Isolated perfused rat liver was used to study the effects of constant taurocholate perfusion, with or without the addition of phosphatidylcholine unilamellar vesicles, upon both the bile salt-dependent and bile salt-independent secretion of bile. Taurocholate introduction increased bile flow and normalized the bile lipid secretion by restoring the bile salt-dependent secretion. At a flow rate of 30 ml/min, the liver was perfused by a single-pass method. The perfusion medium contained 17.5 μM taurocholate with or without 5.83 μM phosphatidylcholine. In light of a recent quantitative dynamic concept on the interphase partition of lipids, it was calculated that more than 99% of the taurocholate reaches the liver as monomers and/or dimers. It was also deduced that the lipids were secreted in bile as small discoidal lipoprotein structures rather than unilamellar lipoproteic vesicles. During the course of the experiments (2 hr), the excellent criteria of viability of this model make it highly suitable for the investigation of hepatic metabolism. Furthermore, the addition of phosphatidylcholine unilamellar vesicles to the perfusate constitutes a potential vector for various liposoluble molecular species.
***Lipids 22,* 1-5 (1987).**

Isolated perfused rat liver is a valuable model for the investigation of physiological, biochemical and pharmacological aspects of liver functions and has been widely used for this purpose by many investigators (1,2).

Under physiological conditions, the rate of bile lipid secretion is dependent on the amount of bile salts (BS) returned in the portal blood (3). Most bile salts stored in the intestinal tract reach the liver in this way (4,5), since the portal flow is 500 times higher than the intestinal lymph flow (6). Preservation of a physiological enterohepatic circulation of BS is a prerequisite for normal bile lipid secretion. Interruption of this circulation by biliary diversion induces a progressive decrease in the bile lipid secretion correlated with the disappearance of the intestinal BS pool. This disappearance is not compensated by a sufficient increase in BS synthesis in the liver. In isolated perfused liver without perfused BS, this phenomenon is rapidly and dramatically accentuated since the liver pool of BS is very small compared to the BS pool in the intact enterohepatic circulation.

The BS-independent secretion of bile is correlated with secretion of water and electrolytes (7,8). BS-dependent bile secretion is an active hepatic process indispensable for normal bile secretion of lipids (9,10), i.e., mainly phosphatidylcholine (PC) and free cholesterol. Most authors have assumed that bile lipids are mixed micelles or unilamellar vesicles (11,12). However, our results (13-15) show that bile lipids may occur as a bile lipoprotein complex (BLC), i.e., that micellar-like structures or unilamellar vesicles are associated electrostatically with IgA fragments and hydrophobically with an anionic polypeptide fraction (APF), which is different from the well-known plasma apolipoproteins (14) that are detected in trace amount in bile by radioimmunoassay (16). Bile contains small amount of plasma, and immunoelectrophoresis of concentrated bile (obtained after delipidation and lyophilization) gives a protein pattern similar to plasma (17), thus explaining the presence of apolipoproteins. Due to their own osmotic activity, BS molecularly dispersed in the aqueous polar phase actively taken up by hepatocytes in the sinusoidal pole (space of Disse) display a choleretic effect. Isolated perfused rat liver is a widely used model for the study of drug biotransformations and biliary excretion of their metabolites. Up to now, however, most of the isolated perfused liver models have taken into account only BS-independent bile secretion and neglected BS-dependent bile secretion (18-20). A recent exception to this oversight is the data of Lowe et al. (21), showing the effect of an intraportal BS bolus on the secretion of PC and free cholesterol. The purpose of the present study was to ascertain the effect of a constant BS perfusion. Under this condition, a stable biliary secretion of both the BS-dependent and BS-independent fractions was observed.

MATERIALS AND METHODS

Liver perfusion. To minimize anoxia of the liver, the portal vein was rapidly catheterized (30 sec). Krebs-Henseleit buffer (22), pH 7.3, containing 2 mM of calcium chloride, 8 mM of glucose and 2% Dextran was infused at a constant flow rate of 30 ml/min. The perfusate was maintained at 38 ± 0.5 C and continuously oxygenated with an O_2:CO_2 (95:5, v/v) mixture at a flow rate of 2 l/min. Osmolarity was monitored with the Fiske 330 D osmometer (the values found were 300 ± 5 mOsm/l). After this procedure, the bile duct was catheterized. The whole operating procedure lasted ca. 10 min. The equipment used was based on the model proposed by Brunengraber et al. (23) under nonrecirculating conditions. The liver left in situ was kept moist throughout the experiments.

Test animals were divided into three groups, one control and two experimentals. The control group (group 1) had two animals and was perfused with buffer without taurocholate (TC) and PC. The two experimental groups (five rats per group) were perfused either with buffer containing 17.5 μM of TC only (group 2) or with buffer containing 17.5 μM of TC and 5.83 μM of PC (group 3). In the experimental groups, after stabilizing the system for 15 min, ^{14}C-TC (1.28 μCi) in 20 ml of perfusion medium was also administered at a flow rate of 1 ml/min. Bile sampling was performed every 20 min in preweighed tubes. The volume of secretion was recorded in grams (bile density equal to 1 g/ml). Alanine amino transferase (ALAT) and aspartate amino transferase (ASAT) transaminase activity as well as creatinin phosphokinase (CPK) activity in the outflowing perfusate were checked every

10 min. The amount of radioactivity not bound by the liver was determined by sampling outflowing perfusate every 10 sec during ^{14}C-TC perfusion.

Chemicals. The following high grade chemicals were used: taurocholate A grade from Calbiochem Boehring Corp. (Meudon, France; purity by TLC 98%); phosphatidylcholine from Sigma (Paris, France; type III-E from frozen egg yolk in hexane, purity 99%); ^{14}C-TC in aqueous solution containing 2% ethanol from Amersham (Les Ullis, France; sp act 64 mCi/mmol); ALAT, ASAT and β-glucuronidase from Boehringer Mannheim Gmbh kit (Meylan, France); goat anti-rabbit IgG and alkaline phosphatase from Sigma; p-nitrophenol from Flow Lab. (Paris, France); NaCl, KCl, KH_2PO_4, $CaCl_2$, $MgSO_4$ and glucose from Farmiglia Carlo Erba (Paris, France); $NaHCO_3$ from Prolabo (Paris, France), and Dextran (mol wt 70,000) from Fluka (Buchs, Switzerland).

Dilution of mixed micelles in the perfusate. Mixed micelles were prepared by carefully evaporating to dryness 17.86 mg of PC in hexane solution under nitrogen and solubilizing the resulting residue in 10 ml of a micellar solution containing 37.60 mg of TC. As calculated in $mol \cdot cm^{-3}$ according to the quantitative dynamic concept on the interphase partition of lipids applied to TC-PC-water ternary system (13,24), the concentration of TC and PC, incorporated after the dilution into unilamellar vesicles, was $0.05 \cdot 10^{-4}$ $mol \cdot cm^{-3}$ and $12.73 \cdot 10^{-4}$ $mol \cdot cm^{-3}$, respectively, in the mixed bilayer interfacial lipid phase. Thus, since the PC/TC molar ratio in the vesicles averages 255, these vesicles can be considered pure PC unilamellar vesicles. On the other hand, the concentration of TC molecularly solubilized in the water polar phase is $17.48 \cdot 10^{-9}$ $mol \cdot cm^{-3}$, which is almost identical to the $17.50 \cdot 10^{-9}$ $mol \cdot cm^{-3}$ obtained with TC perfusate without PC. The advantage of adding TC-PC to the perfusate is that PC unilamellar vesicles can solubilize class 3 and 4 lipids (13,24) without appreciably affecting the concentration of TC molecularly solubilized in the water phase as monomers and dimers. The total inflow of PC through the liver (21 μmol) corresponds to ca. 8% of the total PC pool in the liver (averaging 260 μmol), while the amount of PC secreted in bile (5.1 μmol) corresponds to 2% of the PC content of the liver.

Analytical methods. PC were assayed by the semiautomatic method of Amic et al. (25), TC by the automatic enzymatic method of Domingo et al. (26), β-glucuronidase activity by the method of Fishman et al. (27) with a Sigma Kit and ALAT, ASAT, CPK activity in the perfusate by the Boehringer enzymatic method. ^{14}C-TC was assayed with a liquid scintillation spectrophotometer (Beckman LS 2800) in 5 ml of PCS (Amersham) scintillation fluid.

Detection of the anionic polypeptide fraction (APF) in rat bile. Anti-human APF specific polyclonal serum was prepared from rabbits by the procedure of Henry et al. (28). Work in progress using the ELISA method shows the presence of a common antigenic determinant in the amino acid sequence in human, rat, dog, calf and pig APF. The APF injected into the rabbits was purified using a procedure of zonal ultracentrifugation in 1–15% sucrose density gradient containing glycodesoxycholate at a concentration of 1.5 mM (15).

The principle of the ELISA assay (29,30) is the following: the wells in a polystyrene plate (LINBRO E.I.A. microtitration plate, Flow Laboratories) are coated with diluted rat bile (at a dilution of 1/200), or purified APF (0.5 to 20 μg per 100 μl according to automatic amino acid analysis) for the standard curve, in a carbonate buffer 0.1 M at pH 9.6, and then washed three times to remove the unbound components. The diluted polyclonal anti-APF serum (at a dilution of 1/200 in isotonic phosphate buffered saline, PBF) was added during 90 min at 37 C. The complex antigen-antibodies were washed three times. Bound antibodies are then detected using an anti-rabbit IgG serum (at a dilution of 1/200) conjugated to alkaline phosphatase (Sigma), and the activity was detected by the p-nitrophenylphosphate as the substrate (1 mg/ml). The enzymatic reaction was allowed to proceed for 30 min in the dark at 37 C. The absorbance was measured at 405 nm with a Multiskan Titertek MC (Flow Laboratories) against a blank.

Statistical method. Statistical significance of results was determined by the Student t-test.

RESULTS

Uptake of ^{14}C-TC by the liver is almost complete, and the radioactivity of the exiting perfusate is negligible. Its concentration in bile peaks 20 min after injection and then drops quickly during the following 60 min, regardless of whether the nonlabeled TC perfusion contains PC unilamellar vesicles (Fig. 1). The hepatic clearance of ^{14}C-TC is very high—95% (group 2, TC alone) and 98% (group 3, TC + PC vesicles). No significant difference was observed between these two groups.

Figure 2 shows the concentration of PC and BS recorded in the bile collected from the three groups. When TC with or without PC vesicles is present in the perfusate, PC and BS concentrations and BS/PC molar ratio (10.4 ± 0.3) remain within the physiological range. No significant

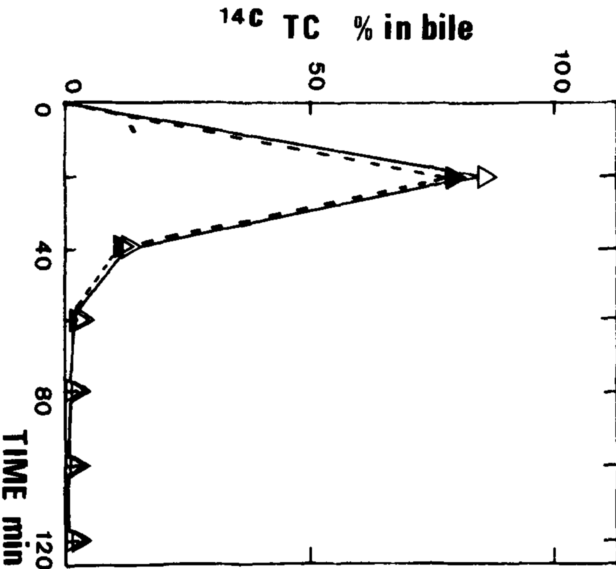

FIG. 1. Bile secretion of ^{14}C-bile salts in function of time in min from perfusion medium containing ^{14}C-taurocholate (TC) or ^{14}C-TC + PC unilamellar vesicles by isolated rat liver (see text). Each point represents the mean value ± SEM (n = 5). Group 2 (TC), △—△; group 3 (TC + PC), ▲—▲.

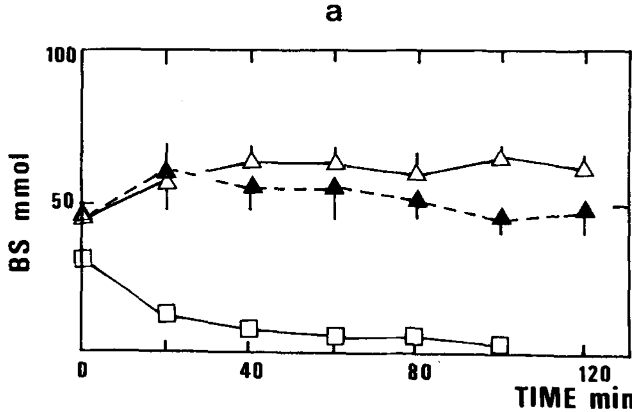

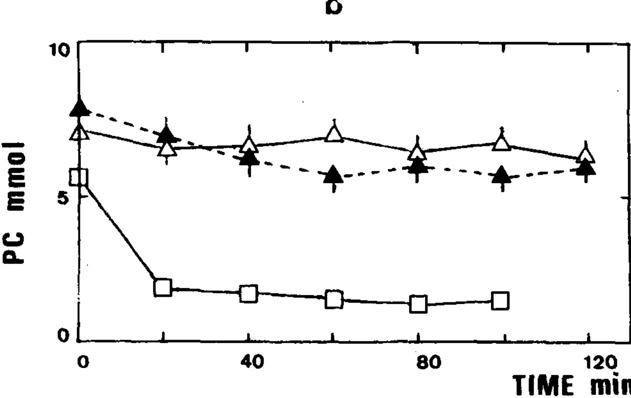

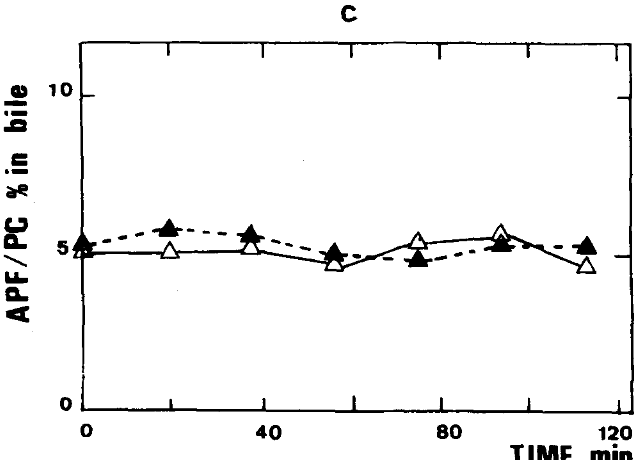

FIG. 2. Concentration of lipids in bile in function of time in min. (a) Bile salts (BS); (b) phosphatidylcholine (PC). Each point represents the mean value ± SEM (n = 5). (c) Determination of the APF/PC weight percentage (see text) in one rat of group 2 and one rat of group 3. Control, □—□; group 2 (TC), △—△; group 3 (TC + PC), ▲—▲.

difference was noted between groups 2 and 3. In group 1 (control), the concentration of PC and BS is very low, but the molar ratio PC/BS remains normal for 40 min. The APF/PC weight ratio in one rat of group 2 and one rat of group 3 (Fig. 2) remains stable (0.045–0.050).

As shown in Table 1, the bile flow from liver perfused with TC with or without PC unilamellar vesicles is 1.5 to 2 times higher than in livers perfused without TC. In experimental groups 2 and 3, bile flow remains stable throughout the 120-min test period.

TABLE 1

Biliary Flow (μl/min)

Time of collection (min)	Control (n = 2)	TC (n = 5)	TC + PC vesicles (n = 5)
0–20	5.5 ± 1.5	11.6 ± 1.68	9.8 ± 1.70
20–40	5.5 ± 1.5	10.8 ± 2.01	8.0 ± 2.37
40–60	5.0 ± 1.0	8.6 ± 2.57	9.1 ± 1.47
60–80	4.0 ± 1.0	8.4 ± 2.60	9.5 ± 1.44
80–100	4.5 ± 1.5	10.1 ± 1.37	9.2 ± 1.11
100–120	4.75 ± 1.75	10.1 ± 0.88	8.7 ± 0.91

Each value represents mean ± SEM in the three groups of rat.

TABLE 2

β-Glucuronidase Activity: Percent of Variation to Basal Value (0–20 min)

	TC	TC + PC vesicles
20–40 min (n = 3)	100	100
60–80 min (n = 3)	175.2 ± 55.0	190.8 ± 46.9
100–120 min (n = 3)	195.5 ± 35.7	145.4 ± 18.0

Although β-glucuronidase activity did double during perfusion (Table 2), it never exceeded the values previously reported in isolated perfused liver (31), but was nevertheless five times lower than physiological values in intact animals (32,33).

To check the viability of the liver, the ALAT, ASAT and CPK activities were assayed in the exiting perfusate. These activities were found to be normal in all three groups (Table 3).

DISCUSSION

The greatest advantage of our experimental model is that bile secretion is maintained at normal physiological levels. Also, perfusion with TC with or without PC unilamellar vesicles stabilized the concentration of BS and PC as well as the molar ratio BS/PC in bile (10.4 ± 0.3) during the 2-hr sampling period. The APF/PC weight ratio in bile studied in two rats remained constant, suggesting a normal formation of the bile lipoprotein complex. The absence of opalescence and the respective concentration of BS and PC in bile favor the presence of the bile lipoprotein complex as small discoidal lipoproteic structures rather than vesicles (13,20); it was previously observed (unpublished data) that, unlike human hepatic bile, the bile lipoproteic complex is present in rat bile only as the low mol wt pseudomicellar family, and not as large discoidal structures or lipoproteic vesicles (the rat is devoid of gallbladder with its concentrating activity). In control liver perfused without TC, lipid levels decreased rapidly and dramatically during the first 40 min after isolation due to an uncompensated wash-out of BS. Interestingly, the low secretion rate continued to be observed in controls; this may indicate the occurrence of

TABLE 3

Enzyme Activity in the Perfusion Medium[a]

Time of perfusion (min)	ALAT (UI/l)	ASAT (UI/l)	CPK (UI/l)
0	2.0 ± 0.46	2.75 ± 0.45	3.37 ± 0.86
10	3.12 ± 0.61	2.37 ± 0.46	1.62 ± 0.37
20	4.25 ± 0.61	2.50 ± 0.56	1.87 ± 0.44
30	5.25 ± 1.08	2.62 ± 0.98	2.37 ± 0.56
40	6.50 ± 1.75	4.37 ± 1.48	2.50 ± 0.42
50	9.37 ± 2.07	6.87 ± 2.29	3.25 ± 0.41
60	11.12 ± 2.59	9.25 ± 2.56	3.25 ± 0.41
70	13.87 ± 2.26	11.37 ± 2.77	5.50 ± 0.65
80	16.62 ± 2.54	14.12 ± 2.87	6.87 ± 1.0
90	18.25 ± 3.42	13.88 ± 3.92	6.37 ± 1.03
100	20.50 ± 2.78	18.50 ± 2.89	7.12 ± 0.95
110	23.25 ± 1.97	23.25 ± 3.25	10.12 ± 2.09
120	29.12 ± 3.05	29.50 ± 4.89	9.75 ± 1.03

[a]The activities of different enzymes have been tested from the exiting perfusate. ALAT, alanine amino transferase; ASAT, aspartate amino transferase; CPK, creatinin phosphokinase. Normal values ALAT – ASAT were 0–46 UI/l (ref. IFFA-Credo). There was no difference in the values obtained from isolated rat liver perfused with minimal perfusion medium, TC or TC + PC vesicles. Therefore, each value represents the mean ± SEM of both livers tested (n = 12).

in situ BS synthesis. The measurement of nearly normal BS/PC molar ratios in control animals perfused for 40 min after isolation would mean that BS-dependent bile secretion is sustained at a very low level and that the liver PC pool is far from exhausted. As stated in Materials and Methods, only about 2% of the total liver PC pool was eliminated by animals in groups 2 and 3 during the 2-hr study period. Thus, within a short period, bile secretion in controls became largely BS-independent. The maintenance of this type of secretion was formerly the only bile criteria for liver viability. By simulating normal enterohepatic circulation, addition of BS to the perfusate activates secretion of PC and BS in the bile. In this respect, i.e., normalization of the lipid content of secreted bile, TC perfusion with or without PC unilamellar vesicles had the same effect in our concentration conditions. Judging from the levels of ALAT, ASAT and CPK measured in the hepatic perfusate effluent, enzyme activity remains in the normal range during the 2-hr perfusion period. Unlike Krell et al. (34) and Sugano et al. (35), who reported a 50% decrease in bile flow after 40 and 70 min of perfusion, we observed a stable flow; this observation is strong evidence for the viability of our model. Given the level of the β-glucuronidase activity, the hepatic detoxification process would appear to remain intact. This finding was further supported by the measurement of normal osmolarity in exiting perfusate, which is an indication of limited cell damage. It previously has been demonstrated that a hemoglobin-free perfusate can be used without affecting the viability of the liver; Sugano et al. (35) showed that perfusion of a saline bicarbonate mixture without macromolecules at a flow rate of 3–3.5 ml/min/g of liver was adequate to preserve the fine structure of the entire liver for 70 min. To prolong viability by maintaining normal hydrostatic pressure and preventing cellular distension, the perfusate used in this study was supplemented with dextran (mol wt 70,000), which does not interfere with TC and PC.

To avoid the depletion of the perfusate and thus better duplicate the consistent quality of the portal flow, the perfusate was not recirculated. In addition to simplifying the experimental technique and avoiding artefacts due to perfusate variations, the unrecirculated mode has two main experimental advantages. First, exiting perfusate can be collected and used to investigate any number of parameters. The second benefit of not recirculating the perfusate is a great improvement in the reproducibility of results. In our experiments, clearance of TC by the liver was highly efficient since it was 98 and 95% in animals perfused with or without PC unilamellar vesicles. Assays carried out with ^{14}C-TC showed that uptake was almost immediate, since all the label was taken up within 20 sec. At the end of the experiment, no label was even detected in the liver of experimental animals of groups 2 and 3, thus indicating that clearance of TC was practically complete. A rapid transfer of TC from perfusate to bile is shown by the fact that 90% of the label of the perfused TC is secreted in the bile within 20 min. With regard to uptake, excretion and kinetics, this model behaves identically to the in vivo model using desoxycholate (unpublished data). Uptake of BS, which is practically unsaturable under physiological conditions, seems to be independent of hydroxylation and conjugation (36). The addition of TC with or without PC unilamellar vesicles to the perfusate did not affect uptake and secretion of BS. With or without PC unilamellar vesicles in our conditions, BS reach the liver as monomers and dimers; the incorporation of TC into the lipid bilayer interfacial phase of the PC unilamellar vesicles is negligible (13,24).

The model proposed presents several advantages for use in pharmacological and physiological studies. These advantages include preservation of active bile secretion, constant bile flow, normal bile lipid secretion and excellent organ viability. To furnish a vehicle for liposoluble molecular species, PC unilamellar vesicles can be added to the perfusate without altering the quality of bile secretion.

The effect of *trans* fat on the activities of liver mitochondrial and peroxisomal fatty acid oxidation enzymes was examined in various strains of rats. When Wistar and Sprague-Dawley rats were fed for 30 days diets containing either olive oil or partially hydrogenated corn oil as a source of *cis*- or *trans*-octadecenoate, respectively, the activities of various enzymes of mitochondrial and peroxisomal β-oxidation measured with *cis*- and *trans*-9-octadecenoic acid as substrates showed little dietary fat-dependent change. In Fischer 344 rats, feeding *trans* fat for 15 mo increased only moderately various enzymes of β-oxidation except for carnitine acyltransferase. The rate of mitochondrial ketogenesis and the activity of carnitine acyltransferase measured with *trans*-9-octadecenoic acid as a substrate were about half those with the *cis*-counterpart. Peroxisomes oxidized *trans*-9-octadecenoyl-CoA at a rate comparable to the *cis*-counterpart. It was concluded from this study and previous ones that the difference in the geometry of dietary fatty acid had only a marginal effect in modulating the hepatic fatty acid oxidation system, in spite of marked differences in the metabolic behavior of *cis*- and *trans* fatty acid in cell-free preparations and perfused liver.
Lipids 22, 6–10 (1987).

Hydrogenation products of edible oil usually contain varying amounts of *trans* fatty acids, most exclusively as *trans*-octadecenoate (1–3). A number of studies have unequivocally demonstrated that liver and heart mitochondria oxidize *trans* fatty acid at a rate lower than that observed with the corresponding *cis* isomer (4–8). In addition, we have recently observed that the peroxisomal β-oxidation system is also able to discriminate the geometrical difference of fatty acids (9).

There is a possibility that dietary *trans* fat and *cis* fat exert different effects on the fatty acid oxidation pathway. In some studies, dietary *trans*-octadecenoate affected the activities of mitochondrial (5,10) and peroxisomal β-oxidation (11,12). The results obtained in these studies, however, were inconclusive, since the *trans* effect was compared inappropriately among fat sources in which the difference in the fatty acid composition was not confined to the geometrism alone. In addition, little is known about the effect of *trans* fat on the activities of respective enzymes in mitochondrial and peroxisomal β-oxidation. In this context, activities of key enzymes involved in fatty acid oxidation were compared currently in various strains of rats fed either *trans* or *cis* fat. The fatty acid composition of these dietary fats was made similar except for the difference in the geometrical configuration.

MATERIALS AND METHODS

Animals and diets. In experiment 1, specific pathogen-free male Wistar (Kyudo Co., Kumamoto, Japan) or Sprague-Dawley (Seiwa Experimental Animals, Fukuoka, Japan) rats at 5 weeks of age weighing 120–150 g were housed individually in a temperature-controlled room (20–23 C) with illumination from 0800 to 2000 hr. The animals were divided into two groups of six rats each and for 30 days were fed purified diets containing either 15% olive oil or 15% partially hydrogenated corn oil supplemented with safflower oil as the source of essential fatty acid; they then were killed by decapitation. In experiment 2, the long-term effect of dietary *trans* fat was examined in male Fischer 344 rats (Shizuoka Experimental Farm, Shizuoka, Japan). The animals, 4 weeks old and weighing about 75 g, were fed purified diets containing either 10% olive oil or a 10% partially hydrogenated corn oil/safflower oil mixture for 15 mo. Fatty acid compositions of dietary fats are shown in Table 1. The two dietary fats had similar fatty acid compositions and contained octadecenoic acid as the major component, but differed in the geometrical configuration. The composition of the purified diet was the same as that described previously (13); it contained 20% casein, 1% vitamin mixture, 4% mineral mixture, 0.2% choline chloride and 2% cellulose and made up to 100 with sucrose.

Enzyme assays. The rate of ketogenesis in the heavy mitochondrial fraction of the liver was measured by the method of Ontko et al. (14,15) in which optimal concentration of Ca^{2+} (0.4 mM) was used. The liver particulate fraction containing both light and heavy mitochondria (16) was used for the measurement of palmitoylcarnitine-dependent ferricyanide reduction (mitochondrial β-oxidation) (17), cyanide-insensitive acyl-CoA–dependent NAD reduction (peroxisomal β-oxidation) (18), peroxisomal acyl-CoA oxidase (19), carnitine acyltransferase (20) and mitochondrial acyl-CoA dehydrogenase (21). Carnitine acyltransferase is primarily a mitochondrial enzyme but is located also in peroxisomes (20).

[b]Partially hydrogenated corn oil/safflower oil mixture.

Lipid analyses. Serum and liver lipids were analyzed for triglyceride, cholesterol and phospholipid as described previously (22). The fatty acid composition of mitochondrial phosphatidylcholine isolated by thin-layer chromatography (23) was determined by gas-liquid chromatography using a combination of OV-275 and DEGS columns as described previously (24).

Materials. The *cis*- and *trans*-9-octadecenoic acids, their chlorides and palmitoylchloride were purchased from Sigma Chemical Co. (St. Louis, Missouri). CoA esters of fatty acids were prepared by the method of Wieland and Rueff (25). Bovine serum albumin (fraction V, fatty acid-free) was purchased from Miles Laboratories Inc. (Elkhart, Indiana). Horseradish peroxidase and 3-hydroxybutyrate dehydrogenase came from Boehringer (Mannheim, Federal Republic of Germany). ATP, ADP, NAD and NADH were from Oriental Yeast Co. (Tokyo, Japan). Otsuka Pharmaceutical Co. (Tokushima, Japan) provided l-carnitine and palmitoylcarnitine. CoA was a gift from Kohjin Biochemicals (Tokyo, Japan).

Statistical analysis. Data were analyzed by two-way analysis of variance; differences of the pair of means were inspected at the level of $p < 0.05$ (26).

RESULTS

Effect of short-term feeding of trans *fat on fatty acid oxidation enzymes (experiment 1).* Table 2 shows activities of fatty acid oxidation enzymes in Wistar and Sprague-Dawley rats fed *cis* or *trans* fats for 30 days. No differences were found in food intake or growth of animals among the various groups (values not shown). Activities were measured with *cis*- and *trans*-9-octadecenoic acid or their CoA esters as substrates. The effect of *trans* fat on enzyme activities was rather marginal, and a moderate increase in cyanide-insensitive NAD reduction (peroxisomal β-oxidation) was the sole effect observed. No significant differences in the enzyme activities were noted between different strains of animals except for mitochondrial ketogenesis in one instance. The rates of ketone body formation from *trans* fatty acid were about half those from *cis* isomer in various situations and paralleled well the activities of carnitine acyltransferase. Mitochondrial acyl-CoA dehydrogenase, peroxisomal β-oxidation and acyl-CoA oxidase activities were approximately the same among different substrates.

Strain- or dietary fat-dependent changes were not confirmed in serum lipid levels, while dietary *trans* fat decreased the hepatic triglyceride level in Sprague-Dawley but not in Wistar rats (Table 3). Hepatic cholesterol contents in rats fed *trans* fat were lower than those in animals fed *cis* fat, and the difference was marked in Sprague-Dawley rats. Concentrations of liver phospholipid were approximately the same among various groups.

Table 4 shows fatty acid composition of mitochondrial phosphatidylcholine in rats fed *cis* and *trans* fat. Accumulation of *trans*-octadecenoic acid in rats fed *trans* fat was accompanied by a decrease in the content of saturated fatty acid (palmitic and stearic acids) rather than that of *cis*-octadecenoic acid. The amount accumulated was significantly higher in Wistar rats. Linoleic acid content increased and highly unsaturated fatty acids decreased in rats fed *trans* fat.

Effects of long term feeding of trans *fat on fatty acid oxidation enzymes (experiment 2).* Table 5 shows activities of fatty acid oxidation enzymes in Fischer 344 rats fed *cis* or *trans* fat for 15 mo. No differences were found in food intake or growth of animals fed different fats (27). In this experiment, activities of mitochondrial β-oxidation were measured spectrophotometrically using palmitoylcarnitine as the substrate; other enzyme activities were measured with palmitoyl-CoA as well as *cis*- and *trans*-9-octadecenoyl-CoA as substrates. As Table 5 shows, activities of peroxisomal β-oxidation and acyl-CoA oxidase were slightly but significantly increased in rats fed *trans*

fat, irrespective of the difference in the fatty acid substrate. Acyl-CoA dehydrogenase but not carnitine acyltransferase and mitochondrial β-oxidation also increased significantly in rats fed *trans* fat. The activity of the various enzymes examined was highest when saturated fatty acyl-CoA was used as a substrate and was uninfluenced by the geometrical difference of octadecenoyl-CoA substrates, except for a significantly low value for carnitine acyltransferase with the *trans* counterpart.

Consistent with the preceding experiments, concentrations of hepatic cholesterol, serum cholesterol and phospholipid were lower in rats fed *trans* fat than those fed *cis* fat (data have been reported elsewhere [27]). Although the fatty acid composition of hepatic organelles was not determined in this experiment, examination of the fatty acid compositions of serum lipids (27) revealed the same line of changes in rats fed *trans* fat as observed in experiment 1.

DISCUSSION

A wealth of experiments done with isolated heart or liver mitochondria has demonstrated a distinctly lower rate of oxidation of *trans*-octadecenoic acid compared to the *cis* counterpart. We have shown previously that *trans*-9-octadecenoic acid is oxidized to ketone bodies at a rate about one-half to one-third that found with the *cis* counterpart in liver mitochondria, and the response parallels well that of the activities of carnitine acyltransferase measured with *cis*- and *trans*-9-octadecenoyl-CoA as substrates (9). These results were confirmed in the present study (Tables 2 and 5). It is thus plausible that the substrate specificity of carnitine acyltransferase is responsible for the impaired rate of oxidation of the *trans* fatty acid in isolated mitochondria.

Although the rates of peroxisomal β-oxidation were approximately the same for *cis*- and *trans*-9-octadecenoic acids (Tables 2 and 5) (9,28), we recently demonstrated that the affinity of the *trans*-acyl-CoA toward acyl-CoA oxidase was considerably lower than that of the *cis* counterpart (9). Thus, the fatty acid oxidation systems not only in mitochondria but also in peroxisomes seem to oxidize the *trans* acid less efficiently.

The mitochondria have very limited ability to oxidize monosaturated fatty acids with 22-carbons, apparently due to the substrate specificity of acyl-CoA dehydrogenase. When rats were fed a diet rich in docosadienoic acid (22:1) such as in rapeseed oil and hydrogenated fish oil, however, a striking increase in the activity of peroxisomal β-oxidation occurred (11,12,28,29). This type of compensatory mechanism may not operate in the hepatic fatty acid oxidation system of rats fed *trans*-octadecenoate fat, since activities of enzymes involved in the systems were virtually uninfluenced by the geometry of dietary fats.

Several studies have examined the effect of *trans*-octadecenoic acid on the activities of the fatty acid oxidation pathway (6,10–12). However, these results are hard to evaluate as the *trans* effect was compared inappropriately, i.e., between hydrogenated fat and unhydrogenated fat from which hydrogenated products were prepared; thus the difference in the fatty acid composition was not confined to geometrism. If the effect of *trans* fat on the fatty acid oxidation enzyme is compared with the fat source with the difference of geometrical configuration as a sole variable, as in the present experiment, the results can be regarded as a reflection of the geometrical effect of dietary fat. It is possible that olive oil and corn oil contain different minor components that might cause differences in enzyme activities. In this context, the *trans* effect with regard to cholesterol metabolism was reproduced even when camellia oil, with a fatty acid composition similar to olive oil, was used as the control *cis* fat (30).

In experiments in which Wistar and Sprague-Dawley rats were fed dietary fats with different configurations, the *trans* effect, although moderate, was observed only in the peroxisomal β-oxidation on one occasion, and no other changes were confirmed in various fatty acid oxidation enzymes. In a long-term feeding study with Fischer 344 rats, *trans* fat increased the activities of various fatty acid oxidation enzymes except for carnitine acyltransferase; however, the increases were rather moderate. Thus, it could be concluded that the geometry of dietary fat has only a marginal effect in modulating hepatic fatty acid oxidation enzymes, in spite of a marked difference in the metabolic behaviors of *cis* and *trans* fatty acids in the cell-free preparations (Tables 2 and 5) (4–9) and the isolated perfused liver (9,23).

