive effect of CP-46,665 vs ET-18-OCH_3 and BM 41.440 was not reflected by similar differences in their cytostatic and cytotoxic activities in vitro on cells from human tumors and leukemias (8,9). This discrepancy, together with the minor effect of ET-18-OCH_3 on MO_4 cell proliferation (2), suggested different molecular targets for antiinvasiveness as compared to cytostasis or cytotoxicity. 12R1C-RK cells (Fig. 1) were more sensitive than MO_4 cells to the antiinvasive activity of ET-18-OCH_3, whereas LLC-H61 cells were less or not sensitive (Table 1).

Effect of ET-18-OCH_3 on cell surface glycopeptides. To investigate the effect of ET-18-OCH_3 on the carbohydrate moieties of surface glycoproteins, the three types of cells were incubated for 48 hr with ET-18-OCH_3 at the lowest concentration that inhibited invasion. Figure 2 illustrates the elution profiles of glycopeptides derived from treated as compared to untreated MO_4 cells, 12R1C-RK cells and LLC-H61 cells. The glycopeptides from cells treated with ET-18-OCH_3 showed a slight shift in the gel filtration profiles toward higher apparent molecular weight classes, which was most obvious in MO_4 cells. Since the effect of ET-18-OCH_3 concerns the degree of glycopeptide sialylation (5), the differences in the effect of the drug on various types of cells might depend on the amount of sites amenable to sialylation. Figure 2 suggested that the surfaces of MO_4 as well as LLC-H61 cells contain relatively more such sites than the surface of 12R1C-RK cells.

It is unlikely that inhibition of invasion in the present experiments was due solely to alterations in glycopeptides in the malignant cells, since ranking of the sensitivity of the three cell types to the antiinvasive effect of ET-18-OCH_3 was not reflected by corresponding shifts in their glycopeptide profiles.

More probably the effects of ET-18-OCH_3 on the invasion of the three cell types have to be interpreted on the basis of glycopeptide profiles, not only from the confronting cells but also from PHF, for the following reasons: i) Nonmalignant cells transiently became invasive after pretreatment with ET-18-OCH_3, which caused similar alterations in glycopeptides as permanently present in malignant cells (5); ii) Pretreatment of PHF, causing a shift in gel filtration profiles toward that of malignant cells, inhibited invasion. One explanation of these observations is that invasion depends upon differences between cell surface glycoproteins of the PHF as compared to the confronting cells (5,16).

[Received January 30, 1987]

Ether Lipids Inhibit the Effects of Phorbol Diester Tumor Promoters[1]

Larry W. Daniel[a,*], Lori A. Etkin[a], Bennett T. Morrison[a], Judy Parker[a], Susan Morris-Natschke[b], Jefferson R. Surles[b] and Claude Piantadosi[b]

[a]Department of Biochemistry, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, North Carolina, and [b]University of North Carolina, School of Pharmacy, Division of Medicinal Chemistry and Natural Products, Chapel Hill, North Carolina

Recent studies have shown that the tumor promoter 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA) stimulates protein kinase C (PKC), whereas the ether-linked phospholipid 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycerol-3-phosphocholine ($ET\text{-}18\text{-}OCH_3$) inhibits PKC activity in vitro. Therefore, the antitumor effects of $ET\text{-}18\text{-}OCH_3$ could be due to its inhibition of PKC activity and the effects of tumor promotion. TPA stimulates arachidonic acid release, prostaglandin synthesis, phosphatidylcholine synthesis and the degradation of phosphatidylcholine by phospholipase C in Madin Darby canine kidney (MDCK) cells. Therefore, we have determined the effects of $ET\text{-}18\text{-}OCH_3$ on these consequences of TPA stimulation. Preliminary experiments determined that $ET\text{-}18\text{-}OCH_3$ inhibited PKC partially purified from MDCK cells by ion-exchange chromatography on DEAE-cellulose. In addition, $ET\text{-}18\text{-}OCH_3$ inhibited the TPA-stimulated phosphorylation of a 40,000-dalton protein in intact MDCK cells. These data indicate that $ET\text{-}18\text{-}OCH_3$ is an effective inhibitor of PKC activity in MDCK cells. In addition, $ET\text{-}18\text{-}OCH_3$ was found to inhibit arachidonic acid release and prostaglandin synthesis. The inhibition of prostaglandin synthesis appears to be secondary to inhibition of arachidonic acid release, since $ET\text{-}18\text{-}OCH_3$ does not inhibit TPA-stimulated synthesis of prostaglandin H synthase or the activity of the enzyme directly (Parker, J., Daniel, L. W., and Waite, M. [1987] *J. Biol. Chem. 262,* 5385–5393). $ET\text{-}18\text{-}OCH_3$ also inhibits TPA-stimulated phosphatidylcholine synthesis and phosphatidylcholine degradation by phospholipase C. These data provide evidence that the antineoplastic ether lipids inhibit the biochemical effects of the tumor promoter TPA in intact cells and indicate that this inhibition may have a role in their biological activities.

Lipids 22, 851–855 (1987).

The phorbol diester tumor promoter 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA) causes profound changes in the metabolism of cultured cells. Among these changes are stimulated release of arachidonic acid from cellular phospholipids and increased prostaglandin synthesis (1,2).

In addition, TPA causes an increase in synthesis of choline-containing phosphoglycerides (PC) and an increase in PC degradation by a phospholipase C (Scheme 1) (3). This stimulated cycling of cellular PC results in transient increases in diglycerides. It has been suggested that this "PC cycle" provides an alternate mechanism for generating bioactive diglycerides that is independent of the turnover of phosphatidylinositol (3,4).

Thus, an inhibitor of the PC cycle would be useful in determining the biological significance of these reactions. Furthermore, these alterations in lipid metabolism are of interest since the stimulatory activity correlates well with the tumor promoting activities of the phorbol diesters (5). TPA has been shown to activate Ca^{2+}-activated phospholipid-dependent protein kinase (PKC) (6), which is thought to mediate many of the biological activities of TPA (7). Thus, it was logical to test the effects of a variety of PKC inhibitors on TPA-stimulated PC turnover. Structurally diverse inhibitors of PKC were chosen (Fig. 1): 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine ($ET\text{-}18\text{-}OCH_3$), 1-*S*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine ($ET\text{-}18S\text{-}OCH_3$), 1-*O*-octadecylpropane-

Abbreviations: TPA, 12-*O*-tetradecanoyl-phorbol-13-acetate; PKC, Ca^{2+}-activated, phospholipid-dependent protein kinase; MDCK, Madin Darby canine kidney; PC, choline-containing phosphoglycerides; CI, 1-(5-isoquinolinsulfonyl)piperazine; CP 46,665, 4-aminomethyl-1-[2,3-(di-n-decycloxy)n-propyl]-4-phenylpiperidine dihydrochloride; $ET\text{-}18\text{-}OCH_3$, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine; ET-18-H, 1-*O*-octadecylpropanediol-3-phosphocholine; $ET\text{-}18\text{-}S\text{-}OCH_3$, 1-*S*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine; TLC, thin layer chromatography; PC-PLC, a TPA-stimulated phospholipase C that degrades PC.

diol-3-phosphocholine (ET-18-H) (8), 1-(5-isoquinolinsulfonyl)piperazine (CI) (9) and 4-aminomethyl-1-[2,3-(di-n-decycloxy)n-propyl]-4-phenylpiperidine dihydrochloride (CP 46,665) (10). ET-18-OCH_3 is a diether-linked phospholipid with antitumor activity (11). CI is an isoquinolinosulfonylpiperazine, structurally similar to those developed by Hidaka et al. (12); CP 46,665 is a lipoidal amine, with antineoplastic activity (13,14). Madin Darby canine kidney (MDCK) cells were used in these experiments because they had previously been shown to respond to low concentrations of TPA, and their response to TPA has been well characterized (1–3).

MATERIALS AND METHODS

MDCK cells and cell culture reagents were purchased from Flow Laboratories (Rockville, MD). $[^{32}P]_i$ (carrier-free) was obtained from ICN (Irvine, CA). [Methyl-^{3}H]-choline chloride (78 Ci/mmol) was obtained from Amersham Corp. (Arlington Heights, IL); En^{3}Hance and [methyl-^{3}H]choline chloride (80 Ci/mmol) were from NEN Research Products (Boston, MA). All solvents were purchased from Fisher Chemicals (Pittsburgh, PA) and were either reagent grade or redistilled in the laboratory. Cell cultures were harvested and the lipids were extracted as described by Daniel et al. (3). Phospholipids were separated by thin layer chromatography (TLC) using a solvent system of chloroform/methanol/acetic acid/water (50:25:8:4, v/v/v/v). The radiolabeled products were located by autoradiography (3) or by scanning the chromatograms with a Bioscan radiochromatogram scanner (Bioscan Inc., Washington, DC). Lipid standards for TLC were obtained from Serdary Research Laboratories (London, Ontario, Canada). Silica Gel 60 plates were from E. Merck (Darmstadt, FRG). TPA, mezerein and phorbol retinoate acetate were obtained from LC Services Corp. (Woburn, MA).

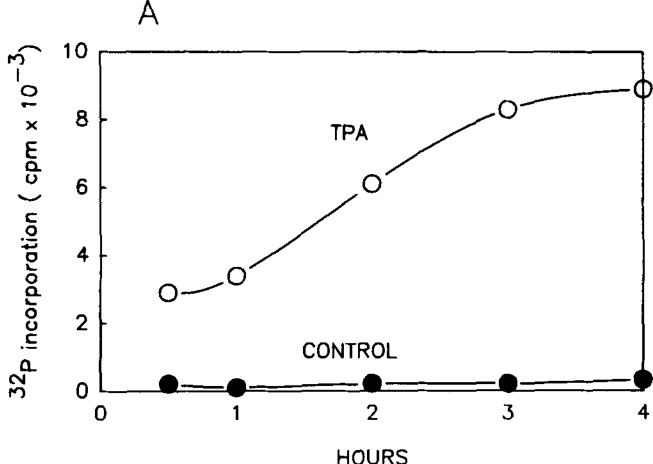
ET-18-OCH_3 and ET-18-H were gifts from Dr. W. E. Berdel, Munich, FRG. CP 46,665 was a gift from Dr. K. E. Jensen, Central Research, Pfizer, Inc., Groton, CT. CI was a gift of Dr. Craig Gerard, Bowman Gray School of Medicine, Winston-Salem, NC, and was prepared as described by Gerard et al. (9). ET-18S-OCH_3 was prepared as described previously (15).

Some variability was observed in the total incorporation of radiolabel among experiments. This variability made compiling data from different experiments difficult; therefore, the data are presented as the average of two separate samples from a representative experiment, which was one of three or more separate experiments for each graph.

RESULTS

Preliminary experiments were done to further characterize the stimulation of PC synthesis by TPA. To determine the time course of stimulation, cells were incubated in phosphate-free medium for various times with and without TPA (10 nM), and $[^{32}P]_i$ (50–100 μCi/ml) was then added for 30 min. At the end of the incubation, the medium was discarded and the incorporation of $[^{32}P]_i$ into PC was determined. There was a significant stimulation of $[^{32}P]_i$ incorporation after 30 min preincubation; however, the stimulation continued to increase with time of preincubation (Fig. 2A). In all further experiments, 3 hr was chosen for preincubation. To determine if other tumor promoters stimulated $[^{32}P]_i$ incorporation in MDCK cells, mezerein and phorbol retinoate acetate were also tested at equimolar concentrations in the range of 1 to 100 nM. These compounds and TPA were found to have similar effects on $[^{32}P]_i$ incorporation (data not shown). TPA also caused a stimulated incorporation of [^{3}H]choline into PC (data not shown).

The stimulation of $[^{32}P]_i$ incorporation was quite specific for PC; $[^{32}P]_i$ incorporation into ethanolamine-, serine- or inositol-containing phosphoglycerides was not stimulated (Fig. 2B). Our previous studies have shown that TPA does not stimulate the incorporation of $[^{32}P]_i$ into phosphatidylinositol, phosphatidylinositol 4-phosphate or phosphatidylinositol 4,5-bisphosphate (16).



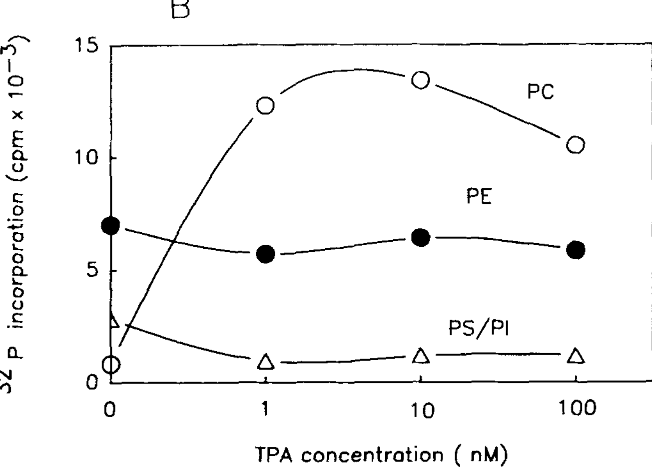


FIG. 2. Effect of preincubation time with TPA and concentration of TPA on the incorporation of $[^{32}P]_i$ into cellular phospholipids. MDCK cells (5×10^5/ml) were preincubated with TPA in serum-free, phosphate-free medium for the indicated times, and the cells were then incubated with $[^{32}P]_i$ (100 μCi/ml) for an additional 30 min. (A) ○, TPA (10 nM); ●, control without TPA. The incorporation into PC was determined as described in Materials and Methods. Cells were also incubated with varying concentrations of TPA for 3 hr and then with $[^{32}P]_i$ as described above, and the incorporation into cellular phospholipids was determined as described in Materials and Methods. (B) ○, PC; ●, phosphatidylethanolamine; △, phosphatidylserine plus phosphatidylinositol.

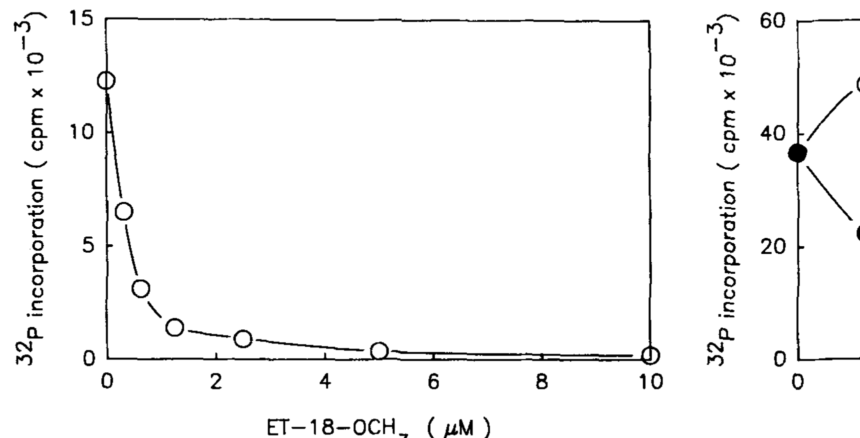

FIG. 3. Effect of ET-18-OCH$_3$ on TPA-stimulated PC synthesis. MDCK cells (5×10^5/ml) were incubated with TPA (10 nM) and the indicated concentration of ET-18-OCH$_3$ for 3 hr, and [^{32}P]$_i$ was added for an additional 30 min.

FIG. 4. Effect of ET-18-H and CP 46,665 on TPA-stimulated PC synthesis. ET-18-H (●) and CP 46,665 (○) were tested using conditions identical to those described in the legends to the previous figures.

FIG. 5. Effect of ether lipid analogs on TPA-stimulated PC hydrolysis. MDCK cells (5×10^5/ml) were prelabeled for 18 hr with [^{3}H]choline (1 µCi/ml); then the medium was removed and replaced with fresh medium containing 10^{-7} M TPA (○) or without TPA (●), and the concentrations of inhibitors were indicated. The release of radiolabel into the medium was determined after 1, 2 and 4 hr of incubation. The data presented represents 4 hr of incubation.

The simultaneous addition of ET-18-OCH_3 during the preincubation of MDCK cells caused a marked dose-dependent suppression of the stimulation of $[^{32}P]_i$ incorporation into PC (Fig. 3). ET-18S-OCH_3 was equally effective when tested under identical conditions (data not shown). When CI was tested in three separate experiments under conditions identical to those given above, no suppression of $[^{32}P]_i$ incorporation into PC was observed in the concentration range of 5 to 500 μM (data not shown). Similarily, CP 46,665 was tested in the concentration range of 1 to 10 μM, and no inhibition of TPA-stimulated $[^{32}P]_i$ incorporation into PC could be demonstrated (Fig. 4). The alkylphospholipid ET-18-H, which is structurally similar to ET-18-OCH_3, was tested and found to inhibit PC synthesis (Fig. 4). The concentration dependence of ET-18-H is similar to ET-18-OCH_3; however, ET-18-H is somewhat less effective.

We have previously shown that the release of water-soluble radioactive compounds from cells prelabeled with [^{3}H]choline is due to a TPA-stimulated phospholipase C that degrades PC (PC-PLC) (3). Therefore, quantitation of water-soluble radiolabel was used to test the effects of PKC inhibitors on PC-PLC. Phospholipids were also extracted and identified by TLC (3) to confirm that PC was the source of the water-soluble product (data not shown). Cells were prelabeled with [^{3}H]choline for 18 hr, then treated with varying concentrations of PKC inhibitors, with or without TPA (10^{-7} M). In these experiments, [^{3}H]choline release was greater in TPA-stimulated cells than in control cells (Fig. 5). ET-18-OCH_3 (Fig. 5A) and ET-18S-OCH_3 (Fig. 5B) inhibited the release of [^{3}H]choline. However, two other PKC inhibitors CI (Fig. 5C) and CP 46,665 (Fig. 5D) were without effect.

DISCUSSION

Vogler et al. (17) recently demonstrated that ET-18-OCH_3 inhibits [^{3}H]choline incorporation into HL60 cells. These authors did not use TPA-stimulated cells; however, they suggested that the mechanism by which ET-18-OCH_3 inhibits PC synthesis may be due to protein kinase C inhibition. The data reported here suggest that the inhibition of PC synthesis by ET-18-OCH_3 and ET-18-H does not involve protein kinase C, since two other inhibitors of protein kinase C, CI and CP 46,665, when used at concentrations proven effective in preventing other effects of TPA treatment, are without effect. Our related studies (18) have shown that ET-18-OCH_3 and CI inhibit PKC partially purified from MDCK cells by DEAE-cellulose chromatography. In addition, both compounds are effective at equimolar amounts in inhibiting TPA-induced arachidonic acid release and prostaglandin synthesis in MDCK cells. This is noteworthy, since CI was without effect in the present study when used at 400-fold molar excess of the IC_{50} for ET-18-OCH_3. The concentrations of CI tested were greater than that required to inhibit TPA or diglyceride-stimulated respiratory burst in human neutrophils (7). Previous studies with CP 46,665 have shown that it is as effective as ET-18-OCH_3. For example, CP 46,665 is as effective as ET-18-OCH_3 in an assay to measure protein kinase C inhibition (8) and in assays to measure cytostatic activity (11).

ET-18-OCH_3, ET-18S-OCH_3 and ET-18-H are structurally similar to lyso-PC, which has been shown to be a potent inhibitor of CTP:phosphocholine cytidylyltransferase, the rate-controlling enzyme in PC synthesis (19), and CDP choline:1,2-diacylglycerol choline phosphotransferase, the last enzyme in PC synthesis (20). Therefore, the alterations in PC metabolism by ET-18-OCH_3, ET-18S-OCH_3 and ET-18-H may be due to their structural similarity to lyso-PC rather than to their effects on protein kinase C. The structural similarities of these ether lipids to lyso-PC may also be important with regard to their inhibition of lyso-PC acyltransferase (21), the inhibition of which correlates with cellular cytotoxicity (22).

These data suggest that protein kinase C is not involved in TPA-stimulated PC synthesis and that TPA may have biological effects other than those involving protein kinase C. This view is supported by recent reports that synthetic diacylglycerides (23,24) and bryostatin (24) stimulate protein kinase C in HL60 cells, but unlike TPA do not induce differentiation (26) or changes in PC metabolism (23).

Diacylglycerol is a precursor of PC and when added exogenously could stimulate PC synthesis by providing more substrate for the CDP choline:1,2-diacylglycerol cholinephosphotransferase. However, exogenous glycerides are converted primarily to the corresponding phosphatidic acid derivative by HL60 cells (27) and do not mimic the TPA-induced changes in PC metabolism. Recent studies have demonstrated that the TPA-induced alteration in PC metabolism results from a cyclic breakdown and resynthesis of PC (3). This pathway is similar to the phosphatidylinositol cycle and provides an alternate source of diglycerides. The significance of this "PC cycle" remains to be determined. Therefore, the lipid inhibitors of this cycle that are structural analogs of lysophospholipids may be useful tools in determining the role of altered PC metabolism in the mechanism of tumor promotion.

The ether phospholipid 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (OM-GPC) is known to be a potent inhibitor of cell growth. Metabolic studies in both Raji and L1210 leukemic cells on OM-GPC, ^{3}H-labeled in the methyl groups of the choline moiety, showed a (diacyl)-phosphatidylcholine as the only labeled metabolite. Since the formation of radiolabeled (diacyl)-phosphatidylcholine showed a direct correlation with cell death, we tested other lipid analogs. One of these compounds, hexadecylphosphocholine (He-PC), which was ^{3}H-labeled in the methyl-choline groups, showed a formation of labeled (diacyl)-phosphatidylcholine similar to that found with OM-GPC. Again, there was a direct linear correlation between the formation of the labeled product and cell death. He-PC was found to be a potent cell toxin in in vitro experiments on cell cultures. However, analogs with an elongated phosphor to trimethylammonium distance showed no toxicity towards the cells in in vitro experiments. From the data, we conclude that the ether phospholipids are substrates for a phospholipase C or related enzyme. This subtrate property may be responsible for the toxicity of the compounds in neoplastic cells.
***Lipids 22,* 856-861 (1987).**

The (ether)-phospholipid 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (OM-GPC) is known to be a potent inhibitor of cell growth (1-7). It is known to stimulate macrophages (8), destroy tumor cells in vitro, and is suggested to be more lethal to tumor cells than to normal cells. The hypothesis on the selectivity of the compound towards neoplastic cells is based on the observation of Soodsma et al. (9) that there is a difference in the level of alkyl glyceromonooxygenase (AGMO; E.C.1.14.16.5) between normal cells and several neoplastic cells. However, later studies showed that OM-GPC is not a substrate for AGMO in vitro (10-12). Thus, the selective action of OM-GPC to tumor cells cannot be explained by the cellular levels of AGMO. This view also is supported by a recent study in which AGMO levels do not show any correlation with the toxic effects of OM-GPC in different cell lines (13). To understand its metabolic fate and learn about its mechanism of action, we synthesized OM-GPC, ^{3}H-labeled in the methyl groups of the choline moiety. The metabolism of the radiolabeled compound in Raji and L1210 leukemic cells was investigated. Analysis of the results on the metabolic fate of these molecules in the different cell lines enabled us to design a new class of antineoplastic agents, the alkyl phosphocholines.

Abbreviations: OM-GPC, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-hoshocholine; OM-G, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycerol; He-PC, hexadecylphosphocholine; Ol-PC, octadecenyl(9,10)phosphocholine; Ol-P(C_6)C, octadecenyl(9,10)phospho-(N,N,N-trimethylamino)hexanol.

MATERIALS AND METHODS

1-*O*-Octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine, hexadecylphosphocholine, octadecenyl(9,10)phosphocholine and octadecenyl(9,10)phospho-(N,N,N-trimethylamino)hexanol were prepared essentially as described elsewhere (14-16). Radiolabeled 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phospho[^{3}H-methyl]choline and hexadecylphospho[^{3}H-methyl]choline were prepared in our laboratory (17), using [^{3}H]methyliodide (Amersham, Braunschweig, FRG). Other chemicals were of analytical grade and used without further purification.

Raji cells (B-lymphoblastic lymphome) and L1210 cells (murine leukemic cells) were grown in RPMI 1640 medium (GIBCO, Karlsruhe, FRG), supplemented with 10% fetal calf serum (Biochrom, Berlin, FRG). Streptomycin (200 mg/l), nystatin (2.10^4 IE/l), and penicillin (2.10^5 IE/l) were added routinely to the culture medium.

Incubation of cells (10 ml, 2×10^5 cells/ml) was performed with 2.5 μg/ml OM-GPC or 10 μg/ml of alkyl phosphocholine per ml. After the indicated time periods, aliquots of the cell suspension were counted in a Neubauer cell-counting chamber and tested for viability using the trypan blue dye exclusion test (18). The cell suspension was then diluted with 10 ml serum-free medium, and the cells were centrifuged at 800 g for 10 min at room temperature. The supernatant was collected, and the cells were washed twice with 10 ml serum-free medium. Of the combined supernatants (40 ml), 100 μl aliquots were taken for ^{3}H counting. The pellet was extracted twice according to Bligh and Dyer (19). The extracts were combined; 2.5 ml water and 2.5 ml chloroform were added for phase separation. The chloroform layer (lower phase) was collected, and the water phase was reextracted with 5 ml chloroform. After phase separation, aliquots of the water and chloroform phases were taken for ^{3}H counting. The chloroform phase was dried under a stream of nitrogen and redissolved in a small volume of chloroform/methanol (9:1, v/v). The organic material was applied to a thin layer chromatography plate, and the plate was developed in chloroform/methanol/acetic acid/water 100:60:20:5, v/v/v/v). After drying, the plate was scanned for radioactive products in an Automatic Linear Analyzer LB 284 complemented with a Data System LB 500 (Berthold, Wildbad, FRG).

Uptake of OM-GPC by the cells was determined by incubation with radiolabeled compound (S.A. 200 mCi/mmol). The cells (2×10^6 cells in 2 ml medium containing 20 μg OM-GPC) were incubated for the indicated time period and then immediately diluted with 4 ml ice-cold medium containing 20% (v/v) fetal calf serum. The cells were centrifuged 10 min at 800 g, and the supernatant was discarded. The cells were washed twice with 10 ml ice-cold medium containing 10% fetal calf serum. After the last centrifugation, the pellet was submitted to a Bligh and Dyer extraction (19). Aliquots of the organic phase were used to determine the amount of radiolabel taken up by the cells.

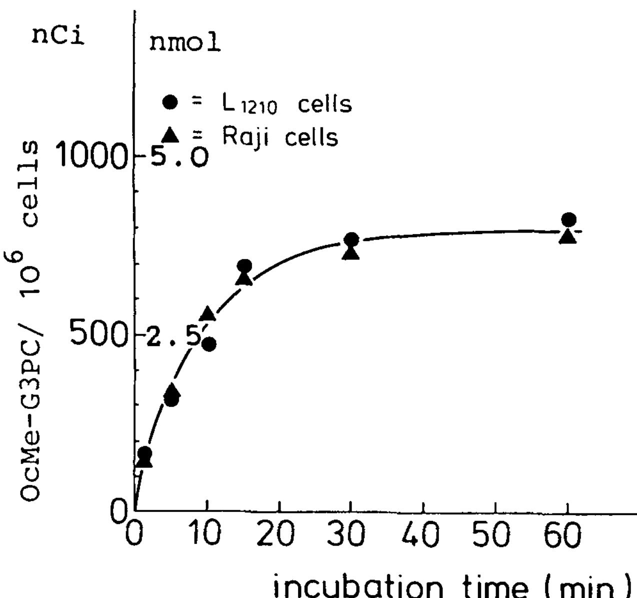

FIG. 1. Kinetics of uptake of OM-GPC in Raji and L1210 cells. Cells were incubated in a RPMI-medium containing 2.5 μg/ml of radiolabeled compound (200 mCi/mmol). At indicated time intervals, the cells were harvested directly after dilution of the cell suspension with an ice-cold RPMI-medium that contained 20% fetal calf serum. After being washed twice with the medium, the cell pellet was extracted according to Bligh and Dyer (19), and the organic phase was counted for radioactivity.

Methanolysis. The newly formed metabolite with Rf-values similar to lecithin was eluted from the thin layer plate with methanol. About 50 nmol lecithin containing 100 nCi ^3H label was treated with a solution of 200 mg potassium tert butylate in 2.5 ml methanol. After 15 min incubation at 50 C, 2 ml each of NaCl saturated water and chloroform were added. The mixture was vigorously shaken. After phase separation aliquots of both phases were counted for radioactivity.

RESULTS AND DISCUSSION

Raji and L1210 cells were incubated with the radiolabeled (ether)-phospholipid OM-GPC. As shown in Figure 1, the rate of uptake was similar for both cell lines; equal amounts of OM-GPC were taken up by both cell lines. From the data, it is evident that the cells already show maximal uptake of the compound after 60 min. Beyond this period, the concentration of OM-GPC per 10^6 cells remains constant (800 pmol/10^6 cells). Additional uptake depends only on the growth rate of the respective cell line.

During the incubation period of three days, we observed the following time dependent effects (Fig. 2). In the case of Raji cells, there is almost no effect on cell growth during the first 48 hr, whereas L1210 cells showed a markedly reduced growth rate. At the end of the third day, cell growth is almost completely stopped for both cell lines. As shown in Figure 3, similar results were obtained using the trypan blue dye exclusion test. The number of trypan

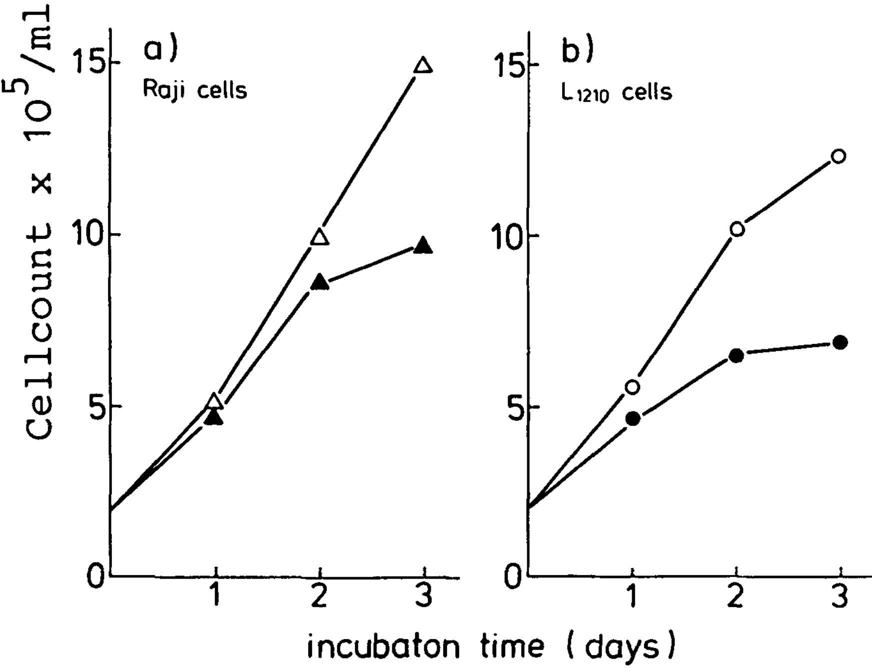

FIG. 2. Effect on cell growth of 2.5 μg OM-GPC/ml for Raji (a, n = 4) and L1210 (b, n = 5) cells. Cells were grown in a RPMI-medium containing 10% fetal calf serum. Cells were counted in a Neubauer cell-counting chamber. Open symbols: control cells (without OM-GPC). Closed symbols: cells in contact with OM-GPC. Standard deviations were 5–10% of total cell count.

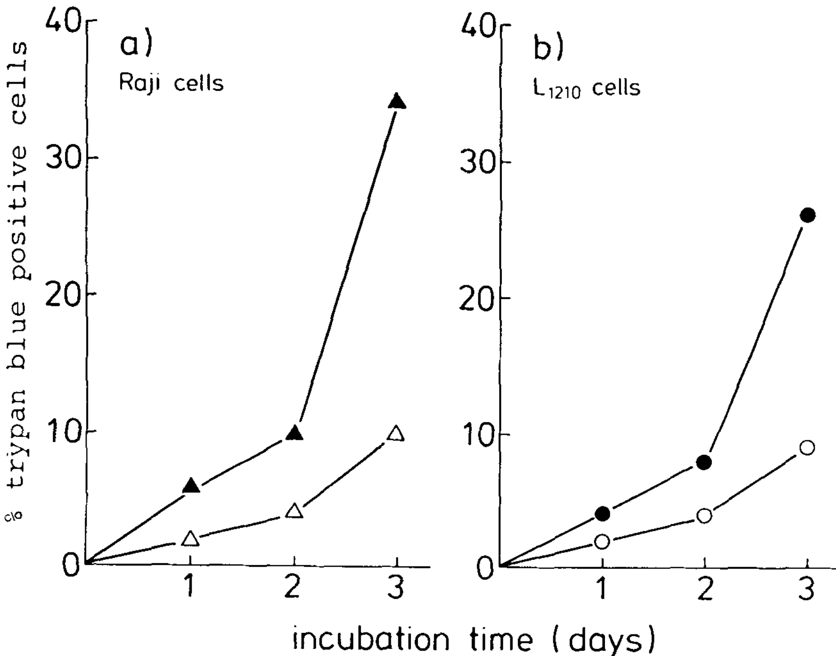

FIG. 3. Effect of OM-GPC on the cell viability for (a) Raji cells and (b) L1210 cells, measured by the trypan blue dye exclusion assay (18). Incubation conditions are as in Fig. 2. Open symbols: cells without OM-GPC. Closed symbols: cells in contact with OM-GPC. Viability data are ±5% (of total cell count) standard deviation.

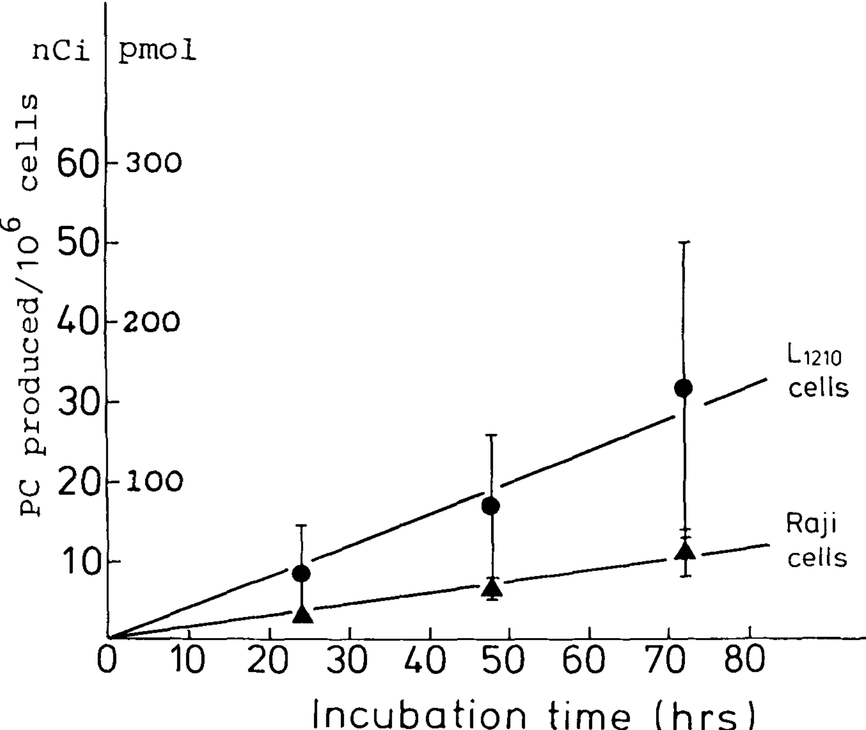

FIG. 4. Time-dependent formation of radiolabeled phosphatidylcholine in in vitro cultures of Raji and L1210 cells. Incubation conditions are as in Fig. 2. Error bars indicate standard deviations.

blue positive cells was low for the first 48 hr (<10%) but much higher after 72 hr (>25%).

The lipid extracts prepared according to Bligh and Dyer (19) were analyzed for radioactivity both in the water and in the chloroform phase. No radiolabeled material was found in the water phase. All of the label taken up by the cells (up to 12% of the label added, 800 pmol per 10^6 cells) was in the organic phase. Thin layer chromatography of the organic phase showed that besides the original compound, only one other radiolabeled product, which had a Rf-value equal to that of phosphatidylcholine, was present. As shown in Figure 4, the amount of product formed per 10^6 cells showed a linear increase with time. After three days, about 10% of the radioactivity taken up by the cells is incorporated in the lecithin fraction. After isolation of the radiolabeled product and treatment with potassium *t.* butylate, the label is detected in the water phase and not in the organic phase, indicating that the apolar part of the product is not originating from OM-GPC. The amount of phosphatidylcholine formed per 10^6 cells and the percentage of trypan blue positive cells show a direct linear correlation (Fig. 5) for both Raji cells and L1210 cells. Compared to L1210 cells, Raji cells obviously show a higher percentage of trypan blue positive cells at the same point of lecithin formation.

The metabolic fate of OM-GPC in both cell lines suggests that OM-GPC could be a substrate for phospholipase C or phospholipase C–like enzymes. According to this hypothesis, compounds of simpler molecular structure, such as the alkyl phosphocholines, should have similar effects on the cells. Indeed, as is shown in Figure 6, Raji cells treated with hexadecylphosphocholine (He-PC) do show production of lecithin. Again, the amount of trypan blue positive cells shows a linear correlation with the amount of lecithin formed from HE-PC as a phosphocholine donor.

Related compounds differing only in the distance between the phosphate and trimethylammonium groups further support this hypothesis. For instance, alkyl phosphocholines such as octadecenyl(9,10)phosphocholine (Ol-PC) and octadecenyl(9,10)phospho-(N,N,N-trimethyl)-aminohexanol (Ol-P(C6)C) behave as predicted (Figs. 7 and 8). Ol-PC is a substrate for phospholipase C and is toxic for Raji cells. Ol-P(C6)C is not a substrate for phospholipase C because of its elongated phosphor to nitrogen distance (20,21), and therefore it does not inhibit the growth of Raji cells.

The transfer of radiolabeled phosphocholine from an ether phospholipid to another molecule, forming a radiolabeled lecithin as described in this study, has not been described before. However, Voelker and Kennedy (22) reported a similar reaction, i.e. the transfer of phosphocholine from phosphatidylcholine to ceramide, forming sphingomyelin and diacylglycerol. In analogy, we suggest that a similar transfer of phosphocholine from an ether phospholipid to diacylglycerol occurs in Raji cells. The result is the formation of lecithin and the appearance of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycerol, a product that was detected by Van Blitterswijk et al. (25) in similar experiments. These authors report that this metabolite inhibits protein kinase C. Their observation that OM-G is a product from OM-GPC also supports our suggestion of a transfer of phosphocholine. The reaction products of this transfer would be labeled phosphatidylcholine and OM-G or a fatty alcohol, depending on the compound used. Since the lecithin formed is a normal membrane constituent, we suspect that the toxic principle in the metabolism of alkyl phosphocholines is the formation of these apolar alcohols.

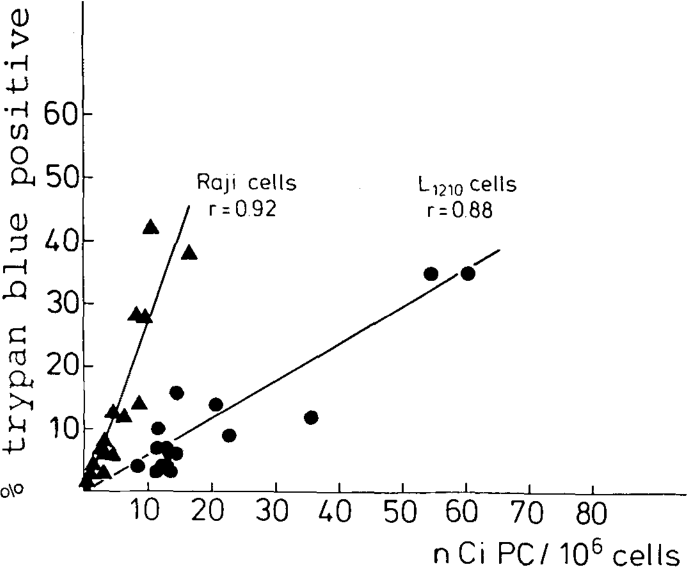

FIG. 5. Correlation of formation of phosphatidylcholine from OM-GPC and cell death (as measured by trypan blue positive cells). Each data point represents one cell culture. Incubation conditions as described in Fig. 2.

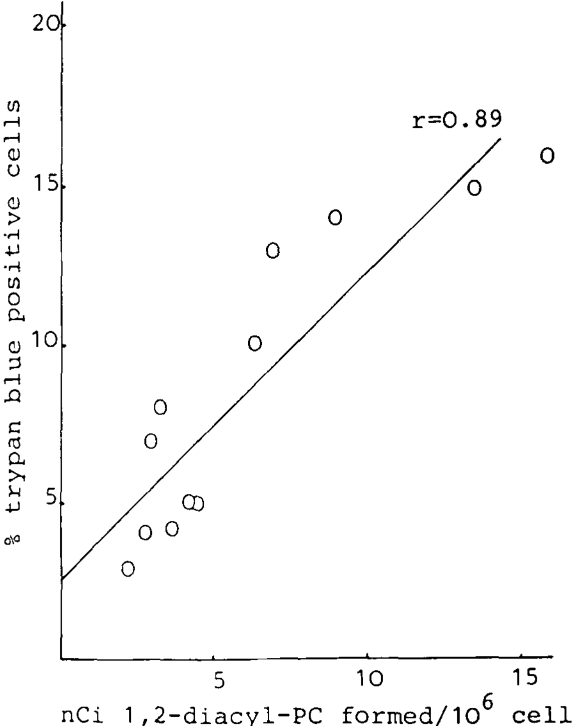

FIG. 6. Correlation between cell death (trypan blue positive cells) and phosphatidylcholine formation from hexadecylphosphocholine for Raji cells. Incubation essentially as described in Fig. 2, except that OM-GPC was replaced by 10 μg/ml of hexadecylphosphocholine. Each data point represents one cell culture.

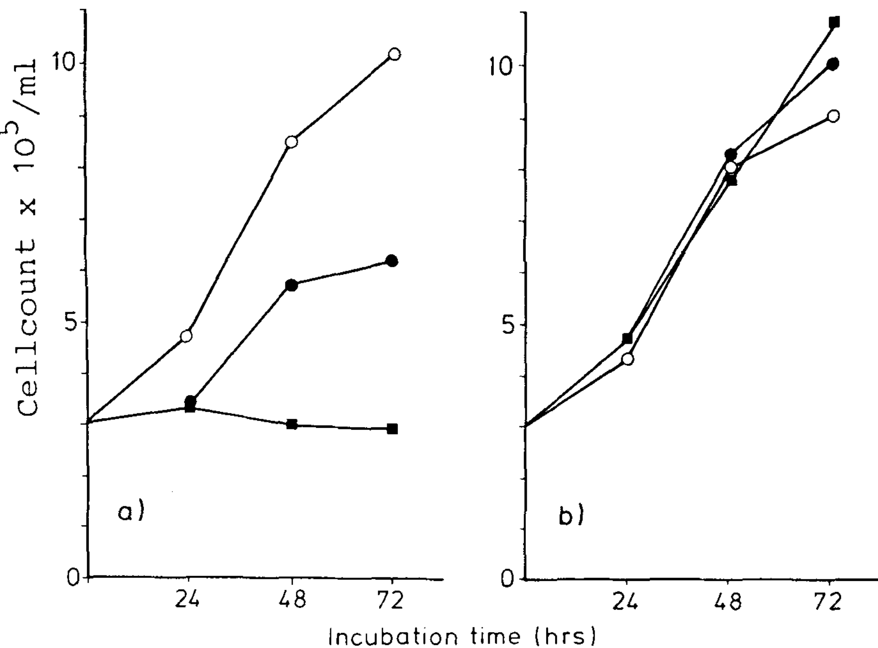

FIG. 7. Influence of elongation of the P-N distance in the alkyl phosphocholines on proliferating the Raji cells. Incubation conditions are described in Fig. 2. OM-GPC was replaced by the respective alkyl phosphocholine. Standard deviations are 5–10% of the total cell counts. Open symbols: cells without alkyl phosphocholines. Closed circles: 10 μg/ml alkyl phosphocholines. Closed squares: 40 μg/ml alkyl phosphocholines. (a) Octadecenyl(9,10)phosphocholine; (b) octadecenyl(9,10)phospho-(N,N,N-trimethylamino)hexanol.

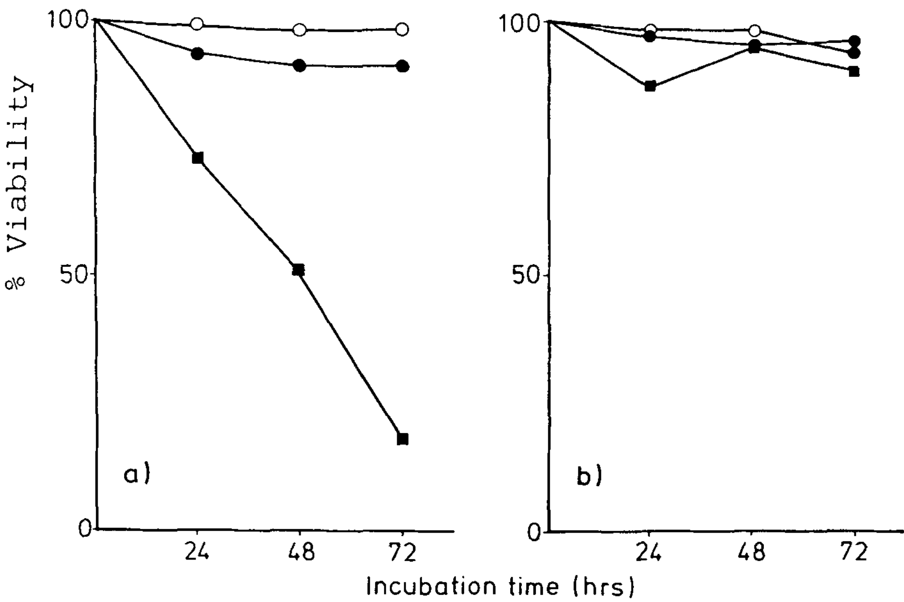

FIG. 8. Influence of elongation of the P-N distance in alkyl phosphocholines on cell viability in Raji cells measured by the trypan blue dye exclusion assay. Viability data are ±5% (of total cell count) standard deviation. Incubation conditions as described in Figs. 2 and 7. Symbols as in Fig. 7. (a) Octadecenyl(9,10)phosphocholine; (b) octadecenyl(9,10)phospho-(N,N,N-trimethyl)aminohexanol.

In summary, the formation of a metabolic product from either OM-GPC or alkyl phosphocholine shows a linear correlation with cell death as measured by the trypan blue dye exclusion assay. Related compounds, which are not a substrate for phospholipase C, do not show inhibition of growth for Raji cells. It is suggested that the formation of apolar alcohols by phospholipase C or related enzymes could be responsible for the toxicity of the ether phospholipids (23,24). The mode of action of these alcohols is not understood yet but their capacity to inhibit protein

kinase C (23) could play a role in their toxicity towards neoplastic cells.

1-*O*-Octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine (ET-18-OMe) has been reported to possess definite antitumor activity in vivo. Twenty-two alkyl lysophospholipid analogs were chemically synthesized, and their antitumor activity against mouse experimental tumors (Sarcoma 180, MM46, P388) was examined. Among them, 1-*O*-octadecyl-2-*O*-acetoacetyl-*rac*-glycero-3-phosphocholine was found to show antitumor activity similar to ET-18-OMe with less acute toxicity.

Intravenous injection of the ET-18-OMe with *sn*-3 configuration retarded the subcutaneous growth of Sarcoma 180 cells effectively, while the growth inhibition by the *sn*-1 isomer was much less effective. This stereospecificity was similar to that observed in their activities as platelet-activating factor (PAF) agonists. The acetoacetyl compound, another PAF agonist, showed similar stereospecific antitumor action in vivo. These findings suggest that some alkyl lysophospholipids may activate host cells to a cytostatic stage against tumor cells in vivo through binding to a PAF receptor. Our preliminary results indicated that the responsible cells under these conditions might be primarily immature macrophages present in the bone marrow. No appreciable or even adverse stereospecificity was observed in the different sets of experiments where the activity of ET-18-OMe against MM46 tumor cells in vivo or the direct cytotoxicity against human promyelocytic leukemia HL-60 cells in vitro was examined. Under some conditions, the antitumor activity of ET-18-OMe in vivo may be revealed through direct cytotoxicity and/or modulation of the host defense system by "nonspecific" mechanisms. Some alkylphospholipids without PAF activity may also show antitumor activity through similar "nonspecific" mechanisms.

***Lipids 22*, 862–867 (1987).**

Some alkyl lysophospholipids (ALP), such as 1-*O*-octadecyl-2-*O*-methyl-glycero-3-phosphocholine (ET-18-OMe), have been known to possess definite antitumor effects in vivo (1). The mode of action was partially explained by selective cytotoxic action against malignant cells (2,3). The specificity originally was explained by the lack of the degradation (*O*-alkyl cleavage) enzyme in the tumor cells; however, this has recently been challenged (4). Alternative explanations for the mechanism of cytotoxic activity and its tumor specificity have been advanced (5,6), but further work is required to clarify this interesting characteristic.

In addition to the direct action, Berdel et al. proposed the possible participation of macrophages activated by ALP in suppression of tumor cell growth. For instance, they showed that intravenous injections of bone marrow macrophages preincubated with ET-18-OMe inhibited the development of metastasis of 3-Lewis lung carcinoma in C57B1/6 mice (7). No information, however, has been available about the mechanism of macrophage activation. The unique phospholipid, PAF, first characterized as a mediator released from IgE-sensitized rabbit basophils (8), has been suggested to act as a potent mediator in pathological processes such as anaphylaxis and inflammation (9). We have recently shown that macrophages as well as platelets and neutrophils are target cells of PAF through specific receptors present on their cell surfaces (10).

In the present study, we examined the relationship between the structure of ALP analogs and their antitumor activity. Our results suggest that the antitumor activity of some ALP might be at least partially through induction of activation of bone marrow macrophages in vivo and that the activation is through their binding to PAF receptors on these cells.

MATERIALS AND METHODS

Chemicals. RPMI1640 and D-MEM media were obtained from Flow Laboratories (Stanmore, Australia). Fetal calf serum (FCS) was purchased from Gibco (New York, New York). [^{3}H]Thymidine was purchased from the Radiochemical Centre (Amersham, United Kingdom). Sheep red blood cells were obtained from Nippon Bio-Supply Center (Tokyo, Japan).

Analogs of alkylphospholipids. All of the alkylphospholipids bearing O-methyl residues at position 2 (10,11), 1-*O*-octadecyl-2-*O*-acetoacetyl-glycero-3-phosphocholine (acetoacetyl compound) (12), 1,2-di-*O*-alkyl-glycerophosphocholine (1,2-dialkyl-GPC, α type) (11,13,14) and 1,3-di-*O*-dialkyl-GPC (β type) (15) used in the present study were synthesized by investigators at Takeda Chemical Industry Ltd. They were purified by column chromatography followed by crystallization from a suitable solvent system, and their purities and structures were confirmed by thin layer chromatography, nuclear magnetic resonance and elemental analysis.

Animals and antitumor test. Specific pathogen-free female ICR and C3H/HeN mice (6–8 wk old) were purchased from the Shizuoka Cooperative for Experimental Animals (Hamamatsu, Japan). The tumor cells used were Sarcoma 180 (S180) obtained from the Institute of Microbial Chemistry (Tokyo, Japan) and mouse mammary tumor MM46, from Teikyo University (Kanagawa, Japan). They were maintained in the ascites form. The 7-day-old S180 ascites tumor cells were transplanted intraperitoneally (1×10^5) or subcutaneously (1×10^6) into ICR mice. Test samples were administered intraperitoneally or

intravenously. The 7-day-old MM46 ascites tumor cells (1×10^4) were transplanted intraperitoneally into C3H/HeN mice, with the test sample also being administered intraperitoneally.

P388 mouse leukemia cells from the Cancer Institute (Tokyo, Japan) and human promyelocytic leukemia HL-60 cells from the Jichi Medical School (Tochigi, Japan) were maintained in vitro and used for cytotoxic assay.

Assay for cytostatic activity. The cell-mediated cytostasis assay was performed as described previously (16). Briefly, test samples were administered intraperitoneally four days prior to sacrifice. Peritoneal cells were harvested and coincubated with EL-4 mouse leukemia cells from the National Institute of Health, Tokyo, Japan. The radioactivity of [^{3}H]thymidine incorporated into acid-insoluble materials was then measured.

Assay for plaque-forming cells. Direct plaque-forming cell assay was performed by the method of Jerne and Nordin (17). Sheep red blood cells (5×10^7) were injected intravenously into ICR mice 13 days after subcutaneous

[a,b,c]ICR mouse was transplanted intraperitoneally with S180 tumor (1×10^5 cells).

[a]A test sample (1 mg per mouse per day) was administered intraperitoneally once 4 days prior to tumor transplantation.

[b]A test sample (0.25 mg per mouse per day) was administered intraperitoneally once a day on days −5, −4, −3 and −2.

[c]A test sample (0.3 mg per mouse per day) was administered intraperitoneally once a day on days 0, 1 and 2.

[d]C3H/HeN mouse was transplanted intraperitoneally with MM46 tumor (1×10^4 cells). A test sample (0.25 mg per mouse per day) was administered intraperitoneally once a day on days −5, −4, −3, −2, 2, 3, 4 and 5.

[e]Percent average life span of tested mice/control mice.

[f]Survivors of tested mice/total mice.

[g]Mouse leukemic cell P388 was cultured in a medium (RPMI1640 with 10% FCS) containing various concentrations of lipids. The viability of treated cells was examined after 24 hr by measuring ^{3}H thymidine incorporation into acid-insoluble fraction. Cultures were pulsed with ^{3}H thymidine 3 hr before termination of incubation.

inoculation of S180 tumor cells (1×10^6). Five days after immunization, splenic cells were prepared and assayed for plaque-forming cells.

RESULTS

Antitumor activity of ALP analogs. Twenty-two ALP analogs were snythesized, and their structure-antitumor activity relationships were examined (Table 1). Those included analogs differed from ET-18-OMe in the structure of the long chain alkyl moiety at position 1 or the N-substituted aminoethylphosphoryl moiety at position 3. Prophylactic effects against death caused by S180 tumor cells were appreciably observed when mice were treated with ALP prior to tumor transplantation (conditions A and B). All mice died within 16 days after intraperitoneal inoculation of 10^5 S180 cells unless they were treated with ALP. However, significant prolongation of life spans and/or cure (60-day survival) were observed in tumor-bearing mice treated with ET-18-OMe analogs that carried a relatively longer alkyl chain at position 1 or dimethyl or monomethylaminoethylphosphate at position 3. No appreciable effect was observed with analogs having an alkyl chain shorter than C_{14} or an aminoethylphosphate at position 3. The antitumor activity against mouse syngeneic tumor MM46 was examined next (Table 1, condition D). In control mice (C3H/HeN) inoculated with 10^4 tumor cells, mortality was 100% within 20 days after transplantation. In contrast, intraperitoneal administration of these alkylphospholipids resulted in, at best, 60% cure of tumor-bearing mice (60-day survival). Derivatives having long alkyl chain (C_{22}) at position 1 or aminoethylphosphate at position 3 showed no appreciable activity.

An alkylphospholipid having an acetoacetyl moiety instead of O-methyl at position 2 showed appreciable antitumor activity against either S180 or MM46.

1,2-Di- and 1,3-di-*O*-alkyl-GPC carrying various chain length were also synthesized and tested. Among them, dioctyl-GPC (both α and β types) were found to have appreciable effects against S180 and MM46. Compounds having aliphatic chains either shorter or longer than dioctyl-GPC tended to lower the activity progressively. However, significant schedule dependency was observed; 1,2-di-*O*-nonyl- or decyl-GPC given intraperitoneally once on day 0 at a dose of 1 mg per mouse produced an appreciable increase in the life span of ICR mice bearing the S180 tumor (236% with dinonyl-GPC and 254% with didecyl-GPC), whereas 1,2-dioctyl-GPC showed weaker activity (195%).

Like ET-18-OMe, the acetoacetyl compound or 1,2-dioctyl-GPC could increase the life span of S180-bearing mice (Table 1, condition C) or inhibit the growth of tumor inoculated subcutaneously, even when ALP were injected only after tumor transplantation (Fig. 1). On the other hand, their direct cytotoxic effects on tumor cells were much weaker than that of ET-18-OMe; IC_{50} values against P388 leukemic cells were 34 μM with acetoacetyl compound, 145 μM with 1,2-dioctyl-GPC and 4 μM with ET-18-OMe.

Stereospecificity of antitumor action of ET-18-OMe and acetoacetyl compound. Intravenous injection of ET-18-OMe with *sn*-3 configuration retarded the subcutaneous growth of S180 cells effectively (Fig. 2A). Although the *sn*-1 enantiomer inhibited tumor growth, it was much less effective than the *sn*-3 compound. Racemic compound showed an intermediate activity. The treatment of mouse with racemic acetoacetyl compound was effective, while that with the *sn*-1 compound was not at all (Fig. 2B). No appreciable stereospecificity of the activity, however, was observed when the antitumor activity of ET-18-OMe was evaluated by prophylactic effect of intraperitoneal injection of ALP against death caused by S180 tumor cells (Table 2). Both the *sn*-1 and *sn*-3 compounds significantly increased the life span of the tumor-bearing mouse; no statistical difference was observed.

Even adverse stereospecificity was observed in a different set of experiments where antitumor effects of ALP against death of C3H/HeN mice caused by MM46 tumor cells propagated intraperitoneally were examined (Table 2). Three out of 5 mice survived 60 days after tumor inoculation when treated intraperitoneally with the *sn*-1 compound; the *sn*-3 compound did not increase the life span of MM46-bearing mice under the same conditions.

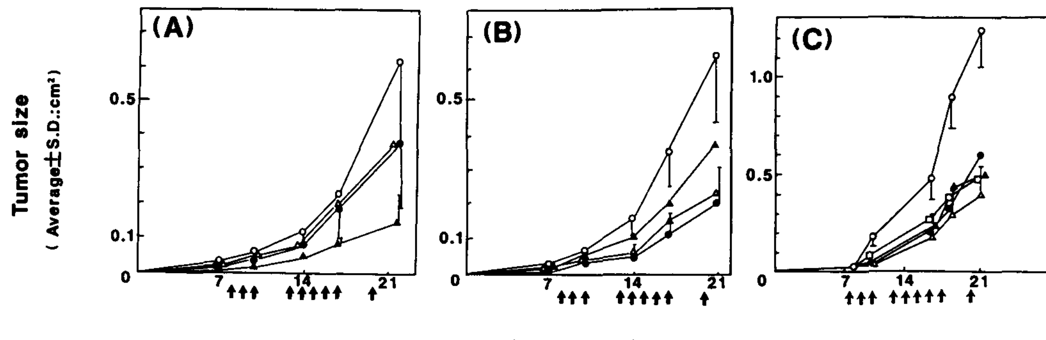

FIG. 1. Retardation of tumor growth by treatment of ALP. ICR mice (each group, 3 or 4 animals) subcutaneously inoculated with S180 (1×10^6 cells) were treated with ALP once a day on days 8, 9, 10, 13, 14, 15, 16, 17 and 20 as indicated by arrows. ALP of various doses were given per mouse per day. (A) ET-18-OMe, intravenous treatment: ○, control (nontreated); ▲, 30 μg (77%); △, 100 μg (39%); ●, 300 μg (33%). (B) Acetoacetyl compound, intravenous treatment: ○, control (nontreated); ▲, 30 μg (44%); △, 100 μg (53%); ●, 300 μg (55%). (C) Dioctyl-GPC, intraperitoneal treatment: ○, control (nontreated); ▲, 6 μg (55%); □, 20 μg (44%); △, 60 μg (60%); ●, 200 μg (50%). Numbers in parentheses represent percentage of retardation of average tumor weight on day 21 of treated mouse per control.

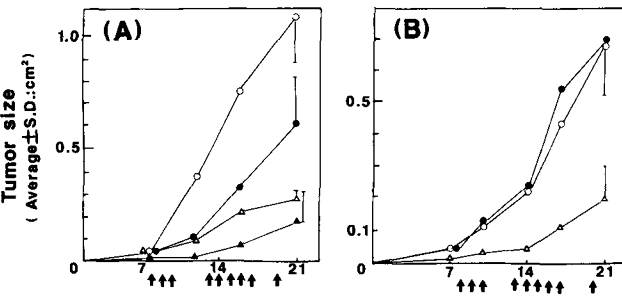

FIG. 2. Stereospecific retardation of the growth of S180 subcutaneously implanted by intravenous injection of ALP. (A) ET-18-OMe, 60 μg daily nine times as indicated by arrows. ○, Nontreated; ●, 3-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-1-phosphocholine (*sn*-1, 43%); ▲, 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine (*sn*-3, 71%); △, racemic 1-*O*-octadecyl-2-*O*-methyl-glycero-3-phosphocholine (69%). (B) Acetoacetyl compound, 300 μg daily nine times as indicated by arrows. ○, Nontreated; ●, 3-*O*-octadecyl-2-*O*-acetoacetyl-*sn*-glycero-1-phosphocholine (*sn*-1, 101%); △, racemic 1-*O*-octadecyl-2-acetoacetyl-glycero-3-phosphocholine (55%). Numbers in parentheses represent percentage of retardation of average tumor weight on day 21 of treated mouse per control mouse.

TABLE 3

Induction of Cytostatic Peritoneal Exudate Cells In Vivo by ALPs

Agent tested	Dose (mg/mouse)	Radioactivity incorporated (dpm)[c] (Average ±SD)

1,2-Didecyl-GPC	1.0	73,525 ± 4,626	

[a]CDF1 mice (8 weeks) or [b]ICR mice (8 weeks) were injected intraperitoneally with ALP 4 days prior to sacrifice.

[c]Peritoneal exudate cells (4×10^5 cells/well) were incubated with target EL-4 cells (2×10^4 cells) for 24 hr at 37 C and the cytostasis was examined as described (16).

[d]Numbers in parentheses are the percent of cytostasis compared with peritoneal cells from untreated mice ($p < 0.001$).

TABLE 2

Antitumor Activity of ET-18-OMe Stereoisomers

Compound	In vivo: S180[a] T/C 0.5 mg	In vivo: S180[a] T/C 1 mg	In vivo: MM46[b] S/T	In vitro: HL-60, IC_{50}; μM[c]	In vitro: Hemolysis, HC_{50}; μM[d]
sn-3	175[e]		0/5	1.6	2.2
sn-1	146	176[f]	3/5	1.6	2.2

[a]Prophylactic effects against S180 were examined by a single intraperitoneal treatment of lipids (0.5 or 1 mg per mouse) as described in Table 1, condition A.

[b]Antitumor activity of lipids against MM46 was examined as described in Table 1, condition D.

[c]According to the method described (3), HL-60 cells (5×10^5 cells/ml) were incubated in D-MEM containing lipids for 24 hr in the absence of FCS. Viable cells were then determined by staining. IC_{50}: concentrations required for 50% growth inhibition.

[d]^{51}Cr-labeled human red blood cells (10^7 cells/ml) were treated with lipid for 30 min as described previously (20). HC_{50}: concentrations required for 50% hemolysis.

[e]$p < 0.01$.

[f]$p < 0.05$.

The tumor retardation, which was observed in vivo upon treatment with the *sn*-1 ET-18-OMe, might be partially due to modification of the host defense mechanism, since peritoneal exudate cells harvested from mice treated with the *sn*-1 compound showed appreciable cytostatic activity against EL-4 cells in vitro (Table 3). The peritoneal exudate cells, which were harvested from animals treated with the *sn*-3 compound, showed weaker inhibitory effect on growth of EL-4 cells. The ET-18-OMe showed direct cytotoxicity independent of its stereochemical configuration, since the *sn*-1 compound showed the same cytotoxicity as the *sn*-3 compound against HL-60 cells cultured in vitro and against erythrocytes.

Cytostasis and immunomodulaton by 1,2-dioctyl-GPC. Athough the antitumor activity of 1,2-dioctyl-GPC in vivo was stronger than that of dialkyl-GPC with longer aliphatic chains, such as 1,2-didecyl-GPC, the direct cytotoxic activity of the former against P388 cells in vitro was weaker than that of the latter (Table 1). On the other hand, the peritoneal exudate cells, which were harvested from mice treated with 1,2-dioctyl-GPC, showed appreciable cytostatic activity against EL-4 cells, whereas 1,2-didecyl-GPC was ineffective (Table 3).

Impairment of the antibody production against sheep red blood cells was observed in mouse-bearing, progressively growing S180 cells. Intraperitoneal injection of 1,2-dioctyl-GPC partially restored this immunodepression (Fig. 3), indicating that the dioctyl-GPC treatment modulates the immune response of the host. These results suggested that the antitumor activity of dioctyl-GPC seemed to be mainly through the enhancement of protective immunity of the host against tumor cells.

DISCUSSION

The acetoacetyl compound showed appreciable antitumor action against S180 and MM46 in vivo. The extent of its effectiveness was comparable to that of ET-18-OMe. In the acute toxicity study, the acetoacetyl compound was less toxic than ET-18-OMe; the LD_{50} values for the ICR mouse, when intraperitoneally administered once, were 104 mg/kg with acetoacetyl compound and 23 mg/kg with ET-18-OMe, respectively. An acetoacetyl compound caused much less necrosis in the tail vein, where the lipids were injected, than ET-18-OMe. The acetoacetyl compound is slightly less cytotoxic in vitro than ET-18-OMe; the IC_{50} value of the acetoacetyl compounds (racemic

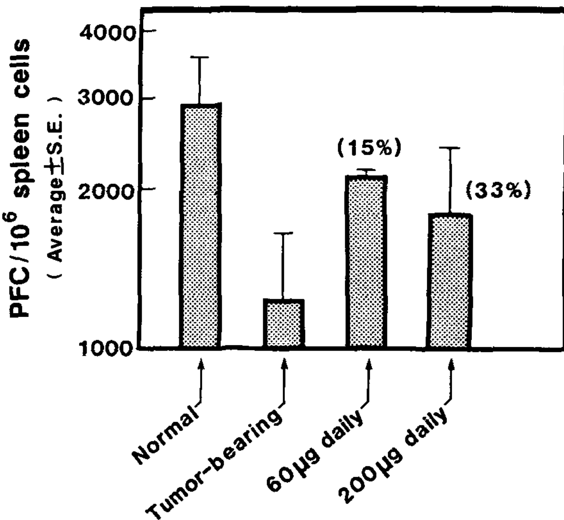

FIG. 3. Effect of 1,2-dioctyl-GPC on the antibody production in tumor-bearing mice. ICR mice bearing S180 tumor were treated daily with 1,2-dioctyl-GPC intraperitoneally six times at days 8, 9, 10, 11, 12 and 13. Antigen (sheep red blood cells) was intravenously injected at day 13, and the antibody production was assayed at day 17 as described previously (16). Each group contained six mice. Numbers in parentheses are the growth inhibition of S180 solid tumor due to lipid treatment.

compound) against HL-60 cells measured as described in Table 2 was 4.2 μM. This value was lower than the IC_{50} value against P388 (Table 1), which was examined in the presence of 10% FCS. The difference might be due to partial degradation of the acetoacetyl compound during incubation because, unlike ET-18-OMe, it was sensitive to phospholipase A_2 (data not shown). These results indicate that the acetoacetyl compound is one of the most attractive and promising antitumor alkyl phospholipids; further studies are desirable to include the elucidation of the molecular mechanism of the therapeutic activity of ALP.

ET-18-OMe as well as the acetoacetyl compound have some activity as platelet-activating factor (PAF) agonists, inducing platelet (18) or macrophage (10) activation, although their activity was considerably lower than that of PAF itself: the ED_{50} values to induce serotonin secretion from rabbit washed platelets were 2.1×10^{-5} (ET-18-OMe), 1.3×10^{-5} (acetoacetyl compound) and 8.1×10^{-10} M (PAF), respectively. The activation may be through specific receptors present on target cells, since the activation was blocked by CV-3988 (10), a well-known PAF antagonist (19). Like PAF, activation of either platelets or macrophages by ET-18-OMe was stereospecific; only the *sn*-3 compound was active (10). Similar stereospecificity was observed in their antitumor activity in vivo under certain experimental conditions, in which the tumor cells were propagated subcutaneously and ALP were injected intravenously through a remote route. The stereospecificity suggests that the observed antitumor effect might be mediated by activation of some host immune cells through their binding to PAF receptors.

The cells harvested from the peritoneal cavity could not be involved in these antitumor effects, since either cytotoxic or cytostatic activity could not be induced when PAF agonists, including ET-18-OMe, were incubated with mouse peritoneal exudate cells. Rat and mouse, unlike human, rabbit and guinea pig, do not have peripheral cells (platelets, polymorphonuclear cells, macrophages), which express specific binding sites for PAF on their surface (Table 4). In our preliminary experiments, however, specific binding of PAF could be detected on bone marrow cells, which include immature macrophages (Hayashi et al., data in preparation). We also detected specific binding sites for PAF on bone marrow cells derived from species other than mouse (guinea pig, rat and probably human [HL-60]). As illustrated in Figure 4, some PAF agonists may interact with bone marrow cells, most probably immature macrophages, inducing their differentiation or maturation. Macrophages matured by PAF agonists may express toxicity against tumor cells. This idea is consistent with previous findings by Munder et al. (19) that bone marrow-derived macrophages treated with racemic ET-18-OMe showed appreciable cytotoxicity against tumor cells. We suppose that the synthesis of pure *sn*-3 isomers of ALP might be important to obtain more effective antineoplastic compounds.

PAF did not show antitumor activity as observed with ET-18-OMe or acetoacetyl compound (data not shown), since it was toxic and induced shock, probably through a cardiovascular effect when injected systemically. The

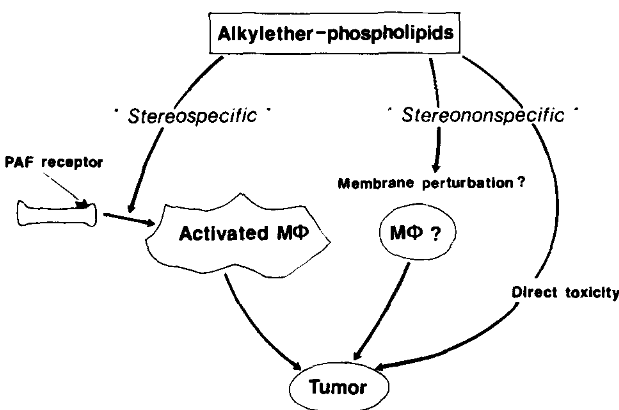

FIG. 4. Proposed mode of antitumor action of synthetic ALP.

antitumor effect might be observed only with PAF agonists that have rather weak cardiovascular effects. There is a possibility that the growth retardation of tumors subcutaneously implanted by PAF agonists may result from their effect on the vascular system developed inside or near the tumor. This possibility is, however, rather small, since a relatively small antitumor effect could be observed when the racemic ET-18-OMe was injected directly into the tumor (data not shown).

Direct cytotoxicity of ET-18-OMe against HL-60 cells and erythrocytes was not stereospecific. The antitumor activity of ET-18-OMe was independent of its stereochemical configuration when intraperitoneally administered to the ICR mouse prior to intraperitoneal inoculation of S180 cells. Adverse stereospecificity was even observed under certain experimental conditions. These findings suggest that the antitumor effect of ET-18-OMe might be primarily through an independent mechanism of a PAF agonist under some conditions. The effect might be due either to direct toxicity or to modification of some host cells. The latter possibility was suggested by findings that the antitumor effect was observable even when ET-18-OMe was injected four days prior to tumor inoculation and that cytostatic activity of peritoneal exudate cells was observed against EL-4 cells in vitro when harvested from mice treated with *sn*-1 ET-18-OMe. ALP analogs such as 1,2-dioctyl-GPC, which has relatively weak cytotoxic activity and is not a PAF agonist, also showed activity as biologic response modifiers since an intraperitoneal administration of 1,2-dioctyl-GPC induced cytostatic peritoneal cells, modulated antibody production in tumor-bearing mice and suppressed tumor growth of subcutaneously transplanted S180 cells. Thus we concluded that the stimulation of host system by ALP was not always through their binding to PAF receptors (Fig. 4).

We do not know whether the activity of dioctyl-GPC is stereospecific. The activity probably is not through binding to their specific receptors in cells, since even the β-type compound (1,3-dioctyl-GPC) showed the same activity as the α-type compound (1,2-dioctyl-GPC). The ET-18-OMe having *sn*-1 configuration as well as dioctyl-GPC may primarily cause nonspecific membrane perturbation, inducing activation of some host cells or suppressing tumor cell growth directly. We cannot explain why the *sn*-1 compound showed even higher antitumor activity in vivo under some conditions. Munder et al. previously reported that 1-alkyl-2-lyso-*sn*-glycero-3-phosphocholine (*sn*-1) retarded the growth of MethA tumor cells much more effectively than a *sn*-3 enantiomer when given orally (1). One possibility is that the *sn*-1 compound is more resistant to metabolic degradation than the *sn*-3 enantiomer.

1-*O*-Hexadecyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine (platelet-activating factor, PAF) is known to stimulate platelet aggregation and serotonin release in concentrations ranging from 10^{-10}–10^{-5} M. Since a variety of synthetic PAF analogues are potent antineoplastic agents in vitro and in vivo, it was the aim of this study to examine the PAF-like activity of 15 analogues, including 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH_3) and a thioether analogue. In platelet-rich plasma from human blood, platelet aggregation and serotonin release were studied to compare the effects of PAF and the analogues. Platelet function was controlled by testing their response to adenosine diphosphate, arachidonic acid, collagen and epinephrine. Our results show that only PAF was able to induce platelet aggregation and serotonin release in concentrations from 10^{-9} to 10^{-5} M, whereas all the tested analogues up to a concentration of 10^{-3} M failed to induce these effects.
***Lipids 22*, 868–870 (1987).**

Platelet activating factor (PAF), a naturally occurring phospholipid, is known to be a very potent stimulator of rabbit and human platelet aggregation and secretion in vitro and in vivo (1–3). It first was discovered when IgE-sensitized rabbit basophils, after an immunological challenge, released PAF (4). Some years ago, the molecular structure of PAF was identified as 1-*O*-alkyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine (5). It has been shown that PAF is synthesized by a variety of cells, including polymorphnuclear neutrophils and mouse macrophages (6). There is evidence that PAF plays a major role in inflammatory reactions (7). PAF also is a very toxic compound. PAF-induced sudden death occurs at doses of 15 μg/kg when given to rabbits intravenously (8) resulting from the increased production of thromboxane A_2 by activated platelets (9), which leads to platelet aggregation, platelet degranulation and pulmonary thrombosis, among other pathophysiological reactions (8). PAF initiates irreversible platelet aggregation in a dose-dependent manner, reaching a maximum effect in a range of about 10^{-8} to 10^{-7} M (2,3). Platelet activation induced by PAF seems to take place independently of the cyclooxygenase pathway (10,11), is highly dependent on extracellular calcium and increases free intracellular calcium (12). In the last years, a variety of PAF analogues was synthesized and found to have antineoplastic properties. The close structural relationship between PAF and synthetic alkyl lysophospholipids made it necessary to examine whether these compounds might be able to cause PAF-like effects on human platelets.

MATERIALS AND METHODS

Materials. PAF (the hexadecyl derivative) and all of the synthetic PAF analogues were synthesized as described elsewhere (13,14). The compounds were dissolved in chloroform/methanol (1:9, v/v) and diluted in 0.9% NaCl containing 0.1% BSA [Sigma Chemical Co. (St. Louis, MO)]. Adenosine diphosphate, collagen, arachidonic acid and epinephrine were obtained from Bio-Data Corp. (Hatboro, PA). [^{14}C]Serotonin (5-hydroxy-[side chain-2-^{14}C]-tryptamine creatine sulfate, 57.4 mCi/mmol) was purchased from Amersham International (England).

Platelet aggregation and serotonin release. Venous blood was collected from young, healthy volunteers who had taken no drugs for at least two weeks; it was mixed with 3.8% (w/v) sodium citrate and blood (1:9, v/v). The anticoagulated blood was centrifuged at room temperature at 400 × g for 10 min, and the upper phase removed. The remaining blood was centrifuged at 1500 × g for 15 min to gain platelet-poor plasma (PPP). The platelet count for the platelet-rich plasma (PRP) was adjusted to 250,000 ± 50,000 per μl with PPP from the same sample. Testing was completed within two hr after blood collection. Platelet aggregation was studied at 37 C at a stirring speed of 1200 rpm using a Bio-Data four channel aggregometer (Model Pap-4, Colora). A volume of 270 μl PRP was incubated for two min at 37 C; then 30 μl of either adenosine diphosphate, arachidonic acid, collagen or epinephrine was added, and aggregation profiles were monitored. Provided the aggregation patterns of the samples were normal, the PAF sensitivity of the same platelets was tested in concentrations ranging from 10^{-9} to 10^{-6} M. Only when the response of each sample to the PAF stimulus was sufficient were aggregation profiles performed for 15 different synthetic PAF analogues up to a concentration of 10^{-3} M.

In a second set of experiments, platelets were labeled by incubating them with [^{14}C]serotonin (0.15 μCi/ml PRP) for 20 min at 37 C. Aggregation profiles were monitored as described above after adding either PAF or one of four selected PAF analogues. Aggregation and secretion were allowed to go on for five min. Subsequently, 70 μl of 6% (w/v) formaldehyde was added, the sample was put in an ice bath and centrifuged for one min at 12,000 × g. Serotonin release was calculated according the method of Holmsen and Dangermaier (15).

RESULTS AND DISCUSSION

As shown in Figure 1, PAF itself stimulates irreversible aggregation of human platelets in the range of 5 × 10^{-8} M

[a]Values are means ±SD. No. of experiments are shown in parentheses.

to 10^{-5} M, whereas reversible aggregation still could be detected at 10^{-9} M.

In contrast, all PAF analogues tested were without effect on platelet aggregation up to concentrations of 10^{-4} M. At 10^{-3} M, a minor reversible aggregation occurred with some analogues (Fig. 2), which most likely results from an unspecific effect on platelet membranes. This result also is obtained for the compounds shown in Figure 2 and for those summarized in Table 1. The same structures also were ineffective with respect to serotonin release when tested up to 10^{-3} M (Table 2) under conditions where PAF initiated release of more than 50% of platelet [^{14}C]serotonin at 10^{-5} M.

The observation of Wykle et al. (16) that 1-*O*-hexadecyl-2-*O*-methyl-GPC is a weak agonist for rabbit platelets does not apply to human platelets. This apparent discrepancy most likely reflects the difference in the species used as a platelet source.

It appears that the existence of a short acyl ester in the 2-position of the glycerol moiety represents a minimum requirement for the 1-*O*-alkyl-glycero-phospholipids in order to exert a physiological response in human platelets. This is in accordance with similar conclusions made by others (17). Because phospholipid analogues of platelet activating factor (PAF) represent a new approach to cancer chemotherapy, it seems important that no interference with the physiological action of PAF is to be expected as long as this minimal structural requirement is considered.

Immunomodulatory and Therapeutic Properties of Alkyl Lysophospholipids in Mice[1]

James E. Talmadge[*,a], **Mark Schneider**[a], **Barbara Lenz**[a], **Hamblin Phillips**[a] and **Cedric Long**[b]
[a]Preclinical Screening Laboratory, Program Resources, Inc., National Cancer Institute-Frederick Cancer Research Facility, Frederick, Maryland and [b]National Cancer Institute-Frederick Cancer Research Facility, Frederick, Maryland

This paper describes the immunomodulatory and therapeutic properties of the alkyl lysophospholipids [ALP; 1-*O*-octadecyl-2-*O*-*rac*-glycero-3-phosphocholine (ET-18-OCH_3)]. ALP was able to activate macrophages both in vitro and in vivo as well as to act as an immunoadjuvant for syngeneic tumor vaccines. However, ALP appeared to be transferred, at least in part, to the macrophage membrane, and some of the tumoricidal macrophage-activating properties seem to be associated with the direct cytotoxic effect of membrane-released ALP. ALP also had some therapeutic activity for experimental and spontaneous metastases, requiring administration three but not two times weekly at near-toxic doses; this suggests that at least some of its therapeutic activity is due to direct cytotoxicity.
Lipids 22, 871–877 (1987).

It has been reported that some immunopotentiators that stimulate host defense mechanisms against infections and tumors have a common biochemical effect. Following endocytosis by macrophages, these immunomodulatory compounds may activate a phospholipase that degrades phosphatidylcholine and phosphatidylethanolamine to the lyso derivatives and free fatty acids (1–5). Lysophosphatidylcholine, for example, was found to be active as an immunopotentiator. Naturally occurring lysophospholipids have been found to be humoral and cellular immunomodulatory agents (5–7). Since these compounds are rapidly metabolized, synthetic alkyl derivatives were developed that have extended half-lives and do not serve as substrates for cellular enzymes (8). The alkyl lysophospholipids (ALP) have been shown to have several effects on the immune system. These compounds have been described as a new class of biological response modifiers (BRM) that inhibit the growth (5,9) and metastasis (10) of syngeneic experimental mouse tumors and experimental rat tumors (11,12). Studies have indicated that the therapeutic activity of ALP may be mediated by augmenting the cytotoxic properties of macrophages (5,9,10). In addition, some ALP can destroy leukemic (13–15) and tumor cells (16,17), indicating a direct cytotoxic effect. Other ALP have been shown to induce differentiation of leukemic blast cells (18) or to counteract tumor cell invasion (19).

We have undertaken an evaluation of several BRM (20,21), including ALP, prior to considering them for clinical trials. Using a systematic approach, we initially examined the effects of BRM on the effector cell populations of normal animals in vitro. Subsequent studies of in vivo immunomodulation provided data on BRM-host interactions, including degradation, inhibition and the requirement for BRM metabolism or cellular cooperation resulting in BRM-induced immunomodulation, as well as information on dosage and toxicity. On the basis of these preliminary investigations, a BRM's therapeutic properties are studied in a quantitative and qualitative manner. We report here our studies of the immunomodulatory properties of ALP and provide information on its therapeutic efficacy.

MATERIALS AND METHODS

Animals. Specific-pathogen-free male C57BL/6 mice (H-2^b) and C3H/HeN (MTV-) mice (H-2^k), 3 or 4 wk of age, were obtained from the Animal Production Area of the National Cancer Institute–Frederick Cancer Research Facility (Frederick, MD).

Tumors. These studies used the radiation-induced fibrosarcoma UV-2237 (22), syngeneic to the H-2^k mouse, and UV-2237 Cl 46, a regressor clone (23) obtained from UV-2237. Lymphomas used included the methylcholanthrene-induced mastocytoma P815 (24), syngeneic to the DBA/2 mouse (H-2^d), and the Moloney virus-induced lymphoma YAC-1 (25) of A/SN (H-2^a) origin. Therapy studies used the metastatic melanoma variant B16-BL6 (26), which was selected in vitro from the B16 melanoma, a spontaneous tumor from a C57BL/6N mouse. The fibrosarcoma and melanoma were maintained as monolayers in minimum essential medium supplemented with 5% fetal bovine serum, glutamine, sodium pyruvate, twofold vitamins and nonessential amino acids (complete minimum essential medium). The P815 and YAC-1 tumor cell lines were grown in RPMI 1640 medium supplemented with 10% fetal bovine serum and the same medium supplements added to Eagle's minimum essential medium. All cell lines were free of *Mycoplasma* and pathogenic murine viruses. The media, supplements and serum contained less than 0.1 ng/ml of endotoxin, as assessed by the *Limulus* lysate assay (21).

Agents. ALP were provided by Dr. W. E. Berdel of the Technical University, Munich, FRG. Polyinosinic-polycytidylic acid complexed with poly-L-lysine and carboxymethylcellulose [poly (I,C)-LC] was donated by Dr. Hilton Levy (National Institute of Allergy and Infectious Diseases, Frederick, MD) and the thymosin fraction 5 was obtained from Hoffmann-La Roche, Inc. (Nutley, NJ).

Technical approach. The experiments were repeated at least three times, and any study in which either the negative or positive control did not function was performed again. In vitro assays were analyzed with the

Abbreviations: ALP, alkyl lysophospholipids; BRM, biological response modifiers; poly (I,C)-LC, polyinosinic-polycytidylic acid complexed with poly-L-lysine and carboxymethylcellulose; MLR, mixed lymphocyte reaction; MLTR-CMC, mixed lymphocyte tumor response–cell-mediated cytotoxicity; HBSS, Hanks' balanced salts solution; NK, natural killer; MTD, maximum tolerated dose.

paired Student's t-test, and the Mann-Whitney U-test was used to compare the median number of metastases.

Mixed lymphocyte reaction (MLR). Responder spleen cells were admixed with irradiated stimulator spleen cells in flat-bottom, 96-well plates in culture medium containing various doses of ALP or thymosin fraction 5, which served as a positive control. The culture medium described by Click et al. (27) was supplemented with 0.5% murine serum. The cultures were pulse-labeled with [^{3}H]thymidine (1 μCi/well) for 24 hr before harvest, which was performed with an automatic cell harvester 4 or 5 days after culture initiation (21).

Effector cells stimulated in an allogenic mixed lymphocyte tumor response-cell-mediated cytotoxicity (MLTR-CMC) assay. In the MLTR-CMC assay, effector cells were stimulated by culturing C3H/HeN (H-2^k) splenic lymphocytes with irradiated P815 (H-2^d) tumor cells. Experimental cultures of responder and stimulator cells contained various concentrations of ALP, whereas control cultures included spleen cells cultured in normal medium or in medium supplemented with ALP. After a 5-day incubation, the effector lymphocytes were washed several times; lymphocyte viability was assessed and the cytotoxic properties were determined in a 4-hr ^{51}Cr-release assay with P815 targets. The effector cell induced was specific for P815 and sensitive to anti-Thy antiserum but not to anti-asialo GM-1 antiserum. Cytotoxicity was calculated with the following formula:

$$\% \text{ of cytotoxicity} = \frac{\text{cpm released by lymphocytes} - \text{cpm released spontaneously}}{\text{Total Triton-released cpm}}$$

Induction of tumor-specific cytotoxic T lymphocytes. Mice were immunized intradermally (i.d.) with 1 $\times$ 10^6 irradiated, collagenase-dissociated UV-2237 tumor cells, with or without an adjuvant, by injecting 0.05 ml of Hanks' balanced salts solution (HBSS) containing 2 $\times$ 10^5 cells into five discrete sites. Experimental vaccines consisted of tumor cells admixed with HBSS or one of several doses of ALP. Control vaccines consisted of HBSS or ALP without tumor cells. Target cells for the cytotoxic T lymphocyte assays were added to a flat-bottom, 96-well plate in 0.1 ml of complete minimum essential medium containing 5% fetal bovine serum and 5000 viable tumor cells radiolabeled with [^{75}Se]methionine. Ten days after immunization, specific effector cells were added in triplicate at various effector-to-target cell ratios. The cocultures were incubated at 37 C for 18 hr and centrifuged for 3 min. Aliquots (0.1 ml) were removed, and the amount of radioactivity was determined. The percentage of cytotoxicity was calculated according to the following formula:

$$\% \text{ of cytotoxicity} = \frac{\text{cpm released in cultures with effector cells} - \text{cpm released spontaneously}}{\text{Total Triton-released cpm} \times 100}$$

Assay of macrophage-mediated cytotoxicity. Thioglycollate-elicited peritoneal exudate macrophages were collected, and the macrophage cytotoxicity assay was performed as previously described (20). In brief, macrophage suspensions were plated into a 96-well plate and incubated for 2 hr, and nonadherent cells were removed. The monolayers were incubated with control medium or an activating agent for 24 hr, after which the medium was removed and replaced with medium containing 1 $\times$ 10^4 IUdR-radiolabeled B16-BL6 target cells. In experiments using in vivo-activated macrophages, mice were given intraperitoneal (i.p.) injections of HBSS, poly (I,C)-LC (which served as a positive control), or ALP. Twenty-four hr later, peritoneal cells were harvested, adherence-purified and cocultured with radiolabeled target cells. The cytotoxicity assays were terminated 72 hr after the addition of target cells; the monolayers were washed, viable adherent cells were lysed and radioactivity was monitored. Under the conditions of our assay, normal (untreated) macrophages were not cytotoxic to neoplastic cells. The cytotoxic activity of the macrophages was calculated with this formula:

$$\% \text{ of cytotoxicity} = \frac{100 \times \text{cpm in target cells cultured with normal macrophages} - \text{cpm in target cells cultured with test macrophages}}{\text{cpm in target cells cultured with normal macrophages}}$$

Augmentation of natural killer (NK) cell activity. The ability of ALP to augment NK activity in vitro was determined by incubating spleen cells for 24 hr with control medium or medium containing various doses of ALP. The in vivo augmentation of NK activity was assessed after intravenous (i.v.) injection of various doses of ALP or HBSS, which served as the negative control. Three-wk-old C3H/HeN mice were routinely used for NK augmentation studies since they have a low initial level of NK activity. NK cell activity was assessed in a 4-hr ^{51}Cr-release assay using YAC target cells, as previously described (20).

Therapy of established metastases. Eight-wk-old syngeneic C57BL/6N mice were given i.v. injections of a single cell suspension of 4 $\times$ 10^4 in vitro-propagated B16-BL6 melanoma cells in calcium/magnesium-free HBSS. The schedule of therapeutic injections varied for each experiment. Therapy was continued for 4 wk; experimental mice that were alive 1 wk after the last control animal had died were killed and necropsied. Determinations of therapeutic efficacy were based on survival of the mice and the extent of pulmonary metastasis as analyzed by the Mann-Whitney U-test.

The therapeutic efficacy of ALP was also evaluated against spontaneous metastases from B16-BL6 melanoma cells. Eight-wk-old syngeneic mice were inoculated in a posterior footpad with 5 $\times$ 10^4 B16-BL6 melanoma cells in 0.05 ml of calcium/magnesium-free HBSS. When the primary tumor achieved a diameter of 0.8 to 1 cm, the tumor-bearing leg was resected at midfemur to include the popliteal lymph node. Twenty-four hr later, we initiated therapy using a protocol of injections three times per week for 4 wk. Necropsies were performed 1 wk after the last injection. The lungs were fixed, and the extent of spontaneous pulmonary metastasis was determined by counting the metastases using a dissecting microscope.

RESULTS

Augmentation of NK cell activity. Incubation of spleen cells with ALP at doses of 1.0 to 0.00001 μg/ml did not significantly augment NK cell activity in vitro (Table 1). However, the positive control, poly (I,C)-LC, did activate NK cells in vitro at 5 μg/ml. In addition, ALP is inactive in promoting NK cell augmentation in vivo at doses between 10 and 0.001 μg/animal (results not shown) when measured 1 or 3 days after injection.

TABLE 1

Effect of ALP on NK Cell Activation In Vitro[a]

Agent	Concentration (μg/ml)	Percent cytotoxicity[b] 50:1	25:1	12:1	6:1
Medium	—	17	9	2	1
Poly (I,C)-LC	5.0	66[c]	49[c]	32[c]	14[c]
ALP	0.00001	19	11	3	0
ALP	0.0001	31[c]	14	5	3
ALP	0.001	23	12	6	1

ALP	0.01	1846[b]	2030[b]	3693[b]
ALP	0.1	2183[b]	2347[b]	4123[b]
ALP	1.0	135[b]	158[b]	309[b]

[a]Irradiated C57BL/6 mice stimulator spleen cells were admixed with C3H mouse responder spleen cells at a stimulator-to-responder cell ratio of 1:10. The cultures were incubated with medium alone (negative control), thymosin fraction 5 (positive control) or various concentrations of ALP for 4 days before harvest and were pulsed with 1 μCi of [^{3}H]thymidine for 24 hr. Quadruplicate cultures were performed.

[b]Significant difference in cpm compared to medium control, as determined with Student's t-test ($p \leq 0.01$).

MLR. ALP was added to allogenic MLR cultures, which were initiated at a suboptimal stimulator-to-responder ratio (1:8) to demonstrate maximum immunomodulation (29). As a positive control, spleen cells were cocultured with thymosin fraction 5 (Table 2), which induced a significant increase in the cpm incorporated into responder lymphocytes following 4 or 5 days of coculture. Coculturing spleen cells in the presence of ALP (Table 2) significantly increased the incorporation of [^{3}H]thymidine into responder cells in the presence or absence of stimulator cells. At 4 days following coculture, ALP produced a stimulator index of 3.1 to 3.8 at concentrations ranging from 0.1 to 0.0001 μg/ml. However, at a concentration of 1 μg/ml, ALP was significantly toxic to the spleen cells, such that the coculture resulted in background levels of [^{3}H]thymidine into responder cells in the presence or absence of allogenic stimulator cells, i.e., a slight "blastogenic" activity was observed.

MLTR-CMC. ALP was also tested in an allogenic MLTR-CMC assay. These assays were performed at a suboptimal stimulator-to-responder ratio (1:300) to permit the demonstration of immunostimulation (28). At ALP concentrations ranging from 1 to 0.0001 μg/ml, cytotoxicity was not significantly increased compared to levels of activity observed with cultures in normal medium (Table 3). The positive control in this experiment, thymosin fraction 5, did significantly stimulate cytotoxic effector cell activity. The percent viability of the cells following 5 days of coculture ranged from approximately 60% to 87% in either the presence or absence of stimulator cells. However, at 1 μg/ml of ALP, the percent viability was reduced to 33% (with stimulator cells) or 36% (without stimulator cells). In addition, the number of cells per culture ranged from 6.4 to 12 $\times 10^6$ cells per culture following 5 days of coculture, whereas this number was reduced to 1.2 to 1.6 $\times 10^6$ cells per culture at 1 μg/ml of ALP. Thus, as in the MLR, ALP at 1 μg/ml had significant toxicity against spleen cells following 4 or 5 days of coculture. This was also seen in the effector cell function of spleen cells cultured with stimulator cells in the presence of ALP at 1 μg/ml. Control cultures with stimulator cells had 40% cytotoxicity at an effector-to-target cell ratio of 50:1, whereas the level of cytotoxicity was 0% following coculture with 1 μg/ml of ALP. Thus, on the basis of a number of parameters, including [^{3}H]thymidine incorporation, effector cell activity, cell numbers and percent viability, ALP at doses equal to 1 μg/ml were judged to be toxic to lymphocytes.

Specific adjuvant activity of ALP. The immunoadjuvant activity of ALP was assessed by examining their effect on the in vivo generation of splenic cytotoxic T lymphocyte activity. Normal syngeneic mice were immunized with an i.d. injection of lethally irradiated tumor cells obtained by the collagenase-DNase dissociation of subcutaneous tumors. Spleen cells from mice immunized with tumor cells alone had significantly increased splenic cytotoxic activity compared to control spleen cells (Table 4). Adding 0.01 and 0.001 μg of ALP per site to the tumor cell baccine significantly increased the level of cytotoxic effector cell activity compared to the vaccine alone. It was observed that ALP did not stimulate the cytotoxic T lymphocyte effector cell activity in the absence of syngeneic tumor vaccine.

Macrophage activation. The ability of ALP to activate

[a]C3H mice were immunized with collagenase-DNase-dissociated syngeneic UV-2237 tumor cells (5 × 10⁶ cells total in 5 i.d. injections) in HBSS or ALP. The adjuvant was administered at time 0 as an admixture. Eight days after immunization, effector cell activity was examined in a 24-hr radiorelease assay with [^{75}Se]methionine-labeled Cl-46 cells; these were obtained from clonal subpopulations of UV-2237 and more sensitive to cytotoxic T cell activity than the parent tumor (spontaneous release, 26%). Each group contained 3 mice.

[b]Cytotoxicity was determined at effector-to-target cell ratios of 200:1, 100:1, 50:1 and 25:1.

[c]Significant increases compared to sham-treated animals, as determined with the paired Student's t-test ($p \leqslant 0.01$).

[d]Significant change in cytotoxicity compared to tumor vaccine without adjuvant, as determined with the paired Student's t-test ($p \leqslant 0.01$).

macrophages in vitro was studied by incubating C57BL/6N thioglycollate-elicited macrophages with ALP for 24 hr in vitro. Cytotoxicity was assessed using syngeneic [^{125}I]IUdR-labeled B16-BL6 target cells in a 72-hr assay. ALP appeared to activate macrophages to become cytotoxic over a range from 500 to 0.0001 μg/ml (Table 5). However, ALP at concentrations greater than 10 μg/ml produced cytotoxic effects independent of macrophage activation. This high-dose toxicity is evident in Table 6, which presents the results of an assay from which macrophages were omitted. Doses of ALP from 500 to 0.01 μg/ml were cytotoxic for target cells in the absence of macrophages when M109 cells were used as a substitute monolayer for the macrophages (Table 6). These results strongly suggest a direct cytotoxic effect, which is increased in the presence of a monolayer of cells. Thus, much of the macrophage activation that has been reported in vitro, as assayed by tumoricidal activity, may be associated with nonspecific adsorption of ALP to either the tissue culture plastic or the cellular monolayer. ALP administered in vivo did, however, induce macrophage-mediated cytotoxicity, as shown in Table 7. In this study, poly (I,C)-LC served as the positive control. ALP induced macrophage tumoricidal activity at doses from 10 to 0.1 mg/kg when administered i.p., and peak activation was observed at 1 mg/kg. Thus, unlike the in vitro incubation of macrophages, the ability of ALP to activate macrophages in vivo was clearly demonstrated.

Therapy of experimental and spontaneous metastases. Experimental and spontaneous metastasis treatment models were used to investigate the therapeutic potential of ALP. In the experimental metastasis model, therapy was initiated 3 days after the i.v. injection of B16-BL6 tumor cells and was continued for 4 wk (Table 8). At the beginning of therapy, numerous microscopic pulmonary tumor nodules were histologically evident. Injecting ALP i.v. twice a week did not significantly reduce the number of experimental metastases at any dose study. By contrast, the positive control, poly (I,C)-LC, did produce a significant therapeutic effect. It

[a]Thioglycollate-elicited peritoneal macrophages were incubated for 24 hr with medium, poly (I,C)-LC (positive control) or ALP at various doses. [^{125}I]IUdR-labeled B16-BL6 tumor cells were plated onto the peritoneal macrophage monolayers in triplicate, incubated for 72 hr and assayed for cytotoxicity.

[b]Significantly increased cytotoxicity compared to medium control, as determined with the paired Student's t-test ($p \leqslant 0.05$).

[c]M109 tumor cells (an adherent cell line) were attached to the wells of the 96-well plate and coincubated with ALP for 24 hr. This allowed us to determine a control value of ALP adherence to the cell monolayer.

TABLE 7

In Vivo Activation of Peritoneal Macrophage-Mediated Cytotoxicity by ALP[a]

Agent	Dose (mg/kg)	Macrophages per animal ($\times 10^5$)	cpm (Day 3)	Percent cytotoxicity
Spontaneous release		—	1059	—
HBSS		1.9	1030	2.7
Poly (I,C)-LC	2.5	2.5	678	35.9[b]
ALP	10.0	1.2	895	15.4[b]
ALP	1.0	2.2	541	48.9[b]
ALP	0.1	2.1	909	14.1[b]

[a]C57BL/6 mice (n = 5/group) received i.p. injections of poly (I,C)-LC or ALP. Twenty-four hours later, peritoneal exudate cells were harvested. The macrophages were purified by adherence and used as effector cells with [^{125}I]IUdR-labeled B16-BL6 tumor cells in a 72-hr assay.

[b]Significant decrease in cpm compared to HBSS control Student's t-test ($p \leqslant 0.05$).

TABLE 8

Effect of ALP on Experimental Metastases[a]

Agent	Dose (mg/kg)	Median survival (days)	Median no. of metastasis (range)
HBSS	—	32	>300 (180->300)
Poly (I,C)-LC	1.5	34[b]	32[c] (24-292)
ALP	100.0	21[d]	240 (28->300)
ALP	10.0	28	>300 (208->300)
ALP	1.0	32	>300 (72->300)

[a]Syngeneic C57BL/6 mice (n = 10/group) received i.v. injections of B16-BL6 tumor cells (2.5×10^4). Three days later, therapy was initiated with twice weekly i.v. injections for 4 weeks. The study was terminated on day 70.

[b]Significant prolongation in survival according to the Kruskal-Wallis analysis ($p < 0.05$).

[c]Significant reduction in the median number of pulmonary colonies according to the Mann-Whitney U-test ($p < 0.01$).

[d]Fifty percent of the animals died of ALP toxicity, with a resultant median survival time of 21 days.

should be noted that the injection of ALP at 100 mg/kg significantly reduced the survival of these mice. Thus, even doses of ALP greater than the maximum tolerated dose (MTD) had no significant therapeutic activity when administered twice a week.

In a second study in which ALP was injected i.v. three times a week for 4 wk, we found a significant therapeutic response in animals with spontaneous metastases (Table 9). Mice began the therapeutic protocol 3 days after the resection of the primary B16-BL6 footpad tumor. Those that received excipient (HBSS) injections developed a median of 90 spontaneous metastases, and a significant reduction in the median number of lung nodules was observed in mice treated with ALP at 10 and 25 mg/kg. At 0.5 mg/kg, the positive control, poly (I,C)-LC, also produced a significant level of therapeutic

TABLE 9

Effect of ALP on Spontaneous Metastases[a]

Agent	Dose (mg/kg)	Median no. of metastases (range)	Median survival (days)	Percent cure[b]
HBSS	–	90 (0->300)	31 (28-521)	10
Poly (I,C)-LC	0.5	27[c] (0->300)	37[d] (31-521)	20
ALP	50.0	32 (0->300)	35[d] (25-521)	10
ALP	25.0	13[c] (0-205)	43[d] (22-521)	40
ALP	10.0	11[c] (0-65)	31 (25-521)	28

[a]Mice (n = 10/group) received injections of 5 × 10^4 B16-BL6 tumor cells into a hind footpad. When the tumors reached a diameter of 0.8-1.0 cm, the tumor-bearing limb was resected at midfemur to include the popliteal lymph node. Therapy was initiated 3 days later and consisted of i.v. injections twice weekly for 4 weeks. Necropsies were performed 22 days after the last injection.

[b]Animals that were grossly tumor-free 52 days (censored) after tumor resection.

[c]Probability of no differences as determined using the Mann-Whitney U-test.

[d]Significant prolongation in survival according to the Kruskal-Wallis analysis ($p < 0.05$).

activity. In contrast to the results, when ALP was administered twice a week, if it has been administered three times a week, a significant therapeutic response was observed. Interestingly, a significant prolongation of survival was observed in mice receiving 25 or 50 mg/kg of ALP with significantly greater therapeutic activity observed at 25 mg/kg ($p = 0.041$ by the Kurskal Wallis analysis) as compared to 50 mg/kg. By contrast, no significant reduction in metastatic activity was observed at 50 mg/kg of ALP, and the greatest reduction in neoplastic foci was observed at 10 mg/kg.

DISCUSSION

Previous studies with ALP have shown that this class of compounds possesses antitumor properties in several experimental animal systems (29) and specific cytotoxic or cytostatic effects in vitro against animal and human tumor cells (30-32). Studies of the primary mode of action have focused on the augmentation of cytotoxic macrophages in vitro and in vivo (13,33). Most recently, Andreesen et al. (33) demonstrated augmentation of cytotoxic human macrophages.

The present study has shown that ALP had no NK cell-augmenting effects in vivo or in vitro. However, ALP significantly increased [^{3}H]thymidine incorporation into an allogenic MLR or into lymphocytes cultured alone, i.e., it demonstrated blastogenic activity. By contrast, ALP is unable to increase the development of cytotoxic effector cells following an in vitro allogenic MLTR-CMC assay. Nonetheless, ALP had significant adjuvant activity in vivo when administered with syngeneic tumor vaccines to generate cytotoxic T lymphocytes. However, this was a modest level of activity, and other positive controls such as muramyl dipeptide demonstrated greater activity (results not shown). In addition, ALP were able to activate macrophages both in vitro and in vivo. However, the ability to activate macrophages in vitro was obscured by the nonspecific adsorption of ALP. There was significant nonspecific adherence to the tissue culture plastic, resulting in cytotoxicity in the absence of macrophages when appropriate control studies were undertaken. In addition, when we used a control cell line rather than macrophages as effector cells, nonspecific adsorption of ALP was increased compared to the level observed in tissue culture wells containing ALP alone. Under these circumstances, we observed no difference in cytotoxicity in the presence or absence of macrophages. By contrast, the results of in vivo augmentation of peritoneal exudate macrophages with ALP were somewhat easier to understand. Under these conditions, significant tumoricidal activity was observed 24 hr following the i.p. injection of ALP. Nonetheless, it is still possible that ALP was membrane-associated and resulted in direct cytotoxicity rather than activation of the macrophages. This explanation is somewhat unlikely since the ALP was injected 24 hr prior to lavage of the peritoneal exudate cells, and the macrophages were allowed to attach for 2 hr and then were extensively washed to remove both nonadherent cells and any ALP that might have been membrane-associated. Studies by Andreesen et al. (33) have also addressed the specific adherence of ALP; these authors concluded that ALP could be adsorbed onto macrophage membranes in addition to directly activating the macrophages. In the present study, the therapeutic activity of ALP was observed in both experimental and spontaneous metastases. In the experimental metastasis model (Table 8), no therapeutic activity was seen when ALP were administered twice a week, although significant toxicity was observed at the highest dose. In contrast, in the spontaneous metastasis model (Table 9), significant therapeutic activity was observed, in the absence of overt toxicity, when ALP were injected three times a week. However, no toxicity was observed when ALP were administered at 50 mg/kg in this experiment, whereas significant toxicity was observed in the experimental model at 100 mg/kg of ALP (Table 8). This suggests that the therapeutic activity of ALP may be associated with a near-toxic dose. Another difference between the two models is that ALP was administered three times and two times per week in the spontaneous and experimental metastasis models, respectively (Tables 8 and 9). In other studies, therapeutic activity has been observed in experimental metastases, as determined by prolongation of survival at 5 and 15 mg/kg of ALP when it was administered three times per week.

The tendency of ALP to kill tumor cells at low concentrations and normal cells only at higher concentrations may result from metabolic differences between the two cell types. For example, synthetic ALP can be degraded by an enzyme that is present in normal cells; this substance is absent from tumor cells, leading to an accumulation of ALP in tumor tissues (8,34-36). Recent reports have suggested that incorporation of ALP into cytomembranes, with consequent disturbances of normal phospholipid metabolism, may result in cytostatic or cytotoxic properties (19). Further, other studies have shown that 1-alkyl glycerophosphatide analogs that activate macrophage cytotoxicity can inhibit enzymes involved in regulation of cytoplasmic arachidonic acid in murine macrophages (36).

In summary, ALP has some slight immunomodulatory and immunotherapeutic activities. Much of the in vitro macrophage activation associated with ALP appears to result from nonspecific adsorption of ALP rather than to "true" activation of macrophages. In addition, the therapeutic activity of ALP, while significant, is relatively minor and can only be achieved at nearly toxic doses. Thus, much of the therapeutic activity of ALP may relate to their direct toxic activity against tumor cells (8,34-37) rather than to their immunomodulatory properties.

Bioactive phospholipid analogs of platelet-activating factor (PAF) represent a new approach to cancer chemotherapy. Various modifications of the basic structure of PAF lead to different ether lipid (EL) analogs. Data from the evaluation of thioalkyl and amidoalkyl glycerophosphocholine and of glycerophosphoinositol EL analogs against different experimental tumors in vitro (HL60 and K562 human leukemia cells, BG1 and BG3 ovarian adenocarcinomas) are presented. Exclusion of trypan blue after short exposure to the drugs determined cytotoxicity, and a soft agarose clonogenic assay measured the ability of the analogs to inhibit tumor cell proliferation. The thioalkyl EL are very active against the cell lines using both end points, and the amidoalkyl EL showed efficacy against the leukemic cell lines, whereas the phosphoinositol EL are active only at high concentrations. Combined use of EL analogs, which are membrane-interactive, with classical DNA-interactive chemotherapeutic drugs revealed that the combinations have additive antiproliferative effects. These results are promising leads in the development of the anticancer potential of ether lipid analogs.
***Lipids 22*, 878–883 (1987).**

Bioactive phospholipid analogs of platelet-activating factor [1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, PAF] possess a broad range of biological activities and represent a new approach to cancer chemotherapy (1,2). These ether lipid (EL) analogs express their antitumor properties by direct cytostatic or cytotoxic action (1–3), by activation of macrophages (2–4) and by differentiation of malignant cells (5). They interact with the plasma membrane but not with DNA: they do not interfere with DNA synthesis or function and are not mutagenic (1). Definition of their mechanisms of antitumor action requires further research.

In view of this, we have initiated a comprehensive program on the design and synthesis of new EL analogs, together with parallel biochemical, biological and pharmacological studies and structure-activity correlations, aimed at identifying new active EL analogs of possible clinical interest. Some structure-antitumor activity studies have been done (6,7); this report updates the structure-activity data of our collaborative program. We have described preliminary results with 1-thioalkyl-2-alkylglycero-3-phosphocholine analogs (thioether GPC lipids) (8–11). This communication presents further data on the thioether lipid analogs and gives preliminary results of studies with two new classes of ether lipids: 1-amidoalkyl-2-alkylglycero-3-phosphocholine analogs (amidoether GPC lipids), reported for the first time, and 1,2-dialkylglycero-3-phosphoinositol analogs (GPI lipids), which have been described briefly before (12) (Fig. 1). In view of the fact that early clinical trials have already begun with two EL analogs (1,13,14), these new thioalkyl, amidoalkyl and GPI EL analogs are of particular interest. Also, to explore the potential of EL analogs as cancer chemotherapeutic agents, experiments were conducted to determine their antiproliferative activity in combination with conventional cytotoxic agents.

MATERIALS AND METHODS

All of the new EL analogs used in this study were synthesized at the University of North Carolina at Chapel Hill. Synthesis of the thioether lipid analogs has been described (9). Reports on the synthesis of the glycerophosphoinositol (GPI) and the amidoether lipid analogs are in preparation (12,15). ET-18-OMe was provided by Wolfgang Berdel, Technical University of Munich (Federal Republic of Germany); CP 46665 was a gift from Keith Jensen, Pfizer Co. (Groton, CT). Structures and abbreviations of the EL analogs studied are given in Figure 1. The structure of CP 46665 is given in ref. 20. The EL analogs were dissolved in ethanol with the exception of ET-18-OAc-GPI, for which chloroform was used. These stock solutions were diluted with phosphate saline buffer (PBS) prior to use; the final concentration of the organic solvent in the assay mixture did not exceed 0.5% for the viability test or 0.2% for the clonogenic assay.

Adriamycin was obtained from Adria Laboratories (Dublin, OH); Cisplatin was from Bristol-Myers (Wallingford, CT); and 4-hydroperoxycyclophosphamide (the active form of cyclophosphamide) was provided by O. Michael Colvin, Johns Hopkins Oncology Center (Baltimore, MD). Aliquots of these drugs were dissolved in PBS and cryopreserved under liquid nitrogen.

Cell lines of human leukemias HL60 and K562 (American Type Culture Collection, Bethesda, MD) were cultured in RPMI 1640 medium containing 10% fetal bovine serum, 100 units/ml of penicillin and 100 μg/ml of streptomycin (all from Gibco, Grand Island, NY). Human ovarian carcinoma cell lines BG1 and BG3 (16) were propagated as monolayers in McCoy's 5A culture media (Gibco) with 10% fetal calf serum, 0.1% penicillin and 100 μg/ml of streptomycin. Serial passaging following mild trypsinization was done weekly in culture flasks (Costar, Cambridge, MA). Cells were free of mycoplasma contamination (17).

The biological activity of the drugs was evaluated using two different techniques. The cytotoxic potential of the compounds against HL60 and K562 was measured by a vital stain, trypan blue (18). Different concentrations of each drug were incubated with 5×10^5 cells/ml in 16-mm culture dishes. After 48 hr at 37 C in the presence of 5% CO_2 and 95% humidified air, viable cells were enumerated as those that retained a cell membrane permeability barrier against trypan blue dye intrusion. A hemocytometer was used to count the cells.

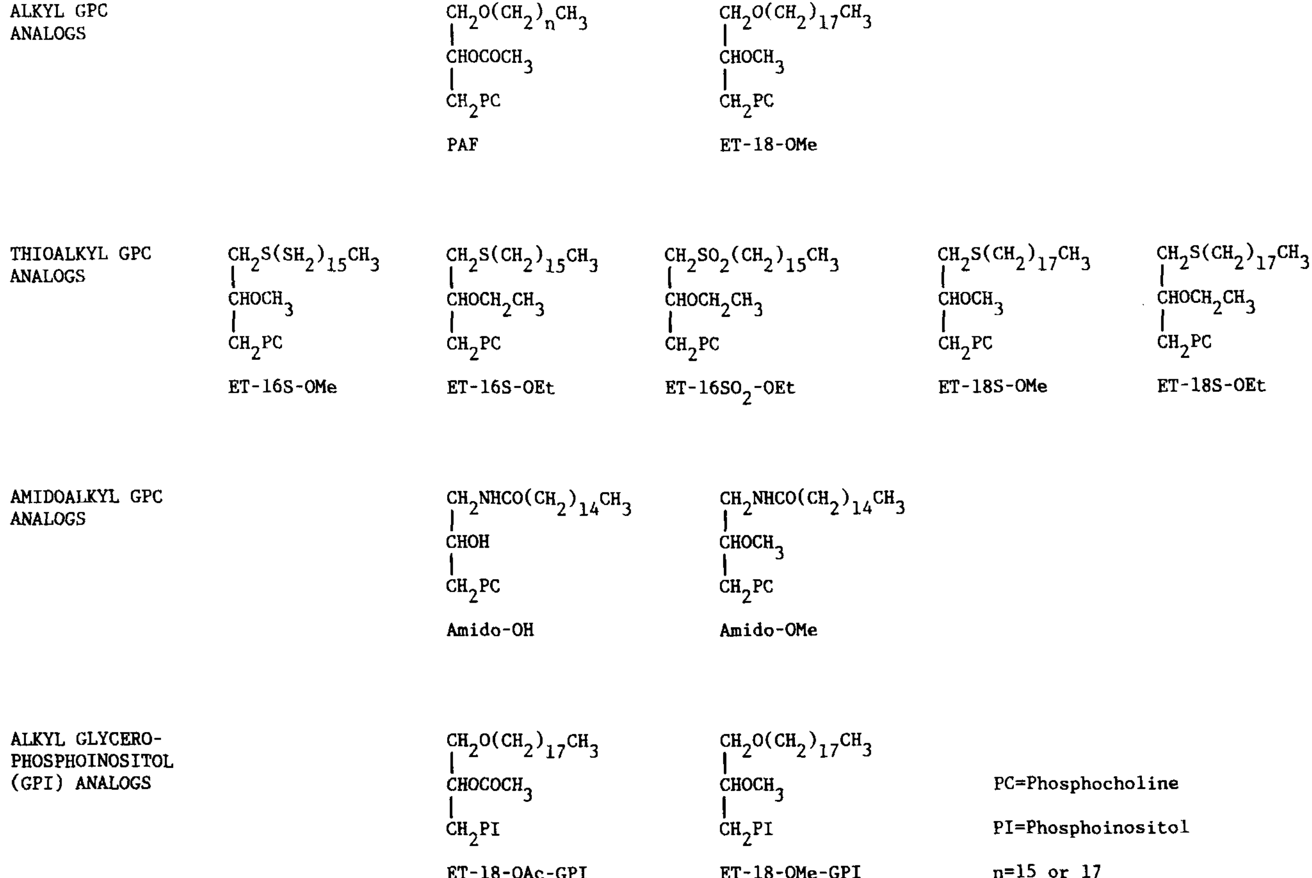

FIG. 1. Structures of PAF, 1-alkyl, 1-thioalkyl and 1-amidoalkyl glycerophosphocholine (GPC) ether lipid analogs and 1-alkyl glycerophosphoinositol (GPI) ether lipid analogs.

To determine changes in the clonogenicity of tumor cells resulting from treatment with drugs, a modified two-layer semisoft agarose assay was used (19). In brief, underlayers of 0.8% agarose in McCoy's media were prepared in 35-mm culture dishes and allowed to gel at 4 C. Single cell suspensions of the cell lines were prepared in McCoy's (BG1 and BG3) or in RPMI 1640 (HL60 and K562) with standard supplements and were mixed with molten agarose to achieve a final agarose concentration of 0.3%. One ml aliquots containing 3×10^4 ovarian carcinoma cells or 5×10^4 leukemic cells were applied to the underlayers and allowed to gel. Briefly laying the culture plates on a chilled marble slab ensured the formation of an even, firm gel. Drugs were diluted from reconstituted stock and applied one time to the two-layer agarose culture. Drugs were made as a 10× concentration of the desired final treatment in sterile PBS. Aliquots of 220 μl (1:10 dilution in the 2 ml agarose assay) were applied. (For the combination chemotherapy experiments, drugs were made as 20× concentration of the final treatment by inverted microscopy, and 110 μl aliquots of each drug were applied.) All agarose dishes were examined by inverted microscopy to ensure that cells were plated as a single-cell suspension. The cultures were incubated at 37 C and 7.5% CO_2 in humidified air for 7–10 days, during which time cell growth was monitored by inverted microscopy. Colony enumeration was done by automated image analysis (20). Colonies were defined as cell aggregates greater than 40μm in diameter. Each experiment was done in triplicate. Controls were run with a solution of 0.2 or 0.5% of solvent (ethanol or chloroform) in PBS.

RESULTS

Thioalkyl EL analogs. The thioalkyl analogs proved very effective against both leukemic cell lines in the cytotoxicity test in comparison with ET-18-OMe, which served as a reference compound (Table 1). When K562 cells were used, higher doses were required to detect some activity, because this cell line appears to be less sensitive than HL60 to the cytotoxic action of EL (21,22). However, some thio analogs were very effective against K562, particularly ET-16S-OEt. The clonogenic assay using HL60 leukemic cells confirmed, in general, what was found in the viability tests (data not shown). Although it is clear that in the cytotoxicity assays HL60 cells are more responsive to EL inhibition than K562 cells, preliminary data using K562 in the clonogenic assay did not show this difference in sensitivity between the two cell lines (data not shown). These data, however, need further confirmation.

The thioalkyl analogs were very active against the two ovarian adenocarcinomas (Table 2); in most cases they were significantly more active than ET-18-OMe. In

Each value (mean ± SD of n assays) represents colony survival as percentage of control; control values are 1549 ± 337 (BG1) and 1965 ± 236 (BG3) colonies/well. Colonies ⩾ 40 μm in diameter were counted. Values in italics indicate greater activity than ET-18-OMe. 3 × 10^4 Cells/well were plated for each tumor. *, $p < 0.05$ and **, $p < 0.01$ compared to ET-18-OMe.

this proliferative assay, both cell lines indicated that the 2-ethyl analog was more active than the 2-methyl.

The 1-sulfonyl analog is less active than ET-18-OMe and the thioalkyl analogs (Table 3). This is particularly evident with the BG1 tumor. Our ID_{50} value for ET-18-OMe against HL60 cells agrees with that published previously (23).

Amidoalkyl EL analogs. The 1-amido-2-methyl analog was as cytotoxic as the reference compound against the HL60 leukemic cell line, whereas the 2-unsubstituted analog was significantly less potent (Table 1). There was no statistical difference in inhibition of K562 cells by the 1-amido-2-methyl analog or by ET-18-OMe (Table 1).

GPI EL analogs. Synthetic modification of the EL analogs to introduce phosphoinositol instead of phosphocholine into the molecule (12) substantially reduced potency (Tables 1 and 2). Inhibitory activity was observed only at high concentrations, at levels considerably higher

TABLE 3

Comparison of ID_{50} of ET-16SO_2-OEt and ET-18-OMe in Two Different Assays

	ET-16SO_2-OEt ID_{50} (μM)	ET-18-OMe ID_{50} (μM)
HL60, cytotoxicity test	3.1 ± 0.5	2.5 ± 0.4
BG1, clonogenic assay	5.2 ± 0.1**	1.4 ± 0.1

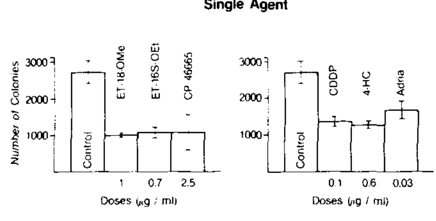
These values are the mean ± S.D. of 10 (HL60) and 3 (BG1) assays for ET-16SO_2-OEt and of 18 (HL60) and 6 (BG1) assays for ET-18-OMe. **, $p < 0.01$ compared to ET-18-OMe.

than the thioalkyl or dialkyl EL. The GPI EL analogs with either acetyl or methyl substitution at position 2 had similar degrees of inhibitory activity.

Combination chemotherapy. Figure 2 shows results of a combined administration of three different EL analogs with adriamycin, cisplatin and cyclophosphamide. The EL analogs were ET-18-OMe, ET-16S-OEt and CP 46665, a lipoidal amine for which antitumor activity has been previously described (24). These agents have different potencies in our system (8,10). Doses that inhibited ca. 50% of colony growth were used for all six drugs against the BG1 ovarian adenocarcinoma in the clonogenic assay.

The data obtained indicate that simultaneous use of these two different classes of agents provides enhanced inhibition of neoplastic cell growth. Statistical analysis of the data (16) revealed that the binary combinations of each EL analog with each DNA-interactive drug produced independent and additive effects and that neither synergism nor antagonism occurred. The thio analog had the strongest additive effect, followed by ET-18-OMe. Combinations of DNA-interactive drugs with CP 46665 showed weak additive activity.

Single Agent



Combination

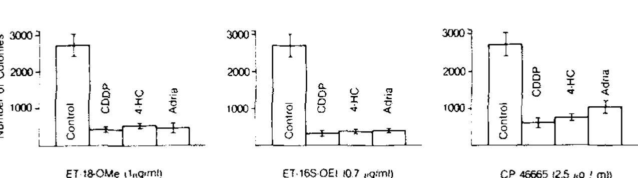


FIG. 2. Combination chemotherapy with DNA-interactive drugs: Adriamycin (Adria), Cisplatin (CDDP) and 4-hydroperoxycylophosphamide (4-HC) were used in a combined treatment with three ether lipid analogs in a semisoft agarose clonogenic assay against BG1 ovarian adenocarcinoma cells. The structure of CP46665 is given in ref. 20.

DISCUSSION

Thioalkyl EL analogs. The thioalkyl EL were designed to be more lipophilic compounds, which might therefore interact more readily with the cell membrane (8,9), the presumed lethal target for EL compounds (1). Three of these derivatives (ET-16S-OEt, ET-18S-OMe and ET-18S-OEt) were found to be very active against all the cell lines tested and in many cases significantly better than the reference compound, ET-18-OMe. ET-16S-OMe and the 1-sulfonyl analog showed cytotoxic activity comparable to that of ET-18-OMe only against HL60. Relative to the structure-activity relationship, our results indicate that (i) substitution of the ether linkage with thioether can in some cases increase the activity of EL analogs against human tumor cell lines; (ii) ethyl substitution at position 2 generally leads to more activity than methyl group substitution at this position; and (iii) the 1-sulfonyl derivative showed weaker activity than ET-18-OMe. This agrees with similar data recently reported (7).

Our data indicate that the thio analogs are one of the most active classes of EL analogs studied to date. After further preclinical studies, clinical use of one of these agents either alone or in combination with other antineoplastic agents may merit consideration. A thioalkyl EL very similar to our compounds (BM 41440) has been reported (25) to show promising antineoplastic activity in vitro and in vivo; after extensive preclinical evaluation, it is now in early clinical trials (14).

Amidoalkyl EL analogs. A 1-octadecyl-2-amido GPC analog has been described by Hoffman et al. (26) as having high activity against HL60 cells in vitro. Our approach was to assess the effect of substitution at position 2 on the activity of analogs with amido substitution at position 1. The results indicate that the 1-amido-2-methyl EL shows activity comparable to that of ET-18-OMe and superior to that of the 2-unsubstituted EL analog. Whether ethyl substitution at position 2 potentiates activity in amido-substituted EL analogs to the same degree as found in the thioalkyl-substituted compounds remains to be seen. This avenue of investigation is in progress.

GPI EL analogs. GPI analogs were designed on the basis that they might interfere with cellular proliferation by oncogene product inhibition at two points in the phosphatidylinositol cascade (8): (i) by interrupting phosphatidylinositol turnover at an early point in the cycle and (ii) by inhibition of protein kinase C, either directly or through inhibition of diacylglycerol formation, with resulting loss of cell-directed activation of the enzyme. Some activity was observed against experimental tumor cells in vitro (Tables 1 and 2). However, high doses are necessary to document this effect, and these analogs are much less active than ET-18-OMe or ET-16S-OEt.

Detailed biochemical studies are necessary to characterize the nature of the antiproliferative action of these phosphoinositol analogs. The results of the antitumor activity of these compounds are interesting because conclusions about structure-activity relationships can be made. Two GPI analogs of PAF and ET-18-OMe were tested. It has been demonstrated that PAF is far less active than ET-18-OMe as an inhibitory agent against cancer cells (8,26). PAF is readily deacetylated and thus metabolized to an inactive compound (27). This may

account for its diminished efficacy compared to other GPC analogs with methyl or ethyl substitution in position 2 (26–29).

Interestingly, the 2-acetyl GPI analog has the same activity as the 2-methoxy GPI analog; in other words, the difference in inhibitory activity so clearly evident with PC substitution at position 3 is not observed with PI substitution in the same set of analogs.

All these data are derived from in vitro studies. In vivo experimentation is now being carried out with transplantable mouse tumors to determine the therapeutic efficacy of the three groups of compounds. Normal mice and rats are being used to characterize the toxicology, metabolism and pharmacokinetics of these analogs. Also athymic mice bearing subcutaneous BG1 tumors will be treated with the different analogs; this should permit the comparison of in vitro and in vivo data directly with the same human malignant cells.

Combination chemotherapy. A most interesting and unusual feature of the EL analogs is that they act through a membrane interaction without affecting the DNA (1). Even though the precise molecular mechanism by which the antiproliferative action is exerted is still unknown, this drug-membrane relationship is well established (30–32). We have recently reported that the EL can easily interact with model membranes altering their physical properties (33). Thus it seemed reasonable to evaluate these drugs in combination with agents with a different mechanism of action to determine if this would lead to a potentially effective new approach to chemotherapeutic treatment. Additive interactions were observed for combinations of three different EL with DNA-interactive drugs (Fig. 2). This suggests that the two classes of agents operate via independent mechanisms in expressing their antiproliferative effects. ET-18-OMe has been reported to exhibit synergistic inhibition of human leukemic cells in vitro in combination with vincristine (34).

This preliminary finding is important from two points of view. First, these data indirectly confirm that the membrane is a specific target for the EL analogs; a synergistic inhibition might be expected if the EL analog enhanced the uptake of the DNA-interactive agent, as observed for vinblastine uptake in KB cells in the presence of lysophosphatidylcholine or phosphatidylinositol (35). Second, further preclinical investigation may be warranted, as this combination chemotherapy approach may provide a means of modifying the toxicity of both drugs while increasing their therapeutic efficacy.

Our results suggest three significant points in the development of EL analogs for antitumor therapy: (i) thio substitution at position 1 potentiates cytotoxic and antiproliferative activity of these compounds; (ii) a 1-amido analog is as cytotoxic as ET-18-OMe; and (iii) in combination with DNA-interactive drugs being used, EL show additive antitumor effects. Substitution of sites on the EL backbone with the goal of optimizing activity is under active investigation by our institutions as a promising approach to advancing this new class of anticancer compounds.

ACKNOWLEDGMENTS

This work was supported in part by NCI research grant CA 41314 and by a research fellowship to A.N. provided by Luciano Berti, Champion Industries, Winston-Salem, North Carolina. Thioether glycerophosphocholine EL analogs were synthesized by Susan Morris-Natschke, amidoether glycerophosphocholine EL analogs by Michael H. Marx and glycerophosphoinositol EL analogs by Khalid S. Ishaq and Maria Capobianco. J. Gaines White and Yvonne W. Dennard gave technical contributions and Susan I. Britt typed the manuscript.

SRI 62-834, an analog of the antitumor agent ET-18-OCH_3 in which the oxygen atom at carbon atom 2 has been incorporated into a five-membered heterocycle, has been prepared and evaluated as an antitumor agent. The compound exhibited good cytotoxicity in vitro against a variety of tumor cell lines and was as effective as ET-18-OCH_3 given orally in the mouse Meth A sarcoma model. SRI 62-834 was shown to be an inhibitor of platelet-derived growth factor (PDGF), possibly at the receptor level, and platelet-activating factor (PAF) at the receptor level.

Lipids 22, 884–890 (1987).

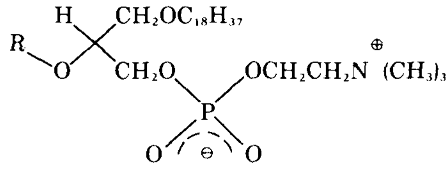

FIG. 1. Structure of ET-18-OCH_3 (R = CH_3) and platelet-activating factor (R = $COCH_3$).

The ether phospholipid ET-18-OCH_3 (Fig. 1) has been shown to exhibit neoplastic activity in vitro and in vivo against a wide variety of tumor cell lines (1). Considerable preclinical studies suggest that the antitumor action of this agent may be attributed to generation of cytotoxic macrophages (2–4), direct cytotoxicity (5), diminished activity of the alkyl cleavage enzymes present in tumors (6–9), selective cell membrane interactions (10) and inhibition of a phospholipid cofactor of a phospholipid-sensitive Ca^{++}-dependent protein kinase (11). In addition, it has been shown that ET-18-OCH_3 can purge murine leukemic bone marrow, eliminate leukemic blasts and allow hematopoietic reconstitution to occur (12). Unlike most substances being used in the clinical treatment of tumors, ET-18-OCH_3 does not appear to have a direct effect on DNA synthesis or functions, and it is nonmutagenic (5,13). Clinical phase I and II studies with ET-18-OCH_3 against a variety of advanced solid tumors have recently appeared (1,14).

Our laboratories have been involved in the synthesis and evaluation of a variety of cyclic ether analogs of ET-18-OCH_3 as potential antitumor agents (Houlihan, W.J., Munder, P.G., Lee, M.L., Parrino, V.A., and Cheon, H., unpublished data). Here we present our findings with SRI 62-834, a tetrahydrofuran analog of ET-18-OCH_3 (cf Fig. 2), against a variety of tumor cell lines, platelet-derived growth factor (PDGF) and platelet-activating factor (PAF).

MATERIALS AND METHODS

Chemical synthesis. Melting points were determined on a Thomas Hoover melting point apparatus and are uncorrected. Nuclear magnetic resonance (NMR) data for ^1H-NMR were taken on JEOL-FX-90 (90 MHz) or JEOL-FX-200 (200 MHz) spectrophotometers and are reported in δ (ppm) downfield from tetramethylsilane (TMS). ^{13}C-NMR were determined at 22.5 MHz or 50.1 MHz on the JEOL instruments, respectively, with $CDCl_3$ (77.0) and TMS (0.0) as internal reference. ^{31}P-NMR was measured at 80.76 MHz on a JEOL-FX-200 with H_3PO_4 as external reference. If not otherwise specified, chemicals and reagents were obtained from the Aldrich Chemical Co. (Milwaukee, Wisconsin). Solvents were of reagent grade and dried prior to use. Reaction progress and purity of final products were determined on E. Merck Silica Gel 60 chromatography plates. Column chromatography was carried out using E. Merck Silica Gel CH83 (0.06–0.20 mesh) with the indicated eluants. Eluants and Rf values are reported where appropriate. The purity of SRI 62-834 was also assessed by high pressure liquid chromatography (HPLC) at 1500 psi on a Beckman 345 instrument with RI detection using a Lichrosorb Si 60 5 μ dp column eluted with methanol/chloroform/water (6:5:0.5, v/v/v) at 1.5 ml/min. Retention time is reported at a chart speed of 0.2 cm/min.

(±)Methyltetrahydro-2-furoate. A suspension of 2-furoic acid (34.9 g, 0.31 mol), 95% ethanol (125 ml) and 10% palladium on carbon catalyst (1.6 g) in a pressure bottle was affixed to a Parr hydrogenation apparatus under 45 psi hydrogen and maintained at room temperature. After hydrogen uptake was complete (ca. 5 hr), the reaction mixture was filtered through a bed of celite at room temperature. The filter bed was washed with 95% ethanol, and the combined filtrates were concentrated in vacuo to yield 37.7 g of crude tetrahydro-2-furoic acid. The acid (37.7 g) was dissolved in a saturated hydrogen chloride–methanol solution (200 ml) and stirred at room temperature for ca. 5 hr. The solvent was removed in vacuo, and the residue was taken up in methylene chloride (150 ml), washed with 10% sodium bicarbonate (twice 150 ml) and water (twice 150 ml), dried with anhydrous magnesium sulfate, filtered and concentrated in vacuo to give 30.0 g (77%) of a colorless oil. Anal. calc. C, 55.4; H, 7.7. Found C, 55.2; H, 7.8.

2,2-bis-Hydroxymethyltetrahydrofuran. A stirred solution of methyltetrahydro-2-furoate (21.0 g, 0.16 mol) in anhydrous tetrahydrofuran (180 ml) under a nitrogen atmosphere was cooled to an internal temperature of −65 ±5 C and then treated dropwise with 25% diisobutylaluminum hydride solution in toluene (102 g, 0.17 mol) at such a rate that the internal temperature did not exceed −60 C. The mixture was stirred for an additional 1.5 hr at −60 C and then treated carefully with anhydr-

ous methanol (23 ml) such that the temperature did not exceed −50 C. The solution was allowed to warm to 5 C and then was added to a stirred solution of 37% aqueous formaldehyde (226 ml, 3.9 mol), sodium hydroxide (52 g, 1.3 mol) and water (170 ml) while maintaining the internal temperature at 10 ± 5 C. The mixture was treated with formic acid (6.8 ml) and then concentrated in vacuo with a water aspirator at 65 ± 5 C until distillation ceased. The residue was cooled to 25 C, treated with methylene chloride (90 ml) and stirred for ca. 0.25 hr. The resultant slurry was filtered, and the solid washed with methylene chloride (360 ml). The filtrate was concentrated in vacuo on a rotary evaporator, and the residue distilled (bp 108–120 C at 0.2–0.3 mm Hg) to give a semisolid that crystallized from toluene to give 10.5 g (50%) of a white solid; mp 58–60 C (lit. [15] mp 51–53 C).

(±)-2-Hydroxymethyl-2-octadecyloxymethyltetrahydrofuran (9.9 g, 0.075 mol) in dimethyl sulfoxide and tetrahydrofuran. To a stirred solution of 2,2-bis-hydroxymethyltetrahydrofuran (1:1, 100 ml) was added at room temperature powdered potassium hydroxide (4.2 g, 0.075 mol) followed by dropwise addition of n-octadecylbromide (8.4 g, 0.025 mol) in tetrahydrofuran (30 ml). The reaction mixture was stirred for ca. 16 hr and concentrated in vacuo. The residue was treated with water (100 ml) and extracted with diethyl ether (100 ml, three times). The ether layer was washed with saturated sodium chloride solution, dried with anhydrous magnesium sulfate, filtered and concentrated in vacuo. The residue (11.0 g) was chromatographed (1:1 methyl t-butylether/hexane followed by 3:1 methyl t-butylether/hexane) to give 5.8 g (33%) of a white sticky solid, Rf 0.52 (methyl t-butylether), MS (isobutane DCI) mz 356 (MH^+). Anal: Calc C, 74.1; H, 12.4. Found: C, 74.0; H, 12.5.

(±)-2-{Hydroxy[tetrahydro-2-(octadecyloxy)methylfuran-2-yl]methoxyl]phosphinyloxy}-N,N,N-trimethylethaniminium hydroxide, inner salt (SRI 62-834). To a stirred solution of (±)-2-hydroxymethyl-2-octadecyloxymethyltetrahydrofuran (2.9 g, 7.6 mmol) in anhydrous benzene (50 ml) maintained under a nitrogen atmosphere was added at room temperature anhydrous triethylamine (1.22 ml, 8.8 mmol), 4-dimethylaminopyridine (86 mg) and 2-chloro-2-oxo-1,2,3-dioxophospholane (16) (1.4 g, 9.8 mmol). The reaction mixture was stirred for 16 hr at room temperature and then concentrated in vacuo. The residue was dissolved in anhydrous acetonitrile (40 ml) and placed in a pressure bottle equipped with a magnetic stirring bar. The bottle was cooled in a dry ice acetone bath and anhydrous trimethylamine gas was bubbled in for ca. 15 min. The bottle was then capped and heated at 60–65 C for 48 hr. After being cooled to ca. −20 C (ice-methanol), the solid was filtered off, washed with acetonitrile (5 ml) and chromatographed (chloroform/methanol/water; 70:35:7, v/v/v) to give a white solid. The solid was dissolved in ethanol (15 ml, three times) and evaporated to remove traces of water. Crystallization from chloroform/acetone (1:1, v/v) (15 ml) gave 2.1 g (49%) of a white solid mp > 230 C; Rf 0.3 ($CHCl_3/CH_3OH/H_2O$; 70:35:7, v/v/v); HPLC retention time 7.22 min.; ^1H-NMR ($CDCl_3/CD_3OD$) δ 0.88 (t, 3H, J = 7.5, CH_3) 1.25 (s, 30 H) 1.51 (m, 2H), 1.91 (m, 3H), 3.21 [s, 9H, $^+N(CH_3)_3$], 3.37 (s, 2H), 3.41 (d, 2H), 3.58 (brs, 2H), 3.82 (m, 4H), 4.25 (brs, 2H); ^{13}C-NMR ($CDCl_3/CD_3OD$) ppm 29.436 and 29.582 [$(CH_2)_n$], 54.254 [$N^+(CH_3)_3$] 67.715 (CH_2N^+), 67.931, 68.707, 71.890, 73.350 (various CH_2O); ^{31}P-NMR ($CDCl_3/CD_3OD$) 1.22 pp.; MS (isobutane DCI) m/z (rel int.) 550 (M^+, 15), 367 (M^+-OPC, 100). Anal. for $C_{29}H_{60}NO_6P{\cdot}H_2O$: Calc. C, 61.3; H, 10.9; H, 2.4. Found: C, 61.4; H, 11.1; N, 2.3.

Cell lines. The tumor cell line Abelson-8.1 was obtained from A.W. Harris (Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia) and the YAC-1 from G. Klein (Department of Tumor Biology, Karolinska Institute, Stockholm, Sweden). The cells were grown in stationary suspension culture in Dulbecco Modified Eagle's Medium (DMEM) and 10% heat inactivated fetal calf serum (FCS) supplemented with 50 μM 2-mercaptoethanol, 100 units penicillin and 1 μg streptomycin. The P815 and L1210 cells were from the Max-Planck-Institut fuer Immunbiologie cell line collection and were passed intraperitoneally (ip) in vivo every week. The MethA fibrosarcoma cells were originally induced in BALB/C mice by administering methylcholanthrene according to the procedure of Old et al. (17).

The human neuroblastoma cells were obtained by dissociating and culturing a freshly explanted tumor specimen. The cells were used after weekly passage for four weeks in DMEM and supplements.

Human foreskin fibroblasts (AG1523) were obtained from the Institute of Medical Research (Camden, New Jersey) and propagated from frozen stock in DMEM (pH 7.8) supplemented with 20% FCS, 1% nonessential amino acids (Gibco Cat. No. 320-1140), 1% essential amino acids (Gibco Cat. No. 320-1135), 1% vitamins (Gibco Cat. No. 320-1120), 6 mM glutamine, 100 units/ml penicillin and 100 μg/ml streptomycin. The cells (passages 6 or 7) were maintained at 37 C under a humidified atmosphere of 95% air/5% CO_2.

Macrophages were grown from the bone marrow cells of (Balb/C × $C57/bl_6)F_1$ mice as described elsewhere (8). Cultivation was effected by placing a suspension of 3 × 10^6 bone marrow cells/50 ml, DMEM, 10% FCS, 5% horse serum and 3% supernatant of L929 fibroblast culture containing stimulating factor into ethylene oxide sterilized 30 × 5 cm Teflon bags (Biofolie, Heraeus, Hanau, FRG) as previously described (18). The cells are cultivated on the hydrophobic side of polymeric fluorocarbon film, and in 8–12 days the precursor cells develop into mature macrophages (19). Macrophages are brought into single cell by rolling the cultivation suspension side of the bag slightly without pressure between two fingertips. After 12 min, the moderately attached macrophages came off. After sterilizing, the cell suspension was centrifuged on a Ficoll hypaque layer at 500 g for 30 min, and the mononuclear cells were washed, first at 400 g for 10 min and then at 250 g for 10 min.

Biochemicals and radiochemicals. ET-18-OCH_3 (rac-1-octadecyl-2-methoxy-3-phosphorylcholine) was obtained from R. Berchthold (Biochemicals Laboratory, Bern, Switzerland); human PDGF (300,000–500,000 units/mg where one unit is defined as the amount of PDGF needed to stimulate the incorporation of [^3H]thymidine into 3T3 fibroblast DNA to the same extent as 5% calf serum [20]) was obtained from Cellular Products, Buffalo, NY; [^3H]thymidine was obtained from Amersham and Buchler (Braunschweig, FRG) or ICN (Irvine, CA); ^{125}I-PDGF was prepared by Dr. Larry D. Witte (Columbia University, College of Physicians and Surgeons, New York City, NY) using the method outlined by Bowen-Pope and Ross (21); ^3H-PAF (9,10-1-O-octadecyl-^3H) was prepared in the

laboratories of the Sandoz Research Institute by the procedure of Morgat (22).

Tumor cell cytocoxicity. Abelson-8.1 tumor cells (1×10^3 cells/well) in DMEM and 10% FCS were placed in flat-bottom microtiter plastic plates (Nunc Roskieide, Denmark) and incubated with 5 μg/ml of SRI 62-834 or ET-18-OCH_3 dissolved in water for 24–72 hr. The number of tumor cells present was determined by measuring alkaline phosphatase activity by a modified procedure of Culvenor (23); the tumor cell plates were centrifuged at 500 $\times$g for 10 min and the supernatant was flicked off. Without further washing, 100 μl of buffer containing 20 μl of diethanolamine, 2 μM magnesium chloride hexahydrate, 2.5 μM p-nitrophenylphosphate and 10 mg Triton X-100 was added. The samples were incubated for 60 min at room temperature, and the enzymatic activity was terminated by the addition of 100 μl of 0.5 N sodium hydroxide. The absorbance was then measured at 405 nM using a Titertek Multiskan apparatus and compared to non-drug-treated cells. The same assay procedure was used to determine P815, YAC-1 and L1210 tumor cells.

The tumor cell growth of the MethA fibrosarcoma and human neuroblastoma were assayed by the procedure of Berdel et al. (4). After the incubation period, 0.5 μCi of [6-^{3}H]thymidine was added to each well, and allowed to incubate for 24 hr. The cells were collected with a multiple automated sample harvester (Mash II, Flow Laboratories, Bonn, FRG) on glass filter paper. The filters were dried at 55 C, and then transferred to scintillation vials containing 4 ml scintillation fluid (Scintigel, Roth KG, Karlsruhe, FRG). The radioactivity was measured in a liquid scintillation counter.

Macrophage cytotoxicity. Mouse macrophages (10^5/well) were incubated with 10 μg/ml of ET-18-OCH_3 for 24 hr in flat-bottom microtiter plates, after which they were centrifuged and washed once. Abelson-8.1 tumor cells (1×10^3/well) in DMEM and 10% FCS plus 5 μg/ml of SRI 62-834 or ET-18-OCH_3 were added to the plates and incubated for 72 hr. With the cytotoxicity of ET-18-OCH_3 (10 μg/ml) alone set at 100%, the enhancement of the cytotoxic effect was assayed by the [^{3}H] thymidine method desribed above.

Mouse MethA fibrosarcoma assay. Ten CBF_1 mice, 10–12 wk of age, were implanted with 10^5 MethA sarcoma cells to serve as control. Ten other CBF_1 mice were implanted with 10^5 MethA sarcoma cells and on day 1 after implant were each treated per os (p.o.) with 50 μg of SRI 62-834 or ET-18-OCH_3; daily drug treatment continued for 27 days. On days 7, 15, 21 and 28 after tumor implant, the entire tumor volume was calculated by the equation $V = 2/3\pi AB(AB + B/2)$, where A and B are measured tumor diameters.

Human fibroblast platelet–derived growth factor (PDGF) mitogen assay. Confluent fibroblast cultures in 96-well plates were quiesced at 37 C in growth medium containing 0.5% calf serum for 28 hr. Compounds to be tested or the appropriate vehicles were added to fibroblasts 1 hr before. The cultures were exposed to PDGF for 15 hr before [^{3}H]thymidine (2.0 μCi/ml) was included in the quiescing medium. Two hr after the addition of [^{3}H]thymidine, the medium was aspirated, and the fibroblasts were washed with Dulbecco's phosphate-buffered saline (ph 7.4) containing 1mM $CaCl_2$ and 1 mM $MgCl_2$ followed by 10% trichloroacetic acid and ethanol/ether (2:1, v/v). Phase-contrast microscopy was used to inspect the microwells for evidence of cell detachment or changes in cell morphology. Acid-insoluble [^{3}H]thymidine was extracted into 0.5 N NaOH, and the radioactivity was quantified with a gamma counter.

[^{3}H]Thymidine uptake. Human foreskin fibroblasts were propagated in 24-well plates (1×10^5 cells/well) and quiesced as described above for estimates of [^{3}H]thymidine incorporation into DNA. SRI 62-834 or its vehicle was added to the quiescing medium 1 hr before the addition of media. Fibroblasts were incubated with 5% calf serum for 15 hr and [^{3}H]thymidine (0.5 μCi/ml) was added. Thirty or 90 min after the addition of [^{3}H]thymidine, the uptake experiments were terminated by aspirating the media and washing the cell sheets twice with cold (0 C) Dulbecco's phosphate-buffered saline (pH 7.4) containing 1 mM $CaCl_2$ and 1 mM $MgCl_2$. [^{3}H]Thymidine was extracted into 10% trichloroacetic acid at 20 C for 15 min. Aliquots of the acid extracts were neutralized with 0.5 N NaOH. Radioactivity in the neutralized extracts was quantified with a liquid scintillation counter.

^{125}I-PDGF specific binding. The specific binding of ^{125}I-PDGF to human foreskin fibroblasts was determined essentially as proposed by Bowen-Pope and Ross (21). Human foreskin fibroblasts which had been seeded into 24-well plates (5×10^4 cells/well) were incubated at 37 C for 96 hr in 1 ml of growth medium containing 20% FCS. The growth medium was not changed during this time. At the end of 96 hr, the growth medium was aspirated and the confluent cultures were washed twice with binding medium, which consisted of phosphate-buffered saline (pH 7.4) containing 1 mM $CaCl_2$, 0.5 mM $MgCl_2$, 2 mg/ml bovine serum albumin and 15 μg/ml phenol red. Fibroblasts were incubated with SRI 62-834 or its vehicle for 1 hr at 37 C, before ^{125}I-PDGF (6–11 ng/ml, 10-20 μCi/μg) was added to the cultures in the appropriate vehicle to a total volume of 350 μl. The incubation was continued for 2 hr at 4 C with gentle shaking. Nonspecific binding of ^{125}I-PDGF (20–40% of total binding) was estimated in the presence of a 50-fold molar excess of unlabeled PDGF. Binding assays were terminated by aspirating the radioactive medium and washing the cell sheets three times with 1 ml of fresh binding medium at 0 C. After the cultures had been inspected with a phase-contrast microscope for morphological changes, the cells were solubilized in 1% Triton X-100 containing 1 mg/ml bovine serum albumin by incubation at 37 C for 30 min. Radioactivity in aliquots of Triton-solubilized cells was quantified with a gamma counter.

Protein kinase C assay. Partially purified protein kinase C was prepared by a modification of the method described by Sahyoun et al. (24). Brains from male Sprague-Dawley rats (175–200 g) were homogenized with a Brinkman Polytron in ice-cold 50 mM Tris/HCl (ph 7.4 at 25 C) containing 10 mM dithiothreitol, 5 mM EGTA and 2 mM EDTA. The homogenate was incubated in the ice for 1 hr and then centrifuged at 100,000 $\times$ g for 30 min. The supernatant was passed through a PD 10 Sephadex G-25 M column and purified on a Pharmacia FPLC Mono Q anion-exchange column using a 0.05 M NaCl gradient containing 50 mM Tris-HCl (pH 7.4 at 25 C), 1 mM dithiothreitol.

Protein kinase C activity was determined by incorporation of ^{32}P into histone from [^{32}P]ATP by a modification of the method described by Castagna et al. (25). The assay

contained 10 μM [γ-^{32}P]ATP (0.5–1.0 μg/mM), 200 μg histone (Sigma, Type III), 5 mM $MgCl_2$, 0.5 mM $CaCl_2$, 0.8 μg diolein, 40 μg phosphatidylserine and purified protein kinase C in 1 ml of 0.05 M Tris/HCl buffer (pH 7.4 at 25 C) together with 0.15–9.00 mM SRI 62-834. The assay was incubated at room temperature for 5 min and terminated by the addition of 1 ml of 25% trichloroacetic acid, and the assay tubes were filtered through Whatman G/F glass fiber filters. The filter papers containing the precipitated histone and incorporated ^{32}P were counted in a Beckman LS 8000 scintillation counter. Blank values were determined by assays run without phosphatidylserine and diolein.

Drug inhibition is expressed as the decrease in phosphatidylserine- and diolein-stimulated ^{32}P incorporation into histone.

Platelet aggregation inhibition. Human subjects were kept aspirin-free for one week and fasted overnight. Platelet-rich plasma (PRP) was prepared by centrifugation (250 × g, 10 min, 24 C) of freshly drawn blood anticoagulated with 0.38% sodium citrate (final concentration). Platelet count was adjusted to 2.5 × 10^5 per μl using platelet-poor plasma (PPP) obtained by a second centrifugation (900 × g, 15 min, 24 C) of the blood sample. An aliquot (0.38 ml) of the PRP was dispensed into cuvettes, incubated at 37 C and stirred at 900 rpm within a Payton Aggregometer, which recorded the light transmission pattern of the platelet suspension. The test compound was then added at final concentrations in the range of 0.1–100 μM. One minute after the addition of test compound, PAF-18 was added to the cuvette in an amount predetermined to give a consistent increase in light transmission (4.8 × 10^{-7} M). All aggregations were allowed to proceed for 5 min from the addition of the PAF. The aggregation response was quantitated by determining the area under the curve (AUC) using a plane polarimeter. The percent inhibition of the aggregation response was determined by dividing the AUC generated in the presence of the compound by the AUC of the PAF alone, multiplying by 100 and subtracting from 100.

Inhibition of [^{3}H]PAF binding to the human platelet PAF receptor. The binding assay is a modification of the procedure of Valone (26) and Kloprorogge (27) and the preparation of platelets a modification of the method of Radomski and Moncada (28). Freshly drawn human blood was anticoagulated with 0.38% sodium citrate and 2.8 μg/ml PGI_2. PRP was prepared by centrifugation of the blood at 250 × g for 10 min at 24 C. The platelets were sedimented by centrifugation at 900 × g for 15 min at 24 C and then washed twice with a solution of Tris-Tyrode's buffer (pH 7.4) containing 0.25% bovine serum albumin (TT/BSA) and 0.3 μg/ml PGI_2. The washed platelets were resuspended to 3.5 × 10^5 per μl in TT/BSA. Aliquots of platelets (500 μl) were mixed with 1.5 nM [^{3}H]PAF (40,000 cpm; 49 Ci/mmol). Nonspecific binding was estimated in duplicate tubes containing excess cold PAF (3.7 × 10^{-7} final concentration). After incubation at 24 C for 1 hr, the reaction was stopped by adding 500 μl ice-cold TT/BSA. The [^{3}H]PAF bound to platelets was separated from the free radioligand by centrifugation at 900 × g for 10 min at 4 C. Pellets were washed with TT/BSA and centrifuged at 900 × g for 15 min at 4 C. The pellets were resuspended in 2.5 ml liquid scintillation fluid, and the tubes were mixed and counted for one minute in a liquid scintillation spectrometer. The amount of specific binding was calculated as the difference in cpm between the total bound [^{3}H]PAF and nonspecifically bound [^{3}H]PAF (bound in the presence of 3.7 × 10^{-7} M cold PAF). The percent inhibition of specific binding was determined by dividing the cpm specifically bound in the presence of the test compound by the cpm specifically bound in the vehicle control, multiplying by 100 and subtracting from 100. An IC_{50} (50% inhibitor concentration) value was generated by evaluating the test compound over the concentration range of 0.1–100 μM.

PAF-induced guinea pig hemoconcentration (HC) and bronchoconstriction (BC). The methodology of Handley (29,30) for evaluation of PAF-induced HC in the guinea pig was used. Briefly, 100 ng/kg^{-1} PAF-18 was given intravenously, and blood samples were taken from the femoral artery for determination of hematocrit changes. For BC studies, animals were similarly prepared, tracheotomized and given flaxedil (gallamine triethiodide, American Cyanamid, Pearl River, NY; 10 mg/kg^{-1} ip) to suppress natural breathing. Animals were artificially ventilated (Harvard Respirator, 60 breaths min^{-1}, tidal volume of 3.5 ml/kg^{-1}), and bronchial resistance was determined from initial values, monitored with pressure transducers and a Gould 2400S recorder. SRI 62-834 in 0.9% saline (three animals per dose) was given intraarterially (ia) 5 min before the PAF challenge. Blood samples and bronchial tracings were taken during the predose time to determine if SRI 62-834 influenced these parameters.

0.30	96
0.90	71
1.80	31
5.40	25
9.00	21

[a]The control enzyme activity was 0.059 μ mol/mg/min.

RESULTS AND DISCUSSION

The synthesis of SRI 62-834 starting from the commercially available 2-furoic acid was accomplished in the seven synthetic steps given in Figure 2.

A summary of the direct cytotoxicity effects of SRI 62-834 and ET-18-OCH_3 on a variety of tumor cell lines is given in Table 1. The proliferation rate of the cells during a 72-hr period was reduced significantly when SRI 62-934 was included in the media at 5 μg/ml. Incubation of SRI 62-834 with preactivated mouse macrophages and Abelson-8.1 lymphoma cells for 72 hr showed the compound to be a highly effective macrophage activator resulting in ~ 98% elimination of the tumor cell inoculum (cf Table 1).

Evaluation of SRI 62-834 at ca. 2.5 mg/kg and 0.25 mg/kg, respectively, in the mouse MethA sarcoma model over a 28-day period showed that the compound had a very positive effect in controlling the size of tumor growth and increasing the number of survivors. The efficacy of SRI 62-834 compared to ET-18-OCH_3 appears to parallel the in vitro antitumor findings since both compounds have similar po activity in the mouse MethA sarcoma model (cf Table 2).

To determine whether SRI 62-834 had any effect on normal cell function in the concentration range that was toxic to tumor cells, it was incubated with human foreskin fibroblasts at 2.5 μg and 5.0 μg/ml, respectively, for a 15-hr period. The cells were then challenged with [^{3}H]thymidine, and 90 min later uptake was measured. At both doses, SRI 62-834 did not cause any alteration of uptake relative to the untreated control cells (cf Table 3). Examination of the cells after drug treatment by phase-contrast microscopy failed to uncover any morphological changes.

In recent years, a number of experiments have provided a connection between oncogenes and human cancer (31). One of the peptide chains of human PDGF, a cationic glycoprotein composed of two disulfide-linked peptide chains, shows amino acid sequence homology with the predicted protein products of viral *sis* oncogene (32) and the cellular *sis* proto-oncogene (33). Moreover, studies linking PDGF to oncogene products, coupled with the findings that human osteosarcomas, fibrosarcomas and glioblastomas in culture synthesize and release biologically active PDGF-like polypeptides into their media, raise the possibility that an inhibitor of this growth factor could represent a useful mechanism for an antineoplastic agent (34–38). SRI 62-834, when added at 10 μM and 1 μM to a human fibroblast cell culture that was then treated with PDGF, caused 100% inhibition of the mitogenic effect of PDGF at the high concentration and 35% inhibition at the lower. At either concentration level, no alteration in cell morphology or cell death was found. These findings suggest that the antimitogenic effect of SRI 62-834 cannot be attributed to the inhibition of thymidine uptake, since it was not inhibited in the absence of PDGF. It is also interesting to note that these concentrations are in the same range as those that gave a good cytotoxic response to the tumors given in Table 1.

To determine whether the PDGF mitogenic inhibition could be receptor mediated, SRI 62-834 was evaluated at 10 μM in the ^{125}I-PDGF receptor assay and found to exhibit only 6% inhibition. At 50 μM, a 100% inhibition of the receptor to ^{125}I-PDGF was achieved. These findings do not support a role for SRI 62-834 as a specific receptor antagonist at the cytotoxic concentration reported in Table 1. It is possible that when administered at higher concentration, SRI 62-834 could perturb the PDGF receptor, alter its interaction with PDGF and exert an antioncogenic effect.

We also investigated the effect of SRI 62-834 on protein kinase C activity, since the binding of PDGF to its receptor has been shown to result in the activation of this enzyme (39). No effect was seen until SRI 62-834 was administered at ca. 1.0 mM (Table 4). This concentration is ca. 100-fold higher than the cytotoxic dose and rules out any involvement of protein kinase C in the antitumor effects of SRI 62-834.

Since SRI 62-834 has a structural resemblance to PAF (Fig. 1), it was evaluated in several tests where PAF has been demonstrated to cause adverse pharmacological results (40). SRI 62-834 at concentrations up to 100 μM did not cause any aggregation of human platelets and demonstrated a protective effect (IC_{50} 19.7 μM) against PAF-induced aggregation. The protective effect of SRI 62-834 against PAF induce aggregation is probably mediated through a receptor mechanism since it inhibited (IC_{50} 27.3 μM) [^{3}H]PAF binding to the human platelet receptor. Administration of SRI 62-834 to guinea pigs at doses up to 2.7 mg/kg ia showed no influence on hematocrit and bronchial resistance. Under similar conditions, 0.001 mg/kg of PAF-18 given IV resulted in marked hematocrit and bronchial changes that led to death. When 2.7 mg/kg of SRI 62-834 was given ia 5 min prior to administration of 75 ng/kg of PAF-18, it failed to protect against the resultant hematocrit and bronchial changes.

In conclusion, we have demonstrated that SRI 62-834 has in vitro and in vivo antitumor activity of the same magnitude as the clinically effective ET-18-OCH_3. The antitumor properties of SRI 62-834 appear to be due to direct and macrophage-induced cytotoxicity. The effect of this agent and related ether phospholipids on PDGF and its relationship to antitumor properties merits additional study.

[Received January 29, 1987]

Liposomes in Chemo- and Immunotherapy of Cancer[1]

Gerrit L. Scherphof*, Toos Daemen, Halbe H. Spanjer and Frits H. Roerdink
Laboratory of Physiological Chemistry, University of Groningen, Bloemsingel 10, 9712 KZ Groningen, The Netherlands

In this paper, we report on the in vivo behavior of liposomes as a function of their size and composition. It is emphasized that by varying these parameters we can influence not only the rate of blood elimination but also the intrahepatic destination of the liposomes. Thus, we show that small liposomes with diameters well below 100 nm can reach and be internalized by the parenchymal cells of the liver, i.e. the hepatocytes. The rate and the extent at which this occurs depends on the liposomal composition. With respect to the application of liposomes as a drug carrier system in anticancer therapy, we put emphasis on the liver macrophage, i.e. the Kupffer cell, as a target cell. Large liposomes with diameters well over 100 nm exclusively are taken up by these cells as far as hepatic uptake is concerned. By encapsulation within liposomes, a drug may be delivered specifically to these macrophages; this will prevent its rapid excretion from the body and/or undesired accumulation in other cell types. Two examples of the way in which this condition may be exploited are presented. First, we demonstrate the formation of intracellular depots in the macrophages of the cytostatic drug 5-fluorodeoxyuridine (FUdR), thus preventing the rapid metabolism of the drug by the hepatocytes and allowing its sustained release from the macrophages and subsequent uptake by adjacent metastatic tumor cells. Second, we show that the liposome-encapsulated immunomodulator muramyl dipeptide is capable of activating liver macrophages both in vitro and in vivo to a tumor-specific cytotoxic state, and this can result in substantial reduction of metastatic growth in the livers of mice inoculated in the spleen with colon adenocarcinoma cells.
Lipids 22, **891-896 (1987).**

Liposomes have been considered as a potential drug carrier system for many years (1-3). For this reason, numerous investigators have engaged in attempts to investigate and characterize the in vivo behavior of liposomes (4-6), their modes of interaction with a variety of cell types (7-10) and their effectiveness in the combat of infectious (11-14) or neoplastic (15-18) disease when carrying antibiotic, cytostatic or immunomodulating drugs. The expected modes of action of such therapeutically designed liposomes include direct uptake of the drug-containing liposomes by the target cells, e.g. tumor cells; alteration of the pharmacokinetic properties of the encapsulated drug, such as rate of clearance and tissue distribution, resulting in an improvement of therapeutic index; or uptake by phagocytic cells such as monocytes and macrophages, leading to activation of such cells to a specific tumoricidal state (18-20).

Uptake of liposomes by nonphagocytic cells, including most tumor cells generally is questionable or, at best, of little significance (21,22). Therefore, beneficial effects of liposome encapsulation of a cytostatic drug on its therapeutic efficacy is most likely to result from a favorable effect on its pharmacokinetic characteristics. We show in this paper the dependence of in vivo behavior of liposomes, including intrahepatic distribution, on their size and composition; how this can be applied to modify drastically the pharmacokinetic parameters of a cytostatic drug, 5-fluorodeoxyuridine (FUdR); and that specific uptake of adequately designed liposomes containing muramyl dipeptide by liver macrophages can render these cells in vitro and in vivo cytotoxic to tumor cells and cause them to effectively prevent or reduce metastatic growth in the liver of mice inoculated with colon adenocarcinoma cells.

MATERIALS AND METHODS

Preparation of liposomes. Small unilamellar liposomes (SUV), of the indicated lipid compositions, 25-40 nm in diameter and labeled with encapsulated [^{3}H]inulin in the aqueous space or with a tracer amount of cholesterol [^{14}C]oleate in the lipid phase were prepared by ultrasonication of the appropriate lipid dispersions in buffer as described before (23). Multilamellar liposomes (MLV) with a diameter of approximately 400 nm were prepared from the indicated lipid composition as follows: the lipids, purchased from Sigma Chemical Co. (St. Louis, MO) and stored in chloroform/methanol (8:2) under nitrogen at −20 C, were mixed in appropriate ratios, dried under reduced nitrogen pressure, dissolved in benzene and lyophilized. The lipids then were hydrated in 135 mM NaCl, 10 mM HEPES, pH 7.4 (Hepes/Nace [HN]-buffer) or in HN-buffer containing muramyldipeptide (MDP) or [^{3}H]FUdR and vortexed for 10 min at room temperature. The vesicles formed were sized by extrusion through a series of polycarbonate membranes (Nucleopore) (24) of 1 μm, 0.8 μm, 0.6μm and 0.4 μm pore diameter, respectively. Vesicles were freed from non-encapsulated material on a Sephadex G100 column (Pharmacia [Uppsala, Sweden]). The liposomes were prepared to contain in their aqueous space either [6-^{3}H]-5-fluoro-2′-deoxyuridine (New England Nuclear [Boston, MA], spec. act. 14.7 Ci/mmol) appropriately diluted with unlabeled 5-fluoro-2′-deoxyuridine (Hoffmann-La Roche [Nutley, NJ]) or muramyl dipeptide, from Ciba-Geigy (Basel, Switzerland). Liposome preparations were stored under nitrogen at 4 C and used within two days after preparation.

Isolation of rat liver macrophages. Liver macrophages were isolated by pronase digestion of the liver and purified by centrifugal elutriation as described by Knook and Sleyster (25) and modified by Dijkstra et al. (26). Briefly, the liver was preperfused with Gey's balanced salt solution (GBSS) to remove blood and perfused for three min with 0.2% pronase (Boehringer-Mannheim [Federal Republic of Germany]). The organ was removed, cut into small pieces and incubated in 0.2% pronase for 50 min in the presence of DNase. The cell suspension was washed

once, and non-parenchymal cells were separated from non-viable parenchymal cells and remaining erythrocytes by centrifugation on a metrizamide gradient (analytical grade, Nyegaard, Oslo, Norway) (0.7%) for 15 min, 1500 × g. The top layer containing the nonparenchymal cells was washed once and resuspended in 5 ml GBSS containing DNase. These cells were fractionated into a macrophage and an endothelial cell fraction by elutriation centrifugation (Beckman Instruments [Palo Alto, CA], elutriation rotor type JE-6). The cell suspension was flushed into the rotor at a flow rate of 20.5-21.0 ml/min, rotor speed 2500 rpm, at 4 C. At this flow rate, lymphocytes and endothelial cells were flushed out in 250 ml GBSS. The macrophages were collected at a flow rate of 46.5 ml/min in 150 ml GBSS, concentrated by centrifugation at 700 × g for 10 min and resuspended in culture medium containing 20% fetal calf serum; 2.5 × 10^5 liver macrophages in 200 μl culture medium were seeded per well in 96-well microtiter plates (Costar, Cambridge, MA) to obtain a monolayer of liver macrophages.

Intrahepatic distribution of liposomes. Liposomes, either SUV containing [^{3}H]inulin or MLV containing [^{3}H]FUdR, were injected into the penile vein of ether-anesthesized male Wistar rats varying in body weight between 170 and 260 g. Liposome elimination from blood was determined by blood sampling from the tail vein. The injected dose was 0.1 mmol of total lipid per kg body weight. For determination of liposome uptake by total liver, the organ was perfused in situ via the portal vein with isotonic saline at 37 C to remove blood and homogenized in a Potter-Elvehjem tube; aliquots of the homogenate were assayed for radioactivity. Intrahepatic distribution of liposomes was determined by measuring radioactivity content of the isolated parenchymal and nonparenchymal liver cell fractions, assuming 450 × 10^7 hepatocytes and 194 × 10^7 nonparenchymal cells per kg body weight (27). Parenchymal cells (hepatocytes) were isolated after perfusion of the liver with collagenase and nonparenchymal cells (Kupffer cells and endothelial cells) after digestion of the liver with pronase as described above.

Uptake of liposomes by Kupffer cells in vitro. Kupffer cells were isolated and purified as described above and allowed to attach to 35 mm plastic petri dishes at a density of 1.5 × 10^6-2.0 × 10^6 cells per dish under the conditions described previously (26). After at least 24 hr, the cells were incubated as reported (26) with SUV (70 nmol of liposomal lipid) of the compositions given in Table 1.

In vitro cytolytic assay. Macrophage-mediated cytolysis was assessed by a radioactivity release assay. One day after isolation, isolated liver macrophages in monolayer culture were incubated with free or liposome-encapsulated immunomodulators. Target tumor cells in the exponential growth phase were radiolabeled by a 20-hr incubation in a medium containing 0.3 μCi [^{3}H]deoxythymidine (dThd) per ml. The cells then were washed free from radioisotope and cold-pulsed by incubation in fresh medium for three-four hr to deplete cytoplasmic pools of [^{3}H] dThd and minimize spontaneous release of label. Subsequently, the cells were washed twice with phosphate-buffered saline pH 7.4 (PBS) at 37 C, to remove unbound radiolabel, harvested by short trypsinization (0.05% Difco trypsin, 0.2% ethylenediaminetetraacetic acid (EDTA), for 45 sec at 37 C), washed four times with PBS and resuspended in culture medium at a concentration of 10^5 cells/ml. Four hr after the addition to the macrophage monolayers of 100 μl culture medium (10% fetal calf serum) containing the immunomodulator(s), 100 μl medium containing 10^4 [^{3}H]dThd-labeled tumor cells were added per well. At this ratio of macrophage to target cell (25:1), untreated macrophages were not cytotoxic to neoplastic cells. Radiolabeled target cells also were plated alone as an additional control. Forty-eight hr after addition of the tumor cells, the supernatants were collected, and the radioactivity was measured in a liquid-scintillation counter. Specific cytolysis was calculated as follows:

$$\% \text{ specific cytolysis} = 100 \times \frac{a - b}{c - b}$$

in which a, dpm in supernatant of tumor cells cocultured with test macrophages; b, dpm in supernatant of tumor cells cocultured with control macrophages; c, dpm in total amount of tumor cells added per well.

In vitro cytostatic assay. Macrophage-mediated inhibition of the proliferative capacity of tumor cells was assessed by measuring [^{3}H]-dThd incorporation into the DNA of cocultured tumor cells. After a four-hr

[a]Small unilamellar liposomes, labeled with encapsulated [^{3}H]inulin and composed as indicated, were injected intravenously (0.1 mmol of lipid per kg body weight) into male Wistar rats. After 5.5 hr, the liver was perfused, and parenchymal (P) or nonparenchymal (NP) cells were isolated by collagenase or pronase digestion, respectively. Radioactivity in blood, whole liver and cell fractions was determined. Results are given as % of injected dose (± SD) or as nmol of total liposomal lipid per 10^6 (Kupffer) cells. In the last column, results are presented of in vitro experiments with isolated Kupffer cells in maintenance culture; 1.9 × 10^6 cells were incubated for three hr with 70 nmol total lipid of small unilamellar vesicles of the indicated composition and labeled with a trace amount of cholesteryl-[^{14}C]oleate.
[b]CH, cholesterol; PC, egg phosphatidylcholine; SM, bovine brain sphingomyelin; PS, bovine brain phosphatidylserine.

incubation of the macrophage monolayers with 100 μl culture medium containing immunomodulators, 100 μl medium containing 10^4 tumor cells were added per well. Tumor cells alone were plated as an additional control. After 24 hr cocultivation, 0.01 μCi [^{3}H]-dThd was added per well. Twenty-four hr after the addition of label, the cultures were washed three times with PBS (4 C), and the adherent viable cells were lysed with 0.2 ml of 0.5 M NaOH. The radioactivity of the lysate was measured in a liquid-scintillation counter, and the inhibition of tumor cell proliferation was calculated as follows:

$$\% \text{ inhibition} = 100 \times (1 - \frac{x}{y})$$

in which x, dpm in tumor cells cocultured with test macrophages; y, dpm in tumor cells cocultured with control macrophages.

RESULTS AND DISCUSSION

The rate of elimination from the blood of IV-administered liposomes depends strongly on size and composition of the liposomes. Large liposomes with diameters larger than ca. 0.1–0.2 μm are eliminated rapidly, i.e. with half-lives in the order of 5–15 min. Within this range, rates may depend on lipid composition, such as presence of charged lipids and cholesterol content (28). Small liposomes with diameters below 0.1 μm are cleared much more slowly, with half-lives ranging from one hr up to as much as 15 or 20 hr (29,30). Also, in this case lipid composition largely determines the precise value of the elimination rate, e.g. negatively charged vesicles are eliminated faster than similarly composed vesicles carrying no net charge. Remarkably, elimination rates also may be affected by more subtle differences in lipid composition. For example, small unilamellar vesicles composed of equimolar amounts of cholesterol and sphingomyelin are cleared extremely slowly with a half-life of ca. 12–15 hr whereas vesicles in which the sphingomyelin has been replaced by egg phosphatidylcholine, thus exposing an identical polar head group at their surface, are cleared almost five-fold more rapidly (23). Since resident macrophages in liver and spleen mainly have been held responsible for blood elimination of liposomes, it would seem straightforward that the rate of liposome elimination is related directly to the rate of uptake by these macrophages. Indeed, we observed a correlation between these two parameters when measuring the rate of uptake of differently composed small unilamellar liposomes by rat liver macrophages (Kupffer cells) in vitro (ref. 23, Table 1).

Although resident macrophages, including those in the liver, do display a strong affinity for most types of liposomes, other cells also have been shown to be able to participate in the in vivo clearance of liposomes from the blood. In particular, we found the parenchymal cells of the liver, i.e. the hepatocytes, very active in the uptake of small liposomes. Especially neutral liposomes and of those specifically, the egg-phosphatidylcholine/cholesterol vesicles, showed a relatively high affinity towards the hepatocytes, culminating in relative extents of uptake by these cells of as much as 95% of the total liver uptake as opposed to only a 5% uptake by the Kupffer cells (23).

The discrimination between large and small liposomes with respect to their intrahepatic disposition is attributed to the condition in which the liver's endothelial lining of the sinusoidal spaces that separates the parenchymal cells from the blood compartment is perforated. The liver endothelial cells possess numerous open fenestrations with an average diameter of about 100 nm, allowing passage of >100 nm liposomes and preventing access of larger liposomes to the parenchymal cells (31). In this paper, which is devoted to the use of liposomes in anticancer therapy, we will focus on those liposome species that are taken up by the liver macrophages. Internalization of liposomes by these cells can be exploited in the combat of metastatic growth in the liver by a duplicate approach. First, by encapsulation in liposomes cytostatic drugs may be accumulated at the tumor growth site, i.e. the liver, and form an intracellular depot in the Kupffer cells from which the drug becomes available in a time-dependent way at a rate that can be controlled by adequately manipulating the liposomal composition. The latter will

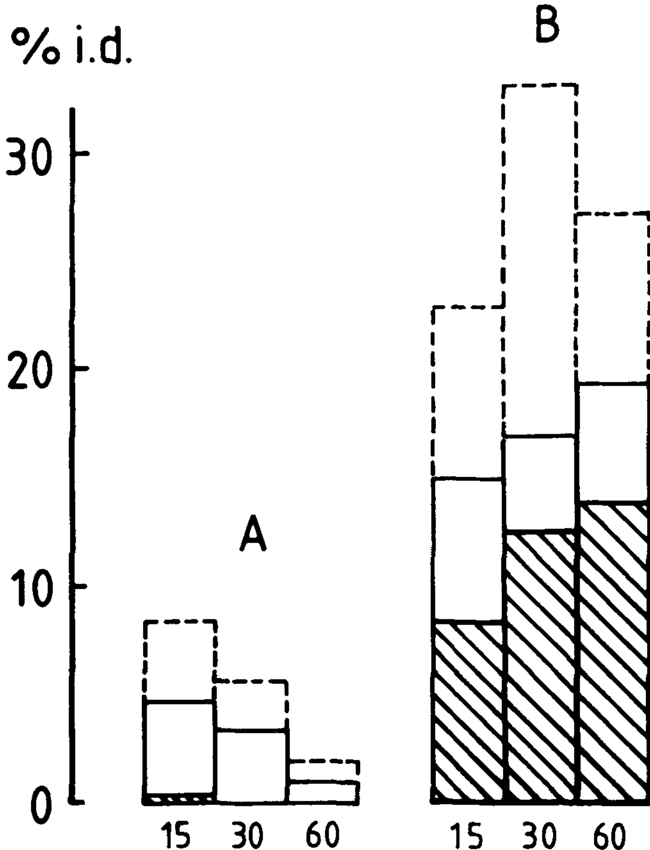

FIG. 1. Multilamellar liposomes containing [6-^{3}H]5-fluoro-2′-deoxyuridine (FUdR) were prepared from sphingomyelin, cholesterol and phosphatidylserine in a 4:5:1 molar ratio as described in Methods. These liposomes were injected at a dose of 50 μmol of total lipid, encapsulating 13 mg of FUdR, per kg body weight. Alternatively, rats were injected with the same amount of unencapsulated [^{3}H]-FUdR. At the times indicated, livers were perfused, and parenchymal and nonparenchymal cells were isolated by collagenase perfusion. Uptake in total liver and the two liver cell fractions was determined and is presented as percent of injected dose. The total lengths of the bars, including the stippled parts, represent uptake by whole liver; the open solid parts, the hepatocyte uptake; the hatched parts, the nonparaenchymal cell uptake. Results are means of three experiments agreeing within 10%.

be a major factor in determining the susceptibility of the liposomal lipid constituents towards lysosomal phospholipases, hence the rate of release of an encapsulated solute (32). Figure 1 shows an example of the alteration of in vivo behavior of a cytostatic drug as a result of its encapsulation in liposomes. The drug in this case was FUdR, a derivative of the widely used 5-fluorouracil. The latter drug particularly has been applied for several years in the therapeutic treatment of patients suffering from liver metastases originating from colorectal cancers, a major cause of cancerous death in the Western world. Both drugs are only moderately effective; one of the reasons is that they rapidly are taken up and metabolized by the parenchymal cells of the liver. Encapsulation of the drugs within liposomes should prevent this because the drug is expected to be directed to the Kupffer cells when administered in encapsulated form. As can be seen in Figure 1, this is previsely what happens. The radiolabeled drug, i.e. the deoxyuridine derivative since the fluorouracil is not sufficiently polar to be retained in liposomes, when administered in free form (A) is found to accumulate only to very limited extents in the liver. Fifteen min after injection, less than 10% of the injected dose is recovered in this organ (stippled bars); when parenchymal and nonparenchymal cells are isolated from these livers, only about half of the total liver-associated drug is recovered, virtually all of which is in the parenchymal cells (open full bars); only negligible amounts of drug can be found in the nonparenchymal cell fraction. Sixty min after injection, nearly all drug radioactivity has disappeared from the liver. However, when the FUdR is injected encapsulated in liposomes an entirely different situation is achieved (B). First, the extent of accumulation is substantially higher; 30 min after injection, more than 30% of the injected dose is recovered in the whole liver. Second, the drug is retained much longer in the liver; at 60 min, still more than 25% of the injected dose is present as opposed to less than 2% for the free drug at that time. Finally and probably most importantly, the intrahepatic distribution of the drug is quite different from that of the free drug. While the latter was found virtually only in the hepatocyte fraction of the encapsulated drug, about two-thirds of the total liver-associated fraction (hatched bars) is found in the nonparenchymal cells, i.e. the Kupffer cells (endothelial cells were repeatedly shown not to participate in liposome uptake whatsoever). The 25-40% that is found in the hepatocyte fraction has to be ascribed partially to contamination of this fraction with nonparenchymal cells and partly to the presence of a substantial amount of relatively small vesicles in the vesicle preparations (extruded MLV) used to encapsulate the drug. We recently observed that liposome preparations (MLV and LUV) subjected to forced filtration through polycarbonate filters may, depending on the lipid composition, contain substantial amounts of vesicles that are much smaller than the pore diameter of the filters. The consistent discrepancies between total liver uptake and the sum of the uptake by the separate cell fractions both for the free and the encapsulated drug have to be attributed to the release of drug that takes place during the time required to isolate the cells.

Our experiments demonstrate that by encapsulation of FUdR in liposomes, the pharmacokinetic characteristics of the drug substantially are altered. The rate of elimination from the blood is somewhat decreased; liver uptake and retention drastically are increased; and the intrahepatic distribution is shifted from the hepatocytes to the Kupffer cells. Obviously, the question now is does this improve the therapeutic efficacy of the drug? This remains to be seen. If so, it likely will depend on the rate at which the drug becomes available from the cell. In turn, this will depend on the rate of intracellular degradation and thus on the lipid composition of the liposome. For example, it is to be expected that encapsulation of the drug in liposomes of phospholipase A-resistant dialkyl phospholipids rather than diacylphospholipids will lead to enhanced retention times in the liver and concomitantly to slower rates of release of the drug.

It is with those considerations that we are studying the intracellular metabolic fate of liposomes as a function of liposome composition and with special emphasis on the Kupffer cells as the cell type most extensively involved with in vivo clearance of liposomes from the blood. In addition, considering the intralysosomal localization of the liposome-encapsulated drug, it will be important to establish how rapidly and in what chemical form the released drug will leak out of the Kupffer cell lysosomes. The presence or absence of enzymes in these cells capable of metabolizing the drug yet has to be established.

A basically different approach that may be taken to eradicate metastatic growth in the liver by means of liposomes is by way of activation of the Kupffer cells to tumorcytotoxicity, i.e. by exploiting part of the body's natural defense mechanism against the proliferation of (metastatic) tumor cells. Fidler and his associates have shown that certain biological response modifiers when encapsulated in liposomes have a much higher macrophage-activating potency than the free substance and thus can cause impressive reduction or even complete eradication of established lung metastases (18,32).