We have observed previously an elevation of triglyceride content in Sprague-Dawley rats fed high (20%) but not low (5%) dietary levels of *cis* fat (31) in relation to the corresponding levels of *trans* fat. In the present study, hepatic triglyceride accumulation was observed in Sprague-Dawley but not Wistar rats fed 15% *cis* fat (Table 3). Although the causes for the observed strain-dependent responses are not clear at present, the experiment with isolated perfused liver indicated a slight difference in the metabolic fate of *cis*-octadecenoic acid between Sprague-Dawley and Wistar rats (9). The effect of the difference in the absorbability of *cis* and *trans* fats (30) may not be disregarded.

The changes observed in the concentration of hepatic cholesterol and the fatty acid composition of mitochondrial phospholipids after feeding *trans* fat were consistent with reported data (24,30–32). Dietary *trans* fat apparently exerted its effect on the metabolism of cholesterol and polyunsaturated fatty acids without seriously influencing the activities of fatty acid oxidation enzymes.

We have compared previously the metabolic fate of *cis* and *trans* fatty acids in isolated perfused livers from Wistar and Sprague-Dawley rats, and found a marked strain-dependent difference in the fate of *trans* fatty acid (9). In addition, the fatty acid oxidation pathway had only a minor role in determining the metabolic rate of *trans* fatty acid in perfused rat liver; rather, the esterification pathway was primarily responsible in this context (9). In cases where the fatty acid oxidation pathway is not an important determinant for the metabolic fate of *trans* fatty acid, the activities of fatty acid oxidation enzymes may not necessarily respond to dietary *trans* fat, as observed in the present study.

[Received January 27, 1986]

Epicuticular Waxes of Maize as Affected by the Interaction of Mutant *gl8* with *gl3*, *gl4* and *gl15*

P. Avato*[,a], G. Bianchi[a], A. Nayak[a,1], F. Salamini[b] and E. Gentinetta[c]
[a]Dipartimento di Chimica Organica dell'Università, V.le Taramelli 10, I-27100 Pavia, Italy, [b]Max-Planck Institut für Züchtungsforschung, D-5000 Köln 30, FRD, and [c]Istituto Sperimentale per la Cerealicoltura, Sezione di Bergamo, Via Stezzano 24, I-24100 Bergamo, Italy

Chemical composition of epicuticular waxes from double mutants of maize *gl2gl8*, *gl3gl8*, *gl4gl8* and *gl15gl8* is compared to that of the wild type and of the single mutants. The wax composition was moderately affected in the double mutants studied. Meanwhile, free fatty acids became a normal class constituent of the waxes. The sites of action of the single mutants as deduced from previous studies are confirmed. The influence of *gl2*, *gl3* and *gl4* on the terminal steps of the chain elongation process in *gl2gl8*, *gl3gl8* and *gl4gl8* genotypes is presented and discussed. The study of *gl3gl8* waxes also confirms that the mutant *gl3* induces a metabolic defect definitely different from those of *gl2* and *gl4*. The pattern of alkanes from *gl15gl8* is unusual, supporting the thesis that *gl15* controls mainly alkane synthesis. However, based on variations induced on wax composition, its manner of action is difficult to account for. Taken together, the available data on single and double mutants affecting wax synthesis in maize suggest that elongases might be heteromeric enzymes.
Lipids 22, 11-16 (1987).

In *Zea mays* plants, the leaf cuticle is typically endowed with wax deposits that decrease in amount with plant aging (1,2). These waxes are synthesized by more than one elongation-decarboxylation (ED) system (reviewed in ref. 3): ED-I, active only at the seedling stage, yields long chain compounds accumulated as alcohols, aldehydes and alkanes and may be split into an early (ED-Ia) and a late (ED-Ib) group of reactions; ED-II, effective throughout the plant's life, is mainly involved in the synthesis of esters.

The biosynthesis and deposition of the epicuticular wax layer in maize is controlled by at least 13 independent genes (4). Several mutations, including *gl8*, influence the metabolic steps leading to the synthesis of or controlling the precursors entering the ED pathways (5-9). Other mutations, such as *gl2*, *gl3* and *gl4*, control the elongation steps of ED-I. In particular, *gl3* affects the step from C_{28} to C_{30}, while *gl2*, *gl4* and *gl16* affect C_{30} to C_{32} (5,6,8). *Glossy-15* has been found to be the only mutation interfering with the ED-II system, showing a metabolic block effective between C_{18} and C_{22} (8).

This paper considers the epicuticular waxes from double mutants of *gl8*, namely *gl3gl8*, *gl2gl8*, *gl4gl8* and *gl15gl8*. A major aim of our research was to evaluate the modifications induced by an abnormal supply of wax precursors on the functioning of the ED pathway in the presence of step specific elongation mutations. The data obtained have permitted us to deduce the sites of action of single *gl* mutants in more detail.

MATERIALS AND METHODS

Double mutants *gl2gl8*, *gl3gl8*, *gl4gl8* and *gl15gl8* were obtained in the background of the inbred line WF9 by crossing single mutants and reselecting by test-crossing plant homozygous for both mutations. Maize seedlings were grown in the greenhouse and collected at the stage of fifth leaf.

The epicuticular waxes were extracted by immersion for 45-60 sec in $CHCl_3$, and their composition was analyzed by thin layer chromatography (TLC) as previously described (10). Individual wax components were fractionated by column chromatography and identified by spectroscopic techniques as already reported (5,10-12). Gas chromatography (GC) analyses of the purified fractions were performed with a 15 m OV1 capillary column (0.3-0.32 mm id; 0.1:0.15 μm film thickness) on a HRGC Carlo Erba gas chromatograph with flame ionization detector, connected to a Spectra Physics SP4100 computing integrator for automatic data processing. Cold on-column injection mode was adopted. Hydrogen was used as the carrier gas; air and hydrogen streams were adjusted to yield optimum separations. Temperature was programmed from 60 to 170 C at 40 C/min, then to 280 C at 5 C/min, with 7 min of final isotherm. The detector port was maintained at 300 C. Alcohols were converted into their trimethylsilyl (TMS) ether derivatives using N,O-bis (trimethylsilyl) acetamide, while acids were analyzed as their methyl (Me) esters as described previously (10). A modified GC program was used to analyze intact esters: starting temperature was set at 90 C, increased up to 280 C at 40 C/min, then to 350 C at 5 C/min and held for 15 min. The detector temperature was 390 C.

Transmethylation of the esters was also carried out to yield their alcohol moieties and the Me esters of their fatty acid moieties (10), which were separated by preparative TLC in $CHCl_3$. Alcohols from ester-transesterification were then transformed into the corresponding TMS ether derivatives before GC analysis. Alkanes and aldehydes were analyzed without any derivatization.

RESULTS

Overall wax composition. Table 1 shows the percentages of the components and the relative yields of the waxes found on *gl2gl8*, *gl4gl8*, *gl3gl8* and *gl15gl8* seedlings compared to their parent single mutants and to the wild type. Worthy of note is the high total yield of waxes of *gl2gl8*, *gl4gl8* and *gl3gl8* (75, 83 and 57% of *Gl*, respectively) compared to their parent mutants, which contrasts with the results of a previous study on other double mutants (13). A similar overproduction of wax was found for an albino strain of maize (10). As in that case, this finding is probably due to the smaller size of the double mutant seedlings, which appeared covered by a more concentrated and thicker layer of wax. In association with *gl15*, *gl8* induced instead a decrease of the wax yield to 36% of the wild type.

[a]Two peaks, amounting to 6% of the total are present in the chromatogram with rt smaller than those of C_{29} and C_{31}.

Double mutant *gl2gl8* appeared similar to *gl8* when percentages of esters and aldehydes are considered. On the other hand, percentages of alkanes and alcohols were more consistently similar to *gl2*. The *gl4gl8* did not show remarkable differences from either single parent mutant, apart from a clear decrease of aldehydes (from 12.16% to 7%). Esters were the most abundant compounds in *gl15gl8* wax. All double mutants waxes contained certain amounts of free fatty acids (2 to 13%), which were not present in their parent mutants.

Alkanes. The composition of the alkanes is presented in Table 2. In all cases but *gl15gl8*, the homologue C_{29} predominated, varying from 39 to 53%. The C_{31} alkane, which was the major homologue (49%) in *Gl* wax and accounted for 26% in *gl8*, represented only 4% of *gl2gl8* alkanes, a value identical to that of *gl2*. Discrete amounts of the same chain length were found in *gl4gl8* (14%) and *gl3gl8* (15%). The distribution of chain lengths among *gl15gl8* alkanes was very peculiar in that odd and even homologues were present in the range from C_{26} to C_{34}, with no significant difference in their relative amounts.

Aldehydes and alcohols. Aldehydes and alcohols from *Gl*, *gl8* and *gl15* genotypes were typically characterized by the C_{32} as dominant chain length. A reduction of the C_{32} homologue compensated for by an increase in the relative importance of the C_{30} chain length, which becomes the most abundant component, was observed in *gl2* and *gl4* (Table 3; see also 5,8). No relevant difference in the chain length distributions was evident for aldehydes and alcohols from *gl15gl8* when compared to their parent mutants and the wild type. In contrast, in *gl2gl8* and *gl4gl8*, the influence of *gl2* and *gl4* predominated over that of *gl8*, as proved by the aldehyde and alcohol compositional percentages (Table 3). *Glossy-4* mutation was less effective than *gl2* in reducing C_{32} accumulation, which accounts for 30% in *gl4gl8* aldehydes and 25% in *gl4gl8* alcohols. Almost equivalent amounts of C_{30} and C_{32} homologues were found among aldehydes and alcohols from *gl3* wax. In *gl3gl8*, the C_{32} aldehyde contributed for 75% of this fraction, whereas the C_{32} alcohol represented 34%. As for the single mutant *gl3*, the alcohols from *gl3gl8* were spread over the C_{24} to C_{32} chain lengths.

Esters. Table 4 presents the composition of the alcohol and acid moieties of the esters. In *gl2gl8*, shorter esterified alcohols having 16 to 24 carbon atoms accounted for almost the same relative amounts as in *gl8*. The long chain C_{32} alcohol, which represents 100% in *Gl*, 9% in *gl8* and 1% in *gl2*, was not present in the double mutant, whereas the C_{30} homologue, dominant in *gl2*, only amounted to 4%. A different spectrum of esterified alcohols was found in *gl4gl8*: C_{30} was 32% and C_{32} 10% of the total. In this double mutant, moreover, the distribution

of C_{20}–C_{28} chains was more similar to that of *gl4*. Higher amounts of C_{30} and C_{32} esterified alcohols than in the parent mutants were found in *gl3gl8*. Moreover, both in *gl3gl8* and *gl4gl8* the distribution of ester alcohol moieties was characterized by C_{24} and C_{26} as most prominent chains. The pattern of esterified alcohols from *gl15gl8* differs from those of the parent mutants: C_{22} (18%), C_{24} (55%) and C_{26} (15%) were present in the largest amount, while the C_{20} homologue only accounted for 5%. Unexpectedly, C_{16} and C_{18} chain lengths have not been found. However, similarly to *gl15*, the C_{28} and C_{30} esterified alcohols were not components of the esters from *gl15gl8*, while C_{32} contributed 7% of the total.

The esterified acids of *gl2gl8* closely resemble those of *gl8*, with C_{16}–C_{22} accounting in total for 94% (vs 87 and 31% in *gl8* and *gl2*, respectively). A similar spectrum was found also in *gl4gl8* and *gl3gl8*. The distribution of the ester acid moieties of *gl15gl8* was peculiar in having 56% of the C_{20} homologue. As a consequence, compared to *gl8* and *gl15*, the total amount of C_{22}–C_{28} chain lengths appeared greatly reduced.

Composition of the intact esters is shown in Table 5. Slight discrepancies are observed between their chain distribution and the expected composition from a random esterification of their alcohol and acid moieties shown in Table 4.

Acids. Acids of *Gl* consisted of all the chain lengths from C_{16} to C_{32}, with high amounts of the shorter C_{16} (25%) and C_{18} (13%), followed by C_{24} (14%), C_{26} (22%) and C_{28} (12%) (Table 6). The *gl2gl8* was characterized by the predominance of the C_{16} and C_{28} chains. Acids C_{26} (12%) and C_{28} (27%) were instead the most abundant in *gl4gl8*, whereas C_{22} (38%) was the largest homologue in *gl3gl8*. Compared to the other double mutants, *gl15gl8* was characterized by large amounts of shorter homologues in the range from C_{16} to C_{24}.

DISCUSSION

The enzyme systems carrying out elongation of palmitic acid to the long fatty acyl chain (C_{20}–C_{34}) components of the epicuticular lipids are known as elongases. The elongated acyl chains can then enter different reaction pathways: (i) decarboxylation to alkanes; (ii) reduction to aldehydes and primary alcohols; (iii) release as free acids; and (iv) esterification to yield esters.

[a]Two peaks amounting to 31% of the total are present in the chromatogram with rt about equal to those of C_{27} and C_{29}.

In several plant species different elongation systems exist (14–18). For instance, two acyl-CoA elongases, of C_{18}-CoA and C_{20}-CoA, recently have been obtained from epidermal cell microsomes of *Allium porrum* L. (17,18).

In maize, the exploitation of the effects of several *glossy* mutations, inhibitors, light and age of the plant in the study of the epicuticular wax formation and deposition made clear the existence of at least two elongating complexes, called ED-I and ED-II (Figure 1; 3,5–11,19–21).

Level of substrate availability for ED-I and ED-II has been shown to be under genetic control, as evidenced by the effect of *gl8*, *gl1*, *gl7* and *gl18* mutations (6,8), which

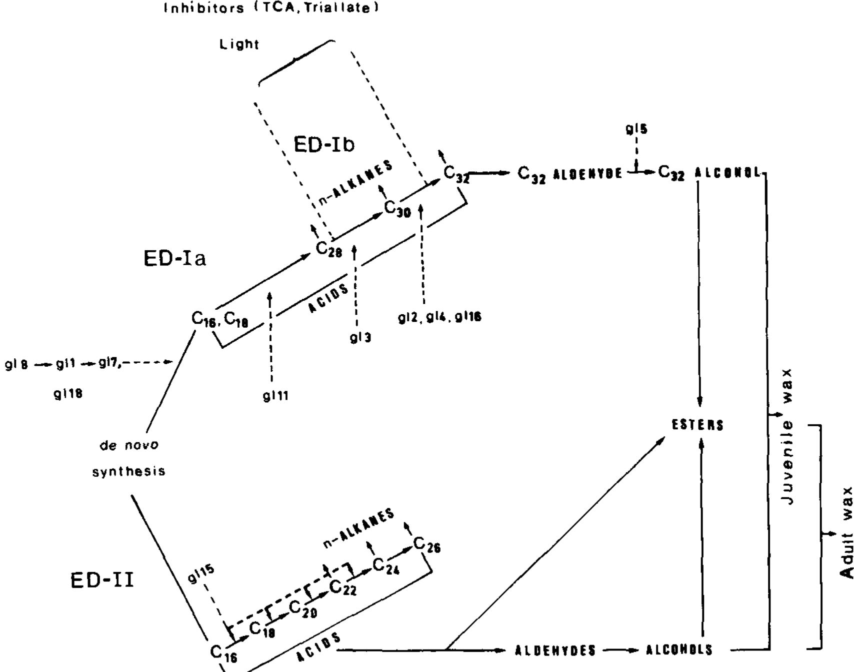

FIG. 1. Biosynthetic scheme of maize surface wax as assessed by studies on the effect of mutations, light, plant age and inhibitors on its composition (3).

resemble the *cer-p*[37] mutant of barley (22), in showing lower accumulation of wax components but unchanged chain length distributions. Results from the study of maize mutant *gl11* sustain moreover the existence of two major groups of reactions in ED-I: ED-Ia, for C_{24}-C_{28} fatty acyl chains, and ED-Ib, which further elongates these chains up to 32 carbon atoms (9).

Mutants *gl2* and *gl4* disclose defective elongation steps in ED-Ib, with a specific block at the C_{30}-C_{32} elongation step (5,8). Combination of each of them with *gl8* into double mutants is expected to produce similar modifications. Genotypes *gl2gl8* and *gl4gl8* show in fact comparable patterns in the distribution of wax classes. As a direct consequence of the metabolic blocks, an accumulation of free fatty acids is evident in the double mutants. This result discloses that in maize the release of acids from the elongating complex is possible as found in other plants (23). Evidently in the wild type waxes it is the high efficiency of maize elongating, decarboxylating, reductive and esterifying systems that prevents the accumulation of free fatty acids.

As in the single mutants, the combined synthesis of alkanes, aldehydes and alcohols deriving from the ED-I complex is much lower in the double mutants *gl2gl8* and *gl4gl8* than in the wild type. Moreover, the influence of *gl2* and *gl4* on the terminal steps of the chain elongation process is confirmed. Although mutation *gl8* differs only quantitatively from the wild type showing a good synthetic activity for the C_{32} chain length (C_{31} for the alkanes), in the two double mutants there is no evidence for any restoration of the activity for the synthesis of those chain lengths, prevailing the biochemical defect brought about by *gl2* and *gl4*. Other mutations are known in plants that affect the intermediate or final steps of the chain lengthening process (15). In maize, besides *gl2* and *gl4*, a third mutation, *gl16*, was found to control the C_{30}-C_{32} elongation step (3). The finding of those three mutants, mapping at different genetic *loci* (24), reveals a very complex biochemical regulation of wax biosynthesis and suggests that elongases might be heteromeric enzymes.

In *gl2gl8* and *gl4gl8* the ED-II system appears unaffected: esters, in fact, account for almost the same amount as in *gl8* with a very similar composition. This was expected, considering that single mutants *gl2* and *gl4* affect ED-Ib and *gl8* influences only substrate availability of wax precursors.

Mutation *gl3* controls the ED-Ib pathway at the C_{28}-C_{30} elongation step, leading to the accumulation in comparable amounts of C_{29}, C_{31} alkanes and C_{30}, C_{32} aldehydes and alcohols (6). In the double mutant *gl3gl8*, the precursor acyl chains are abnormally supplied (*gl8* effect); they, moreover, are utilized by ED-Ib at a low rate (*gl3* effect) and probably are forced to enter associate pathways or to be released from the elongase(s). In fact, as in *gl2gl8* and *gl4gl8*, combination into a double mutant of *gl8* and *gl3* results in an accumulation of free fatty acids. The homologue distribution is, however, peculiar. In *gl3gl8* free fatty acids of the shorter C_{22}, C_{24} and C_{26} chains totally account for 88%, whereas C_{28} represents 12%. The situation found in the esters further confirms the effect of *gl3* on the earliest reactions of ED-Ib. Resembling *gl3*, in fact, the esterified alcohol C_{26} accumulates in *gl3gl8* (22% vs 9% in *gl8*). No significant differences are observed in the esterified acid distribution of *gl8* and *gl3gl8*, revealing an ED-II complex normally functioning.

The biochemical regulation of the acyl chain lengthening due to *gl3 locus* must be, however, different from that of *gl2* and *gl4 loci*. Neither the single mutant *gl3* nor the double mutant *gl3gl8* evidences a very drastic block of the synthesis of the longest C_{30}, C_{32} chains associated with an accumulation of the preceding homologue, C_{28}. For instance, the amounts of the C_{30} and C_{32} esterified alcohols

in *gl3gl8* are 12% and 11%, respectively, which is much more than in the single mutants. Both of these chains are also present in discrete amounts in the free alcohol fractions, a situation resembling more closely that of *gl3*. In the aldehydes, the C_{32} homologue even accounts for 75%, whereas in *gl3* it represents 42%, suggesting that the double mutant partially restores the synthetic activity for this chain length. This observation indicates that the *gl3* metabolic defect is definitely different than those brought about by *gl2* and *gl4*.

Mutation *gl15* compared to *Gl* shows only minor modifications in wax composition. An unusual accumulation of alcohols of 16 and 18 carbon atoms incorporated into the esters is peculiar to this mutant. This was considered evidence that *gl15* affects ED-II between C_{18}–C_{22} elongation steps. Data from wax analysis of *gl15gl8* clearly indicate that neither *gl8* nor *gl15* affects the elongation processes controlled by ED-I. In the double mutant, in fact, the prevailing chains of those wax fractions have 32 carbon atoms, like the wild type and the single mutants. On the other hand, the reduced synthesis of alcohols and aldehydes induced by *gl8* in the double mutant *gl15gl8* confirms that the *gl8* mutation affects the supply of precursors entering the ED-I pathway. Moreover, in *gl15gl8*, the reduced availability of the 32 chain length for the ester synthesis, because of the low efficiency of ED-I due to *gl8*, is remarkable.

The spectrum of alkanes from *gl15gl8* is very unusual and to our knowledge unprecedented in plant waxes. Compared to the parent mutants, higher amounts of even chain alkanes are present, making up the 53% of this fraction. As a consequence, the synthesis of C_{27}, C_{29} and C_{31} alkanes, major homologues in *gl8* and *gl15*, appears reduced in the double mutant. It may be of interest to recall the data obtained from a study on the interaction between trichloroacetic acid and *gl2* that indicated the possible existence of an ED complex specific only for alkanes (19). It is evident from the data of the double mutant that *gl15* affects alkane synthesis, even if there is no obvious explanation of how the interaction of *gl8* and *gl15* should lead to the formation of even chain alkanes.

[Received May 22, 1986]

The Major Gangliosides of the Bovine Pineal Body

Margaret M. Whalen[1] and **Gaynor C. Wild***
Department of Biochemistry, University of New Mexico, School of Medicine, Albuquerque, NM 87131

Acetone powders of fresh-frozen pineals were extracted with chloroform/methanol mixtures. By column chromatography on silicic acid, mild alkaline methanolysis, ion-exchange high performance liquid chromatography and a final thin layer chromatography on silicic acid, the major glycosphingolipids were purified from the extracts of a total of 300 bovine pineal bodies. Chromatographically purified fractions were characterized by gas chromatographic analysis. The most prominent glycosphingolipid appeared to be cerebroside. In addition, five different gangliosides were found in detectable levels. The two major gangliosides have the chromatographic and component characteristics of GD_3 and GM_3, with disialoganglioside predominating. Gangliosides indistinguishable from purchased standards of GM_1 and GD_{1a} were third and fourth, respectively, in amount. The fatty acid profiles of the two lactosyl gangliosides are similar and significantly different from those of the two gangliotetraose gangliosides. The fifth most prominent ganglioside, present at a level of 1.09% of total recovered ganglioside sialic acid, appears to be a novel trisialoganglioside, called GT_x. This new molecule has a component ratio of gal:glc:sialic acid:amino sugar of approximately 1:2:3:1. Similarities between bovine pineal and rod outer segments are discussed.
Lipids 22, 17–21 (1987).

The pineal body is unique in the mammalian central nervous system in that its innervation may be synaptically homogeneous (2). These synaptic endings appear noradrenergic, but they also contain large amounts of serotonin (3). Excised pineals have a relatively large fraction of total volume as synaptic endings (3), and the bulk of the remainder is composed of the pinealocytes themselves. Pinealocytes contain a high concentration of serotonin as the precursor for melatonin, which is the major hormonal product of the pineal body (4). The presence of serotonin in the synaptic endings may be due to "leakage" from pinealocytes, with subsequent uptake into nerve terminals (3). Therefore, excised pineals are enriched in membranes that interact with two major neurotransmitters, noradrenaline (norepinephrine) and serotonin.

Glycoconjugates are localized in membranes, and there is evidence that some of them, such as gangliosides, are concentrated in synaptic membranes (5,6). There is additional evidence that some gangliosides may be evenly distributed on neuronal membranes, and that some predominate in cells other than neurons (7,8). Recently, however, a particular ganglioside has been indicated as a marker for mouse brain synapses (9). Knowledge of the gangliosides of pineal might provide important evidence for hypotheses about the many membrane-associated activities of noradrenaline and serotonin. Finding a membrane molecule in an unusually large concentration or finding unusual membrane molecules in pineals would be sufficient reason to study these molecules further for a possible functional role. With this approach in mind, we have examined the glycosphingolipids of fresh-frozen bovine pineals.

MATERIALS AND METHODS

Glycolipid extraction. Fresh-frozen bovine pineals (Pel-Freeze, Rogers, Arkansas) were treated with a total of 10 vol (vol/wt) of acetone after an initial hand grinding in a mortar and pestle in a small volume of acetone (A). The total mixture was stirred overnight at 4 C and filtered to yield pineal acetone powder. Glycolipids are extracted from the acetone powder by a modification of the method of Wolfe (10). The acetone powder was first stirred with 19 vol of chloroform/methanol (C/M; 2:1, v/v) at room temperature for 2 hr, followed by a 4-min, high-speed mechanical homogenation. The residue was rextracted with C/M (1:1, v/v) to which 5% water had been added, without the room-temperature stirring. Finally, the residue was extracted with C/M (1:2) with 5% water (v/v/v). The extracts were combined and evaporated. All solvents were analytical grade or better.

Silicic acid column chromatography. A modification of the procedure of Ishizuka et al. (11) was used. Pure silicic acid powder (Mallinckrodt SilicAR CC-7, 100–200 mesh) was heated at least 24 hr at 100–110 C, suspended in chloroform and poured into a glass column, using 1 g silicic acid per 25 mg of sample. Sample was applied as a suspension in chloroform, and the column was eluted batchwise. Each fraction consisted of seven column volumes of solvent mixtures with increasing polarity. The solvents are the following (all ratios by volume): 1, C; 2, A/C (1:3); 3, A/C (1:1); 4, A/C (3:1); 5, A; 6, M/C (1:3); 7, M/C (1:1); 8, M/C (3:1); 9, M.

Alkaline methanolysis. This treatment is used to break ester linkages (12), with only minor cleavage of amide and glycosidic bonds (13). The dried sample is solubilized by agitation (sonication or vigorous stirring) in a small volume (usually 15 ml) of 0.1 M methanolic NaOH and warmed at 37 C for 2 hr. The solution is taken nearly to dryness by rotary evaporation (to remove most of the methanol and to concentrate glycolipids into nondialyzable micelles) and dialyzed against two changes of distilled water at 4 C for 24 hr. The dialyzed sample is then dried by rotary evaporation. This procedure, used on an eluent fraction from the silica column, resulted in essentially complete removal of phospholipids, with nearly complete retention of glycolipids. The resulting mixtures were then further purified by HPLC.

High performance liquid chromatography (HPLC). HPLC was performed in an ion-exchange mode, using Waters Radial-Pak microBondapak NH_2 columns, 10 μm column packing, in the procedure of Whalen et al. (14).

The ganglioside nomenclature is according to the system of Svennerholm (1): GM_3, NeuAcα2 → 3Galβ1 → 4Glc-Cer; GM_1, Galβ1 → 3GalNAcβ1 → 4Gal(3 ← 2αNeuAc)β1 → 4Glc-Cer; GD_{1a}, NeuAcα2 → 3Galβ1 → 3GalNAcβ1 → 4Gal(3 ← 2αNeuAc)β1 → 4Glc-Cer; GD_{1b}, Galβ1 → 3GalNAcβ1 → 4Gal(3 ← 2αNeuAc8 ← 2αNeuAc)β1 → 4Glc-Cer; GT_{1b} NeuAcα2 → 3 Galβ1 → 3 GalNacβ1 → 4 Gal(3 ← 2αNeuAc8 ← 2αNeuAc)β1 → 4 Glc-Cer.

Gangliosides are eluted from the column by a gradient of 1 M aqueous NaCl into methanol. Different individual columns result in slightly different elution times for the same ganglioside, but the variation within a single column, from run to run, is less than one minute, in a 60-min procedure. Solvents were HPLC grade, purchased from MCB (Los Angeles, California).

Thin layer chromatography (TLC). The solvent most commonly used, both for qualitative and preparative TLC, was C/M/2.5 M aqueous NH_3 (60:35:8, v/v/v) (solvent A). Glycolipids were determined on qualitative plates by spraying with the phenolsulfuric reagent, positive for carbohydrate (15). Preparative plates were exposed to iodine vapor (<3 min), followed by evaporation overnight before elution. Glycolipids were eluted from scraped-off silica by C/M/water (5:5:1, v/v/v). Thin layer plates were Brinkmann aluminum-backed plates, precoated with silica gel 60, F-254. Preparative plates were the same, except 2-mm thick, on glass. Standard glycolipids were purchased from Supelco (Bellefonte, Pennsylvania).

Gas liquid chromatographic analysis (GLC). Methanolyses were performed by the procedure of Yoshida and Mega (16). The trimethylsilyl ethers of saccharides and the methyl esters of fatty acids were initially determined by gas chromatography on a 6′ packed column, containing 2.5% SE30 on 100–200 Gas Chrom Q with nitrogen carrier gas. All quantification was done on a 30-m fused quartz capillary column, coated with SE-30 (J&E, Los Angeles, California), using a flame ionization detector. A program of 110–250 C at 4 C per minute was used. Helium at a flow rate of 2 ml/min was the carrier gas. Each methanolysis of purified, extracted lipids was quantified by comparison to samples of purchased glycolipid standards, in approximately equal amounts. Each individual saccharide and the total fatty acid components were quantified by determination of a correction factor, which was calculated to take account of the entire methanolysis procedure, as well as the GLC detector response. Purchased standards of purified gangliosides, either GM_1 or GD_{1a}, were taken through the methanolysis and GLC procedures with each group of pineal preparations, in approximately the same molar amount. Although a large series of comparisons was done, for routine purposes 50 nmol of standard was used for comparison to samples of GD_3 and GM_3. Twenty-five nmol was used for comparison to samples of isolated GD_{1a} and GM_1, and 10 nmol of standard was used for the GT_x samples. Successive determinations of a correction factor with any one amount of standard typically varied less than 5% from run to run, except for the 10 nmol standards. The 10-nmol level gave variations as high as 15%. The overall correction factor for each component was determined from an average of at least three such determinations. Standards were gas chromatographed at the beginning and end of each series of experimental samples. Glucose was used as the normalizing component in the purchased gangliosides because, in our work, it gave the most complete yield. For example, sialic acid gave, from a 50 nmol sample of purchased GM_1 standard, 68% as much peak area on the gas chromatogram as did glucose. In the pure molecule, they should be present in equimolar amounts, so a correction factor of 1.46 was used for sialic acid in the samples of GD_3 and GM_3. Because the correction factors were found to vary significantly with the amount of standard used, different correction factors were determined for each significantly different amount of sample.

Carbohydrate standards were purchased from ICN (Irvine, California). Peak identifications were made by comparison to individual carbohydrate standards, carried through the same procedure. Peak quantification was by both electronic integrator and triangulation.

Colorimetric tests. Crude preparations were analyzed for hexose by the method of Radin et al. (17), in the form of galactose equivalents. Sphingosine and sialic acid (N-acetyl neuraminic acid) were measured by the procedures of Yamamoto and Rouser (18) and Jourdian et al. (19), respectively.

Purification protocol. The C/M extract of the acetone powder was first separated on a silicic acid column. The cerebroside-containing fractions, determined by qualitative TLC, were then separated on preparative thin layer plates, and the cerebroside fractions were eluted. The 50% C/M fractions (containing essentially all of the gangliosides) were subjected to mild alkaline methanolysis and separated by ion-exchange HPLC. HPLC fractions, with the exceptions of GT_x and the second peak of GD_3, were finally purified by TLC and eluted. GLC analysis was performed on the purest preparation of each molecule.

RESULTS

Fresh-frozen bovine pineals averaged 168.5 mg. Three hundred pineals yielded a total of 10.42 g of acetone powder, a loss of about 80% of total weight. The combined, dried C/M extracts of three different acetone powders represented 2.4 ± 0.3% of the fresh tissue weight, or 12 ± 1.5% of the weight of the acetone powders.

Neutral glycosphingolipids. The C/M extract is highly enriched in glycolipids, and especially in sphingolipids, although some phospholipids remain. The fractions that are eluted from the silica column in A/C (1:1) and A/C (3:1) contain relatively nonpolar lipids, the major one of which then chromatographed in thin layer solvent A indistinguishably from purchased standards of cerebroside. It gave two carbohydrate-positive spots, R_f 0.70 and 0.78, when commercial cerebroside on the same plate gave spots at 0.69 and 0.77. All of the 0.78 R_f material was eluted from the silica column by A/C 1:1. The 0.70 R_f material was spread between both fractions. Methanolysis and GLC analysis of material from both bands yielded only galactose, fatty acids and peaks with the relative retention times of sphingosine derivatives. These were not sufficiently reproducible to quantify. The ratio of galactose to total fatty acid was 1.01 for the combined, eluted material from the two bands. The fatty acids of the more polar band could only be quantified after trimethylsilylation, which may be because of the presence of 2-hydroxy fatty acids. The combined bands, identified as galactocerebroside, are present in a quantity of 1.45 μmol/g fresh tissue. This represents 30.2% of the total lipid-bound hexose in the C/M extract. This level is about one-third of the usual quantity for cerebroside in mammalian central nervous system gray matter, and about 3% of that for white matter. While this figure for cerebroside content must be regarded as an approximate minimum, it has previously been reported that cerebroside was not present in bovine pineal (20). We would anticipate that procedural losses were greater for cerebrosides than for

gangliosides, as significant amounts of neutral lipid might be expected to dissolve in the original acetone extraction. Losses of standards during silicic acid chromatography average less than 15%.

The major gangliosides. All of the sialic acid-containing material in the extract was eluted from the silicic acid column by C/M, 1:1. This fraction was further purified, after mild alkaline methanolysis and dialysis, by ion-exchange HPLC (14). Because of overlap between gangliosides with a similar number of sialic acid residues, especially among monosialogangliosides, early peaks from the chromatogram were further purified by TLC. Each band, eluted from TLC plates after chromatography in solvent A, was methanolyzed, and the resulting methyl glycosides and fatty acid methyl esters were identified and quantified by GLC, as described in Methods. Table 1 shows the component ratios, as determined by methanolysis and GLC, of the major gangliosides of pineal. The ratios were determined with the use of correction factors in the manner described in Methods. The names given to each are partially based on these data. Table 2 shows the TLC R_f in solvent A, the position(s) of elution in HPLC and the relative amounts in fresh pineal of each of the five detectable gangliosides, compared to the behavior of purchased standards in the same systems. Peaks eluting from HPLC prior to 0.35 M NaCl require further purification on TLC, as there is significant overlap. The early part of the elution is also the portion of the chromatogram in which those contaminants destroyed by alkaline methanolysis appear. The portion of the chromatogram eluting after 0.35 M NaCl, containing the second peak of GD_3 and all of GT_x, appears to provide purified gangliosides directly, even without the alkaline treatment. GD_3 has been observed to separate into two different peaks in other chromatographic systems (8), possibly due to variation in its hydrophobic moiety.

These ganglioside identifications are based on the chromatographic characteristics and gas chromatographically determined component ratios of each extracted molecule. More definitive identification will have to await precise physical analysis, by techniques such as fast atom bombardment mass spectroscopy.

GD_3 and GM_3 combined accounted for 82.8% of the total ganglioside of the tissue, with GD_3 alone present

TABLE 1

Component Ratios of the Five Major Gangliosides of Bovine Pineal[a]

Ganglioside[b]	N-Acetyl neuraminic acid	N-acetyl galactosamine	Galactose	Glucose	Total fatty acid
GD_3	2.01 ± 0.16	<0.01	1.02 ± 0.13	1.0	0.92 ± 0.19
GM_3	0.97 ± 0.06	<0.01	0.94 ± 0.05	1.0	0.77 ± 0.10
GD_{1a}	1.80 ± 0.004	0.88 ± 0.09	1.82 ± 0.03	1.0	0.76 ± 0.12
GM_1	1.08 ± 0.19	0.64 ± 0.08	1.85 ± 0.06	1.0	1.07 ± 0.45
GT_x	2.99 ± 0.33	0.72 ± 0.49	1.05 ± 0.01	2.0	N.D.