Encouraged by the results of Fidler and coworkers, we embarked on an attempt to follow a similar approach for liver metastasis. From earlier work, we knew that isolated Kupffer cells in monolayer culture are able to endocytose and degrade substantial amounts of liposomes (26,33,34). Uptake rates in those experiments amounted to ca. 2 nmol of lipid per hour per 10^6 cells, a value that we also found in the present work using liposomes of slightly different composition. First, we established the ability of rat liver macrophages (Kupffer cells) to become activated to a tumoricidal state as a result of an exposure to liposomes containing the immunomodulator MDP. Kupffer cells were isolated, purified and allowed to attach to microtiter plates. One day after attachment to the plates, the cells were incubated with various amounts of liposomes containing encapsulated MDP. The extent of cytotoxicity attained by the cells (i.e. cytolysis) was assessed by measuring release of [^{3}H]-dThd from tumor cells (B16 melanoma or C26 colon adenocarcinoma) that were labeled in their DNA with [^{3}H]-dThd (35). Alternatively, we determined cytostasis by measuring the effect of the activated liver macrophages on the proliferative capacity of the tumor cells, assayed as [^{3}H]-dThd incorporation. Table 2 shows that the Kupffer cells, upon incubation with MDP-containing liposomes, acquire strong cytolytic and cytostatic properties in a dose-dependent way. With the highest amount of liposomes (ca. 0.8 μmol of liposomal lipid per 10^6 cells), the extent of cytolysis amounted to

TABLE 2

Cytolytic and Cytostatic Activity of Liver Macrophages Following In Vitro Incubation With MDP-containing Liposomes[a]

	Cytolysis			Cytostasis		
Liposomal lipid added (nmol)	200	100	50	200	100	50
Macrophages treated with MDP liposomes	1306 ± 3 (56)	1082 ± 84 (41)	929 ± 64 (31)	121 ± 16 (99)	220 ± 79 (98)	962 ± 21 (89)
Macrophages treated with control liposomes	485 ± 42 (1)	455 ± 28 (0)	439 ± 111 (0)	9367 ± 56 (1)	9734 ± 508 (0)	9092 ± 868 (0)
Macrophages treated with medium only		463 ± 43			9105 ± 572	
No macrophages; B16 cells only		420 ± 21			8668 ± 556	

[a]Rat liver macrophages (Kupffer cells) were isolated and allowed to attach to culture plates; one day after isolation 2.5 × 10^5 cells were incubated for four hr with multilamellar liposomes composed of cholesterol, egg phosphatidylcholine and dicetylphosphate (5:4:1, molar ratio) and, when applicable, containing 1 μg MDP/μmol of lipid. 10^4[^{3}H]deoxythymidine-labeled B16 melanoma cells were added; after 24 hr, release of ^{3}H radioactivity into the medium was measured. Alternatively, unlabeled tumor cells were added to the activated macrophages and after 24 hr of coculturing [^{3}H]deoxythymidine (^{3}HdThd) incorporation into tumor cells was measured. Data represent radioactivity (dpm) released from (cytolysis) or incorporated into (cytostasis) tumor cells. All values are means of triplicate experiments ± SD. Numbers in parentheses are % specific cytolysis or, in case of cytostasis, % of inhibition, both calculated as described in Methods.

well over 50% (corrected for proper control values) while cytostasis was nearly complete under those conditions. When the macrophages were incubated with the same amounts of MDP in a free, unencapsulated form, no significant cytolysis or cytostasis could be detected. Interestingly, we observed that a fixed amount of MDP when encapsulated in a certain quantity of lipid resulted in much higher extents of cytotoxicity than when it was encapsulated in a 10-fold smaller quantity of lipid (35). This may suggest that the rate of intracellular degradation of the liposomes is correlated with the potency of the liposome-encapsulated MDP and thus may provide a clue as to the mechanism of action of this immunomodulator. In attempts to activate the liver macrophages in vivo as a result of uptake of MDP-containing liposomes following IV administration, we generally observed that when the Kupffer cells were isolated 18 hr after liposome administration extents of tumorcytotoxicity were significantly lower than those obtained in vitro, particularly when the B16 melanoma cells were used as target cells. Remarkably, we found no clear dose-response effect; MDP encapsulated in a small amount of liposomal lipid produced the same degree of cytotoxcity as the same amount of MDP in a 10-fold higher quantity of liposomes. Similarly, no significant differences in tumorcytotoxicity were observed between various subpopulations of Kupffer cells, which were isolated according to size, despite substantial differences in liposome uptake between those subpopulations (36). Also, this observation suggests a lack of dose-response relationship. An alternative, although rather improbable explanation would be that the low liposome uptake by the smaller cell sizes is compensated precisely by a high potential of these cells to become tumoricidal. A satisfactory explanation for these observations obviously has to await further experimentation. However, it is clear that the potential to become activated to tumorcytotoxicity is a property of the total Kupffer cell population; this should be considered a favorable condition for the in situ activation of the Kupffer cells in order to eradicate or prevent metastatic growth throughout the liver.

In spite of many unanswered questions with respect to the mechanism of action of the liposome-encapsulated MDP under in vivo conditions, we did observe a definitely favorable effect of this therapeutic modality on the growth of C26 adenocarcinoma cells in the liver following intrasplenic inoculation of these tumor cells and IV administration of MDP-containing liposomes. While in 95% of the control animals the livers were studded with numerous metastatic foci, the livers of 40% of the treated animals were completely free of metastases; another 40% contained fewer than four metastatic nodules.

In conclusion, this paper serves to show that liposomes have the potential to be used as a drug carrier system to both the parenchymal and the nonparenchymal cells of the liver. Of the nonparenchymal cells, it is only the Kupffer cell fraction, i.e. the macrophages, that is capable of internalizing the liposomes; we show how this can be exploited to prevent the development of metastatic growth in the liver. By encapsulation within liposomes, the pharmacokinetic properties of a cytostatic drug such as FUdR can be altered so as to create a relatively long-lasting intracellular depot from which the active drug is released in the immediate vicinity of the target cells. On the other hand, the liposomes may be applied to carry an immunomodulator such as MDP, which in free form rapidly would be cleared through the kidneys, very effectively to the liver macrophages, thus causing these to become activated to a tumoricidal state in which they are able to kill low tumor burdens. Not only did we show that liver macrophages are susceptible to this kind of activation both in vitro and in situ, we also demonstrated the therapeutic effectiveness of this approach in a liver-metastasis model in mice.

A series of halogen-containing alkylglycerolipid analogs has been checked for their cytostatic activity both in vitro and in vivo. The compounds included alkyldeoxyhaloglycerols (I), alkyldeoxyhaloglycerophosphocholines (II), and alkyldeoxyhaloglycerophosphoric acids and alkyl esters (III). While compounds I and III were moderately active, compounds II were found to have a strong inhibitory effect on the proliferation of Ehrlich ascites tumor cells in vitro. Cell growth inhibition of 50% or more was found mainly in the late S- or G_2-phase of the cell cycle as revealed by flow cytometry. Alkyl lysophospholipid analogs II and cholesterol form liposomes with high encapsulation efficiency and low permeability for entrapped substances. Compounds II were active against Lewis lung carcinoma in mice when applied in free form or as liposomes.
***Lipids 22,* 897-903 (1987).**

The structural modification of metabolites and other naturally occurring compounds often has yielded substances with interesting biological effects. Thus, by the introduction of a halogen atom, e.g. fluorine or chlorine, into nucleosides, antimetabolites of nucleic acid metabolism, endowed with cancerostatic properties, have been obtained (1). Since recent evidence indicates that phospholipid metabolism is involved in the regulation of cell proliferation (2,3), it has been of considerable interest to modify the structure of phospholipids and their natural precursors to obtain antimetabolites of phospholipid metabolism as potential cancerostatically active substances. We have prepared a series of halogen-containing neutral lipid and phospholipid analogs and checked their cytostatic activity.

Table 1 shows the types of compounds investigated, including analogs of *O*-alkyl(acyl)- and di-*O*-alkyl(acyl)-glycerol, *O*-alkylglycerophosphoric acid, *O*-alkylglycero-

phosphoric alkyl ester and *O*-alkylglycerophosphocholine (racemic forms). These analogs are characterized structurally by the presence of the long-chain alkyl (or acyl) group and a halogen (partially instead of an OH-group) at various positions of the molecule.

The latter compounds are of special interest because of their structural similarity to platelet activating factor (PAF) as well as to other alkyl lysophospholipids (ALP) with antitumor activity (4,5). They represent lysophosphatidylcholine analogs,which do not serve as substrates for lysophospholipase and acyltransferases.

MATERIALS AND METHODS

Syntheses, isolation, purification and analytical data of the halogen-containing lipid analogs investigated have been described (6–11). Also, the cytostatic effects of alkyl(acyl)glycerol analogs have been determined (12). For estimation of the in vitro activity of phospholipid analogs, EAT cells were obtained from the intraperitoneal (ip) cavity of mice five to seven days after transplantation.

Erlich ascites tumor (EAT) cells (5×10^4/0.5 ml) were cultured in suspension (Eagle-MEM) in the presence and absence of the substance to be tested. After 48 hr, the

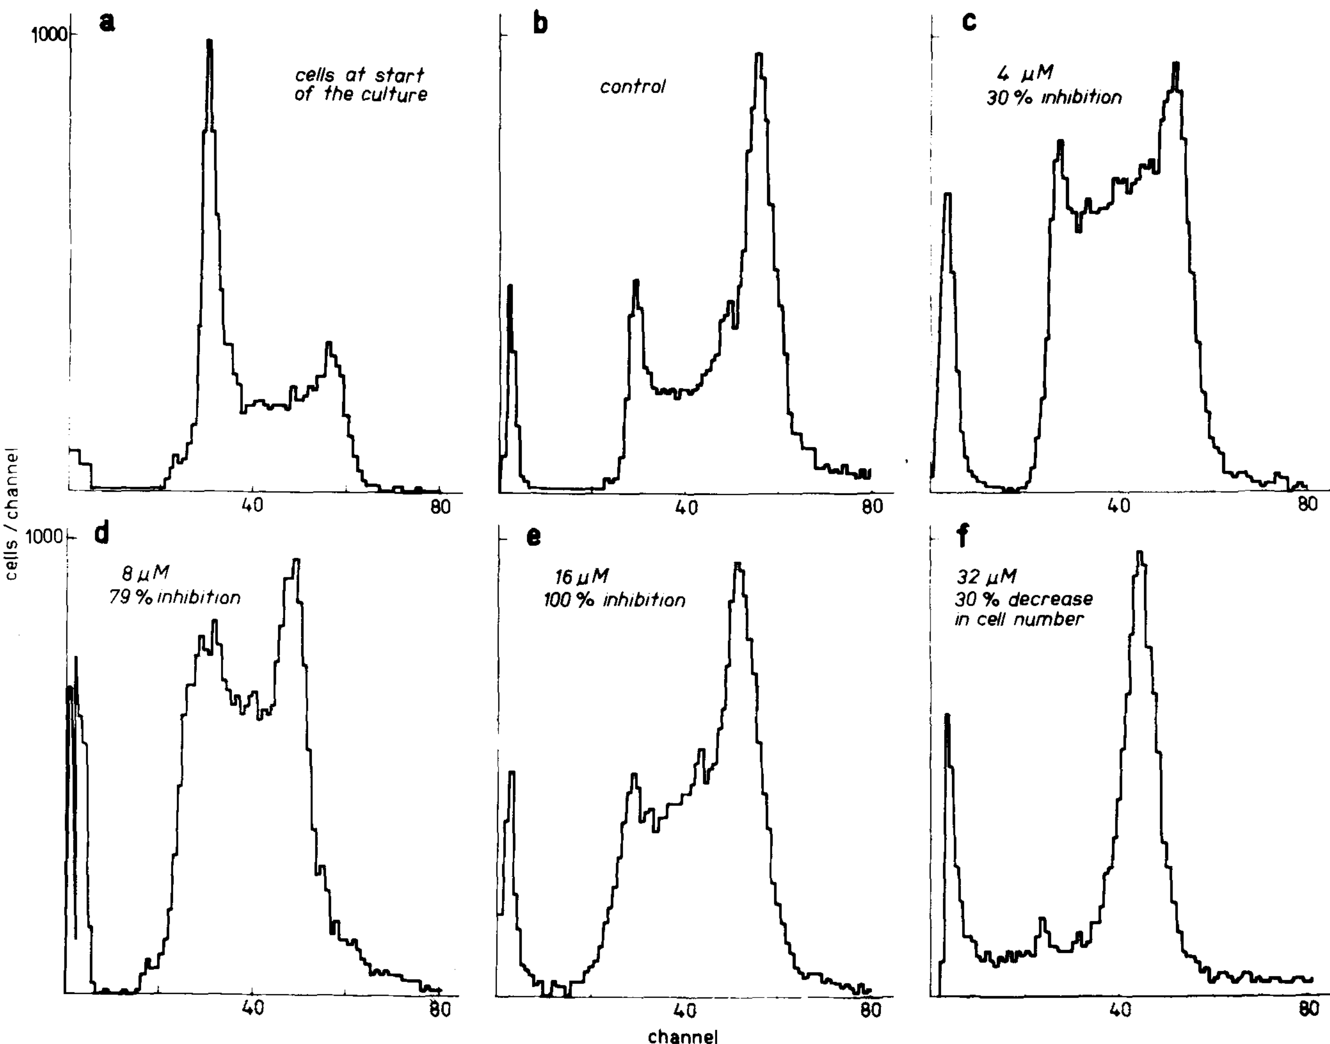

FIG. 1. Flow cytometry study on the influence of 2-chloro-2-deoxy-1-*O*-hexadecyl-glycero-3-phosphocholine on EAC cells in vitro (24 hr suspension culture). The increase in cell number in the controls was 91%.

increase in cell number, which was about five-fold for the untreated controls, was determined. For flow cytometry studies, EAT cells were obtained from mice eight days after transplantation and cultured in suspension for 24 hr. The cells were fixed in ethanol and stained with a mixture of ethidium bromide and olivomycin. The DNA-distribution histograms were obtained with a Phywe ICP-11 instrument. The PIP and PIP_2 turnover in human erythrocyte membranes was investigated according to Müller et al. (13). The membranes were incubated with γ-^{32}P-ATP in the presence and absence of the lipid analogs for 15–20 min, followed by acidic lipid extraction, thin layer chromatography (TLC) and scintillation counting.

Proteinkinase C (PKC) was isolated from porcine brain homogenate as described by Uchida and Filburn (14). The influence of halo analogs of ALP on PKC activity was determined using histone H1 as substrate. Multilamellar vesicles (MLV) and small unilamellar vesicles (SUV) were produced as follows: the solutions of phospholipids (40 μM) and cholesterol, in a 1:1 molar ratio (chloroform), were mixed in a round-bottom flask and evaporated. To the film obtained, 1.5 ml of phosphate-buffered saline (PBS), pH 7.2, or 1.5 ml 0.2 M CF solution were added. The suspension was shaken at room temperature for 12 hr to give MLV. SUV were obtained by subsequent sonication under nitrogen for 16 min followed by centrifugation at 100,000 × g for 1 hr to remove MLV and titanium particles.

In the presence of CF, the supernatant fluid was subjected to Sephadex-G 50 column chromatography (10 ml gel) to remove extravesicular CF. Entrapment efficiency and leakage on storage were measured (15). For the determination of antineoplastic activity in vivo, the murine tumor models, P 388 leukemia and Lewis lung carcinoma, all growing in C57Bl/6 × DBA/2 (BDF_1) mice, were used. The ascitic cells of the leukemia (5 × 10^5/mouse) were inoculated ip or IV; treatment began one day later. The Lewis lung carcinoma was inoculated in the left hind footpad of the animals (brei, 1:4 diluted with Hank's balanced salt solution, 0.05 ml/mouse). In half the animals, the primary tumor was surgically removed on day 10. Drug treatment was accomplished either on days 4–7 without surgery or on days 11–14 after surgery. In this way, both

the effect on the primary tumor and the lung metastases could be followed. For the estimation of toxicity, body weight difference between the first treatment day and after therapy was determined. The substances were administered in a dose of 0.5 or 5 mg/kg/d. With these doses, no signs of toxicity were observed. Statistical significance was determined by the U-test of Mann and Whitney.

RESULTS AND DISCUSSION

Cytostatic activity in vitro. The effects of selected halo analogs of alkyl(acyl)glycerols on the growth of EAT cells in vitro have been described (12). The diacyldeoxyhaloglycerols have been found to be inactive; the monoalkyl(acyl)deoxyhaloglycerols showed a fairly strong activity. The strongest effects were obtained with the glycerol ethers, e.g. the different structural isomers of hexadecylchlorodeoxyglycerol (12).

In Table 2, the cytostatic effects of selected halogen-containing *O*-alkylglycerophospholipid analogs and some related compounds on EAT cells in vitro are shown.

While the compounds of Type A at 100 μM are hardly active on EAT cells in vitro, some of the alkylglycerophosphoric ester analogs of Type B, especially the 1-*O*-alkyl-2-deoxy-2-halo derivatives B1-3 are moderately active. Since the alkyl esters B1a and 2a show a similar activity as the halo-alkyl esters B1 and 2, the effect is not due to the alkylating properties of the 2-halo-ethyl group. The presence of the glycerol moiety seems to be important for the cytostatic effect (loss of activity of B8). The lysophosphatidylcholine analogs (Type C) exhibit strong cytostatic activity against EAT cells, being in the same order as that of compound C7 investigated by Munder et al. (4). The analog 4 is the most effective compound of Type C. Almost the same efficiency is found for the structural isomers C1-3, 5 and 6. The presence of long-chain alkyl as well as phosphocholine, is of major importance for the inhibitory action, while the relative position of these groups and the presence of additional substituents (halogen, short-chain alkyl) is less relevant.

The effectivity is not due to the choline group, since several N,N-dimethylethanolamine derivatives, e.g. analogs of C1 and C2, are also active (not shown). P. G. Munder has performed further experiments with other tumor cells. He has shown that the direct cytotoxic effect on tumor cells (oesophagus carcinoma cells, Meth A sarcoma cells) as well as the enhancement of cytotoxic properties on bone marrow macrophages (Meth A sarcoma cells), by halogen-containing ALP analogs are of the same efficiency as the reference compound ET-18-OCH_3.

Flow cytometry studies. To elucidate the influence of the alkyl lysophospholipid analogs on the passage of the cells through the cell cycle, the effect of 2-chloro-2-deoxy-1-*O*-hexadecylglycero-3-phosphocholine was studied by flow cytometry (Fig. 1).

Cell numbers in the controls approximately doubled in 24 hr. The corresponding histograms (Fig. 1,a and b) show that a majority of cells passed through the greater part of the cycle a second time during this period, entering the G_2-phase. In contrast, cells inhibited in their proliferation by 30%, 80% or completely (Fig. 1, c, d and e) are found in the late S- or G_2-phase of the first cycle. It follows that under treatment, the cells do not remain simply in the phase in which they were at the beginning of the experiment; they pass through the cycle at a slower rate. However, a further doubling of the inhibitor concentration results in some cell loss (Fig. 1, f). Under these conditions, one single peak (late S-phase) is found; this could be explained by cell lysis. Similar distribution patterns were obtained in all of the four experiments.

Mechanism of action. The cytostatic activity of ALP has been explained by a serious disturbance of the membrane phospholipid metabolism of the tumor cell and by the generation of tumoricidal macrophages (4,5). Contrary to normal cells, most tumor cells are thought to lack an *O*-alkyl cleavage system (16,17). This difference in enzyme pattern may cause a predominant accumulation of ALP in tumor cells and a selective antitumor effect (4,5). The higher levels of ALP may disturb membrane function, including lipid-related enzymes (17) and phospholipid-dependent protein kinase C (18). Moreover, ALP were found to induce differentiation of cultured human and murine myeloid leukemia cells (19). The induction of interferon is another biological effect worth mentioning in regard to antitumor activity. Initial experiments have indicated that some halo analogs of ALP and of *O*-alkylglycerophosphoric esters cause an increase in interferon production of human leukocytes stimulated by various mitogens (20).

The halogen-containing ALP analogs 1-3, 5 and 6 (Table 3, C) were found to stimulate human and rabbit platelets. At 50-500 μM, a concentration-dependent platelet aggregation is triggered in human platelet-rich plasma. Distinctly lower concentrations up to 10 μM activate the platelets in rabbit platelet-rich plasma. Moreover, the halo analogs enhance aggregation and release reactions triggered by suboptimal concentrations of ADP (21). It recently has been demonstrated (3) that an increased turnover of phosphatidylinositol (PI) and its phosphorylated derivatives, e.g. PI-4-phosphate (PIP) and PI-4,5-diphosphate (PIP_2), is an early event in the initiation of cell proliferation and other cellular responses.

TABLE 3

Effects of Various Concentrations of *O*-Alkyl(acyl)glycerol Analogs on the Incorporation of ^{32}P-Phosphate into Phosphatidylinositol-4-phosphate (PIP) and Phosphatidyl-inositol-4,5-diphosphate (PIP_2) of Human Erythrocyte Membranes

Concentration (μM)	Incorporation of radioactivity % of control			
	O-$C_{16}H_{33}$ / O-CH_2CF_3 / OH		O-$COC_{15}H_{31}$ / F / OH	
	PIP	PIP_2	PIP	PIP_2
0.75	111	86	85	70
2.25	101	85	99	93
7.50	92	92	91	93
22.50	85	78	87	57
75.00	54	53	56	39

A stimulus-mediated PIP_2-breakdown releases two second messengers, 1,2-di-*O*-acylglycerol (DG) and inositol-1,4,5-triphosphate (IP_3). DG and the elevation of Ca^{++} synergistically activate Ca^{++}- and phospholipid-dependent protein kinase C (PKC), which is further involved in catalyzing phosphorylation of membrane protein. Moreover, DG analogs recently have been found to stimulate a rapid increase in the levels of PIP and PIP_2 (22). Thus, the ability of DG to function as a bioregulator in phosphoinositide turnover and PKC activation, as well as the phospholipid dependence of PKC activity, prompted us to investigate (a) the influence of synthetic mono- and dialkyl(acyl)glycerols on the PI metabolism and (b) the effects of *O*-alkylglycerophosphocholine analogs on the PKC activity.

Table 3 shows the dose-dependent inhibition by 1-*O*-hexadecyl-2-(2,2,2-trifluorethyl)glycerol and 2-deoxy-2-fluoro-1-*O*-palmitoylglycerol on the incorporation of [^{32}P]-phosphate into PIP and PIP_2 of human erythrocyte membranes. This demonstrates for the first time that several monoalkyl(acyl)deoxyhaloglycerols are inhibitors of PIP and PIP_2 turnover in human erythrocyte membrane. Also, a number of other selected halogen-containing alkyl(acyl)-glycerol analogs inhibited this process up to about 40% at 50 μM concentration. Whether this effect contributes to the inhibition by these substances of the proliferation of EAT cells in vitro is still an open question.

In further experiments, it could be shown that the *O*-alkyl-glycerophosphocholine analogs 1, 2 and 6 (Table 2, C) are inhibitors of PKC, the activation of which is thought to be a prerequisite for the induction of cell proliferation. The ID_{50} of the most effective compound 2-*O*-hexadecyl-1-*O*-(2,2,2-trifluorethyl)glycero-3-phosphocholine (compound 6, Table 2, C) was about 42 μM. The corresponding values for the other compounds tested were of the same order of magnitude (data not shown). This ability to inhibit PKC also might contribute to the cytostatic action of the ALP analogs studied. The inhibitory action of ET-18-OCH_3 on PKC of leukemia cells and cultured human cell lines (HL 60, K 62) recently has been demonstrated by Helfman et al. (18).

Effects of halogen-containing lipid analogs in vivo. Some of the halogen-containing monoalkyl- and monoacylglycerol analogs investigated were found to have a distinct cytostatic activity on EAT cells in vivo (12). They are active only when in direct contact with the tumor cells, e.g. after ip application in ascites tumor-bearing animals. They hardly are active when given

subcutaneously or by another route, although the doses applied in these cases theortically should yield a sufficient level of the drug. It follows that the compounds are either degraded, poorly transported or lose their proper dispersion state. The latter apparently is important for the activity, because they only are active in vitro when applied in aqueous emulsions, and they are inactive when given in a clear solution of dimethylsulphoxide.

We also examined the efficiency of selected ALP analogs (1-3, Table 2, C) on murine ascitic P 388 leukemia and Lewis lung carcinoma. In order to compare the influence of different dispersion states, we used the substances in free form and as liposomes.

It was found that in the presence of cholesterol (CH) in 1:1 molar ratio, the isomeric chlorodeoxy-*O*-hexadecylglycerophosphocholines 1-3 form liposomes when the lipid-cholesterol mixture is hydrated. This was demonstrated by electron microscopy (not shown) and also by the entrapment of aqueous solutions containing 6-carboxyfluorescein (CF). The efficiency of entrapment of CF in liposomes (MLV, SUV) formed from the synthetic alkyl lysophospholipids, hydrogenated (HEPC) and normal egg phosphatidylcholine (EPC) is shown in Table 4.

Surprisingly, the entrapment for the water-soluble CF is much more efficient when using alkyl lysophospholipids for encapulation. Further studies show that SUV made of synthetic ALP analogs 1-3 (Table 2) are stable over 25 days, while those made of HEPC or EPC (also with cholesterol in 1:1 molar ratio) released half of their entrapped 6-carboxyfluorescein within 15 days.

Table 5 shows the results obtained with Lewis lung carcinoma in mice. Treatment with the synthetic alkyl lysophospholipids (free drug or as empty liposomes) results in a moderate life prolongation. In each case, the smaller concentrations produced better effects. No toxicity was observed. In spite of the fact that in another experiment large vesicles like MLV preferentially were taken up by lung tissues, no favorable therapeutic activity resulted in the treatment of lung metastases after surgical removal of the primary tumor (data not shown). In the leukemia P 388 of different treatment schedules (ip; op; 0.5 or 5 mg/kg/d), no differences in the T/C values in comparison to the control group were observed.

Similar results were obtained in our experiments with the compound ET-18-OCH_3. There is a noteworthy discrepancy between the strong cytostatic activity found in vitro and the low efficiency in vivo; there also is discrepancy with data reported on a significant antineoplastic activity in special tumor models (23), which should be elucidated by further experiments. It has been shown by others that the effects of phospholipid analogs on animal tumors in vivo is not as striking as the one of other known cytostatic compounds, e.g. alkylating agents or antimetabolites of the nucleic acid metabolism, and that they exert a "soft" effect. However, because their mode of action is completely different from that of the classical cytostatica, they still may be of great value in clinical practice either in combination with other agents or alone (e.g. in treatment intervals).

ACKNOWLEDGMENTS

The authors wish to thank Drs. H. Hegewald, R. Klinger, E. Müller and R. Wetzker at the Institute of Physiological Chemistry, University of Jena, for their contributions to the investigation of inositol phospholipid turnover. We also thank Drs. Haase, Holzhauer and Vetter at the Academy of Sciences of the German Democratic Republic, Central Institute of Cardiovascular Research, Berlin, for their studies on protein kinase C.

[Received December 29, 1986]

Cytotoxic Effects of Ether Lipids and Derivatives in Human Nonneoplastic Bone Marrow Cells and Leukemic Cells In Vitro[1]

Hans D. Schick[a,*], Wolfgang E. Berdel[a], Michael Fromm[a], Ulrich Fink[a], Ulrich Jehn[b], Kurt Ulm[c], Anneliese Reichert[a], Hansjörg Eibl[d], Clemens Unger[e] and Johann Rastetter[a]

[a]Division of Hematology and Oncology, Department of Medicine I, Technische Universitaet, Munich; [b]Division of Hematology and Oncology, Department of Medicine III, University, Munich; [c]Department of Medical Statistics and Epidemiology, Technische Universitaet, Munich; [d]Max Planck Institute for Biophysical Chemistry, Goettingen; and [e]Division of Hematology and Oncology, Department of Medicine, University, Goettingen, Federal Republic of Germany

The effects of 2-lysophosphatidylcholine (2-LPC), the alkyl lysophospholipid derivatives (ALP) 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH$_3$) and 1-*O*-hexadecyl-*sn*-glycero-3-phospho-trimethyl-ammonio-hexanol, the 2-acetamide analog of platelet-activating factor (PAF) 1-*O*-octadecyl-2-acetamide-*sn*-glycero-3-phosphocholine, the thioether lysophospholipid derivative (TLP) BM 41.440 and the ether-linked lipoidal amine CP-46,665 on tritiated thymidine uptake and trypan blue dye exclusion were tested in vitro in various freshly explanted cell samples from human nonneoplastic bone marrow and human leukemias. In both assay systems, a dose range of 1–20 μg/ml of the compounds was tested after 24, 48 and 72 hr of coincubation with the cells.

The trypan blue dye exclusion revealed statistically significant preferential cytotoxicity in leukemic cells for three compounds with the order of quantitative selectiveness: ET-18-OCH$_3$ > BM41.440 > 2-acetamide analog of PAF. CP-46,665 was the most toxic compound, but did not reveal significant differences between nonneoplastic bone marrow and leukemic cells when added in concentrations greater than 1 μg/ml. The trimethyl-ammonio-hexanol compound showed only minor activity in the majority of tests, when added at concentrations < 20 μg/ml. 2-LPC was rather ineffective.

The tritiated thymidine uptake showed only preferential antiproliferative effects towards leukemic cells of ET-18-OCH$_3$ and, sometimes, within the dose time frame tested of BM 41.440. All compounds tested except 2-LPC and the trimethyl-ammonio-hexanol compound were active also in this assay (inhibition of uptake >50% of the controls). Based on these results, ET-18-OCH$_3$ and BM 41.440 are recommended for experimental bone marrow purging.

***Lipids 22,* 904–910 (1987).**

Recently there has been increasing interest in the question of selective antineoplastic cytotoxicity of ether lipids. The conflicting data accumulated so far have been reviewed (1). Interestingly, Vogler et al. have observed remarkable purging activity of the alkyl lysophospholipid derivative (ALP) ET-18-OCH$_3$ in investigating syngeneic bone marrow transplantation with a simulated remission bone marrow of the WEHI-3-B-leukemia in a mouse model in vivo (2). However, the same laboratory could not show antileukemic selectivity of ET-18-OCH$_3$ in in vitro testing of thymidine uptake and clonogenicity of human leukemic cells and normal human bone marrow cells (3). In this report we have addressed the question of antileukemic selectivity, testing the influence of a variety of different ether lipids and derivatives on thymidine uptake and trypan blue dye exclusion in vitro of nonneoplastic bone marrow cells and leukemic cells from humans.

MATERIALS AND METHODS

Drugs. The chemical structures of the lipids tested are depicted in Figure 1. 2-Lysophosphatidylcholine (2-LPC;

FIG. 1. Chemical structures of 2-LPC (A), ET-18-OCH$_3$ (B), 1-*O*-hexadecyl-*sn*-glycero-3-phospho-trimethyl-ammonio-hexanol (C), 1-*O*-octadecyl-2-acetamide-*sn*-glycero-3-phosphocholine (D), BM 41.440 (E) and CP-46,665 (F).

[1]Presented at the symposium on "Ether Lipids in Oncology," Göttingen, Federal Republic of Germany, December 1986.

Abbreviations: ALL, acute lymphocytic leukemia(s); ALP, alkyl lysophospholipid derivative(s); ANLL, acute non-lymphocytic leukemia(s); AUL, acute undifferentiated leukemia(s); CML/BC, chronic myeloid leukemia/blast crisis; FCS, fetal calf serum; 2-LPC, 2-lysophosphatidylcholine; PAF, platelet activating factor; TLP, thioether lysophospholipid derivative(s).

A) was purchased from C. Roth (Karlsruhe, FRG). The ALP ET-18-OCH_3 (B) was purchased from Medmark Chemicals (Gruenwald bei Muenchen, FRG). The 1-*O*-hexadecyl-*sn*-glycero-3-phosphotrimethyl-ammoniohexanol (C) was synthesized by one of our group. The 2-acetamide-analog of platelet-activating factor (PAF) 1-*O*-octadecyl-2-acetamide-*sn*-glycero-3-phosphocholine (D) was supplied by J. Hajdu, Department of Chemistry, California State University (Northridge). The thioether lysophospholipid derivative (TLP) BM 41.440 (E) was synthesized by Boehringer Mannheim GmbH (Mannheim, FRG). CP-46,665 (F) was supplied by K. E. Jensen, Pfizer Central Research (Groton, CT).

Cells. Cells of 36 bone marrow samples from patients without neoplastic bone marrow disease and cells of 30 patients with different types of leukemias (14 acute nonlymphocytic leukemias [ANLL], 11 acute lymphocytic leukemias/acute undifferentiated leukemias [ALL/AUL], 5 chronic myeloid leukemia/blast crisis [CML/BC]) were tested. Bone marrow samples were taken from patients who were referred for diagnostic bone marrow puncture for diseases other than solid tumors or hematologic malignancies, e.g., with anemia. The cells from the patients with the leukemias were collected predominantly from venous blood but in a few cases from the bone marrow. Informed consent of every patient was obligatory before the blood or bone marrow samples were taken for experiments. Venous blood or bone marrow was diluted with Roswell Park Memorial Institute (RPMI) 1640 medium (1:2), subsequently layered over a density gradient and spun at 400 × g for 30 min. The isolated fractions from the leukemic samples consisted morphologically of ≥95% of leukemic blasts with ≤5% of lymphocytes. The isolated fractions from the bone marrow samples contained a high percentage of granulopoietic cells, predominantly precursor cells including some band forms. In addition, these samples contained erythropoietic precursors, including normoblasts, and rarely lymphopoietic and reticulohistiocytic cell forms.

Tests. The trypan blue dye exclusion and the [^{3}H]-thymidine uptake test were performed as described before (4). In both assay systems, the cells were coincubated with the test compounds at a final concentration of 1, 5, 10 and 20 μg lipid/ml in 10% fetal calf serum (FCS)-containing medium for 24, 48 and 72 hr. Cytotoxic and cytostatic/antiproliferative activity of the lipids was measured as a decrease in trypan blue dye exclusion and an inhibition of tritiated thymidine uptake into the nuclear fraction of the cells given as percentage of the controls.

Statistical methods. The statistical comparison of the cytostatic-antiproliferative and/or cytotoxic activity of the test compounds against leukemias and bone marrow was performed by the U-test of Wilcoxon, Mann and Whitney (two-tailed).

RESULTS AND DISCUSSION

Viability of the cells based on trypan blue dye exclusion before testing was >90%. Relaible results in [^{3}H]thymidine uptake test and trypan blue dye exclusion were found in all 30 leukemias and 33 of 36 bone marrows. Three bone marrows could not be evaluated because of sterility

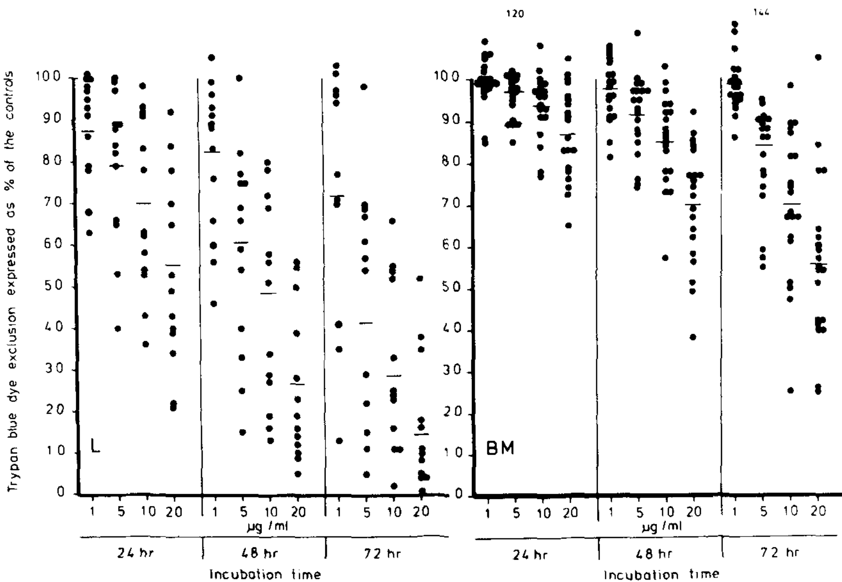

FIG. 2. Trypan blue dye exclusion of cells from non-neoplastic bone marrows (BM) and leukemias (L) from human origin after different times (24, 48 and 72 hr) of incubation with ET-18-OCH_3 at 1, 5, 10 and 20 μg/ml. The y axis gives the viability values (trypan blue dye exclusion) expressed as percentage of the controls. The x axis shows two blocs, results obtained for L on the left and BM on the right. Each block gives three compartments of values, one for a single incubation time as indicated. Each compartment contains four vertical columns of dots representing the results. Each dot and each arabic number represent the results of one patient's sample. Bars represent means of results obtained with one certain concentration of the compound at one incubation time as indicated. The significance levels from the comparisons between the cytotoxicity in L and BM cells are given for each concentration and incubation time (columns) in Table 1.

problems during culture. Furthermore, cell numbers were limited in some of the samples obtained. Thus, it was not possible to test every substance in every experiment. However, the results of all experiments performed are given here without exception, and the actual number of samples tested with each single compound can be observed in the figures.

Trypan blue dye exclusion. The cytotoxicity of the compounds as measured in the trypan blue dye exclusion test is depicted in the scattergrams of Figures 2–6. Figure 2 visualizes a higher cytotoxicity of ET-18-OCH_3 on the leukemic blast populations of various donors than on the nonneoplastic bone marrow cell samples of various donors. The viability based on trypan blue dye exclusion of the leukemic cell samples decreases with lower concentrations and shorter incubation times with the drug than the viability of the nonneoplastic cell samples. Comparable findings were made testing BM 41.440 (see Fig. 3) and the 2-acetamide analog of PAF (see Fig. 4). CP-46,665 clearly was the most toxic substance (see Fig. 5). Its LC_{50} value (the lethal concentration for 50% of the cells; mean of all tested samples) after 24 hr of incubation with leukemic cells was ≤5 μg/ml. The order of cytotoxic efficacy in leukemias was CP-46,665 > ET-18-OCH_3 ≥

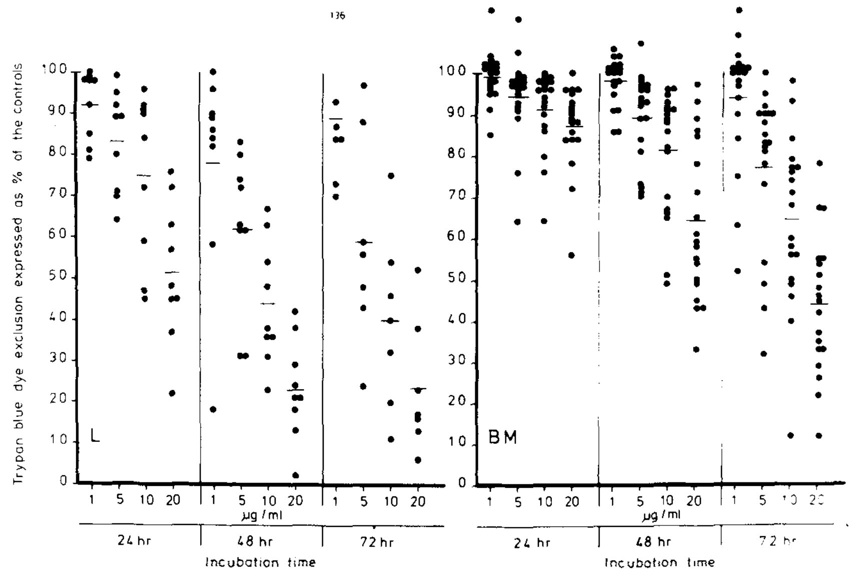

FIG. 3. Trypan blue dye exclusion of non-neoplastic bone marrow and leukemic cell populations after incubation with BM 41.440. For details see legend to Fig. 2.

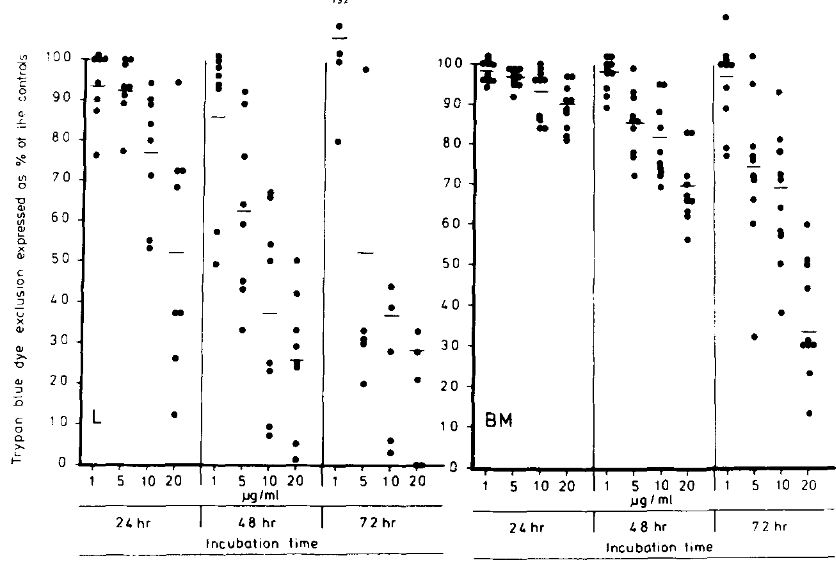

FIG. 4. Trypan blue dye exclusion of nonneoplastic bone marrow and leukemic cell populations after incubation with the 2-acetamide analog of platelet-activating factor 1-*O*-octadecyl-2-acetamide-*sn*-glycero-3-phosphocholine. For details see legend to Fig. 2.

BM 41.440 ⩾ 1-*O*-octadecyl-2-acetamide-*sn*-glycero-3-phosphocholine. These compounds revealed a clear dose- and time-dependent relationship in their cytotoxicity profiles. 1-*O*-Hexadecyl-*sn*-glycero-3-phosphotrimethyl-ammonio-hexanol (see Fig. 6) failed to show considerable cytotoxicity and reached an LC_{50} only at ⩾20 μg/ml, after more than 48 hr of incubation with the leukemic cells. 2-LPC, which was tested as a reference for detergent-like surface activity, remained without major effects within the dose and time schedule tested (details not shown). All six compounds were compared in μg/ml because of their similar molecular weight.

Statistical comparison of the viability in trypan blue dye exclusion test of all bone marrow samples with all leukemic samples after incubation with the ether-lipid derivatives demonstrated significant quantitative selectivity of the cytotoxicity of three compounds in leukemic cells (see Table 1). In this evaluation (Table 1) each p-value represents the significance level from the comparison of the according data pairs (columns) in Figures 2–6. The order of selectivity among these three lipids was ET-18-OCH_3 > BM 41.440 > 2-acetamide analog of PAF. However, there was considerable variability in the sensitivity of both bone marrow samples and leukemic

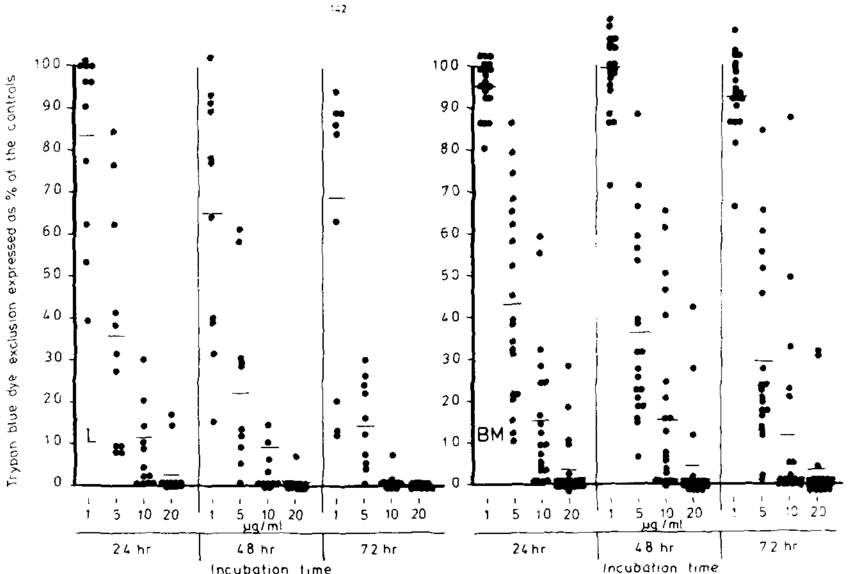

FIG. 5. Trypan blue dye exclusion of nonneoplastic bone marrow and leukemic cell populations after incubation with CP-46,665. For details see legend to Fig. 2.

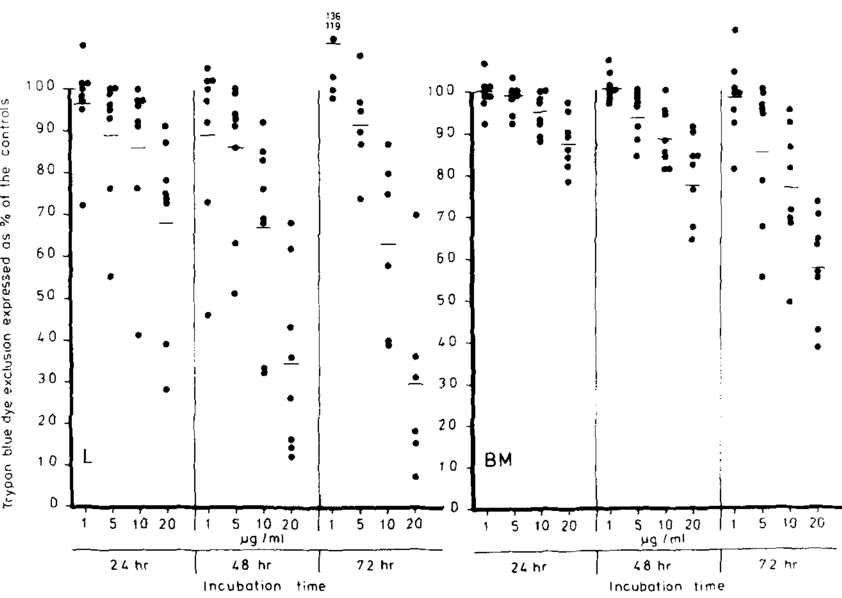

FIG. 6. Trypan blue dye exclusion of nonneoplastic bone marrow and leukemic cell populations after incubation with 1-*O*-hexadecyl-*sn*-glycero-3-phospho-trimethyl-ammonio-hexanol. For details see legend to Fig. 2.

samples (see figures), excluding qualitative or complete selectiveness of the drugs. Furthermore, whereas an incubation of 48 hr was better than 24 and 72 hr to show this antileukemic selectivity, it was not possible to determine an optimal concentration between 1 and 20 μg/ml. CP-46,665 failed to demonstrate considerable antileukemic selectivity when added in concentrations higher than 1 μg/ml, and the selectivity pattern of the trimethyl-ammonio-hexanol compound is questionable because of its low activity in the dose range tested.

Tritiated thymidine uptake. Figure 7 depicts the effects of ET-18-OCH_3 on thymidine uptake of leukemic and non-neoplastic bone marrow cells. There was a high variability among the various donor samples with regard to sensitivity. After 48 hr of incubation, 5 and 10 μg ET-18-OCH_3 per ml seemed to have selective preferential antiproliferative effects on leukemic cells in this assay (see Fig. 7 and Table 1). With few exceptions (e.g., BM 41.440; 5 μg/ml after 48 hr and ≥ 10 μg/ml after 72 hr), the scattergrams and statistical analyses of all other compounds tested revealed no selective antiproliferative effects on leukemic cells (details not shown). However, all substances tested except 2-LPC and the trimethyl-ammonio-hexanol compound were also active in this assay and reached LC_{50}-values at concentrations of ≤10 μg/ml and with ≥48 hr of incubation. The activity and putative selectivity of the trimethyl-ammonio-hexanol compound can only be judged after incubation in a higher dose range.

In both assays, our results indicated neither a higher sensitivity of bone marrows over leukemias nor significant differences in the sensitivity of ALL, AUL, ANLL or CML/BC. However, we have included leukemia patients with relapses after previous chemotherapy in this series, which may be an explanation for the variable sensitivity observed.

These data contradict previous in vitro results reported by Vogler et al. (3), who did not find selective antileukemic activity of ET-18-OCH_3 testing tritiated thymidine uptake and clonogenicity of leukemic cells from patients in comparison with normal bone marrow samples. However, these authors discussed in detail that a substantial percentage of the leukemic cell populations failed to grow colonies under their test conditions and that the plating efficiency was low. We had the same experience with freshly explanted leukemias irrespective of conditioned media, since ca. 1/3 of the cell samples did not grow colonies, which might introduce selection bias. Thus, we have concluded that clonogenicity might not be the exclusively

[b]For ET-18-OCH_3, the P-values for both trypan blue dye exclusion test (above) and tritiated thymidine uptake (below) are depicted. For all other test compounds only the values for trypan blue dye exclusion test are given.

[c]Not significant.

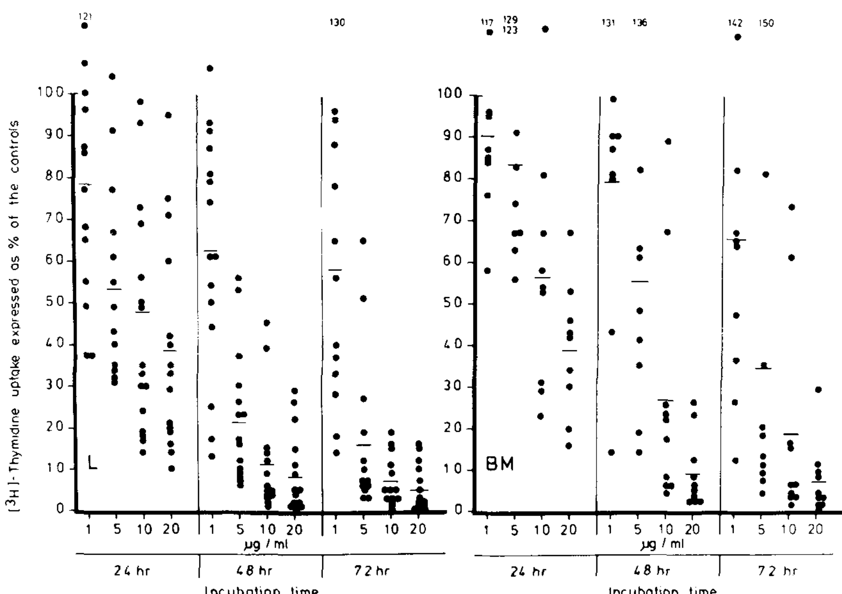

FIG. 7. Uptake of tritiated thymidine of cells from nonneoplastic bone marrows (BM) and leukemias (L) from human origin after different times (24, 48 and 72 hr) of incubation with ET-18-OCH$_3$ at 1, 5, 10 and 20 μg/ml. Each dot and each arabic number represent the mean of triplicates of one patient's sample. Bars represent means of the samples tested at the same incubation time and with the same concentration.

appropriate technique to answer statistically the question of quantitative selectivity. On the other hand, since ether-lipid derivatives are known to produce membrane damage (1,4–7), this being their major direct mode of action, an assay system measuring single cell viability and membrane damage as the trypan blue dye exclusion test seems also appropriate. In addition, previous experiments have shown a good correlation of trypan blue dye exclusion assay and clonogenicity for ether lipids in leukemic cell lines and cells of solid tumors (4). Furthermore, our data are in accordance with the in vivo experiments of Vogler's group (2) as mentioned above, which are well reflected by our in vitro findings.

The reason for the differences between [^{3}H]thymidine uptake and trypan blue dye exclusion remains speculative. However, in our hands [^{3}H]thymidine uptake is very sensitive, already detecting sublethal cell injury.

In addition, our results regarding the preferential antineoplastic cytotoxicity of these types of ether-lipid derivatives are in accordance with the results of others comparing various virus-transformed and leukemic cell lines of murine and human origin with different types of normal cells (1,8–12). Malignant cell lines, however, may represent an artificially sensitive target, and adult neutrophils or skin fibroblasts (10) do not reflect adequately the toxicity pattern of cytotoxic chemotherapy. Thus, our study is a necessary prerequisite for both experimental procedures for autologous bone marrow transplantation in leukemic patients and further drug design, with the aim of finding lipid derivatives with a better therapeutical index. The order of quantitative selectivity that we have found (ET-18-OCH$_3$ > BM 41.440 > 2-acetamide analog of PAF) indicates a recommendation in favor of the first two structures for bone marrow purging. However, this study has not been designed to find effective purging concentrations and times for the lipids for leukemic blasts or safe concentrations and times for survival of BM cells, since this can be better addressed in an experimental in vivo study observing, for example, syngeneic bone marrow "take" and survival in rodents.

Finally, if among the various modes of actions by which ether-lipid derivatives influence neoplastic cells either via mediators or directly (for further discussion see ref. 1), the direct membrane-based cytotoxicity plays a dominant role for therapeutic activity, then it seems reasonable to examine the potential value of lipid structures designed to exploit metabolic differences between normal and neoplastic tissue by our in vitro approach. In this respect, earlier papers have emphasized the O-alkyl-cleavage enzyme (12–14). To further test this hypothesis, it might be necessary to add higher concentrations of the "tailor-made" trimethyl-ammonio-hexanol compound to check on the selectivity theoretically warranted in an active dose range. This compound can be metabolized by the O-alkyl-cleavage enzyme, but not by phospholipases, and thus might selectively accumulate in cells that lack this enzyme. However, various other enzymes within lipid metabolism should be examined and metabolites of phospholipase C deserve more attention (1,15,16).

Eleven lipids have been tested for cytotoxic (trypan blue dye exclusion) activity in cells from eight freshly explanted human leukemias in vitro. 4-Aminomethyl-1-[2,3-(di-N-decyloxy)*N*-propyl]-4-phenylpiperidine (CP-46,665), 1-mercapto-hexadecyl-2-methoxymethyl-*rac*-glycero-3-phosphocholine (BM 41.440), the 2-acetamide analog of platelet-activating factor (PAF) and 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH$_3$) were found among the most active compounds. 2-Lysophosphatidylcholine (2-LPC) showed the lowest activity. However, in addition there was variation among the results regarding the activity of the 1-octadecyl-*rac*-glycero-3-phosphocholine (ET-18-OH) and its D- and L-forms, but a significantly higher cytotoxic activity of D-ET-18-OH compared with L-ET-18-OH on the basis of 2-LPC as control after an incubation time of 48 hr. We conclude that with the limited number of structures available, this type of study is not sufficient to yield further information about the mode of the accumulation and toxicity of this type of lipids.
Lipids 22, **911–915 (1987).**

During recent years, there has been increasing interest in the antitumor activity of certain ether lipids and their derivatives (1). Among various modes of action, some alkyl lysophospholipid derivatives (ALP) have shown direct effects on neoplastic cells, since they destroy leukemic (2–4) and tumor cells (5,6) during coincubation. In former studies (7), the relationship between in vitro toxicity and structure of a variety of ALP has been tested after incubation with neoplastic cells from solid human tumors and HL 60 leukemic blasts. From these studies, it was concluded that the alkyl-linkage in the *sn*-1 position of the molecule is a necessary prerequisite for cytotoxicity. Furthermore, in the majority of tumors tested the substitution of the *sn*-2 position is necessary for cytotoxicity.

The aim of the study, which is summarized in this communication, was to learn more about structure-toxicity relationship concerning the cytotoxic (trypan blue dye exclusion) activity of various ether lipid derivatives in cells from freshly explanted human leukemias.

MATERIALS AND METHODS

Drugs. Eleven lipids have been tested for cytotoxic activity in human leukemic blasts in vitro. In detail, the following substances have been studied: (A) the ether-linked lipoidal amine 4-aminomethyl-1-[2,3-(di-N-decyloxy)*N*-propyl]-4-phenylpiperidine (CP-46,665) (provided by K. E. Jensen, Pfizer Central Research, Groton, CT, (B) the thioether-lysophospholipid derivative 1-mercapto-hexadecyl-2-methoxymethyl-*rac*-glycero-3-phosphocholine BM 41.440 (Boehringer Mannheim GmbH, D-6800 Mannheim, FRG), (C) the 2-acetamide-analog of platelet-activating factor (PAF) 1-*O*-octadecyl-2-acetamide-*sn*-glycero-3-phosphocholine (synthesized and provided by J. Hajdu, Department of Chemistry, California State University, Northridge, CA) (8), (D) the 1-*O*-hexadecyl-*sn*-glycero-3-phospho-trimethyl-ammonio-hexanol (synthesized by one of our group), the alkyl lysophospholipid derivatives (E) 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH$_3$) (Medmark Chemicals, D-8022 Gruenwald bei Muenchen, FRG), (F) 1-*O*-octadecylpropane-3-phosphocholine (ET-18-H), (G) 1-*O*-dodecylpropanediol-3-phosphocholine (ET-12-H), (H) 1-*O*-octadecyl-*rac*-glycero-3-phosphocholine (ET-18-OH) (provided by P. G. Munder, Max Planck-Institute for Immunobiology, D-7800 Freiburg, FRG), (I) D-ET-18-OH and (J) L-ET-18-OH (synthesized by one of our group) and (K) the ester-linked 2-lysophosphatidylcholine (2-LPC) (Fa. Roth, D-7500 Karlsruhe, FRG). The chemical structures are given in Figure 1.

Cells. Cells of eight freshly explanted human leukemias (four ALL, three ANLL, one CML/BC) were tested. The leukemic blasts were obtained by density gradient preparation of venous blood or bone marrow aspirate. The isolated fractions consisted of $\geq$95% of leukemic blasts with $\leq$5% of lymphocytes. Viability of the cells based on trypan blue dye exclusion before testing was $\geq$90%.

Trypan blue dye exclusion was performed by a method described recently (9). In this assay system, 5×10^5 cells/ml were coincubated with the test compounds at a final concentration of 1, 5, 10 and 20 μg lipid/ml 10% serum-containing medium for 24, 48 and 72 hr. Cytotoxic activity of the tested lipids was measured as a decrease in trypan blue dye exclusion given as percentage of the controls. Comparison of simultaneous evaluations by different individuals revealed a reproducibility of the method within a range of $\leq$10%.

Statistical analysis. The values for trypan blue dye exclusion have been examined in the Wilcoxon matched-pairs, signed-ranks test (2-tailed).

FIG. 1. Chemical structures of the various lipids being tested for cytotoxic activity in human leukemic blasts in vitro. A, CP-46,665; B, BM 41,440; C, 2-acetamide analog; D, trimethyl-ammoniohexanol compound; E, ET-18-OCH_3; F, ET-18-H; G, ET-12-H; H (I, J), ET-18-OH (I, D-form; J, L-form); K, 2-LPC.

RESULTS AND DISCUSSION

Data concerning trypan blue dye exclusion of the leukemic blasts under the influence of the various lipids are summarized in Table 1. In most of the examined leukemias, loss of the ability of trypan blue dye exclusion proved dependent on dosage of the drug and incubation time. 2-LPC showed only minor activity in all of the eight leukemias in the dose range of 1–20 μg/ml. In one case resistant to previous chemotherapy (ANLL 1), the leukemic blasts revealed low sensitivity to 10 of the 11 lipids. The only effective compound was CP-46,665, which had a complete cytotoxic activity after 48 hr of incubation. CP-46,665 showed the highest efficacy in all examined leukemias after at least 24 hr of drug exposure.

For the other lipids, except 2-LPC and CP-46,665, there was variation among the results regarding their cytotoxic activity in the different leukemias. To rank the tested compounds concerning their cytotoxic activity, the values of each compound were compared statistically to the values of each other at each dose level and incubation time (Wilcoxon test). Because of similar molecular weight, all compounds were compared in μg/ml. Resulting p-values are summarized in Table 2, in which as one example the values after an incubation time of 48 hr are shown. Interpretation of the cytotoxicity-relationship between the compounds starting on the x-axis reveal (A) CP-46,665, (B) BM 41.440, and (C) the 2-acetamide analog as being the most cytotoxic drugs with significantly higher activity than most of the other lipids.

However, when Table 2 is evaluated starting with the y-axis the (A) lipoidal amine CP-46,665 does not meet any other drug with significantly higher cytotoxicity, which is not true for (B) BM 41.440 and (C) the 2-acetamide analog. Thus, data indicate (A) CP-46,665 as being the structure with the highest cytotoxic activity. (B) BM 41.440, (C) 2-acetamide analog and (E) ET-18-OCH_3 follow in this order of activity when evaluated starting on the x- and the y-axis, since only (A) CP-46,665 shows significantly higher cytotoxicity. (K) 2-LPC shows the lowest activity. Evaluation of significance levels at other incubation times did not add more information to this study (data not shown).

There was variation among the results regarding the cytotoxicity of the (H) *rac* ET-18-OH and its (I, J) D- and L-forms. In contrast to the results obtained with HL 60 leukemic cell line (7) in which the D-form of ET-18-OH showed higher activity than the L-form, we have found in freshly explanted leukemias four cell samples (ANLL 1, 3; ALL 2, 3) in which D- and L-forms were rather ineffective and four cell samples (CML/BC; ANLL 2; ALL 1,4) in which both isomeres had nearly the same cytotoxicity. Table 2 shows no significant p-values between (H) *rac*-, (I) D- and (J) L-ET-18-OH in direct comparison at the same dose levels after 48 hr of incubation time, which was also true for the other times of incubation. (I) D-ET-18-OH, on the other hand, showed a significant effect at 20 μg/ml after 48 hr compared with (K) 2-LPC at 20 μg/ml after 48 hr ($p = 0.04$).

To obtain more information, Figure 2 shows the significant differences of each compound, compared with 2-LPC as the reference compound for direct detergent-like activity at each dose level after 48 hr. CP-46,665, BM 41.440 and the 2-acetamide-analog are again the most active compounds. Regarding the *rac* ET-18-OH and its D- and L-isomers, D-ET-18-OH showed a higher activity than the L-form and the racemate, as the *rac* ET-18-OH and the L-ET-18-OH showed a lower number of significant values than the D-form. Evaluation of significance levels at each dose level after 48 hr also has been done for each

*p-values < 0.05 indicate that the compound on the x-axis shows a significantly higher cytotoxic effect than the compound on the y-axis at the same dose level.
p-values < 0.05 for compounds on the y-axis indicate, however, that this compound has a significantly lower cytotoxic activity than the compound on the x-axis at the same dose level.

+p-values between 0.05 and 0.10 are given to show tendencies of borderline significance.

A=CP-46,665; B=BM 41.440; C=2-acetamide analog; D=1-O-hexadecyl-*sn*-glycero-3-phospho-trimethyl-ammonio-hexanol; E=ET-18-OCH_3; F=ET-18-H; H=racemic ET-18-OH; I=D-ET-18-OH; J=L-ET-18-OH; K=2-LPC.

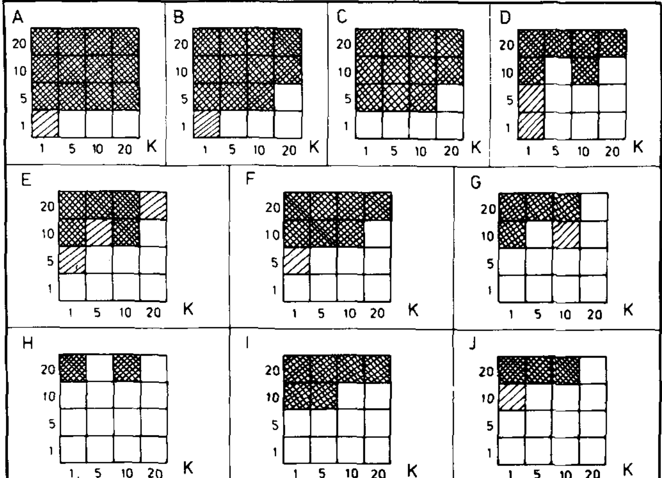

FIG. 2. Significant p-values for each compound concerning their cytotoxic activity compared with 2-LPC as reference drug at each dose level after an incubation time of 48 hr. Hatched box, $p < 0.05$; which indicates a significantly higher cytotoxic activity of the compound on the y-axis compared with (K) 2-LPC at the different dose levels (1, 5, 10 and 20 μg/ml) after an incubation time of 48 hr. Lined box, $0.05 \leqslant p < 0.10$; which indicates a borderline significance concerning the cytotoxic activity of the compound on the y-axis compared with (K) 2-LPC at the different dose levels (1, 5, 10 and 20 μg/ml) after an incubation time of 48 hr. Open box, no significant p-value ($p \geqslant 0.10$).

compound that is compared with another but did not add further information.

Trypan blue dye exclusion showed a correlation with the corresponding values obtained from [^{3}H]-thymidine uptake as another test system (data not shown). However, thymidine uptake was a more sensitive assay system showing toxic effects of the lipids on a lower dose level and after shorter incubation times. Furthermore, in comparison to other series (2,4,9) the results presented here with a group of patients resistant to or relapsing after previous chemotherapy showed comparably poor toxity of all tested lipids, which underlines the variability of the cytotoxicity when freshly explanted cells from patients in contrast to cell lines are tested (Schich et al., this issue of *Lipids*).

We conclude from our data that there is remarkable individual variation among different freshly explanted human leukemias concerning their sensitivity to the cytotoxic effect of glycerol-backbone lipid derivatives. The compounds analyzed for structure-activity relationships have shown the necessity of a metabolically stable *sn*-1 position for activity, and that activity increases with stable *sn*-2 and *sn*-3 positions. However, with the limited number of structures available, this type of study is not sufficient to yield additional information about the mode of accumulation and toxicity of this type of lipid.

Thioether lysophospholipid derivatives (TLP) inhibited the in vitro uptake of [^{3}H]thymidine into blasts of eight leukemias and cells of 12 different solid tumors of human origin. This effect correlated with trypan blue dye exclusion, which was used to assess cell damage.

Cytostatic and cytotoxic effects of TLP were dependent on dosage and incubation time. Destruction of leukemic blasts was completed with >5 μg/ml after an incubation of >48 hr, but 10 to 20 μg/ml were necessary in solid tumors. Ester-linked 2-lysophosphatidylcholine was ineffective in the same dose range, which points to the requirement of the alkyl moiety in *sn*-1 and a stable *sn*-2 substitution of the molecule for the antineoplastic effect.

To assess putative antileukemic selectivity, the cytotoxicity (trypan blue dye exclusion) of TLP was compared in human cell samples of 19 non-neoplastic bone marrows and 9 leukemias. Results revealed a significantly higher activity of the TLP BM 41.440 in leukemic blasts.

***Lipids 22,* 916–918 (1987).**

Thioether lysophospholipid derivatives (TLP) are analogs of the naturally occurring 2-lysophosphatidylcholine (2-LPC), which is an important intermediate in the phospholipid metabolism of cell membranes (1). Analogs of 2-LPC (e.g., the alkyl lysophospholipid derivative [ALP] ET-18-OCH_3) have previously been shown to possess antitumor activity. They destroy leukemic (2,3) and tumor (4,5) cells in vitro, inhibit the growth (6,7) and metastasis (8) of syngeneic murine tumors and have been used successfully in treating experimental rat tumors (9).

This activity is suggested to be partially mediated by enhancing the cytotoxicity of macrophages (8) and direct effects on neoplastic cells, such as disturbance of the phospholipid metabolism (10) and inhibition of protein kinase C (11). However, induction of cell differentiation of leukemic blasts (12) and antiinvasiveness (13) are also discussed as possible modes of action.

TLP have been synthesized in order to obtain a new class of antitumor lipids with increased metabolic stability and possible higher antineoplastic effects than the analogs investigated earlier. First results on the cytotoxicity of TLP have been previously published (14). In this report, we summarize our experiments on cytotoxicity of TLP in human leukemic blasts, some solid tumors and on antileukemic selectivity of BM 41.440.

MATERIALS AND METHODS

TLP derivatives. Five different TLP derivatives were synthesized by Boehringer Mannheim GmbH (Mannheim, FRG) and tested in comparison with the ALP ET-18-OCH_3 and the ester-linked 2-LPC. The chemical structure of BM 41.440 (1-hexadecyl-mercapto-2-methoxymethyl-*rac*-glycero-3-phosphocholine) is given in Figure 1.

Cells. Blasts of eight leukemias (four acute leukemias [AL], four blast crises of chronic myelogenous leukemia [CML/BC]) and cells of 12 different neoplastic cell lines of human origin (four non-Hodgkin's lymphomas of T- and B-cell origin, six hypernephromas, one medulloblastoma, one glioblastoma) were incubated with various concentrations (1–20 μg/ml) of the test compounds for 24–72 hr. To measure possible selective antileukemic cytotoxicity of BM 41.440, cell samples of 19 non-neoplastic human bone marrows and nine human leukemias were compared.

Test systems. Two test systems were used to assess the antiproliferative and cytotoxic effects. In the [^{3}H]thymidine uptake, the antiproliferative action of the lipids was measured as a decrease of [^{3}H]thymidine uptake into the cells. The trypan blue dye exclusion test was used to identify the cytotoxic effects of the test substances.

Statistical analysis. The Friedman two-way analysis and the U-test according to Wilcoxon, Mann and Whitney were used.

Details on the characterization, isolation and cultivation of the cells tested and the test systems used have been published before (14,15).

RESULTS AND DISCUSSION

In the first set of experiments, five different TLP and the ALP ET-18-OCH_3 were tested, comparing their cytostatic and antiproliferative effects in various leukemias and solid tumors. No striking difference in efficacy could be observed between the test substances. All analogs significantly reduced the proliferation rates of the cells in a time- and dose-dependent way. Incubation with

$H_2C-S-(CH_2)_{15}-CH_3$

$HC-CH_2-O-CH_3$

>5 μg/ml (>10 μg/ml in solid tumors) resulted in a complete inhibition of proliferation in the cell types tested. For further studies, we concentrated on BM 41.440. Figure 2 displays the cytostatic effect of BM 41.440 in cells of four AL and four CML/BC. More than 24 hr of incubation and a concentration of at least 5 μg/ml were necessary to reveal full antineoplastic activity. 2-LPC, tested in the same dose range, was ineffective or showed only minor action (data not shown).

In 12 cell lines from lymphomas (4×) and solid tumors (one glioblastoma, one medulloblastoma, six hypernephromas) of human origin, up to 20 μg/ml of BM 41.440 were required to produce proliferation rates around 10% of the controls. Except for one medulloblastoma, all cell lines were sensitive to the test compound in a time- and dose-dependent way (details not shown).

To assure that incubation with TLP not only decreased proliferation of neoplastic cells as measured in [³H]-thymidine uptake assay, but actually caused cell death, the trypan blue dye exclusion test was performed. A correlation was found between viability, expressed as

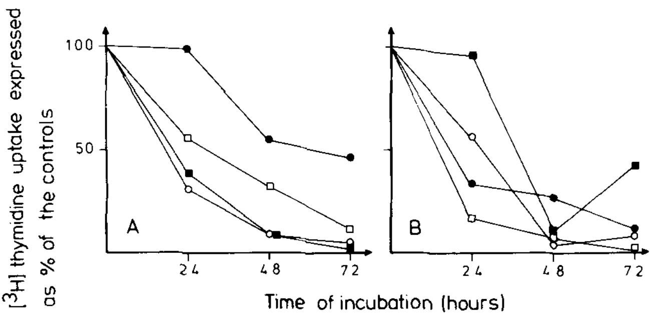

FIG. 2. (A) [³H]Thymidine uptake of cells of four different acute leukemias after incubation with 5 μg/ml BM 41.440 for the times indicated. (B) [³H]Thymidine uptake of cells of four different blast crises of chronic myelogenous leukemias after incubation with 5 μg/ml BM 41.440 for the times indicated.

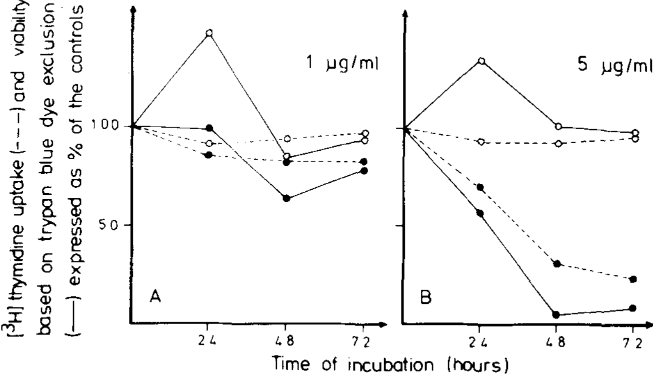

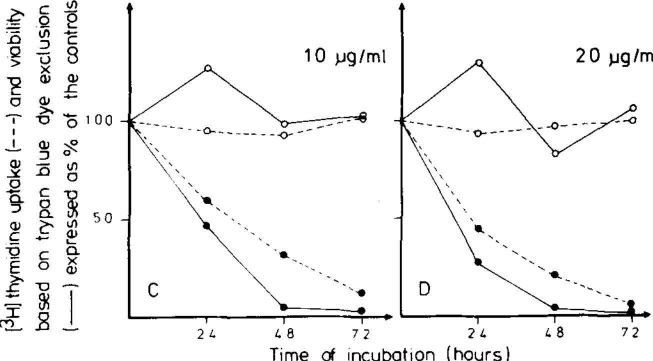

FIG. 3. [³H]Thymidine uptake (— — —) and viability based on trypan blue dye exclusion (———) of a blast crisis of chronic myelogenous leukemia after 24, 48 and 72 hr of incubation with 2-lysophosphatidylcholine (O) and BM 41.440 (●).

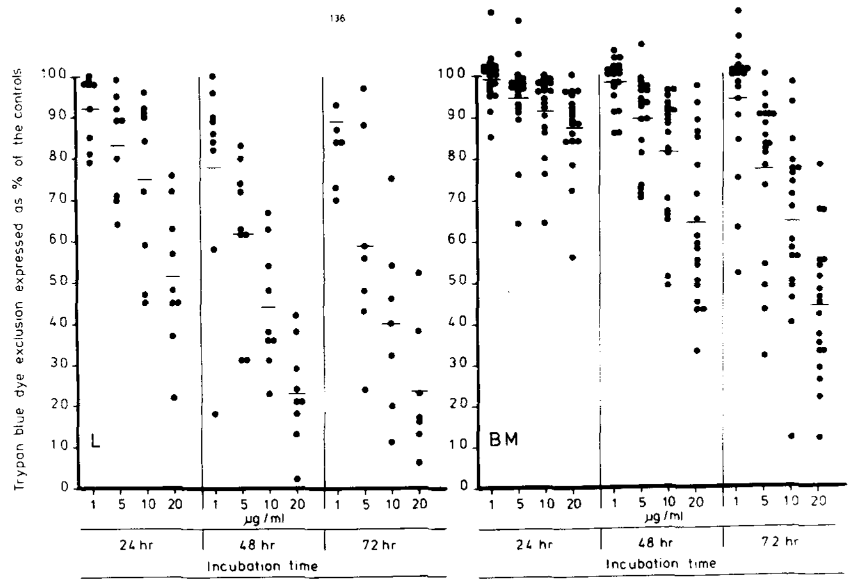

FIG. 4. Trypan blue dye exclusion of leukemias (L) and non-neoplastic bone marrows (BM) after incubation with BM 41.440 at the times indicated. Each dot and each arabic numeral represent one patient's sample. Bars represent mean values of all samples at a given dose and time.

[b]n.s., Not significant.

percent of the controls, and inhibition of [^{3}H]thymidine uptake in leukemic blasts and, with few exceptions, in cell lines of solid tumors. Dependency on dosage and incubation time as well as inactivity of 2-LPC was confirmed by the trypan blue dye exclusion in the tested dose range. However, trypan blue dye exclusion proved to be less sensitive than thymidine uptake. Examples are given in Figure 3. This figure furthermore shows that after incubation times of more than 48 hr, a saturation of the cytotoxic/cytostatic properties of BM 41.440 could be reached. Previous studies on the destructive effects of TLP on outer cell membranes, as visualized by scanning electron microscopy (14), indicate membrane destruction as an important factor in the cytotoxicity of these compounds.

Possible selective antileukemic cytotoxicity of BM 41.440 was assessed by comparing the results of the trypan blue dye exclusion in human cell samples of 19 non-neoplastic bone marrows and nine leukemias, including patients with relapses after previous chemotherapy. Significantly higher activity of BM 41.440 was found in leukemic blasts, again in a time- and dose-dependent way. Results are given in Figure 4 and Table 1. Table 1 depicts the statistical processing of the results given in Figure 4.

Results indicate that TLP, as a new group of ether-lipid derivatives, exert strong cytostatic and cytotoxic activity in vitro in cells of human leukemias and solid tumors in a time- and dose-dependent way. Five μg/ml or more of the analog BM 41.440 completely inhibited the [^{3}H]-thymidine uptake into cells of leukemic blasts after an incubation time of more than 24 hr; 10–20 μg/ml were necessary in solid tumors. Ester-linked 2-LPC proved to be ineffective in the same dose range; thus with due caution the alkyl moiety in *sn*-1 and a stable *sn*-2 substitution of the molecule seem to be required for the antineoplastic effect.

Results of cytotoxic activity in human leukemic blasts compared with non-neoplastic bone marrow cells indicate a significantly higher activity of BM 41.440 in leukemic blasts, which recommends this compound for experimental bone marrow purging, including further in vitro and in vivo research. However, based on the study outlined here and other in vivo studies, clinical phase I trials with BM 41.440 are underway (16).

[Received January 13, 1987]

Experimental Studies on the Role of Alkyl Lysophospholipids in Autologous Bone Marrow Transplantation[1]

William R. Vogler[a,*], Anita C. Olson[a], Shinichiro Okamoto[a], Lewis B. Somberg[a] and Lewis Glasser[b]
[a]Emory University School of Medicine, Atlanta, Georgia, and [b]The University of Arizona, Tucson, Arizona

The selective cytocidal effect of alkyl lysophospholipids against neoplastic cells while sparing normal cells make these ideal candidates for purging leukemic cells from bone marrows obtained during remission. To test the feasibility of such an approach, a murine model and an in vitro human cell model were developed. In the murine system a mixture of normal bone marrow cells and WEHI IIIB myelomonocytic leukemic cells was incubated with varying doses of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-Me) for 24 hr before being injected into tail veins of lethally irradiated Balb/c mice. At doses of 20 and 100 μg/ml, long-term survivors were noted. The additonal steps of freezing and thawing following incubation resulted in significantly longer survival with doses of 10 to 50 μg/ml, but were toxic to marrow stem cells at 100 μg/ml.

In the in vitro model, normal marrow progenitor cells and leukemic cells (the promyelocytic cell line HL60) were exposed to varying concentrations of ET-Me for 1 and 4 hr alone or mixed, and clonogenicity was assayed by colony formation in semisolid medium during 7–14 days' incubation. At doses up to 100 μg/ml exposed for 4 hr normal progenitor cells were spared and HL60 colonies eliminated. Other phospholipids analogues were less effective in eliminating leukemic cells, but spared normal progenitor cells.

A survey of fresh leukemic cells found varying degrees of sensitivity to ET-Me, indicating the need for testing a variety of compounds.

These studies clearly indicated the potential usefulness of alkyl lysophospholipid compounds in selectively purging leukemic cells from remission marrows for autologous bone marrow transplantation.
Lipids 22, 919–924 (1987).

Alkyl-lysophospholipids (ALP) have been reported to have selective cytocidal activity against neoplastic tissues while sparing normal cells (1–3). The mechanism of action appears to be directed against the cell membranes. If so, these compounds would be excellent candidates for treating neoplastic diseases. Some antitumor activity has been observed in laboratory animals and humans (4–9).

The reason for this selectivity has been thought to be the ability of normal tissues to metabolize the compounds through an O-alkyl cleavage enzyme that splits the fatty acid off the glycerol backbone at the *sn*-1 position. A number of neoplastic tissues have been shown to lack this enzyme, and the compound accumulates, damaging the cell membrane (10,11). However, there is evidence that some of the more active compounds are poor substrates for the cleavage enzyme, and thus some other mechanisms may be active (12,13).

Regardless of the mechanism for selectivity, these compounds warrant investigation. Although the full toxicity spectrum of these agents is unknown, in preliminary clinical trials some toxicity has been observed (9). An alternative use of these agents would be to serve as purging agents to rid remission bone marrows, obtained from patients treated for leukemia, of residual neoplastic cells, allowing the collection and cryopreservation of leukemic-free marrow for autologous transplantation. To test the feasibility of such an approach, we have developed a murine model and an in vitro human model. The results of most of these studies have been previously published and are presented here along with some new data (14–16).

METHODS

Compounds. For the in vivo experiments using the murine model, only one compound was used; 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-Me) was supplied initially by Dr. Paul Munder of the Max Planck Institute, Freiburg, FRG, and later by Dr. Wolfgang Berdel of the Technical University, Munich, FRG. A stock solution of the compound was prepared by dissolving 1 mg in 1 ml of Roswell Park Memorial Institute (RPMI) medium containing 20% fetal bovine serum (FBS) (Hazelton Dutchland Laboratories, Denver, PA) and stored at −20 C.

For the in vitro experiments, additional compounds used included the lipoidal amine (4-aminomethyl-1-[2,3-(di-n-decycloxy)-n-propyl]-4-phenylpiperidine dihydrochloride [CP] supplied by Dr. K. E. Jensen, Central Research, Pfizer, Groton, CT [17]). CP was dissolved in RPMI medium containing 10% FBS prior to use. 1-Hexadecyl-2-acetamide-deoxyglycero-phosphorylcholine (ET-Ac) was a gift from Dr. Joseph Hajdu, Northridge, CA. A stock solution of ET-Ac and ET-Me was prepared by dissolving 1 mg in 1 ml of RPMI 1640 medium containing 10% FBS and was stored at −20 C.

In all instances, the solutions were sterilized by micropore filtration (0.22 m, Gelman Sciences, Ann Arbor, MI).

Cells. For in vivo studies, WEHI IIIB leukemic cells, a myelomonocytic leukemia (18), which has been passaged in Balb/c mice in our laboratory since 1972, were obtained from ascitic fluid. Normal murine bone marrow cells (NMB) were obtained from 12-wk-old female Balb/c mice by flushing femoral shafts with RPMI medium. The cells were passaged through wire mesh (300 microns) to make single cell suspensions into medium containing 20% FBS and 1% PNS (penicillin-neomycin-streptomycin) antibiotic solution (Gibco Laboratories, Grand Island, NY). To

Abbreviations: ALP, alkyl lysophospholipid; CFU-S, colony forming units spleen; CP, 4-aminomethyl-1-[2,3-(di-n-decycloxy)-n-propyl]-4-phenylpiperidine dihydrochloride; ET-Ac, 1-*O*-hexadecyl-2-acetamidodeoxyglycero-phosphocholine; ET-Me, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine; FBS, fetal bovine serum; LC, leukemic; NBM, normal bone marrow; RPMI, Roswell Park Memorial Institute; SRM, simulated remission marrow; TBI, total body irradiation.

simulate a remission marrow (SRM), mixtures of normal marrow cells and WEHI IIIB cells were made at a ratio of 50:1.

For in vitro studies, the promyelocytic leukemia cell line HL60 (19) was obtained from Dr. Robert Gallo, National Institutes of Health, Bethesda, MD. Earlier studies had shown the line to be quite sensitive to ET-Me (20). These cells were passaged twice weekly in RPMI 1640 medium containing 10% FBS. All studies were carried out in log phase growth. NBM cells were obtained from bone fragments provided at surgery for orthopedic procedures. The fragments were crushed, suspended in supplemented McCoy's 5A medium (Gibco) and mononuclear cells separated by centrifugation over Ficoll-Hypaque (Histopaque-1077, Sigma Chemical Co., St. Louis, MO). The interface cells were washed twice with RPMI 1640 medium and resuspended in RPMI 1640 with 10% FBS. SRM was prepared by mixing normal marrow cells from male donors with HL60 cells in a ratio of 1000:1.

Cells obtained by aspiration from the posterior iliac crest at the time of diagnosis or relapse of leukemic (LC) patients who gave informed consent were used to test the spectrum of sensitivity of these compounds.

Spleen colony assay (CFU-s). All mice wre 12-wk-old female Balb/c obtained from Jackson Laboratories (Bar Harbor, ME) or from our own breeding colony. Irradiated mice received a total dose of 750 rads of total body irradiation (TBI) from ^{137}Cesium source (Gamma Cell Atomic Energy Ltd., model GC-40, Ottawa, Ontario, Canada) 24 hr before transplantation. Cell preparations were injected into the tail veins. The spleen colony assay was similar to that previously described (14). The mice were killed at eight days, spleens were removed and fixed in H_2O/glacial acetic acid/formalin/95% ethanol (5:1:1:3, v/v/v/v) and the number of macroscopic colonies on the antihilar surface was counted.

Survival. Mice not killed were followed for survival dating from the time of initiation of experiments. Fifteen to 30 mice were used for each time point. Autopsies were performed on all mice. Those surviving seven months were killed then.

Assay for in vitro colony formation. Mixed hematopoietic colonies, erythroid bursts, erythroid colonies and granulocyte-macrophage colonies and clusters were assayed by the method of Fauser and Messner (21). Clusters contained less than 40 cells. The cells were cultured in medium containing 0.8% methylcellulose, 30% FBS, 0.3% bovine serum albumin, 5×10^{-5} M mercaptoethanol, 5.6×10^{-8} M selenium, 10% normal human serum, 10% human placental conditioned medium (22), 5% phytohemagglutin in stimulated lymphocyte conditioned medium and 1 U/ml of erythropoietin (Step III, Connaught, Ontario, Canada) and were scored at 14 days.

Incubations and cryopreservation procedures. For the in vitro studies, 1-ml suspensions of 5×10^6 cells (NBM, SRM or LC) or 500–1000 HL60 cells were incubated at varying concentrations of phospholipid analogs for 1 and 4 hr at 37 C in 5% CO_2. They were washed twice in RPMI 1640 medium containing 10% FBS, either plated directly or frozen at −1 C/min to −80 C in 10% dimethyl sulfoxide and stored in the vapor phase of liquid nitrogen in freezing vials (Nunc, Denmark). Rapid thawing was accomplished by immersion of the vials in a 37 C water bath and followed by stepwise dilution of the dimethyl sulfoxide to 0.1% by medium. Deoxyribonuclease (type I, Sigma) at a final concentration of 100 μg/ml was used when there was cell clumping.

Murine cell suspensions (NBM, SRM or WEHI IIIB) containing varying concentrations of phospholipid analogs were incubated at 37 C in 5% CO_2 in freezing vials for 24 hr and were either injected directly into tail veins of lethally irradiated mice or were subjected to controlled-rate freezing as described above and cryopreserved. After a minimum of 24 hr, the cells were rapidly thawed and diluted with medium, and 8×10^4 cells were injected into tail veins of irradiated mice.

Statistical methods. The student t-test was used for comparisons of means and the Chi-square test for comparisons of enumeration data. A p value of <0.05 was considered significant.

RESULTS

Murine studies. The effect of 24-hr exposure of NBM cells to ET-Me on CFU-s is illustrated in Figure 1. As can be seen, there was only a small reduction at 20 μg/ml, indicating a sparing effect on murine stem cells. There was a 30% reduction following cryopreservation, but an adverse effect of ET-Me was not observed until doses of 100 μg/ml were reached (data not shown).

The role of ET-Me in purging LC cells from SRM is shown in Figure 2. As can be seen, doses of 2.5 and 5 μg/ml were no different from untreated SRM, and the mice died of leukemia between days 23 and 28. At 10 μg/ml there was some effect, but all mice eventually died of leukemia. At 20 and 100 μg/ml there was significant prolongation of life with 80% for 20 μg and 100% for 100 μg surviving

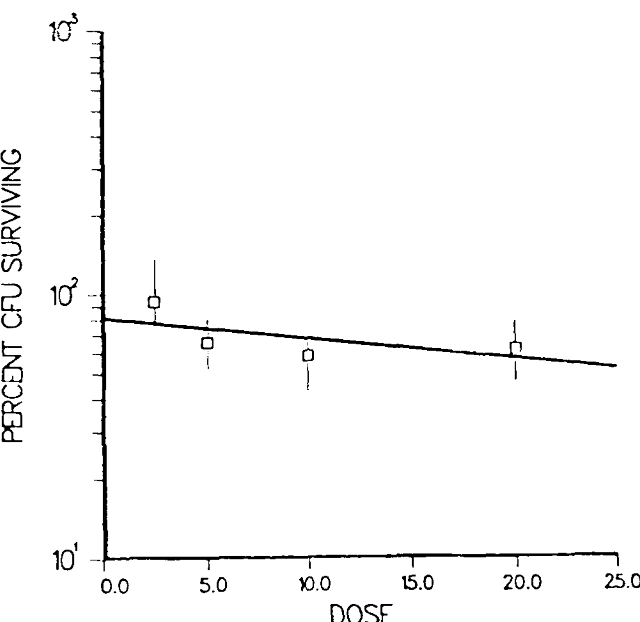

FIG. 1. Ten mice at each point were given 730 rads total body irradiation followed 24 hr later by intravenous injection of normal bone marrow cells after 24 hr of exposure in vitro to varying concentrations of ET-Me at 37 C. Macroscopic colonies were counted on the antihilar surface of spleens obtained from mice killed on day 8. Data are expressed as percentages of control ± SEM. Dose refers to μg/ml of ET-Me in the in vitro incubation mixture.

100 days. This survival is similar to mice receiving NBM and TBI. In contrast, survival of mice only irradiated without infusing NBM died within 11.5 days.

To determine if the combination of ET-Me treatment and cryopreservation would accomplish a similar result, these experiments were repeated with the additional step of freezing the cells after exposure to ET-Me. As can be seen in Table 1, doses of 10, 20 and 50 μg/ml increased the median survival time in a dose-dependent fashion and significantly increased the number of long-term survivors. However, the 100 μg/ml dose was too toxic to the stem cells after cryopreservation and thawing. These studies demonstrate the selective cytotoxic effects of ET-Me on leukemic cells while sparing NBM stem cells.

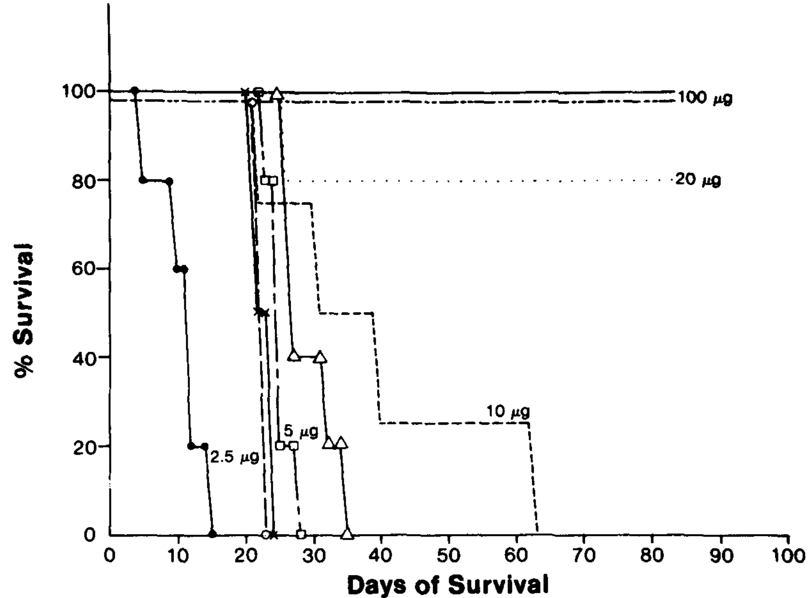

FIG. 2. Survival of Balb/c mice not transplanted or transplanted with normal bone marrow (NBM), simulated remission marrow (SRM) or SRM exposed in vitro to varying concentrations of ET-Me. ●—●, Not transplanted; ——, received NBM cells; ×—×, received SRM; ○—○, received SRM exposed to 2.5 μg/ml; □—□, received SRM exposed to 5 μg/ml; — — —, received SRM exposed to 10 μg/ml; · · · ·, received SRM exposed to 20 μg/ml; —··—··, received SRM exposed to 100 μg/ml; △—△, received SRM, not irradiated. All received 750 rads total body irradiation.

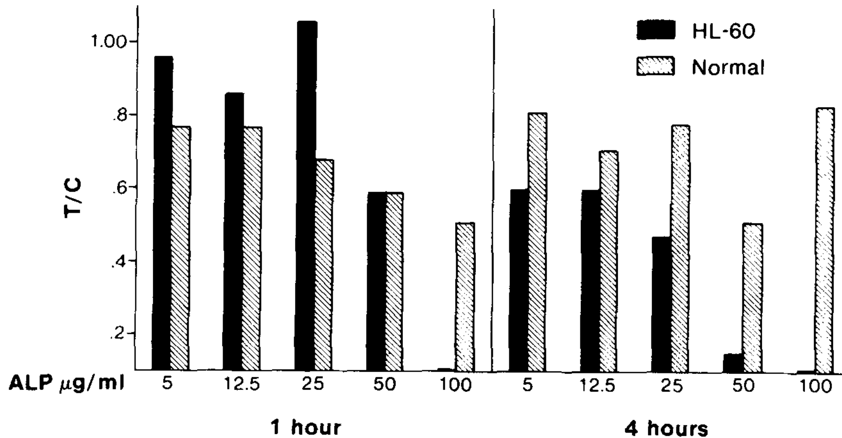

FIG. 3. The effect of alkyl lysophospholipid (ET-Me) on clonogenicity of HL60 cells and total normal bone marrow (NBM) progenitor cells. The cells were incubated for 1 or 4 hr with varying concentrations of ET-Me prior to plating. There were 500 HL60 cells plated and 10^5 NBM cells plated. Results are expressed as percentage of controls.

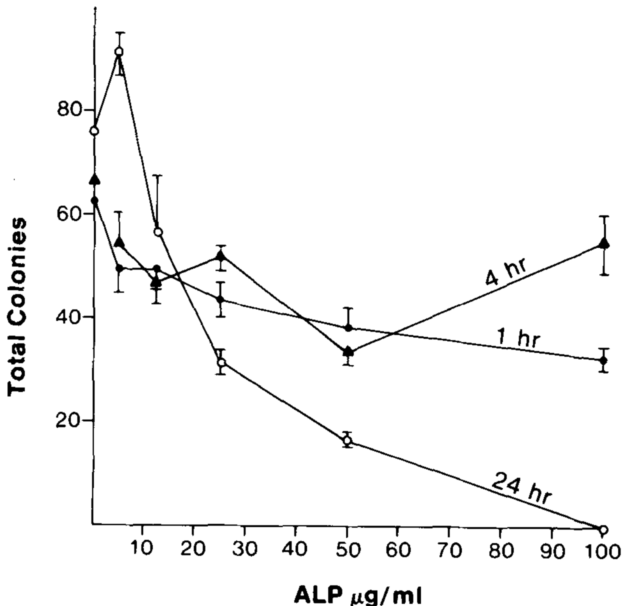

FIG. 4. The effect of alkyl lysophospholipid (ET-Me) concentration on clonogenicity of total marrow progenitor cells exposed in vitro for 1, 4 or 24 hr prior to plating. Conditions are as described in Methods. 10^5 Cells/plate were scored at 14 days. The bars are standard errors of the mean of quadriplicate samples.

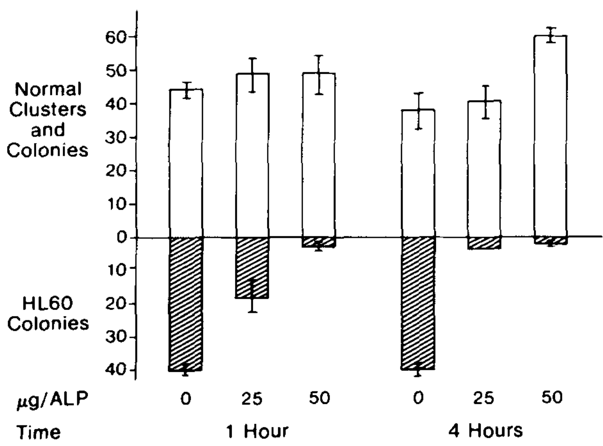

FIG. 5. The effect of alkyl lysophospholipid (ET-Me) on clonogenicity of mixed cultures of normal blood marrow (NBM) and HL60 cells. Cultures of 10^5 NBM cells and 10^2 HL60 cells were incubated with 0, 25 or 50 μg/ml of ET-Me for 1 or 4 hr. Colonies were identified by morphologic appearance.

In vitro human studies. The effect of ET-Me on clonogenicity of HL60 cells and NBM progenitors is shown in Figure 3. The HL60 cells were cultured as described above, except that erythropoietin was not added. As shown, incubation of HL60 cells for 1 or 4 hr with ET-Me resulted in a significant inhibition of colonies at 100 μg/ml and above. The effect on the total proportion of normal progenitor cells at 1 or 4 hr of incubation was minor at doses up to 100 μg/ml. However, as shown in Figure 4, there was a progressive dose-related inhibition when cells were incubated for 24 hr before cloning. Figure 5 demonstrates the purging effect of ET-Me using mixtures of HL60 cells and NBM progenitors. The colonies were identified morphologically.

These studies were repeated after cryopreservation and thawing. Between 60 and 70% of the prefreeze normal colonies could be recovered after freezing and thawing, and no dose effect of ET-Me could be observed. HL60 cells were not significantly reduced in the controls following freezing and thawing, but were further reduced by cryopreservation after exposure to ET-Me. Exposure to 50 μg/ml of ET-Me for 4 hr followed by freezing and thawing reduced HL60 colonies to zero. Thus, the combination of ET-Me and cryopreservation resulted in enhanced killing of HL60 cells while preserving 60–70% of the progenitor cells.

Effect of CP and ET-Ac on HL60 and NBM cells. Table 2 compares the effect of the compounds on colony formation by NBM cells and HL60 cells. As can be seen, neither CP nor ET-Ac was as selectively cytotoxic to HL60 cells as ET-Me. Other compounds are under development and will need to be tested in a similar fashion.

TABLE 2

Comparative Effects of Phospholipid Analogs on Clonogenicity of HL60 and Normal Bone Marrow (NBM) Progenitors

1 hr	Compounds (μg/ml)	Percent of control		
		ET-Me	CP	ET-Ac
HL60	0	100	100	100
	25	39.0 ± 0	57.5 ± 2.1	66.1 ± 0.1
	50	10.8 ± 3.1	31.8 ± 5.6	30.5 ± 0.9
NBM	0	100	100	100
	25	—	—	95.9 ± 1.6
	50	98.8 ± 1.3	88.6 ± 2.9	96.5 ± 6.0

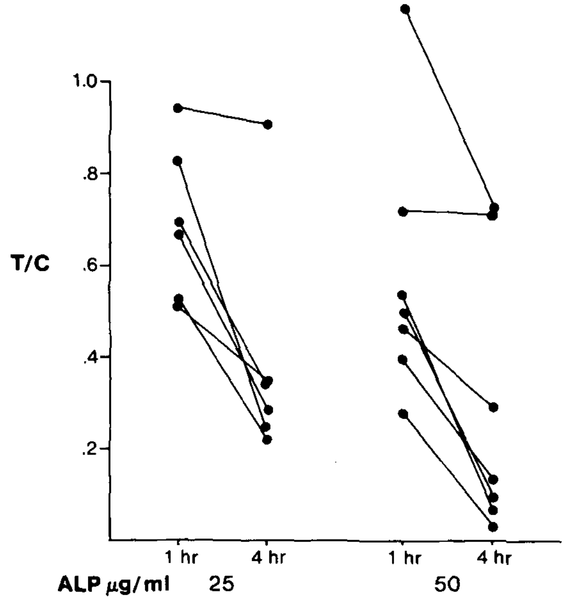

FIG. 6. The effect of alkyl lysophospholipid (ET-Me) on clonogenicity of leukemic cells obtained from patients at diagnosis or relapse expressed as ratios of treated to control values. Cells were incubated with 0, 25 or 50 μg/ml of ET-Me for 1 and 4 hr at 37 C prior to plating. Colonies were counted on day 14.

Clinical survey. Figure 6 illustrates the effects of ET-Ac on colony formation by cells obtained from LC patients at diagnosis or relapse. A wide spectrum of activity was present, and a dose effect was observed. The mean inhibition after incubation at 50 μg/ml was 50% at 1 hr and 31% at 4 hr. However, as shown, cells from some individuals were exquisitely sensitive. Other phospholipid analogs have not been tested in this fashion.

DISCUSSION

These experiments clearly demonstrate that phospholipid analogs are active antileukemic compounds and that some degree of selectivity is apparent. NBM stem cells in the mouse and NBM progenitor cells in humans appear to be much less sensitive to these compounds than neoplastic cells. The biochemical mechanisms for this selectivity have not been fully elucidated, and more studies are needed. Furthermore, an indirect antitumor effect as elicited by macrophages exposed to these analogs (23) was not studied in this series of experiments.

We attempted to demonstrate selectivity and to develop a practical, clinically feasible approach utilizing short incubation times with suitable doses and assessing the added effect of cryopreservation. It appears that the conditions necessary to initiate a clinical study have largely been established.

A clinical survey indicated that there was variability in sensitivity to ET-Me among patients. Therefore, it would be important to test the relative efficacy of a series of these compounds against a spectrum of leukemic cells as well as test the sensitivity of a particular patient's cells to a number of compounds. In this way, the most active agents to use could be defined for the individual patient for subsequent purging.

In conclusion, these studies have demonstrated the relative selective antitumor activity of three compounds. ET-Me appears to be the most effective and conditions for its use have been established to initiate clinical studies in bone marrow purging. Nevertheless, variability has been demonstrated in the sensitivity of leukemic cells obtained from patients and more of these compounds should be tested against a wider spectrum of leukemic cells and progenitor cells to find those that are most promising.

Distribution and metabolic fate of radiolabeled hexadecylphosphocholine (He-PC) has been studied in mice. It is demonstrated that He-PC is well-absorbed from the intestinal tract, intravenous (IV) and oral administration lead to similar distributions throughout the body, the highest accumulation of radioactivity occurs in liver, lung and kidney, and the metabolic products are radioactive choline, phosphocholine and 1,2-diacylphosphatidylcholine. The occurrence of these metabolites indicates that phospholipases C and D may be involved in He-PC breakdown.

Lipids 22, 925–926 (1987).

Alkylphosphocholines (APC) represent a new class of antineoplastic agents with remarkable antitumoral activity in vitro (1) and in vivo (2). APC have been developed in studies on the structure-activity relationship of alkyl lysophospholipids (ALP) and possibly represent the minimal structural requirement of ALP. It was the aim of this study to analyze the biodistribution of hexadecylphosphocholine (He-PC) as a representative compound of APC. In addition, initial investigations were carried out on the in vivo metabolism of He-PC in mouse liver.

MATERIAL AND METHODS

Hexadecylphospho-[^{3}H]choline was obtained by methylation of the corresponding hexadecylphosphoethanolamine with [^{3}H]methyl iodide (3); He-PC was synthesized as earlier described (4,5).

Biodistribution. Female NMRI mice (25 to 30 g) were used in this study. Twenty-five μg of He-PC (specific activity: 50 μCi/μmol) was dissolved in 200 μl of 0.9% NaCl and injected into the tail vein. Oral applications were via a stomach tube. The instillation solution used was 200 μl 0.9% NaCl, containing 5 μCi He-PC (specific activity: 10 μCi/μmol). After various time intervals, the animals were killed by cervical dislocation. The kidney, lung, liver, spleen, small and large intestine, heart, stomach, thymus, blood, brain and a sample of hind-leg muscle were removed, weighed and combusted in an incinerator (Packard). The percentage radioactivity in the blood was calculated under the assumption that blood represents 7.5% of the total mouse body weight (6). Radioactivity was determined in a Mark III scintillation counter (Searle).

Metabolism. Female NMRI mice (25 g) received 50 μCi of He-PC (specific activity: 105 μCi/μmol) in the tail vein. After 24 or 72 hr, the animals were killed and their livers removed and homogenized in 0.9% NaCl (1:3, w/v). Lipid extraction was done according to Bligh and Dyer (7). The organic phase was evaporated, dried, and the residue redissolved in methanol/chloroform (9:1, v/v). The organic material was applied to a silica gel thin layer chromatography (TLC) plate, and the plate was developed in chloroform/methanol/ammonia (50:50:5, by vol). The upper inorganic phase of the Bligh/Dyer extract also was dried, redissolved in water and applied to a cellulose TLC plate (Merck). The plate was developed in tert butanol/water/acetic acid (90:40:5, by vol). After drying, the plates were scanned for radioactivity using an Automatic Linear Analyzer LB 284 complemented with a Data System LB 500 (Berthold, FRG). For comparison with unlabeled reference compounds, the plates were stained with iodine vapor.

RESULTS

The time-dependent distribution of total radioactivity in different organs after IV injection and oral application is shown in Tables 1 and 2. After IV administration of He-PC, the blood radioactivity showed an initial half-life of ca. 90 min. However, after 192 hr, 12% of the initial radioactivity still remained in the blood indicating a slow elimination of the compound from the blood stream. The highest amounts of radioactivity were recovered from the kidney, liver and lung. Accumulation of the radioactivity in the kidney far exceeded the enrichment of activity in other organs; after 5 hr, the activity in the kidney was 25 times higher than in the blood. In contrast, most other

Phosphocholine	3	3
Choline	32	53

Data represent the means of two experiments for the indicated times.

organs contained similar but lower levels of radioactivity at the different time points measured. In contrast to the other organs, the brain showed a distinct increase in radioactivity up to 192 hr. After oral administration, He-PC behaved similar to the IV route. Again, there was a large enrichment of radioactivity in the kidney, liver and lung.

The metabolic fate of He-PC was studied in detail in the liver. Twenty-four hr after IV injection, the liver contained ca. 63% of the extractable radioactivity as a parent compound; 37% of activity was found to be associated with metabolic breakdown products. As shown in Table 3, the main metabolite of He-PC was choline (32%), whereas phosphocholine (3%) and 1,2-diacylphophatidylcholine (2%) were labeled to a much smaller extent. After 72 hr, the total radioactivity recovered from the liver was decreased slightly. However, the formation of labeled choline and 1,2-diacylphosphatidylcholine increased to 53% and 7%, respectively; phosphocholine remained unchanged.

DISCUSSION

The data presented in this study demonstrate that He-PC irrespective of the administration route is distributed throughout the body. It appears that the compound is efficiently absorbed as such from the intestinal tract and thus makes oral application possible. A calculation of the amount of He-PC absorbed from the gut currently is not possible because, in this experiment, total blood radioactivity was measured. The data given represent the radiolabeled parent compound and radiolabeled metabolites.

Organs showing a large enrichment of He-PC after either route of administration are the liver, lung and kidney. This finding is in line with the biodistribution reported for alkyl lysophospholipids such as 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (OM-GPC) (8). However, in contrast to ALP, the accumulation of He-PC in the kidney is three times higher than that of OM-GPC. This suggests that the kidney may be a target organ for the toxic effects of He-PC in treatment protocols. Comparing the distribution of He-PC in different organs, it is noteworthy that the brain shows a distinct accumulation of radioactivity through the entire period (Tables 1 and 2). We do not know yet if this is due to accumulation of the parent compound or of choline, the latter being one of the main products of He-PC catabolized on the liver. Choline cannot be synthesized in the brain and must be obtained from the blood stream (9).

Metabolism of He-PC in the liver results in the time-dependent formation of radiolabeled choline, phosphocholine and 1,2-diacylphosphatidylcholine. This suggests the importance of the phospholipases C and D in He-PC catabolism. Studies on the in vitro hydrolysis of He-PC with phospholipase C *(Bacillus cereus)* and phospholipase D (partially purified from cabbage) support the finding that APC are substrates for these enzymes (10,11). Formation of 1,2-diacylphosphatidylcholine labeled in the polar head group is consistent with earlier results obtained with OM-GPC. In the latter study, it was shown that the labeled phosphocholine group was transferred from OM-GPC to 1,2-diacylglycerol, resulting in the formation of phosphatidylcholine (3).

[Received July 16, 1987]

Therapeutic Activity of ET-18-OCH$_3$ and Hexadecylphosphocholine Against Mammary Tumors in BD-VI Rats[1]

H.R. Scherf, B. Schuler, M.R. Berger and D. Schmähl
Institute of Toxicology and Chemotherapy, German Cancer Research Center, D-6900 Heidelberg, Federal Republic of Germany

The present therapy experiments with two different transplantable mammary tumors were performed to compare the therapeutic efficacy in BD-VI rats of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH$_3$) and hexadecylphosphocholine (HPC). Both compounds were administered orally, subcutaneously or intracutaneously at equimolar doses ranging from 4.8 to 88 μmol/kg/day five times per week for two weeks. Under the experimental conditions, both transplanted mammary carcinomas were moderately sensitive to the therapy with either HPC or ET-18-OCH$_3$. Comparing both tumors, TMA2 was more sensitive than TMA1. The activity and toxicity of both compounds were dose-related in both tumor lines. Females seemed to be less sensitive with respect to antineoplastic activity and toxicity. Like ET-18-OCH$_3$, HPC was active also at low, probably noncytotoxic doses associated with no detectable toxicity according to body weight development. This suggests that there are at least two different mechanisms of action that lead to tumor growth inhibition.
Lipids 22, 927-929 (1987).

The therapeutic efficacy of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18)OCH$_3$) as a representative of alkyl lysophospholipids was previously tested in several tumor models in vivo and in vitro (1-3). Hexadecylphosphocholine (HPC) belongs to a new class of compounds, the alkylphosphocholines. Originally HPC was synthesized as a "negative control," as this compound was not supposed to be cleaved by the *O*-alkyl cleavage enzyme. Its anticancer activity has so far been tested only against autochthonous tumor models such as the MNU-induced mammary carcinoma, the benzo(a)pyrene-induced fibrosarcoma and the acetoxymethylmethylnitrosamine-induced colorectal carcinoma. The results of these studies are reported by Muschiol et al. (4).

Chemically induced autochthonous mammary carcinomas are a mixture of neoplasms of different morphology and malignancy, especially when they appear at multiple sites. We therefore simplified the system by using transplantable tumors and an inbred animal strain.

The aim of these investigations was to assess the effect of these compounds against homologous mammary tumors. We also wanted to find out to what extent female hormones have an influence on therapy and therefore used rats of both sexes.

MATERIALS AND METHODS

Isogenic female and male BD-VI rats were used as experimental animals. Two invasively growing methylnitrosourea-induced mammary adenocarcinomas, TMA1 and TMA2, were transplanted to female BD-VI rats. The experiments were performed with passages 5-8 of these tumor lines. Tumor cells derived from the donor animals were transplanted subcutaneously (s.c.) or intraperitoneally (i.p.). Therapy started when the tumor diameter averaged 1 cm. The chemical compounds ET-18-OCH$_3$ and HPC were supplied by P. G. Munder (Freiburg, FRG) and H. J. Eibl (Goettingen, FRG), respectively. Equimolar doses of both compounds were administered orally by gavage, intracutaneously (i.c.) or s.c. The animals were treated five times per week for two weeks, then were killed and dissected. As a therapeutic parameter we used T/C%, i.e., the quotient of the tumor-volume difference between treated animals and the control group × 100 (evaluation at week 2).

RESULTS

Table 1 shows the treatment of female BD-VI rats bearing s.c.-transplanted TMA1 or TMA2 tumors by oral administration of equimolar doses of HPC and ET-18-OCH$_3$. The activity and toxicity of both compounds were dose-related in both tumor lines except for treatment with HPC in TMA1 tumor-bearing rats. Moderate antineoplastic activity of high doses was correlated with rather high toxicity. The TMA2 tumor was more sensitive to active dosags of ET-18-OCH$_3$ and HPC than TMA1.

Table 2 shows the treatment of male BD-VI rats bearing i.p.-transplanted TMA1 tumors by oral administration of ET-18-OCH$_3$ and HPC at the same dosages as shown in Table 1. Identical doses caused increased toxicity following i.p. compared to s.c. transplantation. The anticancer efficacy was similar following both dosages of ET-18-OCH$_3$, whereas a dose-response relationship was observed following treatment with HPC.

Tables 3 and 4 show several experiments in which males and females bearing s.c.-transplanted TMA1 or TMA2 tumors were treated with equimolar doses of ET-18-OCH$_3$ or HPC. On a mg/kg body weight basis, females seemed less sensitive than their male counterparts with respect to anticancer activity and toxicity observed after treatment with HPC or ET-18-OCH$_3$. The experiments again demonstrated that the TMA2 tumor was more sensitive to therapy than the TMA1 tumor. The moderate antineoplastic activity and toxicity seen in treated male animals and assessed by body weight development was dose-related for both tumor lines.

Table 5 illustrates the treatment of male BD-VI rats bearing s.c.-transplanted TMA1 or TMA2 tumors by i.c. administration of HPC. Therapy with low doses of HPC was associated with significant anticancer efficacy on both TMA1 and TMA2 s.c.-growing tumors, while lower toxicity was observed.

DISCUSSION

Under the experimental conditions used, the two transplanted mammary carcinomas TMA1 and TMA2 were moderately sensitive to the therapy with HPC or ET-18-OCH$_3$. The different administration modes are

comparable because high resorption was found for HPC (5). Comparing the tumor lines, TMA2 was more sensitive than TMA1. Female animals seemed less sensitive than males with respect to antineoplastic activity as well as toxicity. ET-18-OCH_3 is known to be active at high cytotoxic concentrations, probably due to interaction with cellular membranes, and at low, probably non-cytotoxic, doses, which seem to influence the immune response (1–3). Although we did not measure the immune response following treatment with ET-18-OCH_3 and HPC in this experiment, we suppose that the treatment-related effects of both compounds follow similar modes of action at low dosages.

The study reports on the investigation of acute and subacute toxicity and on antineoplastic activity of hexadecylphosphocholine (HPC), the first compound of a new class of antineoplastic chemotherapeutics. In rats, the LD_{50} of HPC was 606 μmol/kg; the maximum tolerable dose over four weeks was 39 μmol/kg. Symptoms of toxicity were enteritis, spider cell activation in the liver, hemosiderosis in the spleen and reversible transaminase increase. The best therapeutic effect was observed on methylnitrosourea (MNU)-induced mammary carcinoma in the rat. Two transplantable mammary carcinomas in the rat and autochthonous benzo(a)pyrene-induced sarcomas exhibited low-grade sensitivity to HPC. The MXT mammary carcinoma of the mouse, the Walker 256 carcinosarcoma of the rat, and autochthonous acetoxymethylmethylnitrosamine-induced colonic tumors of the rat were not chemosensitive to HPC.
Lipids 22, 930-934 (1987).

In the course of assessing the toxicological and preclinical therapeutic value of alkyl lysophospholipids, we also investigated hexadecylphosphocholine (HPC). The experimental results of the toxicity and therapy studies with HPC are described below.

MATERIALS AND METHODS

Chemicals. Methylnitrosourea (MNU) and acetoxymethylmethylnitrosamine (AMMN) were synthesized by M. Wiessler (Institute of Toxicology and Chemotherapy, German Cancer Research Center, Heidelberg, FRG). Benzo(a)pyrene (BaP) was purchased from Sigma (Munich, FRG). The alkylphosphocholine HPC was synthesized by H. J. Eibl (Max Planck Institute of Biophysical Chemistry, Göttingen, FRG). All compounds were dissolved shortly before use at adequate concentrations.

Animals and tumor induction. Male and female Sprague-Dawley rats (Zentralinstitut für Versuchstierkunde, Hannover, FRG) were kept under conventional, controlled conditions. Autochthonous mammary carcinomas (1), colorectal carcinomas (2-4) and fibrosarcomas (5) were induced as described previously. TMA1 and 2 mammary carcinomas were transplanted in BD VI rats as described elsewhere in this issue (6). MXT mammary carcinoma was processed for treatment by s.c. implanting 30 mg tumor tissue into female $B_6D_2F_1$ mice. Treatment started at defined stages of macroscopically visible tumor development. Comparison of drug effectiveness was based on the increase in median survival time (ILS) and on differences in tumor volumes expressed as percent of untreated control (T/C%). National Cancer Institute criteria were used for assessing the activity of the compounds evaluated (7). Statistical evaluation of tumor growth was performed using a non-parametric multivariate test (8) and Student's t-test.

Evaluation of toxicity. For acute toxicity studies, HPC was administered p.o. to Sprague-Dawley (SD) rats that had been fasted overnight. Surviving animals were observed for 14 days. LD_{50} values were determined by the method of Spearman and Kärber (9). Additionally, subacute toxicity (four weeks) was determined in SD rats and in dose-finding experiments in white New Zealand rabbits and emetic effects in beagle dogs.

RESULTS

Toxicological studies. In experiments in rats, the acute LD_{50} after oral administration of HPC by gavage to four groups of 10 adult Sprague-Dawley rats of either sex was 246 mg/kg body weight (bw) (corresponding to 606 μmol/kg) (Table 1). The symptoms of intoxication were sedation, salivation, weight loss and diarrhea. Dissection of those in the high-risk group revealed intestinal rubor, swelling of the intestinal mucosa and ulcers of the

forestomach. Animals generally died two to three days after the single dose of HPC. Histopathological examination confirmed the enterocolitis diagnosed macroscopically. No additional symptoms were seen. In the final analysis, death occurred from desiccation and possible toxin absorption.

In another experimental design, the subacute toxicity of HPC was determined in a four-week experiment (Table 2). The four experimental groups each consisted of 20 male and 20 female adult SD rats. The daily doses administered amounted to 0, 16, 20 and 25 mg/kg bw, respectively. No deaths occurred in the lowest dose group (16 mg/kg) during the observation. Unlike this, significant retardation in weight development was seen in the two high-dose groups. Five percent of the animals in the 20 mg/kg dose group died, and 10% of the females and 20% of the males in the highest-dose group died. The symptoms of intoxication corresponded to those observed in the acute toxicity experiment. As expected, the intoxication was clearly dose-related. The histopathological examinations disclosed activated spider cells in the liver and hemosiderosis and enterocolitis in the spleen. Damage to the kidneys, such as nephrosis, pyelonephritis and epithelial hyperplasia, were also found in animals of all treated groups. These changes were seen in about one-third of the animals. According to the findings, the lowest dose is considered the maximum-tolerable dose (MTD).

In accordance with clinical chemical investigations in the acute and subacute toxicity experiments, transaminases increased two- to threefold the normal value (Fig. 1) but normalized when the administration was discontinued. The other parameters determined by clinicochemical examination (differential hemogram, erythrocytes, leukocytes, hematocrit, MCV, Hb, LDH, kreatinine, Na, K, Ca) did not deviate from normal.

Additionally, a subchronic three-month experiment, in which doses of 6, 10, 16 and 20 mg/kg bw were administered, was carried out. The findings have not been

[b]Equivalent to 10 mg/kg.

evaluated completely yet but the trend is that the MTD is about 10 mg HPC/kg bw in males and females.

Rabbits were used only for a dose-finding test on acute toxicity (Table 1). Two adult female rabbits tolerated a dose of 100 mg/kg bw five times a week without any symptoms of diarrhea. Thus, the response in rabbits was not more sensitive than in rats.

Two female beagle dogs were used for testing only emetic effects of HPC (Table 3). Single doses of 5 and 10 mg/kg bw were administered by means of capsules that were soluble in the stomach or the small intestine. Emesis resulted only after administering the high dose of capsules soluble in the stomach but not after capsules soluble in the small intestine. Consequently, possible emetic effects might be avoided by inhibiting the release of HPC in the stomach.

Therapeutic studies. These were carried out, using several experimental tumor models (Tables 4-7). The autochthonous MNU-induced mammary carcinoma in Sprague-Dawley rats was investigated in detail (1,8) (Table 4). This adenocarcinoma again proved to be a

suitable model for testing the therapeutic efficacy of drugs because of its surprisingly sensitive response to HPC. Fifty-one µmol/kg HPC, corresponding to 21 mg/kg bw, was the optimum dose. It yielded complete remissions lasting over the whole administration period, but it did not induce toxic reactions. The tumor volume increased again when the administration was discontinued (Fig. 2). After renewed administration of HPC, the tumor growth again came to a standstill. This indicates that no resistance was induced (Fig. 3).

The experiments on transplantable mammary carcinomas of the rat (Table 5) revealed moderate sensitivity of the TMA 1 and 2 tumors, whereas the Walker 256 carcinosarcoma did not respond to the HPC therapy. The MXT mammary carcinoma of the mouse was similarly insensitive (Table 6).

The growth of another autochthonous tumor, i.e. the colonic carcinoma of the rat (2–4), was not inhibited by HPC despite administration of maximum doses (Table 7).

Yet another autochthonous tumor was investigated: the benzo(a)pyrene-induced sarcoma of the rat (5). The results are presented in Figure 4. Comparatively good chemosensitivity of the tumors was observed in some animals; others showed no response. Therefore, mere comparison of the mean tumor growth curves would reveal little difference to the untreated control during the period of treatment. However, evaluation by Koziol and Donna of the growth development using the multivariate test proved

significant tumor-inhibiting effects of HPC at a dose of 51 μmol/kg.

DISCUSSION

The most important finding of the experiments described was that hexadecylphosphocholine affected growth retardation of autochthonous mammary carcinomas in rats. This effect was superior to the inhibitory effect induced, for instance, by cyclophosphamide (1). HPC thus proved to be an interesting new model compound in the development of active anticancer drugs. This is more important because its toxicity is obviously quite different from that of known antineoplastic agents such as alkylating compounds or antimetabolites. Remarkable, though not exceptional, is the fact that the therapeutic activity of HPC manifested itself markedly against only one tumor, i.e. the autochthonous mammary carcinoma of the rat, while other experimental tumors were not sensitive at all. Perhaps this offers the possibility of developing compounds of the described type especially for use against certain organ tumors. Such an "aimed" therapy surely would be more favorable than the "shotgun" therapy that many presently available compounds exert. First clinical results tend to support this hypothesis.

ACKNOWLEDGMENT

Dymitr Komitowski, Institute of Experimental Pathology, German Cancer Research Center, is thanked for carrying out the histopathological examinations.

[Received December 29, 1986]

Modulation of Chemical Carcinogenesis in Rats by Alkyl Lysophospholipids[1]

Martin R. Berger* and **Dietrich Schmähl**
Institute of Toxicology and Chemotherapy, German Cancer Research Institute, Im Neuenheimer Feld 280, 6900 Heidelberg, Federal Republic of Germany

The influence of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH_3) and 1-hexadecylmercapto-2-methoxymethyl-*rac*-propyl-3-phosphocholine (TLP, BM41.440) on methylnitrosourea (MNU)-induced rat mammary carcinomas and of ET-18-OCH_3 on 7,12-dimethylbenzanthracene (DMBA)-induced leukemias was investigated. Both agents effectively delayed MNU-induced mammary tumor formation at high, cytotoxic dosages but TLP had no influence at low "immunomodulatory" doses. ET-18-OCH_3 also significantly protected against leukemia development in DMBA-treated Long-Evans rats.
Lipids 22, 935–942 (1987).

Modulation of tumor occurrence by selected drugs is a modern field of research with growing importance. From the two types of effective modulation that either enhance or reduce tumor incidence, the latter type has been investigated by groups of researchers, including ourselves, who are interested in "chemoprevention" of cancer.

Some agents chemically inhibit the reaction of certain carcinogens with desoxyribonucleic acid (DNA) by scavenging or more specific mechanisms of action (1,2). Other compounds are able to interfere later on during the interval between initiation and manifestation of tumors.

Therefore, we investigated the ability of retinoids (3–5) and sulphur-containing agents such as disulfiram (6,7) and mesna (8) to inhibit the formation of certain chemically induced tumors in animals. Reduced fibrosarcoma expression in methylcholanthrene-induced mice following administration of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH_3) (9) prompted us to investigate the potential of alkyl lysophospholipids to modulate chemical carcinogenesis on a larger scale. Two compounds that had shown promising chemotherapeutic properties in animal systems and in first trials in man (10,11) were selected, i.e. ET-18-OCH_3 and 1-hexadecylmercapto-2-methoxymethyl-*rac*-propyl-3-phosphocholine (TLP, BM 41.440, Ilmofosine), as indicated in Figure 1.

This article summarizes our experiments on these two agents with regard to their influence on the occurrence of rat mammary carcinomas induced by N-methylnitrosourea (MNU; experiments A,C) and on the manifestation of rat erythroleukemia induced by 7,12-dimethylbenzanthracene (DMBA; experiment B).

MATERIALS AND METHODS

Chemicals. MNU was synthesized by Dr. M. Wiessler (Institute of Toxicology and Chemotherapy, German Cancer Research Center, Heidelberg) and dissolved at 1% in Sörensen buffer, pH 6 and distilled water (20:80, v/v). DMBA was obtained as a 0.5% fat emulsion (5 mg/ml) (intralipid) from Upjohn Company (Kalamazoo, MI). ET-18-OCH_3 (Fig. 1) was supplied by Paul Munder (Max-Planck Institute for Immunobiology, Freiburg) and dissolved at 0.1% in physiological saline or at 1% in human serum albumin (Human Albumin 20%, Immuno GmbH, Heidelberg) and physiological saline (5.95, v/v). TLP (Fig. 1) was obtained from Boehringer Mannheim (Mannheim, FRG) and dissolved at 0.2% and 3% in tap water. Etretinate (Tigason®) was supplied by Hoffman-LaRoche, Basel and administered as 0.05% solution in tap water contained in light-protected bottles. All solutions were prepared shortly before use.

Animals and tumor induction. Rats were purchased from commercial sources (Zentralinstitut für Versuchstierzucht [Hannover, FRG]) and kept under conventional conditions. Altromin pellets and tap water were given ad libitum.

Induction of mammary carcinomas in SD-rats and of leukemias in LE-rats were performed basically as described elsewhere (12–14). Female SD-rats received a single IV injection of 50 or 25 mg/kg MNU on day 50 of life. Male and female LE-rats were injected with 30, 10, 20 and 10 mg/kg DMBA on days 27, 42, 57 and 70 of life, respectively.

All animals were observed while alive; only moribund animals were sacrificed. Dead animals were dissected. Specimens of macroscopically changed organs were examined histologically to determine tumor incidences and causes of death.

The number of tumors per animal and the induction time for the first tumor of each animal were analyzed by the Krustal-Wallis test to find significant differences (15). Tumor rates were analyzed by comparison of organ-specific, age-adjusted observed vs. numbers of affected animals expected according to Peto et al. (16). The administration schedule of experiments A, B and C are given in Tables 1 and 3 and in Figure 5.

RESULTS

Influence of ET-18-OCH_3 on MNU-induced rat mammary carcinoma. The results of oral administration of ET-18-OCH_3 to female SD-rats induced with MNU are given in Figure 2 and Table 2. Rats receiving 50 mg/kg MNU developed only multiple mammary carcinomas (100%) within 10 weeks after injection of the carcinogen. Two–nine tumors (median: 5) were found per rat at the experiment's termination. The total tumor load per rat was 1.6–45.4 cm^3 (median: 15.9 cm^3). Administration of ET-18-OCH_3 inhibited the occurrence and growth of mammary lesions. After 10 weeks of administration, only 80% of the animals had developed tumors. The size of these tumors was distinctly smaller, ranging from 1–16.2 cm^3 (median: 6.8 cm^3). Moreover, the number of tumors per

tumor-bearing rat was significantly lower during the last three weeks of the experiment (Fig. 2). However, no significant difference was found in the occurrence of the first tumor per rat, the median manifestation time being 43 days in ET-18-OCH_3-treated animals and 44 days in untreated control animals.

Protection by ET-18-OCH_3 against leukemia development in DMBA-treated Long-Evans rats. Induction of LE-rats with DMBA is a highly effective method of generating predominantly erythroleukemias within a short period of time (Fig. 3). These leukemias affect a median survival time of 10 days following diagnosis (range: 2–25 days; Fig. 4). In both experiments (I and II, Table 4), treatment with four pulse doses of DMBA resulted in rapid and almost complete leukemia induction. Median survival times from the start of experiment amounted to 102 days at an incidence rate of 90% in experiment I and 113 days at 96% in experiment II. Regular administration of ET-18-OCH_3 as shown in Table 3, effected an increase in median survival times of 17–53% compared with the respective untreated control (groups Ia–d, Table 4). Later onset of administration appeared to be at least as successful in increasing the median life span as an earlier start of treatment. However, treatment-related reduction in leukemia incidence was observed concomitantly with increased crude incidence of neoplasias of the mammary

gland (41% vs 16% in untreated controls) and of other malignant tumors (28% squamous cell carcinomas of the ear duct vs 11% in untreated controls). This increase was at least in part due to the longer survival of treated rats. Statistical analysis allowing for differences in survival revealed no significant increase in mammary neoplasias or other tumors. Combined administration of ET-18-OCH_3 and the retinoid etretinate, also a chemopreventive agent (IIb, Table 4) failed to prolong remarkably the lifespan of animals but significantly lowered the incidence of mammary neoplasias.

Suppression of MNU-induced mammary carcinoma by TLP. Since the onset of alkyl lysophospholipid administration influenced the leukemia incidence following DMBA induction, the time schedule of TLP administration was varied (Fig. 5). The period of administration was restricted to a total of 12 weeks. Additionally, the doses of the carcinogen and of TLP were varied to compose both low "immunomodulatory" or high cytocidal doses of TLP and varied to compose tumor induction schemes affecting rapid or delayed tumor manifestation.

The tumor occurrence following MNU alone is shown in Figure 6. At week 40, the tumor incidences were 98% after 50 mg/kg and 85% after 25 mg/kg MNU. The effect of the low TLP dose is given in Figure 7. The manifestation of mammary lesions induced with 50 mg/kg MNU clearly was not suppressed by a 12-week administration of TLP. Tumor occurrence was slightly delayed

in rats by application starting at day 21 after induction. However, the higher dose of TLP suppressed the tumor growth for a considerable time (Fig. 8). The growth inhibition was maintained for three to seven weeks after the end of the respective treatment period.

Longer delay in tumor manifestation was seen when the higher dose of TLP was administered to rats who were induced with 25 mg/kg MNU (Fig. 9). In comparison with the higher induction scheme, the observed suppression was relatively stronger. At week 40, a 68% reduction in

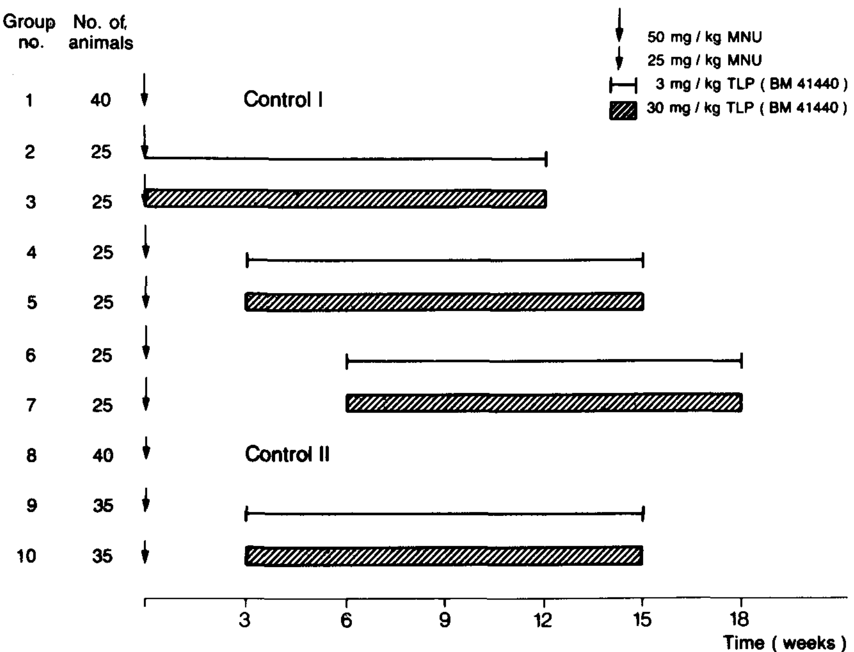

FIG. 5. Experimental design of administering TLP to groups of female SD-rats induced with MNU.

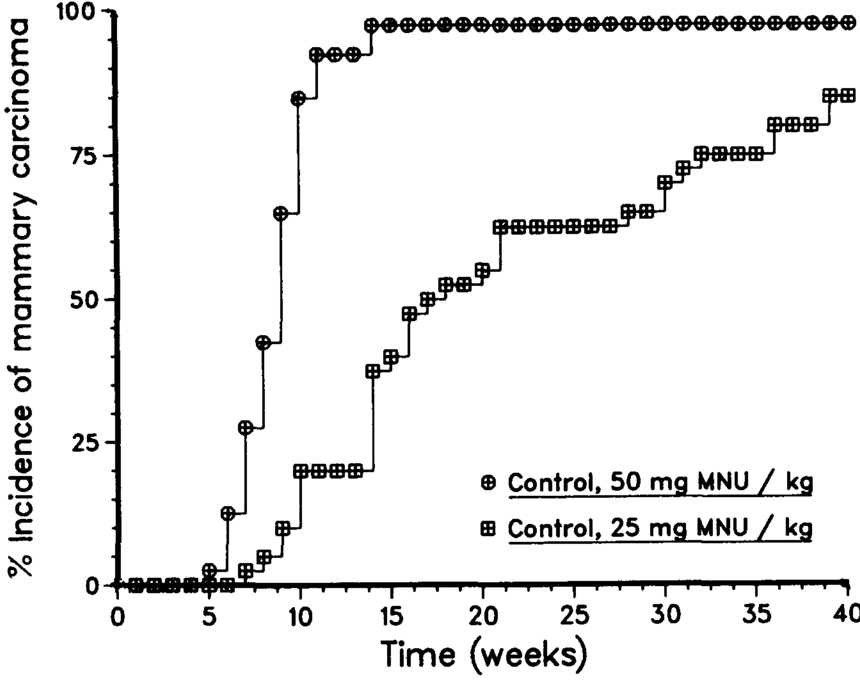

FIG. 6. Increase in mammary carcinoma incidence (%) of SD-rats induced with MNU.

tumor incidence was seen as compared to a 30% difference following the optimal treatment of animals induced with the high dose of MNU. The low dose of TLP, however, did not effect any tumor growth suppression.

DISCUSSION

Alkyl lysophospholipids belong to a new class of antineoplastic agents that seem to combine cytotoxic and immunological mechanisms of action. However, both activities are observed at different dose ranges. The "immunomodulatory" activity is exerted at low dosages, probably activating macrophages and/or natural killer cells (17). Concomitantly, significant enlargement of the spleen is detected whereas high dosages considerably reduce the spleen size (unpublished data).

In the present paper, the values of both anticancer mechanisms of action were investigated regarding their

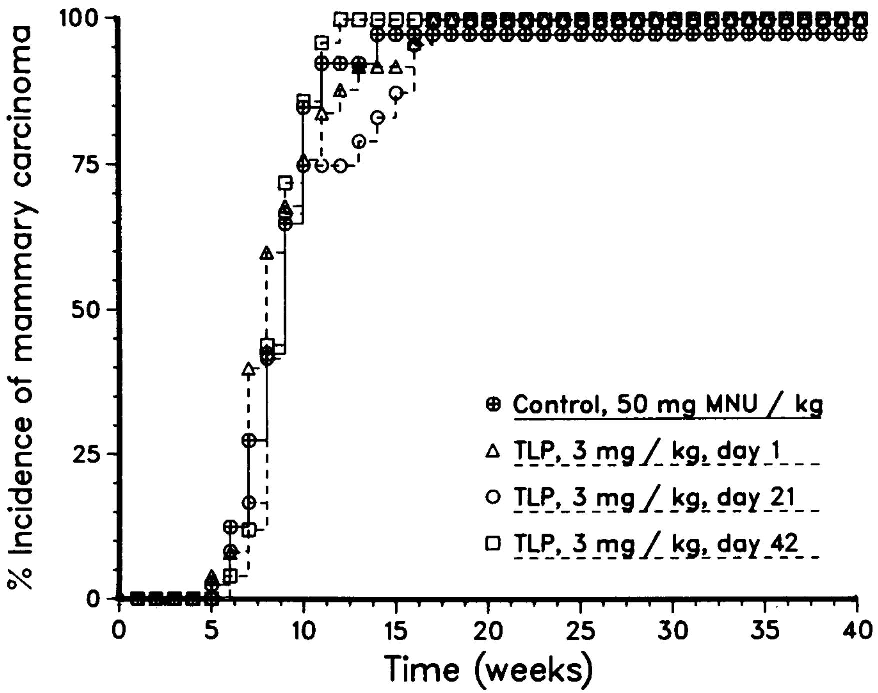

FIG. 7. Influence of TLP (3 mg/kg) on the increase in mammary carcinoma incidence of SD-rats induced with 50 mg/kg MNU.

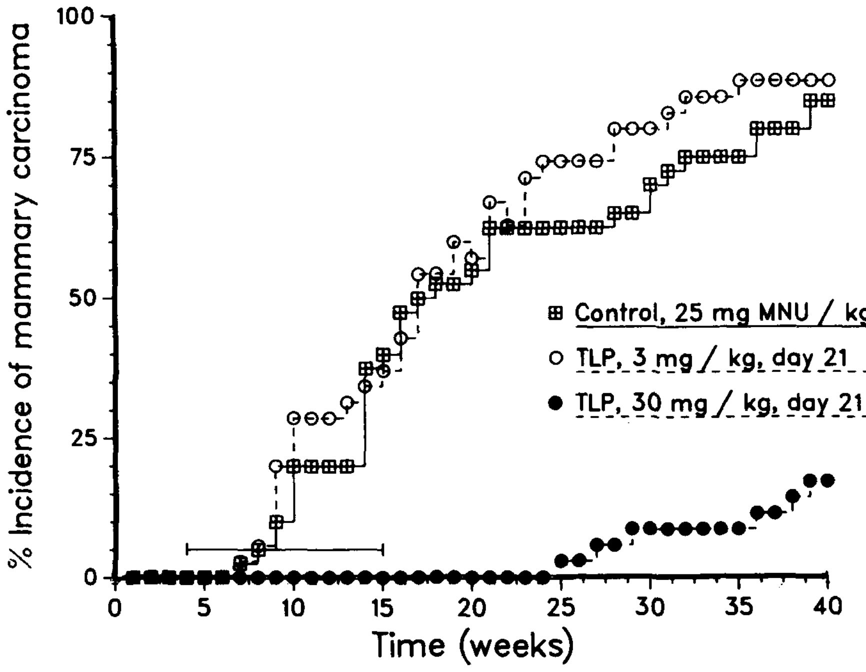

FIG. 9. Influence of TLP (3 or 30 mg/kg) on the increase in mammary carcinoma incidence of SD-rats induced with 25 mg/kg MNU (|——|): duration of TLP-administration).

modulatory efficacy on the carcinogenic effect of two different carcinogens. Low doses of the alkyl lysophospholipid TLP were ineffective in suppressing the formation of MNU-induced tumors. This is in accordance with the results of Berdel et al. (18), who administered 50 μg ET-18-OCH_3/mouse equivalent to 2.5 mg/kg and failed to modulate the occurrence of leukemias in genetically determined AKR mice or in C57Bl/6 mice that had been irradiated to induce lymphomas. It differs from the results of Munder et al. (9), who administered the same dose of ET-18-OCH_3 to 20-methylcholanthrene-induced Balb C mice and observed significant reduction of tumor incidence. However, the administration of higher doses of either compound was associated with significant inhibition of rat mammary tumor occurrence. It is interesting to note that the effect following TLP was pronounced more as compared with the respective control when the lower dose of MNU was used (25 instead of 50 mg/kg).

In preceding experiments on the therapeutic efficacy of ET-18-OCH_3 and TLP, both agents exhibited antineoplastic activities against established mammary lesions when sufficiently high doses were used (11).

However, ET-18-OCH_3 did not prolong the life span of LE-rats bearing overt leukemia (unpublished data). Since the manifestation of both types of tumors was at least partly suppressed when the onset of administration lie between induction and manifestation of tumors, different mechanisms of action might be involved.

Unlike various conventional cytotoxic agents, alkyl lysophospholipids do not affect DNA (19); therefore, they could be used for cancer prevention. Only compounds without irreversible or severe side effects are suited for the prevention of cancer, since the onset of administration would lie before any visible cancer growth and would last over a considerable period of time. Our results indicate that alkyl lysophospholipids act between the time of initiation and the time of manifestation of tumors. Consequently, a treatment following an exposure to certain carcinogens might be recommended.

In summary, the observed modulation of chemically induced carcinogenesis is promising, and it should be the basis for studies on the presently unknown basic mechanisms of action.

[Received December 23, 1986]

Antineoplastic Activity of Conjugates of Lipids and 1-β-D-Arabinofuranosylcytosine[1]

Wolfgang E. Berdel[a,*], Susanne Danhauser[a], Hans D. Schick[a], Chung Il Hong[b], Charles R. West[b], Michael Fromm[a], Ulrich Fink[a], Anneliese Reichert[a] and Johann Rastetter[a]

[a]Division of Hematology and Oncology, Department of Medicine I, Technische Universitaet, Munich, Federal Republic of Germany, and [b]Department of Neurosurgery, Roswell Park Memorial Institute, Buffalo, New York

Five different lipid conjugates of 1-β-D-arabinofuranosylcytosine (ARA-C) were tested in comparison with ARA-C, the ether lipid ET-18-OCH₃ (1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine) and their equimolar mixtures. The compounds were tested in vitro for cytotoxicity in the trypan blue dye exclusion test with cells from six different leukemias, one glioblastoma and two bronchogenic carcinomas of human origin. The compounds were given in vivo to assess their therapeutic activity against 3-Lewis lung carcinoma (3-LL) of syngeneic $C_{57}Bl_6$ mice. Although some of the conjugates have shown cytotoxic activity in vitro against the cell samples tested, they have not revealed higher cytotoxicity than ET-18-OCH₃, ARA-C or their equimolar mixtures. In these experiments, ARA-CDP-D,L-MBA was the conjugate with the highest cytotoxicity. Some of the conjugates significantly inhibited tumor growth and also increased survival of $C_{57}Bl_6$ mice with intraperitoneally (ip) implanted 3-LL. In these experiments, ARA-CDP-D,L-PTBA, ARA-CDP-D,L-PBA, ARA-CDP-L-dipalmitin and ARA-CDP-D,L-PCA were more active than either the parent compounds ARA-C and ET-18-OCH₃ alone or their equimolar mixtures. Furthermore, when the conjugates were injected as adjuvant chemotherapy shortly after the surgical removal of the primary 3-LL, they inhibited the metastasis of 3-LL to the lungs of the animals, demonstrated by an increase of the survival time and the number of surviving animals. The mode of action of these new antineoplastic compounds still is speculative.
***Lipids 22,* 943–946 (1987).**

Recently, there is an increasing interest in the antineoplastic properties of certain ether lipids and analogs. This subject has been reviewed in detail (1). Among other modes of action, some of those compounds exert direct cytotoxicity during incubation with neoplastic cells (1). Since favorable activity of 1-β-D-arabinofuranosylcytosine (ARA-C) conjugates of nontoxic ester-linked phospholipids was found in experimental leukemia and myeloma (2,3), we tried to improve these results by synthesizing and testing ARA-C conjugates of a variety of cytotoxic ether lipids (4–6). Here we report on the antineoplastic in vitro and in vivo efficacy of five lipid conjugates of ARA-C, including four conjugates of either lipids with a 1-*O*-alkyl- or a 1-S-alkyl linkage in the *sn*-1 position of the lipid moiety.

MATERIALS AND METHODS

Drugs. The chemical structures of the conjugates tested are depicted in Figure 1. Details on synthesis, chemical properties and preliminary preclinical toxicity data have been published (5,6). The chemical structures of the parent compounds, including the ether lipids 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH₃) and BM 41.440 also have been published (5,6). The compounds were added to 10% serum-containing culture medium for the in vitro assays and were added to saline for the treatment experiments in vivo.

In vitro assays for antineoplastic activity. Cell cultures and cytotoxicity assays were performed as recently described (7). In the trypan blue dye exclusion assay, cells were incubated with the test compounds for various times in serum-containing medium and cytotoxic action of the drugs was measured as an increase of trypan blue uptake into the cells given as percentage of the controls.

3-Lewis-lung experiments in vivo. The tumor model has been used as described recently (8,9). Briefly, 3-LL was

studied in syngeneic $C_{57}Bl_6$ mice that were kept under standard conditions. For experiments regarding primary tumor growth, 3-LL cells were given intraperitoneally (ip) at day 0. Ip treatment was performed on days 1–5. Survival was determined at day 20 and after ≥60 days. Death from a tumor occurred within 40 days after the tumor transplantation. For metastasis experiments, 10^6 3-LL cells were given subcutaneously into the foot pad at day 0. The tumor was removed surgically at a diameter of 0.6 cm. Treatment was given ip after randomization on days 1–5 after operation. The end-point of the experiments was either death from metastasis or survival. Survival was determined at days 30, 40 and after >60 days.

Statistical analysis. This was performed with the 2 × 2 contingency table (two-tailed test) and p-values were obtained as published (10).

RESULTS

In vitro. The compounds were tested in vitro for cytotoxicity using the trypan blue dye exclusion test in cells from six different leukemias, one glioblastoma and two bronchogenic carcinomas of human origin. Although the conjugates have shown cytotoxic activity against the cell samples tested, they have not revealed higher cytotoxicity than ET-18-OCH_3, ARA-C or their equimolar mixtures. In these experiments, the LC_{50} values (LC_{50} = lethal concentration for 50% of the cells) for ET-18-OCH_3 after 48 hr of incubation were found to be <3 μM for the leukemias and ca. 20 μM for the solid tumors. The order of efficacy against leukemias was ARA-C > equimolar mixtures > ET-18-OCH_3 > conjugates (ARA-CDP-D,L-MBA). The order of efficacy against the solid tumors was ET-18-OCH_3 > equimolar mixtures > conjugates (ARA-CDP-D,L-MBA) > ARA-C. ARA-CDP-D,L-MBA was found to be the conjugate with the highest cytotoxicity in vitro. Table 1 summarizes the results for the human leukemic cell line HL 60 as an example. More details and the exact LC_{50} values for the other cell lines tested recently have been published (5).

3-Lewis lung carcinoma in vivo. Table 2 summarizes our experiments testing the therapeutic efficacy of the conjugates, an equimolar (1:1) mixture of ARA-C and ET-18-OCH_3 at the same dose level and the parent compounds ARA-C and ET-18-OCH_3 alone on the primary 3-LL growth. [a]10^6 3-LL cells were given subcutaneously into the footpad at day 0; the tumor was surgically removed at a diameter of 0.6 cm; treatment was given ip on days 1-5 after the operation. The end point of the experiment was either death from metastasis or survival. Survival was determined at days 30 and 40 and after >60 days.
[b]Significance level in 2 × 2 contingency analysis, two-tailed test.
*Values indicate experiments in which the outcome of control was superior to the treatment group.
[c]See Table 2.

leukemia (5,6), 80–100 mg/kg/day given for five consecutive days proved to be optimal for the conjugates; higher doses started to produce toxicity. ARA-C dose levels and treatment schedules were chosen according to National Cancer Institute protocols (11) with some modifications. Doses up to 200 mg/kg/day of ARA-C given for five consecutive days were nontoxic for healthy mice. The ET-18-OCH_3 was given at a dose range of 5–20 mg/kg/day, using previous experience as a guideline (8,9). ARA-CDP-D,L-PBA and ARA-CDP-D,L-PTBA and ARA-CDP-L-Dipalmitin revealed the strongest therapeutic efficacy, leading to a significant increase of surviving animals up to a tumor load of 5×10^5 3-LL-cells and to an increase of survival time of the treated mice even with a tumor load of 10^6 3-LL-cells. Interestingly, the ARA-CDP-D,L-MBA was less effective. Systemic therapeutic efficacy on 3-LL metastasis was tested; conjugates of ether lipiuds and ARA-C were given as adjuvant chemotherapy shortly after the surgical removal of the primary tumor. In these experiments, ARA-CDP-D,L-PBA and ARA-CDP-D,L-PTBA showed a moderate therapeutic activity measured as an increase of survival time and absolute numbers of surviving animals, which was superior to equimolar mixtures of ARA-C and ET-18-OCH_3. Table 3 summarizes some of these experiments.

DISCUSSION

Among various conjugates of lipids and 1-β-D-arabinofuranosylcytosine (ARA-C), the thioether lipid conjugate ARA-CDP-D,L-PTBA and the 1-O-alkyl lipid conjugate ARA-CDP-D,L-PBA showed therapeutic efficacy against the 3-LL primary tumor growth and its metastasis to the lungs of syngeneic $C_{57}Bl_6$ mice. Both conjugates were superior to ARA-C and ET-18-OCH_3 by themselves or their equimolar mixtures at the same dose level. Effective therapeutic regimens were relatively well-tolerated by the mice. The activity of the conjugates found in the 3-LL model followed prior observations, which described therapeutic effects of these compound in mouse leukemias L1210 and P388 (4–6).

Interestingly, this in vivo activity does not correlate directly with in vitro cytotoxicity because the ARA-CDP-D,L-MBA, which is one of the most active conjugates in vitro with regard to direct cytotoxicity, produced only minor therapeutic effects in vivo. Thus, further experiments are necessary to elucidate both the metabolism and the mode of conjugate action. However, the hypothesis leading to these conjugates, which is to produce a drug that might release two cytotoxic metabolites with different cytotoxicity targets, remains speculative. In conclusion, the comparatively high therapeutic activity of the two ether lipid conjugates of ARA-C, ARA-CDP-D,L-PTBA and ARA-CDP-D,L-PBA in the 3-LL and leukemias in mice is a strong incentive to further investigate these compounds as experimental drugs for cancer treatment within a wider preclinical test program.

Synthesis of Thioether Phosphocholine Analogues[1]

Elmar Bosies, Dieter B.J. Herrmann*, Uwe Bicker, Rudi Gall and Wulf Pahlke
Boehringer Mannheim GmbH, 6800 Mannheim 31, Federal Republic of Germany

The synthesis of thioether phospholipids, which represent a new class of antitumor agents, is reported here. In particular, the route of synthesis of 3-hexadecylmercapto-2-methoxymethylpropyl-2′-trimethylammonio-ethyl phosphate (BM 41.440, Ilmofosine), one of the most potent cytostatic/cytotoxic derivatives, is described in detail. Starting with diethyl *bis*-hydroxymethylmalonate, ethyl 2-phenyl-1,3-dioxane-5-carboxylate is formed via diethyl 2-phenyl-1,3-dioxane-5,5-dicarboxylate and 5-ethoxycarbonyl-2-phenyl-1,3-dioxane-5-carboxylic acid. Reduction of ethyl 2-phenyl-1,3-dioxane-5-carboxylate with $LiAlH_4$ affords 5-hydroxymethyl-2-phenyl-1,3-dioxane. Alkylation with dimethyl sulfate gives 5-methoxymethyl-2-phenyl-1,3-dioxane. The ring structure then is opened by *N*-bromosuccinimide, resulting in the formation of 3-bromo-2-methoxymethylpropyl benzoate. Reaction of 3-bromo-2-methoxymethylpropyl benzoate with the sodium salt of hexadecanethiol leads to 3-hexadecylmercapto-2-methoxymethylpropanol, which is reacted with a cyclic chlorophosphate to give the corresponding phosphorylated 3-hexadecylmercapto-2-methoxymethylpropanol. Treatment with trimethylamine yields BM 41.440. This compound already has been tested in clinical phase I/II trials in West Germany.
Lipids 22, 947-951 (1987).

Ether phospholipids are among the most potent biologically active phospholipids (1,2) and have been shown to be required for a series of vitally important physiological processes such as platelet activation (2), vasodilation (3) and chemotaxis (4). During recent years, synthetic thioether phosphocholine analogues have gained increasing interest due to their antitumor activity in a variety of tumor models in vitro and in vivo (5-9). Furthermore, the implication of platelet-activating factor (PAF), which has been identified as 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (10,11) as a primary mediator of acute inflammatory and allergic reactions (12), has stimulated great interest, particularly in analogues similar in structure to biologically active PAF (13,14). 3-hexadecylmercapto-2-methoxymethylpropyl 2′-trimethylammonio-ethyl phosphate (BM 41.440) (prop. INN: Ilmofosine) is one of the most potent antineoplastic thioether phosphocholine analogues reported so far (5-7,15). This compound recently has been tested in clinical phase I/II trials in refractory cancer patients in West Germany (16). This report describes general synthetic routes to thioether choline phospholipids (Scheme 1) and, in particular, the synthesis of BM 41.440 (Scheme 2[8]).

Abbreviations: BM 41.440, 3-hexadecylmercapto-2-methoxymethylpropyl-2′-trimethylammonio-ethyl phosphate; DMF, dimethyl formamide; NBS, *N*-bromosuccinimid; PAF, platelet activating factor.

EXPERIMENTAL

Diethyl 2-phenyl-1,3-dioxane-5,5-dicarboxylate (Scheme 2 [1]). Twenty-two g (0.1 mol) of diethyl *bis*-hydroxymethylmalonate (Aldrich) in 200 ml toluene is refluxed with 10.6 g (0.1 mol) of benzaldehyde and 0.2 g *p*-toluenesulfonic acid for three hr using a Dean Stark trap. The toluene then is evaporated in vacuo and the residue purified by distillation to afford 26.6 g (86%); $bp_{1.1}$ 167-170 C.

5-Ethoxycarbonyl-2-phenyl-1,3-dioxane-5-carboxylic acid (Scheme 2[2]). To 4 g (0.072 mol) of potassium hydroxide in 100 ml ethanol, 15.4 g (0.05 mol) of Scheme 2[1] is added. After stirring for four hr, the ethanol is evaporated in vacuo and the residue treated with 72 ml 1 N hydrochloric acid with cooling. The precipitate is filtered off by suction; yield: 13.0 g (93%); mp 111-113 C.

Ethyl 2-phenyl-1,3-dioxane-5-carboxylate (Scheme 2[3]). A mixture of 16.2 g (0.058 mol) of Scheme 2[2] and 0.1 ml piperidine in 30 ml absolute pyridine are heated under reflux for five hr. After cooling, the solution is poured onto 30 ml ice-cold 12 N hydrochloric acid. The solution is extracted twice with dichloromethane, and the combined organic layer is dried and evaporated in vacuo; yield: 13.4 g (98%); mp 68-71 C.

5-Hydroxymethyl-2-phenyl-1,3-dioxane (Scheme 2[4]). The mixture of 11.53 g (0.049 mol) of Scheme 2[3] and 1.05 g (0.028 mol) of $LiAlH_4$ in 100 ml absolute diethyl ether is stirred for 3.5 hr at room temperature. The slurry is worked up under ice, cooling by subsequently adding 8 ml ethyl acetate, 4 ml water, 4 ml 15% sodium hydroxide solution and 12 ml of water. The ethereal layer is separated, dried and evaporated in vacuo to afford 9.17 g (96%) of a pale-yellow oil.

5-Methoxymethyl-2-phenyl-1,3-dioxane (Scheme 2[5]). Seven ml (0.073 mol) of dimethyl sulfate is added dropwise to a vigorously stirred mixture of 9.17 g (0.047 mol) of Scheme 2[4] in 50 ml dichloromethane and 0.5 g tetrabutylammonium iodide. After stirring for 18 hr, 10 ml conc. ammonia and 40 ml water are added. The solution is extracted three times with 60 ml dichloromethane. The combined organic layer is washed consecutively with 15 ml 2 N hydrochloric acid and water until neutral. The organic layer is dried and evaporated in vacuo. Distillation of the residue yields 9.1 g (93%), $bp_{0.1}$ 117-120 C.

3-Bromo-2-methoxymethylpropyl benzoate (Scheme 2 [6]). A mixture of 9.4 g (0.045 mol) of Scheme 2[5], 8.8 g (0.049 mol) of *N*-bromosuccinimide and 1 g barium carbonate in 100 ml dichloromethane are refluxed for 2.5 hr. After cooling, the reaction mixture is evaporated in vacuo, the residue triturated with hexane, filtered and the filtrate evaporated in vacuo to afford 12.9 g of a light-yellow oil. The oil is used without further purification in the reaction.

3-Hexadecylmercapto-2-methoxymethylpropanol (Scheme 2[7]). The oil residue of the foregoing reaction, 12.9 g of Scheme 2[6], in 35 ml ethanol is added to a prepared solution of 1.15 g Na (0.05 mol) in 40 ml ethanol and 12.9 g (0.05 mol) hexadecanthiol in 40 ml ethanol and stirred for 20 hr at room temperature. The mixture is acidified with hydrochloric acid/ethanol and evaporated

in vacuo. The residue is taken up in water and extracted three times with dichloromethane. The combined organic layer is treated with $NaHCO_3$ and water, dried and evaporated in vacuo. Most of the ethyl benzoate formed is distilled off in vacuo and the residue purified by silica gel (150 g) chromatography using diethyl ether/hexane (1:5, v/v) as eluant; yield: 10.7 g (66%); mp 42-44 C.

3-Hexadecylmercapto-2-methoxymethylpropyl 2'-trimethylammonio-ethyl phosphate (Scheme 2[8] = BM 41.440). A solutoin of 14.3 g (0.1 mol) of 2-chloro-2-oxo-1,3,2-dioxaphospholane in 50 ml absolute dichloromethane is added drop-wise with stirring to a solution of 21.2 g (0.059 mol) of Scheme 2[7] and 23 ml triethylamine in 170 ml absolute dichloromethane while the temperature is kept below −25 C. After 30 min, the reaction mixture is evaporated in vacuo at a bath temperature of 35 C; the residue is treated with 250 ml diethyl ether and filtered by suction. The filtrate is evaporated in vacuo and the residue dissolved in 200 ml absolute acetonitrile saturated with trimethylamine. The solution is stirred at room temperature for four days, the precipitate formed is filtered off by suction and consecutively washed with 30 ml absolute acetonitrile and 30 ml absolute acetone. The crude material, 25.6 g, is dissolved in 12.5 ml dichloromethane, filtered; then 50 ml acetone is added at 10 C with stirring. After one hr at 10 C, the precipitate is filtered off by suction and dried over phosphorus pentoxide; yield: 15.7 g (46%). The product contains 3 mol of water.

RESULTS AND DISCUSSION

Depending on the nature of the final product, the synthesis of thioether phospholipid analogues starts either with a malonate derivative (Scheme 1[1a]) or with glycerol (Scheme 1[1b]). Scheme 1 shows two routes, A and B, which are representative for the synthesis of most of the thioether phospholipids.

Route A: the substituent R_1 in the diethyl malonate (Scheme 1[1a]) stands for an alkyl, benzyl or phenyl group that may be substituted again by other groups/atoms. Such substituted diethyl malonates either are available commercially or can be synthesized easily. Reduction of Scheme 1[1a] by $LiAlH_4$ affords the corresponding propane-1,3-diol (Scheme 1[2a]) usually in yields of 80-90%. The following ring closure of Scheme 1[2a] to a 1,3-dioxane derivative (Scheme 1[3]) is performed with benzaldehyde (PhCHO) in the presence of *p*-toluenesulfonic acid. The sequence of the last two reactions also can be reversed.

Route B: starting with glycerol (Scheme 1[1b]), 1,3-benzylidene glycerol (Scheme 1[2b]) is formed in yields of about 50% by reaction with benzaldehyde in the presence of gaseous hydrochloric acid (17). The sodium salt of Scheme 1[2b], provided by sodium hydride in toluene or dimethyl formamide (DMF), is converted to a 2-alkoxy-1,3-benzylidene glycerol (Scheme 1[3]) by reaction with an alkyl halide or a dialkyl sulfate.

The dioxane ring of Scheme 1[3] is opened by *N*-bromosuccinimid (NBS) in dichloromethane, resulting in

the formation of a benzoylated propyl bromide derivative (Scheme 1[4]) (18,19). This intermediate usually is not purified. Intermediate (Scheme 1[4]) then reacts with the sodium salt of a long-chain thiol (RS-Na) to form a 3-alkylmercaptopropanol (Scheme 1[5]) with ethyl benzoate as side-product. The yield for the last two reaction steps is about 60–70%. The reaction of benzoate as side-product. The yield for the last two reaction steps is about 60–70%. The reaction of Scheme 1[5] with a cyclic chlorophosphate in the presence of a base-like triethylamine gives the corresponding phosphorylated 3-alkylmercaptc propanol (Scheme 1[6] (20,21). The cyclic phosphate o Scheme 1[6] is split by trimethylamine ($(CH_3)_3N$; 20,21] The last two steps usually afford acceptable yields (40–75%) of the desired thioether phosphocholine analogues (Scheme 1[7]).

In some cases, the final product crystallizes after standing for three or four days and is sufficiently pure. On the other hand, some of the analogues have to be purified by silica gel chromatography using dichloromethane/methanol/water (65:25:4) (27) as eluant. Scheme 2 illustrates as an example for thioether phospholipids the synthesis of BM 41.440. Details are given in the experimental section. The structures of intermediates and end products were confirmed by ^{1}H-NMR spectroscopy and/or mass spectrometry. The purity was established by elementary analysis. As an example, the ^{1}H-NMR spectrum (Varian XL-300) of BM 41.440 is given in Figure 1.

In conclusion, the synthetic pathways as outlined in Scheme 1 have a great deal of flexibility, providing a convenient general method for the preparation of a wide scope of structurally related thioether phospholipid analogues suitable for structural, chemical, enzymological and therapeutic studies.

[Received January 19, 1987]

Pharmacokinetics of the Thioether Phospholipid Analogue BM 41.440 in Rats[1]

Dieter B.J. Herrmann*, **Eberhard Besenfelder**, **Uwe Bicker**, **Wulf Pahlke** and **Erwin Böhm**[1]
Boehringer Mannheim GmbH, Federal Republic of Germany

BM 41.440 (1-hexadecylmercapto-2-methoxymethyl-*rac*-glycero-3-phosphocholine) is a cytotoxic thioether phospholipid analogue that recently has entered phase I trials in cancer patients. The objective of this study was to evaluate the pharmacokinetics of this compound in female rats after administration of a single oral dose (15 mg/kg body weight [bw]). Furthermore, BM 41.440 serum concentrations were determined under a daily oral treatment of up to 13 weeks. Blood samples were obtained via permanent catheters from the femoral arteries before and after drug administration for a total of 120 hr. Urine was collected in 24 hr-intervals for 120 hr; the volume was measured, and aliquots were stored at −20 C until analytical determination of the thioether derivative. BM 41.440 was assayed in serum and urine by means of a specific, newly developed reverse-phase high pressure liquid chromatography technique. Mean maximum serum concentrations (1.7 μg/ml, n = 4 animals) were attained after seven hr. A terminal half-life of ca. 27 hr was calculated from the rate constant for the terminal elimination phase ($\lambda_z \sim 0.026$/hr). The mean serum BM 41.440 concentration-time-area-under-the-curve was 52.9 mg × hr/l. The ratio of total body clearance to absorption fraction was 4.7 ml/min × kg bw. Only a small amount of the drug was found in the urine. The quantity excreted in the urine during a 24 hr-interval never exceeded 1.5% of the administered dose. Under a daily oral schedule (15 mg/kg bw × day) up to 13 weeks, mean BM 41.440 serum concentrations of 3.3 ± 0.5 μg/ml and 5.2 ± 1.2 μg/ml (mean ± S.D., n = 10 animals) were found after five and 13 weeks, respectively. Taken together, the data indicate that BM 41.440 was absorbed from the gastrointestinal tract after oral administration and that accumulation of BM 41.440 can occur in rats.
Lipids 22, 952–954 (1987).

Alkyl lysophospholipids (ALP) are analogues of lysophosphatidylcholine, which is a minor but important intermediate in the continuous exchange and renewal of phospholipids in cellular membranes via the deacylation/reacylation cycle (Lands pathway) (1,2). ALP represent a new class of antitumor agents (3-6). The prophylactic and therapeutic, antineoplastic, antimetastatic and anti-invasive effects of ALP have been demonstrated in different murine and rat tumor models (3-8), including autochthonous neoplasms (9) and different transplantation tumors (10,11).

The antitumor activity of ALP has been explained by a direct and selective cytotoxic action on neoplastic cells and by the generation of tumoricidal, immuno-competent cells of the monocyte/macrophage lineage in vitro and in vivo (3-5,12). In addition, the induction of a differentiation process in human and murine myeloid leukemia cells has been described (13).

The molecular mechanism whereby these compounds exert their direct antineoplastic effect is related to a possibly specific interference with the phospholipid metabolism of neoplastic cells (12-15), although the precise mode of action is not explained completely yet.

This investigation deals with the pharmacokinetic behavior of cytotoxic 1-hexadecylmercapto-2-methoxymethyl-*rac*-glycero-3-phosphocholine (BM 41.440, prop. INN: Ilmofosine) in rats (Scheme 1). It reports the first pharmacokinetic study performed with a nonradiolabeled ether lipid analogue, thus providing information about the various kinetic parameters for the first time. Pharmacokinetics with a radiolabeled phospholipid analogue closely related in structure to BM 41.440 have been reported by our group (16) and others (17).

MATERIALS AND METHODS

BM 41.440 was supplied as a white, crystalline powder by Boehringer Mannheim GmbH (Mannheim, FRG).

Concentrations of the thioether phospholipid analogue were determined in serum and urine of fasted Sprague-Dawley rats (260-380 g body weight [bw]) after administration of a single oral dose of 15 mg/kg bw. Furthermore, BM 41.440 serum and urine concentrations were evaluated under a daily oral schedule of 15 mg/kg bw after five and 13 weeks, respectively. For administration by gavage, the drug was dissolved in a 0.5% methyl cellulose solution (Tylose, Fluka AG, Buchs, Switzerland). Samples of arterial blood (1 ml) were collected through permanent catheters placed in the femoral arteries at the following times after BM 41.440 administration: 0, 0.5, 1, 2, 3, 5, 7, 24, 31, 48, 55, 72, 96 and 120 hr. Excessive blood loss of each animal was avoided by dividing all animals investigated into four groups of four rats each and by withdrawing blood from animals of only one group

[1]Presented at the symposium on "Ether Lipids in Oncology," Göttingen, Federal Republic of Germany, December 1986.

*To whom correspondence should be addressed at Boehringer Mannheim GmbH, Department of Immunopharmacology and Cancer Research, Sandhofer Strasse 116, 6800 Mannheim 31, Federal Republic of Germany.

Abbreviations: ALP, Alkyl lysophospholipid analogue(s); BM 41.440, 1-hexadecylmercapto-2-methoxymethyl-*rac*-glycero-3-phosphocholine; HPLC, high pressure liquid chromatography.

at each time indicated between 0 and 120 hr. Then, all samples for each time-point of blood withdrawal were pooled. Upon collection, blood samples were kept on ice and immediately centrifuged at 4 C for 10 min at 2000 rpm. Serum was decanted and stored at −20 C until analysis.

Urine was collected in 24 hr-intervals for 120 hr, the volume was measured and aliquots were stored frozen at −20 C until analytical determination of BM 41.440.

BM 41.440 was assayed in serum and urine by means of a specific, newly developed reverse-phase high pressure liquid chromatography (HPLC) technique. To 1 ml serum in a 10 ml glass centrifuge tube, 0.1 ml internal standard (BM 41.448; Boehringer Mannheim GmbH) was added, mixed and the mixture was lyophilized. The dry residue was extracted first with 2 ml, then 1 ml $CHCl_3/CH_3OH$ (2:1, v/v), using a whirlmix and an ultrasonic bath (for two min) and centrifuged at 3000 × g for five min. The combined supernatants were applied onto a disposable silica cartridge (Analytichem Int. [Frankfurt, FRG]) preconditioned with 4 ml CH_3OH/CH_2Cl_2 (1:1, v/v) and 1 ml CH_3OH/glacial acetic acid (9:1, v/v). The cartridge was washed twice with 2 ml CH_3OH/glacial acetic acid (9:1, v/v) and twice with 1 ml CH_3OH. The cartridge was rinsed dry and elution started slowly with two times 2 ml plus 1 ml CH_3OH/25% NH_4OH (9:1, v/v). The combined eluates were evaporated at 40 C under a stream of nitrogen. The dry residue was reconstituted with 0.5 ml CH_3CN/H_2O (4:6, v/v) using the whirlmix and ultrasonic bath. The suspension then was transferred into 300 μl micro autosampler glass tubes and centrifuged in an Eppendorf centrifuge for three min at 10,000 rpm. The clear supernatant was transferred into another micro autosampler tube and 200 μl injected onto the column.

The modular HPLC system consisted of an ISS-autosampler (Perkin-Elmer), a model 64 HPLC pump (Knauer) and a model 5100 A electrochemical detector (ESA) using 850 millivolts (mV) for the analytical and 900 mV for the guard cell, range 50 × 1. The column (125 × 4.6 mm) was slurry-packed with Nucleosil 5-CN (Machery and Nagel). The flow rate was 1.5 ml/min. The mobile phase consisted of 40% CH_3CN and 60% 0.02 M KH_2PO_4, pH 2.0 (v/v). The retention time for BM 41.448 and BM 41.440 was 9.7 and 8.2 min, respectively. Total analysis time was 15 min. The limit of detection was 15 ng/ml. In order to preserve the necessary sensitivity, the system had to be purged with mobile phase for 30 min under reductive conditions (−850 mV) every morning.Calibration graphs were prepared by assaying samples to which known amounts of BM 41.440 had been added. Peak height ratios of BM 41.440 relative to internal standard were plotted against the known concentrations. The resulting correlations were linear with coefficients of correlation between 0.98 and 0.99.

TABLE 1

Pharmacokinetic Data of BM 41.440 in Rats after a Single Oral Dose of 15 mg/kg bw

Parameter	
C_{max} (mg × l^{-1})	1.7
t_{max} (hr)	7
Cl/f (ml × min^{-1} × kg^{-1})	4.7
AUC, 0–120 hr (mg × hr × l^{-1})	52.9
λ_z	0.026
$t_{1/2}$ (hr)	27.1
C_z (mg × l^{-1})	1.3
A_e, 0–120 hr (5)	1.4

C_{max}, maximum serum concentration; t_{max}, time of maximum serum concentration; Cl/f, ratio of total body clearance/absorption fraction; AUC, area under the curve up to 120 hr; λ_z, rate constant for the terminal elimination phase; $t_{1/2}$, half-life for the terminal elimination, calculated from l_z; C_z, intercept of the extrapolated curve for the terminal elimination with the ordinate; A_e, parent substance excreted in the urine during 120 hr (percentage of administered dose).

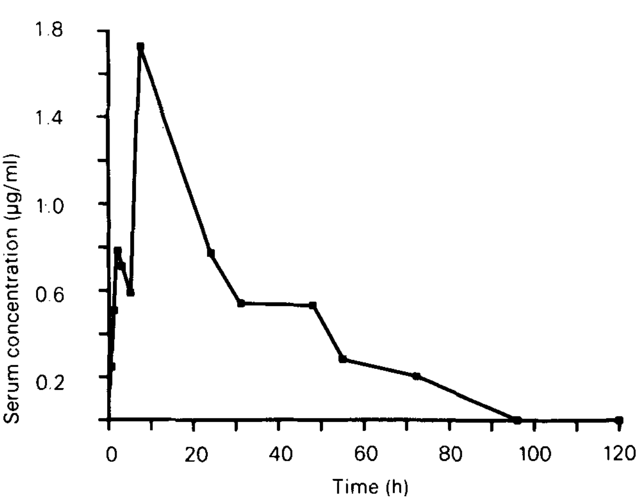

FIG. 1. Mean serum concentration-time profile of BM 41.440 after a single oral dose of 15 mg/kg bw. Blood samples from female rats (n = 4 animals/group, 260–380 g bw) were obtained at the times indicated through permanent catheters placed in the femoral arteries. Extraction of phospholipids and quantification of BM 41.440 was done by means of reverse-phase HPLC.

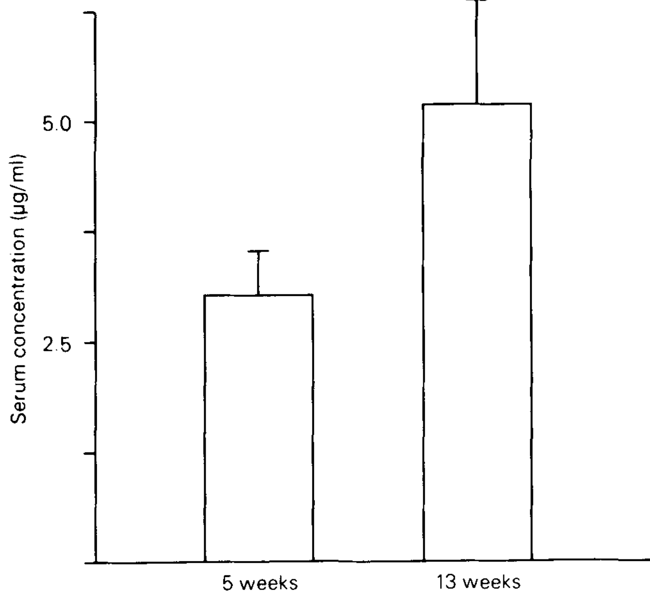

FIG. 2. Mean serum concentrations of BM 41.440 under a daily oral schedule (15 mg/kg bw × day) after five and 13 weeks, respectively. Mean ± S.D., n = 10 animals.

RESULTS AND DISCUSSION

Figure 1 illustrates the BM 41.440 mean serum concentration vs time after a single oral dose of 15 mg/kg bw. Drug concentration increased slowly, and mean peak serum levels (1.7 μg/ml, n = four animals) were attained seven hr after BM 41.440 administration indicating that the thioether analogue is absorbed at a low rate in female rats. A terminal half-life of ca. 27 hr was calculated from the rate constant for the terminal elimination phase ($\lambda_z \sim 0.026$/hr).

All pharmacokinetic parameters are summarized in Table 1. The mean serum BM 41.440 concentration-time-area-under-the-curve (AUC) was 52.9 mg × hr/l. The ratio of total body clearance to absorption fraction was 4.7 ml/min × kg bw.

Recovery of BM 41.440 in urine was examined in all animals receiving a single oral dose of 15 mg/kg bw over 120 hr. In five of 17 animals very small amounts of the drug were found in urine during the first 24 hr. The percentage of administered dose excreted in the urine never exceeded 1.5%. Essentially no drug was detected after 24 hr.

Under a daily oral treatment with 15 mg/kg × day up to 13 weeks, mean BM 41.440 serum concentrations of 3.3 ± 0.5 μg/ml and 5.2 ± 1.2 μg/ml (mean ± S.D., n = 10 animals) were found after five and 13 weeks, respectively (Fig. 2). In accordance with the long half-life and the low excretion rate after single oral administration, these data indicate that accumulation of BM 41.440 can occur in female rats with a calculated factor of accumulation of 2.2 for a dosage interval of 24 hr.

This report is the first pharmacokinetic study done with a non-radiolabeled ether lipid analogue, called BM 41.440 or Ilmofosine. Recently, we described the pharmacokinetic profile of a structurally related alkyl lysophospholipid derivative, 1-[^{3}H]octadecyl-2-methyl-*rac*-glycero-3-phosphocholine, in (Balb/c × C57Bl)F_1 mice (16). This investigation revealed a high in vivo plasma stability of the radiolabeled ether lipid, either after oral or IV administration, with a mean half-life of about 36 hr. So, our results confirmed and extended the findings obtained by others with the same alkyl lysophospholipid analogue in female NMRI mice (17).

Beside avoidance of exposure of humans to radioactivity, the development of a sensitive HPLC technique for determination of ether phospholipids like BM 41.440 offers some major advantages compared to methods utilizing radiolabeled material: (a) in vivo investigations in patients can easily and rapidly be performed in parallel to clinical phase I/II studies, thus providing information on the pharmacokinetics and on the bioavailability of this new class of cytostatics (18) and (b) the compliance of patients entering oral treatment trials can be followed by monitoring the BM 41.440 serum concentrations.

In conclusion, the present data demonstrate that (a) the thioether phospholipid analogue BM 41.440 is absorbed from the gastrointestinal tract after oral administration and (b) under long-term oral treatment high serum concentrations of BM 41.440 can be attained in rats.

ACKNOWLEDGMENT

We wish to thank J. Schneider for typing the manuscript.

[Received January 19, 1987]

Cytotoxic Activity of the Thioether Phospholipid Analogue BM 41.440 in Primary Human Tumor Cultures

Dieter B.J. Herrmann*,[a] and **Herbert A. Neumann**[b]

[a]Boehringer Mannheim GmbH, Department of Immunopharmacology and Cancer Research, Sandhofer Str. 116, 6800 Mannheim 31, Federal Republic of Germany and [b]Medizinische Universitätsklinik, Hugstetter Str. 55, 7800 Freiburg, Federal Republic of Germany

The inhibitory effect of the new thioether alkyl lysophospholipid analogue 1-hexadecylmercapto-2-methoxymethyl-*rac*-glycero-3-phosphocholine (BM 41.440, Ilmofosine) on colony formation of different spontaneous human tumors was studied in vitro using a methyl cellulose monolayer assay. The most sensitive tumors were lung (small cell, squamous cell and adenocarcinomas), gastrointestinal and ovarian cancers and hyernephromas. On the basis of the current definition of sensitivity by the National Cancer Institute, Bethesda, MD, i.e. more than 70% inhibition of colony formation at an arbitrary concentration of 10 μg/ml, 34 out of 64 malignancies tested were susceptible to BM 41.440.
Lipids 22, **955–957 (1987).**

Human tumor stem cell assays provide a means of performing drug sensitivity measurements on human tumor cells in primary cultures. Since 1977 when Hamburger and Salmon (1,2) introduced a two-layer soft agar system for cloning tumors taken directly from patients, a number of assays have been developed for a series of human solid cancers to use in selecting the most appropriate chemotherapy for patient's tumor (3–9). Besides the potential use of such colony-forming systems in defining patterns of drug sensitivity, which possibly offers a means of optimizing chemotherapy for individual patients (10), a second potential application of clonogenicity assays is in the area of screening for and developing of new anticancer drugs (11–13).

1-Hexadecylmercapto-2-methoxymethyl-*rac*-glycero-3-phosphocholine (BM 41.440, Ilmofosine) (Scheme 1) is one of the most potent cytotoxic alkyllysophospholipids (ALP) (14–16). ALP are analogues of the cell membrane component lysophosphatidylcholine and represent a new class of antitumor agents (17). In a variety of tumor models, these ether lipids have been shown to exert antitumor activity in vitro (15,16,18,19) and in vivo (15,20).

H_2C-O ... R

$HO-CH$

H_2C-OH

SCHEME 1. BM 41.440.

The direct antimalignant effect of ALP is related to a specific interference with the normal phospholipid turnover, preferentially of neoplastic cells (21,22).

This investigation was designed to evaluate the inhibition of human tumor colony formation induced by the thioether analogue BM 41.440, which has recently entered phase I/II trials in human cancer therapy (23).

EXPERIMENTAL

The thioether phospholipid BM 41.440 was supplied as a white, crystalline powder by *Boehringer Mannheim* GmbH (Mannheim, FRG) and stored at 4 C as a stock solution of 100 μg/ml plus 20% FCS.

The culture system used in this study has been extensively described elsewhere (9,24). In brief, single-cell suspensions of spontaneous human tumors to be tested were prepared by mechanical disaggregation. Cell clumps were removed by filtration through sterile nylon sieves down to pore sizes of 20 μm. After repeated washing in serum-free Iscove's modified Dulbecco's medium (IMDM), cells were plated in IMDM plus 30% fetal calf serum (FCS), supported by 0.9% (w/v) methyl cellulose

TABLE 1

Plating Efficiency and Response to BM 41.440 Treatment of Different Spontaneous Human Tumors

Tumor types	Colonies/10^5 cells ± S.D. (range)[a]	Number of sensitive tumors/number of tumors tested[b]
Malignant melanoma	81 ± 30 (41–144)	1/16
Lung		
Small cell	127 ± 51 (41–164)	3/4
Squamous cell	88 ± 11 (80–103)	4/5
Large cell	69 ± 14 (50–83)	1/3
Adenocarcinoma	87 ± 22 (47–108)	4/6
Stomach	90 ± 8 (77–101)	4/5
Colon	76 ± 27 (42–109)	3/5
Ovary	91 ± 36 (50–163)	3/4
Myosarcoma	79 ± 17 (59–101)	3/3
Liposarcoma	65 ± 20 (44–88)	0/3
Hypernephroma	111 ± 16 (84–130)	2/2
Pleuramesothelioma	62 ± 9 (50–72)	2/1
Breast	70 ± 23 (44–90)	1/2
Gall bladder		1/1
Histiocytoma		1/1
Cervix uteri		1/1
Corpus uteri		1/1
		34/64

[a]Viable cells (1 × 10^5) were plated (37 C, 7.5% CO_2) in petri dishes in IMDM plus 30% FCS and 0.9% (w/v) methyl cellulose with or without various doses of BM 41.440. After 8–10 days of continuous incubation with the drug, tumor colonies were counted under an inverted microscope. Mean ± S.D., standard deviation.

[b]NCI sensitivity criteria: ≥70% inhibition of tumor colony formation at an arbitrary screening concentration of 10 μg BM 41.440/ml.

[1]Presented at the symposium on "Ether Lipids in Oncology," Göttingen, Federal Republic of Germany, December 1986.

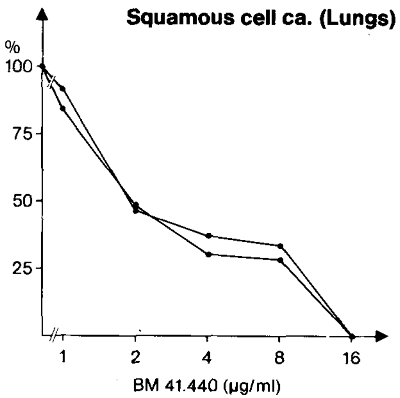
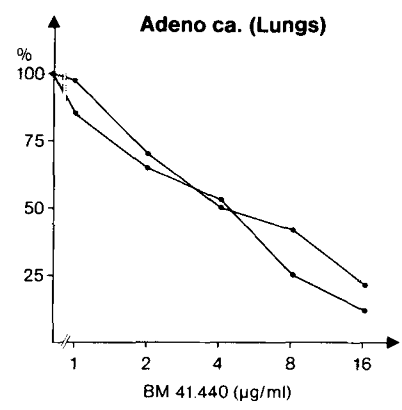
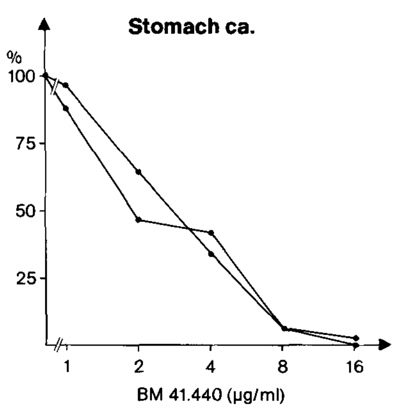
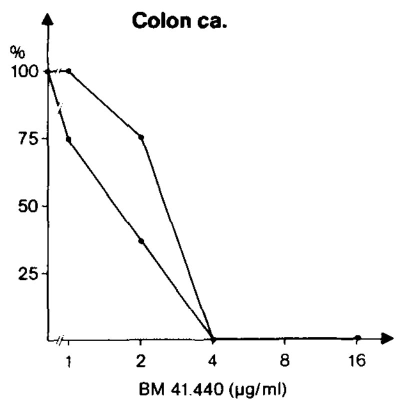
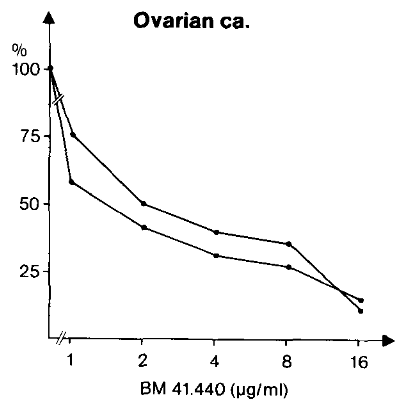
Abbreviations: ALP, alkyl lysophospholipid; BM 41.440, 1-hexadecylmercapto-2-methoxymethyl-*rac*-glycero-3-phosphocholine; FCS, fetal calf serum; IMDM, Iscove's modified Dulbecco's medium.











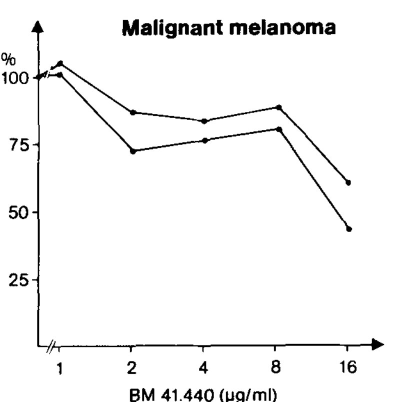


FIG. 1. Dose-response curves of different spontaneous human tumor colonies treated with BM 41.440. Untreated controls are set as 100%. Inhibition is expressed as percent survival of colonies as a function of BM 41.440 concentration. Two specimens of each tumor were tested in duplicates.

and incubated at 37 C, 7.5% CO_2 in a humidified atmosphere with no additional feeding. To assure the presence of an excellent single-cell suspension, positive controls and quality controls, for instance were used as day 1 colony counts and microscopic inspection of control plates were performed immediately after plating. Quality controls have been shown to greatly increase the reproducibility of human colony-forming assays (10). Colonies (>30 cells) usually appeared by days 8–10, and the number of colonies on the plates was determined using an inverted light microscope.