[a]Determined as described in Methods. Normalized to glucose. N.D., not determined. Each number is the average of at least three separate determinations.

TABLE 2

Comparative Chromatographic Characteristics of the Major Gangliosides of Bovine Pineal

Pineal ganglioside[a]	Standard ganglioside	R_f in solvent A[b]	M NaCl for peak(s) elution[b]	Amount (nmol/g fresh tissue)
GM_3		0.39	0.095 ± 0.019 0.154 ± 0.025	100
GM_1		0.19	0.095 ± 0.019 0.154 ± 0.025	40
	GM_1	0.18	0.108 ± 0.004	
GD_3		0.21	0.271 ± 0.033 0.382 ± 0.016	300
GD_{1a}		0.13	0.276 ± 0.026	40
	GD_{1a}	0.12	0.268 ± 0.027	
	GD_{1b}	0.05	0.386 ± 0.002	
GT_x		N.D.	0.462 ± 0.005	3
	GT_{1b}	0.05	0.536 ± 0.01	

[a]Tentative assignments—see text.

[b]Average of at least three separate runs.

Extracted and standard gangliosides on same TLC plate. N.D., not determined.

in pineal at 4.4 times the concentration found in normal gray matter (21). GM_1 and GD_{1a}, the major gangliosides of whole brain, are present only at about 1/8 of their whole brain level (21). The fatty acid profiles of the two lactosyl gangliosides were similar to each other and different from those of the gangliotetraose molecules GD_{1a} and GM_1. Table 3 gives the average values for all those fatty acid methyl esters present in >1% of the total. The pineal lactosyl gangliosides are characterized by significantly less stearate and significantly more long chain saturated fatty acids (C20, C22 and C24) than are usually found in brain gangliosides (22). This suggests the possibility of a metabolic relationship between the two lactosyl gangliosides, but no data about their metabolism in pineal are available.

GT_x. The ganglioside in fifth largest quantity in bovine pineal, designated GT_x in the tables, was reproducibly isolated from the freshly prepared acetone powder, but only in amounts of 0.62% of the total ganglioside. The carbohydrate composition was reproducible from three separate isolations and purifications, but a large enough quantity of material for total characterization will have to await a significantly larger extraction. On the basis of its chromatographic behavior, solvent extraction characteristics and carbohydrate content, it is reasonable to conclude that the molecule is a novel trisialoganglioside, having a glucose/galactose ratio of 2:1, in addition to the three sialic acid residues and a single amino sugar. It elutes from ion-exchange HPLC earlier than a GT_{1b} standard, but later than any standard disialoganglioside.

The sum of the five detectable gangliosides comes to 0.48 μmol/g fresh tissue. This represents about 1/4 (24.2%) of the level of total gangliosides of mammalian gray matter and about 60% of that of mammalian white matter (21). In our work, measurements of total sphingosine (18) and total sialic acid (19) in the crude C/M extract consistently gave figures less than that of the combined, isolated glycosphingolipids. The combined total anthrone-positive hexose of the isolated gangliosides represents about 27% of the total hexose in the C/M extract. Therefore, all five gangliosides combined with both cerebrosides represent a 57 ± 6% recovery of total measurable hexose from the C/M extract. Losses during chromatography undoubtedly account for a portion of the remainder. In addition, bovine pineals have a small quantity of non-sphingosine-containing glycolipids (23). However, the combined yield of lipid-bound sialic acid reported here (0.829 μmol/g fresh tissue) is more than fourfold higher than that previously reported (24) for bovine pineals, and both the pattern and yield are reproducible.

TABLE 3

Fatty Acid Profiles of Four Major Gangliosides of Bovine Pineal, in Mole %[a]

Fatty acid	Lactosyl gangliosides	Gangliotetraose gangliosides
16:0	3.5 ± 4.9	2.5 ± 3.5
16:1	2.5 ± 0.71	7.0 ± 0.001
18:0	56.5 ± 7.78	82.0 ± 2.83
18:1		8.5 ± 0.71
20:0	18.0 ± 2.83	
22:0	13.0 ± 2.83	
24:0	6.5 ± 2.12	

[a]Only those found in as much as 1% of the total.

DISCUSSION

GD_3 has previously been shown, in the rat's central nervous system, to be most highly concentrated in the locus coeruleus (25). The locus coeruleus has the largest number of noradrenaline-containing neurons in the brain, and it also contains many noradrenergic receptors, in feedback collateral synapses (26). In vitro studies have, in the past, led some investigators to hypothesize that GD_3 was specifically involved in the action of neurotransmitters (27,28). While our data combined with the above evidence might indicate a possible correlation between GD_3 and noradrenaline, other data indicate that that may not be the case. GD_3 is also the predominant ganglioside in whole retina (29) and in rod outer segments (ROS) (30). ROS presumably contain no synapses or transmitters at all, and noradrenaline is not a significant presence in retina. In addition, many investigators have found GD_3 to be the predominant ganglioside in some tumor cells (31) and in some embryonic nervous tissue (32). These observations have prompted the hypothesis that a high concentration of GD_3 is characteristic of undifferentiated cells. Further, Seyfried and Yu (8) have shown that GD_3 is the major ganglioside of some glia. Pineal bodies contain glia, noradrenergic synapses and intracellular membrane structures somewhat similar in appearance to rod discs (33). The GD_3 present in pineal could be associated with any one or more of these structures. Without specific localization studies, the question of anatomical location of GD_3 in pineal cannot be answered. It is clear that GD_3 is present in diverse locations and may have diverse functions.

Dreyfus et al. (34) demonstrated that neuraminidase is active in ROS, with greatest activity expressed on GD_3. GM_3, the product of the removal of a single sialic acid from GD_3, was also a good substrate. This evidence places these two gangliosides in a separate metabolic pool from the other known gangliosides of ROS, for most of the others give the same product (GM_1) from neuraminidase activity, and are not catabolized to non-gangliosides in situ. The fact that GD_3 and GM_3 share a similar fatty acid profile in pineals, which is different from that of the other gangliosides, may also reflect their being in a separate metabolic pool and may represent a further similarity between the two tissues. The evidence from both tissues for a precursor-product relationship between gangliosides is in contrast to the usual situation in neurons, where a complete pattern of gangliosides is synthesized, and later catabolized, in the cell body. There is usually no metabolic relationship among gangliosides in their functional membrane locations (7).

Pineal and retina have similarities other than ganglioside content and metabolism. Both tissues are light responsive, although the response is indirect for the pineal (4). Both tissues are high in cGMP (35), and they both synthesize melatonin, the pineal hormone (36). In any case, clarification of the anatomical localization of GD_3 and GM_3 in pineal will be a meaningful advance in pineal physiology.

Of the glycosphingolipids of pineal, that which appears to be most characteristic of the tissue, based on these studies, is GT_x. While the data we have presented about

it are incomplete for the hydrophobic moiety, its chromatographic behavior and carbohydrate content would indicate that it is a trisialoganglioside. The content of glucose is twice that of galactose, which is unusual for mammalian gangliosides, but has been previously reported for embryonic chicken brain (37). A more complete determination of the detailed structure of GT_x would be interesting. If GT_x is in fact characteristic of pineal, its localization in the tissue would also be significant and possibly instructive about function.

It is reasonable to expect at least one of the pineal gangliosides to be concentrated in, and associated with, the noradrenergic synapses which innervate it. GD_3 and GM_3 appear to be either associated with glial cells (8) or localized intracellularly (30) in other studies. GM_1 and GD_{1a} may be associated with synapses, but their prominence in whole brain would imply that they are not specifically associated with noradrenaline. Therefore, GT_x may be the most likely to have a specific association with pineal synapses. The clarification of this interesting possibility will have to await future histological studies of its localization.

[Received June 9, 1986]

Onset and Persistence of Changes in Intestinal Transport Following Dietary Fat Manipulation

A.B.R. Thomson, M. Keelan and M.T. Clandinin*
Department of Medicine, University of Alberta, Edmonton, Canada

In this study we determined the time-course for the onset and the loss of the effect of short-term feeding rats isocaloric semisynthetic diets containing a high content of saturated (HS) or polyunsaturated (HP) fatty acids on the jejunal and ileal uptake of medium- and long chain fatty acids, cholesterol and glucose. Animals were fed HP or HS for 3, 7 or 14 days; then the diet was switched to standard Purina® rat chow for a further 3, 7 or 14 days. The uptake of medium chain fatty acids was unchanged. The differences between HP and HS in glucose uptake occurred within 3 days, but persisted for 14 days, whereas there were qualitative as well as quantitative changes in the pattern of lipid uptake: differences in uptake of stearic, oleic, linoleic and linolenic acids and cholesterol occurred after 7 days of feeding HP or HS. Jejunal uptake of linoleic acid was greater in HP than HS on day 7, but HS was greater than HP on day 14. The effect of diet on lipid uptake was similar in the jejunum and ileum. The altered uptake of stearic and oleic acids persisted after the rats were switched back to chow, whereas the uptake of the other nutrients became similar. Thus, (i) changes in dietary content of saturated and polyunsaturated fatty acids have early effects on intestinal transport function; (ii) some of these changes persist even when animals are returned to feeding on chow; and (iii) glucose transport is rapidly altered by dietary changes, whereas lipid uptake changes only after 7 days. We conclude that the transport function of the intestine is responsive to changes in dietary fatty acids.
Lipids 22, 22–27 (1987).

The passive permeability properties of intestine are altered in response to manipulations in the dietary content of cholesterol, fatty acid, carbohydrate, protein and essential fatty acids (1–4). Manipulation of dietary lipid composition also influences the jejunal adaptive response following ileal resection in rabbits (5). Feeding rats a semisynthetic isocaloric diet containing a high or a low ratio of saturated-to-polyunsaturated fatty acids alters jejunal active transport of glucose and leucine as well as passive uptake of fatty acids, cholesterol and bile acids (6). Dietary alteration in the amount of the macronutrients alters jejunal morphology as well as jejunal brush border membrane lipid composition in control and diabetic rats (7). Substitution of polyunsaturated fatty acids for saturated fatty acids has no significant effect on brush border membrane content of cholesterol or phospholipids (6). On the other hand, Brasitus and coworkers (8) reported that modification in the saturation of dietary fatty acids is associated with changes in the fatty acyl content of intestinal membrane phospholipids; we have reported similar findings of changes in brush border membrane phospholipid fatty acids after two weeks' feeding with the diets used in this study (9). The present study extends these observations by indicating the rapid onset of these transport changes and their persistence when the diets are stopped.

METHODS

Animals and diets. Female Wistar rats (40–56 days old), 220–250 g, were used. Principles for the care and use of laboratory animals approved by the Canadian Federation of Biological Societies and the Council of the American Physiological Society were observed. Animals were allowed access to water and food ad libitum until the morning of the study. They were fed one of three diets for 3, 7 or 14 days: standard Purina® rat chow or a semipurified diet with 20% (w/w) fat of either a high or low polyunsaturated-to-saturated fatty acid (P/S) ratio (6). The semipurified diets were nutritionally adequate, providing all known essential nutritional requirements. The diet high in polyunsaturated fatty acids (HP) provided ca. 22% of calories and 55% of total fatty acids (% w/w) as 18:2ω6 (linoleic acid), whereas the diet high in saturated fatty acids (HS) provided ca. 2.2% of calories and 5% of total fatty acids as 18:2ω6. The percentages of the total fatty acids were approximately as follows: for 16:0, chow 16%, HP 10% and HS 21%; for 18:0, chow 5%, HP 2% and HS 34%; for 18:1, chow 24%, HP 22% and HS 32%; for 18:2, chow 41%, HP 55% and HS 5%; and for 18:3, chow 4%, HP 5% and HS 1%. Other groups of rats fed either the HP or the HS fatty acid diet for two weeks were then switched back to chow for 3, 7 or 14 days.

Animals were weighed at the beginning of the study and about twice weekly thereafter. Intestinal weights were determined at the time of the absorption studies.

Probe and marker compounds. [^{3}H]Inulin (mol wt ∿5,000) as supplied by the manufacturer (New England Nuclear Corp., Boston, Massachusetts) was used in each experiment. [^{14}C]Labeled probes included hexanoic acid (6:0), octanoic acid (8:0), decanoic acid (10:0), lauric acid (12:0), stearic acid (18:0), oleic acid (18:1), linoleic acid (18:2), linolenic acid (18:3), cholesterol and D-glucose. Unlabeled and [^{14}C]labeled probes were supplied by Sigma Co. (St. Louis, Missouri) and by New England Nuclear, respectively. Probes were shown to be more than 99% pure by high performance liquid chromatography.

Tissue preparation. Animals were anesthetized by intraperitoneal injection of sodium thiopentol. A 15-cm length of proximal jejunum or distal ileum was rapidly removed and gently rinsed with 50 ml of cold saline, as described in detail elsewhere (10,11). The intestine was opened along its mesenteric border and the mucosal surface was carefully washed with cold saline to remove visible mucus and debris. Pieces of intestine were cut from the segment, mounted as flat discs in the incubation chambers and placed in preincubation beakers. Preincubation beakers contained oxygenated Krebs-bicarbonate buffer (pH 7.4) at 37 C. Tissue discs were preincubated for 10 min to allow for equilibration at this temperature.

The transport chambers were then transferred to other incubation beakers for specific experiments. Preincubation and incubation solutions were mixed at identical stirring rates with circular magnetic bars, and the stirring rates were precisely adjusted by means of a strobe light. Stirring rates were reported as revolutions/min (rpm) at which the stirring bar was driven. The stirring rate of 600 rpm was selected to achieve low effective resistance of the intestinal unstirred water layer (11).

Determination of uptake rates. After preincubation, chambers were transferred to other beakers containing [^{3}H]inulin and various [^{14}C]probe molecules in oxygenated Krebs-bicarbonate buffer. After incubation of intestinal discs in labeled solutions for 6 min, each experiment was terminated by removing the chamber and quickly rinsing the tissue in cold saline for ca. 5 sec. The exposed mucosal tissue was then cut out of the chamber with a circular steel punch and gently blotted on filter paper. Tissue was dried overnight in an oven at 75 C. The dry weight of this tissue was determined, samples were saponified with 0.75 N NaOH, scintillation fluid was added and radioactivity was determined by means of an external standardization technique to correct for variable quenching of the two isotopes (11).

Individual experiments. Micellar solutions of the long chain fatty acids (18:0, 18:1, 18:2 and 18:3) and cholesterol were prepared (12) by solubilizing these lipids in 20 mM taurodeoxycholic acid (TDC). The concentrations of solutes were: cholesterol, 0.05 mM in 20 mM TDC; stearic acid, 0.1 mM; and long chain unsaturated fatty acids (18:1, 18:2 and 18:3), 1.0 mM in 20 mM TDC. Glucose-containing solutions (1 mM and 40 mM) were prepared in Krebs-bicarbonate buffer without TDC. These concentrations of glucose were selected to represent values at (1 mM) and above (40 mM) the Michaelis constant for D-glucose uptake into rat jejunum (13). A change in uptake of 1 mM glucose would be achieved by alteration in the value of the apparent Michaelis constant, whereas a change in uptake of 40 mM glucose would be achieved by alteration in the value for maximal transport rate and/or passive permeability coefficient (14).

Dietary changes. One group of animals was fed Purina® rat chow throughout the study, one group was fed the semisynthetic high polyunsaturated fatty acid diet (P) for 3, 7 or 14 days, and one group was fed the high saturated fatty acid diet (S) for 3, 7 or 14 days. A subgroup of animals was fed S or P for 14 days and was then switched back to Purina® rat chow for a further 3, 7 or 14 days.

Morphology. Morphometric measurements were completed on 1-cm sections of jejunum and ileum fixed in Bouin's solution, dehydrated, embedded in paraffin wax, sectioned for light microscopy and stained with H & E using standard techniques. The mucosal surface area was determined as reported previously (7,15,16).

Expression of results. The rate of uptake of solutes was calculated after correcting the total tissue [^{14}C]radioactivity for the mass of the solute molecule present in adherent mucosal fluid. Uptake rates were expressed as nmol of the solute molecule taken up into the mucosa per 100 mg dry weight of tissue/min (nmol/100 mg/min). Values obtained from different dietary groups are reported as the mean ± SEM of results observed for a minimum of six animals in each group.

The student's t-test was used to test the significance of the difference between the means of animals fed HP vs HS. Analysis of variance (ANOVA) demonstrated that there were no significant differences in means among 3,7 and 14 days off HP or HS, and therefore the values for 3, 7 or 14 days off a given diet were combined to provide one mean for HP-off and one mean for HS-off.

RESULTS

Animal characteristics. Body weight gain on days 3, 14, 21 and 28 was similar for animals fed the high polyunsaturated (HP) or high saturated (HS) diet or chow (Fig. 1A). In jejunum and ileum of P, the weight of the tissue declined between days 3 and 7, but remained constant from day 7 to 28. For S, the weight of the ileal tissue remained constant, whereas the weight of the jejunum fluctuated. The jejunal mucosal surface area (MSA) of animals fed HP increased above control or HS values on day 3, but at all other times on or off HP or HS, there was no diet-associated effect on jejunal or ileal mucosal surface area (Fig. 2).

Uptake of glucose. Feeding HP or HS had no effect on the jejunal or ileal uptake of 1 mM glucose, except for greater uptake in HP than HS after 3 days (Fig. 3).

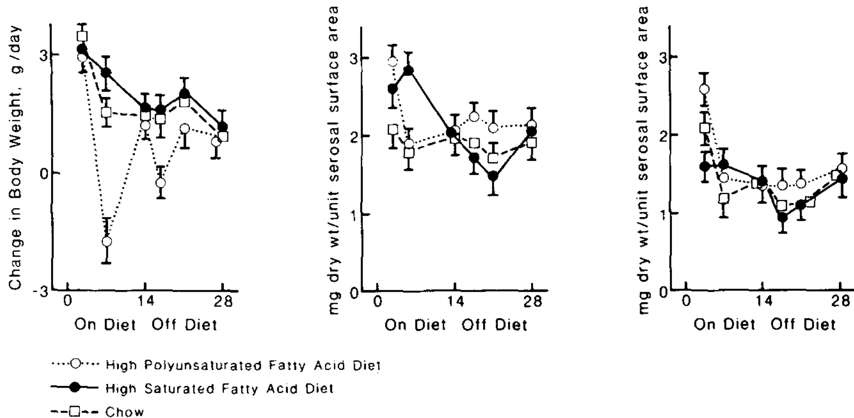

FIG. 1. Characteristics of rats while on or off the high polyunsaturated or high saturated fatty acid diets. (A) Body weight; (B) jejunal weight; (C) ileal weight. Mean ± SEM of the results of 6–9 animals.

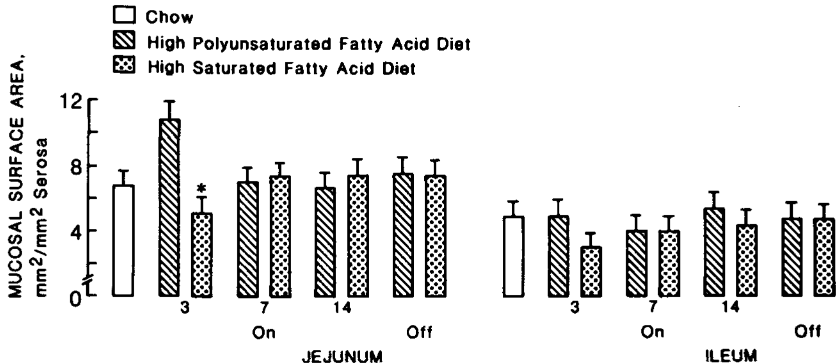

FIG. 2. Effect of feeding the high polyunsaturated or high saturated fatty acid diets on the jejunal and ileal mucosal surface area. Mean ± SEM of the results of 6–9 animals. An asterisk indicates a significant difference between the animals fed the high polyunsaturated fatty acid diet vs chow or the high saturated fatty acid diet and chow.

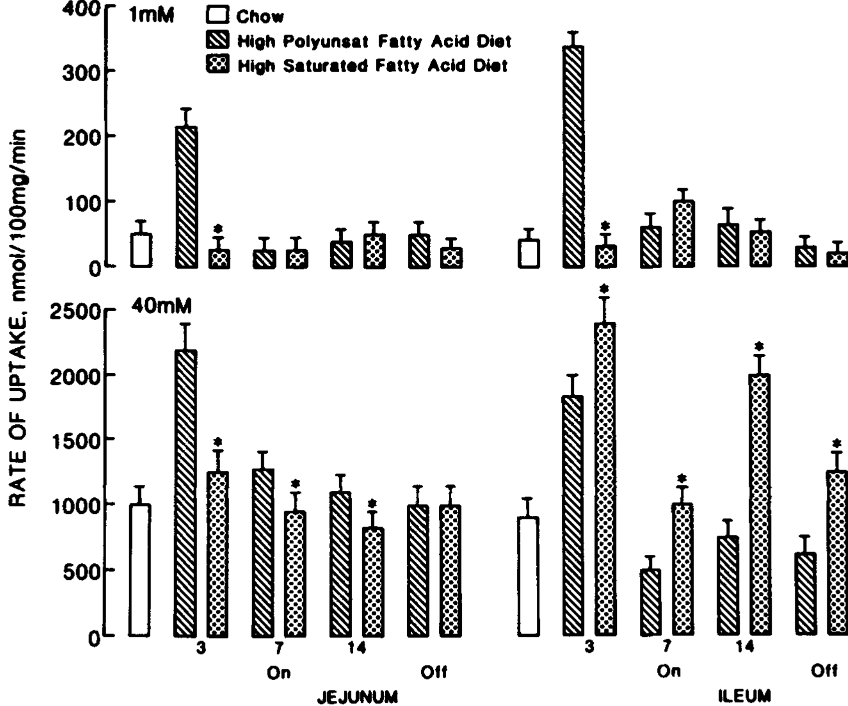

FIG. 3. Effect of feeding the high polyunsaturated or high saturated fatty acid diets on the jejunal and ileal uptake of 1 mM and 40 mM glucose. Mean ± SEM of the results of 6–9 animals. An asterisk indicates a significant difference between the animals fed the high polyunsaturated fatty acid diet vs chow or the high saturated fatty acid diet and chow.

Jejunal uptake of 40 mM glucose was also greater in HP than HS on day 3, 7 or 14, whereas in the ileum uptake was greater in HS than HP, and this difference persisted when the rats were switched back to chow.

Lipids. The uptake of hexanoic, octanoic and decanoic acids was similar at all times in HP and HS, whereas jejunal and ileal uptake of lauric acid was greater in HP than in HS at days 3 and 7 (not shown). The jejunal uptake of stearic acid was greater in HP than HS at day 7, but lower in HP than HS at day 14 (Fig. 4); in the ileum uptake was greater for HP than HS at both days 7 and 14. The jejunal uptake of oleic acid was similar in HP and HS, although ileal uptake was greater for HP than HS at days 3 and 7. Linoleic acid uptake into the jejunum was higher in HP than HS at day 3; no differences were noted with larger periods of feeding. Finally, cholesterol uptake was greater in HS than in HP only at day 14. When the animals were switched from HP or HS to chow,

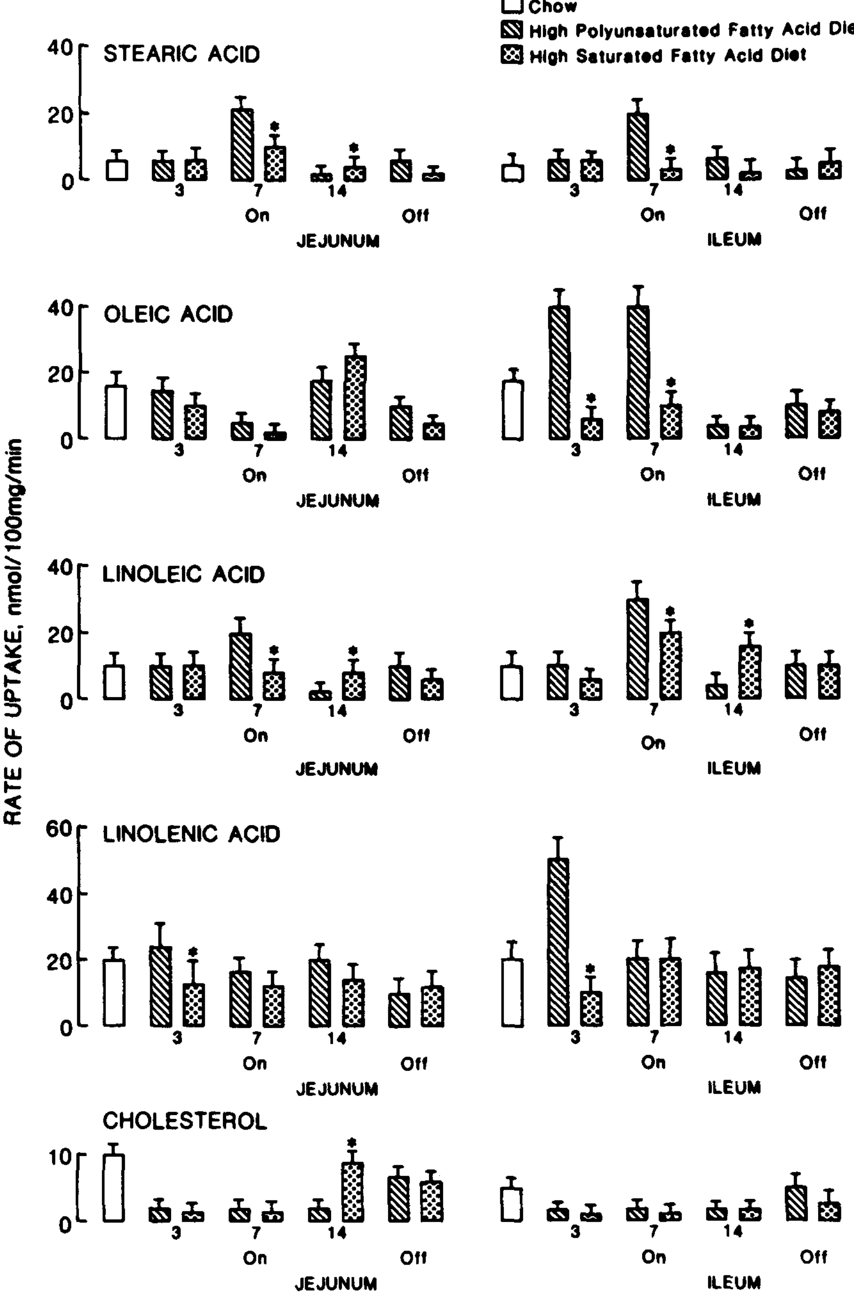

FIG. 4. Effect of feeding the high polyunsaturated or high saturated fatty acid diets on the jejunal and ileal uptake of fatty acids and cholesterol. Mean ± SEM of the results of 6–9 animals. An asterisk indicates a significant difference between the animals fed the high polyunsaturated fatty acid diet vs chow or the high saturated fatty acid diet and chow.

uptake of cholesterol, linolenic and linoleic acids became similar, but uptake of oleic and stearic acid remained lower in animals previously fed HS than HP.

DISCUSSION

An enhanced awareness of the importance of the effect of dietary manipulation on intestinal transport function (17) arose from studies of intestinal adaptation following intestinal resection (5,18). Starvation or semistarvation alters intestinal transport function (19), but the specific nutrient composition of the diet is also important in modulating the form and function of the intestine (1–4). Changes in intestinal uptake of lipids occur under a variety of experimental conditions, such as aging, diabetes, ileal resection, chronic ethanol exposure, and following abdominal irradiation (20). These changes cannot be fully explained by alterations in the effective resistance of the unstirred water layer (21), but may be associated with changes in the "fluidity" of the intestinal brush border

membrane (7,22) and with an alteration in the quantity or type of brush border membrane phospholipids (16, 23–26). Modifications in the dietary content of carbohydrate, cholesterol, essential fatty acids or protein influence intestinal transport function in both control and diabetic rats (3,4), and these dietary manipulations are associated with changes in the phospholipid content of the brush border membrane (7). For these reasons, it seems likely that the brush border membrane phospholipids play an important role in the modulation of intestinal transport. However, changes in the P/S ratio in the diet of rats also altered intestinal uptake of lipids, hexoses and leucine without associated changes in villus morphology or brush border membrane phospholipids (6).

A recent report has suggested that variations in the saturation of dietary fatty acids will give rise to changes in fluidity of brush border membranes and to changes in the fatty acyl content of membrane phospholipids (9,21). Before making further attempts to define the relationship between brush border membrane phospholipids, fatty acids and nutrient uptake, we have explored the time-course of changes in intestinal uptake of nutrients by feeding semisynthetic diets high in saturated or polyunsaturated fatty acids for variable periods. Based on the previous study, which demonstrated alterations in uptake of lipids, glucose and leucine 14 days after feeding mature rats the semisynthetic diets high in HS or HP fatty acids (6), it was anticipated that shorter periods of feeding HS or HP would be associated with qualitatively similar findings. The effect of feeding HS or HP for 14 days on uptake of 40 mM glucose, stearic and linoleic acids and cholesterol was confirmed (Figs. 3 and 4). However, in no instance were the changes progressive: the lower uptake of 1 mM glucose in HS than HP occurred only on day 3, and the difference in jejunal uptake of 40 mM glucose was greater on day 3 than on day 14 (Fig. 3). In addition, the qualitative nature of the changes varied with time; for example, uptake of stearic and oleic acids was greater in HP than HS on day 7, but greater in HS than HP on day 14. Furthermore, although glucose uptake changes on day 3, lipid uptake changed only after 7 days of feeding HS or HP. This suggests that a different mechanism was responsible for the rapid alterations in glucose uptake but slower alterations in lipid uptake in response to diet. Changing dietary saturation of fatty acids does not result in perturbations of brush border membrane cholesterol or phospholipids (6), although feeding HP and HS results in alterations in membrane acyl components (unpublished observations; 8). It is uncertain which portion(s) of the membrane are affected, but previous authors have suggested that there may be discrete microdomains within the lipid membrane involved in the binding of different proteins (27,28). This possibility has previously been raised on the basis of theoretical studies (29). In addition, the major portion of intestinal uptake of palmitic acid occurs from the upper third of the villus (30). It is possible that the diet-associated changes in lipid uptake may be mediated by another domain, such as the bulk phase lipids in the membrane.

Feeding a diet enriched in linoleic acid increases the proportion of membrane lipid comprised of this fatty acid (8) and increases its uptake on day 7 but not day 14. However, dietary supplementation with linolenic acid did not alter the uptake of this fatty acid. Thus, an alteration of a given lipid in the membrane does not necessarily change the uptake of that lipid. Furthermore, the uptake of cholesterol is increased in HS compared with HP (Fig. 4), even though the membrane cholesterol is unchanged (6). It is likely that alterations in lipid uptake are due to complex metabolic alterations that change the "fluidity" of the membrane and thereby alter passive permeability properties and lipid uptake rates.

The time-course of changes in uptake varied between the jejunum and ileum (Figs. 3 and 4). It is unknown how far along the intestine the dietary challenge extends, but presumably the magnitude of the challenge would diminish with passage along the intestine. However, the microsomal membrane lipids are qualitatively different in the jejunum than in the ileum (unpublished observations). Furthermore, the hydroxymethylglutaryl CoA reductase activity is different in the proximal as compared with the distal intestine (31,32). Thus, the different transport response of the ileum and the jejunum to dietary changes may be due to more than a gradient of the dietary load along the length of the intestine. While manipulation of dietary fatty acids might be predicted to have an influence on lipid uptake (since qualitatively similar changes were noted along the length of the intestine) (Fig. 4), the greater uptake of 40 mM glucose into the ileum of HS than HP might counteract the lower jejunal uptake (Fig. 3). Thus, any predictions must be made cautiously about the potential role of feeding a saturated fatty acid diet to alter blood glucose concentrations after a meal.

Since the mechanism of the altered intestinal uptake in response to dietary changes has not yet been established, it is not possible for us to indicate the explanation for the persistent difference between HS and HP in the uptake of stearic and oleic acid (Fig. 4). None of the alterations in uptake could be explained by differences in the animal's body weight, intestinal weight, or mucosal surface area (Fig. 2). Nonetheless, it is important to determine for just how long there is a late effect of dietary lipids on intestinal transport function.

[Received March 25, 1986]

Intestinal Cholesterol and Oleic Acid Uptake from Solutions Supersaturated With Lipids

M.O. Reynier*, C. Crotte, J.C. Montet, P. Sauve and A. Gerolami
Unité de recherches de Pathologie Digestive, U 31 INSERM, 46 bd de la Gaye, 13009 Marseille, France

To test the role of nonmicellar phases in lipid absorption, intestinal uptake of fatty acids and cholesterol has been studied in vitro from supersaturated and micellar solutions. The micellar solubility limit at equilibrium was established for cholesterol and oleate/monoolein (2:1) at pH 6.7 with 10 mM taurocholate. Uptake by rat intestinal everted sacs was measured during incubation of 5 min. Cholesterol uptake increased linearly with the cholesterol content of micellar or supersaturated solutions up to a supersaturation of 150%. Oleate uptake, by contrast, remained essentially the same from either saturated or supersaturated (130–280%) mixtures. The difference between cholesterol and oleate uptake rates is explained by their distinct effects on micellar size, which is unchanged by cholesterol supersaturation but is increased by oleate. Solutions largely supersaturated (280%) with oleate-monoolein are polydisperse and contain viscous isotropic and paracrystalline phases similar to those observed during lipid absorption. These results suggest that, in the presence of such solutions, uptake occurs from both the micellar saturated and nonmicellar supersaturated phases.
Lipids 22, 28–32 (1987).

Lipid absorption is thought to occur from a micellar phase resulting from fatty acids and monoglyceride solubilization by bile salts in the intestinal lumen. Micelle formation could be necessary to overcome the resistance of the unstirred water layer so that lipolysis products reach the epithelial brush border. More recently it was shown that during fat digestion this micellar phase is probably mixed with a lamellar liquid crystalline phase and a viscous isotropic phase (1,2). These two phases are partially soluble in water and cannot be clearly separated from the micellar phase by centrifugation. It has been suggested that they could be substrates from which fat absorption occurs. The aim of this work was to test this hypothesis by measuring intestinal uptake of lipids from saturated micellar solutions and from largely supersaturated solutions so that they contain micelles in equilibrium with nonmicellar phases.

MATERIALS AND METHODS

Chemicals. Sodium taurocholate was purchased from Calbiochem (La Jolla, California). Sodium oleate, monoolein and cholesterol, 99% pure, were obtained from Sigma Chemical Co. (St. Louis, Missouri). Ninety percent of the monoolein was the α-isomer and the balance was the β-isomer. [4-^{14}C]Cholesterol (40–50 mCi/mmol) and [1-^{14}C]oleic acid (45–55 mCi/mmol) were purchased from CEA-France (Saclay, France) and were found to be greater than 98–99% pure. [^{3}H]Inulin was obtained from Amersham-France SA (Les Ulis, France), 97% pure.