Two specimens of each tumor type were tested in duplicate. Viability of cells was checked by trypan blue exclusion (25). Drug sensitivity of a tumor was defined according to the sensitivity criteria of the National Cancer Institute (Bethesda, MD), i.e. at least 70% inhibition of colony formation at an arbitrary BM 41.440 concentration of 10 μg/ml (10).

RESULTS AND DISCUSSION

The 64 different tumor types evaluated in this study showed a wide range of culturability. Tumor types, plating efficiency and responses to BM 41.440 treatment of the neoplasms tested are listed in Table 1. Approximately 30% of the experiments were judged as unevaluable, mainly due to a lack of adequate growth or to a wide variability of colony counts in control cultures.

The plating efficiency ranged from 0.04 to 0.17%. The data are in accordance with previous findings from our group (9,13,24) and with results reported by others using modifications of the original Hamburger-Salmon technique (3–8,26).

Incubations with BM 41.440 were performed continuously in order to maximize assay sensitivity (27). The in vitro doses of the drug, 0–16 μg/ml, were scheduled empirically according to the concentrations that have been shown to be effective in tumor growth inhibition on different cell lines of murine and human origin (14–17,20).

The tumor colonies showed individual dose-response curves. Some examples are given in Figure 1. The most susceptible malignancies proved to be small cell, squamous cell and adenocarcinomas of the lung, gastrointestinal tumors, ovarian cancers, myosarcomas and hypernephromas with numbers of sensitive tumors (≥70% inhibition of colony formation at an arbitrary BM 41.440 concentration of 10 μg/ml) to numbers of tumors tested of 3/4, 4/5, 4/6, 3/5, 3/3 and 2/2, respectively. Only one out of 16 malignant melanomas and none out of three liposarcomas tested fulfilled the above mentioned sensitivity criteria.

The feasibility and validity of human tumor colony-forming assays for preclinical drug screening and for identifying of, at least, resistance of a tumor to chemotherapy have been shown by several groups (28–33).

Retrospective and prospective clinical trials have revealed true positive rates for colony-forming systems between 47 and 82%, while true negative rates have ranged from 84 to 98% (28–33). Therefore, the present results and the data from the ongoing study on inhibition of tumor colony formation induced by the thioether phospholipid BM 41.440 may provide helpful information for the assessment of indications for BM 41.440 clinical phase II evaluations in the near future.

In Vitro and In Vivo Cytotoxicity of Alkyl Lysophospholipid ET-18-OCH_3 and Thioether Lipid BM 41.440[1]

G.H. Leder*, H.H. Fiebig, E. Wallbrecher, B.R. Winterhalter and G.W. Löhr
Department of Internal Medicine, Division of Hematology and Oncology, University of Freiburg, Freiburg i. Br., D-7800, Federal Republic of Germany

Screening for cytotoxicity in the clonogenic assay in human tumor xenografts and L1210 mouse leukemia revealed comparable dose-dependent effects of the alkyl lysophospholipid ET-18-OCH_3 and the thioether lipid BM 41.440. The efficacy in human tumors only was marginal at low doses. In vivo tests of both agents were carried out in nude mice bearing two of the tumors that proved most sensitive in vitro and in mice inoculated with L1210 leukemia. Only small effects on the growth of the human tumors and no effects on L1210 leukemia were observed. In view of clinical rules for definition of remission, no convincing antitumor effects were obtained.
***Lipids 22,* 958-961 (1987).**

Alkyl lysophospholipids and analogues have gained increasing interest as a new class of potential anticancer agents. Data on activity in various cell lines (1-3), isolated leukemic (2,4) or tumor cells (5,6), and in tumor-bearing animals (1,7), as well as no or minor effects in vitro (3) and in vivo (6,8) have been reported. Furthermore, there are hints that some tumors are susceptible (9,10) and others resistant (9,10) to the same drug under identical conditions. This might indicate that tumor-specific properties cannot be excluded. To gain further insight, additional experimental evidence is required.

Therefore, we tested the alkyl lysophospholipid ET-18-OCH_3 (1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine) and thioether lipid BM 41.440 (1-hexadecylmercapto-2-methoxymethyl-*rac*-glycero-3-phosphocholine) in a variety of human tumors in the clonogenic assay recommended as the in vitro method for anticancer drug screening (11). The responses of two of the most sensitive tumors in vitro to the tested agents subsequently were studied in nude mice. The combination of both methods especially seems to be promising. It provides the advantage of testing a substance in human material from the beginning under in vitro conditions and allows selection of only the most sensitive tumors for in vivo studies (12). In addition, L1210 mouse leukemia cells were used for experiments in vitro and in vivo since 24 out of 26 clinically used drugs proved active in this model (13) and since immunocompetent mice could be used for therapy trials.

EXPERIMENTAL

Human tumors established in serial passage in NMRI nude mice in our laboratory were used (14-16). L1210 leukemia was obtained from G. Atassi, Brussels, subpassaged and maintained as recommended by the National Cancer Institute (17). Tumors were mechanically disintegrated with scissors and by shear force (Stomacher 80, Colworth, London, UK); they were incubated with enzymes (collagenase 0.04%, DNAse 0.07% and hyaluronidase 0.1%) at 37 C for 30-40 min. Cells were washed and passed through stainless steel sieves of 200- and 50-μm mesh size to obtain single cell suspensions. Cell counts were performed in a hemocytometer, and the percentage of viable cells was determined by trypan blue exclusion. The culture method is a modification of the double-layer soft agar system introduced by Salmon et al. (18) as described recently (12). One ml 0.3% agar (with 30% fetal calf serum and Iscove's modified Dulbecco's medium with L-glutamine) containing 0.8-4.5 $\times$ 10^5 cells/ml (depending on the individual growth rate of each tumor) was pipetted onto 1 ml of 0.5% agar bottom layer (with 10% fetal calf serum) in 35 $\times$ 10 mm culture dishes. Tests were carried out in triplicate.

Drugs were administered in 1 ml medium containing 30% fetal calf serum. Controls received the vehicle only. Additional growth factors were required for the L1210 leukemia (5 $\times$ 10^{-5} mol/l medium 2-mercaptoethanol). Control plates were monitored for growth using an inverted microscope every other day. Final colony counts were obtained with an automatic image analyzer (Omnicon FAS III, Bausch & Lomb, Rochester, New York), at the time of optimal colony formation (5-18 days in culture). In our experience, the optimal time for counting the colonies depended on the individual growth of the tumors, but it was before the medium turned yellow. Colonies had to be ⩾60 μm in diameter and distinct enough so they could be detected separately by the camera. To increase detection, all dishes were incubated with 0.5 ml tetrazoliumchloride (1 mg/ml) 24 hr before the final count. This stains only viable cells and colonies (19). Quality control was achieved by staining plates with tetrazoliumchloride on days 0 and 2 and subsequent freezing at −20 C until the final count was taken after adding 1 ml glycerine.

The criteria for identifying evaluable assays (20) were a slight modification of Shoemaker's approach (11,21). The coefficient of variation in the control group was ⩽50%. A compound was considered active if it reduced colony formation to ⩽30% of the control value. The frozen plates must not exceed ⩾20% counts of the controls. For in vivo testing, two of the most sensitive in vitro tumors were selected, and two tumor slices (size: 5 $\times$ 5 $\times$ 0.5-1 mm) were subcutaneously implanted into the flanks of each of the 4-6 nude mice per group (14,16,22,23). Treatment began when the tumors exhibited an average diameter of 7-8 mm, and the estimated depth was at least half of the smaller diameter. This was reached by the lung cancer on day 24 and by the melanoma on day 31 after transplantation. Animals with yellow tumors reflecting a high amount of fibrous tissue were excluded (24).

Substances were injected intraperitoneally in dosages of 10 and 30 mg/kg body weight (bw) 5-10 times within 12 days. Tumor growth, which was the product of two perpendicular diameters, was recorded every week.

Abbreviations: ALP, ET-18-OCH_3, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine; BM 41.440, 1-hexadecylmercapto-2-methoxy-methyl-*rac*-glycero-3-phosphocholine.

Relative tumor size was calculated for each single tumor by dividing its size on day X by its size on day 0 at the time of randomization multiplied by 100. Final evaluation was performed after four weeks. Statistical computation was done by comparing groups with the Mann-Whitney test (25) at the end of the in vivo experiments. This minimized α-inflation. The significance test was done according to Holm (26) at the 5% level.

In vivo experiments with L1210 leukemia were carried out with six CD2F1 mice per drug and dosage and with eight control animals. Cells (10^5) were intraperitoneally (ip) injected and the animals treated with 3, 10 and 30 mg/kg bw ALP or 3 and 30 mg/kg bw BM ip one day later until death. ALP was provided by Andreesen, Medical Department, University of Freiburg, Germany; BM was obtained from Pahlke, Boehringer Mannheim GmbH, Mannheim, Germany.

RESULTS AND DISCUSSION

Table 1 shows the screening results of the clonogenic assay of 22 human tumors. ALP and BM displayed some dose-dependent effects. Efficacy was achieved especially in the lung cancers, whereas the gastrointestinal tumors proved to be more resistant to conforming to their behavior in man. Furthermore, a response of melanomas was demonstrated at low concentrations of ALP and BM. On the whole, growth was suppressed in five of 22 tumors at a concentration of 10 μg/ml. Therefore, this concentration better is suited to select the most responsive tumors with success rates of 61% at 30 μg/ml or 100% at 100 μg/ml. Consequently, the adenocarcinoma of the lung LXFA 526 and the melanoma MEXF 274 were selected for therapy in nude mice.

TABLE 1

Effectiveness of ALP and BM on Human Tumor Xenografts in the Clonogenic Assay

		Concentration (μg/ml)				
Tumor type	Compound	1.0	3.0	10.0	30.0	100.0
Large intestine	ALP		0/1	0/2	0/2	1/1
	BM		0/1	0/2	0/2	1/1
Gastric	ALP		0/1	0/3	1/3	2/2
	BM		0/1	0/3	0/3	2/2
Lung, "small" cell	ALP			1/1	1/1	1/1
	BM			1/1	1/1	1/1
"Large" cell	ALP	0/3	1/4	1/7	2/5	4/4
	BM	0/3	0/4	1/7	3/5	4/4
Melanoma	ALP	0/1	0/2	1/2	1/1	
	BM	0/1	0/2	2/2	1/1	
Sarcoma	ALP			0/2	2/2	2/2
	BM			0/2	2/2	2/2
Mammary	ALP	0/1	0/1	0/1		
	BM	0/1	0/1	0/1		
Thyroid	ALP		0/1	1/1	1/1	
	BM		0/1	1/1	1/1	
Mesothelioma	ALP			1/1	1/1	1/1
	BM			0/1	1/1	1/1
Renal	ALP			0/1	1/1	1/1
	BM			0/1	1/1	1/1
Testicular	ALP			0/1	1/1	1/1
	BM			0/1	1/1	1/1
Human tumors	ALP	0/5	1/10	5/22	11/18	13/13
Total	BM	0/5	0/10	5/22	11/18	13/13
Percent	ALP	0%	10%	23%	61%	100%
	BM	0%	0%	23%	61%	100%

Efficacy: colony number in test ≤30% of control group.

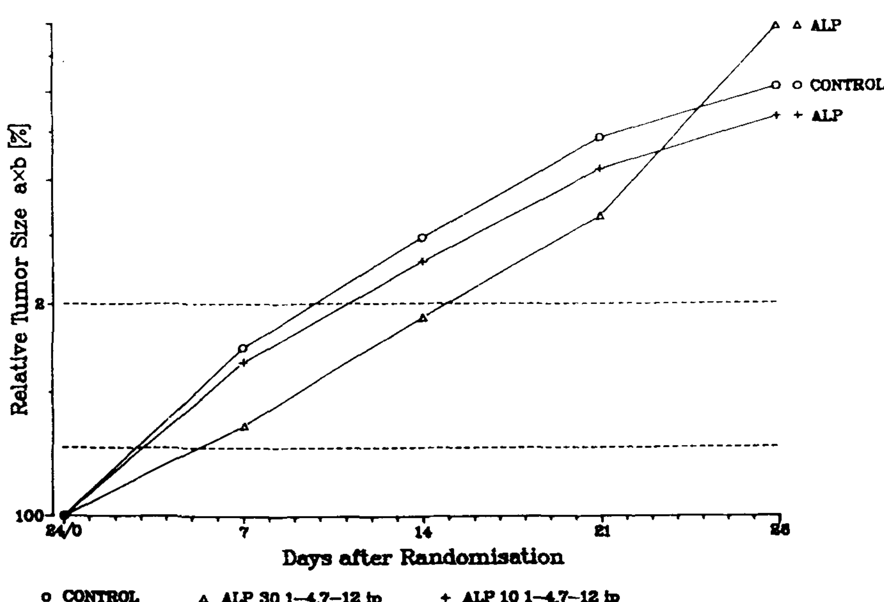

FIG. 1. Relative tumor size during chemotherapy with two doses of ALP (10 or 30 mg/kg bw given days 1-4 and 7-12 ip), number of animals at the beginning/end: control 6/6; 10 mg/kg ALP 5/4; 30 mg/kg ALP 6/4, Holm test at the end of experiment: ns.

Likewise, tests were carried out in mice inoculated with L1210 because this cell line responded to both compounds at 10 μg/ml in our assay. In vivo efficacy of ALP in the lung LXFA 526 is shown in Figure 1. Tumor growth was reduced by ALP at dosages of 10 and 30 mg/kg bw. While this effect was small at the lower dose, it was more apparent at 30 mg/kg bw. However, tumor growth was enhanced as compared with the controls 9–16 days after the last injection. BM was not effective in the same lung carcinoma.

In contrast to the lung cancer, the growth of the melanoma (Fig. 2) was reduced by the therapy with ALP or BM during the first week of treatment; this retardation was not compensated until the end of the experiment. Tests according to Holm revealed growth retardation significance for 30 mg/kg ALP only. Similar, yet more favorable, results are reported for gynecologic tumors (9). Experiments with an anaplastic ovarian carcinoma intravenously or orally treated with ALP especially are comparable. An almost complete growth inhibition was achieved by 500 μg ALP IV twice daily for three weeks. The same dose given orally or only half of it given by IV resulted in a slower proliferation compared with controls. Some differences between these and our experiments should not be overlooked. Two of the 10 mice in each IV-injected group experienced a complete remission (9). However, these beneficial effects were not obtained for two other gynecologic tumors treated identically (9). Certainly, there are differences between the above-mentioned and our procedure concerning the application schedules and the onset of therapy. Compared to others, we administered drugs for a short time, imitating common clinical strategy since the promising approach of long-term application yielded inconsistent results (8,10). The time until the initiation of therapy may be essential for its outcome because our method avoids the phase of ischemic regression after the tumor transplantation (24).

In view of the different results with the various tumors, it seems most likely that tumor-specific properties are extremely significant for success or failure of therapy trials. This assumption is in accord with Berger and Schmähl (27), who like others (8) could not observe any effects of ALP or BM in acetoxymethyl methylnitrosamine-induced rat colonic adenocarcinomas, whereas BM displayed activity superior to ALP in methylnitrosourea-induced rat mammary carcinoma.

With regard to the known effects of clinically introduced cytostatic agents in the L1210 in vivo (13), our results with ALP and BM may be of some interest (Table 2).

Both substances did not increase the survival time of the inoculated animals. This was surprising for us because, first, since like others (28) we found the ip cell and drug application to be very sensitive to drugs and superior to ip cell and IV drug injection (29). Second, both compounds possessed cytotoxic activity in vitro. Third, application into the same compartment appeared ideal for direct cytotoxic mechanisms. Furthermore, ip application of ALP increases the amount of peritoneal macrophages, which seem to mediate ALP activity (31). It appears that L1210 is not very susceptible to alkyl lysophospholipids, which is consistent with observations made in other laboratories (30; Munder and Vogler, personal communication).

In conclusion, ALP and BM exhibited only limited antitumor activity in vivo in two of in vitro's most sensitive malignancies. If one attempts to imitate "clinical conditions," i.e., if one uses human material, high tumor burden, tumors adapted to their hosts and discontinuous treatment, no convincing antitumor effects are observed. Especially, remissions are not achieved. However, a comparison with the literature suggests that some tumors may be more sensitive to ALP and BM. Although the final significance of all currently reported data is difficult to judge, it is encouraged to design further studies that concentrate on the questions of tumor specificity and optimized applications.

Chemotherapy of MEXF 274

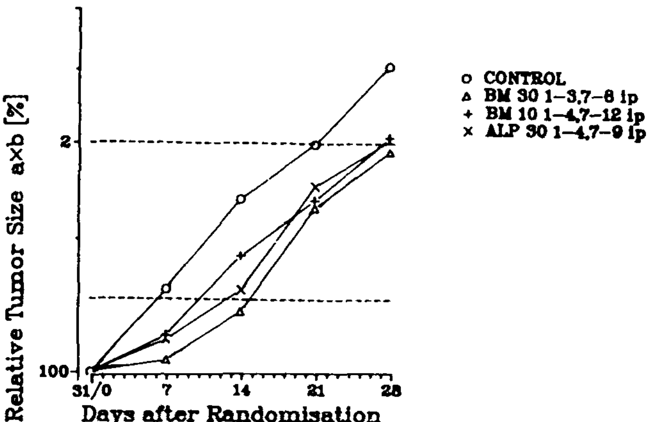

FIG. 2. Relative tumor size during chemotherapy with one dose ALP and two doses BM (30 mg/kg ALP given days 1–4 and 7–9; 10 mg/kg BM days 1–4, 7–12; 30 mg/kg BM 1–3, 7–8) ip, number of animals at the beginning/end: control 4/4, 30 mg/kg ALP 5/4; 10 mg/kg BM 5/5; 30 mg/kg BM 5/3), Holm test at the end of experiment: $P_{ALP} = 0.014$, $\alpha^* = 0.017$; for BM ns.

TABLE 2

Effectiveness of ALP and BM on the L1210 Mouse Leukemia

	Dosage (mg/kg/day)	Lifespan median (days)	Lifespan range (days	Cures/total
ALP	30	7	6–9	0/6
	10	7.5	2–9	0/6
	3	8	8	0/6
BM	30	8.5	7–9	0/6
	3	8	7–8	0/6
Controls		8	7–9	0/8

10^5 cells ip into CD2F1 ♀ and ♂ mice. Therapy: day 1–9, ip, dissolved in 0.9% NaCl.

ACKNOWLEDGMENTS

This study was supported by Grant PTB 8712 from the Bundesminister für Forschung und Technologie. We wish to thank C. Berg, W. Bieser, K. Braun, U. Dentler, E. Hackenberg, K. Meinhardt and J. Schmid for their excellent contributions to this project. We also thank C. Shulz for his critical review of the manuscript.

[Received January 31, 1987]

Phase I Trial of the Thioether Phospholipid Analogue BM 41.440 in Cancer Patients[1]

Dieter B.J. Herrmann*,[a], Herbert A. Neumann[b], Wolfgang E. Berdel[c], Manfred E. Heim[d], Michael Fromm[c], Dietmar Boerner[a] and Uwe Bicker[a]
[a]Boehringer Mannheim GmbH, Department of Clinical Research, Sandhofer Str. 116, 6800 Mannheim 31, Federal Republic of Germany, [b]Medizinische Universitätsklinik, Hugstetter Str. 55, 7800 Freiburg, Federal Republic of Germany, [c]I. Medizinische Klinik rechts der Isar, Technische Universität, Ismaninger Str. 22, 8000 München, Federal Republic of Germany, and [d]I. Medizinische Klinik, Theodor-Kutzer-Ufer, 6800 Mannheim 1, Federal Republic of Germany

BM 41.440 (1-hexadecylmercapto-2-methoxymethyl-*rac*-glycero-3-phosphocholine) is a new thioether phospholipid, which has been shown to possess antineoplastic, antimetastatic, anti-invasive and immunomodulating properties in several tumor models. The mechanism whereby this compound exerts its direct antineoplastic effect is thought to be related to specific interference with the normal phospholipid metabolism, preferentially of neoplastic cells. BM 41.440 was evaluated in a multicenter phase I study in patients (pts) with refractory cancers. In phase I A, 34 pts were orally treated with doses ranging from 0.5 to 7.0 mg/kg body weight (bw). Three different formulations were tested. The maximum-tolerated dose (MTD) was ca. 5 mg/kg bw. The limiting side effects were nausea and vomiting. There was no evidence for systemic toxicities like myelosuppression, nephro-, neuro-, hepatotoxicity or hematological side effects. The current phase I B is designed to determine the MTD of BM 41.440 administered orally on a daily schedule for at least eight weeks. So far, 19 pts have entered this trial at dose levels ranging from 1.0 to 5.0 mg/kg bw/day. Some pts receiving 1.0 and 2.5 mg/kg bw/day, respectively, have been treated, up to now, for more than nine months. Clinical progress was followed with at-least-weekly blood counts, chemistry profiles, urine analysis, liver function tests and recordings of side effects. Tumor parameters were evaluated at eight-week intervals. In parallel, pharmacokinetic investigations were performed in some pts in phase I A and IB. First results on tolerability and therapeutic efficacy of the long-term BM 41.440 treatment are reported in this intermediate evaluation.
Lipids 22, 962–966 (1987).

BM 41.440 or 1-hexadecylmercapto-2-methoxymethyl-*rac*-glycero-3-phosphocholine (prop. INN: Ilmofosine) is a synthetic 1-S-thioether alkyllysophospholipid derivative (1) (Fig. 1). Alkyl lysophospholipids (ALP) are structurally related to lysophosphatidylcholine, which is a minor constituent of most cellular membranes (2,3) and plays an important role as a metabolic intermediate in the continuous turnover of the fatty acid moiety of phosphatidylcholine via the deacylation/reacylation cycle (Lands pathway) (4,5). ALP represent a new class of cytostatic drugs (6). The antitumor activity has been studied in different tumor models in vitro (7–9) and in vivo (6,10). The mechanism of direct tumor cell destruction by BM 41.440 and other ALP is related to a selective interference of these compounds with the cellular phospholipid metabolism of tumor target cells (9,11–13).

FIG. 1. Chemical structure of BM 41.440.

BM 41.440 was selected for clinical trials because preclinical screens demonstrated differential activity on malignant cell types of murine and human origin (1,14,15). Moreover, notable antitumor effects within in vivo tumor systems were observed, including the methylcholanthrene-induced fibrosarcoma (MethA), L1210 leukemia, Lewis lung carcinoma (1,14) and the methylnitrosourea (MNU)-induced mammary carcinoma (16). BM 41.440 caused significant reduction in tumor size and significant increases in the life span of mice bearing these tumors. Antitumor activity in the MNU-induced mammary carcinoma was dose-dependent. Recent data also indicate that BM 41.440 has antineoplastic activity against different spontaneous human tumor cells in a methyl cellulose colony-forming system (17,18).

Animal toxicology studies conducted in rats and dogs showed the rats to be the more sensitive species (14). The side effects of oral BM 41.440 were non-hematological and included vomiting and diarrhea.

Here, we report the interim results of the first clinical phase I study of BM 41.440 in adult patients with refractory cancers. We also include a preliminary examination of drug pharmacokinetics.

EXPERIMENTAL

Drug formulation. BM 41.440 was synthesized by Boehringer Mannheim GmbH, 6800 Mannheim, Federal Republic of Germany. In this study, three different formulations were tested: a soft gelatine capsule, a film tablet and a coated, gastric juice–resistant film tablet. The drug was supplied in 25, 50 and 100 mg quantities. Quality controls for all formulations were performed before submission for application in patients according to international standards.

Patient selection. The present clinical phase I trial of BM 41.440 was divided into two parts: part I A and I B. Patient characteristics are shown in Table 1 and Table 2. Up to now, a total of 53 patients with histologically

documented, advanced malignancies refractory to known forms of effective therapy were entered into this trial. Thirty-four patients were entered into phase I A and 19 patients into phase I B. Other eligibility criteria included patients ranging from 18–70 years old, an ambulantory performance score of ≥50% (Karnofsky), no anticancer therapy for at least four weeks before entering the study, life expectancy of at least three months, and adequate organ function as defined by bone marrow (white blood cell count ≥4000/mm³, platelet count ≥100,000/mm³), liver (bilirubin ≤1.5 mg/dl, normal SGOT, SGPT, γGT and AP values) and kidneys (creatinine ≤1.5 mg/dl). Informed consent was obtained from all patients before therapy began.

Ineligibility criteria were malabsorption and/or maldigestion, pregnancy, psychotic disorders, metastases in the brain or brain tumors, major organ disfunctions, e.g. cardiac insuffficiency, and active systemic infections.

Study design. The study protocol was reviewed and approved by the ethical boards of the universities of Freiburg, Munich and Mannheim. The study was performed following German regulations. The primary objectives in phase I A were (a) determination of the maximum-tolerated dose (MTD) of a single or multiple oral administration of BM 41.440 for one day, (b) characterization of possible toxic effects and (c) definition of the dose-limiting toxicities according to the World Health Organization grading (19). A minimum of two patients evaluable for toxicity were treated sequentially at each dose level, starting with a low dose. The dose levels in phase I A were 0.5, 0.75, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0 and 7.0 mg/kg body weight (bw). After the second patient was treated with a given dose and evaluated for toxicity, patients were entered at the next higher dose level. The dose was escalated until a dose-limiting toxicity was observed.

The objectives of the phase I B were (a) determination of maximum-tolerated dose and of possible side effects of a continuous daily oral administration over at least eight weeks and (b) determination of the responses to BM 41.440 treatment according to the WHO criteria for "Reporting Results of Cancer Treatment" (19). In this part of the study, a minimum of four patients were treated at each dose level. The starting dose was 1.0 mg/kg bw/day. Dose escalations proceeded from 1.0 to 2.5 to 5.0 mg/kg bw/day. If after four weeks unacceptable toxicity did not occur at a specific dose level, the next dose level was started. There was no escalation of dose for any individual patient.

Patient monitoring. Prior to therapy, all patients underwent a complete history and physical examination. Patients who were entered into the long-term treatment of phase I B were comprehensively evaluated on measurable diseases by the appropriate modality, including a physical examination, x ray, scans and other studies as necessary for documentation of the extent of the diseases. Pretreatment evaluation included complete blood count with white blood cell (WBC) count differential, hemogram, full chemistry profile, creatinine, calcium, uric acid, blood sugar, liver function tests, lactate dehydrogenase, cholesterol, protein, prothrombin, thrombin time and urine analysis. In phase I A, patients were carefully monitored on day 1, 2 and 7 for toxicity by repeated physical examinations, complete blood counts with WBC differential, chemistry profiles and all other parameters listed above. During the time of treatment in phase I B, patients were followed closely for signs of toxicity and for all study parameters at a minimum of weekly intervals up to eight weeks. At that time, an evaluation of tumor size was done by physical examination, appropriate radiological studies and scans, and by tumor markers. WHO standard tumor response criteria were used to evaluate the antitumor effect of the drug (19). These criteria included (a) complete response (disappearance of all known disease, determined

TABLE 3

Tolerability of BM 41.440 (Phase I A)

Dose (mg/kg × day)	No. of patients with side effects/ no. of patients treated	Nausea (WHO grade)[a]			Diarrhea (WHO grade)[b]
		1	2	3	1
0.5	0/2	0	0	0	0
0.75	0/2	0	0	0	0
1.0	0/2	0	0	0	0

7.0 (Tablet)	3/3	1	1	1	2
7.0 (Fc. tablet)[c]	4/4	2	1	0	4

Patients were treated orally with single or multiple (up to four times) doses of BM 41.440 for one day. Three different formulations were tested: soft gelatine capsule, film tablet and coated film tablet. The no. of patients with side effects to no. of patients treated and the side effects are separately listed for each formulation administered for the particular dose levels 3.0 and 7.0 mg/kg bw, respectively, on the two lines under the appropriate dosage.

[a]WHO grade 1, nausea only; grade 2, transient vomiting; grade 3, vomiting requiring therapy.

[b]WHO grade 1, transient (≤2 days); grade 2, tolerable but >2 days.

[c]Formulations: Sg. capsule, soft gelatine capsule; Fc. tablet, film-coated tablet resistant to gastric juice.

by two observations not less than four weeks apart); (b) partial response (50% or more decrease in total tumor size of the lesions, which have been measured to determine the effect of therapy by two observations not less than four weeks apart), (c) no change (a 50% decrease in total tumor size cannot be established nor has a 25% increase in the size of one or more measurable lesions been demonstrated) and (d) progressive disease (25% or more increase in the size of one or more measurable lesions, or the appearance of new lesions).

If patients showed tumor response or showed no changes after eight weeks of treatment with BM 41.440, the therapy was continued as long as no progression occurred. In these cases, patients were monitored with study parameters every second week up to 12 weeks of treatment and at a minimum of four-week intervals thereafter. Assessments of the disease's extent to determine antitumor activity of the drug were performed at eight-week intervals. Individual patients were removed from the study if they experienced unacceptable toxicity or if objective disease progression occurred.

Pharmacokinetics. Sixteen out of 34 patients in phase I A were studied following the single oral BM 41.440 administration. Blood samples were obtained immediately before starting with the drug application and then 0.5, 1, 2, 4, 6, 8, 12, 24 and 32 hr as well as seven days after p.o. doses. Blood samples were centrifuged, and the plasma was decanted and stored frozen at −20 C until analysis. BM 41.440 was measured by a newly developed high-pressure liquid chromatography method, using a structurally closely related analogue of BM 41.440 as an internal standard. Details on the analytical technique for detection of BM 41.440 are published in this issue (20).

RESULTS

Tolerability. Fifty-three patients were entered on this phase I study; 34 patients were treated on the one-day schedule in phase I A. The patients' characteristics are shown in Table 1. Of the 34 patients entered on phase I A, all were evaluable for toxicity. Drug-related effects were nonhematological. The number of patients treated at each dose level and the toxicities are summarized in Table 3. Gastrointestinal irritations were seen in 17 out of the 34 patients entered on this part of the trial. The dose-limiting toxicities were nausea and vomiting, WHO grades 1–3, and diarrhea, WHO grade 1.

Two out of four patients treated with the soft gelatine capsule at a dose level of 3.0 mg/kg bw showed gastrointestinal side effects (Table 3). However, neither of the two patients treated with the coated film tablet experienced similar toxicity at the same dose level. Therefore, dose escalations from 3.0 to 7.0 mg/kg bw were continued with the coated film tablet formulation. At the dose level of 7.0 mg/kg bw, three out of three patients showed gastrointestinal intolerabilities. Therefore, the same dose was administered to four other patients using a coated film tablet that is resistant to gastric juice.

TABLE 4

Tolerability of BM 41.440 (Phase I B)

Dose (mg/kg × day)	No. of patients with side effects/ no. of patients treated	Nausea (WHO grade)[a]			Diarrhea (WHO grade)[b]	
		1	2	3	1	2
1.0	1/4	1	0	0	0	0
2.5	5/6	3	1	0	1	1
5.0	5/7	1	2	2	4	0

Patients were daily treated p.o. with single or multiple (up to three times) doses of BM 41.440 for at least eight weeks (film tablet).

[a,b]For WHO-grading, see legend to Table 3.

However, these four patients all also experienced dose-limiting toxicities, indicating that changing the formulation did not benefit the patients.

Up to now, 19 patients were in the current long-term treatment study of phase I B. The patients' characteristics are shown in Table 2. Fifteen of these patients were pretreated by different therapy modalities; four patients had not received any cancer treatment prior to BM 41.440 therapy. Seventeen out of the 19 patients entered on this part of the study were evaluable for toxicity. The two inevaluable patients had just entered the study when the compilation of this intermediate report was performed.

As seen in phase I A, dose-limiting toxicity consisted of gastrointestinal irritations. Eleven out of 17 patients developed nausea and vomiting, WHO grades 1-3, and diarrhea, WHO grades 1-2 (Table 4).

No other toxicities were observed, neither in phase I A nor in phase I B. Although some patients were treated on a daily oral schedule with BM 41.440 for more than 36 weeks, up to now there was no evidence for myelosuppression, hepatic or renal toxicities, allergic reactions, hypotension or hematological side effects.

The maximum-tolerated dose of BM 41.440 administered as a single or multiple oral dose for one day in adult patients was around 5 mg/kg bw (Phase I A). For a long-term treatment with BM 41.440 on a daily oral schedule, doses up to 5.0 mg/kg bw/day can be recommended for treatment of more than nine months with the film tablet.

Clinical responses. The current clinical phase I B trial of oral BM 41.440 in 12 patients with refractory cancers who were evaluable for antitumor activity revealed three partial responses. In one patient with a metastatic adenocarcinoma of unknown primary localization, two liver metastases (2 cm × 2 cm, 3 cm × 3 cm) completely disappeared after eight and 15 weeks of treatment, respectively. In another patient with a metastatic malignant melanoma, a more than 50% reduction of two liver metastases (9 cm × 9 cm, 5 cm × 5 cm) occurred within eight weeks of treatment with BM 41.440. However, in both of these patients, the disease progressed after 26 and 10 weeks, respectively. In a third patient with a malignant melanoma, one liver metastasis (3 cm × 3 cm) disappeared within eight weeks of therapy. Another lung metastasis remained constant for, up to now, 36 weeks. These three patients have been treated with 1.0 mg BM 41.440/kg bw/day.

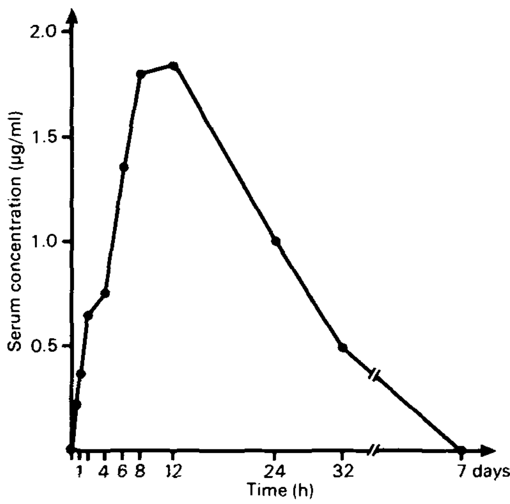

FIG. 2. Time course of plasma BM 41.440 (1-hexadecylmercapto-2-methoxymethyl-*rac*-glycero-3-phosphocholine) concentrations after a single oral administration to a patient with an adenocarcinoma of the lung. Dose: 4 mg/kg bw (275 mg).

Furthermore, out of 12 patients evaluable for response, six patients had no observable changes with durations, up to now, of seven to 24 weeks (three adenocarcinomas of the lung, two malignant melanomas, one metastatic parotid gland carcinoma). Progressive disease was seen in three other patients. Four patients dropped out of the study, three of them due to side effects.

Pharmacokinetics. Figure 2 illustrates a BM 41.440 plasma concentration vs time profile for a patient with an adenocarcinoma of the lung, treated with 4 mg/kg bw (275 mg) BM 41.440 p.o. (film tablet). Mean peak plasma concentrations of 1.8 µg/ml were attained within 8-12 hr after BM 41.440 administration. In phase I B, pharmacokinetic parameters were studied in all patients who had been entered into the trial. The summary of the results of the pharmacokinetic investigations will be given in the final report.

DISCUSSION

BM 41.440 is an interesting compound because of its completely different mechanism of tumor cell destruction as compared to all known cytostatic drugs (9,11-13,15). Its antineoplastic, antimetastatic and anticarcinogenic activity has been investigated in different in vitro and in vivo tumor models (14-16,18,20-22). In this current multi-institutional phase I trial, BM 41.440 was administered orally on a one-day and daily schedule of at least eight weeks, respectively. The dose-limiting toxicities in both parts of the study were nausea, vomiting and diarrhea. Hematological or other non-hematological side effects related to BM 41.440 treatment were essentially absent until now. In phase I A (one-day administration), drug formulation was changed at a dose level of 3.0 mg/kg bw. Since the soft gelatine capsule seemed to be less tolerable, further dose escalations were continued using a BM 41.440 film tablet up to 7.0 mg/kg bw. Changing drug formulation to a coated film tablet, which is resistant to gastric juice, at a dose level of 7.0 mg/kg bw did not enhance tolerability.

Similar results in side effects were obtained from our preliminary experience on the long-term treatment schedule (phase I B). Doses up to 5.0 mg/kg given daily for at least nine months seem to be quite safe. In this part of the study, the toxicities observed, e.g. nausea, vomiting and diarrhea, appear to be dose-related (Table 4).

The preliminary pharmacokinetic data in this phase I study revealed gastrointestinal absorption of BM 41.440 after single oral administration. Further explorations that are aimed at clarification of the metabolism and the major routes of elimination of BM 41.440 in humans are underway.

Although three clinical responses and six no changes were observed in the long-term treatment part of this trial, the limited number of patients entered, tumor types studied, and extent and heterogeneity of prior therapy preclude conclusions about the antitumor efficacy of this drug. However, these intermediate results encourage us to introduce BM 41.440 into clinical phase II studies.

ACKNOWLEDGMENTS

We wish to thank A. Voigt for her secretarial assistance in preparing the manuscript. We are also grateful to M. Harig and T. Bayer for aid in figure preparation.

[Received January 19, 1987]

Clinical Phase I Pilot Study of the Alkyl Lysophospholipid Derivative ET-18-OCH_3[1]

Wolfgang E. Berdel*, **Ulrich Fink** and **Johann Rastetter**
Division of Hematology and Oncology, Department of Medicine I, Technische Universitaet, Ismaninger Str. 22, 8000 Munich 80, Federal Republic of Germany

Sixteen patients suffering from widespread malignant disease, the majority pretreated and found in poor general health, were treated in a phase I pilot study with the alkyl lysophospholipid derivative 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH_3). Eleven patients were treated intravenously, and five were given oral therapy. Prolonged IV administration of 15-20 mg/kg/day at a concentration of 5 mg ET-18-OCH_3 per 1 ml 20% human serum albumin could be continued safely. The maximum-tolerated dose was either 50 mg/kg as a single injection or 20 mg/kg during daily dispensions. Grade 2-4 toxicity, as pulmonary edema and impairment of hepatic function, then occurred during daily treatment. Toxicity was reversible. Mitogen stimulation and mixed lymphocyte culture studies revealed possible immunosuppressive effects of higher doses of ET-18-OCH_3. There were no chromosomal changes in cytogenetic studies. Frequent post-mortem examinations revealed no further toxicity. IV and oral treatment showed few encouraging response data since there were two partial remissions in non-small cell lung cancers and a reduction of leukemic blasts to less than 10% in an acute myelomonocytic leukemia.
Lipids 22, **967-969 (1987).**

Alkyl lysophospholipid (ALP) derivatives represent the first generation of ether lipids with antineoplastic properties in vitro and in vivo. A detailed review of this area of investigation has been published recently (1). Some of these compounds have substantial therapeutic efficacy in various rodent tumor systems. This activity has been interpreted to be mediated partially by cytotoxic effector cell populations, e.g. macrophages and direct effects of this material on tumor cells as cytotoxicity, induction of differentiation and anti invasiveness. After toxicologic investigations (1), which included studies with subhuman primates (Munder and Andreesen, personal communication), we have introduced 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH_3) into a first clinical phase I pilot trial (2,3).

MATERIALS AND METHODS

Sixteen patients with solid tumors (seven non-small cell lung cancers, one bowel carcinoma, one hypernephroid carcinoma, one urothelial carcinoma, one adrenal cortex carcinoma, one thyroid gland carcinoma, one glioblastoma) and leukemias (one acute myelomonocytic leukemia, two chronic myeloid leukemias/blast crisis) were treated in our institution from 1979-1982. There were 11 male and five female patients. The median age of those with solid tumors was 64 years (range: 19-85 years). The median age of the leukemic patients was 37 years (range: 17-39 years). With the exception of two patients with non-small cell lung cancers, all patients have been refractory to prior therapy as surgery, radiation or chemotherapy; ten patients had obtained multi-modality treatment before entering the study. All patients suffered from metastatic or widespread disease, and the performance score (Karnofsky index) before the study was below 50 for the majority of the patients. Written informed consent of the patients was obligatory.

The chemical structure of the ALP 1-*O*-octadecyl-2-O-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH_3) is given in Figure 1. The compound was synthesized according to methods modified from procedures previously published (4-6), stored in a desiccator at −20 C, dissolved aseptically in 20% human serum albumin (HSA) up to a concentration of 5 mg/ml and infused intravenously at 37 C. For oral treatment, the ET-18-OCH_3 was dissolved in milk (3.5% fat content) at various concentrations. Routine checks on purity (chromatography), sterility (microbiology) and pyrogen content (animal experiments) were performed on each batch.

The study was performed in accordance with German law. The study protocol has been reviewed and approved by an ethical board. Eleven patients were treated intravenously. For dose finding, we began with single applications of 2 mg/kg, which is 10% of the lowest dose that produces moderate toxicity in toxicologic studies with subhuman primates (Munder and Andreesen, personal communication). Single application doses then were increased by doubling the amount of ET-18-OCH_3 and beyond 10 mg/kg by adding smaller amounts. Some patients were treated by prolonged daily applications, beginning with 1 mg/kg/day and using the same dose escalation procedure. Five patients were treated orally, following a similar dose escalation but starting with daily applications. Since we faced a shortage of the noncommercial drug during this first pilot study, dose increases for individual patients were performed at due intervals to obtain a maximum of information.

Prior to treatment, the following studies were performed on every patient: a case history, A (chest x ray,

electrocardiography, echocardiography, abdominal sonography, pulmonary function, tumor/leukemia staging with the necessary examinations, Coombs-tests, bone marrow) and B (physical examination, performance-status, weight, cellular blood count including erythrocyte morphology, reticulocytes, erythrocyte osmotic resistance, differential white blood count, thrombelastography, blood sedimentation rate, serum [blood urea nitrogen, creatinin, uric acid, electrolytes, bilirubin, glytamic oxalo-acetic transaminase, glytamic pyruvic transaminase, γ-glutamyl transferase, alkaline phosphatase, cholinesterase, gamma-lactate dehydrogenase, lactate dehydrogenase, amylase, lipase, creatinin phosphokinase, β_2-microglobulin, haptoglobin, hemopexin, plasmatic coagulation, triglycerides, cholesterin, glucose, electrophoresis, immunoglobulins, complement C_3 and C_4 and antinuclear factors], creatinin-hippurane-clearance, urine-profile, urine-protein, urine-glucose and urine-electrolyes). A-values were repeated when necessary, at least once every month and at the end of the treatment. B-values were repeated at least once every week. Other examinations, such as thyroid hormones and chromosome analysis in peripheral blood cells, were done facultatively.

Toxicity was determined according to the Southeastern Cancer Study Group criteria with some minor modifications. Maximum-tolerated dose (MTD) was defined as the occurrence of grade 2 (moderate) toxicity after single or during daily applications and was evaluated for IV treatment.

For response evaluation partial remission (PR) has been defined as regression of all measurable tumor parameters of more than 50% with a remission duration for at least one month. Tumor regression of less than 50% for more than one month has been referred to as minor response (MR). Progressive disease (PD) was stated if one or more tumor parameters or white blood count in patients with leukemia developed progressively under therapy, paralleling a drop in performance status. No change (NC) or complete remissions (CR) have not been observed.

RESULTS AND DISCUSSION

Eleven patients were treated intravenously. Generally, toxicity was mild, i.e. grade 1 of the Southeastern group criteria. Two patients developed transient indurative erythema, which so far lacks a pathophysiological explanation on some parts of their skin. Six patients experienced gastrointestinal side effects of vomiting and diarrhea, which we found to be independent of dose level but correlated with the concentration of ET-18-OCH_3 in HSA and the infusion rate. Both side effects could be avoided by choosing an ET-18-OCH_3 concentration in 20% HSA, not exceeding 5 mg/ml, and by keeping the infusion rate below 20 ml per hr. Grade 1 liver toxicity was observed in three patients as an impairment of hepatic synthesis function monitored by a temporary drop in serum cholinesterase, and in one occasion as a drop of the Quick test. One patient showed grade 2 liver toxicity, as there was a cholestasis with increased alkaline phosphatase and bilirubin. Grade 1 renal toxicity was found in two patients with an elevation of serum creatinine and glucosuria, and proteinuria was found in one case. Life-threatening toxicity (grade 4) was observed in one patient, who developed an interstitial pulmonary edema, which correlated with a change of performance status. Similar pulmonary edema in a second patient reached only grade 2 toxicity because of prompt drug removal. Grade 1–2 toxicity was found to be reversible within a few days after removal of ET-18-OCH_3; it did not require any special treatment. Grade 4 pulmonary edema was found to be completely reversible under assisted ventilation and corticosteroids with the drug removed.

The MTD during single IV applications, given to five patients with weekly intervals, was 50 mg/kg infused within 24 hr. This dosage was reached in two patients, and the limiting factor was the infusion rate, since gastrointestinal toxicity occurred. MTD during daily applications was 20 mg/kg/day, reached by four patients. One patient could be treated with 20 mg/kg/day for 10 days without grade 2 toxicity. The other patients experienced either liver or lung toxicity reaching grade 2 or more (see Table 1). Additionally, after accidental extravasal infusion, there were two episodes of thrombophlebitis.

Five patients were treated orally. Grade 1 toxicity was concentrated on the gastrointestinal tract, hepatic function and renal function, and it had the same characteristics as those induced by IV treatment. Five mg/kg/day could be given safely to four of the patients for longer time intervals, 10 mg/kg/day produced life-threatening pulmonary edema after 10 days in one patient, which was completely reversible under short-term assisted ventilation and corticosteroids with the drug removed. However, oral MTD was not established in this pilot trial since better galenic formulations of this type of drug are under way.

Mitogen stimulation and mixed lymphocyte culture (MLC) studies in the blood lymphocytes of six patients were performed to reveal possible in vivo immunosuppression of higher doses of ET-18-OCH_3, which had been found in vitro (7). The results so far remain contradictory. However, since there was a significant decrease of mitogen stimulation and MLC reactivity in one patient, which showed reversibility after the end of the treatment, further studies in this direction should be performed.

Cytogenetic studies have been performed in lymphocytes of patients under treatment with negative results (8). Pathological and histological post-mortem examinations were performed in eight of the 16 patients who died of progressive disease after various time intervals. There were no further signs of toxic alterations exceeding the common findings in advanced neoplastic disease and death.

TABLE 1

Maximum-Tolerated Dose (MTD) and Limiting Toxicity for IV ET-18-OCH_3

- MTD for single infusion of ET-18-OCH_3 (20% HSA, 5 mg/ml): 50 mg/kg

  Limiting toxicity: Gastrointestinal toxicity (nausea, diarrhea)

- MTD for daily infusions of ET-18-OCH_3 (20% HSA, 5 mg/ml): 20 mg/kg/day

  Limiting toxicity: Lung, liver

Details of response and survival data are in previous reports (2,3,9). In summary, there were two PR in intravenously treated patients with non-small cell lung cancer, which were controlled by both x ray and bronchoscopy, and showed a remission duration for five and six months. Minor responses were found in one patient with a hypernephroid carcinoma and another patient with a thyroid gland carcinoma. In a patient with an acute myelomonocytic leukemia that was treated intravenously, we observed a ca. 1-log reduction of leukemic blasts in the peripheral blood ($78.7 \times 10^3/\mu l$ to $3.4 \times 10^3/\mu l$) within 15 days of treatment with a parallel recovery of granulopoiesis. However, this did not qualify for response since we could not obtain a second bone marrow examination from this patient. All other patients were found with progressive disease. However, all patients finally died from progressive disease; none of the patients survived longer than one year after study.

In summary, we have treated 16 patients suffering from widespread malignant disease; the majority has been refractory to previous treatments and was found to be in poor general performance. MTD for single IV administration of the drug was ca. 50 mg/kg with nausea and vomiting as the limiting toxicity. Prolonged daily IV applications of doses less than 20 mg/kg/day at 5 mg ET-18-OCH_3/1 ml 20% HSA seemed to be safe. Limiting toxicity occurred in liver and as interstitial pulmonary edema giving 20 mg/kg/day. The etiology of the pulmonary edema remains speculative. However, residual platelet-aggregating effects of the ET-18-OCH_3 similar to the chemically related platelet-activating factor (PAF) may play a role (10). Thus, it seems to be essential to look for antitumor ether lipids and derivatives for future clinical trials without PAF effects. On the other hand, typical side effects for antitumor cytotoxics as myelosuppression or alopecia were not found within the study; the drug also remained genetically inactive.

The purpose of this study performed with a limited amount of drug was only to obtain basic information on the applicability and possible value for further clinical testing of this material in cancer patients. Since we have partially characterized the tolerability of this first antineoplastic ether lipid have found some limited antitumor activity of the material, the information obtained from this pilot trial represents basis and justification for further clinical testing of related structures within a wider scope of phase I and II trials (see also Herrmann, D. et al., this issue).

REVIEW

Ether Lipids and Analogs in Experimental Cancer Therapy. A Brief Review of the Munich Experience[1]

Wolfgang E. Berdel
Division of Hematology and Oncology, Department of Medicine I, Technische Universitaet, Ismaninger Str. 22, 8000 Munich 80, Federal Republic of Germany

This review covers the work of our laboratory on the antineoplastic activity of some ether lipids and derivatives that are related to platelet-activating factor (PAF). Various 1-*O*-alkyl lysophospholipid derivatives (ALP) show therapeutic activity in mouse transplant tumor models and in metastatic 3-Lewis lung carcinoma in vivo. However, certain autochthonous mouse leukemias and radiation-induced lymphomas are resistant to ALP treatment. The therapeutic effects of these compounds are partially due to the activation of cytotoxic macrophages and direct cytotoxicity.

Approximately 20 ether lipids and derivatives were tested for direct cytotoxicity in cells from human solid tumors and leukemias using [^{3}H]thymidine uptake, trypan blue dye exclusion, human tumor clonogenic assays (HTCA) and cell morphology as criteria. Certain ALP, thioether lysophospholipid-derivatives (TLP), ether-linked lipoidal amines, *sn*-2 analogs of PAF, and conjugates of ether lipids and cytosine arabinoside were found cytotoxic in a dose- and time-dependent fashion. Cytotoxicity of some of the ether lipids tested is based on destruction of cell membranes. Structure-activity studies were performed to better understand the mechanisms leading to accumulation and cytotoxicity of ALP. Comparative studies with normal bone marrow cells and leukemic blasts from humans revealed preferential antileukemic cytotoxity of three ether lipids.
***Lipids 22,* 970–973 (1987).**

In the early seventies, three independent laboratories observed antitumor effects of certain ether lipids for the first time. Munder et al. (1) examined synthetic analogs of 2-lysophosphatidylcholine (2-LPC) and reported prophylactic and therapeutic efficacy of certain alkyl lysophospholipid (ALP) derivatives in some allogeneic and syngeneic mouse transplantation tumors. These ALP originally were synthesized as a new class of biological response modifiers. Figure 1 depicts the chemical structures of some first generation ALP. Ando et al. (2) reported on therapeutic effects of certain alpha-glycerylethers in the Ehrlich ascites tumor. Boeryd et al. (3) described therapeutic activity of methoxy-substituted alkyl-glycerols in some metastasizing sarcomas induced by methyl-cholantrene in mice.

Whereas the alpha-glyceryl ethers and alkyl-glycerols so far have not led to the systematic development of anticancer drugs that are applicable in clinical oncology, this attempt is under way with different ALP and other ether lipid-derivatives. This review briefly summarizes the contribution of our laboratory in this area.

RESULTS OF ANIMAL EXPERIMENTS

When it became evident that ALP could inhibit the growth of different primary tumors in mice, we began studying the influence of these compounds on experimental metastasis, using the 3-Lewis lung carcinoma (3-LL) growing in syngeneic $C_{57}Bl_6$-mice (4,5). In a first series of experiments, we observed only minor activity of the ALP, trying to retard the growth of 3-LL primary tumor. However, application of the compounds either shortly before or shortly after the surgical removal of the primary tumor significantly retarded and inhibited the 3-LL metastasis; this was demonstrated by an increase of the median survival time and the number of surviving animals. In these experiments, the compounds showed

activity when they were given intradermally, intravenously or even orally. Among various ALP, the analogs with a long aliphatic side chain in the *sn*-1 position of the molecule and a substitution of the *sn*-2 position of the molecule, e.g. with a methyl-group, showed the highest activity.

Subsequently, in vitro and in vivo experiments performed with macrophages from the peritoneal cavity or the bone marrow of $C_{57}Bl_6$ mice could show that the inhibition of metastasis of 3-LL by ALP partially is mediated by an activation of macrophages to a cytotoxic effector cell population after contact with these compounds. In these experiments, macrophages from the peritoneal cavity of $C_{57}Bl_6$ mice could be rendered cytostatic and cytotoxic for 3-LL cells in vitro by a preincubation with the lipids. Furthermore, pure syngeneic bone marrow macrophages have shown some therapeutic antimetastatic activity in vivo when used in the 3-LL. However, preincubation of these macrophages with various ALP in vitro yielded in a significantly improved therapeutic antimetastatic activity in vivo when these cells then were intravenously reinjected into the animals after surgical removal of the primary tumor, and the incidence of death from metastasis was observed.

In the experiments summarized above, the ALP had to be given daily for a minimum of three weeks to produce visible therapeutic effects. In contrast, with some of our new conjugates of ALP or TLP with 1-β-D-arabinofuranosylcytosine (Ara-C) a treatment duration of only five days was necessary to inhibit the intraperitoneal growth of the 3-LL primary tumor or to inhibit the development of metastasis of the 3-LL with an adjuvant treatment approach. Figure 2 shows four of the lipid-ARA-C conjugates, including the most active Ara-CDP-D,L-PBA and Ara-CDP-D,L-PTBA. (Further details concerning these experiments are published in a separate paper of this *Lipids* issue.)

In another series of experiments, we so far could not show prophylactic efficacy of the ALP ET-18-OCH_3 or ET-18-OH on the development of radiation-induced lymphomas in syngeneic $C_{57}Bl_6$-mice or the spontaneous development of leukemias in AKR-mice (6). The reason for the lack of therapeutic activity of the lipids in these tumor models remains unknown. However, experiments with radiation-induced mouse tumors, which use a wider dose range of the lipids, are underway.

RESULTS OF HUMAN TUMORS AND LEUKEMIAS EXPERIMENTS IN VITRO

More recently, we performed another series of experiments to study the phenomena of macrophage activation and direct cytotoxicity of certain ether-lipid derivatives with human tumors and leukemias in vitro. Over 30 lipids and lipid-derivatives were tested for cytotoxicity in more than 100 human tumors and leukemias. We used the tritiated thymidine uptake, the trypan blue dye exclusion, the human tumor clonogenicity assay (HTCA), and microscopic and scanning electron microscopic (SEM) procedures as test systems. In these experiments, 1-*O*-alkyl-lysophospholipid-derivatives (ALP), thioether-lysophospholipid-derivatives (TLP), ether-linked lipoidal amines, analogs of the platelet-activating factor (PAF), PAF-antagonists and conjugates of lipids and cytotoxics revealed cytostatic and cytotoxic activity in neoplastic cells of human origin.

Figures 1, 2 and 3 show representative structures of these lipids and lipid-derivatives. In general, more than 24 hr of incubation were necessary to obtain full cytotoxic efficacy of the compounds. Besides this relation to time, there was a clear dose-response relationship for the cytotoxic activity of the vast majority of the compounds; There were few exceptions. ET-18-analogs of ALP (see

Fig. 1), which were extensively examined in this respect, have shown a clear dose-response relationship between the concentrations of 1–10 μg/ml. The majority of tumors and leukemias tested were sensitive to the cytotoxic properties of, e.g., the ET-18-analogs of ALP, and they showed viability of less than 50% when incubated with concentrations of these compounds <20 μg/ml for at least 48 hr. However, it is important that there also were certain cell types that proved resistant to this material. Examples are given in Table 1. For the group of ALP, an alkyl-ether-linkage in the *sn*-1 position of the molecule and a substitution of the *sn*-2 position of the molecule were necessary for reproducible cytotoxicity. The ester-lysophospholipid 2-LPC, which always was tested in parallel as a reference compound for direct detergent-like surface activity, has shown either none or minor activity within the same dose range. The lyso-PAF ET-18-OH was cytotoxic in only some tumors and leukemias, furthermore, this cytotoxicity could be inactivated by preincubation with a microsomal tetrahydropteridin-requiring 1-*O*-alkyl-cleavage enzyme. Different laboratories have shown that this enzyme is present in a variety of normal tissues but characteristically absent from neoplastic cells (for further literature, see ref. 7). Further structure-activity analysis with the D- and L-forms of the ET-18-OH in the HL 60 leukemic cell line showed that the activity of the racemic compound is due to the activity of the D-form (8). However, this could not be reproduced by testing various freshly explanted human leukemic cell samples including patients refractory to, or with relapses after previous chemotherapy (for details, see the publication of Danhauser et al., this issue of *Lipids*). Furthermore, microscopic and SEM studies could show that the cytotoxicity of ALP, TLP, the lipoidal amine CP-46,665

and the PAF-analogs is correlated with destruction of the outer cell membranes. Detailed results of our investigation concerning the cytotoxic properties of these lipids and lipid derivatives have been published before (for further literature, see ref. 7).

In an additional series of experiments, we were able to show that preincubation of monocytes/macrophages of human origin with certain ether lipids in vitro renders these cells cytostatic for autologous tumor cells of the same patient (9). This effect was observed with various human hypernephroid carcinomas and non-small cell lung cancers but not with human brain tumors. Cytotoxity studies with six ether lipid derivatives comparing the sensitivity of bone marrow to leukemia cells revealed preferential antileukemic cytotoxity of three lipids, including ET-18-OCH_3 and BM 41.440 (for further details, see the publication of Schick et al., this issue of *Lipids*).

DISCUSSION

There is increasing experimental evidence that certain ether lipids and derivatives represent a new group of antineoplastic compounds. This notion is supported by the results of first clinical pilot trials (10). The activity of these structures partially is mediated by tumor cytotoxic cells and due to direct effects of this material on neoplastic cells. These direct effects consist of cytostatic-cytotoxic properties discussed here and also consist of the induction of the differentiation in neoplastic cells (11) and an inhibition of the invasive properties of neoplastic cells (12). Although the molecular mechanisms leading to these direct effects are yet unknown, accumulation of these lipids in neoplastic cells, disturbance of lipid metabolism, and destruction of cell membranes seem to be important. ET-18-OCH_3 and other ALP represent a first generation of toxic ether lipids that are now widely used as reference compounds. The high synthetic potential in lipid chemistry possibly will open a new area for the acquisition of toxic molecules useful for experimental anticancer therapy. Although a deeper understanding of the molecular mechanisms of this cytotoxicity might be helpful in drug design, the value of these structures for clinical oncology has to be shown in the various in vitro and in vivo activity-screening systems and finally proven in clinical trials.

[Received January 13, 1987]

Concluding Remarks

Otto Westphal
Max-Planck-Institut für Immunbiologie, Freiburg, Germany

Synthetic ether lipids and related substances, originally conceived as analogs of natural lysolecithin, have been established as a new class of tumoricidal agents, first by Munder about 10 years ago and confirmed by many others. Ether lipids produce strong biological signals!

Organic chemists have synthesized series of analogs in which the glycerol substituents of natural lysolecithin have been varied in several directions, especially by Eibl and his group, and also by others. I would also like to mention, by the way, the elgant stereospecific PAF-synthesis by Mangold.

Biochemists have done much work on the biosynthesis and metabolism of ether lipids, concentrating, for example, on the 1-*O*-alkyl cleavage enzyme system elaborated by Snyder. Enzymic studies included the phospholipases A_2, C and D and other hydrolases, as well as acyltransferases, their occurrence and relative activity in normal and malignant cells and, especially, in cell plasma membranes and in the endoplasmic reticulum.

Natural ether lipids have been known for some time, but interest was greatly stimulated by the findings of Hanahan and others that the platelet-activating factor (PAF) is a 1-*O*-alkyl glycerol derivative. Also, work on plasmalogens and on their metabolism should be mentioned as well as observed genetic aberrations in ether lipid metabolism that occur in Zellweger syndrome, as described by van den Bosch.

Data were presented on the influence of alkyl lysophospholipids (ALP), such as ET_{18}-OCH_3, on phospholipid biosynthesis, turnover and degradation. Of special interest appears to be the inhibition by ALP of phosphorylation reactions, for example, those catalyzed by protein kinase C.

Membranologists have contributed to the understanding of the relation of the physicochemical make-up of ether lipids with regard to their influence on membrane dynamics, such as the change in membrane properties with regard to uptake and/or release of biologically active materials, hormones, etc., by synthetic ether lipids, including the cholesterol ethers discussed by Stein. Changes that occur in membrane-bound enzyme reactions is another demonstration of the potential importance of the new substances, as are findings about the binding of ether lipids and their metabolites to cellular subfractions.

Many interesting remarks were made on new and more sophisticated types of liposomes for various clinical applications (reduced toxicity and/or prolonged action of drugs, liposome-bound antigens plus adjuvants, etc.) or about liposomes as vehicles with affinity to specific organs, such as the liver.

Biologists and clinical investigators have studied the action of ether lipids on tumor and normal cells in vitro and in vivo. Several promising substances have tumor prophylactic as well as inhibitory or even, hitherto in animals, curative properties. Some representatives of the new class seem to act selectively enough on certain, but not all, tumor cells that further intensified work appears to be warranted. Some model types of ether lipids have been studied extensively. The development of possibly still more efficient antitumor compounds can now be based on biochemical, pharmacological and biomedical criteria at hand. This means that coming from phenomenology, we have gone a good way towards a more logical approach. We are at a beginning in an exciting field; our optimism appears justified.

Reports on the first clinical studies, notably on far-advanced cancer cases, seem to call for further efforts and have emphasized the importance of combined basic and applied clinical research. We are still discussing possible mechanisms of the tumoricidal action of ether lipids and its selective character. Candidates are macrophage- (and probably also NK cell-) activation, immune tumor cytotoxicity, direct toxic effects on malignant cells with disturbance of their membrane lipid metabolism, enzyme inhibition or activation, etc. Some clinicians, like Andreesen, stressed the importance of studying mediators, such as interleukin I and II, under ALP treatment. Also, anti-infective and radio-protective properties of the substances were stressed.

There are good reasons not to restrict our attention only to the antitumor activities of ether lipids but also to consider, for example, suppressive effects on certain hitherto not well-controlled autoimmune conditions.

It should be kept in mind that, apparently, one and the same ether lipid is not equally effective on all kinds of tumors. In comparative studies, some tumors are more, others are less, sensitive some may be even resistent. As an example, we may remember the selective cytotoxicity of Eibl's hexadecyl phosphocholine on mammary tumors, as Schmähl and Berger stated, or the alkylglycerol "cascade" of Unger and Eibl in the treatment of skin tumors. Most of the synthetic ALP tested so far were racemic. However, Inoue observed a higher biological activity of the "natural" L-isomer, *sn*-1, of ET_{18}-OCH_3 on macrophages and a somewhat higher toxicity of the D-isomer in vivo but not in vitro.

The antiinvasive properties of ALP were beautifully demonstrated in mixed cell cultures by Storme. There were also contributions showing changes in the sialic acid conjugation or incorporation by ALP into cell surface glycosyl groups, which seem to influence invasive properties of cells.

Of great interest is the relatively high sensitivity of leukemic cells towards ALP and the induction of differentiation of immature stem cells by low ALP doses. One of the possible applications was discussed by Vogler: by purging of bone marrow stem cell cultures taken from leukemic patients, with ALP the leukemic cells can be almost or fully eliminated without damaging normal cells, so that auto-retransfusion of the "purified" cultures could be envisioned.

Thus, there seem to be various possibilities for clinical applications of ether lipids, which should be carefully followed.

We were bombarded with so much interesting and new data that we will go home enriched with many ideas for further work in our field of interest and expertise. Publication of our discussions in the journal *Lipids* will help to keep our memory of these days awake. Personally, I feel that we should try to keep contact and to further exchange information as much as possible.

LETTER TO THE EDITOR

A Suggested Shorthand Nomenclature for the Eicosanoids

Sir:

In preparing comprehensive reviews of the eicosanoid literature for the CRC handbook of eicosanoids (1,2), it was necessary to summarize the known eicosanoids biosynthesized from arachidonic acid and related polyenoic precursors. In doing this, we had to standardize some useful nonambiguous shorthand nomenclature for oxygenated fatty acids (HETEs, for example) that did not form part of the prostaglandin, leukotriene or other well-named families of eicosanoids. As minimal criteria, we wanted the nomenclature system to (1) reflect previous usage as much as possible; (2) avoid ambiguity; and (3) be easy to use in spoken communication.

There currently is some confusion regarding the use of a shorthand nomenclature for hydroxyeicosapolyenoic acids. Previously in the literature, some discrepancies have existed among authors in devising their own shorthand versions using a "HETE"-type nomenclature. For instance, some authors have named dihydroxy derivatives of arachidonic acid "diHETEs," while others have used "DHETEs." With the discovery of epoxide-containing eicosanoids, this has been even more confusing. For example, 10-hydroxy-11(12)-epoxy-5-*cis*,8-*cis*,14-*cis*-eicosatrienoic acid has been called "EPHETA" by one group (3) and "10,11,12-HEPA" by another (4). In addition, some related compounds have been named (hepoxilins, trioxilins, for example) by Pace-Asciak and colleagues (5).

For newcomers to the field, systematic nomenclature is described in great detail in the eicosanoid handbook (1,2) but we present here a summary of this overview with emphasis on an abbreviated nomenclature.

As a beginning framework, all of the universally accepted and used shorthand nomenclature systems also are used in this system. These include the classic prostaglandins, which have nomenclature based upon the prostanoic acid system first introduced by the Karolinska group (6); thromboxanes A_2, B_2, A_3, B_3 (as TXA_2, etc.), which is used with a systematic nomenclature that may be based either on the original heptadecenoic acid system (7,8) or on the more recent thrombanoic acid system (9); and the leukotriene nomenclature proposed by Samuelsson's group (10,11). In addition, the more recently proposed names "trioxilins" and "hepoxilins" by Pace-Asciak (5) and "lipoxins" ("LX") for recently described compounds by Serhan and Samuelsson (12,13) also are used here, since these compounds may have important and unique biological effects. Examples of some other compounds for which shorthand names may be derived

FIG. 1. Conversion of arachidonic acid to 12-HETE; hepoxilin A_3 (8,11(12)-HEpETrE); trioxilin A_3 (8,11,12-TriHETrE); hepoxilin B_3 (10,11(12)-HEpETrE); and trioxilin B_3 (10,11,12-TriHETrE) (1,5).

FIG. 2. Conversion of eicosapentaenoic acid to 15-HpEPE, to 5,15-DiHpEPE, and to lipoxene A (5,6,15-TriHEPE) and lipoxene B (5,14,15-TriHEPE) via postulated 5(6),15-EpHEPE intermediate (1,23).

from common or original usage include Bc-PGE_2 (bicyclo PGE_2) (14); LGD_2 and LGE_2 (levuglandins D_2 and E_2) (15); and $PnGA_3$ and $PnGA_4$ (punaglandins 3 and 4) (16), with "A" designation added because of a PGA-ring in their structures. (See Reference 1.)

For the other eicosanoids, we have adopted the following rules: (1) Oxygenated substituents on the fatty acid chain. (a) These are numbered in sequence from the usual terminal (number 1) carboxyl group of the fatty acid molecule. Wherever an epoxide (or oxane bridge) occurs, the position of the carbon atom covalently linked also is defined but in parentheses: for instance, the 5(6)-epoxide derived from arachidonic acid by a cytochrome P-450 dependent monooxygenase system (17,18). (b) To describe the nature of these substituents, we have adapted slightly and standardized the common usage of other authors. For instance, "H" denotes hydroxy; "Hp" denotes hydroperoxy; and "Ep" denotes epoxy. The use of the lower case letter "p" denoting peroxy is done to avoid a confusion with the large "P," which is used in this nomenclature to denote the five double bond (pentaenoic) system. (c) To describe the number of hydroxyl or other substituents, we suggest standardizing the use of "Di" for 2, "Tri" for 3, "Tetra" for 4, etc. (e.g.: 5,15-DiHETE). For monohydroxy, no such prefix is required and previous common usage is retained. Use of "TH" (as in THETE, etc.) would present ambiguity because it could mean *either* "tri" or "tetra"; and use of "DH" or "TrH" would produce names that would be difficult to vocalize. (2) Number of double bonds and chain length. After description of the nature and position of substituents, the number of double bonds and chain length is described by adaptation of the usual nomenclature. Thus, "ETE" means eicosatetraenoic acid ("T" always denoting tetra and the final "E" denoting enoic acid). By contrast, "ETrE" means eicosatrienoic acid. Again, the lower case is used to avoid the ambiguity previously existing in this case between "trienoic" and "tetraenoic." For example, the heptadecatrienoic acid formed as a byproduct of the cyclooxygenase enzyme once commonly was called "HHT." We propose that it now should be called 12-HHTrE and HHTE now would designate a tetraenoic acid derivative. Notation of chain length is based on previous common usage, unless severe ambiguity results. The "H" denoting heptadeca (C_{17}); "O" denoting octadeca (C_{18}); "N" denoting nonadeca (C_{19}); and "T" denoting tetradeca (C_{14}) are adopted from previous long-term common usage (e.g., the old "HHT," now 12-HHTrE). By contrast, we reserve use of "HD" for hexadeca (C_{16}), which avoids confusion with heptadeca. This is consistent with our suggested use of "DD" for dodeca (C_{12}), which avoids confusion with "D" for docosa (C_{22}). Using these criteria, 13-hydroxyoctadecadienoic acid (from linoleic acid) (19) would then be called (as previously) 13-HODE; and the shorthand form for 8 and 9 carbon compounds, if such were found later, could be "octa" and "nona."

Descriptive examples of this nomenclature are shown in Table 1. Examples of structures of some of these compounds derived from arachidonic acid and eicosapentaenoic acid are shown in Figures 1 and 2.

Are there any ambiguities remaining in this system for shorthand nomenclature of the eicosanoids? It could be argued that "H" could mean either hydroxy or heptadeca. However, this is dealt with by designation of position number and order of appearance. For example, in 12-HHTrE, the first "H" (immediately following position number) means hydroxy, whereas the second "H" (appearing after the hydroxy substituent), means heptadeca.

Another possible ambiguity is the position of the double bonds. This was not a disadvantage to the original Holman system (20) (described below) since the fatty acids had no substituents and all-*cis* methylene interrupted double bonds (skipped unsaturation) always were assumed. However, in the case of substituted fatty acids the original position of the double bonds is often altered, and the original all-*cis* configuration might change in different ways. This drawback can be minimized by defining use of the shorthand (at least once in any paper using it) in terms of structure or systematic name, provided for all known eicosanoids in the review by Smith in *Handbook of the Eicosanoids* (1). Alternatively, we suggest using the Δ nomenclature within parentheses to indicate position of double bonds. For example, 5,15-DiHETE could be called ($\Delta^{6,8,11,13}$)5,15-DiHETE. Should *trans* configuration occur, as in this example, further elaboration (at the expense of brevity) also is possible by denoting

TABLE 1

Examples of Shorthand Nomenclature

Precursor	Compound	Position number prefix	Substituent prefix		Chain length		Suffix: Number of unsaturations		Comments
			Symbol	Description	Symbol	Description[a]	Symbol	Description	
Arachidonic acid (20:4ω6)	5-HETE	5-	H	Hydroxy	E	Eicosa (20)	TE	Tetraenoic acid	
	12-HHTrE	12-	H	Hydroxy	H	Heptadeca (17)	TrE	Trienoic acid	Cyclo-oxygenase by-product
	15-HpETE	15-	Hp	Hydroperoxy	E	Eicosa (20)	TE	Tetraenoic acid	
	5(6)-EpETrE	5(6)-	Ep	Epoxy	E	Eicosa (20)	TrE	Trienoic acid	
	12(S)-HETE	12(S)-	H	Hydroxy	E	Eicosa (20)	TE	Tetraenoic acid	(S) and (R) denote sterochemistry of hydroxy group (see ref. 2)
	12(R)-HETE	12(R)-	H	Hydroxy	E	Eicosa (20)	TE	Tetraenoic acid	
	5,15-DiHETE	5,15-	DiH	Dihdroxy	E	Eicosa (20)	TE	Tetraenoic acid	
	13,14(15)-HEpETrE	13,14(15)-	HEp	Hydroxyepoxy [13] [14(15)]	E	Eicosa (20)	TrE	Trienoic acid	
	5(6),15-EpHETE	5(6),15-	EpH	Epoxyhydroxy [5(6)] [15]	E	Eicosa (20)	TE	Tetraenoic acid	
	14-Oxo-TTE	14-	Oxo-	Oxo (aldehyde)	T	Tetradeca (14)	TE	Tetraenoic acid	
	12-Oxo-DDTrE	12-	Oxo-	Oxo (aldehyde)	DD	Dodeca (12)	TrE	Trienoic acid	
Dihomo-γ-linolenic acid (20:3ω6)	12-HETrE	12-	H	Hydroxy	E	Eicosa (20)	TrE	Trienoic acid	
	8,9,12-TriHEDE	8,9,12-	TriH	Trihydroxy	E	Eicosa (20)	DE	Dienoic acid	
	8,15-DiHpETrE	8,15-	DiHp	Dihydroperoxy	E	Eicosa (20	TrE	Trienoic acid	
	12-HHDE	12-	H	Hydroxy	H	Heptadeca (17)	DE	Dienoic acid	Cyclo-oxygenase by-product
	10,11(12)-HEpHE	10,11(12)-	HEp	Hydroxyepoxy [10] [11(12)]	H	Heptadeca (17)	E	(mono)enoic acid	Possible cyclo-oxygenase product
Adrenic acid (22:4ω6)	14-HDTE	14-	H	Hydroxy	D	Docosa (22)	TE	Tetraenoic acid	
	14-HNTrE	14-	H	Hydroxy	N	Nonadeca (19)	TrE	Trienoic acid	Cyclo-oxygenase by-product
Eicosapentaenoic acid (20:5ω3)	12-HEPE	12-	H	Hydroxy	E	Eicosa (20)	PE	Pentaenoic acid	
	5,15-DiHpEPE	5,15-	DiHp	Dihydroperoxy	E	Eicosa (20)	PE	Pentaenoic acid	
	12-HHTE	12-	H	Hydroxy	H	Heptadeca (17)	TE	Tetraenoic acid	Cyclo-oxygenase by-product
Mead acid (20:3ω9)	(5,8,10t)12-HpETrE (previously [ref. 1] ω9-12-HpETrE)	(5,8,10t)12- (previously [ref. 1] ω9-12-)	Hp	Hydroperoxy	E	Eicosa (20)	TrE	Trienoic acid	ω9 (Holman nomenclature [ref. 20]) distinguishes this from 12-HpETrE formed by 12-oxygenation of 20:3ω6
Docosahexaenoic acid (22:6ω3)	14-HpDHE	14-	Hp	Hydroperoxy	D	Docosa (22)	HE	Hexaenoic acid	
	10,13,14-TriHDPE	10,13,14-	TriH	Trihydroxy	D	Docosa (22)	PE	Pentaenoic acid	
Linoleic acid (18:2ω6)	13-HODE	13-	H	Hydroxy	O	Octadeca (18)	DE	Dienoic acid	

[a]Number of carbons is in parentheses.

stereo chemistry of the double bonds as c *(cis)* or t *(trans)*, hence ($\Delta^{6t,8c,11c,13t}$)5,15-DiHETE. However, we suggest that an easier shorthand for *routine* use would be to put the double bond position in parentheses, without the Δ symbol, and only insert t (for *trans*) when needed. For example, 13-HODE could be elaborated as (9,11t)13-HODE (Table 1).

We feel that there now is a pressing need for a system of shorthand nomenclature of the eicosanoids that (like ours) accommodates previous usage and does not artificially force people into an officially designated system that may be clumsy and not related to previous common usage. For example, Holman (20) popularized the use of ω-6, ω-3 to define nomenclature of the polyunsaturated fatty acids, and the omega nomenclature* now is used widely even among the general public since the ingestion of fish oil now is fashionable. By comparison, the IUPAC (21) use of n-6, n-3 almost has fallen out of use! For a second example, since the present IUPAC system already has defined eicosanoids as icosanoids (22), any logical extension of this to a committee decision to use the term "HITEs" to define hydroxyeicosapolyenoic acids then would have to overturn 15 years of usage of HETEs!

It is hoped that this system of nomenclature will be as useful to others as it is to us and that it may serve as a basis for future developments.

Hydroxylation of Fatty Acids and Alcohols by Hepatic Microsomal Cytochrome P-450 System from the Mongolian Gerbil[1]

Yoshiro Miura[*,a], **Harumi Hisaki**[a], **Werner Siems**[2,a] and **Sen-ichi Oda**[b]

[a]Department of Biochemistry, School of Medicine and Laboratory of Chemistry, Department of General Studies, School of Literature, Teikyo University, Tokyo, Japan, and [b]Research Institute of Environmental Medicine, Nagoya University, Nagoya, Japan.

The liver microsomes of the Mongolian gerbil *Meriones unguiculatus* catalyzed the hydroxylation of various saturated fatty acids (C_8-c_{18}), alcohols (C_{12} and C_{16}) and hydrocarbon (C_{12}) to the corresponding ω- and (ω-1)-hydroxy derivatives. Lauric acid was hydroxylated most effectively among saturated fatty acids and the order of activity as hydroxylation substrates was $C_{12} > C_{14} > C_{13} > C_{16} > C_{10} > C_{18} > C_8$. The specific activity of laurate hydroxylation (5.99 nmol/mg microsomal protein/min) in gerbil liver microsomes was higher than that observed in other species. 1-Dodecanol was also hydroxylated very effectively (4.58 nmol/mg microsomal protein/min) by gerbil liver microsomes, but in general the hydroxylation rates for fatty alcohols were much lower than those for the corresponding acids. It was found from both inhibitor and cofactor studies that the enzyme catalyzing the hydroxylation of fatty acids and alcohols in the liver microsomes of the Mongolian gerbil was a typical cytochrome P-450-linked monooxygenase, and at least two different cytochrome P-450 species were involved in the hydroxylation.

Lipids 22, **987-993 (1987).**

Although mammals such as rat, mouse, guinea pig or rabbit are generally used in both basic and clinical research, some mammals other than these have been successfully developed as novel experimental animals (1—4) and used for a variety of specific research (5–7). In a previous paper (8), we described the substrate specificity and other properties of a fatty acid hydroxylase system in the liver microsomes of the house musk shrew (*Suncus murinus*), which has received attention as a possible laboratory animal because of such desirable traits as small size, rapid breeding and environmental flexibility. The cytochrome P-450 monooxygenase system in the shrew liver microsomes catalyzed specifically ω- and (ω-1)-hydroxylation of fatty acids to a high extent, and the correlation between the high rate of ω- (ω-)-hydroxylation of fatty acids and the energy metabolism in the shrew was discussed. The Mongolian gerbil (*Meriones unguiculatus*), which has also received attention as a possible laboratory animal for the same reasons, has been used for several studies on lipid biochemistry in recent years (7,9–12). However, no information is available concerning the fatty acid hydroxylating system in the gerbil liver. In this paper, the substrate specificity and kinetic properties of a cytochrome P-450-dependent monooxygenase system in the gerbil are described.

MATERIALS AND METHODS

Chemicals. ^{14}C-Labeled fatty acids, 1-dodecanol and hexadecane (sp acti 19–58 mCi/mmol) were purchased from Amersham International (Amersham, U.K.). Hexadecanol, labeled in the 1-position with ^{14}C, was prepared from [1-^{14}C]palmitic acid by $LiAlH_4$ reduction in dry ether at room temperature. Dodecane, labeled in the 1-position with ^{14}C, was chemically synthesized from [1-^{14}C]dodecanol. The alcohol was converted to [1-^{14}]dodecyl bromide (13), which in turn was refluxed with $LiAlH_4$ in dry tetrahydrofuran. Labeled dodecane was purified by silica gel chromatography and had a radiopurity of 99% by radio-gas chromatography. The ω-hydroxy derivatives of C_{10}, C_{12}, C_{14} and C_{18} fatty acids and (ω-1)-hydroxy derivatives of C_{12} and C_{14} fatty acids were synthesized chemically (14). ρ-Chloromercuribenzoate (PCMB), iodoacetic acid, KCN, NaN_3, menadione and 7,8-benzoflavone were purchased from Tokyo Kasei Chemical Co. (Tokyo). NADPH and NADH were from Oriental Yeast Co. (Tokyo). Cytochrome *c* (horse heart) was from Sigma Chemical Co. (St. Louis, MO). SKF 525A was a gift from Prof. M. Kusunose, Toneyama Institute for Tuberculosis Research, Osaka City University Medical School. Metyrapone was from Aldrich Chemical Co. (Milwaukee, WI). Sodium dodecylsulfate, sodium cholate, sodium deoxycholate, Triton X-100 and Tween 20 were from Tokyo Kasei. Emulgen 913 was supplied by Kao-Atlas Co. (Tokyo). The organic solvents were reagent grade and freshly distilled before use.

Preparation of gerbil liver microsomes. The Mongolian gerbils used in this study were obtained from our breeding colonies. Eight to 10 male gerbils (5 mo) weighing 51–66 g were used. The preparation of gerbil liver microsomes was caried out in the same manner as described for the preparation of frog liver microsomes (15). The microsomes were washed with 0.25 M sucrose and resuspended in the same medium. The protein concentration of the microsomal suspension was determined by the method of Lowry et al. (16). The cytochrome P-450 and cytochrome b_5 contents of the microsomes were determined by the methods of Omura and Sato (17) and Omura and Takesue (18), respectively. NADPH-cytochrome *c* reductase and HADH-cytochrome b_5 reductase activities were determined as described by Omura and Takesue (18,19).

Assays for hydroxylation of fatty acids, fatty alcohols and hydrocarbons. The standard incubations for the hydroxylation assay of fatty acids and 1-dodecanol contained microsomes (80–100 μg protein), 100 μmol potassium phosphate (buffer A, pH 7.5), 0.25 μmol NADPH and 30 nmol (4.7–5.3 × 10^4 cpm) of the appropriate ^{14}C-labeled fatty acids (added as the potassium salt) or 1-

[1]Presented in part at the AOCS annual meeting (a joint meeting with the Japan Oil Chemists' Society), Honolulu, Hawaii, May 1986.

Abbreviations: PCMB, *p*-chloromercuribenzoate; SDS, sodium dodecylsulfate.

dodecanol. The final volume was 0.5 ml, and the incubation was 10 min at 37 C. Since the hydroxylase activity of 1-hexadecanol and hydrocarbons was low, the incubation mixture contained a greater amount (0.6–1.0 mg) of microsomes, 200 μmol buffer A, 0.5 μmol NADPH and 100–200 nmol of [1-^{14}C]hexadecanol or hydrocarbons (final volume 1.0 ml). The hydroxylase activities of the fatty acids and alcohols were assayed by the same method as described previously (20,21). ^{14}C-Labeled products (1- and 2-dodecanols) formed by the incubation of the microsomes with [1-^{14}C]dodecane were removed from silica gel with 7% ether in hexane while the substrate was eluted with 3% ether in hexane. The radioactivity in each fraction was determined by scintillation counting to determine the percentage of hydroxylation. All experiments were done in duplicate.

Isolation and identification of ω- amd (ω-1)-hydroxy fatty acids and alcohols. The several procedures used for isolation and identification of reaction products [ω- and (ω-1)-hydroxy fatty acids and alcohols] have been described in detail previously (20,21). The procedures used for radio-gas chromatographic analyses of the O-acetyl derivatives of hydroxy fatty acids and alcohols have already been described (8,20,21). ^{14}C-Labeled 1- and 2-dodecanols formed by the incubation of the gerbil liver microsomes with [1-^{14}C]dodecane were also analyzed by radio-gas chromatography.

RESULTS

Hepatic microsomal electron transport components and hydroxylase activity of Mongolian gerbil. Since no information is available on hepatic microsomal enzyme activities in the Mongolian gerbil, the cytochrome P-450 and cytochrome b_5 contents, NADPH-cytochrome *c* reductase and NADH-cytochrome b_5 reductase activities and laurate hydroxylase activity were measured (Table 1). Body weight, liver weight and microsomal protein of the Mongolian gerbils are also shown in Table 1.

TABLE 1

Hepatic Microsomal Electron Transport Components and Fatty Acid Hydroxylation in The Mongolian Gerbil, *Meriones uniguiculatus*[a]

Body weight (g)	59 ± 5
Liver weight (g/100 g body weight)	4.57 ± 0.53
Microsomal protein (mg/g liver)	2.41 ± 0.51
Cytochrome P-450	
nmol/mg microsomal protein	1.60 ± 0.16
nmol/g liver	3.92 ± 0.62
Cytochome b_5 (nmol/mg microsomal protein)	0.79 ± 0.01
NADH-cytochrome *c* reduction (μmol/mg microsomal protein/min)	0.18 ± 0.02
NADPH-cytochrome b_5 reduction (μmol/mg microsomal protein/min)	5.38 ± 0.29
Laurate hydroxylation[b]	
nmol/mg microsomal protein/min	5.99 ± 0.66
nmol/nmol P-450/min	4.03 ± 0.55

[a]Each value is the mean ± S.D. for 8–10 male Mongolian gerbils.
[b]The sum of ω- and (ω-1)-hydroxylaurate formed.

Substrate specificity for hydroxylation. After it was found that [1-^{14}C]laurate could be hydroxylated by gerbil liver microsomes, other saturated fatty acids and an unsaturated fatty acid (oleic acid) were tested as substrates, and the radioactive polar products formed enzymatically were analyzed by thin-layer chromatography and radio-gas chromatography. Table 2 shows the effect of substrate chain length on hydroxylation and distribution of ω- and (ω-1)-hydroxy products of fatty acids. Several points should be noted: laurate was the most active substrate. The ω/ω-1-hydroxylation ratio increased with increasing carbon chain length of fatty acids from 8 to 12. However, the ratio is constant (0.69–0.75) for the fatty acids rang-

TABLE 2

Substrate Specificity of Fatty Acid Hydroxylation by Gerbil Liver Microsomes

Saturated fatty acids (chain length)	Hydroxylation activity (nmol/mg microsomal protein/min)	Distribution of hydroxy isomers (%)		ω/ω-1-Hydroxylation
		ω	ω-1	
8	1.02 (17)[a]	7	93	0.075
10	2.70 (45)	16	84	0.19
12	5.99 (100)	51	49	1.04
13	4.79 (80)	43	57	0.75
14	4.91 (82)	43	57	0.75
16	3.17 (53)	41	59	0.69
18	1.20 (20)	43	57	0.75
18:1[b] (oleic acid)	3.83 (64)	43	57	0.75

[a]Values in parentheses are percentages of the specific activity of laurate hydroxylation.
[b]18:1 gave unknown products (0.92 nmol/mg microsomal protein/min) besides ω- and (ω-1)-hydroxy isomers. The products were not counted in the hydroxylation activity of 18:1.

TABLE 3

Hydroxylation Activity with Various Substrates in Gerbil Liver Microsomes

Substrate	Relative hydroxylation activity	Distribution of hydroxy isomers (%)	
		ω	ω-1
1-Dodecanol	78	56	44
Dodecane	6	89	11
Lauric acid	100[a]	52	48
1-Hexadecanol	6	53	47
Hexadecane	0	—	—
Palmitic acid	53	41	59

[a]Actual hydroxylation activity: 5.42 nmol/mg microsomal protein/min.

ing in chain length from 13 to 18 carbons. The hydroxylation activity of oleic acid was higher than that of its saturated analog (stearic acid), but the ω/ω-1-hydroxylation ratio for oleate was the same as that for stearate. Since fatty acids were effectively hydroxylated by gerbil liver microsomes, analogs such as fatty alcohols and hydrocarbons were also tested (Table 3). The hydroxylation activity of 1-dodecanol (lauryl alcohol) was high, but the activity of dodecane and 1-hexadecanol was much lower than that of 1-dodecanol or lauric acid. Hexadecane was not hydroxylated by gerbil liver microsomes.

Properties of the microsomal laurate hydroxylation. Since it was found that laurate was the most favored substrate among several fatty acids and alcohols, various properties of laurate hydroxylase of gerbil liver microsomes were investigated. The rate of ω- and (ω-1)-hydroxylation of laurate was linear with microsomal protein concentrations up to 180 μg for ω-hydroxylation and 200 μg for (ω-1)-hydroxylation (Fig. 1) and with time for about 15 min for ω-hydroxylation and 25 min for (ω-1)-hydroxylation (Fig. 2). The variation of hydroxylation activity with pH was determined (Fig. 3), and pH optimum was

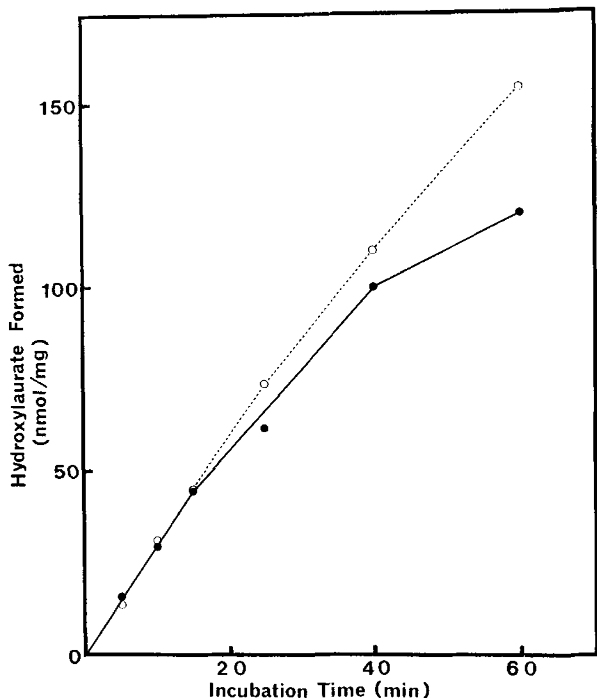

FIG. 2. Effect of time on rate of laurate hydroxylation by gerbil liver microsomes. The amount of microsomal protein was 98 μg. ●, ω-Hydroxylation; ○, (ω-1)-hydroxylation.

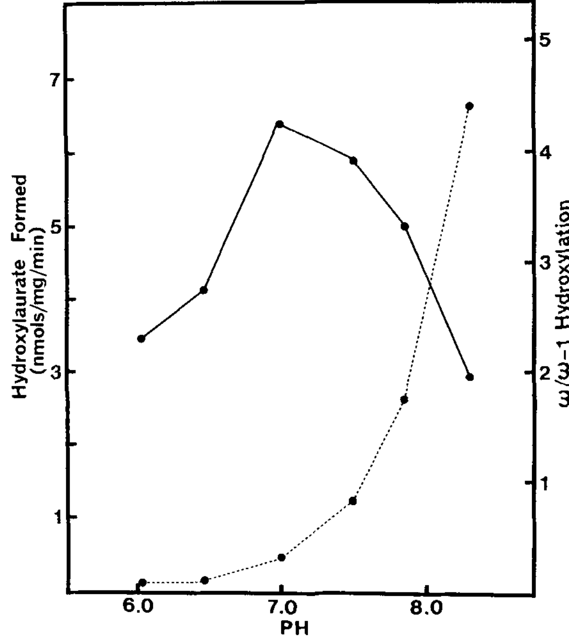

FIG. 3. Effect of pH on laurate hydroxylation by gerbil liver microsomes. The amount of microsomal protein was 114 μg. Solid line, total hydroxylation (the sum of ω- and [ω-1]-hydroxylation); dashed line, ω/ω-1-hydroxylation ratio.

TABLE 4

Effect of Reduced Pyridine Nucleotides on Laurate Hydroxylation by Gerbil Liver Microsomes

Reduced pyridine nucleotide	Relative hydroxylation activity	Distribution of hydroxy isomers (%)	
		ω	ω-1
NADH (50 μM)	8	8	92
NADH (100 μM)	16	8	92
NADH (500 μM)	25	26	74
NADPH (50 μM)	42	49	51
NADPH (500 μM)	100[a]	52	48
NADH (500 μM)			
+ NADPH (50 μM)	44	50	50
+ NADPH (500 μM)	102	54	46
None	4	—	—
NADPH (500 μM), anaerobic (helium)	9	37	63

[a]Actual hydroxylation activity: 6.70 nmol/mg microsomal protein/min.

observed at pH 7.0, but there was no significant difference in activity at pH 7.5. The ω/ω-1-hydroxylation ration increased with increasing pH.

The requirements of reduced pyridine nucleotides for laurate hydroxylation are shown in Table 4. NADPH was the preferred electron donor. NADH had little effect at 50 μM, but it showed 25% of the activity of NADPH (500 μM) at 500μM. When NADH was used for an electron donor, the percentage of the (ω-1)-hydroxy isomer was much greater than that of ω-hydroxy isomer. However, the percentage of the ω- and (ω-1)-hydroxy isomers was almost equal when NADPH was used as an electron donor. Although NADH was added together with NADPH, a synergistic effect of NADH was not observed. Molecular oxygen was also required for the hydroxylation of laurate.

Since laurate and 1-dodecanol has a similar hydroxylase activity, the data were plotted by the method of Lineweaver-Burk, and kinetic parameters for ω- and (ω-1)-hydroxy derivatives of lauric acid and 1-dodecanol were obtained. The apparent Km values for ω- and (ω-1)-hydroxylauric acid were 1.3×10^{-5} M and 3.5×10^{-5} M, respectively, and for ω- and (ω-1)-hydroxydodecanol were 9.1×10^{-5} M and 8.7×10^{-5} M, respectively. The Vmax for ω- and (ω-1)-hydroxylation of lauric acid were 2.84 and 2.67 nmol/mg microsomal protein/min, respectively, and for ω- for (ω-1)-hydroxylation of 1-dodecanol were 2.56 and 2.02 nmol/mg microsomal protein/min, respectively. Table 5 shows the effect of inhibitors on laurate hydroxylation activity. Carbon monoxide and PCMB strongly inhibited the total hydroxylation (the sum of ω- and [ω-1]-hydroxylation). Iodoacetate (0.1 mM), SKF 525A (1 mM), KCN (2 mM), menadione (0.01 mM) and NaN_3 (1 mM) inhibited total hydroxylation by 23%, 43%, 34%, 69% and 42%, respectively. Metyrapone did not inhibit the hydroxylation. Although iodoacetate, SKF 525A, KCN and menadione inhibited the total hydroxylation, they did not change the ω/ω-1-hydroxylation ratio (Table 5). On the other hand, PCMB and carbon monoxide were more inhibitory to the ω-hydroxylation of laurate than the (ω-)-hydroxylation, while NaN_3 was more inhibitory to the (ω-1)-hydroxylation than to the ω-hydroxylation. Although, 7,8-benzoflavone had almost no effect on the total hydroxylation, it showed a somewhat stimulatory effect on the ω-hydroxylation but an inhibitory effect on the (ω-1)-hydroxylation.

As detergents are often used for stimulation requirement of hydroxylation reaction by liver microsomes of various species, the effect of detergents on the laurate

TABLE 5

Effect of Inhibitors on Laurate Hydroxylation by Gerbil Liver Microsomes

Inhibitor	Laurate hydroxylation activity (nmol/mg microsomal protein/min)			ω/ω-1-Hydroxylation

[c]Sodium dodecylsulfate.
[d]Deoxycholate.

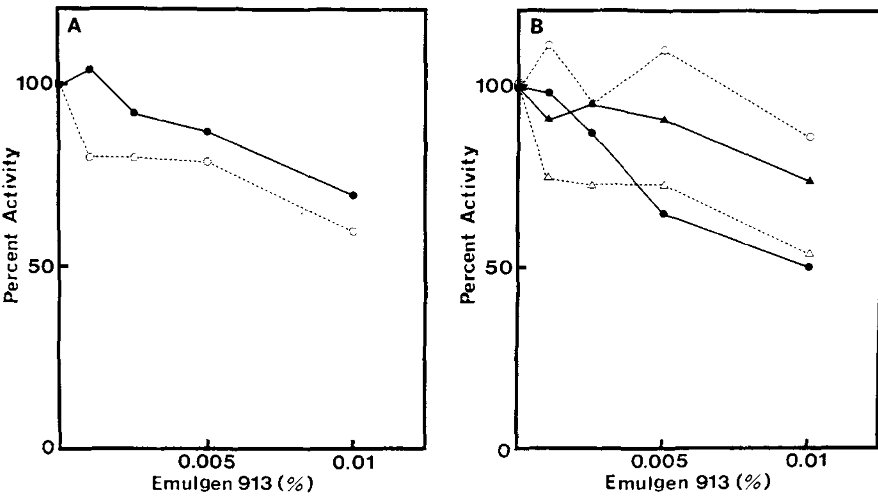

FIG. 4. Effect of Emulgen 913 on laurate hydroxylation activity of gerbil and rat liver microsomes. Experiment A: ●, gerbil; ○, rat. Experiment B: ●, ω-hydroxylation and ○, (ω-1)-hydroxylation by gerbil liver microsomes. ▲, ω-hydroxylation and △, (ω-1)-hydroxylation by rat liver microsomes. The amount of microsomal protein was 175 μg for both microsomes.

hydroxylation by gerbil liver microsomes was examined (Table 6). All the detergents were inhibitory to the total hydroxylation rather than stimulative to that. Sodium dodecylsulfate (SDS) was the most potent inhibitor. SDS and sodium cholate were inhibitory to the ω-hydroxylation of laurate than to the (ω-1)-hydroxylation. However, sodium deoxycholate, Emulgen 913, Triton X-100 and Tween 20 were inhibitory only to the ω-hydroxylation.

Since Emulgen 913 has been used for several studies on cytochrome P-450 (15,22,23), its effect on the laurate hydroxylase system in gerbil and rat liver microsomes was compared (Figs. 4A and 4B). Emulgen 913 was more inhibitory to the total activity of laurate hydroxylation by rat liver microsomes than to that by gerbil liver microsomes. However, Emulgen 913 had almost no inhibitory effect on the (ω-1)-hydroxylation by gerbil liver microsomes and the ω-hydroxylation by rat liver microsomes, but it was inhibitory to the ω-hydroxylation by gerbil liver microsomes and the (ω-1)-hydroxylation by rat liver microsomes.

DISCUSSION

Although several studies on lipid biochemistry of the Mongolian gebils have been reported in recent years (cf. the introduction), no information is available concerning their hepatic microsomal electron transport components or fatty acid–hydroxylating system. In this study, we in-

TABLE 7

Hydroxylation Activity of Fatty Acids by Various Microsomes (MS)

[a]Values in parentheses are percentages of the specific activity to gerbil liver microsomes.

vestigated various properties of the fatty acid– and alcohol-hydroxylating systems from the liver microsomes of the animals. The content of cytochrome P-450 (1.60α0.16 nmol/mg microsomal protein) in liver microsomes from the Mongolian gerbils is somewhat higher than that (0.87–1.22 nmol/mg microsomal protein) in male rat liver microsomes (24,25), but NADPH-cytochrome *c* reductase activity in the Mongolian gerbils is lower than that in male rat (24,25). The content of cytochrome b_5 in the gerbil liver microsomes is somewhat higher than that in male rat liver microsomes (24). Our present work demonstrated that gerbil liver microsomes, like the liver microsomes of other species, catalyzed the hydroxylation of fatty acids only at the ω- and (ω-1)-positions. Hydroxy isomers such as α-, β, (ω-2)- or (ω-3)-hydroxylaurates were not formed by gerbil liver microsomes. It was also demonstrated that the fatty acid hydroxylase in gerbil liver microsomes is a typical cytochrome P-450-dependent monooxygenase, because carbon monoxide, PCMB and SKF 525A are potent inhibitors of laurate hydroxylation, and molecular oxygen and NADPH were required for the hydroxylation. However, several characteristics of data in this study should be noted. First, the specific activity of fatty acid hydroxylation in gerbil liver microsomes is higher than that in other species except the shrew (*S. murinus*) (Table 7). We have reported already that hydroxylation activity of fatty acids in the liver microsomes of the shrew is much higher than that in other species (8). Thus, our previous and present results demonstrated that a cytochrome P-450 monooxygenase system in the liver microsomes of laboratory animals such as the shrew or the Mongolian gerbil catalyzed specifically the hydroxylation of fatty acids to a high extent. Secondly, the hydroxylation activity of 1-dodecanol (lauryl alcohol) is similar to that of lauric acid. Although the hydroxylation activity for fatty alcohols was much lower than that for the corresponding acids (21,27), it was found in this study that a cytochrome P-450 monooxygenase system in gerbil liver microsomes catalyzed specifically the hydroxylation of 1-dodecanol to a higher extent. Further experimental work is needed to definitively answer the question of why the hydroxylation activity of 1-dodecanol is markedly high in gerbil liver microsomes.

Since alcohol and aldehyde dehydrogenases are involved in the liver microsomes (21,28–30), a significant amount of fatty alcohols was comverted to fatty acids during the incubation of fatty alcohols with liver microsomes from various species (21,29). When 1-dodecanol or hexadecanol was incubated with gerbil liver microsomes, the conversion rate of 1-dodecanol to lauric acid was lower than that for liver microsomes of other species (data not shown), and 1-hexadecanol was not converted to palmitic acid. This suggests that dehydrogenase in gerbil liver microsomes is less active towards fatty alcohols.

Finally, the fact that the ω/ω-1-hydroxylation ration increased for the fatty acids ranging in chain length from 8 to 12 and is constant for fatty acids for which chain lengths were from 13 to 18 carbon atoms suggests that more than two cytochrome P-450 species in gerbil liver microsomes are involved in hydroxylation of fatty acids at ω- and (ω-1)-positions. The inhibitory study using PCMB, CO, NaN_3 and 7,8-benzoflavone suggests also the involvement of different cytochrome P-450 species in the ω- and (ω-1)-hydroxylation of lauric acid in gerbil liver microsomes because the ω/ω-1-hydroxylation ratios were changed. A similar result was reported for the laurate hydroxylation by frog liver microsomes (31). The fact that the detergents showed different effects on the ω- and (ω-1)-hydroxylation activity of laurate suggests also that gerbil liver microsomes contain different cytochrome P-450 species catalyzing the ω- and (ω-1)-hydroxylation of laurate. However, further experimental work is needed to elucidate the involvement of different cytochrome P-450 species in fatty acid hydroxylation. It has been reported previously that hepatic microsomal cytochrome P-450-dependent monooxygenases from different sources (15) or other enzyme systems (32) had different responses to detergents. A similar result was observed in our study; the hydroxylase system in gerbil liver microsomes is less susceptible to inhibition by Emulgen 913 in the assay of laurate hydroxylation than the hydroxylase system in rat liver microsomes. Thus,it was found in this study that the microsomal hydroxylase system in gerbil liver has several unique features.

[Received March 6, 1987]

Intake of Different Eicosapentaenoic Acid–Containing Lipids and Fatty Acid Pattern of Plasma Lipids in the Rats

Tomohito Hamazaki[a,*], Masaharu Urakaze[a], Masahiro Makuta[b], Akio Ozawa[b], Yasuji Soda[c], Hiroshi Tatsumi[c], Saburo Yano[a] and Akira Kumagai[d]

[a]1st Department of Internal Medicine, Toyama Medical and Pharmaceutical University, Toyama City, Japan; [b]Central Research Laboratory, Nippon Suisan Kaisha, Ltd., Hachioji City, Tokyo, Japan; [c]Medical and Pharmaceutical Laboratory, Nippon Shoji Co., Ltd., Ibaraki City, Osaka, Japan; and [d]Toyama Medical and Pharmaceutical University, Toyoma City, Japan

The ethyl ester of eicosapentaenoic acid (EPA) is the only pure EPA-containing lipid available in bulk for oral administration. However, there is doubt as to whether EPA ethyl ester can efficiently increase the plasma levels of EPA in comparison with the ability of other kinds of EPA-containing lipids to do so. Therefore, two other kinds of EPA-containing lipids were prepared to study the efficiency of oral administration of those lipids for increasing the EPA content in plasma phospholipids and cholesteryl esters. EPA-containing lipids which were investigated were [A] 1,2,3-trieicosapentaenoyl-glycerol, [B] 2-eicosapentaenoyl-phosphatidylcholine and [C] ethyl ester of EPA. An adjusted amount of lipids [A], [B] and [C] was administered to rats through a gastric tube for 4 days (the first experiment) or for 10 days (the second experiment), and the fatty acid composition of plasma phospholipids and cholesteryl esters was determined. In the first experiment, there were no significant differences in the efficiency for increasing EPA levels in either phospholipids or cholesteryl esters among the lipids. In the second experiment, the EPA levels of both plasma phospholipids and cholesteryl esters of rats administered ethyl ester of EPA were significantly higher than those of rats administered 2-eicosapentaenoyl-phosphatidylcholine. The EPA levels of the rats administered 1,2,3-trieicosapentaenoyl-glycerol were between the levels of the two groups mentioned above, but the differences in the EPA levels were not significant. Although an ethyl ester–type molecule is not a naturally occurring lipid, ethyl ester of EPA is equal to 1,2,3-trieicosapentaenoyl-glycerol and appears to be superior to 2-eicosapentaenoyl-phosphatidylcholine as to the efficiency for increasing EPA levels in total plasma phospholipids and plasma cholesteryl esters.

***Lipids 22,* 994–998 (1987).**

Beginning with epidemiological studies by Bang and Dyerberg in Greenland (1,2), many papers have indicated that fish oil has antiatherosclerotic features (3–10). The active components in fish oil are said to be ω3 fatty acids, among which eicosapentaenoic acid (EPA) has been most investigated. Some clinical trials with ethyl ester (EE) of EPA have been performed (11,12), and others are underway to develop EPA as a drug. At present, EE type is the only pure (~ 90%) EPA-containing molecule available in bulk for oral administration experiments on humans or other animals.

Because EE was not a natural product, we thought that it might not be absorbed very well and that some other natural types of lipid molecule containing EPA might be better in terms of absorption and utilization efficiency. The purpose of this study was to compare the efficiency for increasing EPA levels in plasma phospholipids (PL) and cholesteryl esters (CE) of different EPA-containing lipid molecules.

MATERIALS AND METHODS

Materials. Feeding experiments were performed using the following lipids: [A] 1,2,3-trieicosapentaenoyl-glycerol (EPA-TG); [B] 2-eicosapentaenoyl-phosphatidylcholine (EPA-PC); and [C] ethyl ester of EPA (EPA-EE). EPA-EE was obtained as described previously (13) with slight modifications. EPA-TG was made by chemical condensation of glycerol and 90% pure free EPA, which was obtained by hydrolysis of EPA-EE. EPA-PC was also made by chemical condensation of free EPA and enzymatically prepared lysophosphatidylcholine from soybean PC. Incomplete reaction products of these materials were separated by silica gel columns. Fatty acid analysis of the lipids mentioned above is shown in Table 1. Lipids [A] to [C] contained α-tocopherol (0.2%, w/w) as an antioxidant.

Feeding experiments 1 and 2. In Experiment 1, 18 male Wistar rats weighing about 500 g, which had been fed on the lipid-free powder diet (Funabashi Farm, Chiba) for 20 days, were divided into four groups (A, B, C and D). All rats were given free access to the same diet throughout the experiment. Rats of groups A, B and C were administered EPA (400 mg/kg/day) in the form of a lipid suspension (~ 5 ml) through a gastric tube for four days. The suspensions of groups A, B and C were suspensions of EPA-TG, EPA-PC and EPA-EE, respectively. Rats of group D were administered water (~ 5 ml) containing no lipids. Blood samples were obtained from the abdominal aorta under ether anesthesia one day after the last administration of the lipid suspension or water. Experiment 2 was performed in the same way as experiment 1, except that rats were administered EPA or water for 10 days.

Platelet aggregation and fatty acid analysis. A platelet aggregation study was performed with a PAT-4M aggregometer (Niko Bioscience, Tokyo) on platelet-rich plasma obtained by centrifugation of citrated blood with

EPA-TG, 1,2,3-trieicosapentaenoyl-glycerol; EPA-PC, 2-eicosapentaenoyl-phosphatidylcholine; EPA-EE, ethyl ester of eicosapentaenoicd acid.

[a]Rats were administered adjusted amounts of a suspension containing one of the lipids shown above (400 mg of EPA/kg/day) or water through a gastric tube for four days, while they were fed on a synthetic lipid-free diet. SD is shown in the parentheses. Values with the same superscript in common are significantly different from each other.

[b]$p < 0.05$.

[c]$p < 0.01$.

[d(d')]$p < 0.001$.

1/10 volume of 3.8% citrate, using collagen (10 μg/ml) and ADP (5 μM) as aggregants. For fatty acid analysis, plasma was obtained from EDTA-anticoagulated blood. The fatty acid composition in plasma total PL and CE was measured according to the method of Lasserre (14), with slight modifications. Briefly, plasma lipids were extracted with chloroform/methanol (2:1, v/v). Lipids were then separated using a Bond Elut column (Analytichem International, Harbor City, CA) (15) to get the PL fraction. The CE fraction was further separated on a silica gel plate. Fatty acids in these fractions were transmethylated by BF_3. An Advance-DS capillary column, measuring 0.24 mm × 25 m (Shinwakagaku, Kyoto), was used to analyze fatty acid methyl ester. The column was attached to a GC7A gas choromatograph (Shimadzu, Kyoto). The injection was at 250 C; separation with N_2 gas as a carrier (40 ml/min) was isothermal at 200 C; detection was by flame ionization.

Total PL and CE were measured enzymatically with a Hitachi Autoanalyzer 716 (Tokyo). Analysis of variance and Scheffe's s-test were used to detect significant variations among the groups and to compare two dietary groups, respectively. The difference between experiments 1 and 2 within the same dietary group was analyzed by Student's t-test. Data were expressed as mean ± SD.

RESULTS

Feeding experiment 1. One of the group C rats died on the third day of the diet because of trauma in the esophagus during the intubation. Otherwise, there were no significant changes in body weight during the experiment. The percentage composition of major fatty acids in plasma total PL and CE is shown in Tables 2

and 3, respectively. There were no differences in plasma PL and CE levels among the four groups (data not shown). There were no significant differences in the major fatty acid composition among groups A, B and C either in plasma PL or CE. There were no significant differences in platelet aggregation induced either by collagen or by ADP among the groups (data not shown).

Feeding experiment 2. There was a slight increase in body weight (~ 10 g) in groups A, C and D, but no changes in group B. There were no significant differences in the changes of body weight among the four groups. The percentage composition of major fatty acids in plasma total PL and CE is shown in Tables 4 and 5, respectively. There were no differences in plasma PL and CE levels among the four groups (data not shown). In plasma total PL fraction for Groups A, B and C, 18:2 fatty acid was significantly higher in group B than in group C; EPA was significantly higher in group C than

TABLE 6

Summary of Short-term Feeding Experiments in Rats and Humans[a]

		EPA				
Ref	Source	Amount in diet	Daily dose/kg[b]	Feeding period[c]	Used Fraction for fatty acid analysis[d]	Changes in EPA (%)
Rat experiments						
16	Fish oil	1% fish oil	100 mg/kg	2 wk	Plasma PL	0 to 3.46
		5% fish oil	500 mg/kg	2 wk	Plasma PL	0 to 8.53
17	MaxEPA	10% fish oil	120 mg/kg	2 wk	Total plasma lipids	0 to 8.4
18	EPA-EE	3%EPA-EE	3000 mg/kg	10 days	Total serum lipids	0 to 11.5
Human trials						
19	MaxEPA	20 ml	~ 50 mg/kg	2 wk	Plasma PC	1.5 to 6.7
20	Mackerel	2 cans	~ 30 mg/kg (2.2 g EPA/day)	2 wk	Serum CE	1.5 to 10.9
	Herring	2 cans	~ 14 mg/kg (1.0 g EPA/day)	2 wk	Serum CE	1.9 to 8.2
21	Mackerel	750 g	140-210 mg/kg (10–15 g EPA/day)	3 days	Plasma PL	1.1 to 12.2
22	Cod liver oil	15 ml	~ 19 mg/kg	2 wk	Plasma PL	0.8 to 3.8
					Plasma CE	0.7 to 3.1
23	EPA-EE	6 g	~ 90 mg/kg	6 days	Plasma PL	1.4 to 7.6

[a]Feeding experiments, the periods of which are not more than 2 weeks, are listed.
[b]Daily dose/kg was estimated by assuming that rats ate about 1/10 as much diets as their own body weight or that the human body weight was 70 kg.
[c]Some experiments have a longer feeding period (not shown in this table) besides the listed period.
[d]Some fractions other than PL and CE are omitted.
EPA, eicosapentaenoic acid; PL, phospholipids; EE, ethyl ester; PC, phosphatidylcholine; CE, cholesteryl ester; PL phospholipids.

in group B. In the plasma CE fraction for groups A, B and C, arachidonic acid (AA) was significantly higher in group B than in group C; EPA was significantly higher in group C than in group B. There were no significant differences in platelet aggregation induced either by collagen (group A, 58.7 ± 10.7; B, 61.0 ± 6.2; C, 59.5 ±2.5; D, 61.0 ± 7.3, expressed as % maximum aggregation) or by ADP (A, 56.0 ± 4.6; B, 60.5 ± 5.9; C, 54.0 ± 6.9; D, 58.7 ± 4.0).

DISCUSSION

Details of some feeding experiments with fish oil or EPA are shown in Table 6. In all the experiments listed the blood EPA levels were determined within 2 wk of the start of EPA feeding. The increases in the EPA levels in these experiments with rats (16–18) were all bigger than that of the present study. This discrepancy may be partially explained by the difference in feeding periods and used fractions for fatty acid analysis. However, the major difference seems to consist in the materials used for feeding EPA. We administered pure EPA suspensions. In the experiments of references 16 and 17, fish oil was used, and it contained 25.6% and 9% of DHA respectively. Because DHA is known to increase the plasma PL levels of EPA, probably by the retroconversion of DHA (23), direct comparison of EPA contained in fish oil and pure EPA for ability to increase the blood levels of EPA is difficult. Although a pure EPA-EE was used in case of reference 18, the estimated daily dose of EPA was too high (~3000 mg/kg) to compare with ours (400 mg/kg). It is also possible that EPA mixed in a diet (16–18) may be absorbed and utilized better than that of water suspension, which is administered through a gastric tube like in the present study, although an accurate amount of EPA can be administered in this method.

In experiment 1, three EPA-containing lipids produced essentially the same effect on the composition of major fatty acids either in the fraction of plasma PL (Table 2) or in that of CE (Table 3). As a result of the extension of EPA administration to 10 days, the EPA levels of both plasma PL and CE of group C became significantly higher than those of group B (Tables 4 and 5). The EPA levels of group A were between the levels of the two groups mentioned above. Although an ethyl ester–type molecule is not a naturally occurring lipid, ethyl ester of EPA is equal to EPA-TG and appears to be superior to EPA-PC with regard to the efficiency for increasing EPA levels in plasma PL and CE in rats.

Among the EPA-containing lipids used in the present study, EPA-PC was the only lipid that contained 18:2 fatty acid, and the content of this fatty acid was about half as much as that of EPA in the lipid (Table 1). Therefore, the increment in 18:2 fatty acid (Table 4) and AA (Table 5), a converted fatty acid of 18:2 fatty acid, in group B probably caused a depression of the EPA levels compared to group C.

It is known that platelet aggregation of rats is seldom depressed by the administration of fish oil or EPA; only one out of five papers reported depressed platelet aggregation by EPA feeding (24). Therefore, it is not surprising that in the present two experiments we could not observe any significant depression of platelet aggregation by EPA-containing lipids.

As can be seen from Table 6, there is an important species difference between rats and humans. The EPA levels in humans can be increased with much smaller doses of EPA than in rats. Therefore, the efficiency of EPA-EE for increasing EPA levels in plasma in humans by comparison with other EPA-containing lipids remaining to be studied.

ACKNOWLEDGMENT

The authors are grateful to Akiya Kizu and Akimi Takashima for their excellent technical help.

[Received January 27, 1986]

Properties of Monoacylglycerol Lipase in Rabbit Aorta

Mariette Hee-Cheong and David L. Severson*
Department of Pharmacology and Therapeutics, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 4N1

Monoacylglycerol lipase activity was characterized in a soluble preparation from rabbit aorta (intima-media) obtained by combining a 100,000 × g supernatant fraction with activity solubilized from the 100,000 × g precipitate fraction by treatment with Triton X-100. Rates of hydrolysis with 1-monoolein and 2-monoolein substrates were nearly identical. 1-Monoolein was a competitive inhibitor (Ki 65 μM) of 2-monoolein hydrolysis. 2-Monoolein and 2-monopalmitin were both hydrolyzed more rapidly than 2-monoarachidonin. Lipase activity measured with a 2-monoolein substrate was inhibited by the addition of oleate, NaF and $CaCl_2$ to the assay. Preincubation of the lipase preparation with p-bromophenacyl bromide resulted in a potent inhibition of lipase activity; this inhibition could be prevented by dithiothreitol.
Lipids 22, 999–1004 (1987).

The receptor-mediated breakdown of phosphatidylinositol and the polyphosphoinositides plays an important role in signal transduction (1-3). The diacylglycerol (DG) generated by the phosphoinositide-specific phospholipase C reaction can activate protein kinase C and thus influence cell function (2,3). The metabolism of released DG will result in the termination of this signal. DG can be phosphorylated to form phosphatidic acid (kinase activity) or be hydrolyzed (lipase activity) to release the fatty acids from the *sn*-1 and *sn*-2 positions (2). Since arachidonic acid is the predominant fatty acid in the *sn*-2 position of the DG released from the phosphoinositides, the lipase pathway can provide the arachidonic acid precursor necessary for the synthesis of prostanoids, which are also capable of regulating cell function (1,2). Prostanoids such as PGI_2 are important products of arachidonic acid metabolism in blood vessels (4), where they contribute to the regulation of interactions between platelets and the vessel wall (5).

Recently, we have measured DG kinase and lipase activities in aorta (6) and in coronary and brain microvessels (6,7). The hydrolysis of DG by particulate and soluble subcellular fractions from rabbit aorta (intima-media) proceeded by an ordered two-step reaction sequence in which the fatty acid at the *sn*-1 position of the 1,2-DG substrate was released first, followed by the hydrolysis of the fatty acid from the 2-monoacylglycerol (2-MG) intermediate (6). Evidence for this reaction sequence has also been obtained with platelets (8,9) and decidua vera tissue (10). Since it is a 2-MG lipase activity that actually catalyzes the release of arachidonic acid in the phospholipase C-DG lipase pathway, the objective of the present investigation was to further characterize this enzyme, with respect to substrate specificity and regulation, in preparations from rabbit aorta.

MATERIALS AND METHODS

Materials. [^{3}H]Triolein (glycerol tri[9,10-^{3}H(N)]oleate), [^{14}C]tripalmitin (glycerol tri[1-^{14}C]palmitate) and 1-stearoyl-2[1-^{14}C]arachidonoyl-*sn*-glycero-3-phosphocholine were purchased from Amersham Canada (Oakville, Ontario). 1-[1-^{14}C]Monoolein (1-[^{14}C]monooleoylglycerol) was obtained from RoseChem (Los Angeles, CA). 1-Palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycerol was synthesized as described by Hee-Cheong et al. (7). Unlabeled lipids (1-stearoyl-2-arachidonoyl-*sn*-glycerol, 1-palmitoyl-2-oleoyl-*sn*-glycerol, 1-monoolein, 2-monoolein, 2-monopalmitin, oleic acid and pig brain phosphatidylserine) were obtained from Serdary Research Laboratories (London, Ontario). Essentially fatty acid-free bovine albumin was purchased from Sigma Chemical Co. (St. Louis, MO).

Enzyme preparation. The intima-media fraction was dissected from rabbit aortas (Pel-Freez Biochemicals, Rogers, AR) and homogenized as detailed previously (6). Following centrifugation at 1,000 × g, the low-speed supernatant fraction was centrifuged at 100,000 × g to yield soluble and particulate fractions. The particulate fraction was resuspended in a solution consisting of 0.25 M sucrose, 1 mM EDTA, 1 mM DTT (dithiothreitol) and 10 mM HEPES (N-2-hydroxyethyl-piperazine-N′-2-ethane sulfonic acid), pH 7.5. Triton X-100 was added to a final concentration of 1 mM and after 5 min at 4 C, the sample was sonicated for 30 sec and centrifuged at 100,000 × g for 60 min. This supernatant fraction was added to the first soluble fraction, and the combined solution was concentrated by vacuum dialysis. The protein content of the concentrated fraction was usually 5-6 mg/ml (11).

Preparation of substrates. 2-[^{3}H]Monoolein (2-[^{3}H]monooleoylglycerol) was isolated following the incubation of [^{3}H]triolein with pancreatic lipase as described by Severson and Hee-Cheong (6). The radiolabeled 1-monoolein and 2-monoolein compounds were subjected to thin layer chromatography (TLC) on glass Silica Gel G plates impregnated with 10% (w/w) boric acid (12) to monitor acyl migration of the label. After development in a solvent system consisting of chloroform/methanol (98:2, v/v), the monoacylglycerols were clearly separated with Rf values of 0.43 and 0.66 for the 1- and 2-monooleins, respectively. The synthesized 2-[^{3}H]monoolein was quite stable; 82% of the radioactivity was present as 2-monoolein when monitored after three months of storage in hexane at −20 C. 2-[^{14}C]Monopalmitin (2-[^{14}C]monopalmitoylglycerol) was prepared from [^{14}C]tripalmitin following incubation with pancreatic lipase (6). The 2-monoolein and 2-monopalmitin substrates were adjusted to a specific activity of 1000 DPM/nmol with the addition of the appropriate unlabeled monoacylglycerol. 2-[^{14}C]Monoarachidonin (2-[^{14}C]monoarachidonoylglycerol) was synthesized in two steps. First, 1-stearoyl-2-[^{14}C]arachidonoyl-*sn*-glycerol was prepared by the hydrolysis of 1-stearoyl-2-[^{14}C]arachidonoyl-*sn*-glycero-3-phosphocholine by phos-

Abbreviations: DG, diacylglycerol; 2-MG, 2-monoacylglycerol; DTT, dithiothreitol; TLC, thin layer chromatography; BPB, p-bromophenacyl bromide; PMSF, phenylmethylsulfonyl fluoride

pholipase C (7). The specific activity of the radiolabeled DG was adjusted to 1000 DPM/nmol with the addition of unlabeled 1-stearoyl-2-arachidonoyl-*sn*-glycerol, and 2-[^{14}C]monoarachidonin was then isolated following incubation with pancreatic lipase (6).

Enzyme assays. Emulsions of the monoacylglycerol substrates were prepared by sonication essentially as described by Severson and Hee-Cheong (6). Unless noted otherwise, the standard 2-MG lipase assay was performed as follows. An appropriate quantity of 2-[^{3}H]monoolein (4 nmol/μl of hexane) was dried under N_2 and then sonicated for 30 sec (75 W; BraunSonic 1510 sonicator) in 0.005% Triton X-100. A substrate mixture was prepared by diluting the emulsion with 0.25 M phosphate buffer (pH 7). Lipase assays (0.5 ml final volume) contained 80 μM 2-[^{3}H]monoolein, 50 mM sodium phosphate (pH 7), 0.001% Triton X-100 and appropriate quantities of the soluble lipase preparation. Incubations were terminated after 20 min at 37 C, and the quantity of released [^{3}H]oleate was measured by scintillation spectrometry following liquid-liquid partitioning (6). A unit of lipase activity was arbitrarily defined as the amount of enzyme that catalyzed the release of 1 nmol of fatty acid in 1 hr at 37 C. In experiments where inhibitors were added to the lipase assay, the specific activity of the 2-monoolein substrate was increased to 2500 DPM/nmol.

Monoacylglycerol kinase activity was measured by adding 5 mM ATP and 10 mM $MgCl_2$ to the lipase assay mixture described above. After an incubation of 20 min, the assay was terminated by the addition of butanol (13). Following centrifugation, an aliquot of the clear upper phase (0.75 ml) was dried under N_2, resuspended in chloroform and then applied to glass TLC plates (Sil G-25). Lysophosphatidic acid was isolated after development of the plates with a solvent system (13) consisting of chloroform/methanol/7M ammonia (60:35:5, v/v/v).

Diacylglycerol kinase activity in particulate fractions from aorta (6) was measured as described previously (7), with the exception that the 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycerol substrate was prepared as a co-sonicate with phosphatidylserine (14); the final concentration of phosphatidylserine in the assay was 0.1 mM.

RESULTS

When the initial low-speed (1000 × g) supernatant fraction obtained from rabbit aorta (intima-media) homogenates was centrifuged at 100,000 × g, approximately half of the total recovered 2-MG lipase activity was particulate (6). Sonication of the resuspended particulate fraction in the presence of the nonionic detergent Triton X-100 resulted in the recovery of 65 ± 1% (mean ± SEM; n = 3) of the activity in the supernatant after centrifugation at 100,000 × g. The final specific activity for 2-MG lipase activity after combination of the first and second supernatant fractions and concentration was 325 Units/mg protein (mean of seven preparations), an increase of about 1.8-fold over the activity in the first high-speed supernatant fraction (6). Further attempts to purify the 2-MG lipase by a variety of chromatographic techniques (DEAE-Sephacel, CM-Sephadex, heparin-Sepharose, Ultrogel AcA-34) were unsuccessful in producing a significant increase in lipase specific activity. Therefore, characterization of the enzyme proceeded with this soluble fraction.

The positional specificity of aortic 2-MG lipase activity was examined by comparing rates of hydrolysis in assays with 1- and 2-monoolein substrate preparations (Fig. 1). The reaction rate for both substrates was reasonably linear with respect to time; the rate of hydrolysis of the 1-monoolein substrate was slightly greater than the hydrolysis of 2-monoolein. The presence of 1-monoolein resulted in a concentration-dependent inhibition of the hydrolysis of 2-monoolein (Fig. 2); a concentration of 200 μM 1-monoolein produced a 50% inhibition of aortic 2-MG lipase. The kinetic mechanism for the inhibition of 2-MG lipase activity by 1-monoolein was investigated (Fig. 3). The apparent Km for lipase activity measured with the 2-monoolein substrate was 53 μM. In the presence of 1-monoolein (200 μM or 500 μM), 2-MG lipase activity was inhibited in a competitive fashion (Fig. 3), with a calculated Ki of 65 μM. 1-Monoolein has been reported to inhibit DG kinase activity from pig brain (14). As shown in Figure 2, 1-monoolein also inhibited DG kinase activity in aortic microsomes; the inhibition of DG kinase activity was slightly greater than the inhibition of 2-MG lipase activity at all concentrations of 1-monoolein. No MG kinase activity could be detected in the soluble fraction used in this investigation when lipase assay incubations were modified by the addition of ATP and $MgCl_2$.

The substrate specificity of the lipase preparation for 2-monoacylglycerols was investigated next. As indicated in Figure 4, the relative rates of hydrolysis were 2-monopalmitin > 2-monoolein > 2-monoarachidonin. When a number of assay incubations where time or protein were varied were all considered (n = 14), lipase activity with 2-monoarachidonin as substrate was 71 ± 2% of the activity measured with 2-monoolein.

The sensitivity of aortic 2-MG lipase to product inhibition by oleate is shown in Figure 5. The addition of oleate directly to the assay produced a concentration-dependent inhibition of lipase activity; 50% inhibition occurred at

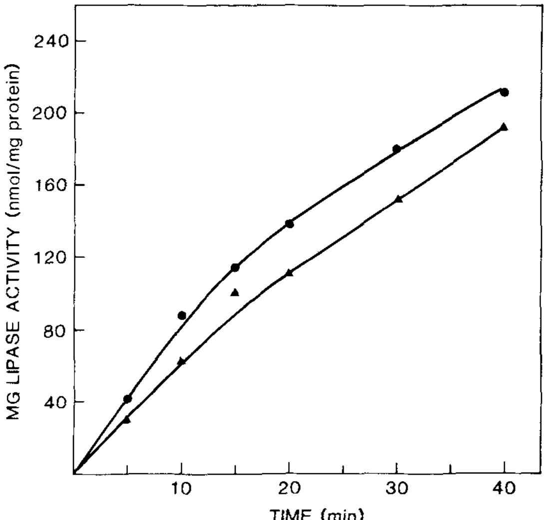

FIG. 1. Positional substrate specificity for aortic 2-monoacylglycerol (MG) lipase activity. The hydrolysis of 1-[^{14}C]monoolein (●) and 2-[^{3}H]monoolein (▲) substrates was determined at the indicated incubation times.

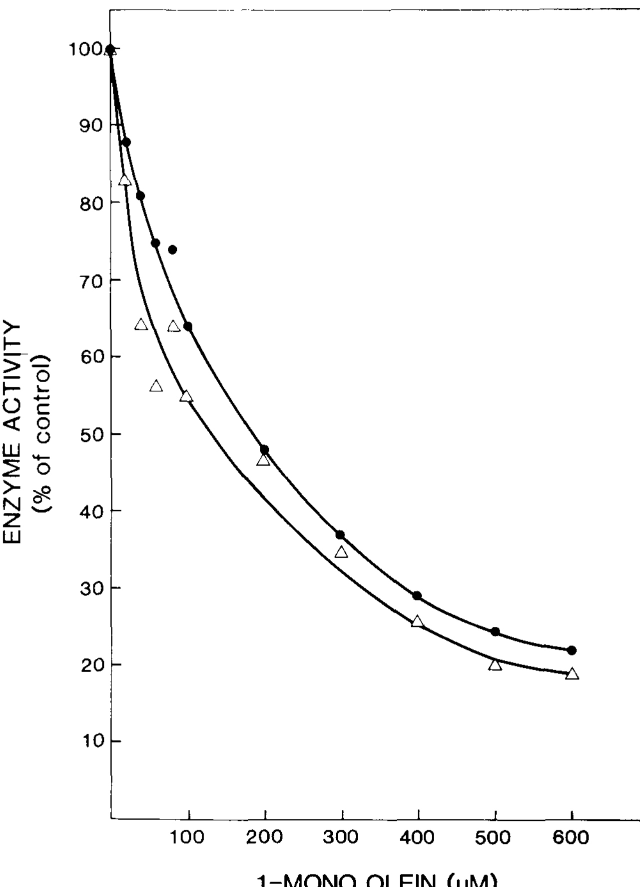

FIG. 2. Effect of 1-monoolein on aortic 2-monoacylglycerol (MG) lipase and diacylglycerol (DG) kinase activities. MG lipase activity (●) in the soluble aortic preparation (99 μg protein per assay; 100% = 301 Unit/mg protein) and DG kinase activity (△) in a microsomal preparation (60 μg protein per assay; 100% = 44.3 nmol phosphatidic acid formed/hr/mg protein) was measured in the presence of the indicated concentrations of 1-monoolein. A stock solution of 1-monoolein was prepared by sonication into 0.01% Triton X-100; activities are expressed as a percentage of control assays that contained the equivalent amount of detergent.

an oleate concentration of approximately 50 μM (panel A). The inhibition of 2-MG lipase activity due to the presence of 40 μM oleate could be prevented when albumin (0.05%, w/v) was also present in the assay (Fig. 5, panel B). Preincubation of the lipase preparation with oleate prior to the addition of the substrate mixture to initiate the assay produced no greater inhibition of lipase activity compared with the inhibition when the fatty acid was introduced directly to the assay incubation (results not shown). Albumin had no significant effect on lipase activity measured in the absence of oleate, presumably since the amount of oleate that would accumulate as the product under standard assay conditions (Figs. 1 and 4) would be less than 20 μM and thus would not appreciably inhibit lipase activity (Fig. 5).

2-MG lipase activity was inhibited by the addition of $CaCl_2$ to the assay (Fig. 6); 50% inhibition was observed at a concentration of 16 mM. Lipase activity was much less sensitive to inhibition by NaF where a concentration of 150 mM was necessary to produce 50% inhibition. By comparison, NaCl had no effect on lipase activity (Fig. 6).

Preincubation of the lipase preparation with p-bromophenacyl bromide (BPB) resulted in a concentration-dependent inhibition of 2-MG lipase activity (Fig. 7A). However, this inhibition could be prevented if DTT was also included in the preincubation (Fig. 7B). Preincubation with 500 μM phenylmethylsulfonyl fluoride (PMSF) for 20 min at room temperature also resulted in a reduction of lipase activity to 56% of control. 2-MG lipase activity was not significantly inhibited by the addition of 500 μM mepacrine or 200 μM indomethacin directly to the assay (results not shown).

DISCUSSION

The subcellular distribution of 2-MG lipase is tissue-specific, with activity reported to be either predominantly soluble in decidua vera (10) and adipose (15) tissues or mainly particulate in platelets (9). In the case of the aorta, 2-MG lipase activity was evenly distributed between soluble and particulate subcellular fractions (6), but a large fraction of the particulate activity could be solubilized with Triton X-100.

The apparent Km of 53 μM for the hydrolysis of 2-monoolein with the aortic lipase preparation is significantly less that other reported values ranging from 200 μM for the enzyme from adipose tissue (15) to 750 μM for the platelet 2-MG lipase (9); differences in the physical properties of the different substrate emulsions may contribute to these discrepancies. In previous work with a particulate fraction from rabbit aorta, an apparent Km of 83 μM was obtained for the release of the fatty acid from the *sn*-2 position of 1,2-DG (6). The soluble aortic lipase preparation demonstrated little or no positional substrate specificity when rates of hydrolysis were determined with 1- and 2-monoolein substrates (Fig. 1); similar results have been reported for MG lipases in platelet membranes (9) and for purified lipase preparations from adipose tissue (15) and intestinal mucosa (16).

This lack of positional specificity provides further evidence for the proposed two-step reaction sequence for the hydrolysis of 1,2-DG by aorta and microvessel preparations (6,7), since the accumulation of the 2-MG intermediate during incubations of 1,2-DG cannot be due to a preferential hydrolysis of 1-MG. The competitive inhibition of 2-MG lipase activity by 1-monoolein (Fig. 3) is evidence that the hydrolysis of both 1-monoolein and 2-monoolein is catalyzed by the same lipase. A concentration of approximately 200 μM 1-monoolein was required to produce a 50% inhibition of 2-MG lipase activity measured with 80 μM 2-monoolein as substrate (Fig. 2), even though rates of hydrolysis of both 1- and 2-monoolein were very similar when compared at a concentration of 80 μM (Fig. 1). This suggests that the affinity of the lipase for 1-monoolein is lower than for 2-monoolein, and indeed the K_i for 1-monoolein (65 μM) was greater than the Km of 53 μM for 2-monoolein (Fig. 3). The affinity and maximal velocity for the hydrolysis of 1-monoolein was not determined, but a lower affinity and higher maximal velocity, perhaps due to differences in the physical state of the substrate emulsion, could result in the same rate of hydrolysis at a single concentration as that observed with 2-monoolein as substrate.

The soluble aortic lipase preparation showed no prefer-

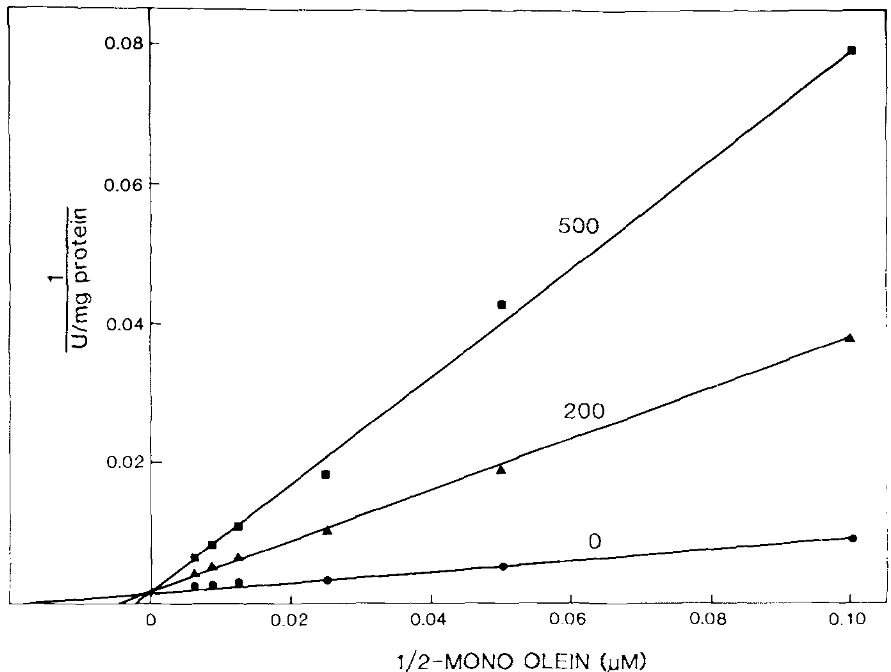

FIG. 3. Effect of 1-monoolein on 2-monoacylglycerol lipase activity. Lipase activity (99 μg protein per assay) was determined at varying 2-monoolein concentrations (10 to 160 μM) in the absence (●) and the presence of 200 μM (▲) and 500 μM (■) 1-monoolein. The respective 1-monoolein concentrations are indicated by the numbers on the lines. Results are presented as a double reciprocal Lineweaver-Burk plot.

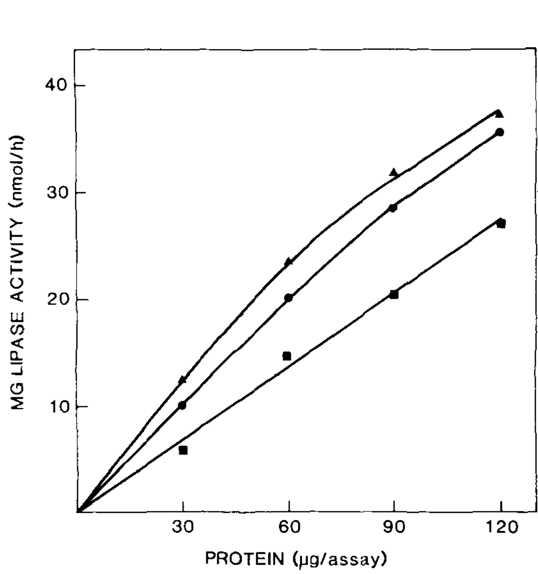

FIG. 4. 2-Monoacylglycerol (MG) substrate specificity for the aortic lipase. Lipase activity was measured after a 20 min incubation of the indicated amounts of enzyme protein with 2-monoolein (●), 2-monopalmitin (▲) and 2-monoarachidonin (■) substrate preparations.

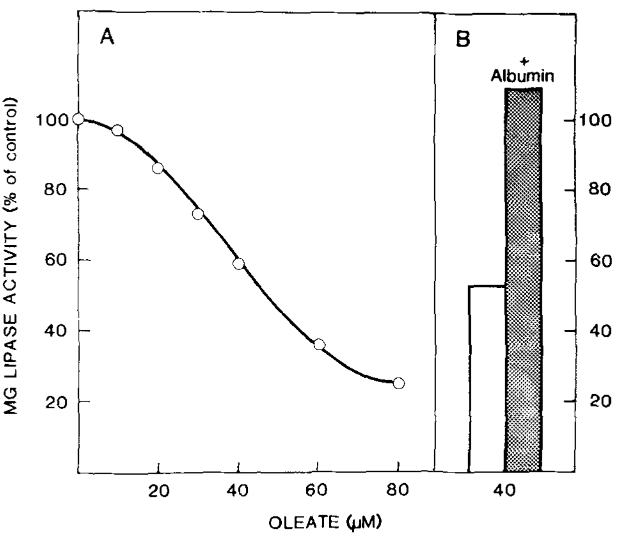

FIG. 5. Effect of oleate on 2-monoacylglycerol (MG) lipase activity. (A) Lipase activity was measured in the presence of the indicated concentrations of oleate. A 1-mM stock solution of sodium oleate was prepared in 10% methanol; control tubes contained an equivalent amount of methanol. Results are expressed as a percentage of the lipase activity determined in the absence of oleate (100% = 262 Units/mg protein). (B) Lipase activity was measured in assays with 40 μM oleate and in the absence (open bar) and in the presence (shaded bar) of albumin (0.05%, w/v). Activity is expressed as a percentage of the control activity with only methanol (100% = 232 Unit/mg protein).

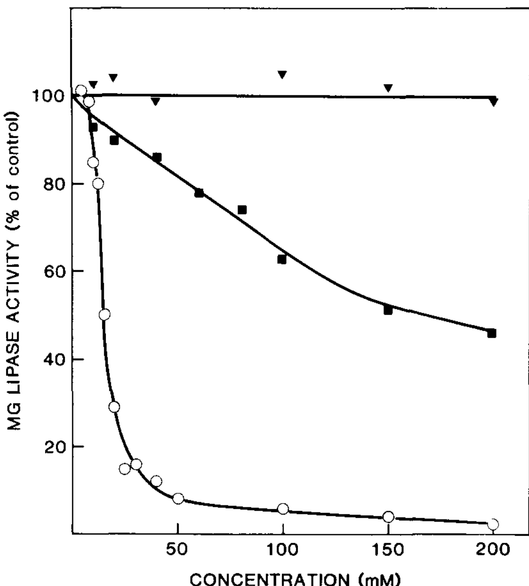

FIG. 6. Effect of NaCl, NaF and $CaCl_2$ on 2-monoacylglycerol (MG) lipase activity. Lipase activity was measured in the presence of the indicated concentrations of $CaCl_2$ (O), NaF (■) and NaCl (▼). Results are expressed as a percentage of control with no additions (100% = 268 Units/mg protein).

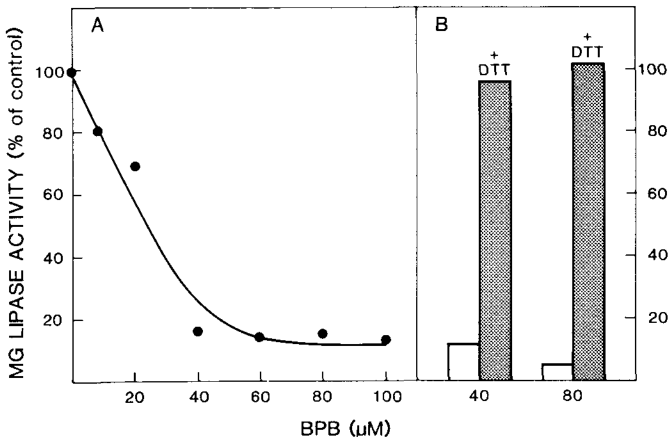

FIG. 7. Effect of p-bromophenacyl bromide (BPB) on 2-monoacylglycerol lipase activity. (A) A 10-mM BPB stock solution was freshly prepared in dimethyl sulfoxide (DMSO). The lipase preparation was preincubated for 20 min at room temperature in the presence of the indicated concentrations of BPB prior to initiation of the assay by the addition of the substrate mixture. Results are calculated as the percentage of control activity that was preincubated with an equivalent amount of DMSO (100% = 250 Units/mg protein). (B) Lipase activity was measured following preincubation with either 40 μM or 80 μM BPB and with no further additions (open bars) or in the presence of 1 mM dithiothreitol (DTT; shaded bars). Results are expressed as a percentage of the control (100% = 249 Units/mg protein).

ence for the hydrolysis of the naturally occurring substrate 2-monoarachidonin; in fact, the release of palmitate and oleate was greater than the release of arachidonate when the 2-MG substrates were compared (Fig. 4). This substrate specificity for the aortic 2-MG lipase is in marked contrast to the enzyme from platelets and decidua vera tissue (9,10), where the presence of arachidonate in the *sn*-2 position of 1,2-DG increased lipase activity. The inhibition of aortic 2-MG lipase activity by PMSF and NaF is consistent with results from other investigations (9,10,16). The aortic 2-MG lipase was also inhibited by oleate (Fig. 5). The ability of albumin to prevent and reverse the effect of added oleate indicates that the fatty acid acted by product inhibition and did not produce an irreversible denaturation of the lipase.

The DG lipase pathway in blood vessel preparations could provide the arachidonic acid precursor necessary for prostanoid synthesis. Alternatively, the arachidonic acid could be released by the direct action of a phospholipase A_2 on aortic membrane phospholipids (17). Recently, Moscat et al. (18) reported that phospholipase A_2 activity could not be detected in endothelial cell homogenates from pig aortas, and so concluded that the phosphoinositide-specific phospholipase C-DG lipase pathway must provide the arachidonic acid for prostanoid synthesis. Negative results for phospholipase A_2 activity measured in in vitro assays are always subject to qualifications concerning the appropriateness of the exogenous radiolabeled substrates (17). Furthermore, phospholipase A_2 activity has been characterized in homogenates and acid extracts of smooth muscle cells from aorta (19). Analysis of pig aortic endothelial cells following the stimulation of PGI_2 synthesis by bradykinin resulted in the conclusion that both phospholipase A_2 and phospholipase C-DG lipase pathways were involved in the supply of arachidonic acid (20).

The relative contributions of these two potential pathways in relation to the release of arachidonic acid for prostanoid synthesis in intact cells is difficult to evaluate without the availability of specific and selective inhibitors. BPB is a potent inhibitor of the aortic 2-MG lipase, presumably due to modifications of sulfhydryl groups, since the inhibition could be prevented by DTT (Fig. 7). However, BPB also inhibits phospholipase A_2 (19-22) and C (22,23) activities. Given this nonspecificity, BPB clearly cannot be used to determine the relative contributions of the two pathways to release arachidonic acid. Similarly, mepacrine (500 μM), although it did not inhibit aortic 2-MG lipase activity, has been reported to inhibit both phospholipase C (23) and A_2 (19) activities and has been demonstrated to interact directly with membrane phospholipids (24). Indomethacin resulted in a potentiation of the accumulation of DG in thrombin-stimulated platelets; indomethacin was reported to inhibit DG lipase activity but not DG kinase activity in platelet sonicates (25). In contrast, indomethacin (200 μM) did not significantly inhibit aortic 2-MG lipase activity. However, it is also well established that indomethacin is an effective inhibitor of phospholipase A_2 (21,26,27). Thus, all these inhibitors are nonspecific to varying degrees. Although RHC 80267 was developed as a selective DG lipase inhibitor (28), this compound has proven to be ineffective when incubated with intact platelets unless used at high concentrations that produce nonspecific inhibition of arachidonic acid release (29,30).

The inhibition of brain DG kinase by 1-monoolein was

first reported by Bishop et al. (14). Treatment of intact platelets with 1-monoolein resulted in a potentiation of the thrombin-induced rise in intracellular DG (14) and an attenuation of the metabolism of exogenous DG (31). Since 1-monoolein reduced the conversion of exogenous DG to water-soluble metabolites, it was suggested that the DG lipase pathway was inhibited along with DG kinase (31). Our results have shown that 1-monoolein is a potent inhibitor of both DG kinase and 2-MG lipase activities in aorta (Fig. 2). The Ki of 65 μM for the competitive inhibition of the 2-MG lipase by 1-monoolein can be compared to the Ki of 91 μM for the inhibition of brain DG kinase (14). If 1-monoolein does not inhibit phospholipase A_2 activity, then this compound could be a useful tool to investigate the contribution of the DG lipase pathway to arachidonic acid release from stimulated vascular endothelial and smooth muscle cells.

The effect of oral L-carnitine administration to rats fed olive oil has been studied. Carnitine significantly decreased triglyceride, cholesterol and phospholipid levels. Particularly, the levels of chylomicron and very low density lipoproteins in the blood were lowered. Low density lipoprotein levels were not affected, and high density lipoproteins were found to be decreased by 20%. Because carnitine did not change the composition of chylomicron and very low density lipoproteins fraction or affect the gastrointestinal triglyceride residue (about 1/3 of the original load), an effect of carnitine on hepatic fatty acid handling is most likely. The lowering of plasma free fatty acid levels by carnitine administration is in favor of an effect of carnitine on fatty acid handling. The effect on the liver is illustrated by the study of acetoacetate formation in in vitro perfused livers from previously olive oil loaded ± carnitine-treated rats. Carnitine pretreatment stimulated ketogenesis. It is speculated that carnitine administration, by promoting β-oxidation, lowers the production of very low density lipoproteins. This may be accomplished partly by an increase in the hepatic level of fatty acid binding protein, which also has been observed.
Lipids 22, 1005-1008 (1987).

L-Carnitine plays an essential role in the uptake of activated long-chain fatty acids into the mitochondria (1). Therefore, under carnitine-deficient conditions long-chain acyl-CoAs accumulate and predominantly participate in extra mitochondrial reactions such as triglycerides (TG) synthesis. Such an event occurs in lipid storage myopathies due to carnitine deficiency in muscles (2-4). In previous experiments, we demonstrated that L-carnitine administration is capable of reducing hyperlipidemia after oral oil bolus (5) and after fat diet feeding (6).

The electrophoretical pattern of plasma lipoproteins showed a decreased intensity of the pre-β band and the chylomicron band by L-carnitine treatment. This experiment was carried out to confirm the above findings through analyses performed with the density gradient ultracentrifugation method as described by Redgrave et al. (7) and to contribute to the clarification of the role played by L-carnitine in lipid metabolism.

EXPERIMENTAL MODEL

Three groups of normally fed, albino female Wistar rats, 200-220 g in weight, were treated as follows: control and L-carnitine groups were given olive oil (30 ml/kg) orally at time 0; one hr later, they received H_2O (20 ml/kg) and 155 mM L-carnitine (20 ml/kg), respectively. The blank group received H_2O (30 and 20 ml/kg) at the same times. At the third hour, blood samples were drawn under a light ether anesthesia for determination of free fatty acids (FFA) (8), TG (9), total cholesterol (CH) (10,11), phospholipids (PL) (12), total carnitine (TCAR) (13) and short-chain acylcarnitines (14) (the latter were obtained by subtracting the amount of free carnitine from total acid-soluble carnitine), protein (15) and lipoproteins (7). Under the same experimental conditions, some animals were used for liver short-chain acylcarnitines (14), intestinal TG determination and as donors of livers for (subsequent) in vitro perfusion studies (16), in which FFA (8) uptake and acetoacetate (17) production were measured. Fatty acid binding protein (FABP) was measured in the livers of the three groups of animals. This was accomplished by rocket electrophoresis of liver homogenates purified supernatant samples made in cold 0.2 M mannitol. The homogenates were centrifuged for 30 min at 48,000 × g at 4 C. The supernatants were heated for 10 min at 60 C and were cooled and centrifuged for 15 min at 48,000 × g. The supernatant was dialyzed against 75% saturated ammoniumsulfate overnight, and the precipitate was removed by centrifugation. The supernatant was dialyzed against water, freeze-dried and tested for FABP content by rocket electrophoresis (18). The 1% agarose used contained antiserum raised in rabbit against purified (19) rat liver FABP. The electrophoresis was run for 16 hr at 50 mV/4 cm.

Statistical analysis. Results were expressed as mean value + SEM. Student's t-test was used to evaluate the statistical significance of the differences.

RESULTS AND DISCUSSION

Plasma FFA, TG, CH and PL levels all are shown to have increased in the fat-loaded group (Table 1) as compared to the blank group. L-carnitine administered to the hyperlipidemic animals significantly reduced FFA (−65%; $P \leqslant .1\%$), TG (−44%; $P \leqslant 1\%$), CH (−35%; $P \leqslant .1\%$) and PL (−32%; $P \leqslant .1\%$), and it induced a dramatic increase in TCAR (six-fold; $P \leqslant .1\%$) (Table 1).

Plasma chylomicron (CHYLO) plus very low density lipoprotein (VLDL) and high density lipoprotein (HDL) fractions, which had raised significantly after the olive oil load, were lowered markedly by treatment with L-carnitine (−54%; $P \leqslant 2\%$, and −20%; $P \leqslant 5\%$, respectively) (Fig. 1). The low density lipoprotein (LDL) fraction in the plasma was affected moderately by the oil load and the successive L-carnitine treatment (Fig. 1).

All constituents of the CHYLO plus VLDL fraction were reduced almost equally (TG, −55%; CH, −59%; PL, −58%; protein, −61%) by the treatment with L-carnitine (Table 2). This suggests that carnitine modifies the quantity without affecting the composition of the CHYLO plus

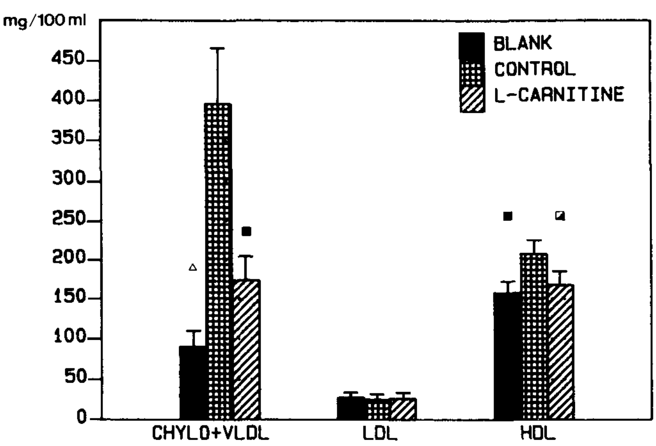

FIG. 1. Plasma chylomicron (CHYLO) plus very low density lipoprotein (VLDL), low density lipoprotein (LDL) and high density lipoprotein (HDL) in blank (H_2O + H_2O), control (olive oil + H_2O) and L-carnitine (olive oil + L-carnitine) groups. Standard errors and P-values vs control (◪ ⩽ 5%; ■ ⩽ 2%; △ ⩽ 1%) are indicated in the figure. Number of animals: eight per group.

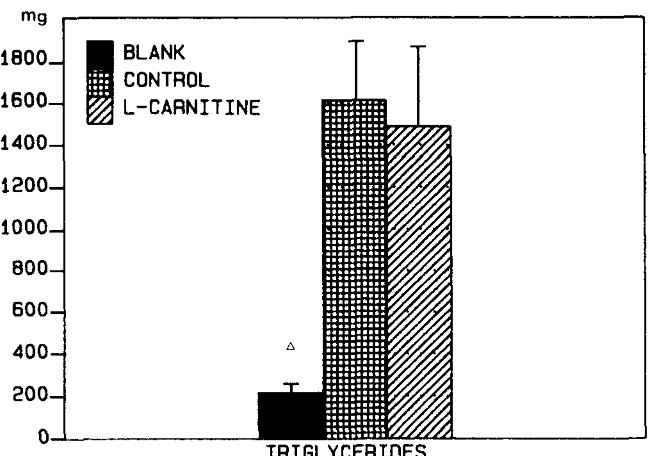

FIG. 3. Entire intestine triglycerides content (tissue + content) of blank (H_2O + H_2O), control (olive oil + H_2O) and L-carnitine (olive oil + L-carnitine) groups. Standard errors and P-values vs control (△ ⩽ 1%) are indicated in the figure. Number of animals: four per group.

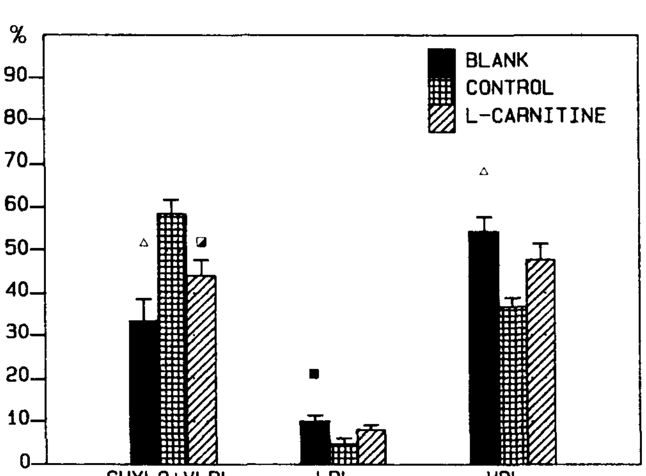

FIG. 2. Percent distribution of plasma lipoprotein components in blank (H_2O), control (olive oil + H_2O) and L-carnitine (olive oil + L-carnitine) groups. Standard erros and P-values vs control (◪ ⩽ 5%; ■ ⩽ 2%; △ ⩽ 1%) are indicated in the figure. Number of animals: eight per group.

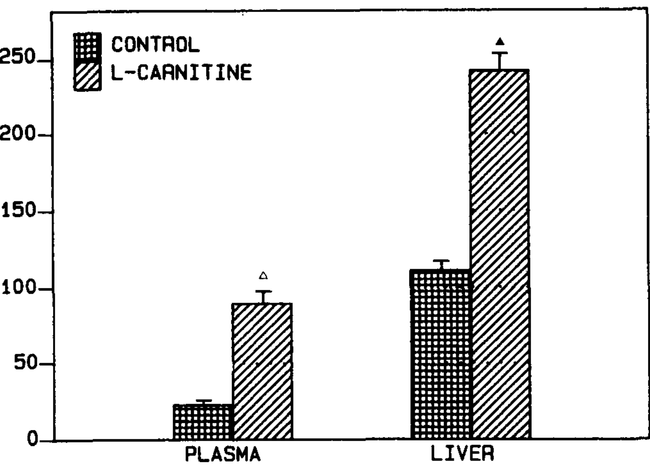

FIG. 4. Plasma (nmoles/ml) and liver (nmoles/g w.w.) short-chain acylcarnitines in control (olive oil + H_2O) and L-carnitine (olive oil + L-carnitine) groups. Standard errors and P-values vs control (△ ⩽ 1%; ▲ ⩽ .1%) are indicated in the figure. Number of animals: 14 per group.

VLDL fraction. As evidenced by previous experiments (5,6), the percentual distribution of plasma lipoprotein components of the L-carnitine group was different substantially from that of the control group (Fig. 2). The blank group, on the other hand, showed no statistical difference from the L-carnitine group (Fig. 2). As mentioned in *Experimental Model*, to ascertain that the effect of L-carnitine was not due to an interference with gastrointestinal lipid absorption, at the third hour some animals from the three groups were used to determine the levels of TG in the whole intestine (tissues and its contents). The same intestinal TG level, about 1/3 of original load, was found in both control and L-carnitine groups (Fig. 3).

Therefore, it is reasonable to assume that the effect of L-carnitine on TG-rich lipoproteins in the blood should not be ascribed to interference with gastrointestinal lipid absorption by the substance but rather to an influence it may exert on the handling of fatty acids by the liver. This hypothesis is in agreement with the following results: it can be seen from Figure 4 that in the L-carnitine group, plasma and hepatic levels of short-chain acylcarnitines were higher than the control group. In accordance with the results obtained by other authors with in vitro experiments (20), the livers of the animals treated with oil plus L-carnitine, isolated and perfused as described in

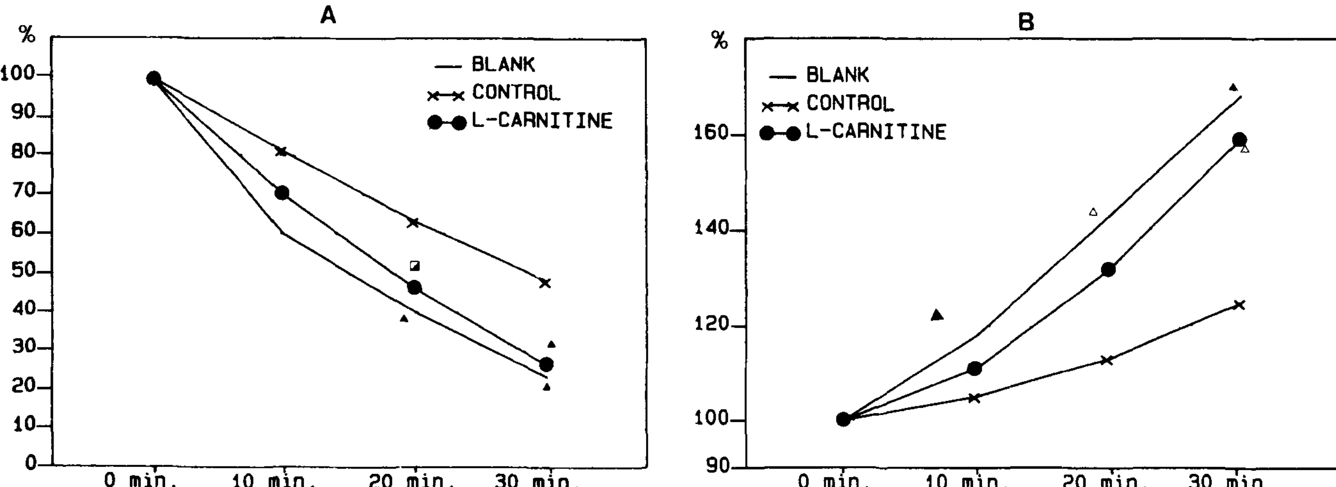

FIG. 5. Fatty acid uptake (side A) and acetoacetate release (side B) in isolated livers from rats previously loaded orally with olive oil and subsequently with carnitine as described in *Experimental Model* and in vitro perfused with recirculated medium (equilibrated with 95% O_2 and 5% CO_2 at 37 C). The medium (60 ml) contained 40% (v/v) serum and 15% (v/v) packed red cells of 48-hr fasted rats, supplemented with Krebs-Ringer bicarbonate buffer (pH 7.4), containing 11.5 mM glucose. The ordinate of side A, % of the initial FFA concentration (100% about 0.8 mM); side B, % of the increase in the acetoacetate level (100% about 0.5 mM). P-values (◪ ⩽ 5%; △ ⩽ 1%; ▲ ⩽ .1%) of blank (H_2O + H_2O) and L-carnitine (olive oil + L-carnitine) vs control (olive oil + H_2O) are indicated in the figure. Number of animals: three per group.

the legend of Figure 5, converted FFA into acetoacetate faster than the control liver did. Therefore, the data of Figures 4 and 5 suggest that carnitine addition after olive oil feeding promotes hepatic β-oxidation. This may be expected to occur at the expense of fatty acid esterification, leading to the lowering of circulating plasma fatty acyl esters.

Preliminary experiments suggest an increase of hepatic acid binding protein concentration (Table 3) by carnitine addition. Fatty acid binding protein promotes fatty acid utilization (21). Therefore, stimulation of fatty acid handling by the liver, promoting β-oxidation, is to be expected after carnitine administration.

[Received December 27, 1986]

The Result of Feeding Palmitoyl Glycerol on Lymph and Plasma Lipids

Paula Trumbo[1], **Margaret Sutherland-Smith, Barbara Kitchell** and **Samuel B. Tove***
Department of Biochemistry, North Carolina State University, Raleigh, NC

Palmitoyl glycerol is toxic when fed to mice, but the toxicity is alleviated by supplementing the toxic diet with 2–4% oleate or linoleate at the expense of sucrose. Lipid and fatty acid composition of lymph and plasma were studied in mice fed chow and palmitoyl glycerol diets to help explain the toxicity mechanism. When mice were fed chow, intestinal lymph contained a high proportion of saturated fatty acids; when they were given palmitoyl glycerol, the proportion approached 90% saturated fatty acids. The cholesteryl ester fraction was higher in lymph from mice fed a toxic diet than when the diet was fortified with supplemental safflower oil. However, there were no differences between diets in lipid composition of blood plasma. Similarly, except for plasma cholesterol esters, there were no differences in fatty acid composition between mice fed palmitoyl glycerol as the only fat or supplemented with a protective unsaturated fat. In the plasma, cholesteryl palmitate was elevated and cholesteryl oleate and cholesteryl linoleate were depressed when mice were given a toxic diet. Although a monoacylglycerol was toxic when fed, the percentages of monoacylglycerols in lymph or plasma were not materially elevated. The findings indicate that neither the total proportion of saturated fatty acids nor the amount of circulating monoacylglycerols was directly involved in the toxicity of palmitoyl glycerol.
Lipids 22, **1009–1015 (1987).**

Rac-1(3)-palmitoyl glycerol was toxic when fed to weanling mice at dietary percentages between 10 and 30% (1). Adding 2% oleate or linoleate (safflower oil) at the expense of sucrose to the *rac*-1(3)-palmitoyl glycerol diet greatly ameliorated the toxicity (1). The symptoms of the toxicity were death, usually within seven days after starting the diet, and poor growth in those mice that survived (2). The toxicity was not as severe in adult mice or weanling rats as in weanling mice (2). There was a pronounced effect of ambient temperature on the toxicity of the palmitoyl glycerol diet (3). Death did not occur when the ambient temperature was greater than 25 C. Moreover, at ambient temperatures below 25 C, the mortality was inversely proportional to the temperature. Although a severe inflammation of the lungs was observed in about 75% of the mice that died, no lung abnormality was observed in the other 25% that died (2). Moreover, the lung lesion was as severe in those mice that survived because they were kept at an ambient temperature above 25 C as in those that died when held at the lower ambient temperature (3).

For these reasons, it is clear that even though the inflammatory lesion of the lung is a symptom of the toxicity, it is not the immediate cause of death. There was no difference between mice fed *rac*-1(3)-palmitoyl glycerol with or without safflower oil in the amount or rate of *rac*-1(3)-palmitoyl glycerol absorbed, oxidative phosphorylation by liver or heart mitochondria or tissue distribution of radioactivity following gavage of *rac*-1(3)-[1-^{14}C]-palmitoyl glycerol (2). The mechanism by which *rac*-1(3)-palmitoyl glycerol induces the toxic symptoms is unknown. Since the *rac*-1(3)-palmitoyl glycerol is fed and is absorbed, it seemed logical to ascertain if the lymph and/or plasma lipids from mice fed the toxic diet might be different from those fed the toxic diet protected by supplementation of an unsaturated fat. Such differences might lead to an understanding of the mechanism behind the toxicity and, more specifically, reveal whether the monoacylglycerol per se is the toxic compound after absorption. Therefore, studies on the fatty acid composition of the lymph and plasma lipids from mice fed varying proportions of *rac*-1(3)-palmitoyl glycerol, with or without dietary supplements of safflower oil or oleic acid, were conducted. The results of these studies are reported in this communication.

MATERIALS AND METHODS

Animals. The animals used in these experiments were weanling and adult mice from the North Carolina State Laboratory of Hygiene (strain: NC St Lab of Hygiene), weanling mice from Charles River (strain: CFW) and adult rats (strain: Charles River Wistar). Usually the mice were fed a basal diet containing 40% sucrose, 20% casein and 5% Wesson salt mixture and supplemented with all known vitamins (ICN Pharmaceuticals, Cleveland, OH). The remaining 34% was composed of *rac*-1(3)-palmitoyl glycerol and safflower oil, oleic acid and sucrose. Some mice and rats were fed an open-formula, commericial rodent diet (chow) to serve as control animals. This contained about 7% fat, with an unsaturated fatty acid composition of 35% oleate and 25% linoleate. Additionally, some weanling mice were fed the same purified basal diet, with all fat replaced by sucrose. Mice were housed individually in galvanized cages with wire-screen bottoms at an ambient temperature of 19–22 C. Food and tap water were provided ad libitum. The *rac*-1(3)-palmitoyl glycerol was prepared as previously described (1) from acetone glycerol (Aldrich Chemical Co., Milwaukee, WI) and palmitic acid and was crystallized from hexane to a purity between 85 and 95%, with free palmitic acid as the major impurity and dipalmitoyl glycerol and tripalmitoyl glycerol as minor impurities. The previous study (1) established the veracity of *rac*-1(3)-palmitoyl glycerol as the dietary toxic compound.

Collection of lymph and plasma. Weanling mice were killed three days, and adult mice seven days, after starting the experimental treatments. Immediately after the mice were killed by cervical dislocation, intestinal lymph was collected by puncture of the mesenteric lymph duct with a tuberculin syringe equipped with a 26-gauge needle. The lymph was withdrawn into the syringe and flushed with 0.2 ml of chloroform/methanol (1:2, v/v) to extract the lipids (4). In this manner, we obtained about 1–3 μl from each animal, and it was necessary to pool the

lipid extracts from six weanling mice or two adult mice to obtain amounts sufficient for the analyses. Because of the small size of the sample, we made no attempt to isolate the chylomicrons. Lymph from each rat was collected and extracted in the same manner.

Blood was collected from the mice by retro orbital puncture using a preheparinized Pasteur pipette. Plasma was collected after centrifugation at 1000 × g for 10 min at 4 C. The plasma was added to six volumes of chloroform/methanol (2:1, v/v), and the lipids were extracted (4).

Lymph and plasma lipid and fatty acid composition. The extracts of the lymph and plasma were taken to dryness by a stream of nitrogen and redissolved in a small volume of chloroform. The lipid classes were separated by thin layer chromatography on Silica Gel H (American Scientific Products, Charlotte, NC) using a solvent mixture of heptane/isopropyl ether/acetic acid (6:4:0.3, v/v/v). The diacylglycerol, triacylglycerol, free fatty acid and cholesteryl ester regions were collected after visualization by a brief exposure to iodine vapor, and lipids were eluted with chloroform/methanol (1:1, v/v). The fraction containing both the phospholipids and monoacylglycerols was eluted from the silica gel with ethanol/chloroform/water/acetic acid (100:30:20:2, v/v/v/v). Then the phospholipid and monoacylglycerol fractions were separated by rechromatography on thin layer plates using a solvent system of acetone/petroleum ether (1:3, v/v) (5). The phospholipids were eluted with the same solvent mixture previously used, and the monoacylglycerols were eluted with a mixture of chloroform/ether (1:1, v/v). All lipid fractions were taken to dryness with a stream of nitrogen, and 10 μg of heptadecanoic acid (NuChek Prep, Elysian, MN) was added as an internal standard in chloroform. Methyl esters of the fatty acids of each lipid class were prepared by transmethylation with a mixture of 2 ml of methanol, 0.2 ml of benzene, 0.1 ml of concentrated HCl and 0.1 ml of dimethoxypropane to serve as a water scavenger. The reaction mixture was kept at 65 C for 30 min and allowed to stand overnight at room temperature. The fatty acid methyl esters were collected by adding 2 ml of water and extracting three times each with 2 ml of petroleum ether. After being brought to dryness with a stream of nitrogen, the fatty acid methyl esters were dissolved in a small volume of ether, and the composition was determined by gas-liquid chromatography on a 1/8-inch stainless steel column packed with 10% diethyleneglycol succinate (Supelco, Bellefonte, PA).

To insure the accuracy of basing lipid analysis on the amounts of fatty acids in the lipid fractions eluted from the thin layer plate, recovery experiments using pure known standards were conducted. In these experiments, known amounts of tripalmitoyl glycerol, dipalmitoyl glycerol, palmitoyl glycerol, cholesteryl oleate, phosphatidylcholine and phosphatidylinositol were spotted on a thin layer plate. These samples were then handled as the experimental samples, with recovery based on the ratio of the amounts of fatty acid(s) to the internal standard of heptadecanoic acid. The recoveries of the pure lipids were, respectively, 96.4%, 95.2%, 98.5%, 90.0%, 91.6% and 98.0%.

Results are expressed as means and standard deviations of the means. Student's t-test was used to determine statistical significance.

RESULTS

Lipid composition of lymph. The lipid composition of rat lymph was similar to that previously reported (6) in that the major lipid was the triacylglycerol fraction and the sum of the remaining fractions constituted only 35% of the total lipids (Table 1). Even when they were fed laboratory chow, the lipid composition of lymph from both weanling and adult mice differed from that of adult rats in that the triacylglycerol fraction, although still the major one, amounted to less than half of the total lipids. This decrease was compensated by higher proportions of cholesteryl esters and free fatty acids.

The triacylglycerol fraction was even lower in lymph from weanling mice fed *rac*-1(3)-palmitoyl glycerol supplemented with safflower oil, and it was lowest in lymph from either weanling or adult mice fed the toxic palmitoyl glycerol diet. The cholesteryl ester fraction was the major lipid in the lymph from both groups of mice fed *rac*-1(3)-palmitoyl glycerol without an unsaturated fat. However,

TABLE 1

Lipid Composition of Lymph[a]

Diet	Animal	N	MG (%)	DG (%)	TG (%)	CE (%)	FFA (%)	PL (%)
Chow	Adult rat	2	11.5	3.9	64.9	8.1	9.2	2.5
Chow	Weanling mice	5	10.4(4.7)	5.5(5.7)	45.6(8.5)	17.9(0.9)	14.5(5.7)	5.8(2.5)
Chow	Adult mice	4	11.7(7.3)	8.7(2.0)	41.3(7.1)	15.7(3.3)	16.1(1.0)	6.2(3.6)
GMP	Weanling mice	4	15.5(3.1)	12.3(3.9)	15.6(2.5)[b]	30.4(5.1)[b]	20.9(6.7)	5.4(1.6)

GMP + SO	Adult mice	5	8.7(2.1)	7.9(1.9)	60.3(6.2)	10.5(3.3)	10.3(2.2)	2.3(0.5)

[a]Values are means with standard deviations in parentheses; N, number of samples analyzed. Each sample represents a pool of lymph from 6 mice. Intestinal lymph from rats and mice fed the indicated diets was collected by aspiration from the mesenteric lymph node. The lipids were extracted and separated by thin layer chromatography. Quantitation was based on fatty acid analysis with recovery monitored by means of a heptadecanoic acid internal standard. MG, monoacylglycerols; DG, diacylglycerols; TG, triacylglycerols; CE, cholesteryl esters; FFA, free fatty acids; PL, phospholipids; GMP, *rac*-1(3)-palmitoyl glycerol; SO, safflower oil.

[b]Statistically different from chow ($p < 0.01$).

[c]Statistically different from GMP ($p < 0.01$).

when weanling mice were fed the safflower oil supplement, the cholesteryl ester fraction was not higher than the chow-fed mice, and the free fatty acids were increased. In contrast, the lymph triacylglycerol and cholesteryl ester percentages from adult mice fed *rac*-1(3)-palmitoyl glycerol and safflower oil were equivalent to that of adult rats fed chow.

It is significant that despite a dietary level of 30% palmitoyl glycerol, the proportion of monoacylglycerols in lymph from all groups of mice was similar and no higher than that of the adult rat.

Lipid composition of plasma. The composition of lipids in the plasma from weanling mice fed laboratory chow, a fat-free diet and 30% *rac*-1(3)-palmitoyl glycerol with and without 4% safflower oil are shown in Table 2. As might be expected, the percentage of triacylglycerols in the plasma of mice fed the fat-free diet was low, and the cholesteryl ester fraction was the major component. In contrast to lymph, the plasma triacylglycerols were higher and cholesteryl esters were lower when mice were fed palmitoyl glycerol with or without safflower oil as compared to those fed chow.

Fatty acid composition of lymph. The fatty acid composition of the lipids of the lymph from adult mice is shown in Table 3 and that from weanling mice in Table 4. With either weanling or adult mice fed chow, the triacylglycerol fatty acids reflected the fatty acid composition of the diet. Similarly, when either age group was fed a palmitoyl glycerol diet, a higher percentage of palmitate was found than when the mice were fed chow. With adult mice, supplementing the palmitoyl glycerol diet with safflower oil elevated the triacylglycerol linoleate, and in weanling animals a similar change was seen, but to a lesser degree. It is interesting that the percentage of palmitate in the lymph triacylglycerols of the mice receiving the safflower oil supplement was not significantly lower than those consuming the palmitoyl glycerol diet without the unsaturated fat.

In either adult or weanling mice, a palmitoyl glycerol diet resulted in higher palmitate in other lymph lipids compared to a chow diet. As with the triacylglycerols, adding a supplement of safflower oil did not affect these proportions significantly. All of the lipid classes of the lymph from weanling mice fed chow contained elevated percentages of stearate that offset the high palmitate percentage. Hence, the proportions of total saturated fatty acids in these lymph lipids from weanling mice were similar whether they were fed a palmitoyl glycerol diet or chow. Furthermore, in adult mice fed the palmitoyl glycerol diets, the linoleate percentages of the phospholipid fraction were considerably higher when the diet was supplemented with safflower oil.

Because the lymph triacylglycerol fatty acids were not markedly affected by safflower oil supplementation of the 30% palmitoyl glycerol diet, the fatty acids of this fraction from mice fed varying percentages of palmitoyl glycerol (ranging from 0 to 30%) and safflower oil (ranging from 0 to 4%) were analyzed. There was a linear increase in the proportion of linoleate (coefficient of correlation = 0.918) when the ratio of dietary safflower oil to palmitoyl glycerol was increased (Fig. 1). In contrast, the proportion of palmitate was not affected by increasing the dietary safflower oil-to-palmitoyl glycerol ratio.

Fatty acid composition of plasma. The proportions of the major fatty acids in the glycerolipids and free fatty acids of plasma from weanling mice fed chow, 30% palmitoyl glycerol as the only lipid, supplemented with either 4% safflower oil or 4% oleic acid, and a fat-free diet are given in Table 5. With the exception of the fat-free diet, the fatty acid compositions of the neutral lipids and free fatty acids from plasma of all diets are surprisingly similar, especially when one considers the wide variation in fat intake. It is only in the phospholipid fraction that consistent differences reflecting the fatty acid composition of the diet were observed. In contrasting the fat-free diet with the others, the most striking difference was its relatively high proportion of myristate.

In contrast, significant differences in fatty acid composition associated with diet were observed in the plasma cholesteryl ester fraction (Table 6). The palmitate percentage in this fraction was considerably higher when mice were fed palmitoyl glycerol alone rather than with either oleate or linoleate. When supplemented with 4% safflower oil, the proportion of linoleate in the cholesteryl ester fraction was 10-fold greater than when just palmitoyl glycerol was fed, and it was equal to that of the chow-fed mice.

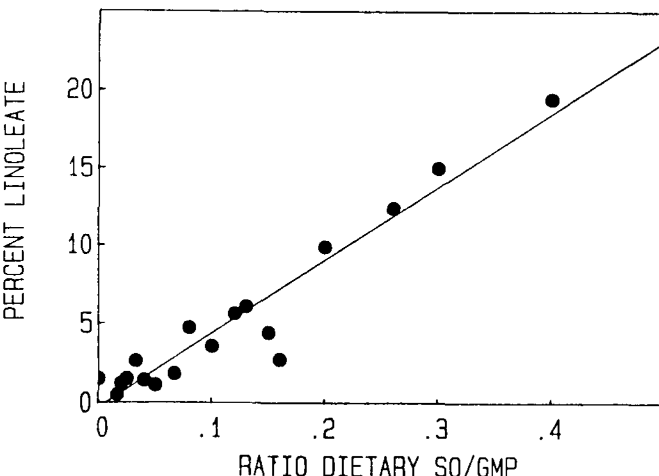

FIG. 1. Percent of linoleate in the triacylglycerol fraction of intestinal lymph from weanling mice fed various combinations of 0, 10, 15, 25 and 30% *rac*-1(3)-palmitoyl glycerol (GMP) plus 0, 0.5, 1, 2, 3 and 4% safflower oil (SO) for three days. Ratio dietary SO/GMP represents the ratio of dietary safflower oil to palmitoyl glycerol fed to the mice. Each point represents an average of one to five ratios of dietary safflower oil to palmitoyl glycerol. The value for each dietary combination was derived from an average of lymph from three to six mice.

When supplemental oleate was given, the percentage of oleate was elevated to the same level as that of linoleate when safflower oil was the supplement. However, when oleate was fed, the proportion of linoleate in the cholesteryl ester fraction was not higher than when only palmitoyl glycerol was fed. The net results of the changes in fatty acid composition were similar; namely that when mice were given a supplement of an unsaturated fat, the percentage of the total saturated fatty acids in this fraction was no greater than that in mice fed chow or mice fed a fat-free diet.

DISCUSSION

Most striking was the extremely high proportion of saturated fatty acids in the mouse lymph. In weanling mice, the proportion of total saturated fatty acids in each lipid class, other than the triacylglycerols, was more than 70%, irrespective of diet. When the mice were fed 30% *rac*-1(3)-palmitoyl glycerol, with or without 4% safflower oil, the sum of the saturated fatty acids was even higher, often approaching 90%. Although this might be expected for animals consuming saturated fat, the degree of saturation is higher for mice than that observed in other animals consuming high amounts of saturated fats. Chu and Hegsted (8) found a similar percentage of saturated fatty acids in the triacylglycerols of intestinal lymph of adult rats given palmitate, but the percentages of saturated fatty acids in the cholesteryl ester and phospholipid fractions were lower than we observed in mice fed either a palmitoyl glycerol diet or chow. Feldman et al. (9) reported lower percentages of saturated fatty acids in whole lymph of rats fed either palmitate or stearate. Even in ruminants, where the dietary fatty acids are largely saturated because of biohydrogenation occurring in the rumen, proportions of saturated fatty acids in the cholesteryl esters and phospholipids were not as great as we found in the corresponding fractions of mouse lymph.

Mouse lymph may not always be as highly saturated. In experiments where the proportions of dietary linoleate and palmitate were varied, the percentage of linoleate increased linearly with the ratio of linoleate to palmitate. However, the percentage of palmitate remained relatively constant. Hence it would appear that in mice, dietary unsaturated fatty acids influence lymph to a much greater degree than dietary saturated fatty acids.

Typically, the triacylglycerol fraction is expected to be the major lipid in lymph when animals ingest fat. This was observed with weanling and adult mice fed chow and with adult mice fed palmitoyl glycerol plus safflower oil. However, when weanling or adult mice were fed 30% palmitoyl glycerol, the cholesteryl ester fraction predominated. The free fatty acid fraction was greater than the triacylglycerols in these groups of mice, as well as in weanling animals fed palmitoyl glycerol and safflower oil. The diacylglycerol fraction was also increased when these diets were fed, although to a lesser degree. The findings would suggest that when mice were fed the palmitoyl glycerol, there was either a decrease in the synthesis of triacylglycerols or an increase in lipolytic activity.

In blood plasma, the cholesteryl ester fraction was greater than the triacylglycerol fraction when weanling mice were fed a low-fat diet, chow or a fat-free diet. This is consistent with studies that showed elevated triacylglycerols in rats fed a high-fat diet compared to chow (7). Although supplementing the palmitoyl glycerol diet with safflower oil affected the lipid composition of the lymph, subsequent metabolism eliminated these differences, and the proportions of the various plasma lipids were the same in weanling mice fed palmitoyl glycerol with or without the unsaturated fat.

As expected, the plasma lipids from weanling mice fed a palmitoyl glycerol diet were more saturated than from those fed chow or a fat-free diet. Unexpectedly, we found only traces of arachidonic acid in any lipid from the plasma of the weanling mice. It is noteworthy that, except for the cholesteryl ester fraction, there was very little difference in fatty acid composition of the plasma lipids between mice fed palmitoyl glycerol alone or with a protective unsaturated fat. On the other hand, the composition of the cholesteryl ester fraction paralleled the overall effects of the palmitoyl glycerol toxicity. The palmitate percentage and total proportion of saturated fatty acids were high only when the mice were fed the unsupplemented palmitoyl glycerol diet. When 4% safflower oil was the supplement, linoleate was increased but oleate was unchanged. Conversely, when 4% oleate was the supplement, oleate increased but linoleate was no higher than in the unsupplemented diet.