Preparation of mixed micelles. Solutions of lipids in 10 mM taurocholate were prepared by coprecipitation (3). The solubility limits were determined at pH 6.7 in phosphate buffer of 0.15 M Na^+ at 37 C after an equilibration time of 7 days. In a first series of experiments, increasing amounts of oleate/monoolein (molar ratio 2:1) were added to a constant taurocholate concentration of 10 mM. In a second series, various amounts of cholesterol were added to taurocholate/oleate + monoolein = 55:45 mixtures with oleate/monoolein = 2 (molar ratios). The different solutions used in the study are plotted (Fig. 1) in rectangular coordinates.

The separation of a second phase (cholesterol crystals, paracrystalline phases) from the isotropic mixtures was monitored by polarizing microscopy and the Tyndall phenomenon following classical criteria (1,4).

Molecular weight determination. These assays were performed at 25 C with the aid of a Spinco-Beckman model-E analytical centrifuge equipped with temperature and speed controls (72 min at 60,000 g). The homogeneity of the micellar solution was tested by the sedimentation coefficient determination, for which a double sector capillary cell with synthetic boundary and a schlieren optical system was employed. A phosphate buffer was used (10 mM, pH 6.7, 0.15 M Na^+). For micellar weights, the Yphantis method (5) was used and the partial specific volume of mixed micelles was experimentally measured in a Parr microdensimeter (6); this value was used for calculating the weight of the micelles.

Cholesterol uptake. The preparation of everted sacs has been previously described (7). The small intestine of male Wistar rats (250–280 g) was removed and rinsed with cold saline and immediately everted over a glass rod. A

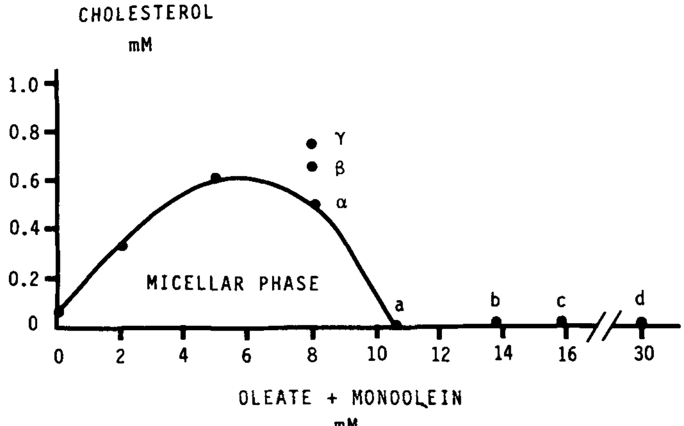

FIG. 1. Composition of the different test solutions in rectangular coordinates. Lipid solubility limits were determined for a constant taurocholate concentration (10 mM). Cholesterol saturated and supersaturated solutions are indicated as α, β and γ (100, 130 and 150% saturation, respectively). Oleate + Monoolein saturated and supersaturated mixtures are indicated as a, b, c and d (100, 130, 150 and 280% saturation, respectively). This diagram does not allow the determination of the physical structures of the test solutions, as they were used before complete equilibrium was obtained. From microscopic examination, all of the solutions except d were homogeneous and behaved like supersaturated micelles.

10–15 cm segment distal to the ligament of Treitz was used in this experiment. Sacs 1.5-cm long from the segment were tied off sequentially and kept in cold buffer solution until used. Incubation was done immediately at 37 C for 5 min and at a stirring rate of 750 rev min^{-1} in micellar solutions that contained [^{14}C]cholesterol or [^{14}C]-oleic acid and trace amounts of [^{3}H]inulin as a radiolabeled volume marker. Following incubation, the sacs were removed, rinsed in cold saline and dried overnight at 60 C. This temperature did not lead to any loss of oleic acid. They were then weighed and solubilized with Soluene-350 and Dimilume-30 (Packard Instruments Co., Downers Grove, Illinois), and the liquid scintillation counting was carried out using Tri-Carb 300C counter (Packard Instruments Co.). The kinetics of cholesterol or oleate uptake were measured between 3 and 15 min. A linear relationship existed between the amount of cholesterol or oleate uptake and time. Therefore, a 5-min incubation time was chosen because 5 min was sufficient for the unstirred water layer to become uniformly labeled with the marker, but not so long as to damage the membrane. The data were expressed as nmoles of cholesterol or oleate per 100 mg tissue dry weight and per 5 min incubation. The results were given as means ± SE and were compared by using Student's t-test.

TABLE 1

Effect of Oleate or Cholesterol Supersaturation on Apparent Molecular Weight of Mixed Micelles of Taurocholate/Oleate/Monoolein With or Without Cholesterol

Supersaturation (%)	V[a]	S[b]	aMW[c] (daltons)

RESULTS

Solubility limit. The cholesterol solubility limit in micellar form was determined at pH 6.7 for a taurocholate/oleate + monoolein = 55:45 (oleate/monoolein = 2:1) molar ratio. The cholesterol solubility limit was 0.49 mM. From these data, we prepared saturated and supersaturated solutions (130% and 150% saturation with cholesterol). The mixtures were used for uptake studies within 24 hr following preparation so that the supersaturated solutions did not contain cholesterol crystals and were optically clear (Tyndall−). The oleate/monoolein solubility limit (oleate/monoolein = 2:1) in 10 mM taurocholate was estimated to be 10.55 mM.

Molecular weight. For saturated and supersaturated solutions, we determined the partial specific volume, the sedimentation coefficient and the apparent molecular weight. As shown in Table 1, the results were different for oleate supersaturation and for cholesterol supersaturation. When oleate concentration increased from 10.55 mM to 15.80 mM, the apparent molecular weight increased significantly from 45,000 to 115,000. By sedimentation velocity, we observed a symmetric peak that indicated that the mixtures were homogeneous.

In the 280% supersaturated solutions, it was impossible to determine the apparent molecular weight because these solutions were turbid and heterogeneous. In contrast, for micelles supersaturated with cholesterol, the apparent molecular weight remained almost constant for cholesterol concentration ranges from 0.49 to 0.74 mM.

Physical state of supersaturated (280%) systems. Mixtures containing sodium taurocholate (10 mM), monoolein (10 mM) and oleate (20 mM) labeled with [^{14}C]oleic acid were opalescent. Examined under a light microscope, they appeared polydisperse. By centrifugation of 100,000 g for 90 min at 25 C, a separation into two phases occurred. The upper phase, turbid and rich in oleate and monoolein, represented about 10% of the total volume and, under polarized light microscopy, showed a texture consistent with the presence of liquid crystals with myelin figure formations. The lower phase, containing 80% of the total oleate, exhibited a Tyndall phenomenon and could pass through a membrane of 0.22 μm porosity. This phase is similar to a mixture supersaturated with lipids (230%) when compared to the micellar solubility limits. We have also generated mixtures containing oleate (14 mM) and monoolein (7 mM) in phosphate buffer, pH 6.7, 0.15 M Na^{+}. The emulsion contained droplets, but no paracrystalline phase could be detected. Upon centrifugation, an upper oil phase could be easily separated from a lower lipid-free aqueous phase. In comparing these two solutions, we concluded that the presence of bile salt allowed the dispersion of an amount of lipid larger than that incorporated in the mixed micelles.

Cholesterol uptake. The cholesterol uptake from everted jejunal sacs of rat intestine was studied from saturated (0.49 mM cholesterol) and supersaturated (0.64 mM and 0.78 mM cholesterol) solutions with 10 mM taurocholate and 8 mM oleate/monoolein.

The results for an incubation time of 5 min are given in Table 2. We observed an increase of cholesterol uptake directly proportional to the quantity of cholesterol solubilized in the mixtures. The difference of uptake is significant ($2p \leqslant 0.05$) between the saturated solutions and the 130% supersaturated solutions and between the 130% and 150% supersaturated solutions.

Oleate uptake. The oleate uptake was measured from saturated (10.55 mM oleate/monoolein) and from supersaturated solutions (13.70, 15.80 and 30.00 mM oleate/monoolein) with 10 mM taurocholate.

As for cholesterol uptake, the oleate uptake was determined after a 5-min incubation time. Control studies showed a constant uptake rate between 3- and 15-min incubation times. The results, presented in Table 3, showed that the oleate uptake is almost constant from saturated and supersaturated solutions, regardless of the quantity of oleate solubilized in the mixtures. This value corresponds therefore to the maximum uptake in our conditions. As shown in Table 3, we verified that the uptake from less saturated solutions (60%) is smaller.

TABLE 2

Cholesterol Uptake after Cholesterol Supersaturation of Mixed Micelle Taurocholate/Oleate/Monoolein/Cholesterol

Cholesterol concentration (mM)	Saturation (%)	n	Cholesterol uptake (nmol·100 mg^{-1}·5 min^{-1})	Adherent fluid volume (μl·100 mg^{-1}·5 min^{-1})
0.49	100	36	77.39 ± 2.17	72.63 ± 3.49
0.64	130	15	92.59 ± 6.30*	77.98 ± 4.99
0.74	150	26	120.59 ± 4.04*	62.03 ± 3.37

The taurocholate concentration (10 mM) and oleate/monoolein concentration (8 mM) are kept constant.
*Indicates a significant difference ($P < 0.05$) between the mean values of cholesterol uptake from saturated and supersaturated solutions.
Each value represents the mean ± SE; n is the number of samples.

TABLE 3

Oleate Uptake after Oleate Supersaturation of Mixed Micelle Taurocholate/Oleate/Monoolein

Oleate/monoolein (mM)	Saturation (%)	n	Oleate uptake (nmol·100 mg^{-1}·5 min^{-1})	Adherent fluid volume (μl·100 mg^{-1}·5 min^{-1})
6.33	60	12	837 ± 36*	60.11 ± 7.31
10.55	100	45	1256 ± 21	76.74 ± 2.96
13.70	130	32	1334 ± 41	87.49 ± 3.08
15.80	150	18	1340 ± 49	75.18 ± 4.51
30.00	280	39	1158 ± 50	62.11 ± 2.82

The taurocholate concentration is kept constant at 10 mM.
*Indicates a significant difference ($p < 0.005$) between the mean values of oleate uptake from unsaturated and saturated or supersaturated solutions.
Each value represents the mean ± SE; n is the number of samples.

TABLE 4

Intestinal Oleate Uptake from Saturated Taurocholate/Oleate Micelle

Micelle	n	Oleate uptake (nmol·100 mg^{-1}·5 min^{-1})	Adherent fluid volume (μl·100 mg^{-1}·5 min^{-1})
A[a]	12	1724 ± 78	84.42 ± 4.55
B[b]	12	2020 ± 52*	77.63 ± 3.50

[a]Micelle taurocholate/oleate (10 mM/9 mM).
[b]Micelle taurocholate/oleate (15 mM/13.5 mM).
*Indicates a significant difference ($P < 0.005$) between the mean values of oleate uptake from A and B micellar solutions.

The maximal uptake rate was not due to a saturation of the mucosal surface of the everted sacs. Oleate uptake was increased further when using saturated solution with 15 mM taurocholate or 10 mM taurocholate containing oleate without monoolein (Table 4).

DISCUSSION

In our studies, the intestinal uptake of lipids was measured in vitro using everted intestinal sacs, and it was necessary to account for possible drawbacks of this model. First, under our experimental conditions, there was no apparent damage of the mucosa when we used taurocholate more than 98% pure. This bile salt has been shown to be without any toxicity for the intestinal mucosa at 10 mM (8), which is lower than the bile salt concentration used in other studies of intestinal uptake (9). This lack of toxicity, even in the presence of high concentrations of fatty acids and monoolein, is further demonstrated by the fact that the mucosal permeability for macromolecules seems to be essentially unchanged by any of the test solutions used in the present work. The adherent fluid volume estimated from [^{3}H]inulin would be increased in case of increased cellular permeability. In

all of our experiments, it was the same as the volume measured with control solutions without bile salts or fatty acids.

It must be emphasized that the adherent fluid volume calculated from inulin binding was not dependent on the amount of lipid present in the bulk phase. This suggests that even the use of 280% supersaturated solutions does not preclude the use of inulin as a marker of extracellular fluid. Another possible limitation of the study was the short time (5 min) during which uptake rates were measured. This could represent only the initial rate of uptake, possibly different from the rate at equilibrium, particularly when supersaturated solutions with a slower diffusion through the unstirred water layer are studied. This did not seem to be the case, as fatty acid uptake remained linear for at least 15 min in even the most supersaturated solutions.

On the other hand, additional experiments showed that oleate uptake was not limited by the ability of intestinal mucosa to bind oleate. Indeed, oleate uptake may be increased above the values obtained in these experiments when more oleate is presented in micellar form (taurocholate 15 mM or oleate/bile salt micelles without monoolein). In fact, the major limitation of the study is that we cannot know if any of the solutions are actually similar to the lipidic phases occurring during fat absorption in vivo. Many other molecules, and particularly proteins and calcium, are present during fat absorption. For solutions supersaturated with oleate and monoolein, however, microscopic examination showed structures that seem analogous to the ones seen during fat digestion (1).

Ultracentrifugation of these mixtures did not show a distinct separation between the clear aqueous phase and the upper lipidic phase rich in liquid crystalline materials. In the clear aqueous phase, the presence of a viscous isotropic phase was shown by microscopic examination exactly as in intestinal contents (1). Under these conditions, these phases seem to have physiological implications, even if the conclusions of the study are obviously valid only for our experimental conditions.

We also observed different results for cholesterol and fatty acid uptake. For cholesterol, the uptake rate increases with cholesterol concentration (10), even for cholesterol supersaturated solutions. Furthermore, the same results have recently been obtained elsewhere (8). This suggests that supersaturation with cholesterol does not induce the formation of oleate/monoolein/cholesterol microdroplets similar to the structures described in dilute bile salt/lecithin/cholesterol supersaturated solutions (11). More likely, the supersaturation state results in a metastable micelle from which cholesterol absorption occurs. This would be consistent with our results, because the size of mixed micelles is not dependent on their cholesterol content, and it has been shown that cholesterol uptake from mixed micelles of a given micellar size increases linearly with their cholesterol content (12).

The results are very different for fatty acids, whose uptake rate from saturated mixed micelles cannot be increased by supersaturation. This is consistent with a role of both micellar and nonmicellar structures in fatty acid absorption for the following reasons: (i) Slightly supersaturated solutions (130% or 150% saturation) are either optically clear or slightly Tyndall+. During analytical ultracentrifugation, they appear to contain homogeneous-sized particles larger than saturated micelles, but oleate uptake from these solutions is similar to oleate uptake from saturated micelles. This shows that diffusion across the unstirred water layer is possible for structures larger (two- or threefold) than saturated mixed micelles. It may be hypothesized that the high concentration of fatty acids compensated for a slower aqueous diffusion of aggregates (10) so that the net result was the same uptake as in the presence of nonsupersaturated micelles. (ii) The role of nonmicellar phases is more clearly shown by the fact that turbid solutions with bile salts and a high concentration of fatty acids and monoolein deliver fatty acids at the same rate as micelles. These solutions are polydisperse solutions containing liquid crystalline phases and saturated micelles with structures of intermediary size as shown by microscopic examination after ultracentrifugation.

The same polydispersity has been observed for bile salt/lecithin mixtures (11) where the bile salts are involved in the formation of paracrystalline phases. The microscopic appearance of the largely supersaturated bile salt/oleate/monoolein mixtures cannot be explained by a simple coexistence of saturated mixed micelles and an emulsion of oleate/monoolein in water. This is clearly shown by the study of sonicated emulsions of oleate/monoolein at concentrations equal to the difference between total lipid concentration of the supersaturated solutions and the concentration corresponding to saturation of the micelles. In such solutions, the lipidic phase separates clearly from the aqueous phase and forms neither liquid crystalline nor viscous isotropic phases. It seems then that in our solutions bile salts are partitioned between mixed micelles and other phases. Under these conditions, intestinal uptake from micelles is certainly lower than that from pure micellar solutions containing the same amount of bile salts as the total concentration present in the mixtures. Since the net uptake is, in fact, the same as from pure saturated mixed micelles, the results suggest that part of the intestinal uptake is due to absorption from other liquid crystalline phases than micelles.

It is obviously difficult to know if a similar phenomenon occurs during digestion in vivo. Some of the solutions studied show the same microscopic structures as seen during in vivo lipolysis. They have approximately the same lipid composition as that measured in the duodenal aqueous phase during digestion of lipids (13–15). However, it must be emphasized that many other components not studied here, such as calcium and proteins, may interfere with lipid absorption in vivo.

[Received January 14, 1986]

Intestinal Absorption of Ester and Ether Glycerophospholipids in Guinea Pig. Role of a Phospholipase A_2 from Brush Border Membrane

A. Diagne[a], S. Mitjavila[b], J. Fauvel[a], H. Chap[a] and L. Douste-Blazy[a]
[a]INSERM Unité 101, Biochimie des Lipides, Hôpital Purpan, 31059 Toulouse Cedex, France, and [b]INSERM Unité 87, 2 rue Francois Magendie, 31400 Toulouse, France

In vivo intestinal perfusion was used to follow the absorption of three different choline glycerophospholipids (CGP) in guinea pig. These included 1-[^{3}H]palmitoyl-2-acyl-*sn*-glycero-3-phosphocholine (diacyl-GPC), 1-[^{3}H]-*O*-hexadecyl-2-acyl-*sn*-glycero-3-phosphocholine (alkylacyl-GPC) and 1,2-di-*O*-hexadecyl-*sn*-glycero-3-phospho-[^{3}H]-choline (dialkyl-GPC). About 80% of diacyl-GPC was absorbed within 4 hr, compared to 60% of alkylacyl-GPC and 30% of dialkyl-GPC. The radioactivity disappearing from the perfusion fluid was recovered in intestinal lipids, mostly triacylglycerol, free fatty acid and CGP from diacyl-GPC, CGP from alkylacyl-GPC and dialkyl-GPC. These results indicated that the nonhydrolyzable substrate dialkyl-GPC was much less absorbed, whereas diacyl-GPC, which released over 80% of [^{3}H]palmitic acid in the perfusion fluid, displayed the highest absorption rate. The intermediate picture observed for alkylacyl-GPC suggested the possible involvement of a phospholipase A_2, which was detected in the entire intestinal tract. This enzyme was further found to concentrate in villus cells, where it is localized in the brush border membrane, as shown using two different subcellular fractionation procedures. These data suggest a possible role of this new enzyme in the digestion of alimentary phospholipids.
Lipids 22, 33–40 (1987).

It is generally accepted that intestinal absorption of glycerophospholipids requires hydrolysis in the intestinal lumen (1,2). Such lipolysis is achieved by pancreatic phospholipase A_2, which specifically removes the fatty acids esterified in the *sn*-2-position of phosphoglycerides (3,4). Further degradation of the lysophospholipids involves pancreatic lysophospholipases (5), but this remains limited to 1-acyl-compounds, since the 1-*O*-alkyl- and the 1-*O*-alkenyl bonds of ether phospholipids resist hydrolysis. Ether glycerophospholipids can represent a substantial portion of phospholipids present in food (6–8). Following hydrolysis, free fatty acids (FFA) and lysophospholipids are absorbed as such through the brush border membrane (1). Guinea pig might well represent an exception to this general scheme, because the secretory pancreatic phospholipase A_2 is absolutely lacking in this species (9), in contrast to the presence of two cationic lipases with high phospholipase A_1 activities (10–12).

The present study was undertaken to investigate comparatively the intestinal absorption of 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (alkylacyl-GPC), 1,2-diacyl-*sn*-glycero-3-phosphocholine (diacyl-GPC) and 1,2-di-*O*-alkyl-*sn*-glycero-3-phosphocholine (dialkyl-GPC) using in vivo perfusion of the guinea pig small intestine. The relationship between phospholipid degradation and absorption led us to describe a phospholipase A_2 in guinea pig intestinal brush border membrane, which could play a significant role in the digestion of alimentary phospholipids.

MATERIALS

Guinea pigs (300–400 g) were obtained from a local distributor. [9-10(n)^{3}H]Palmitic acid (500 mCi/mmol), 1-[^{14}C]linoleic acid (60 mCi/mmol) and [^{14}C]methyl iodide (58 mCi/mmol) were purchased from the Radiochemical Center (Amersham, United Kingdom) and L-α-kephalin (N,N-dimethyl dihexadecyl) was from Serva (Heidelberg, Federal Republic of Germany). Vitride [$NaAlH_2(OCH_2CH_2OCH_3)_2$] was obtained from Labolac (Rueil-Malmaison, France). All other chemicals were from Prolabo (Paris, France) or Merck (Darmstadt, Federal Republic of Germany). The composition of Ringer Locke solution used for intestinal perfusion was as follows: 116 mM NaCl, 20 mM $NaHCO_3$, 5.2 mM KCl, 2.4 mM Na_2HPO_4, 0.4 mM NaH_2PO_4, 1.2 mM $MgCl_2$, with pH adjusted to 7.4 by bubbling a 95% O_2/5% CO_2 mixture. Final osmolarity was between 285 and 318 mOs.

METHODS

Radioactive phospholipids. 1-[^{3}H]Palmitoyl-2-acyl-GPC (13,900 dpm/nmol) and 1-acyl-2-[^{14}C]linoleoyl-GPC (1,500 dpm/nmol) were prepared using rat liver microsomes as described by Waite and van Deenen (13) and van den Bosch et al. (14). 1-[^{3}H]Hexadecyl-2-acyl-GPC (2,040 dpm/nmol) was obtained by the procedure described by Wykle et al. (15,16) with the following modifications: [^{3}H]hexadecanol prepared by Vitride reduction of [^{3}H]-palmitic acid (30 min) was injected intraperitoneally into mice bearing Krebs II ascitic tumor. After 24 hr, ascites cells were collected and their lipids extracted (17). Total choline glycerophospholipids (CGP) purified by thin layer chromatography (TLC) (18) were treated for 7 hr at 41 C with partially purified guinea pig phospholipase A_1 as described previously (8,19). 1-*O*-[^{3}H]Alkyl-2-acyl-GPC was purified by preparative TLC in the basic solvent of Broekhuyse (20). Before the migration, plates were exposed to HCl fumes to hydrolyze plasmalogen (19). 1,2-*O*-Dihexadecyl-*sn*-glycero-3-phospho-[^{14}C-*N*-methyl]choline (115,000 dpm/nmol) was synthesized by the methylation of the corresponding *N,N*-dimethyl-ethanolamine glycerophospholipid with [^{14}C]methyl iodide as described by Stoffel (21). It was then purified by preparative TLC on Silica Gel G plates, 0.25 mm thick (Merck) using chloroform/methanol/water (65:24:4, v/v/v) as a solvent.

Animal experimentation. Intestinal absorption of phospholipids was performed by closed circuit in vivo perfusion (22,23). Nonfasted guinea pigs were anaesthetized with sodium pentobarbital (0.5 ml/kg body weight). After tracheotomy and laparotomy of each animal, the small intestine was ligatured both at the level of the pylorus and after the first intestinal loop. Then two cannula made with polyvinyl tubing were inserted at both ends, and the isolated intestine part was rinsed twice with Ringer Locke solution at 37 C and connected to the perfusion system. For maximal lipid absorption, the flow rate was main-

tained at 1.7 ml/min. During the perfusion, animal body temperature was kept at 37 C with a thermostated plate. CGP (500,000 dpm/245 nmol) were taken to dryness under nitrogen from a chloroform/methanol solution and dispersed by sonication in 10 ml of Ringer Locke solution containing 6 mM sodium taurocholate. The percentage of substrate absorbed was evaluated by withdrawing 0.1 ml of perfusion solution after 15 min and then every 30 min up to 2 or 4 hr. These aliquots were directly put into vials containing 10 ml Aqualuma (Kontron, France), and their radioactivity was determined.

Extraction and analysis of lipids. At the times indicated in Tables 1 and 2, the animals were killed by decapitation. The part of perfused intestine was removed, and the perfused solution was collected. The intestine was washed thoroughly with Ringer solution containing 10 mM EDTA, and its lipids were extracted and washed according to Folch et al. (24). The perfused solution was diluted with EDTA (*10 mM final concentration*), and lipids were extracted according to Bligh and Dyer (17). Lipids were separated by TLC on Silica Gel G plates using hexane/diethyl ether/formic acid (55:45:1, v/v/v) for neutral

[c]X is a substance migrating between FFA and TG.

glycerides (25) and chloroform/methanol/acetic acid/water (65:43:1:3, v/v/v/v) for glycerophospholipids (18). After visualization with iodine vapor, the different lipid spots were scraped off and their radioactivity was determined.

Preparation of mucosal homogenates and subcellular fractionation. Animals fasted for 12 hr were killed by a blow to the head and the small intestine was entirely removed. It was rinsed with ice-cold isotonic NaCl, and the mucosa was homogenized on ice in 20 vol Tris-Sucrose buffer (250 mM sucrose buffered with 10 mM Tris-HCl, pH 7.3) using a Potter Elvejhem homogenizer (26). All the subsequent operations were performed on ice or at 4 C. The homogenate was then subjected to a sequential centrifugation procedure, i.e., 900 $\times$ g for 10 min, 10,000 $\times$ g for 10 min and 100,000 $\times$ g for 90 min. At each step the resulting supernatant was carefully removed and used for the following centrifugation, except the last one (cytosolic fraction). The three pellets were resuspended in Tris-Sucrose buffer using a Potter Elvejhem homogenizer.

In some experiments, the whole small intestine was divided into three equal segments, corresponding to the duodenojejunal area, to the remaining jejunum and to the ileum, from the proximal to the distal part.

Purification of brush border membrane vesicles. This was achieved exactly as described by Schmitz et al. (27).

Isolation of various intestinal cell populations. Intestinal cells were isolated and separated as a villus to crypt gradient according to Weiser (28). Cells were washed, suspended in 300 mM mannitol buffered with 10 mM Tris-HCl (pH 7.3) and used for assay of alkaline phosphatase and phospholipase A_2 activities.

Determination of phospholipase activities. Three different substrates, prepared as described above, were used: 1-[^{3}H]palmitoyl-2-acyl-GPC, 1-acyl-2-[^{14}C]linoleoyl-GPC and 1-[^{3}H]hexadecyl-2-acyl-GPC. Depending on the case, each of them was taken to dryness under nitrogen from chloroform/methanol solution and dispersed by sonication (MSE sonicator at maximal output for 15 sec) in the assay mixture, which contained, in a final volume of 0.1 ml, 0.4 mM substrate, 4.8 mM sodium deoxycholate, 5 mM $CaCl_2$, 200 mM Tris-HCl (pH 7 and 8.5 for phospholipases A_1 and A_2, respectively, unless otherwise stated) and protein fractions from intestine. Incubation was carried out at 37 C for 15 min under shaking. The reaction was terminated by addition of chloroform/methanol and, after extraction (17), the lipids were separated by TLC on Silica Gel G plates using chloroform/methanol/water (65:35:4, v/v/v) as a solvent. After visualization with iodine vapor, the various spots corresponding to choline lysoglycerophospholipids (CLGP), CGP and FFA were scraped off and radioactivity was determined.

Other marker enzymes. The activity of the following marker enzymes was determined according to well-established procedures: alkaline phosphatase (29), succinate cytochrome c reductase (30), N-acetyl-β-D-glucosaminidase (31), NADH-dehydrogenase (32,33), lactate dehydrogenase (34) and sucrase (35).

Other analytical methods. Protein was determined by the method of Lowry et al. (36) using bovine serum albumin as a standard. Lipid phosphorus was measured using a modification of the Fiske and Subbarow method (37). Radioactivity was evaluated with a Kontron Intertechnique Liquid Spectrometer (type SL 400) with automatic quenching correction, using Aqualuma as a scintillation fluid.

RESULTS

Intestinal absorption and metabolism of various radioactive CGP. The rate of radioactivity disappearance from the perfusion solution indicated intestinal absorption of phospholipid, since no decrease in radioactivity present in the perfusion fluid was observed during perfusion in the same system lacking the intestinal segment. Figure 1 shows that both 1-[^{3}H]palmitoyl-2-acyl-GPC and 1-[^{3}H]-hexadecyl-2-acyl-GPC were absorbed through guinea pig intestinal mucosa, although 40% of [^{3}H]alkylacyl-GPC was still present in the perfused solution after 4 hr, compared to 20% of diacyl-GPC. Dialkyl-GPC disappeared to a much lower extent under the same conditions, since 65–70% of the initial radioactivity was recovered in the perfusion fluid after 4 hr.

To study the differences in phospholipase susceptibility of the three substrates, the distribution of radioactivity between the various lipid classes was investigated in the perfused solution. As shown in Table 1, both 1-[^{3}H]palmitoyl-2-acyl-GPC and 1-*O*-[^{3}H]hexadecyl-2-acyl-GPC were almost entirely hydrolyzed into [^{3}H]palmitic acid and 1-*O*-[^{3}H]hexadecyl-2-lyso-GPC, respectively. However, some 12–18% of the alkylacyl compound remained unchanged, whereas no evident degradation could be detected for 1,2-dihexadecyl-[^{14}C]choline-GPC, which resisted hydrolysis by guinea pig phospholipase A_1 and pig pancreas phospholipase A_2 (this was verified during in vitro incubations).

Upon extraction of lipids from the whole intestinal wall, about 12 $\pm$ 1%, 31.6 $\pm$ 5.6% and 4.5 $\pm$ 1.5% of the initial radioactivity were recovered from 1-[^{3}H]palmitoyl-2-acyl-GPC, 1-*O*-[^{3}H]alkyl-2-acyl-GPC and 1,2-dihexadecyl-[^{14}C]choline-GPC, respectively (mean $\pm$ SEM, three determinations). As shown in Table 2, most of the radioactive

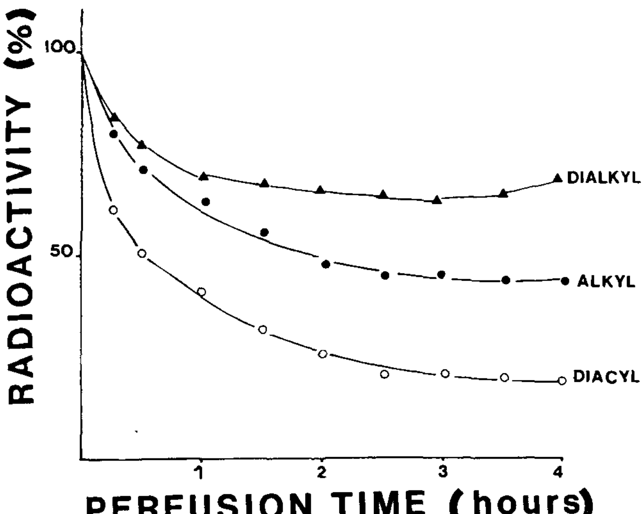

FIG. 1. Rate of disappearance of radioactivity from the perfused solution during intestinal perfusion of 1-[^{3}H]palmitoyl-2-acyl-GPC (○) 1-*O*-[^{3}H]hexadecyl-2-acyl-GPC (●) and 1,2 di-*O*-hexadecyl[^{14}C]-methyl-GPC (▲). The values are means of two experiments for each choline glycerophospholipid.

palmitic acid was detected in TG, CGP and FFA, which represented 33%, 21% and 11% of the total intestinal radioactivity, respectively. Moreover, comparison of data obtained at 2 and 4 hr indicated that some free palmitic acid was progressively incorporated into CGP, ethanolamine glycerophospholipids (EGP) and TG. In contrast, the radioactivity derived from 1-*O*-[^{3}H]hexadecyl-2-acyl-GPC was mostly detected in CGP, although some of it was converted into EGP and TG between 2 and 4 hr perfusion.

Finally, dihexadecyl-[^{14}C]choline-GPC displayed a higher metabolic stability, since 83% of the radioactivity was still present with CGP after 4 hr. It was also hardly converted into diacylglycerol (DG), which still represented 8-10% of the total radioactivity associated with the two other substrates.

Studies on intestinal phospholipases A. The observation that alkylacyl-GPC was better absorbed than dialkyl-GPC, owing to hydrolysis of the former during intestinal perfusion, prompted us to investigate the presence of a phospholipase A_2 in guinea pig intestine. Indeed, incubation of intestinal homogenates at pH 7.0 with 1-acyl-2[^{14}C]linoleoyl-GPC led to the release of [^{14}C]linoleic acid. However, this was accompanied by the simultaneous formation of 2-[^{14}C]linoleoyl-GPC, indicating the concomitant action of a phospholipase A_1. These results were confirmed by data showing that both [^{3}H]palmitic acid and 1-[^{3}H]palmitoyl-GPC were generated under the same conditions when using 1-[^{3}H]palmitoyl-2-acyl-GPC as a substrate. As shown in Figure 2, the two phospholipase activities were stimulated to the same degree by sodium deoxycholate, with optimal activation being attained at 5 mM of the detergent. Moreover, omission or addition of calcium (5 mM) did not modify significantly the results and did not allow discrimination between the two phospholipases A (not shown).

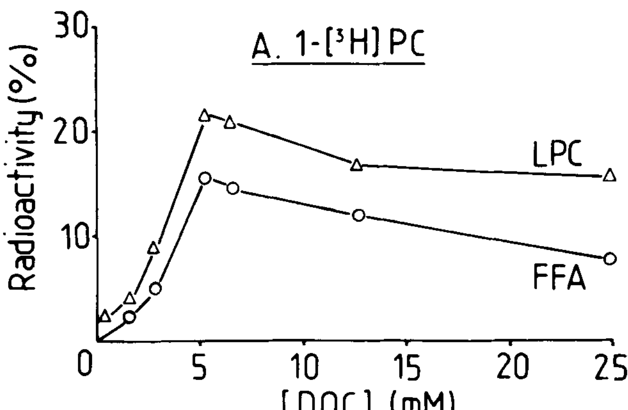
However, the two enzyme activities could be partly separated by submitting intestinal homogenate to subcellular fractionation. As illustrated in Figure 3, four different fractions could be isolated and characterized, based on their content of various marker enzymes: alkaline phosphatase (brush border membrane; 27) in the 900 × g fraction; succinate cytochrome c reductase (mitochondria; 38) and N-acetyl-β-D-glucosaminidase (lysosomes; 31,38) in the 10,000 × g fraction; NADH-diaphorase (endoplasmic reticulum; 32,33,38) in the microsomal fraction; and lactate dehydrogenase (cytosol; 34,38) in the final supernatant. Figure 3 also indicates that phospholipase A_2 activity displayed the same distribution as alkaline phosphatase, especially considering the generation of 1-acyl- or 1-alkyl-GPC, whereas phospholipase A_1 activity displayed the behavior of a cytosolic enzyme.

Such a dual distribution of the two enzymes became more evident upon comparing their pH dependence in the cytosolic fraction and the 900-×-g sediment. As shown in Figure 4A, phospholipase A_1 activity (as detected from the release of [^{3}H]palmitic acid or 2-[^{14}C]linoleoyl-GPC from the corresponding substrate) predominated in the cytosol and displayed a broad optimal pH range between 6.5 and 10, culminating at 7.5. In contrast, the major enzyme activity in the 900-×-g fraction was phospholipase A_2 (as deduced from the liberation of [^{14}C]linoleic acid and 1-[^{3}H]palmitoyl-GPC from their respective precursors), which displayed a stronger pH dependence with a peak at 8.5 (Fig. 4B).

As indicated in Figure 5, other differences between the two phospholipases A included a relatively higher thermostability of phospholipase A_2 vs phospholipase A_1, with the latter displaying the behavior previously described for the pancreatic enzyme (9).

These results suggested a localization of guinea pig intestine phospholipase A_2 in the brush border membrane. Moreover, as shown in Figure 6, sequential elution of intestinal cells according to the procedure described by Weiser (28) revealed that phospholipase A_2 activity decreased from villi to crypts in a manner similar to alkaline phosphatase. Finally, phospholipase A_2 activity was determined in microvesicles purified from brush border membranes (Table 3). Although some differences appeared depending on the substrate used, in all cases phospholipase A_2 activity was enriched in microvesicles to the same extent as sucrase, a very specific marker of brush border membrane (27,35).

To gain further insight into the possible physiological role of this phospholipase A_2, its activity was measured in different segments isolated from guinea pig small intestine. Data presented in Table 4 indicates that the enzyme was distributed throughout the small intestinal tract.



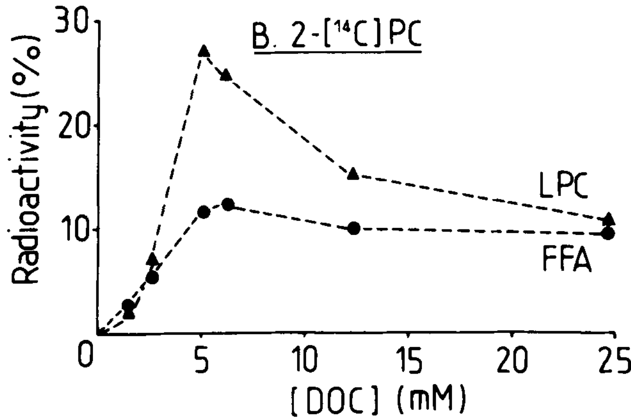


FIG. 2. Effect of sodium deoxycholate on phospholipase activities from homogenates of guinea pig small intestine. Data are expressed in percentages of radioactivity recovered in lysophosphatidylcholine (LPC) or free fatty acid (FFA) using 1-[^{3}H]palmitoyl-2-acyl-GPC (A) or 1-acyl-2-[^{14}C]linoleoyl-GPC (B) as substrates. DOC, sodium deoxycholate.

DISCUSSION

Our results confirm the general view that there is a direct relationship between the absorption level of a given phospholipid and its susceptibility to hydrolysis. This is particularly clear in the case of 1,2-dihexadecyl-GPC, which should not be degraded in the intestinal lumen,

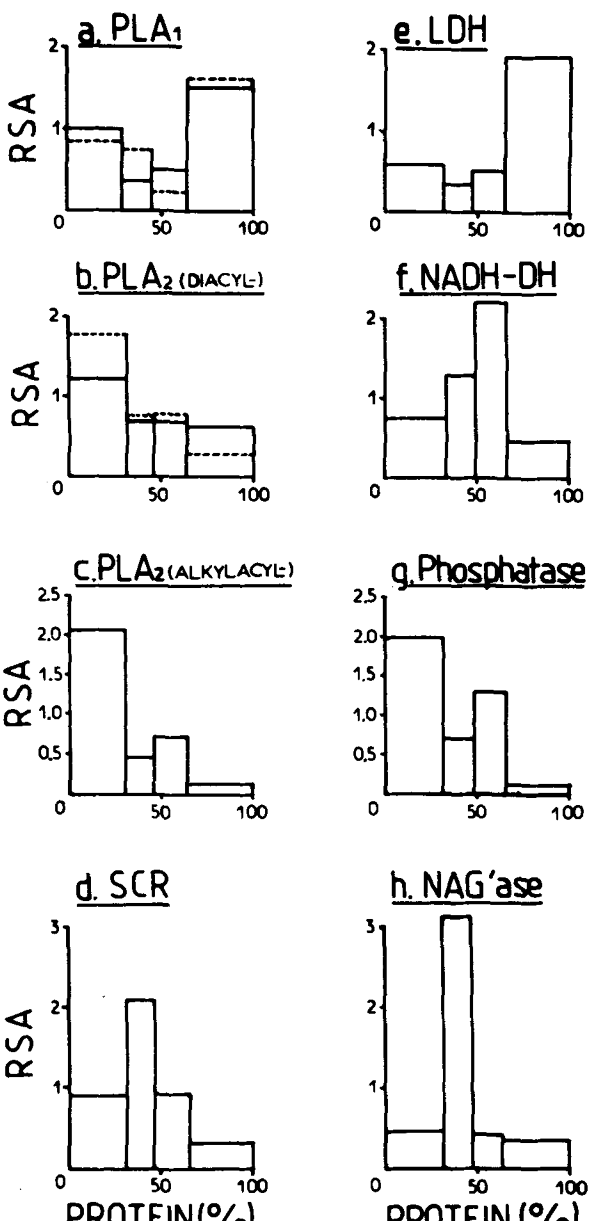

FIG. 3. Distribution of various marker enzymes and phospholipases A in different subcellular fractions isolated from guinea pig small intestine. Relative specific activities (RSA) were calculated according to de Duve et al. (38). (a) Phospholipase A_1, detected by the release of [^{3}H]palmitic acid from 1-[^{3}H]palmitoyl-2-acyl-*sn*-GPC (——) or by the generation of 2-[^{14}C]linoleoyl-GPC from 1-acyl-2-[^{14}C]linoleoyl-GPC (– – –); (b) phospholipase A_2 detected by the liberation of [^{14}C]linoleic acid (——) or by the formation of 1-[^{3}H]palmitoyl-GPC (– – –) from the corresponding substrates; (c) phospholipase A_2, detected by the release of 1-[^{3}H]hexadecyl-GPC from 1-[^{3}H]hexadecyl-2-acyl-GPC; (d) succinate cytochrome c reductase (SCR); (e) lactate dehydrogenase (LDH); (f) NADH dehydrogenase (NADH-DH); (g) alkaline phosphatase; (h) N-acetyl-β-D-glucosaminidase (NAG'ase).

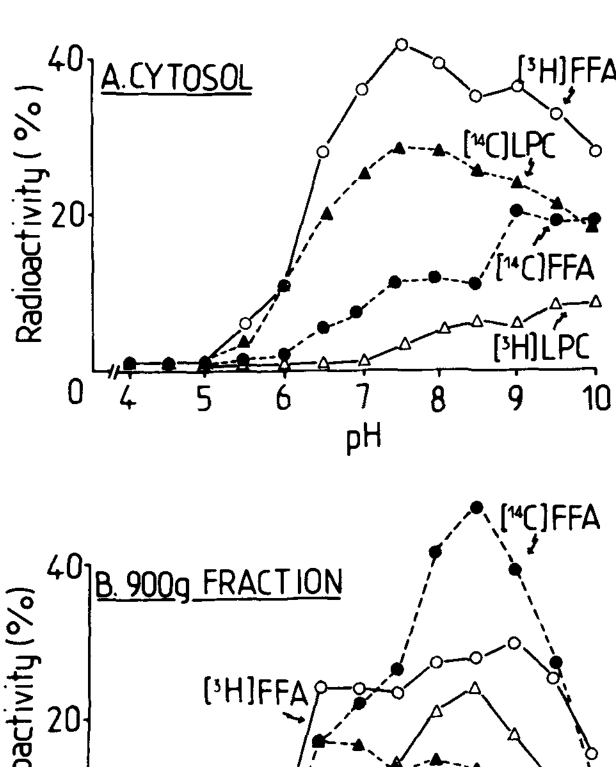

FIG. 4. The pH dependence of phospholipase A activities present in the cytosol (A) and the 900-g pellet (B) isolated from guinea pig small intestine. Buffers were 0.2 M citrate-phosphate for pH 4 to 6.5 and 0.2 M Tris-HCl for pH 7 to 10.

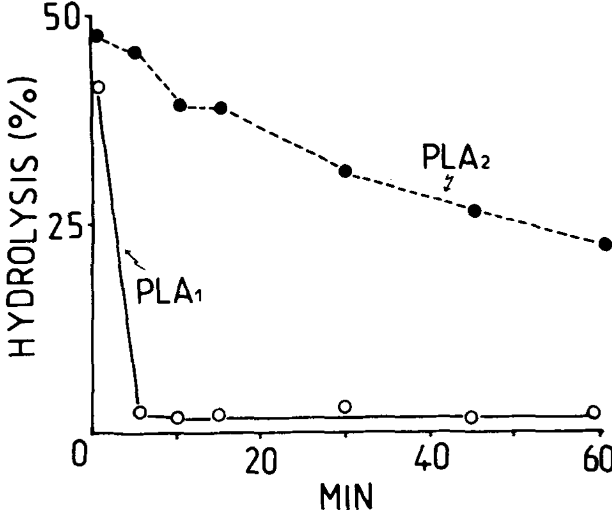

FIG. 5. Effect of heat treatment on the activities of phospholipase A_1 from intestine cytosol (PLA_1) and of phospholipase A_2 from the 900-X-g fraction (PLA_2). Enzyme fractions were treated at 60 C for the indicated times, followed by determination of enzymatic activity. Phospholipase A_1 and A_2 activities were determined by the release of [^{3}H]palmitic acid and [^{14}C]linoleic acid from 1-[^{3}H]palmitoyl-2-acyl-GPC and from 1-acyl-2-[^{14}C]linoleoyl-GPC, respectively.

TABLE 3

Specific Activities of Sucrase and Phospholipase A_2 in Guinea Pig Intestine Homogenate and in Purified Microvesicles from Brush Border Membrane[a]

Enzymes	Specific activities		Enrichment (×-fold)
	Homogenate	Microvesicles	
Sucrase (nmol/min/mg)	206	2480	12
Phospholipase A_2 (nmol/min/mg)			
[^{14}C]Linoleic acid	20.4	204	10
1-[^{3}H]Palmitoyl-GPC	14.0	130	9
1-*O*-[^{3}H]Hexadecyl-GPC	9.0	100	11

[a]Phospholipase A_2 activity was determined using 1-acyl-2-[^{14}C]linoleoyl-GPC, 1-[^{3}H]palmitoyl-2-acyl-GPC and 1-*O*-[^{3}H]hexadecyl-GPC as substrates.

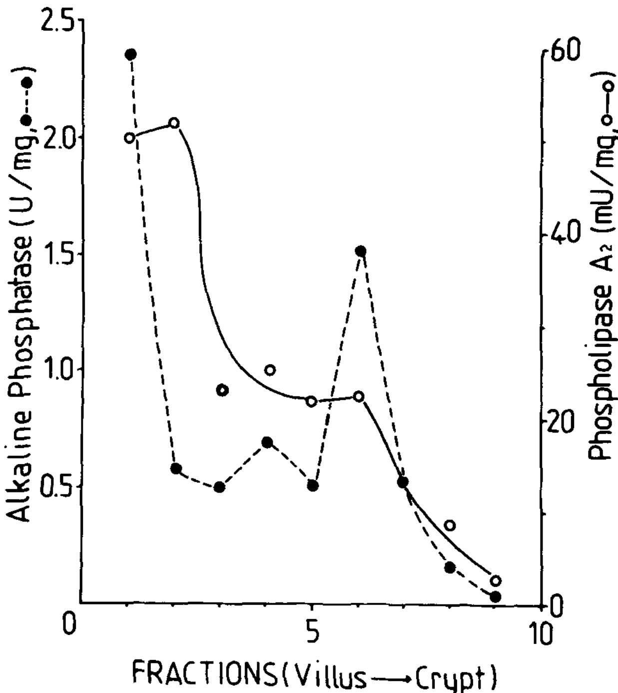

FIG. 6. Distribution of alkaline phosphatase and phospholipase A_2 along the crypt-villus complex. Phospholipase A_2 activity was determined using 1-acyl-2-[^{14}C]linoleoyl-GPC as a substrate. Results are from a typical experiment representative of three different experiments.

TABLE 4

Specific Activities of Phospholipase A_2 in Different Segments of Guinea Pig Small Intestine[a]

Segment[b]	Specific activities (nmol/min/mg)
Proximal	5.03 ± 0.53
Intermediary	9.60 ± 0.76
Distal	6.00 ± 1.96

[a]Phospholipase A_2 activities were determined using 1-acyl-2-[^{14}C]-linoleoyl-GPC as a substrate and are means ± SEM of three determinations.

[b]Proximal, intermediary and distal segments correspond to duodenojejunal area, remaining jejunum and ileum, respectively.

since no evidence for the presence of phospholipases C or D has yet been provided. In this respect, these results confirm previous findings that dialkylphospholipids are not hydrolyzed in the intestinal lumen of rat (39). One could argue that the disappearance of radioactive 1,2-dihexadecyl-GPC might simply reflect a passive adsorption onto the intestinal mucosa or some entrapment within the mucus. However, the radioactive phospholipid could not be removed by extensive washing.

The comparison between diacyl-GPC and alkylacyl-GPC leads to conclusions similar to those obtained by Paltauf (40) in the rat. Indeed, the latter compound is less absorbed than its diacyl analog. This absorption could even be somewhat less than observed, since it was not corrected for the presence of 10% lysocompounds in the substrate used (see Table 1). The lower absorption of alkylacyl-GPC vs diacyl-GPC could be explained by a different fate of the degradation products (lysophospholipid or FFA, respectively, rather than by a difference in the degree of hydrolysis (alkylacyl-GPC was almost entirely degraded).

Furthermore, the nature of the hydrolysis product could direct the metabolic fate of each phospholipid. Thus, palmitic acid is largely used by intestinal cells to resynthesize TG. In contrast, 1-hexadecyl-2-lyso-GPC is essentially reacylated into the corresponding phospholipid. It is tempting to speculate that the relative ratio of ester and ether lipids present in food could influence the lipid composition of chylomicrons and very low density lipoproteins formed in intestine from exogenous lipid (41).

As to the metabolism of 1-*O*-[^{3}H]alkyl-2-acyl-GPC, we found some evidence for a significant conversion into EGP and TG, with some accumulation of radioactivity in DG. Such a metabolic behavior is more difficult to explain than in the case of 1-[^{3}H]palmitoyl-2-acyl-GPC, where [^{3}H]palmitic acid is the direct precursor. One cannot exclude that the *O*-alkyl-bond was not cleaved in intestinal cells by a monooxygenase similar to that described in liver (42), followed by oxidation of hexadecanol to palmitic acid. In this respect, Paltauf (39) observed that 3 hr after oral administration of 1-*O*-[^{3}H]octadecyl-2-acyl-GPC, 93% of intestinal phosphatidylcholine was in diacyl-GPC.

However, it also could be possible that 1-*O*-[^{3}H]hexadecyl-2-acyl-GPC are converted into DG through the reverse action of CDP choline:DG cholinephosphotransferase (43,44) or by a phospholipase C acting on choline phosphoglycerides, as those described in the cytosol from rat brain (45) or from dog myocardium (46). This would provide DG, which could serve as a precursor for EGP. To discriminate between these possibilities, it would be necessary to analyze the various subclasses of intestinal CGP. However, this was not the aim of the present work.

The major purpose of this study was to investigate the intestinal absorption of natural ether glycerophospholipids in the guinea pig, chosen as a model because of the absence of pancreatic phospholipase A_2. Unexpectedly, 1-*O*-alkyl-2-acyl-GPC was absorbed at a rather good level; this involved its hydrolysis by a phospholipase A_2-like enzyme. Although intestinal phospholipases have been described in several species (26,47–53), their physiological role has not been emphasized. Such studies have been hampered by the fact that the small intestine is heavily contaminated by the high phospholipase A_2 activity originating from pancreas. Thus, the lack of phospholipase A_2 in guinea pig pancreas (9) offers significant methodological advantages over other species in investigations dealing with intestinal phospholipase A_2. Indeed, despite the contamination by a high phospholipase A_1 originating from the pancreatic gland, the present study provides clear evidence that guinea pig intestine contains a phospholipase A_2. This conclusion is supported by the observation that intestinal homogenates as well as purified fractions are able to generate 1-[^{3}H]palmitoyl-GPC and 1-[^{3}H]hexadecyl-GPC from the corresponding diradyl-GPC. However, determination of lysocompounds yields enzyme activities lower than those measured by following liberation of [^{14}C]linoleic acid from 1-acyl-2-[^{14}C]-linoleoyl-GPC. This might be explained by the fact that 1-[^{3}H]palmitoyl-GPC can be further degraded by the contaminating phospholipase A_1, which was shown to display a high lysophospholipase activity (12). As to the still lower activity measured with alkylacyl-GPC as a substrate, this might reflect some preferential hydrolysis of diacyl-GPC.

This new intestinal phospholipase A_2 seems to differ from the enzyme described by Mansbach et al. (51) in various mammalian species and purified by Verger et al. (52–53) from porcine small intestine. The latter phospholipase A_2 has been localized in Paneth cells situated in crypts from the jejunum (53), whereas the guinea pig intestine phospholipase A_2 is unambiguously and specifically located in the brush border membrane of the small intestine. Also, the pig enzyme proved almost inactive against phosphatidylcholine and displayed a strong preference for phosphatidylglycerol (51–53), in contrast to the phospholipase A_2 described herein, which was detected using CGP as substrates. Finally, the activity found in the guinea pig intestine does not seem to require calcium. Indeed, although $CaCl_2$ was routinely added to our incubation medium, its omission was without effect on the phospholipase A_2 activity, and so was the addition of EGTA. However, these results must be taken with some caution, since they were obtained with a crude enzyme preparation. Further studies on the purified enzyme are required before the new enzyme can be classified as belonging to a group of some recently described calcium-independent phospholipases A_2 (46,54).

Effect of Lecithin on the Release of 5′-Nucleotidase from Liver Plasma Membrane of Rat by Bile Acids

Munetaka Nokubo
First Laboratory of Clinical Physiology, Tokyo Metropolitan Institute of Gerontology, 35-2, Sakaecho, Itabashi-ku, Tokyo-173, Japan

Bile acids solubilize proteins from liver plasma membrane both in vivo and in vitro. The ability to solubilize the proteins is dependent on the species of bile acid. In this paper, the effect of phospholipid on the solubilization of a membrane-bound enzyme by bile acids was investigated in vitro. Taurocholate (TC) and tauroursodeoxycholate (TUDC) solubilized the enzyme, 5′-nucleotidase, from the liver plasma membrane of the rat in a concentration-dependent manner, although there was a great difference in their effect; at 40 mM, TC solubilized 55.4% of the original 5′-nucleotidase activity of the membrane, but TUDC only 5.7%. While lecithin alone had no solubilizing effect, its addition to the bile acids provoked a 10-fold increase in the solubilizing effect of TUDC, but virtually no change for TC, essentially equalizing the solubilizing effect of the two. Both TC-rich and TUDC-rich bile were obtained from rats infused with the respective bile acids via the jugular vein after their endogenous bile acid pool had been depleted. The solubilization effect of these biles was quite similar to the bile acid-lecithin mixtures. These findings demonstrate that lecithin enhances the ability of the bile acids to solubilize the membrane protein and eliminates the difference in the two bile acid species in their solubilizing ability.
Lipids 22, 41–44 (1987).

A large number of proteins is present in the bile of many mammalian species. It has been suggested that these proteins derive from serum and cells. Mullock et al. (1) indicated that some proteins in rat bile were immunologically related to proteins present in serum. Coleman and coworkers (2,3) showed that there were several plasma membrane-bound enzyme activities in bile. They also suggested that the presence of plasma membrane-bound enzymes in bile may be the result of bile salt action on the plasma membrane in the bile canaliculus.

Hatoff and Hardison (4), using bile-fistula rats, found that alkaline phosphatase, a typical plasma membrane enzyme, was secreted into bile in a bile acid species-dependent manner that was in the order taurodeoxycholate > TC > TUDC. Other investigators (5–7) also reported similar observations.

It is well known that bile acid exists in bile as a form of mixed micelles together with phospholipid and cholesterol (8,9). However, there is little information about the effect of phospholipid on the solubilization of protein from the membrane by bile acid. Therefore, in this paper, the ability of single micelles of bile acid and mixed micelles of bile acid-lecithin to solubilize 5′-nucleotidase from the hepatic plasma membrane of the rat in vitro are compared. TUDC was used because it causes minimal damage to cells and TC because it is the most common bile acid in rat bile.

MATERIALS AND METHODS

Animals. Nonfasted, male Fischer-344 rats weighing 200–350 g were used in all experiments.

Preparation of liver plasma membrane. Rat liver plasma membrane was prepared by the method of Boyer and Reno (10) with a slight modification, using 1 mM $NaHCO_3$ buffer (pH 7.5) containing 0.5 mM $CaCl_2$. The membrane was suspended in 1 mM $NaHCO_3$ buffer (pH 7.5) and stored in liquid nitrogen until used.

Release of 5′-nucleotidase from liver plasma membrane. The liver plasma membrane suspension was centrifuged at 6,000 × g for 10 min. The supernatant fluid was carefully removed. The resultant membrane precipitate was dispersed by pipetting at 4 C in 1 ml Tris-acetate buffer (pH 7.4) containing various concentrations of bile acid. This membrane suspension was incubated at 37 C for 10 min in a shaking water bath. An aliquot fraction of the suspension was removed and assayed for 5′-nucleotidase ("total") activity. The incubation was terminated by centrifugation at 6,000 × g for 10 min at 4 C. The supernatant was carefully separated from the precipitate and filtered through a 0.22 μm Millex-GV filter (Millipore Co., Bedford, Massachusetts). Then the filtrate was assayed for soluble 5′-nucleotidase ("soluble") activity. Relative activity of solubilized 5′-nucleotidase was expressed as percent ratio of the soluble activity to the total activity. When bile was used instead of bile acid solution, the activity of 5′-nucleotidase in the bile was subtracted from the activity in each fraction.

Assay of 5′-nucleotidase activity. The activity of 5′-nucleotidase was determined by the method of Nakamura and Kameyama (11) with slight modifications. The reaction mixtures contained 4 mM 5′-AMP, 4 mM $MgCl_2$, 100 mM Tris-acetate (pH 7.4) and the protein sample in a final volume of 0.5 ml. The reaction was run for 5 min at 37 C and terminated by addition of 1 ml of 8% trichloroacetic acid. Then 2 ml of $CHCl_3$ was added, mixed by vortexing, and centrifuged at 3,000 rpm for 5 min. One ml of the upper aqueous solution was used to determine inorganic phosphate.

Collection of rat bile. Rats were anesthetized by pentobarbital. The bile duct and the jugular vein were cannulated with PE-10 tubing, which was tunneled subcutaneously to emerge from the back of the animal. After the incisions were sutured, the rat was placed in a Bollman-type restraining cage with ad libitum access to food and water. Bile was drained overnight (ca. 14 hr) to deplete the endogenous bile acid pool. One of the bile acids in a 3% albumin solution (pH 7.4, 300 mOs) then was infused into the jugular vein at 0.27 μmol/100 g body weight/min by a constant infusion pump while collecting bile. The bile was collected for 8 hr after the first 30-min infusion. Concentrations of total bile acid and phospholipid in the bile obtained from rats infused with TUDC were 40.0 mM and 5.51 mM, respectively. TUDC was the main bile acid in the bile and 85.2% of the total bile acid (TUDC bile.)

In the case of infusion of TC, TC was 93.1% of total bile acid in the bile (TC bile), and concentrations of total bile acid and phospholipid were 32.3 mM and 5.31 mM, respectively.

Chemical determinations. Total bile acid in bile was determined using 3α-hydroxysteroid dehydrogenase (12).

Analysis of each bile acid in bile was carried out by high performance liquid chromatography (HPLC) with a Bile-pack column (JASCO, Tokyo, Japan) and an immobilized 3α-hydroxysteroid dehydrogenase, Enzymepack (JASCO; 13). Total lipid phosphorus in the bile was determined by the method of Bartlett (14). Protein in the hepatic plasma membrane was determined by the method of Lowry et al. (15) with bovine serum albumin as standard.

Chemicals. TC and TUDC were donated by Tokyo Tanabe Co. (Tokyo, Japan). These bile acids were more than 98% pure when examined by HPLC. Purified egg yolk lecithin was a gift from S. Urano (Isotope Laboratory, Tokyo Metropolitan Institute of Gerontology). 5′-AMP, NAD, and 3α-hydroxysteroid dehydrogenase were purchased from Sigma Chemical Co. (St. Louis, Missouri). All other chemicals were obtained from various sources as analytical grade reagents.

RESULTS

Figure 1 shows the effect of bile acids on the solubilization of 5′-nucleotidase activity from liver plasma membrane of the rat. In the absence of bile acids, a negligible amount of 5′-nucleotidase activity was released into the soluble fraction from the membrane. This result suggested that mechanically disrupted membrane fragments did not pass through the 0.22 μm Millex-GV filter. When the membranes were incubated with various concentrations of bile acids, the release of 5′-nucleotidase activity from the membrane was dependent upon the bile acid concentration. The difference between TUDC and TC's ability to solubilize the enzyme from the membrane was remarkable at higher concentrations (20 and 40 mM). At 40 mM, TC released about 10 times more 5′-nucleotidase activity into the soluble fraction than TUDC.

Figure 2 shows the solubilization of 5′-nucleotidase activity from the membrane by various combinations of bile acid, lecithin and cholesterol. When the membrane was incubated with mixed micelles of TUDC-lecithin (40 and 8 mM), 10 times more 5′-nucleotidase activity was released than with 40 mM TUDC alone, while lecithin alone did not release any activity into the soluble fraction. Mixed micelles of TUDC-lecithin-cholesterol (40, 8 and 0.4 mM) had the same effect as the mixed micelles of TUDC-lecithin. When the membrane was incubated with TC-lecithin (40 and 8 mM) or TC-lecithin-cholesterol (40, 8 and 0.4 mM), these mixed micelles had the same effect as 40 mM TC alone in releasing the activity of the enzyme from the membranes.

In the case of TC, 40 mM TC alone already released the maximal enzyme activity from the membrane. But when lecithin was added to 20 mM TC, the mixed micelles released twice as much 5′-nucleotidase activity as 20 mM TC alone (Fig. 3). The effect of lecithin on the solubilization of 5′-nucleotidase by different concentrations of bile acids is shown in Figure 3. The difference between TUDC alone and TC alone in the ability to release the enzyme

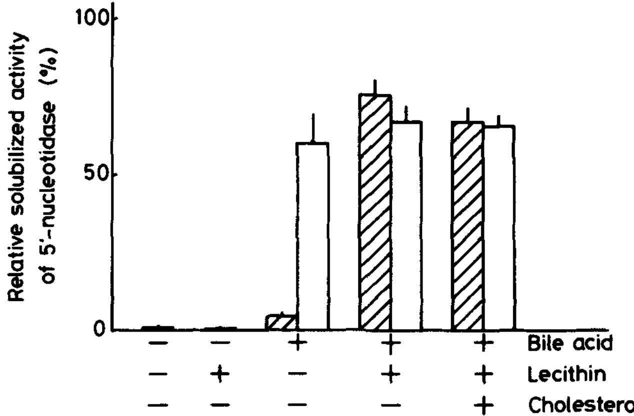

FIG. 2. Solubilization of 5′-nucleotidase from the liver plasma membrane of the rat by bile acids, bile acid-lecithin and bile acid-lecithin-cholesterol. Liver plasma membranes were incubated with mixtures of various combination of 40 mM bile acids (TUDC or TC), 8 mM lecithin and 0.4 mM cholesterol. The relative solubilized activity of 5′-nucleotidase was determined by the method described in the text. Values are means of three or four experiments. Vertical bar expresses S.D.; hatched columns, TUDC; open columns, TC.

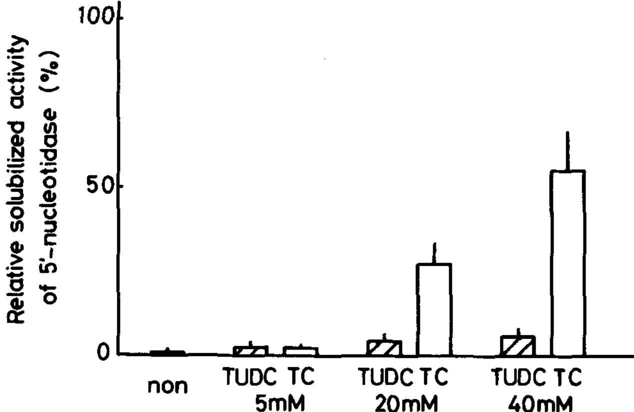

FIG. 1. Solubilization of 5′-nucleotidase from the liver plasma membrane of the rat by bile acids. Liver plasma membranes were incubated with various concentrations of bile acids (TUDC or TC). The relative solubilized activity of 5′-nucleotidase was determined by the method described in the text. Values are the means of three or four experiments; vertical bar expresses S.D.

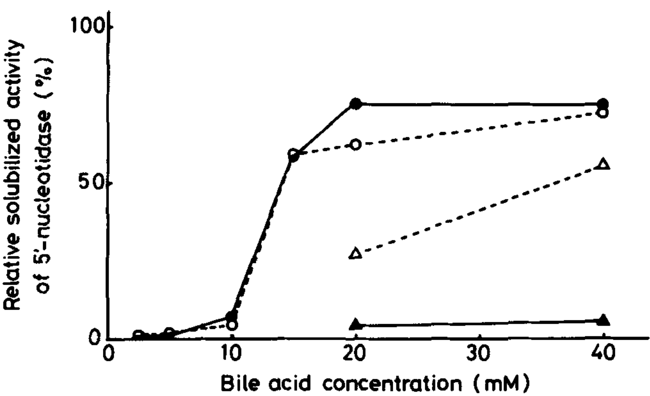

FIG. 3. Effect of lecithin on the solubilization of 5′-nucleotidase from rat liver plasma membrane by different concentrations of bile acids. Liver plasma membranes were incubated with various concentrations of bile acids containing either 8 mM egg yolk lecithin or none. The relative solubilized activity of 5′-nucleotidase was determined by the method described in the text. Values are means of four experiments. ●, TUDC + lecithin; ○, TC + lecithin; ▲, TUDC; △, TC.

disappeared with the addition of lecithin at the concentrations of bile acids tested. At lower concentrations of the bile acids (2.5 and 5 mM), 8 mM lecithin did not show any effect on the solubilization. At bile acid concentrations higher than 10 mM, lecithin had a pronounced effect on the solubilization by both bile acids.

When various concentrations of lecithin were added to 40 mM TUDC, the solubilization of 5′-nucleotidase increased in a concentration-dependent manner up to 2 mM (Fig. 4). Thereafter, the effect of lecithin remained steady.

To compare bile with bile acid-lecithin mixtures in the solubilization of 5′-nucleotidase from rat liver plasma membrane, TUDC bile and TC bile were used. When the membranes were incubated with these biles, the activities of 5′-nucleotidase in the soluble fractions were practically the same (Table 1).

DISCUSSION

In the present in vitro study, TUDC released less 5′-nucleotidase from the liver plasma membranes of the rat than TC. This is consistent with previous reports (4–7). Hatoff and Hardison (4) showed that TUDC was less effective than TC in the release of enzymes from liver plasma membrane both in vivo and in vitro. Barnwell et al. (5,6), using isolated perfused rat livers, and Kitani et al. (7), using bile fistula rats, reported similar observations. In the present study, however, mixed micelles of bile acids and lecithin did not reveal any difference between the bile acid species. Furthermore, the bile obtained from rats infused with TC or TUDC did not reveal any difference in their ability to solubilize 5′-nucleotidase. These findings suggest that there is no specific factor in bile that discriminates between the mixed micelles of native bile and synthetic mixed micelles in respect to the solubilization of 5′-nucleotidase. It cannot be absolutely stated that minor bile acids in TUDC bile are not the cause for its conspicuous ability to solubilize the membrane-bound proteins. But this hypothesis seems unlikely because when ursodeoxycholate was infused into rats, the main metabolite was TUDC and the second metabolite was a small quantity of β-muricholate, which is considered to have little surface activity or detergent effect (16–18).

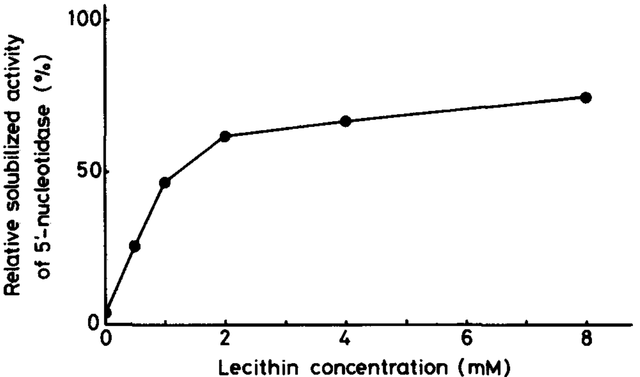

FIG. 4. The effect of different concentrations of lecithin on 40 mM TUDC's solubilization of 5′-nucleotidase from the liver plasma membrane of the rat. The liver plasma membranes were incubated with 40 mM TUDC containing various amounts of lecithin. The relative solubilized activity of 5′-nucleotidase was determined by the method described in the text. Values are means of three experiments.

TABLE 1

Solubilization of 5′-Nucleotidase from the Liver Plasma Membrane of Rat by Biles

Bile	Relative solubilized activity of 5′-nucleotidase (%)
TUDC bile	60.6 ± 3.9
TC bile	57.2 ± 2.7

Values are the means of four experiments ± S.D.

Recently Lowe et al. (19), using a perfusion of isolated rat liver, reported that mixed micelles cannot be formed inside the cell or during passage of bile salts through the membrane. They suggested that the formation of mixed micelles occurs in the bile canaliculus lumen. Their report prompts the speculation that the difference between the in vivo and in vitro effect of bile acids on solubilizing the enzyme from the membrane is that the release of the enzyme occurs soon after bile acid is secreted into the bile canaliculus and before the bile acid forms mixed micelles with the phospholipid. Once mixed micelles are formed, it might be difficult for them to interact with the membrane. Concerning this, Wilson and Dietchy (20), using rat intestine, reported that mixed micelles of bile acid and lecithin were much larger than single micelles of bile acid alone, so that the mixed micelles were more difficult to diffuse through the unstirred water layer that exists at the surface of membranes.

In the present study, the mixed micelles of bile acid-lecithin were more effective solubilizers than single micelles of bile acid alone. Nevertheless, Coleman et al. (21), using rabbit bile and glycodeoxycholate, reported that the release of hemoglobin and acetylcholinesterase from human erythrocytes was greatly reduced by the addition of lecithin. We cannot directly compare these results, since there are many differences in the experimental conditions.

Recently 5′-nucleotidase was purified from rat and mouse liver by several investigators (22–24). Widnell and Unkeless (22) and Nakamura (24) reported that partially purified 5′-nucleotidase contained phospholipids. They reported that 5′-nucleotidase interacted with both sphingomyelin and lecithin, which influenced the stability of the enzyme and the energy of activation, respectively (25). Furthermore, the partially purified enzyme easily reassociated with phospholipid vesicles by treatment with bile acid. Considering these results, the mixed micelles of bile acid-lecithin may include 5′-nucleotidase, released from the membrane by bile acid treatment.