Although weanling mice were given a fat-free diet, the length of the experiment was too short for the classical syndrome of an essential fatty acid deficiency to appear. In these mice, the stearate was higher and the oleate lower in plasma triacylglycerols than was found in four-month-old rats given a fat-free diet (6). We also observed that the lymph lipids from weanling mice fed chow were higher in stearate and lower in oleate than those from adult mice fed chow. In studies with adipose tissue (11), the same trend was observed with the triacylglycerols from weanling versus adult mice. While it is possible that these differences resulted from an increased accumulation of oleate relative to stearate as the animals aged, it is also

possible that the fatty acid desaturases were not as active in the weanling mice. Prasad and Joshi (12) found that in chickens the desaturases developed with age. Additionally, the failure to find more than trace amounts of arachidonate in the plasma of weanling mice is consistent with this hypothesis.

The primary purpose for conducting this study was to lead to an explanation of the toxicity of dietary palmitoyl glycerol to mice. Acylglycerols of other saturated fatty acids, myristic acid (13) and stearic acid (14), were also toxic, as was *sn*-diacetyl-2-palmitoyl glycerol (2). Hence, the toxicity was not specific to *rac*-1(3)-palmitoyl glycerol but could be caused by ingestion of any saturated monoacylglycerol. At first sight, the toxicity may seem to be an acute form of an essential fatty acid deficiency. The toxic diet does not contain an essential fatty acid, and when linoleate is added to the diet the toxicity is ameliorated. Moreover, the addition of saturated fat to a diet deficient in essential fatty acids accentuates the syndrome of an essential fatty acid deficiency (15). However, there are several factors that negate this idea. Prefeeding linoleate for three days was ineffective in preventing the toxicity (2). Dietary oleate was as effective as linoleate in protection (14). Although it is conceivable that dietary oleate might release a supply of an essential fatty acid from some inactive pool, no change in linoleate or arachidonate was observed in plasma when oleate was fed.

With regard to the specific compound responsible for the toxicity, we had considered three possibilities (1): free palmitic acid from the palmitoyl glycerol, the monoacylglycerol itself and some metabolic product derived from palmitoyl glycerol (1). The first had been eliminated, since free palmitic acid was not as toxic as palmitoyl glycerol (1), and diacetyl, dipropionyl and dibutyryl derivaties of palmitoyl glycerol were much less toxic than *rac*-1(3)-palmitoyl glycerol because of hydrolysis of the palmitate (1). Although the results of the current study showed no major differences in fatty acid composition associated with diet (except for the cholesteryl esters), they are significant in that they indicate that the monoacylglycerol per se is not the toxic agent. Thus this finding, coupled with the fact that *rac*-1(3)-oleoyl glycerol was an effective form of an unsaturated fat (14), points to the probability that the immediate toxic agent is a metabolic product of palmitoyl glycerol.

Lipids of more than 70% saturated fatty acids would not be expected to be in a fluid state at the body temperature of a mouse. However, Bennett-Clark et al. (16) have shown that chylomicrons containing a high proportion of saturated fatty acids were produced as supercooled liquids. When they were held at temperatures below 23 C, they lost their spherical shape and appeared flattened and polygonal. There is an effect of ambient temperature on the toxicity of palmitoyl glycerol (3), so it is possible that altered chylomicron structure could be associated with the toxicity. On the other hand, there were no differences in the degree of saturation of lymph between mice that succumbed from consuming palmitoyl glycerol and those given 4% safflower oil that survived. Moreover, even though mice were ingesting diets containing 30% fat, cloudy mouse plasma was never observed, suggesting that the rate of chylomicron clearance is very high.

Except for the cholesteryl esters, there were basically no differences in the fatty acid composition between mice fed the toxic palmitoyl glycerol diet or the diet supplemented with a protective unsaturated fat. Furthermore, decreasing the toxic effects by reducing the percent of *rac*-1(3)-palmitoyl glycerol in the diet to 15% did not significantly affect the fatty acid composition of the plasma lipids (11). Therefore, it seems unlikely that the toxicity was related to the total percentage of saturated fatty acids in the plasma. However, the correlation of the fatty acid composition of the cholesteryl esters with the toxicity does suggest that this plasma lipid may be involved in the mechanism responsible for the toxicity of palmitoyl glycerol. Assuming that a similar correlation would be seen with the other toxic monoacylglycerols, it is possible that the cholesteryl ester fatty acid is a precursor for some vital membrane domain that loses its function when saturated. Extensive analysis of both fatty composition and incorporation of radioactivity from *rac*-1(3)-[1-^{14}C]palmitoyl glycerol (2) failed to show any differences between tissues of mice fed palmitoyl glycerol alone or with a protective unsaturated fat. However, it is possible that the defect may lie in microdomain(s) of a membrane that may not have been detectable in the gross composition studies conducted. Where such domain(s) might exist is unknown, but since death is so sudden following ingestion of the saturated monoacylglycerol, it seems likely that it lies in a vital organ.

[Received February 24, 1987]

Effect of Cupric Ions on Serum and Liver Cholesterol Metabolism

Mitsuo Tanaka*, **Toshihiro Iio** and **Toshikazu Tabata**
Showa College of Pharmaceutical Sciences, 1-8, Tsurumaki-5-Chome, Setagaya-Ku, Tokyo, Japan

Cupric ions were administered subcutaneously to male Sprague-Dawley rats at a single dose of 200 μmol/kg. At 24 hr after administration, a remarkable increase of total and free cholesterol was seen in the rat serum. Also, when lecithin-cholesterol acyltransferase (LCAT) (E.C. 2.3.1.43) activity was expressed as the percentage of the total serum that free cholesterol esterified, the acyltransferase activity in rats treated with cupric ions showed a slight decrease while the triglyceride content in rat serum and liver decreased by 54% and 61%, respectively. However, the content of hepatic cholesterol in rats treated with cupric ions did not show such a marked change.

On the other hand, acid cholesteryl ester hydrolase activity (Acid CEH) (E.C. 3.1.1.14) in liver lysosomes of rats treated with cupric ions showed a marked decrease with increasing cupric ion concentration both in vivo and in vitro. Furthermore, cupric ions caused a marked release of the lysosomal enzymes cathepsin D and β-glucuronidase into the cytosolic fraction. The changes in acid cholesteryl ester hydrolase activity induced by cupric ions appear to be a direct effect of cupric ions on the enzyme. These results suggest that excessive cupric ion concentrations could cause various disorders in lipid metabolism.
Lipids 22, 1016–1019 (1987).

Cupric ions have been recognized as an essential trace element for hematopoiesis (1). Dietary cupric ion deficiency in rat has been shown to produce hypercholesterolemia (2–4). Moreover, several studies have indicated that diets high in zinc:curpic ion ratios are associated with hypercholesterolemia in rat (5,6). However, the role of cupric ions in cholesterol metabolism still is unknown.

The metabolism of cholesterol and cholesteryl esters in serum have been studied extensively. It also has been reported that the synthesis and turnover of bile acids correlate inversely with serum cholesterol in hypercholesterolemia (7,8). In contrast, it has been suggested that the marked accumulation of cholesteryl esters in hypercholesterolemia may be responsible for the structural change in lysosomal membranes that accompanies the decrease in acid cholesteryl ester hydrolase (Acid CEH) activity (9). Although several studies have characterized the activity and properties of lysosomal Acid CEH from liver (10–12), the association of lysosomal Acid CEH with the lipid of serum and liver has not been examined in any detail.

Therefore, we investigated the changes occurring in serum lipid levels, serum lecithin-cholesterol acyltransferase (LCAT) activity and lysosomal Acid CEH activity in cupric ion-treated rats.

Abbreviations: Acid CEH, acid cholesterol ester hydrolase; BANA, α-N-benzoyl-DL-arginine-2-naphthylamide hydrochloride; EDTA, ethylenediaminetetraacetic acid; GLC, gas liquid chromatography; HDL, high density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LDL, low density lipoprotein.

MATERIALS AND METHODS

Chemicals and radiochemicals. Cholesteryl [1-^{14}C]oleate (sp. act. 58.6 mCi/mmol) was purchased from New England Nuclear Corp. (Boston, MA). Phenolphthalein glucuronide, phenylphosphate, hemoglobin and α-N-benzoyl-DL-arginine-2-naphthylamide hydrochloride (BANA) were purchased from Sigma Chemical Co. (St. Louis, MO). Assay kits (free cholesterol C-Test Wako and HDL-cholesterol-Test Wako) were purchased from Wako Pure Chemical Ind. (Osaka, Japan).

Treatment of animals. Young male Sprague-Dawley rats weighing 150–180 g were used for all studies. Rats were given subcutaneously 0.1 ml of saline containing copper chloride (200 μmol/kg body) at a single dose (6 a.m.). At 24 hr after administration, the blood and liver were taken.

Preparation of subcellular fractions. For the preparation of lysosomal and cytosolic fractions from various tissues, the method of Brecher et al. (13) was followed. Rats were killed by guillotine, and the livers were perfused with ice-cold 1.15% KCl solution at 4 C. The liver was homogenized in eight volumes of ice-cold 0.25 M sucrose/1 mM ethylenediaminetetraacetic acid (EDTA)/0.01 M Tris-HCl buffer (pH 7.5). The homogenate was centrifuged at 1,000 × g for 10 min, and the resulting supernatant was centrifuged at 3,300 × g for 20 min. The 3,300 × g supernatant solution was centrifuged at 12,000 × g for 35 min. The pellet was rehomogenized in 0.25 M sucrose solution and recentrifuged at 12,000 × g for 20 min. The resulting pellet was resuspended in 0.25 M sucrose/0.01 M Tris-HCl buffer (pH 7.4). The original 12,000 × g supernatant solution was recentrifuged at 105,000 × g for 60 min to obtain the microsomal and cytosolic fractions.

Lecithin-cholesterol acyltransferase assay. LCAT activity was determined by the method of Nakagawa et al. (14). The standard assay medium contained 0.2 ml of rat serum and 0.3 ml of phosphate buffer (pH 7.4, ionic strength 0.1). The samples were placed in 15 ml screw-capped tubes, which then were flushed with N_2, sealed and incubated at 37 C for two hr with mechanical shaking. Free cholesterol in the reaction mixtures before and after incubation was determined with the Free Cholesterol C-Test Wako kit based on an enzymatic assay.

Acid cholesteryl ester hydrolase assay. The Acid CEH activity was measured by the method of Brecher et al. (13). Benzene solutions of cholesteryl oleate and cholesteryl [1-^{14}C]oleate were mixed, and the benzene was evaporated under N_2. Saline solution with 0.5% albumin was added, and the mixture was sonicated three times for 10 sec. The standard incubation mixture usually contained 0.69 nmol of cholesteryl [1-^{14}C]oleate (0.04 μCi) in 0.15 M acetate buffer (pH 4.5) and 50 μg of lysosomal protein in a final volume of 0.3 ml. The reaction was terminated by addition of 3.0 ml of benzene/chloroform/methanol mixture (1:0.5:1.2, v/v/v), containing unlabeled oleic acid (0.1 mM) as carrier. NaOH (0.6 ml of 0.3 M) then was added. The solution was mixed for 25 sec by vortexing and centrifuged for 10 min at 3,000 rpm. The amount of liberated [1-^{14}C]oleate in the upper aqueous phase was

determined by adding 0.5 ml aliquots to 10 ml of Aquasol 2 liquid scintillation mixture and counting the samples in an Aroka LSC 900 liquid scintillation counter.

Assay of lysosomal marker enzymes. Cathepsin D was assayed by the method of Hirado et al. (15), using hemoglobin as substrate. The amount of reaction products was assayed by the method of Lowry et al. (16). β-Glucuronidase was assayed with phenolphthalein glucuronide as substrate. Phenolphthalein liberated from the substrate was measured by the method of Gianetto and de Duve (17). Protein was assayed by the method of Lowry et al. (6).

Determination of cholesterol and triglyceride content. Total cholesterol and triglyceride in rat serum were determined by the method of Rudel and Morris (18) and van Handel and Zilversmit (19), respectively. Free cholesterol in rat serum was measured with the free cholesterol C-Test Wako Kit based on an enzymatic assay. High-density lipoprotein (HDL) cholesterol in rat serum was measured with the HDL cholesterol-Test Wako kit based on an enzymatic assay.

For determination of total and free cholesterol and triglyceride in rat liver, total lipids were extracted from rat liver homogenates by the procedure of Folch et al. (20). The chloroform extracts were evaporated to dryness, hydrolyzed with 5% methanolic-KOH at 60 C for one hr and extracted with hexane by the method of Uchiyama et al. (21). The hexane extracts were evaporated to dryness, and total cholesterol content as its trimethylsilyl ether derivative was determined by gas liquid chromatography (GLC) as described by Marcel and Vezina (22). Also, the chloroform extracts were evaporated to dryness, and the amount of free cholesterol and triglyceride were determined by the method mentioned above, respectively.

RESULTS

The effects of cupric ions on serum lipids content are shown in Table 1. At a single dose of 200 μmol/kg, the amount of total cholesterol in serum was increased markedly to about 150% of the control value. Also, the ratio of free to total cholesterol was increased in serum from rats receiving cupric ions. However, the serum triglyceride content showed a marked decrease to 55% of the control value. In contrast, the serum HDL cholesterol content showed no change following cupric ion treatment in comparison with the levels found in control rats.

It was thought possible that the increase of free cholesterol observed in cupric ion–treated rats may have been dependent upon a change in esterification activity. Therefore, the level of LCAT activity in serum was determined. If expressed as the percentage of the total serum cholesterol esterified, the LCAT activity in the serum of cupric ion–treated rats showed a slight decrease as compared to that of the control rats.

Changes in the cholesterol content of the liver also were investigated (Table 1). Total cholesterol content in rats receiving cupric ions was increased slightly to 120% of the control value. However, triglyceride content in the cupric ion–treated rats was reduced markedly to 60% of the control values. The time course of serum and liver cholesterol levels in cupric ion–treated rats also was studied. The levels of both reached a maximum after 12 to 24 hr and leveled off gradually until 48 hr (data not shown).

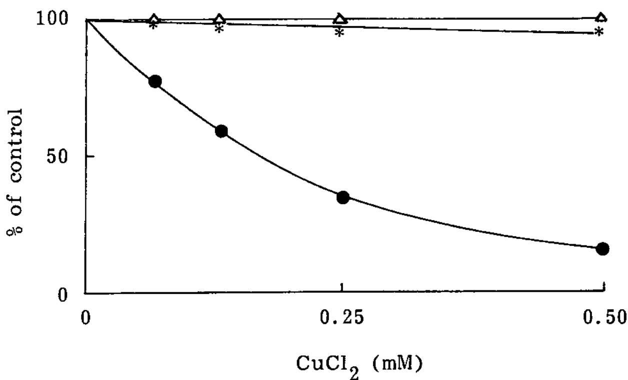

FIG. 1. Effect of cupric ions on lysosomal enzyme activities in vitro. The 100% values is the activity under standard assay conditions. ●, Acid CEH; △, cathepsin D; *, β-glucuronidase.

The effects of various cations on the cholesterol content of serum and liver are presented in Table 2. Serum cholesterol content in Cd^{2+}-treated rats was elevated slightly only at low concentration while Mn^{2+}, Co^{2+} and Zn^{2+} did not show any significant effect on serum and liver cholesterol contents.

Since it has been suggested that cupric ions are sequestered within the lysosome, the changes in cholesterol levels caused by cupric ion treatment may be mediated through this organelle. For this reason, the effects of cupric ions on liver lysosomal Acid CEH were studied. As shown in Table 3, when four different doses (400, 200, 40, 20 μmol/kg body wt) of cupric ions were administered to rats, cupric ions at doses more than 40 μmol/kg body wt caused an increase of cholesterol levels in serum and liver, and inhibition of Acid CEH activity at 24 hr after administration. This decrease occurred in a dose-dependent manner and ranged from 10 to 50% of control values.

The direct effect of cupric ions on lysosomal Acid CEH activity was investigated by incubation with lysosomes derived from normal rat liver (Fig. 1). Acid CEH was inhibited significantly at a cupric ion concentration of 0.25 mM in vitro, although the same concentration of cupric ions did not inhibit other lysosomal enzymes such as cathepsin D and β-glucuronidase. We studied the effect of cupric ions on Acid CEH activity in various tissues. Cupric ions had no effect on Acid CEH activity in the spleen, lung and heart (data not shown).

Lindquist (23) reported that cupric ions caused lysosome rupture and release of hydrolytic enzymes into the cytosolic fraction. Therefore, we studied the levels of lysosomal marker enzymes in the liver lysosomal and cytosolic fractions of both control and cupric ion–treated rats. The activities of the marker enzymes in lysosomes isolated from cupric ion-loaded livers showed a marked decrease of up to about 50% that of controls. On the other hand, the activities of cathepsin D and β-glucuronidase in the cytosolic fraction increased markedly (data not shown).

DISCUSSION

In our experiments, increases in cholesterol level and decreases in triglyceride level were observed in both the serum and liver of rats after administering cupric ions.

TABLE 1

Effect of Cupric Ions on Serum LCAT Activity and Serum and Liver Lipids

Serum	Control	$CuCl_2$
Total cholesterol (μg/ml)	726.6 ± 12.1	1071.4 ± 119.0[a]
Free cholesterol (μg/ml)	244.1 ± 32.8	427.0 ± 37.1[a]
Free/Total	0.33	0.41
HDL cholesterol (μg/ml)	456.3 ± 84.1	416.6 ± 28.0
Triglyceride (mg/dl)	49.65 ± 0.92	26.73 ± 0.46[a]
Esterification		
Net (μg/ml serum)	53.02 ± 1.04	80.14 ± 6.62[a]
% $\left(\frac{\text{cholesterol esterified}}{\text{free cholesterol}}\right)$	21.72 ± 1.52	18.77 ± 0.55[b]
Liver		
Total cholesterol (mg/g of liver)	1.396 ± 0.09	1.658 ± 0.04[b]
Free cholesterol (mg/g of liver)	0.900 ± 0.01	1.153 ± 0.01[b]
Free/Total	0.64	0.69
Triglyceride (mg/g of liver)	5.62 ± 0.90	3.43 ± 1.02[a]

Values are given as mean ± SD of six rats.

[b]Significantly different from control, $p < 0.05$.

TABLE 3

Dose Response of Cupric Ions on Serum and Liver Lipid Contents and Acid CEH Activity

		$CuCl_2$ (μmol/kg)			
	Control	20	40	200	400
Serum cholesterol (mg/ml)	67.1 ± 8.6 (100.0%)	77.1 ± 0.1 (114.9%)	79.1 ± 2.8[a] (117.9%)	93.9 ± 5.2[a] (139.9%)	97.3 ± 6.0[a] (145.0%)
Liver cholesterol (mg/g of liver)	1.30 ± 0.1 (100.0%)	1.28 ± 0.1 (98.5%)	1.43 ± 0.1[b] (110.0%)	1.50 ± 0.1[b] (115.4%)	1.56 ± 0.1[b] (120.0%)
Liver triglyceride (mg/g of liver)	5.25 ± 0.1 (100.0%)	7.15 ± 1.5 (136.2%)	3.85 ± 0.2[a] (73.3%)	3.10 ± 0.2[a] (59.0%)	3.10 ± 0.5[a] (59.0%)
Acid CEH activity ($\times 10^5$ dpm/mg of protein/30 min)	5.62 ± 0.4 (100.0%)	5.06 ± 0.1[b] (90.0%)	3.65 ± 0.3[a] (64.9%)	2.81 ± 0.2[a] (50.0%)	2.81 ± 0.1[a] (50.0%)

Values are given as mean ± SD of six rats. Values in parentheses are percentages of the values obtained in control rats (taken as 100%).
[a]Significantly different from control, $p < 0.01$.
[b]Significantly different from control, $p < 0.05$.

The changes observed were concentration-dependent. Moreover, the ratio of free to total cholesterol in serum increased in cupric ion-treated rats in comparison to controls while HDL cholesterol was unchanged. These results suggest that the elevation of serum cholesterol content as a result of cupric ion treatment may be a cumulative phenomenon. Moreover, the high serum cholesterol in cupric ion-treated rats appears to be due to a selective elevation in serum low density lipoprotein (LDL).

On the other hand, Lei (2) and Allen and Klevay (3) have reported that cupric ion-deficient rats exhibited significant cholesterolemia, and plasma cholesterol showed a significant correlation with hepatic cupric ion concentration. Lefevre et al. (6) reported that cupric ion deficiency was associated with an increase in HDL cholesterol levels. Moreover, Harvey and Allen (24) indicated that the ratio of plasma cholesteryl esters to free cholesterol apparently was not reduced by cupric ion deficiency. These results demonstrate that dietary cupric ion deficiency or excessive levels of these ions can cause marked changes in serum cholesterol levels in rats. When LCAT was expressed on the basis of the percentage of cholesterol esterified, the levels of LCAT activity in the serum of rats treated with cupric ions were decreased slightly in comparison with those of control rats. In addition, according to the data in Table 1, free cholesterol content and the ratio of free to total cholesterol in serum of rats treated with cupric ions were increased compared to those of control rats. These results suggested that the increase in the free cholesterol content of serum from rats treated with cupric ions may have been due to the reduction of LCAT activity and the increase of secretion of total cholesterol from liver to serum. In contrast, Lau and Klevay (25) and Harvey and Allen (24) reported that cupric ion-deficient rats showed a significant decrease in LCAT activity, suggesting that cupric ions may be required for the synthesis or may be a constitutent of the enzyme. However, Morris and Church (26) have suggested that endogenous substrate concentration may be one of the most important factors in LCAT assay. As shown in Table 1, the content of free cholesterol in the serum was increased markedly following cupric ion treatment. These results suggest that elevation of net esterification in the serum of cupric ion-treated rats seems to have been due to an increase in the serum free cholesterol content.

On the other hand, Brown et al. (27), reporting on lipoprotein receptors in liver and on intracellular enzymes located in lysosomes found that the receptors play a special role in the regulation of serum cholesterol levels. Lindquist (23) reported an indirect effect of cupric ions on lysosomal enzymes. In our investigations with cupric ions, it is noteworthy that both lysosomes isolated from cupric ion-loaded liver and those isolated from normal rats and then treated with cupric ions in vitro showed a decrease in Acid CEH activity and an increase in the activity of free lysosomal enzymes in the cytosolic fraction.

These results suggested that the hypercholesterolemia induced by cupric ions may be related partly to a decrease of Acid CEH activity. Moreover, the inhibitory effects of cupric ions in vitro perhaps may occur through direct action on the Acid CEH molecule. However, the hypercholesterolemia induced by cupric ions may be related to proteolysis of the lipoprotein receptor due to the increase in the activity of free lysosomal protease in the cytosolic fraction. It is not clear now whether a reduction in Acid CEH by excessive cupric ion concentrations does contribute directly to hypercholesterolemia.

On the other hand, we have reported previously the presence of Acid CEH in body tissues and found high levels of activity in spleen, lung, liver and heart (12). The extent of the inhibitory effect of cupric ions on Acid CEH in the spleen, lung and heart was not nearly as marked as that in liver. These results suggest that the cupric ion-dependent inhibitory effect of Acid CEH may be a characteristic specific to the liver, which is the organ mainly concerned with the catabolism of cupric ions.

[Received January 23, 1987]

Effects of Ketoconazole on Cholesterol Synthesis and Precursor Concentrations in the Rat Liver

Timo E. Strandberg, Reijo S. Tilvis and Tatu A. Miettinen*
Second Department of Medicine, University of Helsinki, SF-00290 Helsinki, Finland

Ketoconazole, an antimycotic agent, given to rats for a week as 0.05% food addition had no effect on the hepatic concentrations of free and esterified cholesterol or on the activity of acyl coenzyme A: cholesterol-acyltransferase (ACAT). However, the levels of free methylated cholesterol precursors, especially lanosterols, less markedly $\Delta^{8,24}$ and Δ^8-dimethyl sterols and monomethyl sterols, were increased after only one day's treatment, while those of esterified methyl sterols were increased inconsistently, and those of free and esterified Δ^8-lathosterol, lathosterol and desmosterol were not affected at all. Cholestyramine treatment had no significant effect on ACAT in spite of a decrease in the hepatic content of esterified cholesterol and caused a marked increase in the free cholesterol precursor levels, especially in those of lathosterols. Cholestyramine given to ketoconazole-treated rats increased the hepatic levels of Δ^8 and Δ^7-lathosterols but not desmosterol or methylated cholesterol precursors. Ketoconazole increased and cholestyramine markedly decreased plant sterols, sitosterol and campesterol in the liver. In serum, the contents of both lanosterols and lathosterol were increased but that of cholesterol tended to be decreased by ketoconazole (−19%). The results indicate that ketoconazole impairs demethylation processes at C-14 and to some extent at C-4 in the rat liver, resulting in lowered serum cholesterol level.
Lipids 22, 1020–1024 (1987).

Ketoconazole, an imidazole derivative, is an effective oral antifungal drug, which currently is in use for the treating systemic mycoses (1). Its clinical effect is mediated mainly through an inhibition of C_{14}-demethylation of ergosterol synthesis (2). Furthermore, the accumulation of trimethylated sterols due to the inhibition of C_{14}-demethylation could disturb some membrane functions of non-mammalian cells (2,3)

At doses used for the treatment of mycoses, ketoconazole has been quite free from serious side effects, but it seems to affect cholesterol synthesis in mammalian cells. Studies in the rat have indicated that the hepatic C_{14}-demethylation is impaired (2). Clinical studies have revealed that ketoconazole inhibits steroid hormone synthesis (4,5) and also decreases serum cholesterol (6). The drop of serum cholesterol was associated with a marked elevation of serum lanosterol (7), suggesting that the inhibition of C-14 demethylation also could operate in human liver. However, the details of ketoconazole effects on hepatic cholesterol metabolism are unknown largely thus far. To clarify the effects of ketoconazole treatment on hepatic cholesterol synthesis, we have analyzed serum and hepatic concentrations of cholesterol and its sterol precursors and the activity of acyl coenzyme A:cholesterol acyltransferase (ACAT, EC 2.3.1.26) in rat liver under basal conditions and after cholesterol synthesis was stimulated by cholestyramine.

METHODS

Animals. Male Sprague-Dawley rats (Orion, Finland) were accustomed to a reversed-lighting cycle and killed in the middle of the 12 hr dark period. The animals were given ground rat chow (Hankkija, Finland) and tap water ad libitum. One gram of this chow contained 0.5 mg cholesterol and 0.4 mg sitosterol. In the treatment groups, chow was supplemented with 0.05% (w/w) ketoconazole for seven days (Janssen/Orion, Finland), 5% (w/w) cholestyramine resin (Lääkefarmos, Finland) for seven days or cholestyramine combined with ketoconazole for the final three days of the seven-day treatment. Previous experiments showed that cholestyramine treatment almost doubled fecal sterol output and quadrupled the activity of hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase (EC.1.1.1.34), indicating activated cholesterol synthesis.

Analysis of lipids. After exsanguination of the rat under diethyl-ether anesthesia, serum was collected, the liver was removed, and a weighed portion was homogenized in chloroform methanol (2:1, v/v). Another portion was used for microsome preparation. After homogenization in a Dounce homogenizer, the sample was centrifuged for 15 min at 12,000 g, and the washed supernatant was further centrifuged 90 min at 105,000 g. The microsomal pellet was washed once, frozen in liquid N_2 and stored at −70 C for enzyme assays. The chloroform methanol extracts of hepatic and serum samples (8) were analyzed for free cholesterol, esterified cholesterol, its precursors, plant sterols, sitosterol and campesterol by thin layer chromatography (TLC)-gas liquid chromatography (GLC) methods using a SE-30 capillary column (9). The identification of GLC peaks was ascertained using mass spectrometric methods (10).

The SE-30 column does not separate dihydrolanosterol (DHL) from methostenol. The two precursors were separated in two samples by an additional TLC-run (Kieselgel 60 plastic plate in 55:45, v/v, diethylether heptane) before GLC. The precursors that were measured and their position in the cholesterol synthesis pathway are presented in Figure 1 (11). Systematic names of the precursors are presented in "Abbreviations."

Enzyme assays. The ACAT activity of the microsomal fraction was determined by following the incorporation of [1-^{14}C]oleic acid into cholesteryl ester (12). The

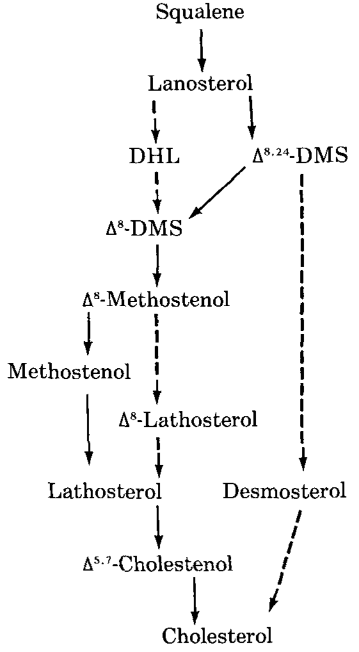

FIG. 1. Cholesterol synthesis from squalene. Solid arrows indicate major pathways, and broken arrows indicate probably weak pathways.

incubation volume was 0.2 ml, containing 100–200 μg microsomal protein and oleyl [1-^{14}C] coenzyme A (35 μM, SA 50 μCi/mol, New England Nuclear, Boston, MA). The incubation time was two min. The activity of the enzyme was linear with respect to time and protein concentrations under the experimental conditions. Microsomal protein was measured by the method of Lowry et al. (13).

Statistical methods. Control and treatment groups were compared using Student's t-test. P-values 0.05 or less were considered significant statistically.

RESULTS

Cholesterol content. Table 1 shows that treatment with 0.05% ketoconazole had no effect on the hepatic-free, esterified or total cholesterol contents. The percentage of esterification also was unaffected. However, cholestyramine treatment alone or in combination with ketoconazole reduced the concentration of hepatic esterified cholesterol significantly from 10% to 5%.

Plant sterol contents. In contrast to free and esterified cholesterol, hepatic contents of free plant sterols, campesterol and sitosterol tended to be increased by ketoconazole, clearly decreased by cholestyramine and virtually were unchanged by the combined cholestyramine-ketoconazole treatment (Table 1).

ACAT activity. Ketoconazole alone had no significant effect on hepatic ACAT activity, whereas in the cholestyramine-ketoconazole group the ACAT activity was lowered significantly as compared to the control group (Table 2).

Sterol precursors. The ketoconazole treatment for seven days increased the hepatic contents of all free methylated cholesterol precursors (Fig. 1). The contents of trimethylated lanosterol and DHL + methostenol were increased by a factor of 25 and eight, respectively, those of dimethylsterols increased from three-fold to six-fold, and

[b] $p < 0.05$ or less vs ketoconazole alone.

[c] Analyzed separately in two samples, as described in Methods.

Δ^8-methostenol increased three-fold. The separation of DHL and methostenol in two samples suggested that ketoconazole increased DHL but not methostenol. Effects of ketoconazole on demethylated precurors, lathosterol, Δ^8-lathosterol and desmosterol were inconsistent. Virtually similar results were obtained after one day's treatment (data not shown). Ketoconazole affected esterified sterols less consistently but increased the levels of esterified lanosterols and Δ^8-methostenol. The slight response of the esterified methyl sterols to ketoconazole decreased the esterification percentage of methyl sterols while that of the demethylated precursors was unchanged (Table 3).

The treatment with resin alone increased markedly all the precursor concentrations, especially those of lathosterols. As compared to the ketoconazole and/or cholestyramine treatments, the simultaneous administration of the two agents had surprisingly little additional effect on precursor accumulation. However, the levels of desmosterol were decreased; the levels of lanosterols and lathosterol were increased more than expected from the combined effects of only the two drugs.

Serum sterols. The complete analysis of free and esterified precursors was performed only in one serum sample at each treatment group. The results not shown here suggested that the changes in methylated precursor levels

(free and esterified) were similar to those observed in the liver with conspicuous elevations in the contents of lanosterols. Total levels of precursors and cholesterol were measured in a larger group of animals (Table 4), and the results showed that in addition to lanosterol and DHL the lathosterols were elevated in rat serum during ketoconazole treatment. Total cholesterol, in turn, tended to be decreased by ketoconazole; the decline was 45% during the combination treatment. However, cholestyramine alone also seemed to decrease cholesterol, whereas lathosterols were increased significantly as compared with control rats. Lanosterols were increased only in terms of μg/mg of serum cholesterol.

DISCUSSION

Accumulation of hepatic cholesterol precursors by ketoconazole treatment in this study suggests that the drug principally affects two steps of cholesterol synthesis in the rat liver. As in yeast cells, the demethylation of C-14 seems to be the major point of inhibition. In addition, also 4α-demethylation and possibly the conversion of Δ^8 to Δ^7 are affected because Δ^8-methostenol accumulates more than methostenol. Furthermore, it should be noted that the contents of lathosterols, which were not affected by ketoconazole in the liver, were elevated by the drug in serum, suggesting that the conversion of Δ^8-lathosterol to Δ^7-lathosterol and further to $\Delta^{5,7}$-cholestenol might also be altered by ketoconazole. In man, large doses of ketoconazole resulted in an accumulation of free lanosterols and to a lesser extent of Δ^8 precursor sterols in serum and bile, suggesting that in addition to 14α-demethylation the conversion of Δ^8-double bond to Δ^7-double bond was inhibited (14). The reduction of Δ^{24}, which is inhibited by triparanol (11), probably is not inhibited by ketoconazole because the desmosterol content was unchanged. However, the desmosterol pathway (see Fig. 1) with the preserved side chain double bond may be inhibited to some extent as a whole because accumulation of lanosterol results in its enhanced conversion to dihydrolanosterol. Thus, predominance of the side chain-saturated pathway of lanosterol metabolism may explain the unchanged desmosterol content in serum and liver during the ketoconazole-resin treatment.

Of the reactions involved in the conversion of lanosterol to cholesterol, 14α-demethylation is cytochrome P450-linked, 4α-demethylation is catalyzed by a mixed function oxidase (methyl sterol oxidase) without cytochrome P450 requirements (11,15), and the synthesis of methostenol from Δ^8 methostenol is catalyzed by microsomal Δ^8 isomerase (16). Thus, the results extend the earlier conception of ketoconazole as a general inhibitor of cytochrome P450-dependent enzymes (17).

It is of interest that despite the clear accumulation of the cholesterol precursors and the decrease of the serum cholesterol concentration, hepatic cholesterol concentrations were not decreased. This can be explained by the short treatment period (seven days), the presence of cholesterol in the rat diet, reduced biliary secretion or possibly by a concomitant inhibition of cytochrome P450-linked cholesterol 7α-hydroxylase or some other hydroxylase of bile acid synthesis in the rat liver. In view that plant sterols reaching the liver are partly eliminated as bile acids (18), their rise by ketoconazole and the decrease by cholestyramine suggest that the bile acid synthesis also could be inhibited by ketoconazole. In fact, human studies have indicated that the drug inhibits chenodeoxycholic acid synthesis (14) while in the rat the drug appears to inhibit cholic acid and β-muricholic acid synthesis also (19).

Depletion of hepatic cholesterol by cholestyramine enhances cholesterol synthesis when the activity of HMG-CoA reductase and methyl sterol oxidase are stimulated (20). This results in an increase in the hepatic and serum squalene and methylsterol contents (21) and, as shown in this study, especially in demethylated precursor concentrations. Accordingly, it was expected that inhibition of this flow by ketoconazole at lanosterol and at later possible steps might deplete dramatically hepatic cholesterol and result in a marked accumulation of methylated cholesterol precursors in the liver. However, the combination of cholestyramine and ketoconazole did not increase conspicuously the hepatic or serum contents of methyl sterols above the expected additional levels. Thus, the

stimulation of cholesterol synthesis by cholestyramine may partly overcome the synthesis blockade induced by ketoconazole. Further accumulation of Δ^7-lathosterol and Δ^8-lathosterol by the combination therapy was quite similar to that during cholestyramine alone and suggests that ketoconazole does not affect double bond formation at C-5.

The activity of ACAT in this study deserves some comment. In the liver, the activity of ACAT was unchanged by ketoconazole treatment, and the esterified precursor sterols generally did not increase proportionately to free sterols. This led to a decreased percentage of esterification of lanosterols especially but also Δ^8DMS. This can be due to low esterification of $4\alpha 4\beta$ methylated intermediates because these sterols are poor substrates for hepatic ACAT (22).

This study demonstrates the complexity of effects of ketoconazole on sterol biosynthesis in mammalian liver and suggests that ketoconazole could offer a tool to study the regulation of the synthesis beyond lanosterol. Furthermore, the hypocholesterolemic action of ketoconazole, observed especially in man (7,14), may imply a role for imidazole derivatives in the treatment of hyperlipidemias, possibly in combination with bile acid-binding resins.

[Received April 7, 1987]

Polyunsaturated Fatty Acids in Tissues of Rats Fed Trielaidin and High or Low Levels of Linolenic Acid

Pierre-Olivier Astorg* and **Joëlle Chevalier**
Institut National de la Recherche Agronomique, Station de Recherches sur la Qualité des Aliments de l'Homme, BV 1540, 21034 Dijon Cedex, France

Male and female weanling rats that were born to dams fed a diet low in linolenic acid received diets of 15% lipids by weight containing 45% elaidic acid (as trielaidin) and 8.5% or 0.1% linolenic acid for 10 weeks. Four other groups, in which palmitic or oleic acid replaced elaidic acid in the diet, served as controls. The fatty acid profiles of several lipid classes were determined in adipose tissue, adrenals, testes, heart and brain. Elaidic acid was incorporated into tissue lipids in varying degrees, depending on the organ and on the lipid class. Feeding elaidic acid induced no changes in the polyunsaturated fatty acid (PUFA) profiles of testes lipids but resulted in definite modifications of the PUFA patterns of heart phosphatidylcholine (PC) and phosphatidylethanolamine (PE). In linolenic acid-deprived rats, arachidonic acid was decreased in PC and linoleic acid was increased in both PC and PE; 22:5n-6 was strongly depressed in both PC and PE. In linolenic acid-fed rats, 22:6n-3 was decreased in PC and PE. These changes, on the whole, were more evident in females, and some also were observed in adrenal cholesteryl esters but only slightly in brain phospholipids. The apparent inhibition of the biosynthesis of PUFA induced by dietary elaidic acid appeared to be complex and of greater intensity in the n-6 fatty acid series than in their n-3 homologues.
Lipids 22, 1025–1030 (1987).

During the process of hydrogenation used to produce hardened fat, the unsaturated fatty acids are isomerized, yielding a mixture of geometric (*cis* and *trans*) and positional isomers (1–3). The effects of isomeric fatty acids on the essential fatty acid (EFA) status of experimental animals and on the metabolism of EFA were the focus of nutritional research (4–12). In these works, linoleic acid and/or its metabolites were extensively studied. On the contrary, linolenic acid, a polyunsaturated fatty acid (PUFA) of high biological importance that possibly is essential for mammals (13) has not received as much attention. However, its dietary supply was controlled in many experimental works, especially the last ones (11,12). In a previous study (14), we investigated the effects of brassidic acid (n-9, *trans* docosenoic acid) and of elaidic acid (n-9, *trans* octadecenoic acid) on the fatty acid composition of organ lipids in rats fed a high or a low supply of linoleic acid. Dietary elaidic acid was found to induce changes in n-6 PUFA, especially in the heart. In this work, the incorporation of elaidic acid in body lipids and the effects of dietary elaidic acid on the PUFA profiles of several organs were studied in male and female rats fed diets with high or low linolenic acid contents.

Abbreviations: ANOVA, analysis of variance; CE, cholesteryl esters; CL, cardiolipin; EFA, essential fatty acid; GLC, gas-liquid chromatography; PC, phosphatidycholine; PE, phosphatidylethanolamine; PHSO, partially hydrogenated soybean oil; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; TG, triacylglycerols; TLC, thin-layer chromatography.

MATERIAL AND METHODS

Animals and diets. Weanling Wistar female rats were fed a purified diet containing 15% sunflower oil by weight and 2% liver meal as sole lipid sources. Apart from the addition of liver meal, the composition of the diet was the same as previously published (15). This liver meal-supplemented diet contained about 100 g/kg of linoleic acid and 400 mg/kg of n-3 PUFA. After three months, the rats were mated, and the diet was continued during gestation and lactation. Twenty-four rats (12 males and 12 females) born to these dams were kept on the maternal diet three to six days after weaning. They then were divided randomly into six groups of four (two males and two females in each) and fed a purified diet ad libitum for 10 weeks. This diet differed from the maternal diet by the absence of liver meal and by 0.4% instead of 0.9% calcium. The digestibility of elaidic acid was 97–98% (15). The experimental diets differed from each other only in the fatty acid composition of the lipids (15% by weight). These were blends of trielaidin (containing 98% n-9, *trans*-octadecenoic acid), triolein, palm oil, sunflower oil and linseed oil in adequate amounts. The fatty acid composition of these mixtures is shown in Table 1. Linolenic acid was present in high amounts in three mixtures (PL, EL and OL) and in very low amounts (0.11–0.13% of dietary fatty acids, i.e. 160–200 mg/kg diet) in the three other mixtures (P, E and O). The sum of linoleic + linolenic acid contents was the same in all mixtures (ca. 21%). This experiment can be considered as a 2^3 factorial design; the factors are the sex of the rats, the dietary essential fatty acids (with or without linolenic acid) and the dietary nonessential fatty acids (elaidic, palmitic or oleic acid). At the beginning of the experimental period, control weanling rats were killed and their organs excised. Weight gain and food intake were recorded individually throughout the experiment. At the end of the 10-week period, the rats were killed; the heart, brain, testes, adrenals and a piece of perirenal adipose tissue were excised,

weighed and stored at −20 C in chloroform/methanol (2:1, v/v) with 0.01% hydroquinone until analysis. In each group, the adrenals were pooled for every two rats of the same sex.

Analytical methods. Organs lipids were extracted according to Folch et al. (16), except adipose tissue, for which only chloroform was used. Neutral lipids and phospholipids of hearts, testes and adrenals were separated using Sep-Pak silica cartridges (17). These fractions were separated further in classes by thin-layer chromatography (TLC) on Silica Gel G, using hexane/diethyl ether/acetic acid (70:30:1, v/v/v) as migrating solvent for neutral lipids, and chloroform/methanol/14% ammonia in water (65:25:4, v/v/v) for phospholipids. Total brain lipids were separated directly by TLC (18). After spraying the plates with 0.02% Rhodamine B and visualizing the separated bands under UV light, adrenal triacylglycerols (TG), cholesteryl esters (CE), phosphatidylcholine (PC) and phosphatidylethanolamine (PE), testes TG, PC and PE, heart TG, PC, PE and cardiolipin (CL), and brain PC, PE and phosphatidylserine (PS) were scraped into teflon-lined, screw-capped tubes for methylation. Methyl esters were prepared by reacting the lipid classes at room temperature, in the presence of the silica gel, with 2 N sodium methoxide in methanol/benzene (60:40 v/v) for 10 min (except for CE: 30 min), then with an excess of 5% sulfuric acid in methanol for 30 min (adaptation of the method of Glass [19]). Water was added to the reaction mixtures, and methyl esters were extracted once with hexane and washed with water. Fatty acid methyl esters were analyzed by gas-liquid chromatography (GLC) using both Carbowax 20M- and Silar 10C-coated glass capillary columns (30m × 0.3 mm I.D.; isothermal analyses with the temperature ranging from 175 to 190 C). The first stationary phase gave a complete profile of all organ fatty acids with the exception of the geometrical isomers that were separated on Silar 10C columns. The gas chromatographs were equipped with Ross injection devices and FID detectors coupled to integrators.

Statistical analysis. Except for adrenal fatty acids, for which no statistical treatment was done, the data were treated by two- or three-way analysis of variance (ANOVA), with complete models (all interactions) (20). In many cases, the heterogeneity of variances between groups required two separate one- or two-way ANOVAs, on the groups with (PL, EL, OL) and without (P, E, O) linolenic acid. Additional methods (method of contrasts, of Newman and Keuls [20]), were used when needed to compare means (i.e. to compare the levels of the three-level factor, or to analyze interactions). All effects or differences described in Results are significant at the 5% probability level. Fatty acid percentages showed, as expected, relatively small within-group variations, allowing many effects or differences to be detected with only two rats per group. Calculations were made with a Commodore CBM 4032 microcomputer.

RESULTS

PUFA content of tissues at start of experimental period. As a consequence of the maternal diet, organ lipids of the weanling rats contained high amounts of n-6 PUFA and comparatively low amounts of n-3 PUFA (Table 2), except for brain PE and PS in which 22:6n-3 amounted to ca. 10%. Feeding dams a commercial stock diet, which generally contains substantial amounts of linolenic acid, would have resulted in high levels of n-3 PUFA in the organ lipids of the progeny (21). These n-3 PUFA, especially 22:6, are known for their relative persistence in body lipids, mostly in the brain (13), even if the post-weaning diet is low in linolenic acid. On the contrary, the tissue PUFA contents of (n-3)-depleted rats were much more sensitive to the subsequent feeding of linolenic acid. For this experiment, it seemed advantageous to use (n-3)-depleted weanling rats.

Incorporation of elaidic acid into organ lipids. Elaidic acid was present in high amounts in the TG of adrenals, testes and the heart, and even higher in adipose tissue

	PE	7.8	9.4	9.6	9.1	—

[a]Percentage of elaidate in each class; means of two rats, except in adrenals: pools of two rats.

(Table 3). In the latter, male rats incorporated slightly more elaidic acid than females. In all organ TG, the *trans* acid was incorporated at the expense of both saturated (mainly palmitic) and oleic acid. In addition to 9t-18:1, adrenal CE of elaidic acid-fed rats (E and EL groups) contained a fatty acid having the retention characteristics of *trans* 20:1 on both Carbowax 20M and Silar 10C columns (ca. 5-6%). The incorporation of elaidic acid into PC and PE was highest in the heart and significant in adrenals; it substituted almost exclusively for stearic acid. Comparatively, testes PC and PE contained very low amounts of the *trans* acid, as did heart cardiolipin and all phospholipid classes of brain. No effect of dietary linolenic acid or sex was detected in any organ or lipid class considered, except for the small difference between sexes observed in adipose tissue.

Fatty acid composition of adipose tissue. The fatty acid composition of adipose tissue reflected that of the dietary lipids, especially the elaidic, linoleic and linolenic acid contents. Minor changes also were observed: linoleic and linolenic acids were slightly higher in males than in females (linoleic acid: group P, E, O, 21.4% vs 18.5%, respectively; groups PL, EL, OL, 13.1% vs 11.9%, respectively; linolenic acid: groups PL, EL, OL, 5.1% vs 4.4%, respectively). Linoleic and linolenic acid were lower in oleic acid-fed rats than in rats fed palmitic or elaidic acid (linoleic acid: groups P, E: 20.6% vs group O: 18.5%; groups PL, EL: 13.1% vs group OL: 11.2%; linolenic acid: groups PL, EL: 5.0% vs group OL: 4.2%).

PUFA of adrenal lipids. The presence of linolenic acid in the diet decreased 22:4n-6 and 22:5n-6 and increased n-3 PUFA (20:5, 22:5, 22:6) in adrenal cholesteryl esters (Table 4). There were always more n-6 22 PUFA, but not n-3 PUFA, in females than in males. Among the linolenic acid-deprived rats, those fed elaidic acid had the lowest contents of 20:4n-6, 22:4n-6 and 22:5n-6. In the linolenic acid-fed series, n-3 PUFA (20:5, 22:5, 22:6) were higher in palmitic acid-fed rats (PL) than in elaidic- or oleic acid-fed rats (EL, OL). PUFA-levels in adrenal PC and PE were influenced by dietary linolenic acid and may be different in each sex, but showed no great changes due to elaidic acid.

PUFA of testis lipids. Rat testis lipids, including TG, were characterized by high contents of long-chain PUFA of the n-6 series, especially 22:5, but also 20:3, 20:4, 22:4, 24:4 and 24:5 (Table 5). Linoleic acid was depressed in TG by dietary linolenic acid (as in the TG of all other organs) but was slightly increased in PC and PE, as well as 20:3n-6. Dietary 18:3n-3 depressed 20:4n-6 in PC, and 22:4n-6 in PC and PE. However, 22:5n-6 and n-6 C24 PUFA remained unchanged in the three classes. Except for linolenic acid in TG, n-3 PUFA levels were low, even in linolenic acid-fed rats. Moreover, the PUFA contents of testis lipids were insensitive to the feeding of elaidic acid.

PUFA of heart lipids. In heart CL, a phospholipid class containing mainly linoleic acid, the oleic acid-fed rats had the lowest linoleic acid content: 64% (O) and 51% (OL) by comparison to 71% (P), 80% (PL), 86% (E) and 81% (EL). This decrease of linoleic acid was compensated by an increase of saturated and oleic acids, as well as of other

[b]<0.1%.

PUFA. Elaidic- and palmitic acid-fed rats had similar fatty acid patterns in heart CL.

The 22:6n-3 contents of heart PC and PE were higher in females than in males for all dietary groups, as well as that of 22:5n-6 for groups P, E and O (Table 6). The inverse was true for 18:2n-6, which almost always was higher in males than in females. Feeding linolenic acid shifted both PC and PE fatty acid profiles towards n-3 PUFA (22:5 and 22:6), which were increased at the expense of n-6 PUFA (20:4, 22:4, 22:5). Contrary to other organs, the PUFA profiles of heart phospholipids strikingly responded to elaidic acid feeding: linoleic acid was raised in both PC and PE of groups E and EL; 22:6n-3 was lowered in both PC and PE of linolenic acid-fed rats. Those fed palmitic acid had the highest content 22:6n-3 in PE (PL > OL > EL). In linolenic acid-deprived rats, dietary elaidic acid depressed 22:4n-6 and 22:5n-6 in both PC and PE, as well as arachidonic acid in PC. The latter PUFA was increased in the PE of linolenic acid-deficient, elaidic acid-fed females (E vs P and O). The most patent of these effects is the drop of PE 22:5n-6 content in the elaidic acid-fed, linolenic acid-deprived rats (group E).

The inhibition of n-6 PUFA synthesis also was seen in heart TG of linolenic acid-deprived rats: arachidonic acid contents were lower in group E (males: 2.4%; females: 1.6%) than in the other groups (group P: 4.5% and 4.0%; group O: 4.0% and 2.8%, respectively); 22:5n-6 was particularly high in group P (7.7% and 9.2%, respectively), present in group O (0.4% and 1.1%, respectively) and nearly absent in group E (0.3% and 0.0%, respectively).

PUFA of brain phospholipids. Differences between males and females in the fatty acid profiles of brain PC, PE and PS either were absent or very slight. For this reason, the data presented are the means of the dietary groups (two males and two females). Feeding of linolenic acid resulted in the replacement of the n-6 PUFA by 22:6n-3 in brain phosphoglycerides. The three n-6 PUFA were not affected equally: arachidonic acid and 22:4n-6 were only slightly reduced by dietary 18:3n-3 but 22:5n-6 underwent a sharp decrease. For a given class, the sum of all PUFA percentages remained remarkably constant, despite significant but small effects of dietary factors in PC and PE. The presence of elaidic acid in the diet had little influence on brain lipid PUFA. However, the slight but significant decrease of 22:5n-6 in PE and PS of linolenic acid-deprived, elaidic acid-fed rats (group E) is noteworthy.

DISCUSSION

The incorporation of dietary *trans* fatty acids, particularly of elaidic acid, in organ lipids has been studied extensively (4–12,14,22–30). Our results are in agreement with the general findings that most *trans* octadecenoic acids, including elaidic acid, readily incorporate into organ TG and in the 1-position of phosphoglycerides, where they substitute for saturated fatty acids. Known exceptions are brain lipids of post-weaning rats (4,5,29) testis phospholipids (4,5,25) and heart cardiolipin (30). This can be explained by the reduced utilization of exogenous fatty

TABLE 7

[a]Percentage of the fatty acids of each class; means of four rats (two males and two females). Other PUFA (<1%): 20:2n-9, 18:2n-6, 20:3n-6, 22:5n-3; 18:3n-3 and 20:5n-3 are absent of the three classes; there is no C22:5n-3 in PC.
[b]PUFA: Sum of the percentages of the four PUFA listed.

acids by brain and testis phospholipids and by the low saturated fatty acid content of CL. The presence of *trans*-octadecenyl chain in the plasmalogens of heart mitochondria, recently demonstrated by Wolff et al. (31), had not been looked for in this study but would deserve confirmation. In a previous work (14), the elaidic acid contents of organ lipids of rats fed elaidic acid were shown to be depressed when the dietary supply of linoleic acid was low. This possibly was caused by an increase of fatty acid oxidation, due to linoleic acid deficiency. This work shows that in linoleic acid-provided animals, the supply of linolenic acid does not influence the elaidic acid contents of tissue lipids.

Female rats are known to have higher levels of PUFA in the lipids of their organs than males (32). The observed sex differences were small in the brain, larger in the adrenals and very marked in the heart. The PUFA profiles, especially of heart PE, showed the ability of female rats over male rats to synthetize and/or to incorporate the end-products of the elongation-desaturation enzyme system: 22:5n-6 and 22:6n-3.

The effects of the dietary supply of linolenic acid on the PUFA profiles varied widely depending on the organ. These effects were remarkably low in testes where the main PUFA, 22:5n-6, was unchanged but were evident in adrenals, heart and brain, as previously observed (33,34). 22:6n-3 still was present in fairly high amounts in brain PE and PS of linolenic acid-deprived rats, illustrating the retention of this fatty acid by nervous tissue, even when the supply is very low (13). On the contrary, 22:5n-6 appears in high amounts in organ phospholipids only in rats that have been fed both high levels of linoleic acid and very low levels of linolenic acid (33-36).

Dietary elaidic acid depresses the levels of some PUFA in the lipid classes of several organs. Although the greatest effects were seen in the heart, the widespread distribution of the phenomenon in the body supports the hypothesis that elaidic acid acts on the biosynthesis of PUFA rather than on the incorporation in organ lipids. These changes are fairly complex: the biosynthesis of arachidonic acid is inhibited (as seen by the decrease of linoleic acid in the lipids of adrenals and heart) but the following steps of PUFA biosynthesis, elongation and −4 desaturation, through which 22:5n-6 and 22:6n-3 are biosynthetized, are most affected. This is more evident in the n-6 than in the n-3 EFA series, therefore in the linolenic acid-deprived rather than in the linolenic acid-fed rats. Moreover, this effect is of greater intensity in females than in males.

Diets containing partially hydrogenated fats have been shown to intensify EFA deficiency (4,6-9) and to induce a decrease of some PUFA contents in organ lipids (4,9,11,24,28,37). The *trans,trans* isomer of linoleic acid when fed to rats is a powerful inhibitor of the biosynthesis of n-6 and n-9 PUFA (38-41) and, more specifically, of the 6-desaturase (39,41,42) in either linoleate-deprived or linoleate-fed rats. Dietary elaidic acid lowers the arachidonic acid and 20:3n-9 contents of tissue phospholipids (blood, liver, heart) of linoleic acid-deficient rats, though to a lesser estent than the *trans,trans* 18:2 isomer (4,22, 28,43,44). In linoleic acid-provided animals, the feeding of elaidic acid causes an increase of linoleic acid and a decrease of 22:5n-6 in organ phospholipids; arachidonic acid is only slightly reduced (14,22). The 9-, 6- and 5-desaturases of rat liver microsomes are inhibited in vitro by a number of *cis*- and *trans* octadecenoic acid isomers, including elaidic acid (45,46). Recently, elaidic acid and other n-9, *trans* monoenes have been found to depress in vitro the 6- and 5-desaturase activities of human skin fibroblasts (47,48). In vivo effects of dietary fats containing trans monoenes are less clear (24,49,50): the decrease of 6-desaturase (49) or the increase of 5-desaturase (24) were not found by all authors. Effects of *trans* fatty acids on fatty acid elongation and 4-desaturation activities have not been directly observed yet.

Feeding partially hydrogenated soybean oil (PHSO) containing ca. 20% *trans* fatty acids to linoleic- and linolenic acid-provided rats, Lawson et al. (11) observed a reduction of the arachidonic acid contents of the phospholipids in all organs studied, mainly in the liver. The inhibition was specific to the n-6 EFA series; n-3 PUFA were either unchanged or increased by the dietary treatment. In feeding concentrates of *trans* or of *cis* 18:1 isomers from the same PHSO to rats, the same authors demonstrated that these effects were due to the *trans* isomers (12). Although the *trans* octadecanoic acids used by Lawson et al. were a complex mixture of positional isomers, their results and ours agree that the inhibition of PUFA biosynthesis produced by feeding *trans* monoenes can be observed in EFA-provided animals and is more marked on the n-6 PUFA series than on their n-3 homologues.

Further research is needed to elucidate the interactions of dietary fatty acid isomers with essential fatty acids and to evaluate the consequences for membrane, cell and organ function, particularly in the heart.

Ltd., Chiyoda-ku, Tokyo, Japan; and [d]The First Division, Research and Development, Daigo Nutritive Chemicals Ltd. Yodogawa-Ku, Osaka, Japan

An injectable emulsion of docosahexaenoic acid (DHA) was prepared. One hundred ml of the emulsion contained 3 g of 93%-pure 1,2,3-tridocosahexaenoylglycerol (DHA-TG), 1.2 g of 93%-pure 2-docosahexaenoyl-phosphatidylcholine as an emulsifier and 2.5 g of glycerol. Thirty ml of the emulsion of DHA-TG was injected into three rabbits on days 1 and 4 of the study. Blood was taken on day 0, on day 4 just before the second injection and on day 7. The percentage of DHA in the total phospholipid fraction of platelets increased from 0.46% (day 0) to 1.88% (day 4, $p < 0.05$) and 3.66% (day 7; $p < 0.02$ vs day 0). The percentage of eicosapentaenoic acid (EPA) increased from 0.46% (day 0) to 1.03% (day 4, $p < 0.02$) and 1.63% (day 7: $p < 0.05$ vs day 0). The percentage of arachidonic acid (AA) decreased from 9.45% (day 0) to 4.31% (day 4, $p < 0.05$) and 6.68% (day 7; $p < 0.02$ vs day 0). The percentage of DHA in the total phospholipid fraction of erythrocyte membranes increased from 0.23% (day 0) to 0.91% (day 4, $p < 0.05$) and 1.52% (day 7; $p < 0.005$ vs day 0); that of EPA increased from 0.21% (day 0) to 0.34% (day 4, $p < 0.005$%) and 0.52% (day 7, $p < 0.01$ vs day 0); that of AA was unchanged. Blood lipids were the same before and after the two injections of the emulsion, except that free fatty acids decreased markedly from 0.32 to 0.06 mEq/l ($p < 0.02$). On day 8, free AA (2 mg/kg) was injected into ear veins of the three treated rabbits and of four control rabbits (not treated with DHA-TG). All the control rabbits died a few minutes after the AA injection, but none of the DHA-treated rabbits died after AA injection ($p < 0.01$). An emulsion of DHA-TG may be useful for patients having immediate risk of thrombosis or for those who need DHA but cannot take it orally.
***Lipids 22,* 1031-1034 (1987).**

It has long been known that ω6 fatty acids are essential to health (1), but it is only fairly recently that several studies have suggested that ω3 fatty acids also are important for normal tissue functions (2–5). Among them, docosahexaenoic acid (DHA) seems to be very important for the nervous system including the retina, since DHA is the major fatty acid in the phospholipid fraction in the gray matter of the brain (6) and in the retina (7). Deprivation of ω3 fatty acids from the diet for two generations could inhibit the development of functionally normal retinas in monkeys (5). Also, it is reported that a disturbance of the peripheral nervous system developed in a 6-year-old girl after long-term, total parenteral feeding of a diet that contained little ω3 fatty acid (3).

Although α-linolenic acid (18:3ω3), whether ingested or administered parenterally, could be converted to DHA, the rate of conversion is low (8,9). Therefore, we thought it was important to develop a DHA emulsion for people who need DHA but cannot take it orally. The purpose of this investigation was to observe how rapidly a DHA emulsion injected into rabbits could increase the DHA levels in blood cells.

MATERIALS AND METHODS

Experimental design. Three rabbits were used, each weighing ca. 3 kg. Throughout the experiment, they were fed a standard rabbit diet (RM-3, Funabashi Farms, Chiba, Japan) (Table 1), the major lipid component of which was soybean oil. Blood was taken from ear veins on days 0, 4 and 7. Thirty ml of 1,2,3-tridocosahexaenoyl-glycerol (DHA-TG) emulsion was injected via the ear veins on day 1, and on day 4 just after the second blood sampling. On day 8, the three rabbits were injected through ear veins with 6 mg of arachidonic acid (AA; Sigma Chemical Co., St. Louis, MO) dissolved in 100 mM sodium bicarbonate. Four control rabbits, each weighing about 3 kg and not treated with the DHA-TG emulsion, were injected with AA in the same manner.

Preparation of emulsion. Sardine oil was extracted from edible parts of sardines, deacidified and decolorized. After separation of saturated lipids by crystallization at −70 C, a polyunsaturated fatty acid–rich triglyceride mixture was saponified and then methylated

TABLE 1

Composition of Rabbit Diet RM-3 (Wt%)[a]

Crude protein	15.8%
Crude lipids	4.0%[b]
Crude fiber	13.3%
Crude mineral	9.6%
Soluble material containing no nitrogen	50.3%
Metabolic energy	3.6 kcal/g

[a]According to the manufacturer's brochure; a vitamin mixture is also added.
[b]Lipids constitute 10 cal% and consist mostly of soybean oil.

(10). Methyl esters of polyunsaturated fatty acids were separated to obtain a DHA methyl ester fraction by high pressure liquid chromatography (11). One tenth mol of glycerol and 0.3 mol of free DHA, which was obtained by hydrolysis of DHA methyl esters, were reacted in dimethyl sulfoxide with 0.3 mol of N,N′-carbonyl-diimidazole as a condenser and imidazole sodium salt as a catalyst. After overnight reaction at room temperature, DHA-TG was extracted by hexane and purified by a silica gel column (12). α-Tocopherol (0.2%) was added to DHA-TG. 2-Docosahexaenoyl-phosphatidylcholine (DHA-PC) was synthesized as follows: 0.1 mol of lysophosphatidylcholine, which was enzymatically prepared from soybean oil phosphatidylcholine with phospholipase A_2, and 0.1 mol of free DHA were reacted in chloroform with 0.1 mol of N,N′-carbonyl-diimidazole and imidazole sodium salt as a catalyst for 1 hr at room temperature. DHA-PC was extracted by chloroform/methanol (2:1, v/v) and purified by a silica gel column. DHA-TG was emulsified with DHA-PC according to the method of Geyer et al. (13). One hundred ml of the DHA-TG emulsion contained 10 g of DHA-TG, 1.2 g of DHA-PC and 2.5 g of glycerol. The fatty acid composition of the lipids used in the experiments is shown in Table 2.

Analysis of fatty acid composition. The fatty acid composition in total phospholipids in platelets was analyzed as follows. Platelet-rich plasma (PRP) was prepared by centrifugation of blood citrated with 1/10 volume of 3.8% sodium citrate. Platelets from 0.4 ml of PRP were washed with 0.9% saline, reconstituted in 0.4 ml of saline and sonicated for 1 min. Total lipids were extracted with 10ml of chloroform/methanol (2:1, v/v) The phospholipid fraction was obtained as the unmoved fraction following thin layer chromatography on silica gel plates using petroleum ether/ether/acetic acid (60:30:1, v/v/v) as solvent. Methyl esters of fatty acids of total phospholipids were prepared with boron trifluoride and methanol (14). A glass capillary column, Advans-DS, 0.24 mm × 25 m (Shinwakagaku, Kyoto), was used to analyze the fatty acid methyl esters. The column was attached to a GC7A gas chromatograph (Shimadzu, Tokyo). The injection was at 250 C; separation with N_2 gas as a carrier (40 ml/min) was isothermal at 200 C; detection was by flame ionization. Erythrocytes were separated from citrated blood, washed and hemolyzed by osmotic shock. The membrane fraction was separated by centrifugation and washed twice. The fatty acid analysis of phospholipids of membranes was then performed as described above.

Blood chemistry, platelet aggregation and statistics. PRP was prepared as described above. Platelet aggregation was measured with an aggregometer (Model PAT-4M, Niko Bioscience, Tokyo), adding 20 μl of 50 μM ADP (Sigma), 100 μg/ml of collagen (Hormon-Chemie, Munich, FRG) or 100 μM AA as an aggregant to 180 μl of PRP to make up a 200-μl mixture. Serum total cholesterol (15), triglycerides (16) and free fatty acids (17) were measured enzymatically; glutamic-oxaloacetic transaminase, glutamic-pyruvic transaminase and γ-glutamyl transpeptidase were measured spectrophotometrically with an autoanalyzer. Data were expressed as means ± SD. Student's t test or χ^2 test was used for data evaluation.

RESULTS

There were no significant differences in body weight between days 0 and 7 in the three rabbits. Changes in blood chemistry are shown in Table 3. There was a significant reduction of free fatty acids following the two injections of DHA emulsion. Changes in the fatty acid composition of total phospholipids of platelets and red blood cell (RBC) membranes are shown in Tables 4 and 5, respectively. In both platelets and RBC membranes, DHA and eicosapentaenoic acid (EPA) levels were increased significantly. There were no significant differences in platelet aggregation induced by any aggregants used in the experiments between days 0 and 7. However, the injection of AA (2 mg/kg) into ear veins on day 8 caused death in none of the three rabbits, while the same injection killed all four control rabbits, which had been on the same diet and were not treated with DHA emulsion ($p < 0.01$).

TABLE 4

Changes in Fatty Acid Composition of Platelet Total Phospholipids[a]

Fatty acids	Fatty acid composition (mol %)		
	Day 0	Day 4	Day 7
16:0	24.2 ± 1.3	31.3 ± 2.4^{b}	22.4 ± 0.4^{b}
18:0	27.4 ± 0.4	23.3 ± 2.0	26.8 ± 1.0
18:1	8.3 ± 0.2	10.0 ± 1.0	8.4 ± 0.6
18:2ω6	19.9 ± 2.0	14.6 ± 3.4	22.2 ± 0.7
18:3ω3	0.61 ± 0.10	0.56 ± 0.11	0.76 ± 0.04
20:4ω6	$9.45 \pm 0.39^{b,c}$	$4.31 \pm 0.80^{b},^{b'}$	$6.68 \pm 0.27^{b',c}$
20:5ω3	$0.46 \pm 0.07^{b,c}$	1.03 ± 0.16^{c}	1.63 ± 0.32^{b}
22:6ω3	$0.46 \pm 0.10^{b,c}$	1.88 ± 0.42^{b}	3.66 ± 0.53^{c}

[a]Thirty ml of DHA emulsion was injected on day 1 and day 4 just after the second blood sampling. Values with the same superscript are significantly different from each other. b(b'), $p < 0.05$; c, $p < 0.02$.

TABLE 5

Changes in Fatty Acid Composition of Phospholipids in RBC Membranes[a]

Fatty acids	Fatty acid composition (mol %)		
	Day 0	Day 4	Day 7
16:0	27.5 ± 0.7	28.3 ± 0.4	28.0 ± 0.5

[a]Thrity ml of DHA emulsion were injected on day 1 and day 4 just after the second blood sampling. Values with the same superscript are significantly different from each other. b(b'), $p < 0.05$; $p < 0.02$; d, $p < 0.01$; e, $p < 0.005$.

DISCUSSION

Almost all the papers dealing with ω3 fatty acids as nutritional components or as drugs have described their oral administration. If one considers the importance of ω3 fatty acids from the standpoint of long-term nutrition, oral administration would appear to be the only feasible means of administration. However, if one considers the pharmacological aspects of ω3 fatty acids, it may sometimes be important to administer them in a manner such that their concentration in the blood can be raised quickly. For immature babies or babies under 6 months of age whose gastrointestinal system does not function, the injection of DHA becomes extremely important because brain nerve cells, the membranes of which contain an enormous amount of DHA, still proliferate during the first six months of life. Indeed, the huge demand of neonatals for DHA is emphasized by the estimate that in the brain tissue up to 50% of the ultimate mass of DHA accumulates after birth (18).

It is only recently that a few papers have described the intravascular administration of lipid emulsions containing α-linolenic acid for the supplementation of ω3 fatty acids. However, the conversion rate of α-linolenic acid to DHA is not very high, and the increment in DHA in tissues may take a long time (9,19). We have already developed an injectable emuslion of 1,2,3-trieicosapentaenoyl-glycerol (EPA-TG) and described the effect of this emulsion on the fatty acid composition in blood (20). Although the injection of EPA-TG into rabbits increased EPA levels in blood, it did not increase DHA levels in blood. Therefore, if patients who cannot eat anything at all need DHA, whether as a supplement or for pharmacological purposes, an emulsion containing DHA is indispensable. It is interesting to note that the injection of DHA-TG emulsion increased not only DHA levels but also EPA levels both in platelets (Table 4) and in RBC membranes (Table 5). The retroconversion of orally administered DHA has already been shown (21). In this study, the retroconversion was shown to occur without any absorption process of DHA in the intestine.

With regard to the effects of blood chemistry of this emulsion, we did not observe any remarkable changes except for a significant decrease in free fatty acid levels in serum after the injection of the DHA-TG emulsion. In our previous study (20), we showed that the levels of serum free fatty acids were not changed significantly by the injections of EPA emulsion (0.31 ± 0.20 to 0.41 ± 0.10 mEq/1), but were increased significantly by injections of soybean oil emulsion (0.32 ± 0.10 to 0.56 ± 0.10 mEq/1, $p < 0.05$) in rabbits. Although the hypolipidemic effect of fish oil is very well investigated (22), only a few studies report the effect of administration of pure or concentrated DHA on enzyme activities related to lipid metabolism (23,24). Iritani et al. reported that the administration of a mixture of docosapentaenoic acid methyl ester and DHA methyl ester decreases fatty acid synthetase activity in the rat liver (23). Morisaki et al. reported that the activities of acyl-CoA synthetase are not changed in the rat aorta by DHA administration (24). Therefore, the depressive effect of DHA emulsion on serum free fatty acids may be mediated at least partially by decrease in fatty acid synthesis. However, the available data are so limited that the mechanism of action of DHA on serum free fatty acids is not clear and remains to be elucidated.

DHA is known to depress platelet aggregation after oral administration (21). However, we did not observe a significant depression of platelet aggregation. This may be due to the small number of experimental animals in the present study.

Talesnik infused free DHA to isolated platelet-free rat heart and observed a protective effect of DHA against AA-induced coronary flow reduction (25). He suggested that the incorporation of DHA by the isolated heart would inhibit the cyclooxygenase (26) in the coronary vessel walls, interfering with the generation of vasoconstrictive metabolites from AA (probably thromboxane) (25). Because we could not observe an inhibition of AA-induced platelet aggregation by the infusion of DHA emulsion, the protective effect of DHA against

the AA-induced thrombosis model shown in the present investigation may be mediated through the inhibition in the vessel walls of cyclooxygenase activity, as suggested by Talesnik.

In conclusion, a DHA-TG emulsion may be useful for patients with immediate risk of thrombosis or for those who need DHA but cannot take it orally.

[Received December 1, 1986]

Effect of Marginal Zinc Deficiency on the Apolipoprotein-B Content and Size of Mesenteric Lymph Chylomicrons in Adult Rats[1]

Sung I. Koo*, **Christine C. Lee** and **John E. Norvell**
Department of Biochemistry, Oral Roberts University, School of Medicine, Tulsa, OK 74171

To investigate the mechanisms underlining the impaired intestinal absorption of lipids in zinc deficiency, the apo-B content and chemical composition of chylomicrons from marginally zinc-deficient rats fed 2.8 ppm of dietary zinc (ZD) were compared with those from pair-fed (PF) and ad libitum control (CT) groups fed an adequate level (30.8 ppm) of zinc. Chylomicrons, obtained by cannulating the mesenteric lymph, were isolated by ultracentrifugation at 1.3×10^6 g/min at 12 C and purified by 2% agarose column chromatography. Apolipoprotein- (apo) B was separated by the method of isopropanol precipitation. The apo-B concentration of chylomicrons was lowered significantly in ZD group. The apo-B contents of chylomicrons in ZD, PF and CT rats, as expressed as % chylomicron protein, were 8.7 ± 0.1, 11.5 ± 0.5 and 10.7 ± 0.7%, respectively. No significant differences were noted between ZD and PF groups in total protein (TP), phospholipid (PL), triglyceride (TG) and cholesterol (CH), although there was a slight decrease in TG and an increase in CH in CT rats compared with ZD and PF groups. The ratio of the core to surface constituents, as determined by TG/(TP + PL), was significantly higher in ZD group relative to the controls, suggesting that chylomicrons from ZD rats were larger. This finding was consistent with the appearance of larger chylomicron particles in the lacteal of the intestinal mucosa following lipid ingestion. These findings suggest that the intestinal synthesis of apo-B may be defective in zinc-deficient rats and may explain in part the impaired absorption of dietary lipids observed in zinc deficiency.

Lipids 22, 1035–1040 (1987).

Possible defects in the intestinal formation of chylomicrons in zinc deficiency was first demonstrated by Koo and Turk (1). In advanced zinc deficiency in young male rats (1), lipid droplets of abnormally large sizes were shown to accumulate in the intestinal mucosa following oral ingestion of triglyceride; this impaired the intestinal transport of mucosal lipids into the circulation. Consistent with this observation, the intestinal absorptive epithelium exhibited marked decreases in the granular endoplasminc reticulum and Golgi complex (2), which are the major sites for the synthesis of chylomicrons (3) and packaging of lipids (4) during mucosal lipid transport. Our recent study (5) indicated that even in marginally zinc-deficient rats, the lipid droplets in the absorptive epithelium displayed a strong tendency to coalesce into larger droplets. The composition of the soluble apolipoproteins of chylomicrons obtained from the mesenteric lymph of these rats was shown to be altered markedly.

However, whether the distribution of apo-B in chylomicrons is affected by zinc deficiency is not known. Apo-B is a major apolipoprotein synthesized in the intestine that is believed essential for chylomicron formation. This experiment was conducted to determine the apo-B content of chylomicrons and to examine further the relationship between the composition and size of chylomicrons appearing in the lacteal, as affected by a marginal level of zinc deficiency.

MATERIALS AND METHODS

Animals and diets. Male Fischer rats (CDF[F-344]CrlBR; Charles River Breeding Lab., Inc., Wilmington, MA) were placed individually in plastic cages with stainless-steel wire bottoms in a windowless room and were subjected to a light cycle with the light period from 1400 to 0200 and dark period from 0200 to 1400. Temperature and humidity of the room were maintained at 23 C and 55–60%, respectively. The rats were acclimatized for one week and fed a commercial rat chow (Wayne Laboratory Animal Diets, Denver, CO) during this period. The rats with the mean weight of 138 ± 5 g were divided into three groups: 1) a zinc-deficient (ZD) group fed ad libitum a basal diet supplemented with 2.0 ppm of zinc as the carbonate. The basal diet, as described in Table 1, contained 0.8 ppm of zinc and the total zinc concentration of the zinc-deficient diet was 2.8 ppm; 2) a pair-fed group (PF), which was matched closely with the ZD group in respect to the body weight at the start of dietary treatment and were fed the basal diet supplemented with 30 ppm of zinc. The rats in this group were fed daily the same amounts

TABLE 1

Composition of Basal Diet[a]

Ingredient	% Diet
Egg white solids	20.0
DL-Methionine	0.3
Sucrose, granular	36.0
Corn starch	30.9
Corn oil	4.0
Cholesterol, USP	1.0
Cellulose, powder	3.0
Choline chloride (Cholfeed, 50%)	0.3
Vitamin mix[b]	1.0
Mineral mix[c]	3.5

[a]Purchased from Zeigler Brothers, Inc. (Gardeners, PA).
[b]According to the recommendations of the American Institute of Nutrition (AIN), except that the concentration of biotin in the mix was increased to 50 mg/kg (ref. 15).
[c]According to the AIN recommendations but with no zinc. The basal diet formulated with the above ingredients contained 0.8 ppm of zinc, as determined by atomic absorption spectrophotometry.

of diet as consumed by ZD rats and 3) another control group was fed the above zinc-adequate diet ad libitum. All rats were given distilled-deionized water via a stainless-steel water delivery system.

Cannulation of lymph duct. The cannulation of the mesenteric lymph duct was performed by a modification of the method of Warshaw (6); the modified procedure has been described in detail in previous studies (5,7). After 10–12 weeks of dietary treatment, the rats were anesthetized with diethylether. With a subcostal incision, the mesenteric lymph ducts were exposed, and the minor duct was cut and sealed with cyanoacrylate glue. The major lymph duct was cannulated with polyethylene tubing (PE-50, Clay Adams, Parsippany, NJ) coated with TDMAC-heparin complex (Polysciences, Inc., Warrington, PA). An indwelling catheter (PE-90, Clay Adams) was placed via the mouth into the pylorusduodenal junction and secured by a ligature. Immediately after closing the incision with suture (4-0 silk, Ethicon Inc., Somerville, NJ), the rats were placed in restraining cages (8) and infused by an infusion pump (Harvard Apparatus, Model 935, South Natick, MA) via the duodenal catheter with a glucose saline (5% glucose, 0.87% NaCl and 0.03% KCl) at the rate of 2.0 ml/hr for 18 to 20 hrs (overnight). During the postoperative recovery, the room temperature was maintained at 27 to 29 C by using an electric heater.

Collection of lymph and isolation of chylomicrons. After the postoperative recovery, the rats were infused with a lipid emulsion via the duodenal catheter. The infusion rate was increased to 3.0 ml/hr to increase the flow and volume of lymph. The lipid emulsion consisted of a 1:1 (v/v) mixture of Intralipid® (10% soybean oil, 1.2% phospholipid and 2.25% glycerin, USP; KabiVitrum, Inc., Alameda, CA) and a glucose saline (5% glucose, 0.87% NaCl and 0.03% KCl). Lymph was collected via the cannula into conical plastic tubes cooled in an ice bath for eight hr and defibrinated by filtration of glass wool. The average volume of defibrinated lymph collected per rat was 10.5 ± 0.9 ml. The filtrate was overlayered with 150 mM NaCl solution containing 0.04% Na_2EDTA, pH 7.4, in polyallomer tubes and centrifuged at $1.3 \times 10^6 \times$ g/min at 12 C using a 50.3 Ti rotor in a Beckman L5-75B Ultracentrifuge (Spinco Division, Palo Alto, CA). The packed top fraction of chylomicrons was collected by slicing the tubes and were purified by a single passage through 2% agarose column (Biogel A-50, 100–200 mesh, Bio-rad Labs., Richmond, CA) according to the method of Sata et al. (9). The column was eluted at 12 C with 150 mM NaCl containing 0.04% Na_2EDTA and 0.02% sodium azide, pH 7.0. Elution of chylomicrons was monitored by absorbance at 280 nm (LKB 2089 Uvicord III, LKB Instruments, Rockville, MD). The column fractions of chylomicrons were combined and concentrated by centrifugation as above.

Determination of chylomicron apo B. The apo-B content of chylomicrons was measured by the method of isopropanol precipitation as described by Egusa et al. (10). One to 1.5 ml of chylomicron suspension in 150 mM NaCl was mixed vigorously with an equal volume of 100% isopropanol (A-416, Fisher Scientific Co.-certified ACS, Fair Lawn, NJ) and incubated at room temperature for 18–20 hr. The mixture was centrifuged at 1500 × g for 60 min, and the supernatant was discarded. The precipitate was washed twice with 2.0 ml of 50% isopropanol and centrifuged as above. The precipitate was dispersed in 100% isopropanol for two hr and recovered by centrifugation as above. Then it was solubilized by incubation in 50 μl of 1N NaOH at 37 C, and the protein (apo-B) content was determined by the method of Kashyap et al. (11).

Analysis of chylomicron protein and lipids. The concentration of total protein was determined by a modified Lowry method after washing purified chylomicrons twice with chloroform (11). The concentrations of triglyceride and cholesterol were determined by the methods of Rudel and Morris (12) and of Neri and Frings (13), respectively. Phospholipid was determined by the method of Raheja et al. (14).

Electron microscopy of chylomicrons in the lacteal. Rats were fasted for 18 hr and fed 1.0 ml of corn oil by gastric intubation. Two hours later, the rats were killed by cervical dislocation, and 1-cm jejunal segments anterior to the ligament of Treitz were removed and immediately fixed in ice-cold 3.5% glutaraldehyde in 0.1 M sodium cacodylate buffer for one hr. The fixed tissues were minced into 1–2 mm blocks, fixed in glutaraldehyde at room temperature for 1.5 hr and postfixed in 1% osmium tetraoxide. The tissue blocks were dehydrated in ethanol and propylene oxide and embedded in Epon 812. The ultrathin cross sections of the jejunal villi were cut and stained with uranylacetate and lead citrate. The sections were examined using an electron microscope (Phillips EM 400, Phillips Electronic Instruments, Inc., Mahwah, NJ). The lacteals located below the basement membranes of the villi were photographed at 7,000 magnification and enlarged 2.5 times for determination of chylomicron sizes. The lacteal lumen that displayed well-dispersed chylomicron particles were selected. The diameters of approximately 1,000 chylomicron particles from four micrographic fields were measured in each group, and the size distributions of the particles were compared statistically.

Plasma zinc analysis. After fasting rats for 18 hours, blood samples were withdrawn from the orbital sinus at the mid-dark phase (0800 to 0900) of the light cycle. Serum zinc was determined by atomic absorption spectrophotometry (Perkin-Elmer Co., Norwalk, CT). The zinc standards were prepared from a Fisher-certified reference standard (Fisher Scientific Co., Fair Lawn, NJ).

Statistics. Analyses of variance and Duncan's multiple range test were used for comparisons among the three group means. The statistical analyses were performed by using a computer software (PC ANOVA, Human Systems Dynamics, Northridge, CA). All data were expressed as mean ± SEM, and the level of significance was determined at $p < 0.05$, unless otherwise stated.

RESULTS

General observations. The food intake, body weight and serum zinc status of the rats, as affected by experimental diets, are shown in Table 2. In order to produce a marginal level of zinc deficiency, the rats in ZD group were fed a diet containing 2.8 ppm of zinc. This level of dietary zinc prevented a drastic decrease in diet consumption and resultant weight loss, as normally observed with extremely low levels of zinc. A significant reduction in food intake in ZD rats was noticeable only after seven weeks. The average body weight of ZD group at the end

of the experiment differed significantly from that of the ad-libitum control (CT) group but not from that of PF group. The serum level of zinc was significantly lower in ZD rats as compared with PF and CT controls but no external signs of zinc deficiency such as alopecia and skin lesions were visible at this stage of zinc deficiency.

The apo-B content and composition of lymph chylomicrons. The apo-B concentrations of lymph chylomicrons are shown in Table 3. The apo-B contents of chylomicrons from ZD, PF and CT groups were 0.25 ± 0.02, 0.41 ± 0.04 and 0.47 ± 0.07 μg per mg chylomicrons, respectively. The apo-B content in ZD group was significantly lower as compared with the PF and CT controls. A similar difference also was noted when expressed in terms of μg per mg chylomicron triglyceride. Apo-B represented 8.7% ± 0.1% of the total apoprotein content of chylomicrons in ZD group as compared with 11.5 ± 0.5 and 10.7 ± 0.7% in PF and CT groups, respectively (Table 3). Table 4 compares the protein and lipid composition of chylomicrons as affected by experimental diets. The percent concentrations of total protein and phospholipid of chylomicrons tended to decrease in ZD groups as compared with PF and CT groups. The dfferences between ZD and the two control groups were not significant statistically. Chylomicrons from CT group were significantly higher in cholesterol but slightly lower in triglyceride content as compared with those obtained from ZD and PF groups. There were no differences in the ratio of triglyceride (TG) to phospholipid (PL) among the three groups.

Size distribution of chylomicrons. In all groups, chylomicrons appearing in the lacteals were much smaller in size than the lipid droplets present in the cytoplasm of the absorptive epithelium. Figure 1 shows the morphological appearance and size distribution of chylomicrons found in the lacteal lumen during lipid transport. The average diameters of chylomicrons from ZD, PF and CT groups were 0.20, 0.13 and 0.14 μm, respectively. Approximately 78% of the chylomicron particles of ZD rats measured between 0.06 and 0.23 μm in diameter. A significant proportion (22%) of the particles was larger than 0.30 μm, with 5.5% of the total exceeding 0.5 μm. In contrast, most (>93%) of the particles of PF and CT controls were smaller than 0.23 μm in diameter, and the rest (<7%) ranged from 0.30 to 0.46 μm.

TABLE 2

Effect of Experimental Diets on the Food Intake, Body Weight and Serum Zinc Status of the Rats[a]

Group	Food intake (g/rat/day)		Body weight (g/rat)		Serum zinc (μg/ml)

DISCUSSION

The gastrointestinal manifestations of acrodermatitis enteropathica, a hereditary human zinc-deficiency disorder, include chronic diarrhea and malabsorption of lipids (16). Lipid malabsorption in zinc deficiency has been well-demonstrated in previous studies using growing and adult rats (1,7). However, the mechanisms underlying the impaired intestinal absorption of lipids remain to be elucidated. In zinc-deficient young rats given an oral dose of triglyceride, abnormally large sizes of lipid droplets were shown to accumulate in the apical cytoplasm of the intestinal epithelium. Such characteristics of cytoplasmic lipid droplets were also demonstrated in marginally zinc-deficient adult rats in the absence of the externally

TABLE 4

The Protein and Lipid Composition of Lymph Chylomicrons[a]

Group	% Chylomicron)				
	Protein	CH[b]	TG[b]	PL[b]	TG/PL

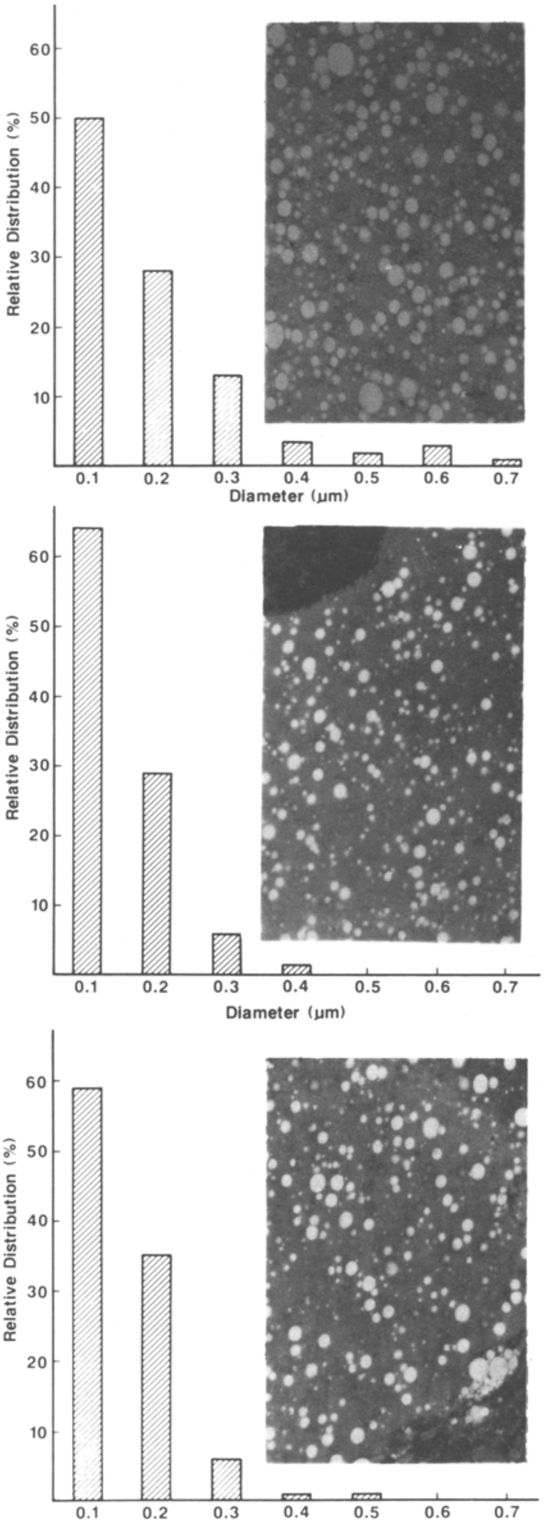

FIG. 1. The size distribution of chylomicrons appearing in the lacteal lumen of the intestinal villi. A significant proportion (22%) of chylomicrons was larger than 0.30 μm and 5.5% of the chylomicron particles exceeded 0.5 μm in diameter in ZD group (top). Most (>93%) of the particles of PF and CT controls were smaller than 0.23 μm in diameter. Chylomicrons greater than 0.5 μm in diameter were not found in the lacteals of the PF and CT controls. The marker bar = 0.5 μm.

manifested signs of zinc deficiency (5). However, specific molecular defects in chylomicrons produced by zinc deficiency currently are not known.

This study provides evidence for the first time that the apo-B concentration of lymph chylomicrons is lowered significantly in even a marginal (or subclinical) stage of zinc deficiency. The apo-B content of chylomicrons from zinc-deficient rats was decreased to 53 to 61% of that of PF and CT controls when compared on the basis of apo-B content per mg of chylomicron mass. The apo-B values for the control rats, as determined by isopropanol precipitation in the present study, are in excellent agreement with those obtained by the method of tetramethylurea (TMU) precipitation (17).

The importance of the protein moiety of chylomicrons in their formation and release into the lymphatics was first demonstrated by Sabesin and Isselbacher (18) in a study using rats treated with a protein-synthesis inhibitor. Further evidence for the impaired chylomicron formation and lipid transport during protein-synthesis inhibition has been provided in subsequent studies (19–22), although controversy still exists concerning the obligatory role of protein synthesis in the release of chylomicrons (23).

In the earlier study (5), we observed that the lipid droplets accumulating in the epithelial cytoplasm of zinc-deficient rats frequently were larger than 5 μm in diameter. Present data showed no evidence for the entry of such large chylomicrons in the lacteal (Fig. 1), suggesting the inability of those lipid droplets (or chylomicrons) to exit into the lymphatic system. Nevertheless, the average diameter of chylomicron particles appearing in the lacteal of zinc-deficient rats still was significantly larger than that of pair-fed and ad libitum controls. Approximately 22% of the chylomicrons from zinc-deficient rats was larger than 0.3 μm in diameter, and 5.5% exceeded 0.5 μm, whereas the majority (93%) of chylomicrons from pair-fed and ad libitum control rats was smaller than 0.23 μm, with ca. 7% ranging between 0.30 to 0.46 μm. A similar increase in the size of lymph chylomicrons also was observed in the rats treated with a protein-synthesis inhibitor (acetoxycycloheximide) (21).