In conclusion, in vitro, single micelles of TUDC or TC released 5′-nucleotidase from rat liver plasma membrane in a characteristic species-dependent manner. TUDC produced less solubilization than TC. These observations are comparable to similar studies in vivo. The differences in the solubilization by bile acids disappeared when the bile acids were mixed with lecithin. Similarly, there was no bile acid species difference for TUDC bile and TC bile in the solubilization of 5′-nucleotidase. These observations suggest that the interactions of bile acid and the membrane are greatly affected by lecithin.

[Received June 27, 1986]

Asymmetric Distribution of Arachidonic and n-3 Polyunsaturated Fatty Acids in Rat Liver Microsomal Membranes Under a Fat-Free Diet

Nobuko Iritani*, **Hisako Mizoguchi** and **Misao Kitaya**
Tezukayama Gakuin College, 4-cho, Harumidai, Sakai, Osaka 590-01, Japan

Rats adapted to a corn oil or a fish oil diet were fed a fat-free diet, and changes in phospholipid polyunsaturated fatty acids (PUFA) in the inner and outer leaflets of liver microsomal membranes were followed for 18 wk. In rats previously adapted to a corn oil diet, arachidonic acid in phosphatidylcholine and phosphatidylethanolamine in the inner and outer leaflets did not decrease quickly; rather, linoleic acid decreased more than arachidonic acid for the first three weeks of feeding the fat-free diet. Even at 18 wk, 40–50% of the beginning arachidonic acid levels were still retained. In contrast, in rats previously adapted to a fish oil diet, the n-3 PUFA were quickly decreased by the fat-free diet to only 10–30% at 18 wk. Due to the appearance and increase of n-9 eicosatrienoic acid in the replacement of the n-3 and n-6 PUFA, total PUFA did not decrease in the inner and outer phosphatidylcholine in either group, but decreased somewhat in the phosphatidylethanolamine due to the insufficient increase of the n-9. On the other hand, the overall degrees of unsaturation in phosphatidylcholine fatty acids were always higher in the outer than in the inner leaflets and were not altered by feeding the fat-free diet even for 18 wk. Thus, the results appear to reveal the physiological importance of unsaturation ratio of fatty acids and the necessity of arachidonic acid in each membrane leaflet.
Lipids 22, 45–50 (1987).

We previously reported that n-3 polyunsaturated fatty acids (PUFA) compete with arachidonic acid for the C-2 position of phospholipids of rat liver, plasma and heart (1). When rats adapted to a fat-free diet were fed a corn oil diet, endogenous n-9 eicosatrienoic acid (the major PUFA) at the C-2 positions of both phosphatidylcholine (PC) and phosphatidylethanolamine (PE) was quickly substituted by arachidonic acid in liver, plasma and platelets (2). Comparably, with a fish oil diet, the n-9 was quickly substituted by n-3 PUFA. In both cases, the n-9 almost disappeared in six days. On the other hand, when the dietary process was reversed, arachidonic acid in both the phospholipid classes decreased slowly, whereas the n-3 quickly decreased in the platelets and the liver mitochondria and microsomes (2). These results may reveal the physiological significance of arachidonic acid in membrane phospholipids. On the other hand, the existence of phospholipid asymmetries in biological membranes has been demonstrated, and the membrane asymmetry would play an important role of physiological significance on membrane function (3–12). In the present experiment, the effects of the fat-free diet feeding on asymmetric distribution of PC and PE PUFA in the inner and outer monolayers of the microsomal membranes of rat liver have been investigated.

MATERIALS AND METHODS

Animals. Male Wistar rats, 4 weeks old, were fed a 5% corn oil or 5% fish oil diet for 2 wk and then a fat-free diet for indicated periods. The fat-free diet contained 68.5% sucrose, 18% casein, 9.5% cellulose, 4% salt mixture (13), 0.1% choline chloride and vitamins (13). The amount of 5% sucrose was substituted by fat in the 5% fat diet. The fatty acid compositions of corn oil were 8.5% palmitic, 3.8% stearic, 40.1% oleic, 46.1% linoleic and 1.5% other minors. Those of fish oil (from pollack liver) were 24.3% palmitic, 6.9% palmitoleic, 4.3% stearic, 14.8% oleic, 0.7% linoleic, 4.0% arachidonic, 10.8% eicosapentaenoic, 25.6% docosahexaenoic and other minors. The rats were maintained under an automatic lighting schedule at 24 C and were given water and food ad libitum.

Preparation of microsomes. The animals were killed by decapitation at 9–10 a.m. on the days indicated in figures and tables. The livers were quickly removed to take microsomes. Liver homogenate was prepared in 3 vol of 0.25 M sucrose using a Teflon-glass homogenizer and centrifuged at 16,000 × g for 10 min. The supernatant was again centrifuged at 105,000 × g for 45 min (Spinco Model L-5 50, Beckman, Palo Alto, California). The 105,000 × g pellets were used as microsomal fractions.

Incubation with phospholipase C and lipid extraction. Microsomes (10–15 mg) were incubated with 2–6 U phospholipase C from *Clostridium welchii* (Type X, Sigma Chemical Co., St. Louis, Missouri) in 2 ml of 0.25 M sucrose, 1 mM $CaCl_2$ and 10 mM Tris-HCl, pH 7.5, at 25 C for 30 min, essentially according to the method of Higgins and Dawson (10). After incubation, an aliquot of the microsomes was taken to be measured for mannose-6-phosphatase, as described below. The incubation mixture with phospholipase C was extracted with 20 ml of chloroform/methanol (2:1, v/v), and lipids were contained in the upper phase. The lipid extract was dissolved in chloroform/methanol (1:1, v/v), and an aliquot was used for separation of lipid classes. PC was separated on thin layers of silica gel (Merck, Darmstadt, Federal Republic of Germany), using a one-dimensional system (chloroform/methanol/water, 65:25:4, v/v/v) and estimated as the amount in inner membranes. Lipid-containing spots were detected by iodine vapor, scraped into test tubes and digested with perchloric acid for 30 min at 230 C to measure phosphorus. Water was added and the tubes were centrifuged to remove the silica gel. Phosphorus was determined on the supernatant by the method of Bartlett (14). An aliquot of lipids was used for analysis of fatty acids. Fatty acids were analyzed by gas chromatography as described previously (2). The amounts of PC fatty acids in the outer monolayer of the membranes were calculated by subtracting the amount of inner fatty acids from total PC fatty acids, which were similarly measured using intact microsomes.

Labeling with trinitrobenzenesulfonate (TNBS). PE in the cytosolic site of membranes was labeled with TNBS

(11). Microsomes (12 mg of protein) were incubated at 25 C in 6 ml of a medium containing 10 mM Tris-HCl (pH 7.7), 0.25 M sucrose and 1 mM TNBS for 20 min (when not otherwise indicated). After incubation, the reaction was stopped by acidification of the medium to pH 6.8 and centrifuged for 20 min at 40,000 × g. The supernatant fluids were discarded, and the pellets were washed twice with 10 ml of the suspending medium without the probes. Lipids were extracted from the layers with chloroform/methanol (2:1, v/v) and the two forms of PE (with and without labeling with TNBS) were separated on thin layers of silica gel using a solvent of chloroform/methanol/water (65:25:4, v/v/v). Phosphorus and fatty acids were determined as described above.

Measurement of leakage of microsomal content. To examine leakage of microsomal content during the incubation of microsomes with phospholipase C, the leak of mannose-6-phosphatase activity was measured (15). For assay of the mannose-6-phosphatase activity, microsomes were incubated with 4 mM mannose-6-phosphate, 1 mM EDTA, 60 mM malate buffer, pH 6.5 and 0.25 M sucrose at 37 C for 15 min. The incubation was stopped by adding 1 ml of 10% TCA, and the phosphorus amount in the supernatant was measured by the method of Bartlett (14). Total mannose-6-phosphatase activity was similarly measured using disrupted microsomes. The disrupted microsomes were prepared to 0 C by supplementing 9 vol of intact microsomes (1 to 2 mg of protein/ml) with 1 vol of 4% sodium taurocholate, pH 7.6. The taurocholate-dispersed microsomes were kept on ice at least 30 min before assays were performed (16).

RESULTS AND DISCUSSION

Treatment of liver microsomes by phospholipase C. Hydrolysis of microsomal PC by increasing concentrations of phospholipase C proceeded until ca. 70–75% of PC phosphate was removed after 30 min of incubation. The hydrolysis was almost constant in the range of 1–3 U phospholipase C/ml (Fig. 1). The amount of PC hydrolyzed increased linearly with microsomal concentrations (5–20 mg), but the percentage remained constant (data not shown). Although hydrolysis of PC was tried by several concentrations of phospholipase C (1–3 U/ml) for each sample, the experimental conditions described above were available for all samples during the long-term feeding of the fat-free diet. The microsomes incubated with 1.5 U phospholipase C/ml were used for the determination of mannose-6-phosphatase and the analysis of PC fatty acids.

Leakage of microsomal content. To determine if microsomal vesicles remained intact under the contributions of incubation with phospholipase C, mannose-6-phosphatase latency was determined at the same protein concentrations as a quantitative index of microsomal integrity. Less than 6% of mannose-6-phosphatase leaked into the incubation medium, indicating that the microsomal permeability barrier remained almost intact.

Labeling of outer PE with TNBS. TNBS labeling of microsomes converted ca. 30% of PE to trinitrophenyl PE, and this value did not increase when the incubation time was increased to 60 min. As shown in Figure 2, the reaction reaches a plateau at 0.5–2 mM TNBS. TNBS labeling of microsomes was conducted in a medium of 1 mM TNBS for 20 min at 25 C, as the conditions were available for all samples under the fat-free diet for 18 wk.

Phospholipid fatty acid composition in inner and outer leaflets of rat liver microsomal membranes. The effects

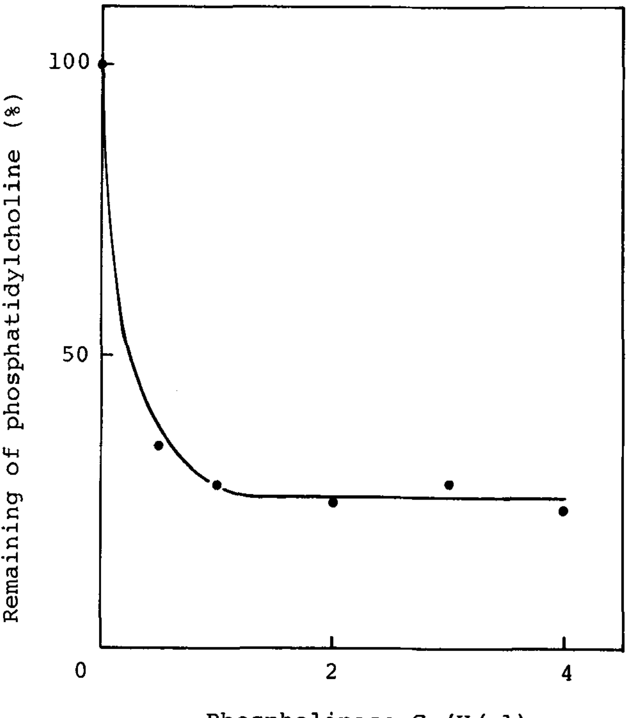

FIG. 1. Hydrolysis of microsomal phosphatidylcholine by phospholipase C. Liver microsomes (10–15 mg protein) were incubated with 2–6 U phospholipase C from *Clostridium welchii* in 2 ml for 30 min at 25 C. The lipids were extracted and remaining phosphatidylcholine was separated on thin layers of silica gel.

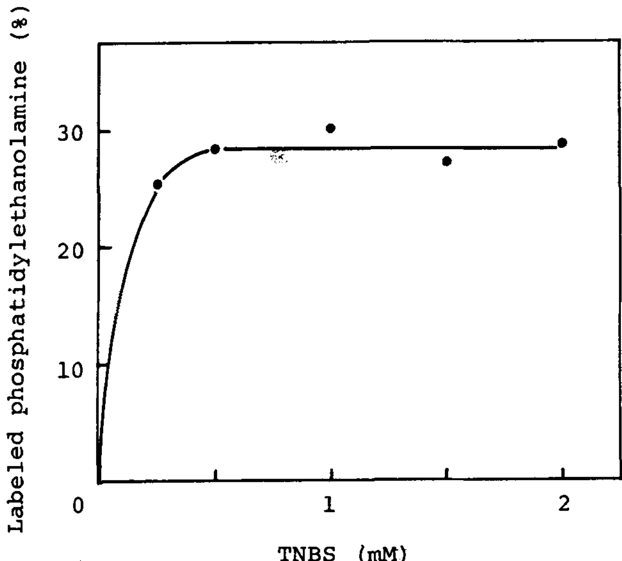

FIG. 2. The extent of reaction of microsomal phosphatidylethanolamine with trinitrobenzenesulfonate (TNBS). Rat liver microsomes (12 mg protein) were incubated with TNBS for 20 min at 25 C. The lipids were extracted and then the two forms of phosphatidylethanolamine (with and without labeling with TNBS) were separated on thin layers of silica gel.

of dietary fat manipulation on distribution of phospholipid fatty acids in the inner and outer leaflets of rat liver microsomal membranes were investigated. The fatty acid compositions in PC and PE of the inner and outer leaflets are shown in Tables 1 and 2. The results in rats adapted to corn or fish oil diets and in those subsequently fed a fat-free diet for 18 wk were compared. The predominant species of fatty acids are the same among the inner and outer PC and PE, except that in the animals adapted to the corn oil diet, linoleic acid is one of the predominant species in the outer PC, but not in the inner PC or the inner and outer PE. The overall degree of unsaturation was used as a parameter for comparing the fatty acid distribution as an "unsaturation ratio," which is defined as the total amount of unsaturated fatty acids divided by the total amount of saturated ones. The unsaturation ratios in the inner and outer PC and PE were unchanged by the long-term feeding of the fat-free diet, as shown in Tables 1 and 2. In PC, however, the unsaturation ratios were significantly higher in the outer than the inner leaflet

Rats adapted to a corn or fish oil diet were fed a fat-free diet for 18 wk. Fatty acid compositions were compared between, at the beginning and the end of the fat-free diet feeding. To avoid complication, only mean values (μg/mg protein) are shown for the amounts of fatty acids in the inner and outer leaflets of liver microsomal membranes. Unsaturation ratios are defined as the total amount of unsaturated fatty acids divided by the total amount of saturated ones. Mean or mean ± SE (n = 3-5). Significantly different from the corresponding outer membrane. *, $P < 0.01$, **, $P < 0.001$ (by Student's t-test).

Rats adapted to a corn or fish oil diet were fed a fat-free diet for 18 wk. To avoid complication, only mean values (μg/mg protein) are shown for the amounts of fatty acids in the inner and outer leaflets of liver microsomal membranes. Unsaturation ratios are defined as the total amount of unsaturated fatty acids divided by total amount of saturated ones. No significant difference was found among the results. Mean or Mean ± SE (n = 3-5).

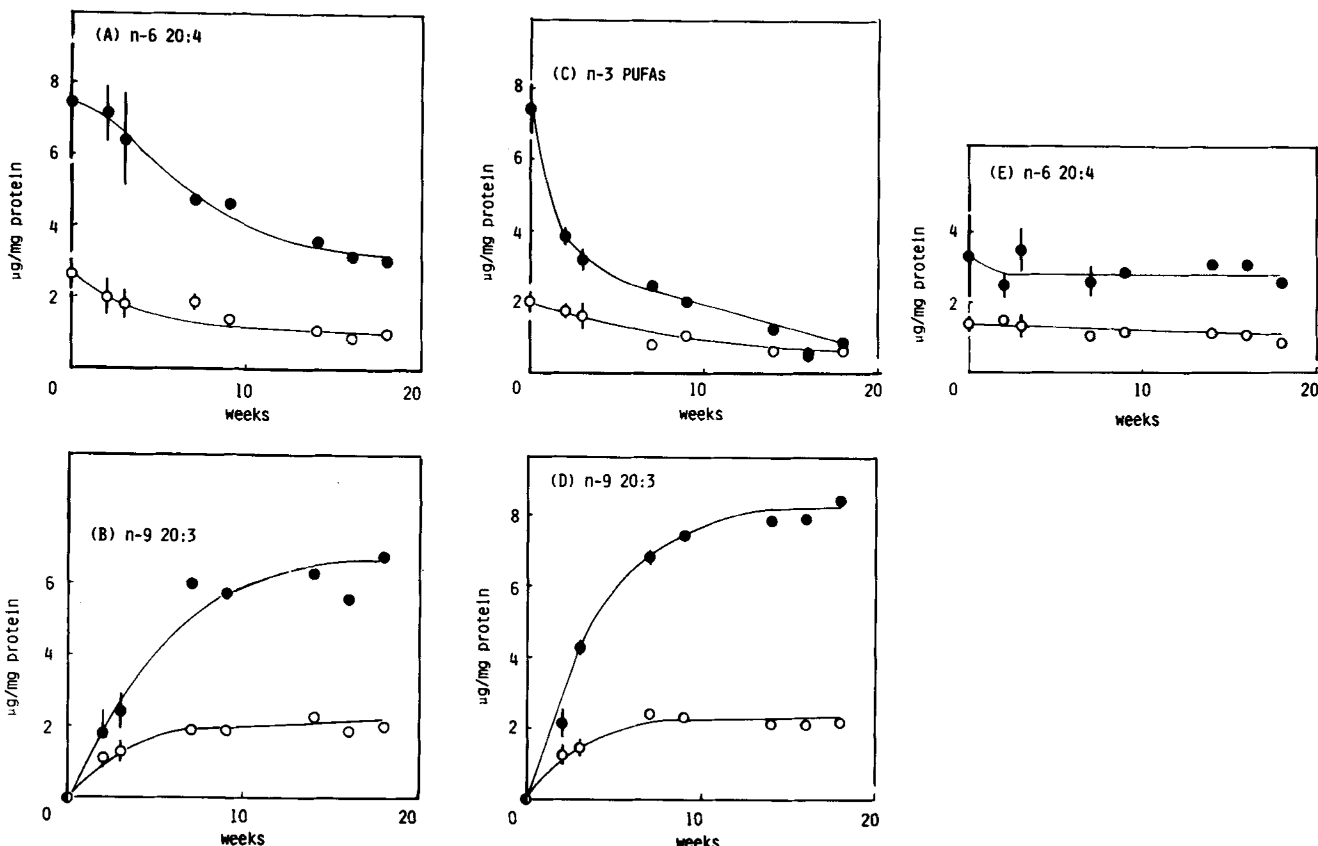

FIG. 3. Effects of feeding a fat-free diet on polyunsaturated fatty acids (PUFA) with more than three double bonds in phosphatidylcholine in the inner and outer leaflets of liver microsomal membranes. In rats previously adapted to corn oil or fish oil diets and then fed a fat-free diet, the levels of PUFA were followed for 18 wk. White and black circles show the PUFA levels in the inner and outer leaflets, respectively. A, B: rats adapted to the corn oil diet; C, D, E: rats adapted to the fish oil diet. Mean or mean ± SE (n = 3–5).

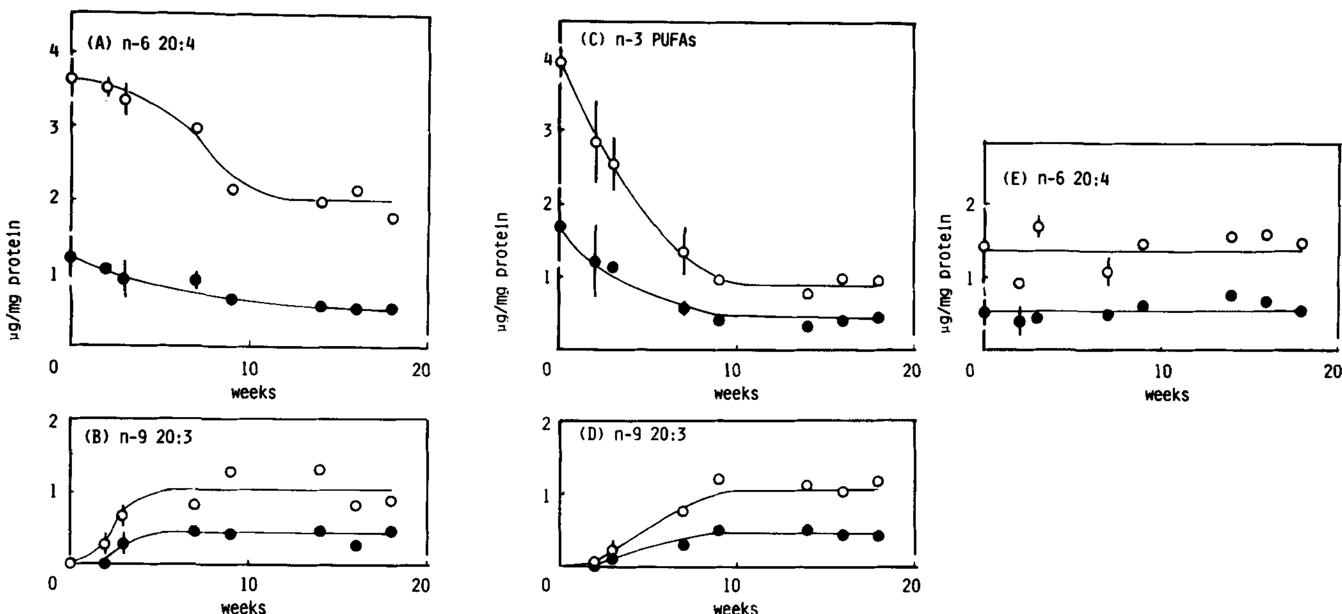

FIG. 4. Effects of feeding a fat-free diet on polyunsaturated fatty acids (PUFA) with more than three double bonds in phosphatidylethanolamine in the inner and outer leaflets of liver microsomal membranes. Levels of PUFA in the inner and outer phosphatidylethanolamine of the liver microsomal membranes in the same animals are shown in Fig. 3. White and black circles show the PUFA levels in the inner and outer leaflets, respectively. A, B: rats adapted to the corn oil diet; C, D, E: rats adapted to the fish oil diet. Mean or Mean ± SE (n = 3–5).

in both the corn oil and the fish oil group, whereas the ratios in PE were similar in the inner and outer leaflets.

Changes in phospholipid PUFA under a fat-free diet. Figure 3 shows time courses of PC PUFA levels in the inner and outer leaflets of liver microsomal membranes of rats previously adapted to corn or fish oil diets and then fed the fat-free diet. The time courses of PUFA in the inner and outer PE are shown in Figure 4.

In rats adapted to a corn oil diet and then fed a fat-free diet, arachidonic acid in PC of the outer leaflets decreased only slightly in 2 wk and to 87% in 3 wk, while arachidonic acid in the inner PC decreased to 68% in 3 wk. In the outer and inner PC, linoleic acid decreased more quickly than arachidonic acid for the first three weeks of the fat-free diet. Linoleic acid decreased to only one-third in 3 wk. This appears to be an arachidonic acid–saving mechanism. The inner and outer PE arachidonic acid likewise did not decrease for the first three weeks. Even after 18 wk of the fat-free diet, arachidonic acid still remained at 40–50% of the beginning levels in the inner and outer PC and PE. The n-9 eicosatrienoic acid appeared in 2 wk and increased enough to replace the decrease of arachidonic acid in the inner and outer PC in 18 wk. Due to the increase of the n-9, the beginning levels of total PUFA with more than three double bonds in PC were kept even for 18 wk. In the inner and outer PE, however, n-9 eicosatrienoic acid increased to only half the level of the decrease of arachidonic acid. Therefore, the total PUFA levels in PE decreased to 80% of the beginning level, due to the insufficient increase of the n-9.

In rats adapted to a fish oil diet and then fed a fat-free diet, the n-3 PUFA in the outer PC was decreased to half the level of the beginning in 2 wk and to only 12% in 18 wk. In the inner PC, n-3 PUFA decreased to 85% of the beginning level in 2 wk and to 33% in 18 wk. The n-3 PUFA decreased to 72% in the inner and outer PE in 2 wk and to 25% in 18 wk. However, the levels of arachidonic acid in the inner and outer PC and also PE were not much changed during the long-term feeding of the fat-free diet. With a fat-free diet, the n-3 PUFA in the inner and outer PC and PE in rats previously adapted to a fish oil diet were quickly and greatly decreased compared to the

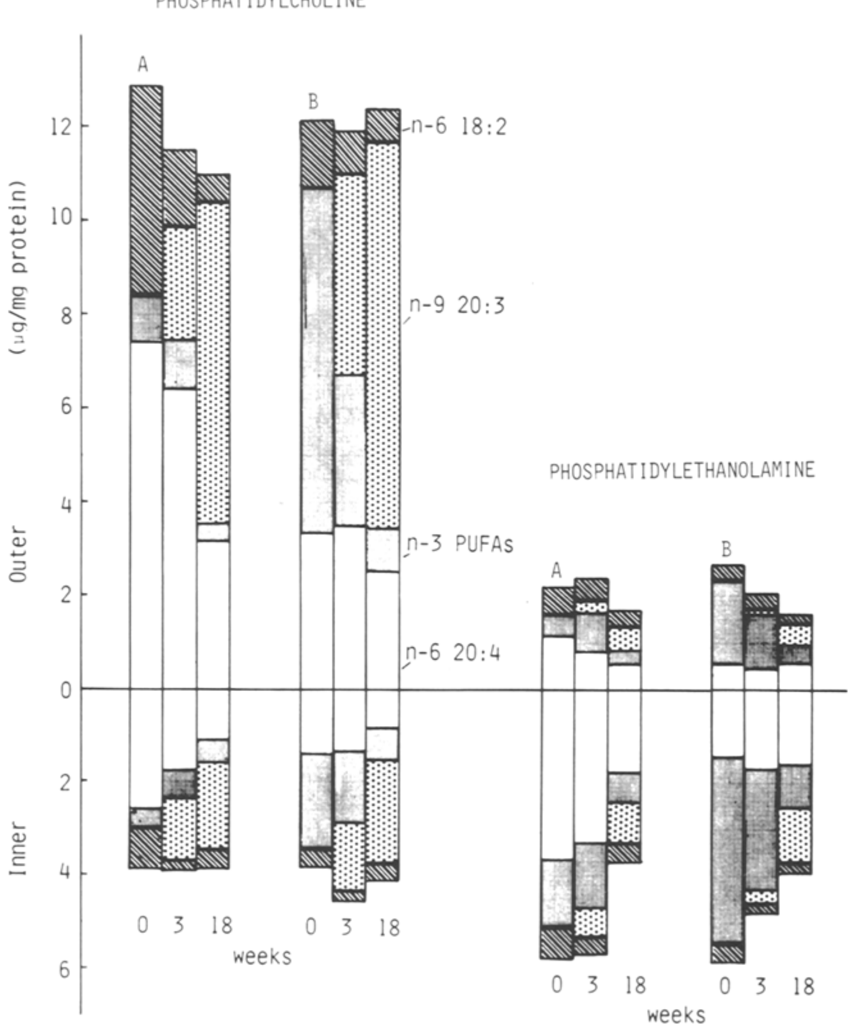

FIG. 5. Effects of feeding the fat-free diet for 3 or 18 wk on total polyunsaturated fatty acids (PUFA) of phospholipids in inner and outer leaflets of liver microsomal membranes. A, rats adapted to the corn oil diet; B, rats adapted to the fish oil diet. Mean (n = 3–5).

arachidonic acid levels of the rats previously adapted to a corn oil diet. In the replacement of n-3 PUFA, n-9 eicosatrienoic acid appeared in the inner and outer PC in 2 wk and slightly in the PE in 3 wk of the fat-free diet. The appearance of n-9 eicosatrienoic acid was delayed in the PE, especially in the fish oil group, as compared to the corn oil group. Moreover, the n-9 did not increase to the same degree as the decrease of the n-3 PUFA in the inner and outer PE.

Figure 5 shows total PUFA with more than two double bonds in PC and PE in the inner and outer leaflets of liver microsomal membranes. Considerable amounts of arachidonic acid still remained in each leaflet, and the amounts were similar between the animals adapted to a fish oil diet and those fed the fat-free diet, even for 18 wk. Therefore, these arachidonic acid levels appear to be the minimum for the physiological membrane functions. Total arachidonic acid levels in PC plus PE were higher in the outer than in the inner leaflet. Further, although linoleic acid decreased more quickly than arachidonic acid in the outer PC, a small amount of linoleic acid was retained in each leaflet even after the long-term feeding of the fat-free diet. The linoleic acid itself also may be retained for a physiological role.

Spector and Yorek (17) reported in a review that membrane fatty acid and phospholipid compositions can be modified in many different kinds of intact mammalian cells, and the modifications are extensive enough to alter membrane fluidity and affect a number of cellular functions. As a result of the present experiment, it is suggested that the unsaturated fatty acid–generating system has a tendency to compensate for the lack of essential fatty acid intake for the regulation of homeostasis in membrane fluidity and some cellular functions.

On the other hand, the endoplasmic reticulum is the major site of phospholipid biosynthesis. Ballas and Bell (12) reported that the biosynthesis of phospholipids and triglycerides occurs asymmetrically on the cytoplasmic surface of the endoplasmic reticulum. We have found that the degree of unsaturation in PC fatty acids was always higher in the outer than in the inner leaflet of the membrane bilayer. In addition, the unsaturation degrees in both the inner and outer PC and PE were not altered even by long-term feeding of the fat-free diet. The asymmetrical distribution of unsaturated fatty acids in the outer leaflet may be related to the similar distribution of the glycerolipid-generating system. The specific saving of arachidonic acid and the retaining of unsaturation degrees of fatty acids in the inner and outer leaflets of membrane bilayers may have an important relationship to membrane functions.

[Received August 1, 1986]

Lipids from *Plasmodium vinckei*-Infected Erythrocytes and Their Susceptibility to Oxidative Damage

Roland Stocker[a], William B. Cowden[b], Ross L. Tellam[b], Maurice J. Weidemann[a] and Nicholas H. Hunt[b,*]
Departments of [a]Biochemistry, Faculty of Science, and [b]Experimental Pathology, John Curtin School of Medical Research, Australian National University, Canberra, ACT 2601, Australia

The constituent lipids of plasma and red blood cells (RBC) from mice late in infection with the malarial parasite *Plasmodium vinckei* were analyzed and compared with those obtained from uninfected animals. On a dry weight basis, the total extractable lipids of RBC increased threefold during infection, while those of the plasma did not change significantly. In general, changes in individual plasma lipid constituents paralleled those found in RBC of infected mice but were of smaller magnitude. While the increase in the total lipids of parasitized RBC was largely attributable to an increase of more than fourfold in total phospholipids, a significant increase in neutral lipids was also observed. Phosphatidylcholine and phosphatidylethanolamine were the major phospholipids present within RBC, and their total and relative concentrations increased as a result of the infection. A parallel increase occurred in the ratio of unsaturated to saturated fatty acids in the parasitized RBC phospholipids. Infection was also associated with decreases in the relative amount of cholesterol present in RBC and in the ratio of cholesterol to phospholipid. Consistent with this, the fluorescence polarization of 1[4-(trimethylamino)phenyl]-6-phenylhexa-1,3,5-triene within parasitized RBC plasma membranes was decreased in comparison with its value in noninfected RBC, indicating that malarial infection decreases the "order" of membrane lipids. These modifications, in conjunction with the increased levels of vitamin E and malonyldialdehyde reported elsewhere, are important determinants of the susceptibility of the different membrane compartments within infected RBC to peroxidative damage.
Lipids 22, 51-57 (1987).

Protozoan parasites of the genus *Plasmodium,* which cause malaria, undergo repetitive cycles of asexual multiplication in appropriate vertebrate hosts. Replication occurs initially within liver parenchymal cells and, subsequently, within circulating red blood cells (RBC) following entry of the merozoite stage by invagination of the host cell membrane (1). This process gives rise to the parasitophorous vacuole, a membrane structure of RBC origin that surrounds the intracellular parasites. The cytosolic compartments of intraerythrocytic parasites therefore are separated from the blood plasma by three membranes: the plasma membrane of the RBC, the boundary membrane of the parasitophorous vacuole and the parasite plasma membrane (1). During its intraerythrocytic development, the parasite participates in dynamic exchanges of a diversity of metabolites with the blood plasma (2), which may be facilitated by changes in the structure and composition of the appropriate intervening membranes (2,3). In general, total lipids increase in malaria-infected RBC, although the extent of this increase varies between species (2-4). There is, in addition, no common pattern linking the changes that occur in the relative amounts of the major fatty acids of neutral lipids and phospholipids in malaria-infected RBCs from ducks, mice and monkeys (3,5,6).

Changes in the lipid composition and degree of saturation of the constituent fatty acids of membrane lipids are generally accompanied by alterations in the physicochemical properties of the membrane. Such changes may influence the activities of membrane-bound enzymes, membrane "fluidity" and the susceptibility of membrane components to oxidative damage (7-10). The latter may be important in the development of new antimalarial drugs, since work from this laboratory has shown that, in vitro and in vivo, murine and human malarial parasites are destroyed within intact host RBC membranes by oxygen radical-producing drugs (11-14). This observation implies a difference in the susceptibility of erythrocytic and parasitic membranes to oxidative damage. Vitamin E is the most powerful lipid-soluble antioxidant, and the large increase in its content that occurs within *P. vinckei*-infected RBC appears to be associated with the host, rather than the parasite, plasma membrane (15). One implication of this uneven distribution is that the membranes in closest proximity to the parasite might contribute selectively to the increase in spontaneous lipid peroxidation that occurs in response to increasing parasite load and maturation (15). However, factors such as differences in the amount and composition of constituent lipids are also likely to be critical in determining the relative susceptibilities of the different membranes to peroxidative damage (16). Thus, to attempt to explain the increased sensitivity of membranes from *P. vinckei*-infected RBC to peroxidative attack (11-15), it was necessary to know the lipid composition of the infected RBC and its uninfected counterpart. However, this has never been analyzed in *P. vinckei*-infected mice, and extrapolation from data obtained with other species is not justifiable because of the variability mentioned above (2-6).

MATERIALS AND METHODS

Plasmodium vinckei subsp. *vinckei,* strain V52, originally obtained from F.E.G. Cox, King's College, London, was used for all experiments. Mice were held in a natural day-night cycle at 22 C and fed with a standard laboratory rat and mouse ration (Barastoc Feeds, Murrumburah, Australia). Male CBA/CaH mice, 6-10 wk old, were infected by intraperitoneal injection of 10^6 parasitized RBC, and the extent of parasitemia was assessed by counting, on a blood smear, 200-300 cells stained with Harleco's Diff-Quik (American Hospital Supply, Sydney, Australia). Blood from control or infected animals was collected under anesthesia from the subclavian artery, heparinized (20 units/ml blood) and separated into plasma and cells by centrifugation at 2200 × g for 10 min at 4 C. Cells were resuspended in phosphate-buffered saline to 10% hematocrit and passed through a cellulose powder CF-11

column (Whatman, Maidstone, United Kingdom) to remove leukocytes before being washed twice with the same buffer. Packed cell volume was determined after the final wash by further centrifugation of the RBC under similar conditions to those described above.

Lipids (total lipids) were extracted from RBCs obtained from the pooled blood of 12–15 control or 15–20 heavily infected mice (parasitemias >80%), as described by Baech et al. (3) using chloroform and methanol containing 0.01% (w/v) butylated hydroxytoluene (Sigma, St. Louis, Missouri). Plasma lipids were extracted by the method of Sperry and Brand (17), applying their procedure 2 for purification of the lipid extracts. Values for "total lipids" were obtained gravimetrically after drying. If necessary, samples of these total lipids in chloroform/0.01% butylated hydroxytoluene were sealed under N_2 and stored at −60 C in the dark until required for further analysis. Samples of total lipids were separated into neutral lipids and phospholipids with silica Sep-Pak cartridges (Waters, Milford, Massachusetts) as described by Bitman et al. (18), and the eluates were dried with a rotary evaporator (Büchi, Flawil, Switzerland) and weighed. Samples of neutral lipids from the silica column were assayed as described for cholesterol (19) and triglycerides (20).

Quantitative analysis of individual phospholipid components in fractions obtained from the silica column was performed by separation on 20 × 20 cm preparative silica gel H TLC-plates (Merck, No. 5744, Darmstadt, West Germany). Aliquots from the phospholipid fraction, containing 2 mg lipid, were applied in 2-cm bands to the plates. A mixture of phospholipid standards (Sigma) containing, in 100 μg, equal amounts of lysolipid (LL), sphingomyelin (SM), phosphatidylcholine (PC), phosphatidylinositol (PI), phosphatidylserine (PS) and phosphatidylethanolamine (PE) was also spotted on the left and right sides of the plates. Phospholipids were developed with chloroform/methanol/acetic acid/water (50:30:10:3, v/v/v/v) (21) and visualized by iodine vapor, and the areas of silica gel that corresponded to individual phospholipids were scraped from the plates. The silica was powdered and phospholipids were eluted sequentially in four separate steps, using different solvent mixtures and vigorous shaking in between with a Rotary Evapo-Mix (Buchler, Fort Lee, New Jersey) (21). Individual phospholipids were dried at 45 C under N_2, and an aliquot was transferred to an acid-washed glass tube for phosphorus analysis. Phosphorus determination was performed according to Chen et al. (22), with the following modification: 25 μl of concentrated sulfuric acid was added to the dried sample, which was then digested at 250 C for 30 min. Phosphate-free perchloric acid (35 μl) was added and the tubes again were incubated at 250 C until the black solution lost its color (about 2 hr). Tubes were cooled, 0.5 ml water and 0.6 ml of 0.4% (w/v) ammonium molybdate plus 0.1 ml of 10% (w/v) ascorbic acid were added and the samples were incubated at 45 C for 20 min. Color formation was quantitated by reading absorbance at 820 nm; the phosphorus content was determined by comparison with standards containing 0–1.6 μg phosphorus.

Aliquots (5–10 mg) of various purified lipids from RBCs and plasmas were taken up in 4 ml of 5% (w/v) KOH (in 50% ethanol, v/v), saponified under N_2 for 1 hr at 70 C and dried at 60 C in a rotary evaporator. Water (5 ml) was added and non-saponified material removed by extracting twice with an equal volume of freshly distilled petroleum ether and discarding the organic phase. The aqueous phase was acidified to pH 1 with 1 M HCl, and the fatty acids were extracted three times with 3 ml diethyl ether, dried over anhydrous Na_2SO_4 and taken to complete dryness in a rotary evaporator. They were then dissolved in 100–400 μl ethanol and analyzed by gas liquid chromatography (GLC).

GLC analyses of fatty acids were performed with a Pye Unicam (Cambridge, England) gas chromatograph series 204 equipped with a flame ionization detector and connected to a Spectra Physics (Santa Clara, California) SP 4100 computing integrator. The glass column (4 mm i.d. × 1 m), packed with pretested 5% DEGS-PS on Supelcoport 100/120 mesh (Supelco, Bellefonte, Pennsylvania), was run at an initial temperature of 200 C with N_2 as the carrier gas set at a flow rate of 55 ml/min. Upon sample injection, a temperature program was initiated that increased the temperature at a rate of 2 C/min to a final value of 225 C. The injection port and detector temperature were set to 210 C and 250 C, respectively. Relative distribution of the individual fatty acids was assessed by comparing the integrated areas under the peaks with those obtained from known amounts of external standards (Sigma).

Labeling of the RBC with 1[4-(trimethylamino)phenyl]-6-phenylhexa-1,3,5-triene (TMA-DPH; from Molecular Probes, Junction City, Oregon) was performed according to Kuhry et al. (23). Briefly, 20 μl of a 500 μM stock solution of TMA-DPH in dimethylformamide was added to 980 μl PBS with vigorous vortexing, and then 600 μl of this suspension was added to a fluorescence cuvette in the dark. RBC (3×10^7 in 100 μl) were added immediately followed by 2.3 ml PBS, and the whole was incubated at 25 C in the dark for 5 min. Maximum incorporation of TMA-DPH into the outer cell membrane is achieved after 1 min (23).

Fluorescence anisotropy measurements were performed at 25 C in a thermostated Perkin Elmer LS-5 Luminescence Spectrometer equipped with an electronically driven polarization unit. The sample was excited with vertically polarized light at 357 nm (slit width 5 nm), and the vertical (I_v) and horizontal (I_H) components of the fluorescence emission intensity were measured at 464 nm (slit width 10 nm). I_v was corrected for the response of the emission monochromator and photomultiplier tube system by multiplying I_v by the correction factor, G (where $G = I_v/I_H$, with horizontally polarized excitation light). The steady-state anisotropy (r_s) was determined as $r_s = (I_v - I_H)/(I_v + 2I_H)$. I_v and I_H were corrected for light scattering using unlabeled cells as described by Kuhry et al. (23).

Malonyldialdehyde was determined as described previously (24) with slight modification (13). Vitamin E was determined by a fluorimetric method (25).

Spectrophotometric grade solvents were used for the extraction and analysis of lipids. Petroleum ether (30–75 C), n-heptane and acetylacetone were redistilled before use.

RESULTS

The relative contributions of the major lipids to the total present in RBC from control CBA/CaH mice were PC (26%), PE (17%), cholesterol (15%) and SM (6%) (Table 1). Other phospholipids were detected in small amounts, as were traces of triglyceride. In control RBC,

[b]Significantly lower ($P < 0.05$) than corresponding control value (Rank test).
[c]Significantly higher ($P < 0.05$) than corresponding control value.

neutral lipids and phospholipids made up 81% of the total lipid content, while in the parasitized RBC their contribution increased to 99% (Table 1). This result indicates that lipid components other than those selected for study in the present experiments, e.g., glycosphingolipids, may change their relative concentrations during the course of malarial infection, as reported by others (2).

The late stage of infection of mice with *P. vinckei* (>80% parasitemia) was characterized by a threefold increase in the amount of total lipids extractable from their RBC (Table 2), this being broadly similar to others' observations with different malaria species (2,4). This increase was associated with even larger changes (4-fold) in total phospholipids, which included marked elevations in PC (5.5-fold) and PE (4.5-fold), while the combined levels of PS and PI doubled. This significant increase in PC was not seen in *P. lophurae* and *P. berghei* infection (2,4). No significant changes were observed in the concentration of SM, in contrast to infections with other malaria species (2), while the amount of LL decreased in response to the infection. Neutral lipids were also elevated (2-fold), with the largest increase occurring in triglycerides. The doubling of the cholesterol content did not match the more striking increase in phospholipids, resulting in a significant decrease in the cholesterol-to-phospholipid ratio (Table 2). This is similar to previous observations with *P. knowlesi* and *P. lophurae*, but not with *P. berghei*, where no change was observed (2).

The relative amounts of the major lipids in plasma from control mice were PC (28%), cholesterol (17%), triglycerides (13%) and LL (4%) (Table 2). PE and SM were minor components, while unesterified fatty acids and cholesterol esters were not included in this analysis. Infection of mice with *P. vinckei* produced no significant change in plasma total lipid content (Table 2), although a substantial increase has been reported in *P. knowlesi* infection (4). Neutral lipid and cholesterol decreased in absolute amounts, in contrast to previous studies with *P. knowlesi*, *P. lophurae* and *P. berghei* (4). The plasma concentrations of total and individual phospholipids did not change significantly, with the single exception of LL, which decreased in parasitized mice (Table 2).

The fatty acids represented most prominently in lipids isolated from RBC and plasma from control and *P. vinckei*-infected mice were palmitic (16:0), stearic (18:0), oleic (16:1), linoleic (18:2) and arachidonic (20:4), although minor amounts of other fatty acids were also present (Tables 3 and 4). Phospholipids extracted from the RBC of infected mice contained relatively higher amounts of polyunsaturated fatty acids, while monounsaturated and saturated fatty acids were proportionately decreased (Table 5), contrasting with other reports (4). This increase in the degree of unsaturation of membrane phospholipids was due mainly to a significant increase in linoleic acid and decreases in palmitic and stearic acids in parasitized RBC (Table 3).

Malaria infection did not cause profound changes in the composition of fatty acids isolated from the phospholipids (Table 3) and neutral lipids (Table 4) of plasma. The only significant differences were a higher concentration of linoleic acid in the plasma phospholipids of infected mice (Table 3), reflecting the situation found in the RBC, and a significant decrease in arachidonic acid in plasma neutral lipids (Table 4).

Although most of the additional lipids in parasitized RBC seem to be associated with the parasite (3,26,27), at least part of the observed fluctuations might reflect changes in the lipid composition or organization of the RBC plasma membrane. Consistent with this suggestion, infected RBC had a decreased steady-state fluorescence anisotropy (r_s) of TMA-DPH (Fig. 1), a cationic fluorescent probe that remains localized in the plasma membrane of intact cells during the first 25 min of interaction (28,29).

In an attempt to assess the potential susceptibility of the membrane lipids of control and parasitized RBC to peroxidative damage, we compared the concentrations of vitamin E, on the one hand, and malonyldialdehyde produced spontaneously during in vitro incubation at 37 C,

on the other, to the RBC content of total peroxidizable lipid (16). The total amounts of vitamin E and malonyldialdehyde detected were about threefold and eightfold higher, respectively, in RBC from infected compared with control mice, when expressed on a cellular basis (Table 6). However, when expressed per unit of peroxidizable lipid, the amount of malonyldialdehyde detected in incubations of RBC from infected mice was barely higher than, and the vitamin E level was only half, that in control RBC (Table 6).

DISCUSSION

Changes in total plasma lipids in response to a malarial infection have not revealed a consistent trend and appear to depend on the experimental model used. In infections with *P. falciparum, P. knowlesi* and *P. lophurae*, for example, total lipids in plasma were reported to increase (3,30,31), while others (32) have reported a decrease in plasma from rats infected with *P. berghei.* Our results in mice infected with *P. vinckei* (Table 2) agree with the

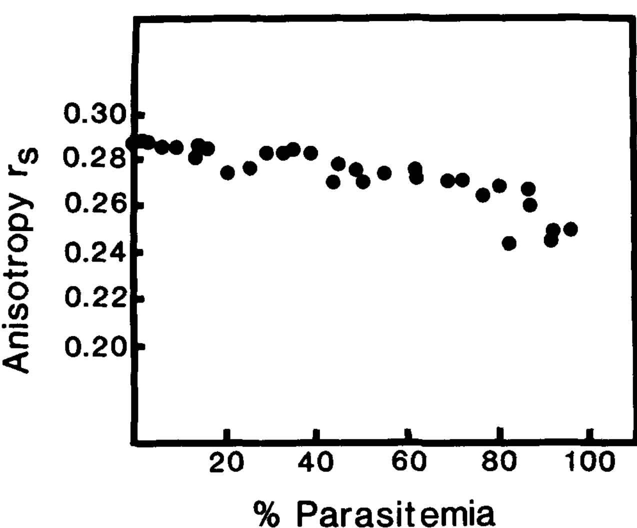

FIG. 1. Steady-state fluorescence anisotropy, r_s, of TMA-DPH as a function of parasitemia. Each point is the mean of triplicate experiments. The r_s value is corrected for light scattering effects and the response of the emission monochromator and photomultiplier tube system.

TABLE 5

Relative Degree of Saturation of Fatty Acids of Erythrocytes of Control and *P. vinckei*-Infected Mice[a]

Saturation	Erythrocytes from control mice	Erythrocytes from infected mice
Saturated	45.9 ± 0.4[b]	39.6 ± 2.1[c]
Monounsaturated	14.2 ± 0.5	10.7 ± 10.5[c]
Polyunsaturated	38.5 ± 1.9	49.7 ± 2.1[d]

[a]Percentages are calculated from results shown in Tables 3 and 4.

[b]Results are expressed as wt % of the total fatty acids (mean ± S.D.).

[c]Significantly lower ($P < 0.05$) than corresponding control value (Rank test).

[d]Significantly higher ($P < 0.05$) than corresponding control value.

TABLE 6

Ratio of the Vitamin E Content and Spontaneous Malonyldialdehyde Production in *P. vinckei*-Infected vs Control Erythrocytes in Relation to Various Parameters

Data expressed in relation to	PRBC/CRBC (ratio)[a]	
	MDA formed	Vitamin E
Cell number or packed cell volume	8.1[b]	2.8[c]
Total lipid	2.7[d]	0.9
Phospholipid	1.9	0.7
PUFA	1.4	0.5

[a]Abbreviations: PRBC, parasitized red blood cells; CRBC, control red blood cells; MDA, malonyldialdehyde; PUFA, polyunsaturated fatty acids.

[b]CRBC and PRBC form spontaneously 5.7 ± 1.4 and 46.2 ± 7.8 nmol MDA/10^{10} cells/hr, respectively.

[c]CRBC and PRBC contain 1.5 ± 0.5 and 3.8 ± 1.0 μg vitamin E/ml packed cells, respectively.

[d]Ratios are calculated from results shown in Table 1.

latter report. In general, the changes in individual components of the total lipids and fatty acids within plasma were small and paralleled the more profound changes observed in RBC (Tables 1, 3). The small decrease in total plasma lipids was due mainly to lower circulating levels of neutral lipids. Plasma triglycerides showed a small increase, which could be the result of increased levels of triacylglyceride-rich lipoproteins, such as chylomicrons and very low density lipoproteins, which are elevated in the serum of animals infected with various strains of *Plasmodium* (33) and may, in fact, precede the very large increase in triglycerides observed within RBC upon infection (Table 2). The hypertriglyceridemic state observed in murine malaria has been attributed to a parasite-induced product, released by reticuloendothelial cells, that inhibits lipoprotein lipase, resulting in suppressed triglyceride clearance (34). It is interesting to note that this factor, previously known as cachectin, has recently been suggested to be identical with tumor necrosis factor (35), a macrophage-derived mediator that has also been implicated in causing the intraerythrocytic death of malarial parasites (36).

The lipid analysis of RBC from control and *P. vinckei*-infected mice confirmed some aspects of previous reports of work in which other host species and strains of *Plasmodium* (2–6) were used, i.e., that the total amounts of lipids and phospholipids are increased in malaria-infected RBC (Table 1), although numerous differences in lipid composition were seen. It is difficult to assign changes in the composition of individual lipids to particular membranes, since the experimental material consisted of a multicompartment membrane system, containing the plasma membranes of the host and parasite, the membranes of the parasitophorous vacuole and the intracellular membranes of various plasmodial organelles. We did not attempt to analyze lipids in isolated parasites, since most published methods of isolation yield parasite fractions that either lack parasite membranes or are contaminated with RBC components (37). Other methods, such as those described by

Nillni et al. (38), were found to be inapplicable to *P. vinckei* (Stocker, R., unpublished observations). Despite these difficulties, there seems to be a consensus that "free parasites" contain more than 60% of the total lipid of the parasitized RBC (3,26,27). If this is the case, a major quantitative contribution to the changes we have observed in *P. vinckei*-infected RBC is likely to be the rapid proliferation of plasmodial membrane lipids as infection proceeds, although the observations with TMA-DPH also imply qualitative changes in the RBC plasma membrane. Notable were the several-fold increases in the levels of triglyceride and PC, a finding consistent with enhanced metabolism of glucose by the parasite to form the intermediate α-glycerol-3-phosphate that acts as a common precursor for de novo biosynthesis of glycerides and phospholipids (39). Less than 5% of the glucose metabolized by the parasite is used for de novo synthesis of fatty acids and sterols like cholesterol (39). This small contribution, taken in conjunction with decreased plasma levels of cholesterol, may explain why the relative concentration of cholesterol decreased from 15 to 10% (Table 1) and why the cholesterol-to-phospholipid ratio decreased in RBC from infected mice (Table 2).

As mentioned above, the parasite exhibits at least a partial dependence upon the extra-erythrocytic environment for its supply of fatty acids. Therefore, the changes observed in the relative concentrations of the fatty acids in phospholipids of infected vs control RBC (Table 3) may be a reflection of the uptake of these compounds from the plasma. This view agrees with the finding that changes in the fatty acid composition of RBC phosphoglycerides from infected animals parallel those observed in the plasma (Table 3). It is important to note that *P. vinckei* infection is associated with an increase in the relative amounts of polyunsaturated fatty acids at the expense of the saturated palmitic and stearic acids in RBC (Tables 3 and 5). Although this does not agree with findings in *P. lophurae* infection in ducks (3), where palmitic and stearic acids were elevated in parasitized RBC, it does parallel the decreases in stearic acid content observed in mouse and monkey RBC infected with *P. berghei* and *P. knowlesi*, respectively (5,6). Furthermore, there are differences in the distribution patterns of the unsaturated fatty acids within parasitized RBC from different combinations of host and plasmodial strains. For example, infections with *P. lophurae* and *P. knowlesi* result in increases in the monounsaturated oleic acid (3,6), while the relative abundance of the polyunsaturated linoleic and arachidonic acids increases within *P. vinckei*-infected RBC (Table 3).

The increases in the total and relative amounts of polyunsaturated fatty acids within parasitized RBC can largely explain why, on a cellular basis, they produce eight times more malonyldialdehyde than do their control counterparts: when analyzed in relation to the increased availability of peroxidizable lipid, there is only a small difference between the two cellular systems in their amounts of lipid autoxidation (Table 6). The latter argument is supported by our recent finding that in neither control nor *P. vinckei*-infected RBC is there any net accumulation of α-tocopherolquinone, one of the oxidation products of vitamin E (40).

Under the experimental conditions used in this study, the observed decrease in steady-state fluorescence anisotropy (r_s) of TMA-DPH in infected RBC (Fig. 1) is probably attributable solely to alterations in the outer leaflet of the RBC plasma membrane (28,29). This change in r_s is interpreted as representing a decreased "order" in the lipids of that compartment (41,42). In other systems, oxidation of membrane lipids results in the depletion of polyunsaturated fatty acids, with concomitant increases in the relative concentrations of saturated (43–45) and shorter chain (45) fatty acids, and an increased "order" of the membrane lipids (43–46). Furthermore, while treatment of RBC with t-butyl hydroperoxide increases their negative surface charge (46), infection of RBC with *P. vinckei* results in a more positive surface charge (47). Taken together, these contrasts cast doubt upon the occurrence of reactive oxygen-induced damage to lipid in *P. vinckei*-infected erythrocytes during the natural course of the infection. "Protection" of the polyunsaturated fatty acids from oxidation may be a consequence of compensatory changes in the antioxidant systems of the parasitized RBC (15,40,48).

As discussed above, most of the observed increase in the unsaturated fatty acid content of infected RBC can be attributed to the presence of parasite membranes. This may explain why they are more susceptible to peroxidative damage than their more saturated counterparts in the host red cell membrane and why the spontaneous malonyldialdehyde formation increases linearly with increasing parasitic load in parasitized RBC (15). Also relevant to the question of increased susceptibility of the parasite lipids to peroxidation is the observation that the relative concentration of the main lipid-soluble antioxidant, vitamin E, is actually decreased in parasitized RBC when it is expressed per unit of polyunsaturated fatty acid (Table 6). With respect to membrane lipids associated with the parasite, such a decrease in the relative amount of vitamin E may well be underestimated, since it has been suggested that the vitamin E detected in *P. vinckei*-infected RBC is associated mainly with the host cell membrane (15).

Thus, we conclude that the relative increase in unsaturated fatty acids and the relative decrease in vitamin E may act synergistically to increase parasite membrane susceptibility to peroxidative damage vis-a-vis that of the host red cell membrane. The possible relevance of this observation to the occurrence of "crisis forms," i.e., degenerating malaria parasites observed within intact RBC (49), remains to be established.

ACKNOWLEDGMENTS

This investigation received support from the malaria component of the United Nations Development Program/World Bank/World Health Organization's Special program for Research and Training in Tropical Diseases and the Australian Research Grants Scheme (grant no. D27915664 to MJW). RS was a recipient of an Australian National University post-graduate scholarship. I. A. Clark gave helpful discussions and K. Rabl provided secretarial assistance.

METHODS

A Micromethod for the Estimation of Blood Dolichol

George N. Morris and **Raju K. Pullarkat**
Department of Neurochemistry, New York State Office of Mental Retardation and Developmental Disabilities, Institute for Basic Research in Developmental Disabilities, 1050 Forest Hill Rd., Staten Island, NY 10314

A micromethod for the estimation of dolichol in blood was developed using high performance liquid chromatography. This method can be applied to whole blood or plasma. With detector sensitivity set at 0.005 Absorbance Unit Full Scale, samples as little as 50 μl are sufficient to carry out the determination. Blood samples from the tail vein of inbred strains of C57 BL/6 NNia-1 mice 3, 6, 12 and 24 mo of age were examined. Blood dolichol levels decreased with age from 163.3 ng/ml at 6 mo to 110.1 ng/ml at 24 mo. The major dolichol homologs were C-85 (10.4%), C-90 (41.6%), C-95 (38.0%) and C-100 (8.1%).
Lipids 22, **58–60 (1987).**

Dolichols are very long chain 2,3-dihydropolyprenols that occur ubiquitously in eucaryotes. In biological fluids and tissues they exist in various forms including phosphate esters, free alcohols and esters of fatty acids (1). In the form of dolichyl phosphate, these compounds function as saccharide carriers for biosynthesis of asparagine-linked glycoprotein (2).

Recently, there have been two reports on the determination of dolichol in blood (3,4). One study by Elmberger and Engfeldt (3) showed an age-associated increase in plasma dolichol, while the other by Yamada et al. (4) showed a decrease. Work from this and other laboratories (5–9) has shown an age-associated increase in the level of unesterified dolichol in various tissues. With focus on a biomarker for aging, we set out to investigate the age-associated changes in dolichol levels in the blood of an inbred strain of mice.

Currently, estimation of plasma dolichol requires samples of 1 to 10 ml (3,4) and the use of a fluorescent derivative to improve sensitivity (4). Since we were interested in working with blood samples from mice, it became necessary to develop a method that can use small volumes of blood from the tail vein. In this paper, we report a very sensitive method that is simple, fast and does not use derivitization, for the determination of blood dolichol.

MATERIALS AND METHODS

Chemicals and reagents. Dolichol standards were obtained from Sigma Chemical Co. (St. Louis, Missouri). Dolichol C-125 (internal standard) was purchased from the Polish Academy of Science (Warsaw, Poland). Reversed phase cartridge columns (SPICE) were obtained from Analtech (Newark, Delaware). All solvents were obtained from J.T. Baker Co. (Bethlehem, Pennsylvania) and were either HPLC grade or resi-analyzed. The high performance liquid chromatography (HPLC) column was from Rainin Instrument Co. (Woburn, Massachusetts).

Animals. C57 BL/6 NNia-1 mice aged 3, 6, 12 and 24 mo were obtained from Charles River Laboratories (Wilmington, Massachusetts) and were fed a commercial diet and water ad libitum.

Quantification of dolichol. Blood samples (50–200 μl) from the tail vein of the mice were collected into heparinized calibrated micropipets and transferred to 18-ml screw-cap culture tubes. One ml 2 N NaOH in methanol and 50 ng internal standard, dolichol C-125, were added. The tubes were capped, and their content was mixed thoroughly and heated at 70–75 C for 1 hr with intermittent mixing. The mixture was cooled and neutralized with 1 N HCl, and the unsaponifiables were extracted twice with 5 ml chloroform. The pooled extract was evaporated at 30 C under nitrogen. The dolichol was taken up in 0.5 ml $CHCl_3$/MeOH (2:1, v/v) and applied in 1–2 ml methanol on a C18 reversed-phase cartridge (SPICE) prewashed with 10 ml MeOH/H_2O (75:25, v/v), 10 ml acetone and 10 ml methanol in that order. The sample was washed with 15 ml methanol and the dolichol eluted with 10 ml acetone. The acetone fraction was taken to dryness and redissolved in 50 μl mobile phase, methanol/isopropanol/hexane (44:44:12, v/v/v). Ten μl of this preparation was used for HPLC analysis.

HPLC system. The HPLC system consisted of a Spectra-Physics 8700 solvent delivery system, a Rheodyne model 7125 sample injector, a Beckman model 160 fixed wavelength UV detector (214 nm, Zinc Lamp), a Rainin reversed-phase C18 column (Microsorb 3 μm, 0.46 × 10 cm) and a Spectra-Physics 4100 computing integrator. All runs were done isocratically using a mobile phase consisting of methanol/isopropanol/hexane (44:44:12, v/v/v) at 0.5 ml/min. All solvents were degassed continuously with helium. The detector sensitivity was set at 0.005 Absorbance Unit Full Scale (AUFS). The analytical procedure was linear at least from 0.5–400 ng per 10 μl of sample injected.

RESULTS AND DISCUSSION

Preliminary experiments in which alkaline concentration, temperature and time of saponification of blood samples were varied showed that heating samples at 70–75 C in 2 N methanolic NaOH for 1 hr was optimum for getting rid of interfering lipids, such as cholesteryl esters, and for dolichol recovery. The recovery of the internal standard after saponification was >95%. Furthermore, results from samples prepared in the absence or presence of pyrogallol (2.5 mg/ml) showed no significant differences; hence the experiments described were done in the absence of pyrogallol.

Figure 1 shows HPLC of dolichols obtained from a 100-μl blood sample, of which an equivalent of 20 μl was injected using detector sensitivity set at 0.005 AUFS. All the major homologs are well separated from each other and from the internal standard. The predominant dolichol homologs are C-85 (10.4%), C-90 (41.6%), C-95 (38.0%) and C-100 (8.1%). All other homologs combined represent less than 3% of the total.

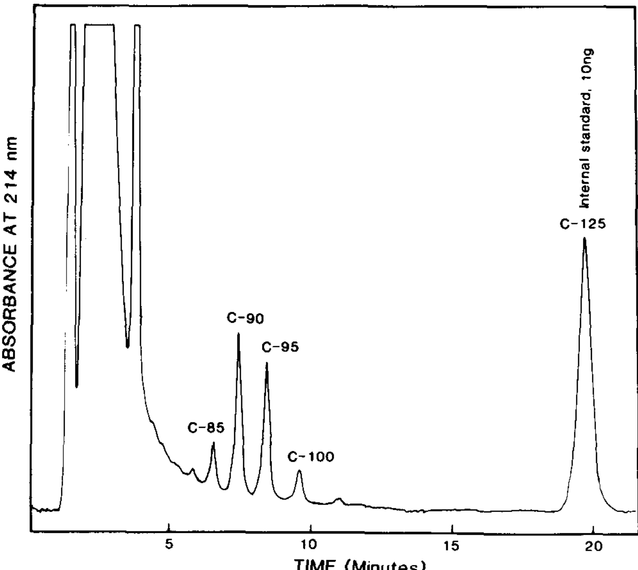

FIG. 1. High performance liquid chromatographic analysis of total dolichol from a 100-µl blood sample of which an equivalent of 20 µl was injected. The internal standard represents 10 ng of dolichol C-125. Conditions of analysis are described in Materials and Methods. The number on peaks indicates the total number of carbons in each dolichol homolog.

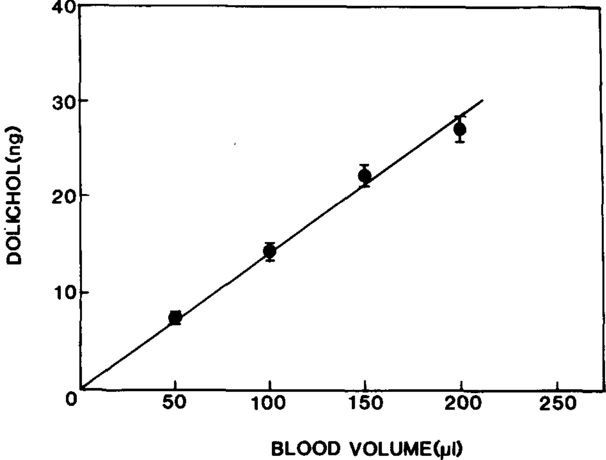

FIG. 2. Calibration curve for blood dolichol of C57 BL/6 NNia-1 mice using the method described in Materials and Methods. Each point is the mean ± S.E. of three replicates.

TABLE 1

Effects of Age on Total Dolichol (ng/ml ± SD) of Blood from C57 BL/6 NNia-1 Mice

Age (mo)	Dolichol (ng/ml)
3(4)[a]	164.2 ± 17.7
6(4)	163.3 ± 22.8
12(4)	143.3 ± 12.5
24(4)	110.1 ± 17.8

[a]Number of animals given in parentheses.

Figure 2 shows a calibration curve obtained by analyzing different amounts of blood (50–200 µl) from 12 mo-old C57 BL/6 NNia-1 mice. The standard deviation for triplicate determinations of the same sample from 50–200 µl blood samples was between 8 and 11% with standard error of 7% or less of the values. The linearity of this graph shows that the procedure is good for at least a 200 µl blood sample.

Table 1 shows results obtained by analyzing blood from 3, 6, 12 and 24 mo-old C57 BL/6 NNia-1 mice. There is a decrease in blood dolichol levels from 163 ng/ml at 6 mo to 110 ng/ml at 24 mo. This age-associated decrease agrees with results obtained by Yamada et al. (4) for human plasma. A possible explanation for this decrease may be a slowdown of de novo biosynthetic processes with age (10).

In addition, we have observed that plasma contributes about 50% and 62% dolichol to the blood dolichol pool of C57 BL/6 NNia-1 mice and human, respectively and that approximately one-third of the dolichol in the blood of C57 BL/6 NNia-1 mice is unesterified.

The method described here is reliable and can be easily adapted for plasma or serum dolichol levels. Compared to other methods (3,4), this procedure is less time consuming and more sensitive. Blood dolichols can be estimated from samples as little as 50 µl compared to samples of at least 1 ml and formation of derivatives for improved sensitivity is not required. The increased sensitivity of the described method is due to the use of highly end-capped 3 µm columns, a fixed wavelength detector of 214 nm that gives a stable baseline at 0.005 AUFS and continuous degassing of the solvents with helium to reduce drift in base line. Sensitivity may also be improved by employing a normal phase HPLC column (11), but a major drawback of this technique is its inability to resolve dolichol homologs.

Useful applications of this method may be found in certain conditions, metabolic or otherwise, in which it may be necessary to monitor the dolichol levels without killing the animal in question or in cases where sample size and availability are minimal, for example, with newborns or elderly subjects. For certain neurological disorders, such as ceroidlipofuscinosis (12), alcoholic syndrome in infants born to alcoholic mothers (13) and metastatic carcinoma (14), dolichol levels of the urine provide valuable information. Blood is more readily available and more stable in metabolite concentrations than urine. By our method, it may be possible to monitor these and other disorders through the levels of dolichol in the blood.

Improved Enzymatic Hydrolysis of Conjugated Bile Acids

W. Edward Highsmith Jr.[a,1] and **Paul M. Hyde**[b,*]

[a]Department of Pathology and [b]Department of Biochemistry and Molecular Biology, Louisiana State University Medical Center, 1901 Perdido St., New Orleans, LA 70112

The hydrolysis of conjugated bile acids by cholylglycine hydrolase (EC 3.5.1.24) using the standard procedure for a commercial enzyme preparation was found to be incomplete, as judged by the use of 24-^{14}C-taurocholic acid as a tracer. A method is proposed that incorporates the nonionic detergent Triton X-100 into the reaction mixture to achieve almost complete hydrolysis. It is proposed that the observed enhancement of enzyme activity is due to the formation of micelles by the detergent.
Lipids 22, **61–63 (1987).**

Prior to the introduction of an enzymatic hydrolysis procedure by Nair and Garcia (1), the method of choice for hydrolysis of bile acid conjugates was 1 N NaOH at elevated temperature and pressure (2). Cholylglycine hydrolase (EC 3.5.1.24) offers a much milder alternative to hot alkali.

When an enzymatic reaction is to be applied to prepare a substrate for further manipulations—for example, derivitization and gas chromatographic analysis—two criteria may be used to judge the suitability of the enzyme for the task at hand. The first is the speed or rate of the reaction; this is primarily a function of the enzyme concentration, pH and temperature. The second is the completeness of the reaction; this is a function of the thermodynamic equilibrium between substrate and product and is independent of the enzyme.

In the course of our investigations on the utility of serum bile acid analysis in the diagnosis of hepatobiliary disease, we observed that when ^{14}C-labeled taurocholic acid was used as a tracer, the enzymatic hydrolysis of taurocholic to cholic acid was not complete. The addition of the nonionic detergent Triton X-100 to the reaction mixture resulted in complete hydrolysis. In cooperation with Davis and coworkers, we have used this method in the determination of bile acids in hepatocyte cell culture fluid (3).

MATERIALS AND METHODS

24-^{14}C-Taurocholic acid (52.0 mCi/mmol, New England Nuclear, Boston, Massachusetts) was judged to have a radiochemical purity of greater than 95% by thin layer chromatography (TLC) (silica gel–impregnated glass fiber paper [Gelman Sciences, Ann Arbor, Michigan], solvent system of isobutanol/acetic acid/water, 80:1:1, v/v/v) and was used without further purification. Conjugated bile acids (synthetic) were from Sigma Chemical Co. (St. Louis, Missouri) and were judged homogeneous using the TLC system above. Triton X-100 (scintillation grade) from Eastman Kodak Co. (Rochester, New York) was purified by dissolving 10 ml Triton in 100 ml 0.1 N KOH and extracting with two 100-ml portions of ethyl acetate and removing the solvent on a rotary evaporator. Ethyl acetate (analytical reagent) from Mallinckrodt Chemical Works (St. Louis, Missouri) was redistilled before use. Cholylglycine hydrolase (partially purified, 107 units/mg protein) was from Sigma. A stock solution of enzyme was prepared by dissolving 7,500 units of enzyme in 7.5 ml of distilled water. Aliquots of 0.05 ml were dispensed into plastic tubes, tightly sealed and stored at −20 C. The working solution of enzyme was prepared immediately before use by adding 1.0 ml 0.025 M acetate buffer, pH 5.6, to a tube of stock solution. All other materials were reagent grade and were used without further purification.

Ten ml of Pico-fluor-30 liquid scintillation cocktail from Packard Instrument Co. (Downers Grove, Illinois) was added to each sample and then counted for 10,000 counts on a Packard Model 3380 liquid scintillation counter, using an external standard radiation source for quench corrections.