Previously, it has been postulated that the defective synthesis of apo-B in the intestinal epithelium may be responsible for such an increase in chylomicron size and cytoplasmic accumulation of lipid droplets during inhibition of protein synthesis (18). Because of the non-specific nature of the protein-synthesis inhibitors, whether such a phenomenon is due specifically to the lack of intestinal apo-B or other apolipoproteins remains debatable. Glickman et al. (24) showed that in acetoxycycloheximide-treated rats both apo-B and apo-A-I were reduced markedly in the intestinal mucosa during lipid absorption. A significant decline in chylomicron apo-A-I was demonstrated in rats injected with acetoxycycloheximide (22). In a previous study (5), we observed that a marginal level of zinc deficiency produces significant decreases in the relative contents of apo-C and apo-E of lymph chylomicrons. Evidence indicates that chylomicrons are released into the circulation despite the deficiency of apo-C (25). Also, the data obtained from tracer studies (26,27) suggest that apo-E is not incorporated into intestinal nascent chylomicrons or very low density lipoproteins during their synthesis in the intestine and that it may not

be an essential component of nascent intestinal lipoproteins for their release into the lymphatics. These apolipoproteins mostly are acquired by nascent chylomicrons from plasma HDL upon their release into the lymphatics and blood plasma (28–31). Therefore, the decreases in chylomicron apo-C and apo-E in zinc-deficient rats (5) may reflect largely the decrease in the circulating level of HDL as previously demonstrated in zinc-deficient rats (32). Our recent data (33) have shown that the relative proportions of apo-E and apo-C of plasma high density lipoprotein (HDL) particles as well as the total plasma levels of the HDL apolipoproteins were decreased significantly in zinc-deficient rats.

The above-cited observations and the present finding of a marked decrease in the apo-B content of lymph chylomicrons in zinc-deficient rats strongly suggest that the limited availability of apo-B during chylomicron formation may be primarily responsible for the massive accumulation of large sizes of lipid droplets in the intestinal epithelium with resulting impairment of lipid transport. The essential role of apo-B in the formation and release of chylomicrons has been demonstrated by the studies on human subjects with congenital β-lipoprotein deficiency (34,35), which is characterized by the inability to synthesize apo-B. The above-described morphological characteristics of cytoplasmic lipid droplets (5) in association with impaired intestinal transport of lipid in zinc deficiency (1,5) are remarkably similar to those described in human β-lipoprotein deficiency (36) and in rats treated with protein-synthesis inhibitors (18).

However, the morphological aberrations in chylomicrons and impaired lipid transport in zinc deficiency, as observed in the earlier (1,5) and present studies, may not be attributable solely to the lack of apo-B. The present data do not exclude the possibility that such defects also may be due to a general lack of other surface constituents including phospholipid and free cholesterol or the limited contents of surface materials in relation to the hydrophobic core constituents of chylomicrons such as triglyceride and cholesterol ester. In this experiment, chylomicron cholesterol was not partitioned into free and esterified cholesterol. However, the ratio of triglyceride (TG) to PL content previously has been shown to be highly correlated with the size of chylomicrons (37). In this study, the TG/PL ratio of lymph chylomicrons tended to be higher in ZD rats as compared with PF and CT controls (Table 4) but the difference between ZD and controls was not statistically significant ($p > 0.05$). However, the ratio of TG to PL plus protein was significantly higher in ZD rats (23.0 ± 1.9) as compared with 18.8 ± 1.0 in PF and 18.0 ± 1.0 in CT controls. This observation is consistent with the increase in the size of chylomicrons appearing in the lacteal of ZD rats (Fig. 1). This suggests that the formation of large-size chylomicrons in zinc deficiency may be partly due to the diminished availability of both surface lipid and protein during chylomicron assembly within the intestinal epithelium.

In summary, this study provides evidence that zinc deficiency, even at a marginal level, produces a marked decrease in the apo-B content of chylomicrons with an increase in the ratio of the core-to-surface constituents of chylomicrons. Such molecular changes in chylomicrons suggest a defect in the mucosal synthesis of apo-B and surface materials of chylomicrons in zinc deficiency. This may lead to the defective formation and release of chylomicrons from the mucosa, hence the impairment in intestinal absorption of lipids (1,7) and possibly lipid-soluble vitamins, which require chylomicrons as their principal carriers. Some of the clinical manifestations of zinc deficiency may be associated partly with such absorptive defects.

**The mammary tumor–promoting effect of a high-fat diet containing 20% evening primrose oil (PO) was compared to that of a 20% corn oil (CO) diet. Mammary tumors were induced in female Sprague–Dawley rats using 10 mg (Study 1) and 5 mg (Study 2) 7,12-dimethylbenz(a)anthracene (DMBA). The 10 mg dose of DMBA gave a total mammary tumor incidence of 47% in rats fed the PO diet and 80% for those fed the CO diet. When only adenocarcinomas were counted, the malignant mammary tumor incidences were 41% in rats fed the PO diet and 73% in rats fed the CO diet. In a second study using 5 mg DMBA to induce mammary tumors, total tumor incidences were 50% for PO-fed rats and 63% for those receiving a CO diet. Again, when only adenocarcinomas were counted, tumor incidences were 27% for PO- and 63% for CO-dieted rats. Analysis of plasma fatty acid profiles indicated that animals fed a 20% PO diet showed significant increases in 18:3 and 20:4 fatty acids and significant decreases in 16:0 and 18:1 compared to animals fed a 20% CO diet. These results indicate that the mammary tumor promoting effect of a diet containing 20% fat can be diminished by substituting PO for CO. Moreover, the promoting effect on mammary cancer by a high-fat diet could be depressed by feeding a source of γ-linolenic acid (GLA).
Lipids 22, 1041-1044 (1987).**

The stimulating effect of a high-fat diet on both spontaneous and carcinogen-induced mammary tumorigenesis in rodents now is well-established (1-8). The mechanism(s) by which a high-fat diet causes this stimulation is not fully understood. However, experimental evidence shows that dietary fat rich in polyunsaturated fat (especially *cis*-linoleic acid) influences tumor growth during the promotional phase of mammary carcinogenesis (3,9-11).

The effect of dietary fat may be mediated by a change in the host defense system. One mechanism by which this could happen is by altering synthesis of eicosanoids. Corn oil (CO) and primrose oil (PO) respectively contain 60% or 75% linoleic acid, the precursor of arachidonic acid and ultimately of the dienoic eicosanoids (prostaglandins) and polyenoic eicosanoids (leukotrienes) (12).

In addition to 75% linoleic acid, PO contains 9% of γ-linolenic acid (GLA). GLA is rapidly elongated to dihomo-gamma-linolenic acid (DGLA) the precursor of monoenoic eicosanoids. Ghayur and Horrobin (13) have shown that the growth rate of a transplanted R3230KAC mammary tumor was significantly reduced in female Fisher rats treated daily with different levels of PO. They speculated that prostaglandin E_1 might be able to inhibit mammary tumor growth.

In other studies, Dippenaar et al. (14,15) and Leary et al. (16) have shown that growth in three malignant tumor cell lines (B16 melanoma, human esophageal carcinoma and human hepatoma) was inhibited by GLA-supplementation. They suggested that malignancy may be related to a GLA-deficiency. Karmali et al. (17) provided evidence that PO inhibits the growth of the R3230AC mammary tumor. When pure GLA was given by gavage to tumor-bearing rats, no effect on tumor growth was seen. However, the maximum dose of pure GLA given was below the limit at which tumor inhibition was observed in the rats given GLA in PO (17).

This study was conducted to compare the effects of a diet containing 20% PO to a diet containing 20% CO on the incidence and growth of 7,12-dimethylbenz(a)anthracene (DMBA)-induced mammary tumorigenesis as well as on plasma lipid profiles.

MATERIALS AND METHODS

Animals, diets and tumor induction. In two separate studies, 40-day-old virgin female Sprague-Dawley rats (Harlan, Madison, WI) were maintained on Purina Lab Chow (No. 5001) and housed in suspended metal cages in a temperature-regulated (23 ± 0.5 C) and light-controlled (12 hr light and 12 hr dark) room. Food and water were available ad libitum. At 50 days of age, the rats (weighing 179 ± 7.9 g) each were given a single intragastric dose of 5 or 10 mg of DMBA (Sigma Chemical Co., St. Louis, MO) in 0.5 ml CO. In Study 1, the rats were given 10 mg DMBA and divided into two groups of 18 each. In a subsequent study (Study 2), more animals were used to determine if the same or greater effect on tumorigenesis would be noted with a smaller dose of carcinogen. In this study, the rats were given 5 mg DMBA and divided into two groups of 30 each. After DMBA administration, the animals were placed randomly on Absorb Dri litter in plastic cages and housed two per cage for the duration of the experiment. At 21 days (Study 1) and 14 days (Study 2) post-DMBA administration, rats were randomly divided into two groups and fed diets containing either 20% CO or 20% PO. Ten kilogram batches of the 20% fat diets were prepared and cold-pressed into jumbo pellets as needed by ICN Nutritional Biochemical (Cleveland, OH) using the formulation shown in Table 1. In our laboratory, 1 kilogram bags of pellets were placed in Seal-N-Serve bags, flushed with nitrogen, sealed and stored frozen until used. The fatty acid composition of the CO and PO diets are given in Table 2.

Tumor measurements and classification. Rats were weighed and palpated weekly for the presence of mammary tumors, and the size and location of each tumor were noted. Three out of 18 of the rats from Study 1 fed a CO diet and 1 out of 18 of the rats fed a PO diet were found dead before the experiment's termination. No rats in Study 2 died before termination of the experiment.

Abbreviations: AA, arachidonic acid; CO, corn oil; DGLA, dihomo-gamma-linolenic acid; DMBA, 7,12-dimethylbenz(a)anthracene; GLA, γ-linolenic acid; LA, linoleic acid; PO, evening primrose oil.

TABLE 1

Composition of the Basic Rat Diet

Ingredient	Weight (gm/100 gm)
Fat[a]	20.0
Casein (Vitamin-free)	20.0
Sucrose	25.0
Corn starch	25.0
Alphacel	5.0
AIN Mineral Mix	3.5
AIN Vitamin Mix[b]	1.0
Choline bitartrate	0.2
dl-Methionine	0.3

[a]Primrose oil was given by Efamol Research Inc., Nova Scotia, Canada. ICN purchased corn oil from Seaway Foods, Inc., Cleveland, OH.
[b]Alpha-tocopherol was added with the AIN vitamin mix so that each diet contained a total of 110 IU of vitamin E/kg (DL-α-tocopherol powder, 250 IU/gm) of diet.

TABLE 2

Percent Composition of Fatty Acid in Rat Diets

Fatty acid chain length	% Fatty acid in oil	
	Corn	Primrose
16:0	11.2	6.5
18:0	2.1	1.5
18:1n-9	25.0	7.5
18:2n-6	59.9	75.0
18:3n-6	0.5	9.0
Others	0.1	0.5

At 16 or 13 weeks post-DMBA, surviving rats were killed with CO_2, blood was drawn from the heart for plasma lipid analysis, tumors were excised, counted and weighed, fixed in 10%-buffered formalin, processed for paraffin embedding, sectioned, and stained with hematoxylin and eosin for histological examination. Mammary tumors were identified according to the criteria of Van Zwieten (18). Both benign tumors (fibroadenoma and cystadenoma) and malignant tumors (adenocarcinomas, e.g. tubulopapillary carcinoma) were reported.

Lipid analysis. Total lipid extracts were prepared by extraction with chloroform/methanol (2:1, v/v) after the method of Folch et al. (19). Briefly, a 0.5 ml aliquot of plasma was added to 12 ml of chloroform/methanol, mixed and the extract washed with 2.5 ml of 0.5% sulfuric acid. The aqueous layer was removed by aspiration; aliquots of the organic layer were dried under nitrogen for preparation of fatty acid methyl esters.

Methyl esters of fatty acids were prepared with boron trifluoride following the method of Morrison and Smith (20). A 3.0 ml aliquot of the total lipid extract was dried under nitrogen, and 1.0 ml of boron trifluoride in methanol (14 g/100 ml) was added. The tubes were sealed and heated at 100 C for 60 min. The reaction was stopped by addition of 1.0 ml of distilled-deionized water; the fatty acid methyl esters were extracted with 10 ml of hexane. The hexane extracts were sealed in tubes under nitrogen and stored at −20 C before analysis.

TABLE 3

Effect of 20% Fat Diet on Body Weight in Rats 16 Weeks Post-DMBA

Diet	Number of rats	Dose of DMBA	Final body wt[a] (g)
CO	30	5 mg	282.5 ± 3.4
PO	30	5 mg	286.9 ± 3.2
CO	15	10 mg	278.5 ± 6.2
PO	17	10 mg	267.1 ± 5.6

[a]Values are means ± SEM.

The fatty acid methyl esters were analyzed using a Hewlett-Packard Model 402 gas chromatograph equipped with flame ionization detector and connected to a Spectra-Physics Model 4270 recording integrator. Chromatography was performed on a 6 ft × 2 mm glass column containing 10% SP-2330 on 100/120 chromosorb W AW (Supelco Inc., Bellefonte, PA).

Statistical analysis. Mammary tumor incidence and plasma fatty acids were compared using Student's t-test. The relationship between the type (malignant vs benign) of tumor incidence and the high fat diets were analyzed using chi-square analysis.

RESULTS

The effects of feeding diets containing 20% PO and 20% CO on weight gain in rats treated with DMBA are shown in Table 3. There were no significant differences in weight gain between rats fed the two diets. This was as expected since neither diet was essential fatty acid nor nutrient-deficient.

As expected, the average number of tumors and tumor-burden per tumor-bearing rat (Table 4) in Study 1 (10 mg DMBA) was significantly greater than in Study 2 (5 mg DMBA). The average latency period was significantly longer in Study 1 than in Study 2. However, in Study 2 the 20% fat diets were begin two weeks post-DMBA rather than three weeks post-DMBA as in Study 1.

Table 5 summarizes necropsy data from Studies 1 and 2. In Study 1, in which rats were placed on a diet three weeks post-DMBA (10 mg), eight of 17 rats fed a PO diet developed tumors, whereas 12 of 15 rats fed CO developed tumors. When tumors were classified histopathologically at necropsy (16 wks post-DMBA), 34 malignant tumors were recovered from rats fed CO; only 20 were recovered from rats fed the PO diet. In addition, the total number of tumors in the PO-fed rats was 31, while there were 61 tumors in the CO-fed rats. In the second study (5 mg DMBA), 15 of 30 rats fed the PO diet had tumors, and 19 of 30 rats fed the CO diet had tumors. There were totals of 33 tumors in the PO groups and 36 tumors in the CO groups. However, 15 of 33 tumors were adenocarcinomas (tubulopapillary carcinomas) in the PO group and 36 of 36 tumors were adenocarcinomas in the CO group. Chi-square analysis of the tumor data (Table 5) showed

that the tumor incidence obtained (malignant vs benign) was dependent on the type of fat being fed. Therefore, feeding PO significantly decreased malignant tumors compared to feeding CO.

Plasma fatty acid profiles at necropsy are shown in Table 6. Linoleate levels in the plasma of rats fed 20% PO and 20% CO were similar; GLA (18:3) and arachidonate (20:4) levels were significantly higher, and oleic acid levels were significantly lower in rats fed PO compared to those fed CO.

DISCUSSION

In two studies using different levels (5 and 10 mg) of DMBA, the total numbers of mammary tumors, malignant tumors and rats with tumors were reduced in rats fed a 20% PO diet compared to rats fed a 20% CO diet. The average number of tumors per tumor-bearing rat and the average tumor-burden per rat were not different significantly in rats fed the two diets. When the two doses of DMBA (5 and 10 mg) were compared, there were

significant differences in these parameters. This result shows that DMBA-induced mammary tumorigenesis was dose-dependent in rats fed both PO and CO diets. However, there was a significant increase in the average tumor latency in Study 1 vs Study 2. It appears that beginning the high fat diet a week earlier in Study 2 shortened the average tumor latency by one week. The plasma fatty acid analyses reflected the fatty acid composition of the oils being fed. Feeding the rats a source of GLA in PO resulted in a plasma pool of GLA 19 times that of feeding CO.

Experiments by Chan et al. (21), Ip et al. (22) and Tinsley et al. (23) have shown that mammary tumorigenesis in rats and mice is positively correlated with the linoleate content of the dietary fat. In this study, the PO diet contained 14% more linoleate than the CO diet, yet tumorigenesis was suppressed. However, PO contains 9% GLA, in addition to 75% linoleic acid (LA). The metabolic pathways for LA, 18:2n-6 are well-established. LA is converted by Δ-6 desaturase (a rate-limiting enzyme) to GLA, 18:3n-6, which is rapidly elongated to DGLA, 20:3n-6 (24). DGLA subsequently is desaturated by Δ-5-desaturase (a rate-limiting enzyme) to arachidonic acid (AA, 20:4n-6), which is converted by fatty acid cyclooxygenase to the dienoic eicosanoids (25). DGLA also is used as a substrate by cyclooxygenase to form the precursor of the monoenoic eicosanoids (12).

It has been shown that an increasing ratio of DGLA/AA may shift eicosanoid synthesis toward monoenoic eicosanoids. This may be beneficial in a number of pathological states by depressing 2-series and/or by enhancing the production of the 1-series eicosanoids (26). PGE_2 has been shown to suppress the immune response and is present in high levels in mammary tumors (12). Therefore, manipulation of the DGLA/AA balance may provide a selective regulation of eicosanoid synthesis, which could be helpful in cancer treatment and/or prevention. Further studies are being conducted to examine the mechanism(s) responsible for the reduction of DMBA-induced malignant mammary tumors in rats fed PO.

ACKNOWLEDGMENT

This work was supported in part by the donation of PO by David Horrobin of Efamol LTD., Guildford, Surrey GU1 1BA, England.

METHODS

Extraction and Quantitation of Total Cholesterol, Dolichol and Dolichyl Phosphate from Mammalian Liver

Dean C. Crick and **Kenneth K. Carroll***
Department of Biochemistry, University of Western Ontario, London, Ontario, Canada, N6A 5C1

A procedure is described for the determination of total cholesterol, dolichol and dolichyl phosphate (Dol-P) in mammalian liver. It is based on extraction of these compounds into diethyl ether after alkaline saponification of the tissue. Extractability is affected by the length of saponification and concentration of potassium hydroxide (KOH) in the saponification mixture. After extraction, total cholesterol and dolichol are quantitated directly by reverse-phase high pressure liquid chromatography (HPLC) on C_{18}. Dol-P requires further purification before quantitation by HPLC, this is accomplished by chromatography on silicic acid. These methods gave recoveries of over 90% for cholesterol and dolichol and about 60% for Dol-P, using [4-^{14}C]cholesterol, a polyprenol containing 15 isoprene units, and [1-^{14}C]Dol-P as recovery standards. Concentrations of total cholesterol, dolichol and Dol-P in livers from one month-old-CBA mice were found to be 5.7 ± 0.7 mg/g, 66.3 ± 1.2 μg/g and 3.7 ± 0.3 μg/g, respectively.
Lipids 22, 1045-1048 (1987).

Dolichyl phosphate (Dol-P) is an obligatory intermediate in the dolichol cycle by which many secretory and membrane-bound N-linked glycoproteins are produced (1). Its concentration can be an important regulatory factor in the formation of these glycoproteins (2-5).

Dolichol and cholesterol readily can be extracted from tissues and quantitated but determination of total Dol-P has proven more difficult. Dol-P was first measured by Dallner et al. (6) using enhancement of Dol-P-mannose formation by a Dol-P-dependent mannosyl transferase following addition of a purified Dol-P-containing fraction. Carson and Lennarz (7) subsequently separated Dol-P from dolichol, enzymatically dephosphorylated it and quantitated it by high performance liquid chromatography (HPLC). Two methods for the direct quantitation of Dol-P by HPLC have been developed. Chaudhary et al. (8) used a reverse-phase C_{18} column, and Keller et al. (9) used a straight-phase silica column.

The problems encountered in the quantitation of Dol-P have been attributed to the extraction and purification before analysis by HPLC (10). Sequential extraction with chloroform/methanol (2:1, v/v) and chloroform/methanol/water (10:10:3, v/v/v) may give incomplete extraction of total Dol-P from rat liver, and conversion of Dol-PP-oligosaccharide to free Dol-P by acid hydrolysis may not always go to completion (9,11). A recent report (9) indicates that total cholesterol, total dolichol and total Dol-P can be extracted from a potassium hydroxide (KOH) saponification mixture into diethyl ether (ether). Dol-PP, and presumably its glycosylated forms, are converted to free Dol-P under these conditions. These workers also reported that the levels of Dol-P in rat tissues are comparable to or higher than the levels of dolichol. Their values for Dol-P are several times higher than those based on other methods of extraction (5,8,12, 13). Furthermore, levels of dolichol reported by Keller et al. (9) are often lower than those observed previously.

Studies in our laboratory indicated that Dol-P was extracted inefficiently from saponification mixtures (14,15). Therefore, we further investigated the extraction of cholesterol, dolichol and Dol-P following saponification of mammalian tissue. We now describe a method for isolation and quantification of these compounds that eliminates the need for separation of cholesterol from dolichol before HPLC analysis and that yields good recoveries of all three compounds.

EXPERIMENTAL

Materials. Mice (one-month-old National Institute of Aging CBA/Ca males) were obtained from Charles River Breeding Laboratories (Wilmington, MA). Human liver was obtained at autopsy. [1-^{14}C]Dolichol (50 mCi/mmol), consisting of a series of homologues containing 15 to 24 isoprene units (18 and 19 predominating), was a gift from the Kuraray Co. (Okayama, Japan). [1-^{14}C]Dolichyl phosphate was prepared according to the method of Danilov and Chojnacki (16) and purified by chromatography on silicic acid (Bio-Rad Laboratories, Richmond, CA). [4-^{14}C]-Cholesterol (57.5 mCi/mmol) of >99% radiochemical purity was purchased from New England Nuclear (Boston, MA). Cholesterol (>99% pure) was obtained from Calbiochem (La Jolla, CA). Polyprenol-15 (α-unsaturated) was obtained from Sigma Chemical Co. (St. Louis, MO). All other chemicals and solvents were of at least reagent grade.

Saponification and extraction. Two methods of saponification and extraction were compared. Method 1, described by Keller et al. (9) for assay of free-and chemically bound Dol-P uses direct saponfication of tissue followed by ether extraction and quantitation by HPLC. The tissue (1 g) was saponified in a boiling water bath for 60 min in a mixture of 1 ml of 60% KOH (w/v) and 2 ml of methanol containing 0.25% pyrogallate. The mixture then was extracted with ether as described by Keller and Adair (17).

Method 2 is a modification of that of Burgos et al. (18), routinely used in our laboratory (14,15). In this case, the 1g tissue samples were saponified for one, two or sixteen hr in a boiling mixture containing 0.3 g KOH, 0.2 ml water and 0.2 ml ethanol followed by ether extraction. In this modified method, pyrogallol was omitted because it is reported to be incompatible with alkaline solutions (19). [1-^{14}C]Dolichol or [1-^{14}C]Dol-P were added as tracers in each case. The final concentrations of KOH were about 15% in Method 1 and 25% in Method 2, assuming liver tissue was 80% water.

*To whom correspondence should be addressed.
Abbreviations: Dol-P, dolichyl phosphate; HPLC, high pressure liquid chromatography; KOH, potassium hydroxide.

On the basis of experience with these two methods, Method 3 was developed as follows: 1 g aliquot of liver was saponified for 16 hr (overnight) in a boiling mixture of 2 ml of 90% KOH (w/v) and 1 ml methanol. The mixture was allowed to cool to room temperature and was extracted three times with equal volumes of ether. The ether extracts were pooled and washed with 4.1 ml of water. The saponification mixture then was diluted to 15% KOH with the water wash plus 4.1 ml of methanol and reextracted three times with 10 ml of ether. The second set of extracts were pooled and washed with 10 ml of 5% acetic acid. Both pooled extracts were dried under N_2. The first ether extract, containing the cholesterol and dolichol, was taken up in chloroform/methanol (2:1, v/v) for analysis by HPLC. The second extract, containing the Dol-P, was resuspended in chloroform and loaded on a 1 g column of silicic acid. The column was washed with 5 ml of chloroform, and the Dol-P was eluted with 10% methanol in chloroform. The eluate was dried under N_2 and taken up in chloroform/methanol (2:1, v/v). Aliquots were taken for determination of radioactivity and analysis by HPLC.

Quantitation by HPLC. Cholesterol, dolichol and Dol-P were analyzed on a Hewlett-Packard 1084-B HPLC using a reverse-phase C_{18} column (Hewlett-Packard #799150d-174) equipped with a variable wavelength detector set to read absorbance at 210 nm with 430 nm as a reference wavelength (8). The mobile phase consisted of a methanol/isopropanol gradient with increasing proportions of isopropanol delivered at 2 ml/min. The gradient used for the cholesterol/dolichol fraction consisted of seven minutes at 1% isopropanol, increasing to 25% over the next 10 min, holding at 25% for three min and increasing to 70% over the next 10 min. For Dol-P, the gradient was increased from 1 to 50% isopropanol over the first six min and then to 70% over the next 14 min of the run. In this case, the isopropanol contained 10 mM phosphoric acid. Quantitation was achieved by summing the areas of all homologous peaks and comparing to human liver dolichol standards. Cholesterol was quantitated by comparison to the cholesterol standard. Radioactivity in the eluate was counted on an LKB 1219 Rackbeta liquid scintillation counter.

RESULTS

Figure 1a shows that when Method 1 is used, dolichol and Dol-P are extracted efficiently from the saponification mixture after a 1 hr saponification. Recoveries of both labeled compounds in the ether extracts were ca. 90% compared to 30% for dolichol and less than 10% for Dol-P in Method 2 (Fig. 1b). This difference was not due to the presence or absence of pyrogallate as the extraction of dolichol and Dol-P was only slightly less efficient when the pyrogallate was omitted in Method 1 (data not shown).

After a 2 hr saponification, about 85% of both dolichol and Dol-P was extracted by the ether in Method 1, with or without pyrogallate. Using Method 2, the longer saponification greatly increased the extraction of dolichol but had little effect on the extraction of Dol-P (Fig. 1c, 1d). Similar results were obtained following a 16-hr-saponification.

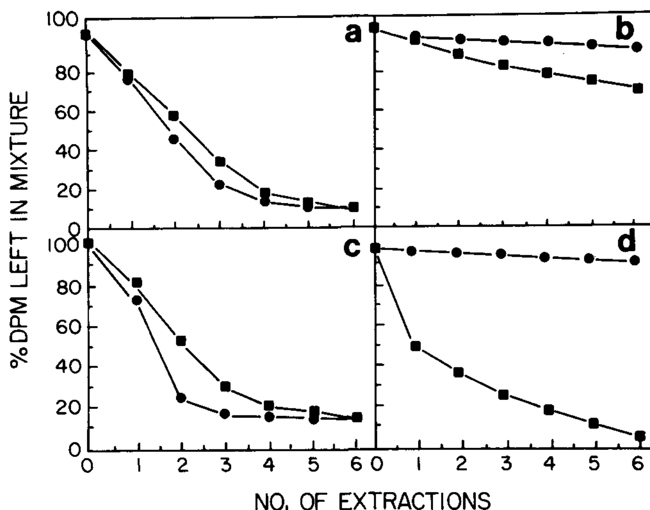

FIG. 1. Percentage of total DPM of [1-^{14}C] dolichol (■) and Dol-P (●) left in the saponification mixture after extraction with ether. Each point represents the average of three observations. (a) One-hr saponification, Method 1. (b) One-hr saponification, Method 2. (c) Two-hr saponification, Method 1. (d) Two-hr saponification, Method 2.

The difference in the extractability of Dol-P in the two methods evidently is related to the concentration of KOH in the saponification mixture. As illustrated in Figure 2, the extraction of Dol-P was improved by diluting with 50% ethanol the KOH in the saponification mixtures from 25% to 15%. Further dilution did not increase the amount of Dol-P extracted. If methanol was substituted for ethanol in Method 2 and the mixture diluted to 15% KOH after saponification, Dol-P was extracted as efficiently as in Method 1.

Saponification of tissue with Method 3's strong KOH solution for a 16 hr period ensured that dolichyl fatty acyl esters in the tissue were hydrolyzed to dolichol. Dolichyl esters were hydrolyzed incompletely after a two-hr saponification of liver tissue (data not shown) or a 17-hr saponification of soybean embryos (Rip and Carroll, unpublished data). The cholesterol and dolichol could be extracted from this saponification mixture with ether, and the extract was suitable for HPLC analysis without further purification (Fig. 3a) even though about 5% of the Dol-P remained in the fraction. This does not interfere with the quantitation of the cholesterol or dolichol as small amounts of Dol-P run in the solvent front when phosphoric acid is omitted from the eluting solvent.

Subsequent dilution of the saponification mixture to 15% KOH made it possible to extract the Dol-P with ether but further purification was required before HPLC analysis. This was necessary to remove residual dolichol (ca. 2% of the total dolichol in the tissue) in the ether extract. The contaminating dolichol amounted to one-third to one-half of the total Dol-P and interfered with quantitation of the Dol-P.

Attempts to purify the Dol-P by back extraction from ether into water did not separate it from the dolichol as cleanly as in experiments on soybean embryos (10). Therefore, the dolichol was removed by silicic acid chromatography, and this gave a Dol-P fraction that could be analyzed by HPLC (Fig. 3b). However, approximately 20%

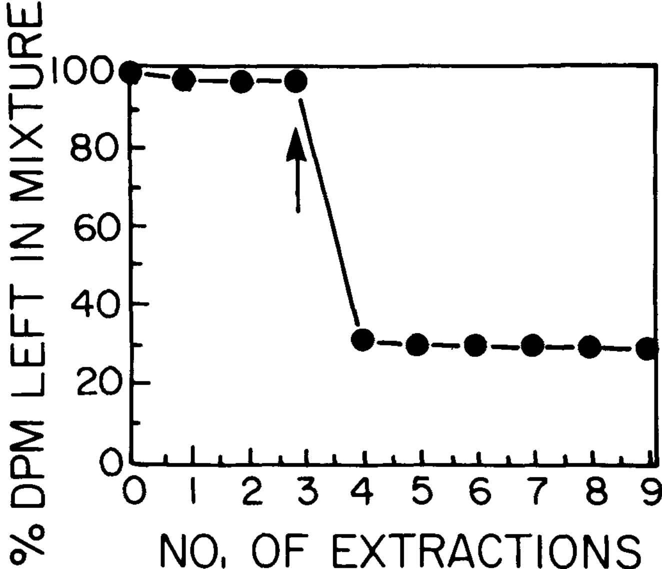

FIG. 2. Percentage of total DPM of [1-^{14}C]Dol-P left in the saponification mixture after extraction with ether. Saponification was done over two hr using Method 2. Each point represents the average of three observations. The arrow indicates the point where the saponification mixture was diluted with 50% ethanol from 25% KOH to 15% KOH.

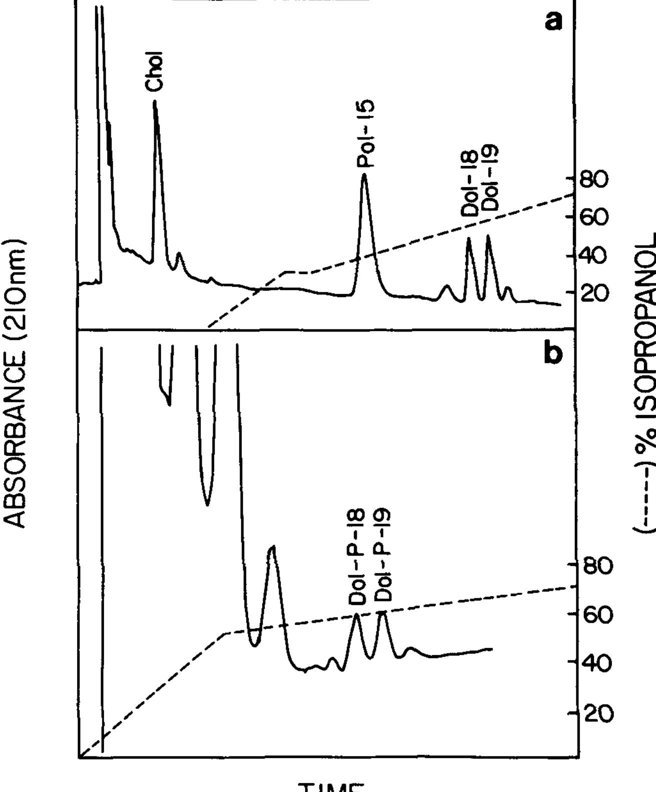

FIG. 3. C_{18} reverse-phase HPLC chromatograms using methanol/isopropanol gradients. (a) CBA/Ca mouse liver extract, cholesterol/dolichol fraction. Absorbance units/full scale deflection decrease by eight-fold between the cholesterol peak and the polyprenol peak. (b) CBA/Ca mouse liver extract, Dol-P fraction. The isopropanol in the eluting solvent contains 10 mM phosphoric acid.

of the tracer Dol-P extracted from the saponification mixture bound tightly to the column and could not be recovered in the eluate. The reason for this is unclear but it is possible that some of the Dol-P is oxidized by the treatment.

The recoveries of cholesterol, dolichol and Dol-P were 92 ± 1%, 94 ± 4% and 61 ± 1% (SEM, n = 4), respectively. Analysis of mouse liver using Method 3 gave values of 5700 ± 700 μg/g of cholesterol, 66.3 ± 1.2 μg/g of dolichol and 3.7 ± 0.3 μg/g of Dol-P on a wet weight basis.

DISCUSSION

Our values for the concentrations of dolichol and Dol-P in mouse liver are similar to those reported for liver of male C57BL/6J mice one month after weaning (20). The concentration of dolichol also is similar to that reported for liver of 12-month-old C57 B1/6 mice (21). Dol-P accounted for about 5% of the sum of the forms of dolichol in the liver, which is somewhat less than the values of 18% and 6.7% reported for mouse liver at weaning and one month after weaning, respectively (20), or values of 7%, 14% and 16% in rat liver as determined by other methods (5,22,23). Our results differ considerably from those of dolichol, Dol-P (17.1 and 14.7 μg/g, respectively) and the percentage present as Dol-P (46%) reported for rat liver by Keller et al. (9). The reason for this discrepancy is not clear but it seems unlikely to be due to species differences.

Keller et al. (9) attributed the high levels of Dol-P found in their experiments to a more efficient extraction of Dol-P from the saponification mixture. Our studies confirm that Dol-P is extracted efficiently from saponification mixtures when the concentration of KOH is appropriate, but the concentration of Dol-P in the liver is still much lower than that reported by Keller et al. (9). It is possible that the difference is related to the use of different methods of analysis by HPLC, although this does not seem very likely.

There is considerable interest in the metabolism and function of dolichol and its derivatives. Therefore, it is desirable to have a simple and reliable method for extraction and quantitation of dolichol and Dol-P. Our studies have indicated that prolonged saponification may be required for hydrolysis of dolichyl acyl esters (unpublished data). The extraction of Dol-P from the saponification mixture by ether is dependent on the concentration of KOH; this can be used to isolate the dolichol and Dol-P separately for quantitation by HPLC. The method described gives excellent recoveries of cholesterol and dolichol in a form that can be analyzed directly by HPLC. The recovery of Dol-P is lower but still much better than that obtained with the earlier method used in our laboratory (8).

Analysis of Disteryl Ethers

Erhard Schulte*,[a] and Nikolaus Weber[b]
[a]Institut für Lebensmittelchemie der Universität, Piusallee 7, D-4400 Münster and [b]Bundesanstalt für Fettforschung, Piusallee 68-76, D-4400 Münster, Federal Republic of Germany

Disteryl ethers isolated from a vegetable oil and a table margarine were analyzed by capillary gas chromatography. The composition of disteryl ethers in such products reveals whether vegetable oils are mixed with animal fats and if these materials have been subjected to industrial bleaching.
Lipids 22, 1049-1052 (1987).

Disteryl ethers are minor but ever-present constituents of industrially refined fats and oils (1-3). They are artifacts generated from plant and animal sterols during the bleaching process (4). Moreover, disteryl ethers are formed by various acid-catalyzed reactions (1). Methods for the thin layer chromatography (TLC) separation of mixtures of disteryl ethers from the unsaponifiable fractions of fats and oils are described in the literature (4-6). However, little is known about methods for the analysis of the individual components of these mixtures.

$R_1 = R_2$:uniform disteryl ethers
R_1, R_2 = H:dicholesteryl ether
$R_1, R_2 = CH_3$:dicampesteryl ether
$R_1, R_2 = C_2H_5$:disitosteryl ether

$R_1 \neq R_2$:mixed disteryl ethers
R_1 = H; $R_2 = CH_3$:cholesterylcampesteryl ether
R_1 = H; $R_2 = C_2H_5$:cholesterylsitosteryl ether
$R_1 = CH_3$; $R_2 = C_2H_5$:campesterylsitosteryl ether

Structure of various disteryl ethers.

This study describes the separation of various individual disteryl ethers by capillary gas liquid chromatography (GLC). Methods for the analysis of these compounds in refined fats and oils may be of interest with regard to food composition and adulteration. In addition, the method described here may be useful for the determination of disteryl ethers in food and feedstuff as well as of their distribution in organs of man and animal after ingestion.

MATERIALS AND METHODS

Chemicals. Cholesterol, sitosterol and stigmasterol were purchased from E. Merck (Darmstadt, FRG). Crude sitosterol, containing about 40% campesterol, was obtained from Sigma Chemie (Deisenhofen, FRG). A mixture of plant sterols containing brassicasterol, campesterol, stigmasterol and sitosterol (plant sterol mix) was a product of Supelco (Sulzbach, FRG).

Preparation of disteryl ethers. Dicholesteryl ether (melting point [mp] 195-198 C), disitosteryl ether (mp 188-193 C), distigmasteryl ether (mp 207-210 C), as well as a mixture of disteryl ethers derived from cholesterol and sitosterol (1:1, mol/mol), a mixture of disteryl ethers derived from the plant sterol mix, a mixture of disteryl ethers derived from the sterol fraction that was isolated from a vegetable oil, and a mixture of disteryl ethers derived from the sterol fraction that was isolated from a table margarine were prepared by heating (200 C, 15 min) of sterols with anhydrous $CuSO_4$ (7). After cooling, the reaction mixtures were extracted three times with hexane. The solvent was removed, and the resulting mixture of reaction products was treated with ethanol to remove dehydrosterols. The resulting brown residue was purified by repeated crystallization from hexane/acetone (4:1, v/v). The purity of the disteryl ethers (R_f 0.45) was checked by TLC on Silica Gel H (E. Merck) with hexane/diethyl ether (95:5, v/v) (4). Chromatograms were visualized by spraying the plates with chromic-sulfuric acid and charring. Mp (uncorrected) and infrared (IR) spectra of disteryl ethers agreed well with the data given in the literature (4,7).

Isolation of sterols and disteryl ethers from oil and margarine. A commercially available vegetable oil and a table margarine containing a mixture of vegetable fats and animal fats as well as genuine olive oil, 30 g each, were subjected to alkaline hydrolysis according to an established procedure (8). The unsaponifiable fraction was isolated by repeated extraction of the reaction mixture with diethyl ether.

The sterols were separated from the unsaponifiable fraction by precipitation with digitonin (9). The precipitate was isolated, dissolved in dimethyl sulfoxide and extracted three times with diethyl ether. The sterol extract was washed with water and dried; the fraction of sterols was further purified by TLC on layers of silica gel using hexane/diethyl ether (3:2, v/v). The resulting sterol mixture was used for GLC and for preparation of disteryl ethers as described above.

The constituents of the remaining unsaponifiable fraction were separated by repeated preparative TLC on Silica Gel H layers (0.5 mm) with hexane/diethyl ether (95:5, v/v). The fraction of disteryl ethers (R_f 0.45) was identified by co-chromatography with a standard and isolated by extracting the silica gel with water-saturated diethyl ether. The resulting mixture of nearly pure disteryl ethers was used for capillary GLC.

Analyses by capillary GLC. Capillary GLC of sterols and disteryl ethers was carried out in a Varian 3700 instrument (Darmstadt, FRG) equipped with a flame ionization detector. Peaks were identified by retention times using synthetic reference compounds. Peak areas and retention times were determined using a Merck-Hitachi D-2000 integrator (Darmstadt, FRG).

*To whom correspondence should be addressed.
Abbreviations: TLC, thin layer chromatography; GLC, gas liquid chromatography; BSA, *N,O*-bis(trimethylsilyl)acetamide; TMS, trimethylsilyl; TMCS, trimethylchlorosilane.

TMS ethers of sterols were prepared by reacting the sterols with trimethylchlorosilane (TMCS) and *N,O*-bis(trimethylsilyl)acetamide (BSA) in pyridine (1:5:10, v/v). They were analyzed on a fused silica column, 30 m × 0.325 mm inside diameter, coated with 0.1 μm SE-54 ("DB-5"; ICT, Frankfurt/M., FRG) at a temperature of 250 C, with injector and detector each set at 270 C. Hydrogen (0.5 bar at column inlet; split 1:10) was used as carrier gas and nitrogen (30 ml/min) as purge gas. The reaction mixtures of trimethylsilyl (TMS) ethers (1.5-2.0 μl; 0.1%) were injected without purification.

Disteryl ethers were separated on a glass capillary, 20 m × 0.27 mm id, coated with 0.05 μm SE-30 from Serva (Heidelberg, FRG) at a temperature of 320 C; the injector and detector each were set at 350 C. Hydrogen (1.5 bar at column inlet; split 1:10) was used as carrier gas and nitrogen (30 ml/min) as purge gas. Solutions (1.5-2.5 μl; 0.05%) of disteryl ethers in cyclohexane were injected.

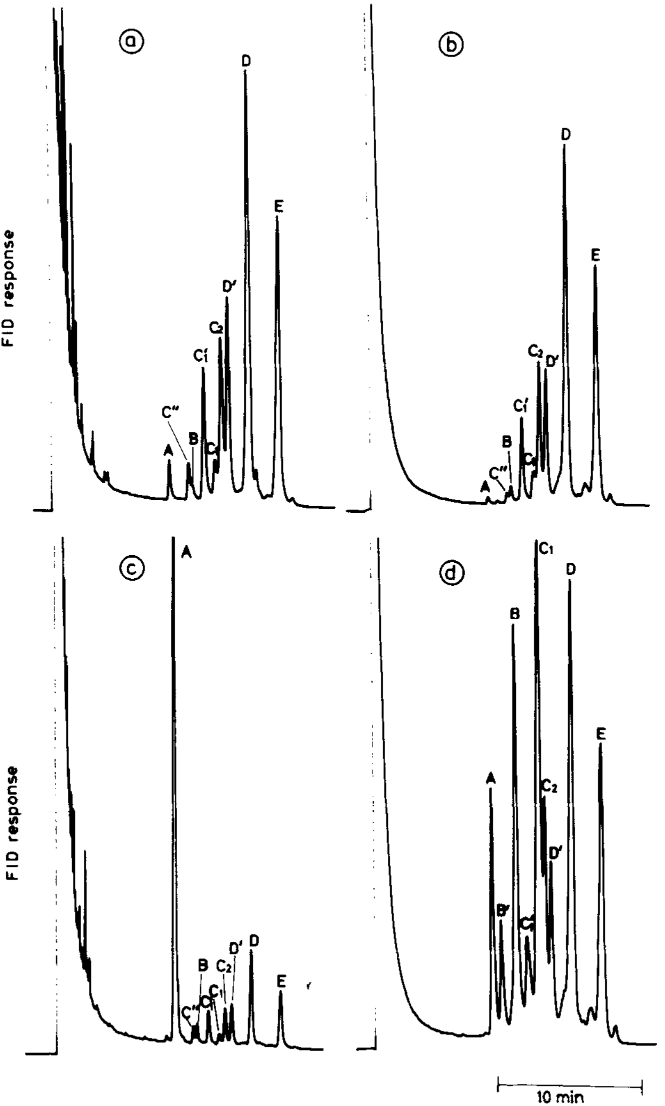

FIG. 1. Capillary GLC of various mixtures of disteryl ethers. (a) Mixture of disteryl ethers isolated from a vegetable oil. (b) Mixture of disteryl ethers that had been synthesized from the sterol fraction isolated from the vegetable oil. (c) Mixture of disteryl ethers isolated from a table margarine. (d) Mixture of disteryl ethers that had been synthesized from the sterol fraction isolated from the table margarine. The disteryl ethers are designated as given in Figure 2. Experimental conditions for GLC are described in *Materials and Methods.* Peaks tentatively are identified from their retention times.

RESULTS AND DISCUSSION

Commercial plant and animal fats and oils pass through various refining steps including deacidification, bleaching and deodorization. Disteryl ethers exclusively are formed during the bleaching process (2,4,5). The formation of these artifactual condensation products is dependent not only on the concentration of sterols in the starting materials and on time, temperature and vacuum during the bleaching process; it also depends on the extent of activation of bleaching earth and its acidity (4,5).

Methods for the analysis of individual disteryl ethers have not been described until now. The separation of dicholesteryl ether from other cholesterol derivatives on a packed column at 240 C has been reported elsewhere (6). However, partial decomposition of disteryl ethers on packed columns at high temperatures was observed by the authors.

In this study, no decomposition of disteryl ethers was detected when capillary GLC was used for the analysis. Figure 1 shows that the most abundant uniform disteryl ethers in refined fats and oils, such as dicholesteryl ether, disitosteryl ether, dicampesteryl ether, distigmasteryl ether, dibrassicasteryl ether and a large number of the corresponding mixed disteryl ethers such as cholesterylsitosteryl ether, campesterylsitosteryl ether and others were resolved sufficiently by capillary GLC (Fig. 2) under the conditions given in *Materials and Methods.*

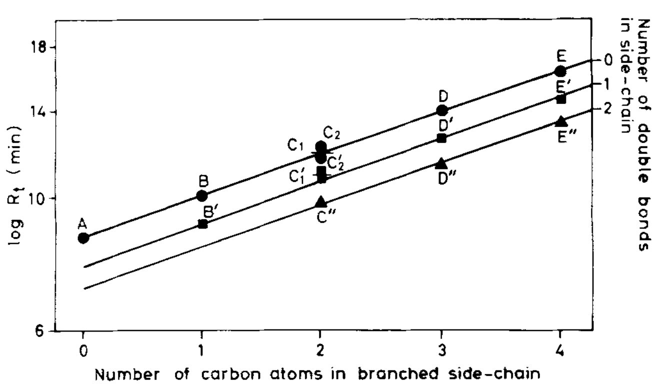

FIG. 2. Retention times, R_t, of various disteryl ethers that had been synthesized from different sterols and sterol mixtures, as a function of carbon atoms and double bonds in the side-chain of steryl moieties. A, Dicholesteryl ether (0:0, number of C-atoms in branched side-chain:number of double bonds in side-chain); B, cholesterylcampesteryl ether (1:0); C_1, cholesterylsitosteryl ether (2:0); C_2, dicampesteryl ether (2:0); D, campesterylsitosteryl ether (3:0); E, disitosteryl ether (4:0); B′, cholesterylbrassicasteryl ether (1:1); C_1', campesterylbrassicasteryl ether (2:1); C_2', cholesterylstigmasteryl ether (2:1); D′, sitosterylbrassicasteryl ether (3:1); E′, sitosterylstigmasteryl ether (4:1); C″, dibrassicasteryl ether (2:2); D″, brassicasterylstigmasteryl ether (3:2); E″, distigmasteryl ether (4:2). Procedures for preparation and isolation of disteryl ethers and experimental conditions of GLC are described in *Materials and Methods.*

It is evident from Figure 2 that retention times of the disteryl ethers increase with the number of C-atoms and decrease with the number of double bonds in the side-chain of the steryl moieties. One might expect that disteryl ethers having a similar arrangement of C-atoms and double bonds in the side-chain, e.g. dicampesteryl ether (2:0) and cholesterylsitosteryl ether (2:0) as well as campesterylbrassicasteryl ether (2:1) and cholesterylstigmasteryl ether (2:1), should show similar retention times; yet, the separation even of such critical disteryl ethers is sufficient under the conditions described (Figs. 1 and 2). In contrast, distanyl ethers and mixed disteryl ethers containing saturated and Δ^5-unsaturated steryl moieties are not separated.

The analysis of disteryl ethers in fats and oils may be of interest with regard to food composition and adulteration. The occurrence of these sterol derivatives proves that refined fats and oils had passed through a bleaching process. Moreover, the analysis of the different disteryl ethers that are formed during commercial processing gives information on whether plant and animal fats and oils have been bleached individually or together. In the former case, the disteryl ether fraction of plant fats would consist of a mixture of disteryl ethers containing only a trace of cholesteryl moieties and that of animal origin would consist almost exclusively of dicholesteryl ether, whereas in the latter case mixed disteryl ethers containing large amounts of cholesteryl moieties would be the main components (Fig. 1).

Analysis of the sterol fraction of the vegetable oil examined here indicates that it may have been derived from rapeseed; however, the table margarine investigated was found to contain a mixture of plant sterols typical for rapeseed oil together with large amounts of cholesterol derived from animal fat (Table 1).

These findings are supported by the composition of disteryl ethers isolated from both the vegetable oil and the table margarine (Table 2). It is obvious that mixed disteryl ethers present in the oil are derived almost exclusively from sterols typical for rapeseed oil (Table 2; Fig. 1a); small amounts of dicholesteryl ether may be formed from traces of cholesterol that have been detected in various vegetable oils (Table 1) (2). The closely resembling pattern of both the disteryl ethers extracted from the vegetable oil (Fig. 1a) and the disteryl ethers synthesized from the sterol fraction of the oil (Fig. 1b) strongly suggests that the vegetable oil does not contain animal fat. However, the table margarine was found to contain large proportions of dicholesteryl ether together with mixed disteryl ethers, the latter having a pattern typical for the disteryl ethers of a refined rapeseed oil (Table 2; Fig. 1a and c). These data clearly indicate that the margarine contained a mixture of fats from animal and plant origin. In contrast, disteryl ethers were not detected in genuine olive oil.

It is commercial practice to blend previously refined fats and oils for the production of margarine. As expected, the results given in Table 1 and Figure 1 show that the constituent vegetable and animal fats of the table margarine must have passed separately through a bleaching process because only traces of mixed disteryl ethers containing cholesteryl moieties were detected in the margarine (Table 2; Fig. 1c). Yet, high proportions of mixed

TABLE 1

Composition of Sterols Isolated from a Commercial Vegetable Oil and from a Table Margarine

Sterols	Vegetable oil[a] (%)	Table margarine[b] (%)
Cholesterol	0.6	27.9
Brassicasterol	9.4	6.1
Campesterol	32.9	25.2
Sitosterol	49.2	34.6
Others[c]	7.9	6.2

[a]Containing 1.9 mg sterols/g oil.

[b]Containing 2.8 mg sterols/g margarine.

[c]Including small amounts of stanols.

TABLE 2

Composition of Constituent Disteryl Ethers Isolated from a Commercial Vegetable Oil and from a Table Margarine

Disteryl ethers	Vegetable oil[a]		Table margarine[a]	
	Found (%)	(Calcd.)[b] (%)	Found (%)	(Calcd.)[b] (%)
Dicholesteryl ether	3	(<1)	—[c]	—[c]
Dibrassicasteryl ether	3	(1)	5	(1)
Dicampesteryl ether	11	(11)	10	(12)
Disitosteryl ether	21	(24)	23	(23)
Campesterylsitosteryl ether	29	(33)	31	(34)
Sitosterylbrassicasteryl ether	13	(9)	12	(8)
Campesterylbrassicasteryl ether	9	(6)	11	(6)
Others[d]	11	(16)	8	(16)

[a]Containing about 1 μg disteryl ethers/g, each.

[b]Calculated for the formation of disteryl ethers from the sterol mixture of the composition given in Table 1.

[c]The disteryl ether fraction of the margarine contains 67% dicholesteryl ether, which was calculated as "100% from animal origin."

[d]Including small proportions of cholesterylcampesteryl ether, cholesterylbrassicasteryl ether, cholesterylsitosteryl ether and traces of disteryl ethers containing stanyl moieties.

disteryl ethers having cholesteryl moieties would be expected if animal and plant fats and oils would have been bleached together. Theoretically, such a mixture of disteryl ethers derived from a sterol fraction (the composition given in Table 1 for the table margarine) should contain as the main components having cholesteryl moieties around 19% cholesterylsitosteryl ether, 13% cholesterylcampesteryl ether and 3% cholesterylbrassicasteryl ether (cf. equation below).

We have simulated such a refining process, in which vegetable and animal fats were bleached together, by preparing a blend of disteryl ethers from the sterol fraction isolated from the table margarine. Analysis by capillary GLC of these mixed disteryl ethers containing cholesteryl moieties showed as the main components cholesterylsitosteryl ether (20%), cholesterylcampesteryl ether (15%) and cholesterylbrassicasteryl ether (4%) (Fig. 1d). These values agree with the calculated data.

For a mixture of four components, a, b, c and d, in which the molecules of each compound are able to react with molecules of the same compound or molecules of each other compound to yield a bimolecular adduct, a theoretical distribution of reaction products has to be expected according to the following equation:

$$(a+b+c+d)^2 = a^2+b^2+c^2+d^2+2(ab+ac+ad+bc+bd+cd).$$

Deviation of our results from the calculated values (Table 2) may be due to further alteration of the sterol composition by other refining steps and differences in the rate of formation of individual disteryl ethers. Thus, we found that under the conditions described in *Materials and Methods* the synthesis of dicholesteryl ether is slightly favored as compared to the synthesis of disitosteryl ether (data not shown). Analysis of disteryl ethers also may be helpful for the detection of part-processed or back-blended vegetable oils that are declared genuine.

Disteryl ethers are formed in many chemical syntheses in which sterols are subjected to acid (1), e.g. transesterification of steryl esters (6) and glycosidation of sterols (10); they also are generated by thermal decomposition of cholesterol 3-sulfate salts (11,12). Obviously, the method described for the analysis of disteryl ethers in fats and oils also may be helpful for the characterization of these compounds if they are formed in various chemical reactions.

Some earlier work has been carried out to study possible biological effects of disteryl ethers, such as cytotoxicity and carcinogenicity (1,13,14). However, little is known on the distribution and metabolism of disteryl ethers in man or animals. The method described for the analysis of these substances may be helpful in the investigation of disteryl ethers and their metabolism in human and animal tissues.

Effects of Eicosatetraynoic Acid on Membrane Lipids of Trout Liver and Intestine

X. Pelletier and **C. Leray***
Centre de Neurochimie, Centre National de la Recherche Scientifique, antenne Cronenbourg, BP 20 CR, 67037 Strasbourg Cedex, France

After two months feeding either an (n-3) or an (n-6) fatty acid-rich diet, two groups of trout were switched to the (n-6) or the (n-3) fatty acid-rich diet, respectively. Half of each group was treated with 0.03% 5,8,11,14-eicosatetraynoic acid (ETYA) in the diet. Liver and intestinal brush border membrane lipids were analyzed. No effect was observed on their cholesterol content. ETYA induced an accumulation of 18:2(n-6), and it did not affect the 20:4(n-6) content but decreased the 22:5(n-6) content. ETYA induced an increase of 18:3(n-3) content in the brush border membrane and a decrease of the 22:6(n-3) content in the liver. Those results suggest that ETYA blocks mainly the Δ6-desaturase, which should have two different sites in the liver and one in the intestine.
Lipids 22, **1053-1056 (1987).**

Eicosa-5,8,11,14-tetraynoic acid (ETYA, Ro 3-1428) is the acetylenic analog of arachidonic acid (1). It first was reported to block cholesterol synthesis between acetate and mevalonate and to exert a suppressive effect on sebaceous gland secretion (2). Later, ETYA also was shown to inhibit arachidonic acid metabolism at the level of cyclooxygenase and lipoxygenase (3). Furthermore, it has been shown to compete with arachidonic acid for esterification enzymes (4). ETYA also has been demonstrated to block the conversion of linoleic acid to arachidonic acid and that of arachidonic acid to more unsaturated (n-6) fatty acids (5).

To analyze in more detail this last effect and the possibility of an influence of ETYA on (n-3) fatty acid metabolism, we investigated the effect of dietary ETYA on the fatty acid composition of phospholipids in the liver and intestinal brush border membranes of rainbow trout. These membranes were selected as easily purified plasma membranes (6) considering their physiological importance and their ability to be modified by dietary treatments (7).

MATERIALS AND METHODS

Fish and membrane preparation. Rainbow trout (250–300 g) were stocked in outdoor tanks that were provided with well-aerated water (12–13 C). Diets were prepared according to Castell et al. (8) and contained 8% linseed oil or grapeseed oil for the (n-3) or (n-6) fatty acid-rich diet, respectively. They were given once daily to the fish (1% body weight) (see Table 1 for the diet's fatty acid composition). The delivered food amount was completely ingested by the fish. Group I was fed the (n-3) fatty acid-rich diet for two months and then switched to the (n-6) fatty acid-rich diet with or without 0.03% ETYA. Group II first was fed the (n-6) fatty acid-rich diet and switched to the (n-3) fatty acid-rich diet with or without 0.03% ETYA. Fish were killed 10 or 30 days after the dietary change. Their livers were quickly removed and frozen. Brush border membranes were purified from scraped mucosa of the middle intestine (6). Membranes of similar purity were selected according to the alkaline phosphatase enrichment (13- to 18-fold).

TABLE 1

Fatty Acid Composition of the Experimental Diets (mol %)

16:0	12.9	8.6
18:0	3.2	3.8
18:1(n-9)	16.1	17.8
18:1(n-7)	0.5	0.6
18:2(n-6)	18.0	69.2
18:3(n-6)	0.7	—
18:3(n-3)	48.5	—

Membrane composition studies. Total lipids were extracted from the preparations according to Folch's procedure (9). Liver phospholipids were separated from the crude lipid extract as described previously (6). Individual phospholipids from intestinal membranes were separated by thin layer chromatography according to the method of Fine and Sprecher (10). The data presented here concern only phosphatidylethanolamine (PE) and phosphatidylcholine (PC) because those two phospholipids represent about 60% of the membrane phospholipids and are the most sensitive to dietary alterations (11). Fatty acid methyl esters (12) were analyzed using a Perkin-Elmer Sigma 1 gas chromatograph equipped with a bonded fused silica open tubular column (0.32 mm id × 50 m; Superox, Alltech France, Paris, France). Peak areas were determined by the in-line Perkin-Elmer Sigma 10 chart integrator. Results are given as molar percentages of the total fatty acids. Cholesterol (13) and phospholipid phosphorus (14) were determined on total lipid extracts.

RESULTS

Whatever the diet and treatment, the relative content of cholesterol, phospholipid and proteins was not affected by ETYA (0.6 mg total lipids and 0.4 mg total lipids/mg protein in brush border membrane and liver, respectively). A significant increase in both 18:2(n-6) and 20:3(n-6)

content occurred in the liver phospholipids of trout from group I treated during 30 days (see Table 2), together with a 53% decrease in the content of 22:5(n-6). A 35% decrease in the 22:6(n-3) content also was observed but only after a 10-day treatment. A similar decrease in 22:6(n-3) content was the only significant modification observed in the fatty acid composition of liver phospholipids in trout fed a (n-3) rich-diet (group II, see Table 3).

Brush border membrane PE and PC of ETYA-treated trout from the group I presented an accumulation of 18:2(n-6) already detected after 10 days but an accumulation of 20:3(n-6) and a decrease in the 22:5(n-6) content were detected only after a 30-day treatment when compared with untreated fish (Table 4). The (n-3) fatty acid content remained unaltered in PE and PC.

In brush border membranes from the group II, ETYA induced a decrease in the saturated fatty acid content of PC (Table 5) together with a slight accumulation of linolenic acid; this increase occurred also in PE but only after a 10-day treatment. Since similar effects could be

observed in phosphatidylserine and phosphatidylinositol, only the fatty acid composition of PE and PC is reported in the tables.

DISCUSSION

In contrast with previous results concerning mammals (15), ETYA had no effect on the cholesterol level either in the liver or in the intestinal brush border membrane of rainbow trout.

The observed accumulation of linoleic acid induced by the drug in both liver and brush border membrane phospholipids of trout fed the (n-6)-rich diet is similar to what was reported for rat liver (16). It is likely that this accumulation is the result of a Δ6-desaturase inhibition, this enzyme system being present with similar activities in trout liver and enterocytes (unpublished results). The Δ5 desaturation step is less sensitive to the drug since a slight accumulation of 20:3(n-6) occurs only after a 30-day treatment. The important inhibition of the 22:5(n-6) synthesis induced by the drug is likely the consequence of the inhibition of the two first desaturation steps rather than that of the Δ4-desaturase since there is no accumulation of 20:4 and 22:4(n-6).

The observed decrease of the 22:6(n-3) content in trout liver after a 10-day treatment with ETYA, regardless of the diet, is unlikely the result of a biosynthesis inhibition since no accumulation of its precursors is detected. Hence, this decrease can be due either to an inhibitory effect on the deacylation-reacylation system of 22:6(n-3)-rich phospholipid species or to an activation of lipoxygenases. Although ETYA has been shown to exert inhibitory effects on trout 14-lipoxygenase (17), the lack of information about the cellular concentration of the drug in our experiments prevents further comments. After a 30-day treatment, no differences remain between treated and untreated groups, which suggests a tight regulation of the essential 22:6(n-3) liver content.

Since only one enzyme molecule almost certainly is required for the Δ6 desaturation of both (n-6) and (n-3) fatty acids (18), the strong inhibition of the trout liver Δ6-desaturase by ETYA only with 18:2(n-6) as substrate suggests that two different sites for either 18:2(n-6) or 18:3(n-3) should be present on the same enzyme molecule. In the trout intestinal epithelium, only one common site should be present since ETYA has the same inhibitory effect on both (n-6) and (n-3) substrates.

Therefore, it seems that the main target reaction of ETYA is the first desaturation step of linoleic acid in both trout liver and intestine. Still, one cannot exclude an inhibition of eicosanoids metabolism by the drug (3), which also should lead to an accumulation of 20:4(n-6) precursors. Furthermore, this work allows the demonstration of some effects of ETYA on the metabolism of (n-3) fatty acids, which are essential compounds in trout (19,20).

ACKNOWLEDGMENTS

Thanks are given to F. Hoffmann-La Roche and Co. (Basel, Switzerland) for supplying ETYA and to G. Gutbier for her technical assistance.

Short-Term Changes in Hepatic HMG-CoA Reductase in Rats Fed Diets Containing Cholesterol or Oat Bran

Micheal J. Kelley[1] **and Jon A. Story***
Department of Foods and Nutrition, Purdue University, West Lafayette, Indiana

In vivo regulation of hepatic HMG-CoA reductase (HMGR) (mevalonate:NADP$^+$ oxidoreductase [acylating CoA]; EC 1.1.1.34] by phosphorylation/dephosphorylation has not been demonstrated. Rats were meal-fed semipurified diets; effects of inclusion of cholesterol (2%) or oat bran (15%) in a single meal on expressed (phosphorylated) and total (dephosphorylated) activities of HMGR were measured from 15 min to 4 hr after presentation of the meal. Expressed activity was not significantly altered in response to the control diet during the time periods examined, while total HMGR activity declined by 15 min and increased through 4 hr to an activity about 1.5 times control levels. Addition of cholesterol resulted in little change in expressed activity but a greater and more sustained reduction in total activity. Oat bran caused reductions in both total and expressed activities, which were maintained through 4 hr. Total HMGR activity was best correlated with apparent demand for cholesterol synthesis.
Lipids 22, 1057–1059 (1987).

It has been proposed that activity of the rate-limiting enzyme of cholesterol biosynthesis, β-hydroxy-β-methylglutaryl-CoA reductase (HMGR; 1), can be regulated by reversible phosphorylation of the enzyme in response to hormones (2). Ingebritsen et al. (3) have demonstrated that the degree of phosphorylation and activity of HMGR in isolated rat hepatocytes can be manipulated by addition of glucagon or insulin to the incubation medium. Evidence for operation of such a mechanism in vivo has been less consistent. Brown et al. (4) reported that modulation of rat microsomal HMGR was not changed when rats were subjected to light cycling, fasting, stress, cholesterol feeding or cholestyramine feeding. Arebalo et al. (5) found that feeding a cholesterol-containing meal to rats resulted in an inhibition of liver microsomal HMGR within 1 hr and that this inhibition could be reversed by incubation of microsomes with phosphatase.

In order to properly investigate this problem in vivo, HMGR activity must be measured within a sufficiently short time following a meal. While the study of Arebalo et al. (5) measured the activity 60 min following the meal, a mechanism dependent on hormone-stimulated phosphorylation would operate within minutes of the start of the meal, due to increased circulating insulin levels. Furthermore, no addition to the diet other than cholesterol has been tested for possible effects on HMGR activity. We report the results of an experiment that followed the course of expressed and total HMGR activity from 15 min to 4 hr following a meal. In addition, we tested the effect of a diet with added oat bran, which has been useful in lowering serum cholesterol in humans (6,7), on the time course of HMGR activity.

Abbreviations: HMGR, HMG-CoA reductase; SP, control semipurified diet; CHL, cholesterol diet; OB, oat bran diet; R_t, total HMGR activity; R_a, expressed HMGR activity.

MATERIALS AND METHODS

Animals were housed under conditions of constant temperature and humidity, lighted from 9 p.m. to 9 a.m. Animals had access to deionized water ad libitum. Male Wistar rats (Harlan-Sprague-Dawley, Indianapolis, IN) weighing 80–116 g were fed a semipurified (SP) diet (50% glucose-hydrate, 20% casein [high nitrogen], 10% corn oil, 15% cellulose, 4% AIN mineral mix and 1% AIN vitamin mix) ad libitum. After 10 days, animals were gradually adapted to meal feeding that consisted of a daily, 2 hr meal at the onset of the dark period and were maintained on the meal pattern regimen for the duration of the experiment. On the final day of the experiment (day 28), animals were randomly assigned to one of three diet groups (18 animals per group) and fed a meal of SP diet, SP diet with 2% cholesterol (CHL; added at the expense of glucose-hydrate) or SP diet with 15% oat bran in place of cellulose (OB). Three animals from each diet group were killed at 0, 15, 30, 60, 120 and 240 min after the beginning of the meal. Liver microsomal fractions were isolated in the presence and absence of fluoride and total HMGR activity (R_t) measured in the absence of fluoride with added protein phosphatase and expressed activity (R_a) on fluoride-containing samples (8). All enzyme activity determinations were carried out in triplicate. Data were compared by analysis of variance with each diet-time group considered as a treatment (0 time and 3 diets at 5 time points yielding 16 treatments). Where appropriate, means were compared using least significant differences based on the pooled standard error from this analysis (33 d.f.; $p < 0.05$).

RESULTS

If HMGR activity is modulated by insulin levels (2), expressed activity of microsomal HMGR (R_a) would be expected to rise shortly after the beginning of the meal. Contrary to this hypothesis, R_a values in animals fed SP diet did not vary significantly during 4 hr after the start of the meal (89 vs 126 pmol/min mg, Fig. 1). By contrast, HMGR total activity (R_t) was reduced significantly, from 1063 pmol/min mg at time 0 to 372 pmol/min mg after 60 min and then increased through 4 hr (1629 pmol/min mg, Fig. 2).

Addition of cholesterol to SP diet caused a much greater reduction in R_a (Fig. 1) than that seen in SP-fed animals, and this reduction was maintained throughout the 4 hr period. Although analysis of variance did not indicate that this change was statistically significant, its magnitude (89 pmol/min mg at time 0 to 10 pmol/min mg at 30 min) and consistency suggest that it is biologically

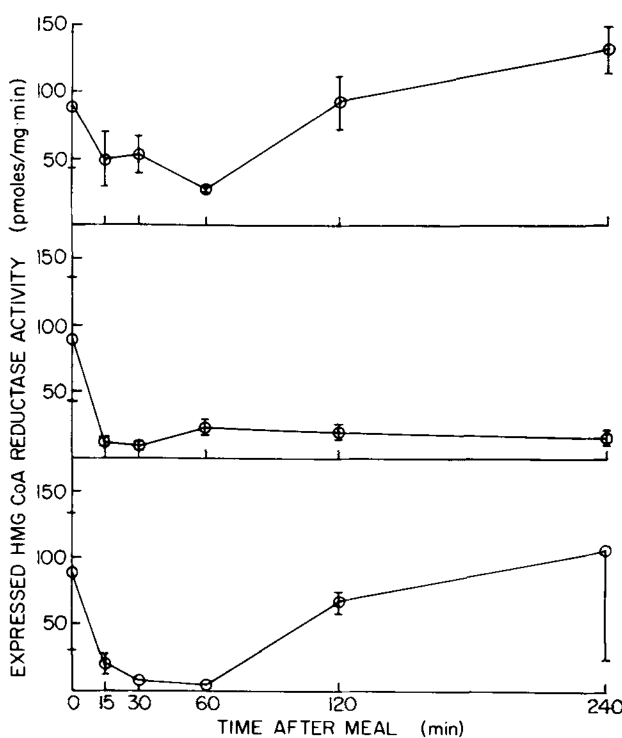

FIG. 1. Effects of dietary cholesterol or oat bran on expressed hepatic HMG-CoA reductanse activity in rats. Results from semipurified diet-fed animals are shown in the top, from cholesterol-fed in the center and from cellulose-fed in the lower figure. Rats were trained to eat meals, were presented control, oat bran or cholesterol diet at time 0 and were killed at the times indicated. Each point represents mean and standard error of activity in livers from 3 animals.

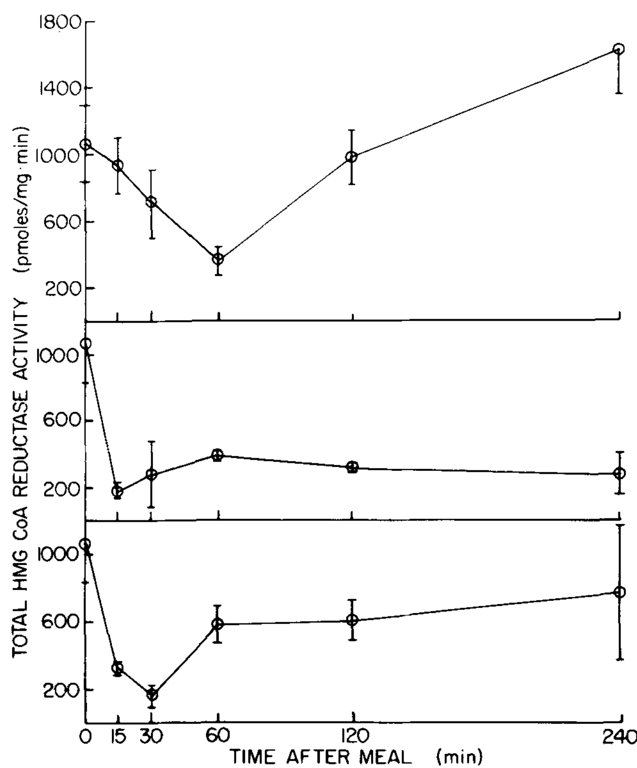

FIG. 2. Effects of dietary cholesterol or oat bran on total hepatic HMG-CoA reductase activity in rats. Results from semipurified diet-fed animals are shown in the top, from cholesterol-fed in the center and from cellulose-fed in the lower figure. Rats were trained to eat meals, were presented control, oat bran or cholesterol diet at time 0 and were killed at the times indicated. Each point represents mean and standard error of activity in livers from 3 animals.

significant. The pattern of R_t in CHL-fed animals differed from that of the SP-fed group (Fig. 2). Total enzyme activity was reduced to 182 pmol/min mg after 15 min and remained low, reaching a maximum of only 388 pmol/min mg at 60 min and remaining constant through 4 hr. Activities at all time points from 15 to 240 min were significantly lower than activity at time 0, indicating an inhibition of HMGR by dietary cholesterol.

Animals fed oat bran also exhibited reduction in R_a immediately after initiation of the meal, reaching a low of 5 pmol/min mg at 60 min (Fig. 1). Activities returned to levels similar to those present before the meal by 4 hr. Analysis of variance again indicated that none of these differences was significant. Total activity decreased to a low value of 163 pmol/min mg at 30 min, returned to 582 pmol/min mg by 60 min and continued to increase through 240 min, when it reached an activity of 776 pmol/min mg (Fig. 2). This level of activity was not significantly different from the total activity at time 0.

DISCUSSION

Several groups have endeavored to answer the question of whether HMGR is regulated by reversible phosphorylation in vivo and the additional issue of what role dietary cholesterol may play in such a regulatory scheme. Brown et al. (4) reported expressed and total activities of HMGR in rats exposed to differences in light cycling, fasting, stress and cholesterol or cholestyramine feeding. They concluded that changes in the rate of cholesterol synthesis in liver slices could not be accounted for by differences in the phosphorylation state of HMGR. Changes in R_t best reflected cholesterol synthesis rates over a wide range (50-fold) of activities. It was suggested that the large proportion of HMGR present in an inactive (phosphorylated) form in vitro was a reservoir of activity that could be called on in the short term. We observed no such change in the present studies. Our observations tended to agree with those of Brown et al. (4): that R_t was best correlated with expected cholesterol synthetic rate after a meal. These effects on R_t are consistent with the work of Dugan et al. (9), who showed a dependence of rat liver HMGR activity on the feeding status of animals.

Data presented here suggest that changes in HMGR in response to food take place in a very short period of time and that differences in diet composition can influence the magnitude of these changes. Dietary cholesterol causes a more rapid reduction in HMGR activity, which is of a greater magnitude than that produced by the SP diet alone (83% vs 65% maximum reductions). Interestingly, substitution of oat bran for cellulose causes a response similar to that of added cholesterol in a similar time frame. This could result from some absorbable component present in oat bran (10) or from some change in chylomicron size and/or composition, resulting in their more rapid clearance and uptake by the liver. These changes confer additional importance to the examination

of changes in the chylomicron-to-liver movement of lipids in response to dietary manipulation.

The Filamentous Fungus *Mortierella alpina*, High in Arachidonic Acid

Nagao Totani* and **Kenkichi Oba**
Biological Science Laboratory, Lion Corporation, 202 Tajima, Odawara, Kanagawa, 256 Japan

Arachidonic acid is not available readily, although it is widely distributed in animal tissue. We found that in some strains of *Mortierella alpina*, arachidonic acid accounted for 68.5–78.8% of the total fatty acids. This is more than twice the arachidonic acid content of any organism previously reported. The content of arachidonic acid per dry cell weight was about 25%. Our findings offer a method for the efficient isolation of arachidonic acid in large amounts.
Lipids 22, 1060–1062 (1987).

Arachidonic acid is present widely in the animal kingdom. It has been isolated from the lipids extracted from pig adrenal gland or pig liver and from sardines, which also are an important source of eicosapentaenoic and docosahexaenoic acids. However, the arachidonic acid content is usually less than 5%, and the yield per dry weight is 0.2% or lower. Hence, large scale production of the acid is difficult.

Methods for culturing microorganisms that would be capable of producing larger amounts of arachidonic acid (1) have been proposed. Iizuka (2) reported on arachidonic acid-producing microorganisms belonging to the genera *Penicillium, Cladosporium, Mucor, Fusarium, Hormodendram, Aspergillus* and *Rhodotorura* that are cultured in media containing hydrocarbons or carbohydrates as carbon sources. This approach can produce an arachidonic acid content up to 7.5% of total lipid weight or less than 1% of dry cell weight. It also has been reported (3) that some strains of the genera *Entomophthora, Delacroixia, Conidiobolus, Pythium* and *Phytophthera* produce relatively high arachidonic acid levels. Arachidonic acid amounted to 27.1% of total fatty acid in *Entomophthora exitialis,* 19.1% in *E. ignobilis* and 18.8% in *E. thaxteriana.* It also has been shown (4) that dried mycelia of *Mortierella renispora* contain 4.8% of lipids, 26.7% of which is arachidonic acid. Ahern (5,6) showed that the red alga *Porphyridium cruentum* produces arachidonic acid with a potential yield of 1–8% of the total dry cell weight.

However, the arachidonic acid content in these species still is not sufficiently high. Hence, it was this study's aim to find microorganisms that would be capable of more efficiently producing arachidonic acid-containing lipids.

MATERIALS

The Institute for Fermentation Osaka, Japan (IFO), and American Type Culture Collection (ATCC) Rockville, MD, supplied the strains of *Mortierella alpina* used: IFO 8568, ATCC 16266, ATCC 32221, ATCC 42430.

Methyl arachidonate (purity 99%) was purchased from Nu Chek-Prep. Inc., Elysian, MN. Malt agar medium was purchased from Nissui Pharmaceutical Co., Tokyo, Japan. Reversed-phase thin layer chromatographic (TLC) plates, RP-18F, were a product of Merck, Darmstadt, West Germany.

Gas-liquid chromatography was carried out using a Hitachi 663-50 gas chromatograph and a 1.5-m glass column of 3 mm bore packed with diethyleneglycol succinate (DEGS) 15%, SE-30 or OV-101. The instrument was fitted with a flame ionization detector. Gas chromatography-mass spectrometry was done on a Hitachi M-80 and followed by data analysis on a Hitachi M-003. ^{1}H-NMR and ^{13}C-NMR spectra were measured using a JEOL Model FX-90Q instrument.

METHODS

Ninety g of malt agar medium was added to 2,000 ml of distilled water and autoclaved for 15 min. The resulting medium was poured into 100 sterilized dishes that were 80 mm in diameter. Four strains of *M. alpina* (IFO 8568, ATCC 16266, ATCC 32221 and ATCC 42430) were inoculated each on 25 malt agar plates and incubated at 25 C for 20 days. On the 6th, 9th, 12th, 15th and 20th day after inoculation, mycelia of IFO 8568 growing on five plates were collected with a spatula and measured for growth and lipid changes. The mycelia of the other cultures similarly were collected, dried in an evacuated desiccator and then crushed by mortar and pestle using chloroform/methanol (2:1, v/v). The lipids were extracted with chloroform/methanol (2:1, v/v), and the solvent was evaporated. The lipids obtained then were converted to methyl esters with sodium methoxide. The fatty acid composition of the esters was analyzed by gas chromatography.

For the preparative purification of arachidonate, 50 mg of methyl esters that was obtained by the esterification of the total lipids from *M. alpina* IFO 8568 was subjected to reversed-phase TLC RP-18F using methanol/acetonitrile (1:1, v/v) as a developing solvent. A band at Rf 0.41 was scraped off, and the lipids were recovered to give 35 mg of methyl arachidonate with a purity of 95.9% (the remaining 4.1% being methyl γ-linolenate).

RESULTS AND DISCUSSION

Mycelium was not observed in any of the cultures until the third day after inoculation. Mycelia collected from five plates of *M. alpina* IFO 8568 from the 6th, 9th, 12th, 15th and 20th day of incubation gave the growth results, methyl esters profiles, and the increase in arachidonic acid shown in Figure 1.

The fungus growth reached a maximum at about 12 days, as did the amounts of total methyl esters and arachidonate. However, the percentage of arachidonate in the methyl esters reached a plateau three days later. When fatty acids other than arachidonic acid were produced beyond a certain level, it appears that excess acids were metabolized to arachidonic acid.

Figure 2 shows the changes in the composition of fatty acid methyl esters obtained from IFO 8568 mycelia between six and 20 days. The sum of the six methyl ester percentages at each incubation time stayed near 92.4 ± 1.5%. Arachidonic acid increased dramatically throughout the incubation whereas palmitic, stearic, oleic, linoleic and γ-linolenic acids decreased. The content of α-linolenic

Abbreviations: DEGS, diethyleneglycol succinate; TLC, thin layer chromatography.

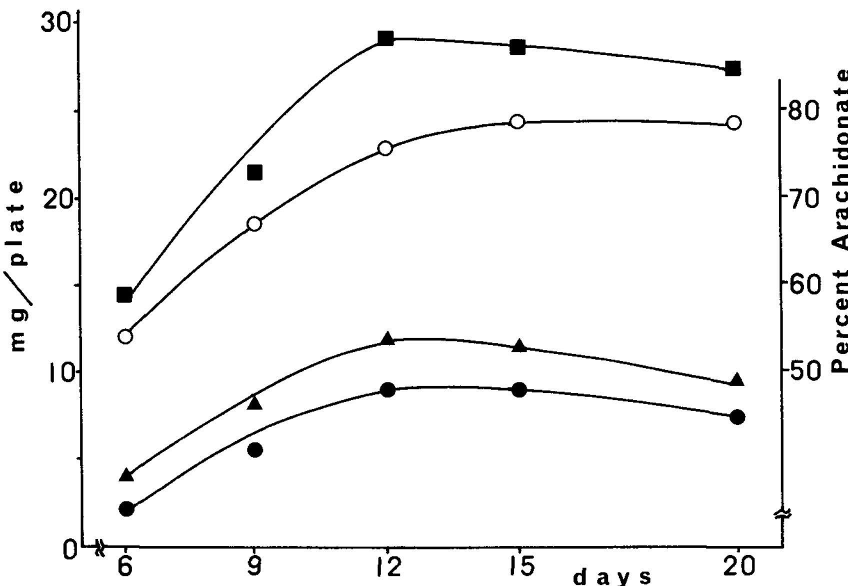

FIG. 1. Growth of *Mortierella alpina* IFO 8568 on malt agar plates at 25 C. Dry cell weight (■), weight of total methyl esters (▲), weight of methyl arachidonate (●) and content of methyl arachidonate (○).

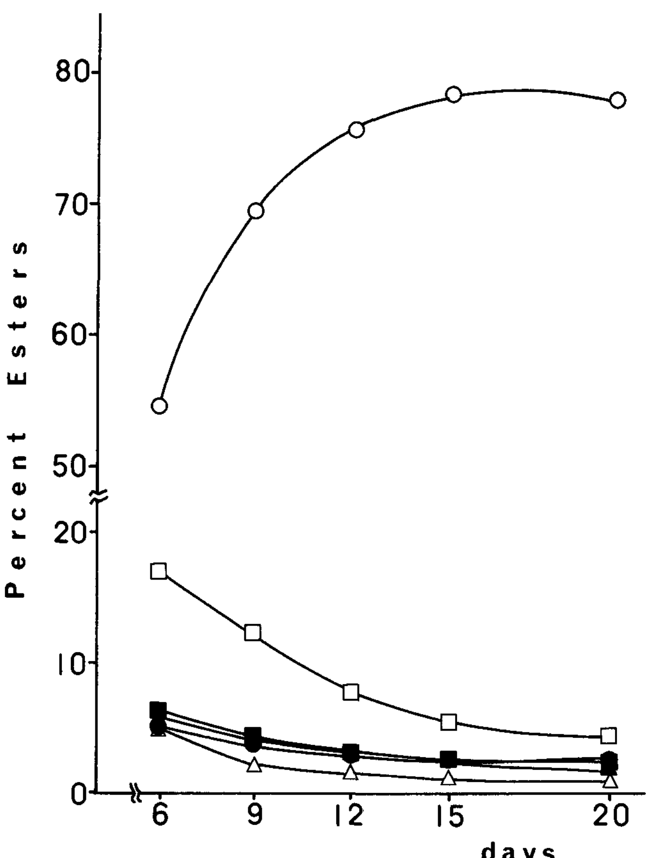

FIG. 2. Changes of methyl esters obtained from *Mortierella alpina* IFO 8568 grown on malt agar plates at 25 C. Palmitate (□), stearate (■), oleate (△), linoleate (▲), γ-linolenate (●) and arachidonate (○).

acid was less than 1%. As is shown in Figure 1, the weight of fatty acid methyl esters excluding arachidonate was constant, but the fatty acid compositions were changing markedly. This may suggest that the metabolic pathway from C16:0 → C18:0 → C18:1 → C18:2 → γ-C18:3 → C20:3(dihomo-γ-linolenic acid) → C20:4 exists also in the fungus. Dihomo-γ-linolenic acid, a precursor of arachidonic acid, amounted to only a small percentage of the total fatty acids, while the content of γ-linolenic acid was a few percent. It appears that younger cells contain higher percentages of saturated fatty acid, and older cells accumulate arachidonic acid.

Arachidonic acid content in the total fatty acids of the four strains of *Mortierella* was 68.5–78.8%, the highest value of which was 2.9 times higher than that from *E. exitialis* (3), the highest source previously known. The arachidonic acid content per dry cell weight was 22.2–26.4%, which was more than 20 times higher than the value reported by Iizuka (2) and three times higher than that reported by Ahern (5,6). The other four strains we examined gave similar values, but other *M. alpina* strains, such as ATCC 8979 and ATCC 36965, did not show exceptional arachidonic acid production when cultured on the malt agar medium.

Experiments with *M. alpina* IFO 8568 showed that similar percentages of arachidonic acid were contained in the fatty acids of neutral and polar lipid fractions, although the amount of total fatty acids from neutral lipids was about five times greater than that from polar lipids.

Methyl arachidonate was identified as all *cis* methyl eicosa-5,8,11,14-tetraenoate using the following criteria:

Elemental analysis. Found: C:79.34%, H:11.21%. Calcd: C:79.15%, H:10.77%.

Gas chromatography. Retention times of the sample on DEGS 15% (column temperature 190 C), SE-30 (column temperature 170 C) and OV-101 (column temperature 170 C) coincided with those of an authentic standard.

Gas chromatography-mass spectrometry. The mass fragmentation pattern obtained by separating the sample on DEGS 10% (column temperature 200 C) and ionizing at 70 eV corresponded closely to that of the authentic standard. The parent peak appeared at m/e 318.

^{1}H-NMR spectrometry. The ^{1}H-NMR spectrum for the sample resembled that of the standard. Taking the three methyl protons of the methyl ester group at 3.6 parts per million (ppm) as standard, there were eight protons (5.0–5.7 ppm) associated with carbon-carbon double bonds and six protons (2.6–3.3 ppm) with methylene groups between double bonds consistent with the structure of a methylene-interrupted tetraenoate. Signals derived from *trans* double bond protons were not detected.

^{13}C-NMR spectrometry. The spectra showed signals at 13.8, 22.4, 24.7, 25.5, 26.4, 27.0, 29.2, 31.4 and 33.0 ppm due to methylene carbon, at 51.2 ppm for the ester methyl carbons, and at 127.0, 127.3, 127.6, 127.9, 128.3 and 129.8 ppm for the olefinic carbons. Signals due to carbons of *trans* double bond were not detected. The spectrum was identical to that of the authentic standard.

In conclusion, we found that mycelia of *M. alpina*, which were incubated on malt agar plates at 25 C for 15 days, produced lipids, the fatty acid of which contained up to 78.8% of arachidonic acid. The arachidonic acid amounted to about 25% of the total dry cell weight. This permits easy isolation and purification of arachidonic acid.

Signals derived from *trans* double bond protons were not detected.

^{13}C-NMR spectrometry. The spectra showed signals at 13.8, 22.4, 24.7, 25.5, 26.4, 27.0, 29.2, 31.4 and 33.0 ppm due to methylene carbon, at 51.2 ppm for the ester methyl carbons, and at 127.0, 127.3, 127.6, 127.9, 128.3 and 129.8 ppm for the olefinic carbons. Signals due to carbons of *trans* double bond were not detected. The spectrum was identical to that of the authentic standard.

In conclusion, we found that mycelia of *M. alpina*, which were incubated on malt agar plates at 25 C for 15 days, produced lipids, the fatty acid of which contained up to 78.8% of arachidonic acid. The arachidonic acid amounted to about 25% of the total dry cell weight. This permits easy isolation and purification of arachidonic acid.

ACKNOWLEDGMENTS

The authors thank Toshihiro Kudo for his helpful comments, Kazuhiko Suzaki for his cooperation in NMR analysis and Toshiko Tezuka for her excellent technical assistance.

[Received November 24, 1986]

ERRATUM

In the paper "Cyclic Fatty Esters: Hydroperoxides from Autoxidation of Methyl 9-(6-Propyl-3-Cyclohexenyl)-(Z)8-Nonenoate" by R. A. Awl, E. N. Frankel, and D. Weisleder, Vol. 22, No. 10, pp. 721–730, there was an error in a figure legend.

The legend for Figure 6 should have read:

FIG. 6. Capillary gas chromatography-mass spectrometry chromatogram of hydroperoxide fraction of autoxidized cyclic ester I after hydrogenation and silylation.

FOREWORD

It is becoming a tradition that in the first week of December, clinical oncologists meet with basic researchers in Göttingen. The aim of these meetings is to continue an ongoing discussion on new aspects of tumor therapy and to stimulate interaction and cooperation. In 1985, the symposium already was devoted to ether lipids. The theme was "The Cell Membrane as Target in Tumor Therapy."[1] The organizers, C. Unger, H. Eibl and G. A. Nagel, realized that the deep interest in new antitumor drugs based on the structure of lysolecithin and its analogues should have a worldwide forum. An outcome of these discussions was the announcement of the First International Symposium on Ether Lipids in Oncology, which was held in Göttingen on December 5-7, 1986.

We were pleased that all invited speakers could attend the meeting to discuss their ideas on tumor therapy. Since Otto Westphal at the Max-Planck-Institute for Immunobiology in Freiburg was involved from the beginning in the different aspects of antitumor therapy based on the use of chemically modified lysolecithins, we were grateful that he accepted our invitation to preside over the symposium.

The organization of the congress was possible only because of the generous support by several industrial sponsors, such as the Behring-Werke, Boehringer Mannheim, Ciba Geigy, Cyanamid, Degussa Pharma, Farmitalia, Renschler, Thomae, Upjohn, and by the Bundesministerium für Arbeit und Soziales. We wish to express our gratitude for their support.

To conclude, we hope to continue this effective exchange of new ideas on the development of antitumor drugs and their clinical applications when we meet again in two or three years. We are looking forward to the Second International Symposium on Ether Lipids in Oncology in Göttingen.

Hansjörg Eibl and Clemens Unger

EDITORIAL

Ether lipids have not always enjoyed regal status. Discovered more than half a century ago, ether lipids seemed important to primitive starfish and primeval sharks. At best, they looked like relics from past millenia trying to remind us that evolution had alternatives to the fatty ester bond.

How things have changed. With the discovery of platelet activating factor (PAF), we have accepted the fact that simple derivatives of ether lysophospholipids can carry cellular messages to specific receptor sites. Through the pioneering work of Otto Westphal and his colleagues, we have learned to understand that alkyl lysophospholipids (ALP) function as immunomodulators and that they deserve recognition of their own because of their rather selective antineoplastic cytotoxicity. One of the intriguing and promising aspects of tumor chemotherapy with alkyl lysophospholipids is that, unlike essentially all other antitumor agents, ALP appear to be targeted at the cell membrane rather than the nucleus. This opens up entirely new approaches to tumor therapy.

Last December, a distinguished, albeit small, group of lipid biochemists, pharmacologists and clinicians convened in the quaint university town of Göttingen to assess the state-of-the-art in ether lipid biochemistry and to tally the successes and promises of the first clinical trials with ALP as antitumor agents. The meeting was prepared meticulously by the local organizing committee under the auspices of the German Cancer Society, the Association of Medical Oncology, the Association of Experimental Oncology and the International Union Against Cancer. By all measures, the meeting was a splendid success.

This special issue of *Lipids* contains 35 peer-reviewed contributions based on papers and posters presented at this First International Symposium on Ether Lipids in Oncology. The issue is a timely document of the current knowledge in this exciting field. We at *Lipids* are proud to be part of this.

We wish to express our appreciation to Professor Otto Westphal, president of the symposium, and to Drs. Hansjörg Eibl and Clemens Unger and the other members of the organizing committee for their commitment and support. I also wish to thank the colleagues who have coedited this issue. We are indebted to the many reviewers for their effort and advice.

Finally, I would like to express my sincere gratitude to Professor Helmut K. Mangold. He not only was instrumental in bringing about this issue but he introduced me to the field of ether lipids when I joined his laboratory as a postdoctoral fellow just 25 years ago. He never left any doubt in my mind that ether lipids deserve regal status.