RESULTS

Ca. 6000 dpm of radiolabeled taurocholic acid was added to a protein-free extract of 0.1 ml of normal human serum prepared by adding 1.0 ml ice-cold ethanol/methanol/dimethoxypropane (2:2:1, v/v/v), centrifuging to remove the precipitated protein, decanting and drying the supernatant under a stream of dry nitrogen. Hydrolysis was carried out according to instructions from Sigma Chemical Co. (Table 1). Cholylglycine hydrolase was used at a nominal concentration of 47.6 U/ml. The incubation temperature was 37 C. At the end of the incubation, each sample was acidified by the addition of 0.1 ml 2 N HCl and extracted with 2 × 2 ml ethyl acetate. Under these conditions, cholic acid is extracted into the organic phase, while taurocholic acid remains in the aqueous phase. The ^{14}C content of each fraction was measured and the percentage of 24-^{14}C-taurocholic acid hydrolyzed was determined. The results are shown in Table 2. The experiment was then repeated with the addition of 0.2 ml 0.25% (v/v) Triton X-100 in distilled water. The results are shown in Table 3.

To determine the amount of conjugated bile acid that could be completely hydrolyzed under these conditions, the experiment was repeated after the addition of varying amounts of unlabeled taurocholic or taurochenodeoxycholic acids, ranging from 0.01 to 1.0 μmol/tube. The results are shown in Figure 1.

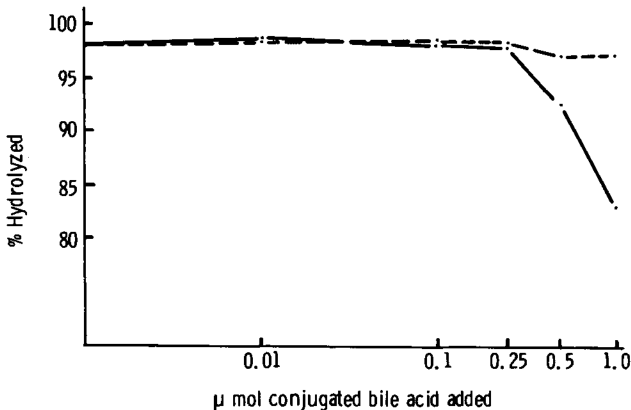

FIG. 1. Effect of excess taurine-conjugated bile acids on the hydrolysis of 24-^{14}C-taurocholic acid. ———, Percentage hydrolyzed after the addition of unlabeled taurochenodeoxycholic acid; ______, Percentage hydrolyzed after the addition of unlabeled taurocholic acid.

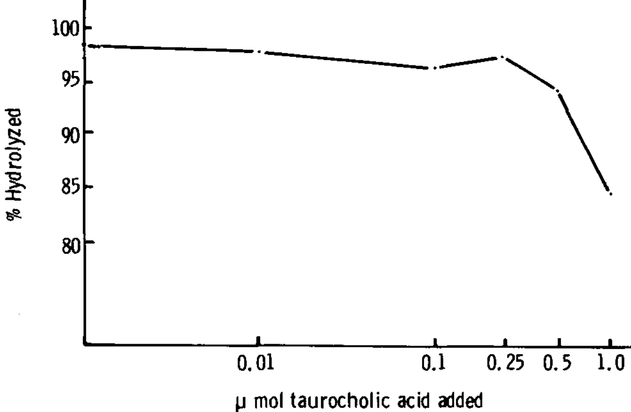

FIG. 2. Effect of excess taurocholic acid on the hydrolysis of 24-^{14}C-taurocholic acid without precipitation of serum proteins.

To test for any inhibitory effects of serum proteins, the experiment was repeated using 0.1-ml aliquots of untreated human serum spiked with 0.01 to 1.0 μmol/tube unlabeled taurocholic acid. The results are shown in Figure 2.

To confirm the nature of the extractable radioactivity, triplicate samples of 24-^{14}C-taurocholic acid were subjected to enzymatic hydrolysis in the presence of Triton X-100 and were extracted with ethyl acetate under acidic conditions as described. The ethyl acetate was removed under a stream of nitrogen. The residue was dissolved in a minimal volume of methanol and subjected to TLC (silica-impregnated glass fiber paper, solvent system of isooctane/isopropyl alcohol/isopropyl ether/acetic acid, 20:1:1:1, v/v/v/v). More than 95% of the applied radioactivity co-migrated with authentic cholic acid (data not shown).

DISCUSSION

Cholylglycine hydrolase has been used extensively in the analysis of bile acids in biological materials (4–6). There remain, however, certain problems with the use of this enzyme as a reagent for the preparation of samples for subsequent manipulation, e.g., gas chromatography. Roovers et al. reported that, at low substrate concentrations (less than 60 nmol/ml), the hydrolysis rate slowed rapidly, with the effect being more pronounced with taurine than glycine conjugates (7). Studies in which the completeness of hydrolysis was assessed by the recovery of free bile acids from added conjugated bile acids have used higher concentrations of substrate (8–10). Furthermore, it is doubtful that the procedures used to assess analytical recovery (colorimetric determination of liberated amino acid or gas chromatographic determination of liberated bile acid using flame ionization detection) possess adequate sensitivity to determine if a small amount of conjugated bile acid was left unhydrolyzed.

The literature reflects a substantial variation in the amount of enzyme used to prepare biological samples for chromatographic analysis of their bile acid content. The amount of cholylglycine hydrolase used is not stated in some reports (1,5); in others it is reported simply as being "in excess" (8). Where the amount of enzyme is stated, the amounts range from <10 units per tube (6,7,10,12) to >200 units per tube (4,12). In light of these discrepancies, we originally thought that complete hydrolysis could be achieved using higher concentrations of enzyme. However, our attempts failed even when the concentration of enzyme was fivefold that shown in Table 1 and the incubation time was extended to 24 hr (data not shown). These results are in accordance with theory, as the amount of enzyme present should not affect the equilibrium between substrate and product, but merely the speed at which equilibrium is established.

Our goal was to develop a gas chromatographic analysis using an electron capture detector, which could be performed on the limited volumes of serum (0.1 ml or less) obtainable from pediatric or geriatric patients. Thus, the behavior of the enzyme relative to small amounts of substrate was critical. We therefore used radiolabeled substrate, by which very small amounts of materials could be monitored easily.

Table 2 shows that, even after a 16-hr incubation, an unacceptable unhydrolyzed fraction of bile acid remained. Table 3 shows that after the addition of 0.25% (v/v) Triton X-100, the reaction proceeded essentially to completion in 1 hr. Under these conditions (9.5 units cholylglycine hydrolase per tube, incubation at 37 C for 1 hr and 0.2 ml 0.25% [v/v] Triton X-100 per tube), up to 0.25 μmol/tube of conjugated bile acid was hydrolyzed without interference from serum proteins (Figs. 1 and 2).

The increase in extractable radioactivity is due to an increased liberation of cholic acid and not merely to a change in the partition coefficient of taurocholic acid in the water/ethyl acetate system. This is demonstrated in two ways: first, there is no increase in extractable radioactivity, due to labeled taurocholic acid in the presence of Triton X-100 (zero time point, Table 3); and second, the extracted radioactivity co-migrates with cholic acid on TLC.

The mechanism for enhancement of the hydrolysis of bile acid conjugates by cholylglycine hydrolase in the presence of Triton X-100 is unknown. However, since the concentration of Triton X-100 in the reaction is in excess of its critical micellular concentration (11), it may enhance the incorporation of bile acid conjugates into the micelle, with the polar conjugate portion exposed for enzyme action. The equilibrium between conjugated and free bile acids is then altered by the sequestration of the free bile in the micelle.

We conclude that when cholylglycine hydrolase is to be used as a reagent for the preparation of free bile acids for further manipulation, Triton X-100 should be included in the reaction mixture to ensure hydrolysis near 98%.

[Revision received September 15, 1986]

Tissue Distribution of Phytanic Acid and Its Analogues in a Kinship with Refsum's Disease

Jeffrey K. Yao* and **Peter James Dyck**
Peripheral Nerve Center, Department of Neurology, Mayo Clinic and Foundation, Rochester, MN 55905

Three of six kin were identified, by high performance thin layer chromatography, capillary gas chromatography and mass spectrometry, as having phytanic acid storage disease. Phytanic acid was found in triacylglycerol and, to a lesser degree, in phosphatidylcholine and free fatty acids. An unsaturated analogue of phytanic acid was additionally identified in plasma and erythrocyte triacylglycerols. In plasma, branched chain fatty acids were primarily localized in the low density lipoprotein fraction. The concentration of plasma major fatty acids was not affected by the presence of these branched chain fatty acids. In contrast to plasma, only small amounts of phytanic acid were found in cerebrospinal fluid and biopsied sural nerve. The nerve phytanate was mainly associated with triacylglycerol in epineurial and perineurial tissues. Lack of phytanate accumulation in sural endoneurium, even in cases with severe fiber degeneration, suggests that demyelination in Refsum's disease may not be due to myelin instability resulting from the incorporation of branched chain fatty acids into peripheral nerve membrane.
Lipids 22, 69-75 (1987).

Refsum's disease is a rare inherited disorder of fatty acid oxidation characterized clinically by peripheral neuropathy, visual loss due to retinitis pigmentosa, icthyosis and bony abnormalities (1). The major pathway for phytanic acid oxidation in humans involves first, an unusual initial α-oxidation to yield α-hydroxy phytanic acid and then the n-1 fatty acid, pristanic acid; and second, a series of successive β-oxidation steps for the further degradation of pristanic acid (2-5). The level of plasma phytanic acid is markedly increased in patients with Refsum's disease (6). Normally, it is virtually undetectable (7). The metabolic error involved in Refsum's disease lies in failure of the converson of phytanic acid to α-hydroxyphytanic acid. This leads to widespread tissue storage of phytanic acid (8-10). The pathogenesis of nerve fiber degeneration in phytanic acid storage disease is unclear. It has been hypothesized that myelin stability may be affected by incorporation of branched chain fatty acids into tissue lipids in place of normal straight chain fatty acids (11,12). If this hypothesis of demyelination is correct, then endoneurial storage of phytanic acid might be expected. We have, therefore, carried out extensive biochemical studies on the plasma, erythrocytes, cerebrospinal fluid and biopsied sural nerve of patients from a kinship with Refsum's disease.

MATERIALS AND METHODS

Sample preparations. Heparinized blood samples (40 ml) were drawn from six kin (III-2, 70 years; III-4, 67 years; III-6, 66 years, III-8, 64 years; III-10, 62 years; and III-16, 59 years; see Fig. 1) and five age-matched normal subjects. After centrifugation, plasma was removed, and the packed cells were washed twice with isotonic saline solution. The method used to fractionate plasma into chylomicrons and fractions of very low density lipoprotein (VLDL, <1.006 g/ml), low density lipoprotein (LDL, 1.006-1.063 g/ml), high density lipoprotein (HDL,

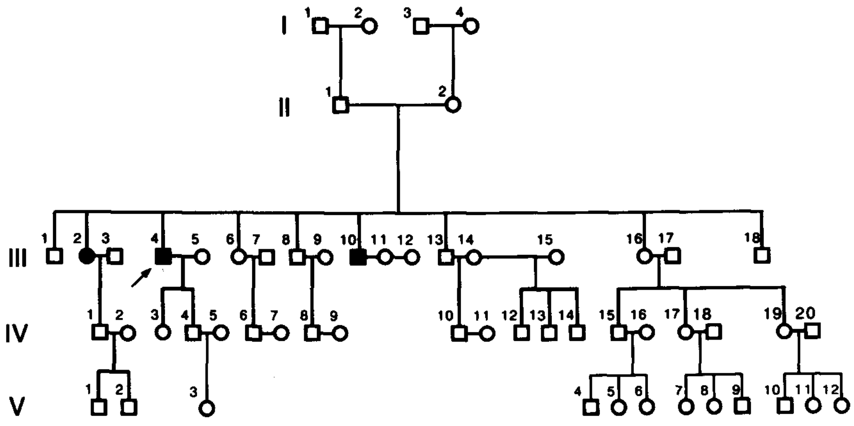

FIG. 1. Kinship of the three patients (III-2, III-4 and III-10) with Refsum's disease. Their clinically unaffected brother (III-8) and sisters (III-6 and III-16) do not show evidence of phytanic acid storage.

*To whom correspondence should be addressed at Biochemistry Section, Psychiatry Service, VA Medical Center, Highland Drive, Pittsburgh, PA 15206.

1.063–1.210 g/ml) and very high density lipoprotein (VHDL, >1.210 g/ml) was essentially the same as that described by Hatch and Lees (13). A cerebrospinal fluid (CSF) sample was obtained from patient III-10, two normal subjects and 14 patients with various neurological disorders. All samples were stored at −70 C.

After obtaining informed consent, using a protocol approved by our Institutional Review Committee, a biopsy of sural nerve was performed, under local anesthesia, on four patients (III-2, III-4, III-6 and III-10) and four healthy volunteers. Immediately after removal, the sural nerve was desheathed on a cold plate (surface temperature, 10 C) under a dissecting microscope. The desheathed portion (endoneurium) contains myelin, Schwann cells, axons, capillaries and interstitial collagen, whereas the sheath (epi- and perineurium) consists mainly of perineurial cells, collagen, fibroblasts, elastic fibers, capillaries and lipocytes (14). The weights of both portions were recorded before and after lyophilization. The lyophilized samples were then stored at −70 C.

Clinical and neuropathologic observations. (As these findings will be presented in detail elsewhere, only the major clinical and neuropathologic observations are provided here.) Patient III-2 had retinitis pigmentosa, progressive restriction of visual fields, bony abnormalities (shortness of metatarsal bones), hearing loss and mild peripheral neuropathy (no obvious weakness or sensory loss but decreased knee and absent ankle reflexes). The number of myelinated fibers (MF) per mm^2 was 4327, which is below normal.

Patient III-4 had retinitis pigmentosa, peripheral visual field loss, short metatarsal bones and clinical (nerve conduction and electromyography) evidence of peripheral neuropathy. The number of MF/mm^2 was 3138—unequivocally below normal.

Patient III-10 had retinitis pigmentosa, restricted visual fields, progressive hearing loss, short metatarsal bones and symptoms and findings indicative of mild neuropathy. The number of MF/mm^2 was 4169, which is unequivocally abnormal. The size distribution of MF was bimodal (normal).

Patient III-6 is an unaffected sibling of patients III-2, III-4 and III-10. The number (6840/mm^2) and size distribution of MF of sural nerve were normal.

Lipid extraction and separation. Extraction of lipids from total plasma (1.0 ml), individual plasma lipoprotein fractions (equivalent to 2.0 ml plasma), erythrocytes (2.0 ml packed cells) and CSF was performed according to the procedure described by Nelson (15). The lipid extraction procedure used for biopsied sural nerve (~10 mg wet weight) was described by Michell et al. (16) and modified by us (17,18).

Separation of triacylglycerol into subclasses containing straight (TG_0) and branched chain (TG_1, TG_2) fatty acyl moieties was achieved by high performance thin layer chromatography (HPTLC) (Whatman, Clifton, New Jersey), using hexane/diethyl ether/acetic acid (90:12:1.5, v/v/v) as the developing solvent system. Total triacylglycerols ($TG_0 + TG_1 + TG_2$), cholesteryl ester and free fatty acids (FFA) were separated from total lipid extracts by TLC on Silica Gel G plates, using a developing solvent system of hexane/diethyl ether/acetic acid (75:23:2, v/v/v) (19). Separation of phospholipids into subclasses was achieved by TLC, using the solvent system described by Vitiello and Zanetta (20) and modified by us (21).

Neutral glycosphingolipids (NGL) were separated from erythrocyte lipids by column chromatography, using Sep-Pak silica cartridges (21). Before sample application, each cartridge was conditioned three times with 8 ml of $CHCl_3$. Lipid extracts (in 0.1 ml $CHCl_3$) from 1 ml of packed erythrocytes were applied to each cartridge. All nonpolar lipids were removed by elution with 40 ml of $CHCl_3$. The NGL were recovered from each cartridge by elution with 160 ml of acetone/methanol (9:1, v/v) mixture. Separation of NGL into monohexosylceramide (GL-1), lactosylceramide (GL-2), trihexosylceramide (GL-3) and globoside (GL-4) fractions was achieved by HPTLC, using the developing solvent system described by Vance and Sweeley (22).

Gas chromatography (GC) and mass spectrometry (MS). Before GC analysis, triacylglycerols and cholesteryl esters were transesterified using sodium methoxide reagent (23), while free fatty acids and phosphatidylcholine were methylated using BF_3-CH_3OH reagent as described by Morrison and Smith (24). Transesterification of total lipids was carried out using both sodium methoxide and BF_3-CH_3OH reagents. The resulting fatty acid methyl esters were further purified by TLC, using the developing solvent system described by Metcalf et al. (25).

The methylated samples were first analyzed on a Packard Gas Chromatograph, Model 419, equipped with dual hydrogen detectors. The operating conditions for GC were as described previously (19). The fatty acid methyl esters were also analyzed on a Hewlett-Packard capillary gas chromatograph, Model 5890A, equipped with a hydrogen flame ionization detector. A 30-m fused silica SP-2330 column, with 0.25 mm ID (Supelco, Bellefonte, Pennsylvania), was used. Each sample was run under an on-column injection mode from 100–240 C at a rate of 7 C/min with hydrogen as the carrier gas. Peaks on the chromatograms were identified by comparing the retention times with those of standard mixtures (Supelco) and were quantified by a Hewlett-Packard 3392 computing integrator using pentadecanoic acid (15:0, 0.5 mg/ml plasma) as an internal standard.

Phytanic acid and triunsaturated phytanic acid methyl esters were further identified by a Carlo Erba (Milan, Italy) gas chromatograph, Model 4160, directly interfaced via a glass capillary to a Kratos (Manchester, England) MS 50 double-focusing mass spectrometer. A 30-m fused silica DB-1 column, with 0.33 mm ID (J & W Scientific, Folsom, California), was used. Samples were applied via on-column injection and the GC was programmed from 140–250 C at 5 C/min. MS ionization was induced by electron bombardment at 70 eV with the source temperature at 200 C. The MS was scanned at 3 sec/decade, from m/z 500-30, at a resolution of 10,000. Data was acquired and analyzed by a Kratos DS55 system.

Plasma lecithin:cholesterol acyltransferase (LCAT). The method used to assay the in vitro rate of cholesterol esterification (LCAT activity) in plasma has been described by us (26). The LCAT activity was expressed either as the percentage of labeled cholesterol esterified per hour or as nmoles of cholesteryl ester formed per ml of plasma per hour. The radiolabeled cholesteryl esters formed during LCAT reaction were isolated by TLC, as described above. The method used to measure the distribution of radioactivity among the different fatty acid fractions of cholesteryl esters was that of Morris (27), as modified by Goodman and Shiratori (28).

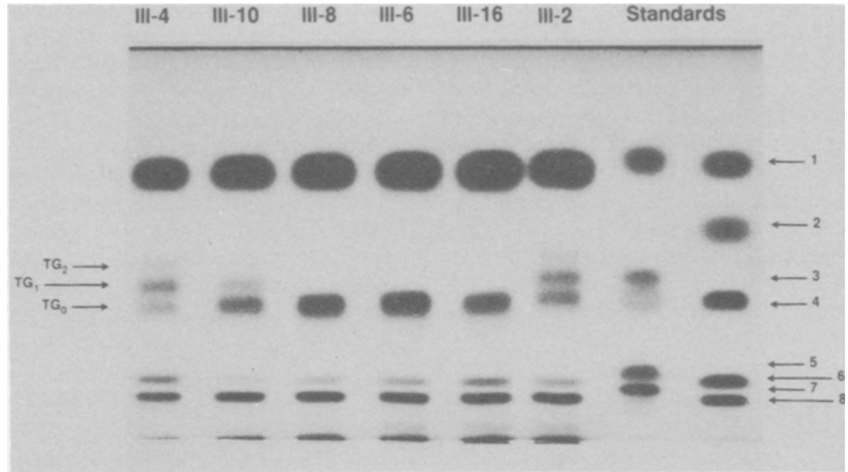

FIG. 2. HPTLC of plasma nonpolar lipids. TG_0, Normal triacylglycerol; TG_1, triacylglycerol with one branched chain fatty acid; TG_2, triacylglycerol with two branched chain fatty acids; 1, cholesteryl ester; 2, methyl palmitate; 3, 1,2-dipalmitoyl-3-phytanyl glycerol; 4, triacylglycerol; 5, phytanic acid; 6, palmitic acid; 7, phytol; 8, cholesterol. Lipid standard mixture (1 to 8) was purchased from Analabs/The Foxboro Co. (North Haven, Connecticut).

RESULTS

Plasma lipids. By thin layer separation, two additional bands, which moved just above normal triacylglycerol (TG_0), were demonstrated in three of the six siblings (patients III-2, III-4 and III-10) (Fig. 2). These two fast-moving bands (TG_1 and TG_2) were triacylglycerols containing one and two molecules of branched chain fatty acids, respectively. By capillary GC (Fig. 3) and MS (Fig. 4) analyses, two types of branched chain fatty acids, phytanic acids and triunsaturated phytanic acid, were demonstrated and identified by their characteristic base peaks (Fig. 4) (m/z 101 and m/z 69, respectively) and molecular ions (m/z 326 and m/z 320, respectively).

Gas chromatograms of the fatty acid compositions from patient III-4 revealed that phytanic acid was found mainly in TG_2 and TG_1 (80% and 45%, respectively), while triunsaturated phytanic acid was associated with TG_1 and TG_0. Phytanic acid, but not triunsaturated phytanic acid, was also found in free fatty acids (5.5%) and phosphatidylcholine (13.5%). No branched chain fatty acids were found in cholesteryl esters. After fractionation by

centrifugation of plasma lipoproteins into different density subclasses, TG_1 and TG_2 were shown by HPTLC to be primarily localized in the LDL fraction (Fig. 5).

Approximately 30–60 mg/dl of phytanic acid and 5–9 mg/dl of triunsaturated phytanic acid were found in the plasma of affected patients (Table 1). The concentration of the major plasma fatty acids (16:0, 18:0, 18:1, 18:2 and 20:4) was not changed substantially by the accumulation of these branched chain fatty acids (Table 1). To further test whether the acylation process is affected by the presence of branched-chain fatty acids, the activity of plasma LCAT was compared between affected patients and control subjects. No significant differences were found in either the rate of cholesterol esterification or the fatty acid composition of radiolabeled cholesteryl esters formed by the LCAT reaction (data not shown).

Erythrocyte lipids. Both saturated and unsaturated phytanic acids were found in triacylglycerols isolated from affected patients (Table 2). The increase of branched chain fatty acids was correlated more closely with a decrease of 18:0, 18:1 and 20:4 and an increase of 18:2. The percentage distribution of 16:0 remained essentially unchanged. By HPTLC, the profile of neutral glycosphingolipids revealed that the ratio of hydroxy to nonhydroxy

fatty acid moieties from affected patients was not substantially different from those of unaffected kins or control subjects (data not shown).

Biopsied sural nerve. The nonpolar lipids of endoneurium and the epi- and perineurium of affected (III-2 and III-10) and unaffected (III-6) patients were compared with their plasma nonpolar lipid profiles using HPTLC (Fig. 6). Both TG_1 and TG_2 bands were absent from endoneurial triacylglycerol isolated from the affected patients. Despite the presence of abundant triacylglycerols in epi- and perineurium, only a faint band of TG_1 appeared in the affected patients. The nonpolar lipids of interstitial

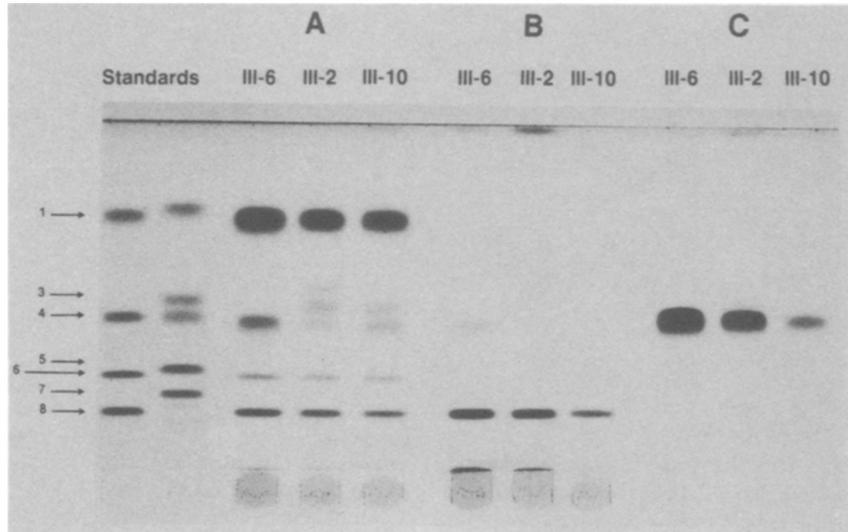

FIG. 6. HPTLC of nonpolar lipids. A, 5 μl plasma; B, 0.1 mg dry wt of biopsied sural endoneurium; C, 0.03 mg dry wt of biopsied sural epineurium and perineurium; 1–8, see legend of Fig. 2.

fat and blood vessels from affected (III-2) and unaffected (III-6) patients were also analyzed by HPTLC (data not shown). Like epi- and perineurium, only a faint band of TG_1 appeared in interstitial fats from the affected patient. There were no fast-moving bands of TG present in blood vessels from this patient.

The fatty acid composition of total endoneurial lipids (Table 3) and of epi- and perineurial triacylglycerols (Table 4) were further analyzed by capillary GC. In normal sural endoneurium, the major fatty acids were 16:0, 18:0 and 18:1. On the other hand, 16:0, 16:1, 18:1 and 18:2 were the major fatty acids in epi- and perineurial triacylglycerols. In affected patients, ca. 2% of the total fatty acids in endoneurium were found to be phytanate, which was probably associated with phospholipids. On the other hand, less than 5% of the total fatty acids in epi- and perineurial triacylglycerols were found to be phytanate. No branched chain fatty acids were demonstrated in either normal subjects or unaffected patients.

CSF. Analysis of CSF by HPTLC revealed that cholesteryl ester, unesterified cholesterol, phosphatidylcholine and sphingomyelin were the major lipid classes. To ascertain whether phytanate accumulation was present in CSF, the fatty acid compositions of cholesteryl ester and phospholipids were analyzed by capillary GC. The major fatty acids of normal CSF cholesteryl esters were 16:0, 18:1 and 18:2, whereas the major fatty acids of normal CSF phospholipids were 16:0, 18:0 and 18:1. In one of the affected patients, III-10, 0.9 μg of phytanate was found in 1 ml of CSF phospholipids. No phytanate was demonstrated in CSF cholesteryl esters.

DISCUSSION

The present study demonstrates that only small amounts of phytanic acid are present in desheathed sural nerves obtained by biopsy from three Refsum's patients with phytanic acid storage. This evidence makes it unlikely that phytanic acids are, in increased amounts, incorporated into the peripheral nerve myelin of affected patients. Thus, the molecular distortion hypothesis (11,12), in which incorporation into the cell membrane of branched chain fatty acids in place of the normal straight chain fatty acids resulting in membrane instability, seems unlikely as an explanation for the neuropathologic alterations. However, one possibility that cannot be excluded at this time is that the small amounts of phytanate might exert some damage on nerve fiber. Other observations also argue against the distortion hypothesis. First, as yet there is no evidence that nerve content of phytanic acid was influenced by a low-phytanate diet on which Refsum's patients were maintained (12). Second, only a low level of phytanic acid accumulated in the brain and nerves of animals fed large amounts of phytanic acid or its precursors (29,30), and neuropathy did not develop, although a low level of incorporation in the nervous system may be due to the serious toxicity of large doses of these branched chain fatty acids (12).

Accumulation of phytanic acid has been demonstrated in the sciatic nerve of Refsum's patients (11,31,32). These reports, however, did not specify whether phytanic acids were located in the myelin or endoneurium. It is conceivable that the accumulation of branched chain fatty acids in these previous cases was confined, as in this study, to the epi- and perineurium, which contains mainly

triacylglycerol (Fig. 6). Because the metabolic (33,34) and compositional (35) differences exist between the endoneurial and epi- and perineurial tissues, it is essential to utilize the endoneurium (desheathed nerve) in the study of the metabolic derangements of peripheral nerve lipids.

Laurell (36) has suggested that a relative deficiency of linoleate may be induced by the accumulation of phytanic acid. His speculation was based primarily on the analysis of plasma triacylglycerol fatty acid composition. However, most of the linoleic acid is normally found in plasma cholesteryl esters and phospholipids. Our data on the fatty acid concentrations of plasma total lipids (Table 1) indicate that the absolute concentration of linoleate and arachidonate are not affected by the presence of branched chain fatty acids. On the other hand, displacement of linoleate and arachidonate has been demonstrated in the phospholipids of liver, heart, kidney and skin (32,37). Thus, it is possible that the utilization of essential fatty acids is abnormal in the presence of branched chain fatty acids.

Two novel branched chain fatty acids, mono- and triunsaturated analogues of phytanic acid, were first demonstrated by Dulaney et al. (38) in the serum and urine of patients with Refsum's disease. Later, Evans and Dulaney (39) identified these unsaturated phytanic acids as 3,7,11,15-tetramethylhexadec-15-monoenoic acid and 3,7,11,15-tetramethylhexadec-6,10,14-trienoic acid. In the present study, we have also been able to demonstrate the presence of triunsaturated phytanate in the plasma (Table 1 and Fig. 3) and erythrocytes (Table 2) of affected patients. The level of these unsaturated analogues is probably proportional to the amount of accumulated phytanic acid. Steinberg (12) has suggested that triunsaturated phytanate may represent a metabolite of geranylgeranyl pyrophosphate. However, the origin of these unsaturated branched chain fatty acids remains speculative.

In conclusion, lack of phytanate accumulation in peripheral nerves, even in cases with severe fiber loss, raises significant doubt that the stability of peripheral nerve myelin, altered by the incorporation of branched chain fatty acids into myelin, is the basis of the neuropathologic alteration. Future studies need to critically assess whether Schwann cells (myelin) or neurons (axons) are preferentially affected and whether demyelination is primary or secondary.

ACKNOWLEDGMENTS

Clifford A. Reed and William Lawrence referred patients III-4 and III-10, respectively. Ian Jardine gave help with the GC-MS analysis, Phillip Low provided criticism and K. Cannon, K. Gross and G. Rastetter gave technical assistance. This work was supported in part by Center grants from NINCDS (NS-14304) and MDA (MDA-12), by Mayo, Borchard, Upton and Gallagher Funds and by grant NS-18012 from NINCDS.

[Received July 3, 1986]

Ether Glycerophospholipids of Gills of Two Pacific Crabs, *Cancer antennarius* and *Portunus xantusi*

S. Chapelle[1], **J.L. Hakanson, J.C. Nevenzel*** and **A.A. Benson**
Scripps Institution of Oceanography, La Jolla, CA 92093

Phospholipids and sterols constituted 70 and 20%, respectively, of the total lipids of the gills of two crabs, *Cancer antennarius* and *Portunus xantusi*. Phosphatidylcholine (46–55% of the total phospholipid phosphorous) and phosphatidylethanolamine (24–25%) were the principal phospholipids present. In both species 1′-alkenyl glycerols were present in about 20% of the phospholipid molecules but were not detected in the neutral gill lipids. The total ether phospholipids of *C. antennarius* gills contained 62% 1-(1′-alkenyl) groups, with the remainder probably being 1-alkyl moieties. Total gill plasmalogen contents were in the range of 163–184 μmol/g lipid, 82–87% of which was in the phosphatidylethanolamine fraction in both crab species.
Lipids 22, 76–79 (1987).

The gill lamellae of crustaceans are exposed to the external aquatic medium; thus their gill membranes, which contain high amounts of phospholipids (1–3), may be directly affected by the environment (4–6). Consequently, the study of gill phospholipids may help us to understand the role of lipids in environmental adaptations. The phospholipids of crustacean gills have been studied in some detail (7), but little information is available regarding the presence of ether-containing phospholipids, i.e., alkylacyl and 1-(1′-alkenyl)-2-acyl (plasmalogen) phosphoglycerides. The plasmalogen levels in gills isolated from various species of aquatic animals have been studied in several laboratories (8–11). Nothing is known about the existence of neutral plasmalogens (1′-alkenyl-diacyl glycerols) or of alkylacyl-phosphoglycerols in gills of marine crustaceans.

Ether lipids appear to be important constituents of many animal cell membranes (12), and some of the functions proposed for this lipid type in membranes have been reviewed briefly by Arthur et al. (13). As background to future study of the role of gill ether lipids in the adaptation of aquatic animals to environmental changes, we quantified the lipid composition and investigated the amounts of alkyl and 1′-alkenyl moieties in the gill lipids of two crabs, *Cancer antennarius* and *Portunus xantusi*, from the southern California coast.

MATERIALS AND METHODS

The large crab *Cancer antennarius* and the swimming crab *Portunus xantusi* were collected locally, and tissues (gills, hepatopancreas and muscle) were rapidly isolated and weighed. Lipid extraction and phospholipid determination by phosphorus analysis were performed as described previously (1,2). Total plasmalogens were measured by iodine uptake according to the procedure of Williams et al. (14), and assays of the content of choline and ethanolamine plasmalogens were carried out as described previously (11).

Total ether-linked glycerolipids were determined quantitatively by the method of Blank et al. (15): a) a 2-mg aliquot of the solvent-free total lipids was dissolved in 2 ml of diethyl ether and vigorously mixed with 0.7 ml of 0.05 M phosphate buffer (pH 7.1) containing about 3 units of phospholipase C from *Bacillus cereus* (Sigma Chemical Co., St. Louis, Missouri). After 2.5 hr at room temperature, the diethyl ether was evaporated under nitrogen, and the lipids were saponified with 2.5 ml of 0.5 M KOH in methanol in a boiling water bath for 8 min to remove acyl groups. Finally, 4.5 ml of methanol/acetic acid (100:6, v/v), 7 ml of chloroform and 6 ml of water were added. The upper phase was extracted again with 7 ml of chloroform, and the combined chloroform extracts were evaporated to dryness under vacuum. The total alkyl and 1′-alkenyl ether contents of the glycerolipids were determined from the aldehydes produced by the oxidation of the glycerol chains: b) the phospholipase C/saponification products from 1 mg of total lipids were treated with 0.5 ml of 0.1 M sodium metaperiodate in 90% acetic acid and heated for 45 min at 50 C. c) A second 1-mg sample of the products from procedure a was dissolved in 0.5 ml of 90% acetic acid containing 0.5 M HCl and heated for 45 min at 50 C to release aldehydes from the 1′-alkenylglycerols. Reaction mixtures from steps b and c were cooled to room temperature and ca. 150 mg of Silica Gel G (E. Merck, Brinkmann Instruments Co., Westbury, Connecticut) was added to remove compounds interfering with the color development. The aldehydes formed were measured at 546 nm after reaction with fuchsin reagent as described by Gray (16). The amounts of 1′-alkenylglycerols (directly) and alkylglycerols (by difference) were calculated from a standard curve determined with 1-*O*-hexadecyl-*rac*-glycerol (Sigma) over the range of 0–30 μg. Note that the mixture of reaction products assayed in steps b and c would also include glyceryl ethers from any neutral diacylglyceryl ethers and/or 1-(1′-alkenyl)-2,3-diacyl glycerols present.

Hydrolysis of the phospholipids was monitored on thin layer chromatograms using Phospray (Supelco, Bellefonte, Pennsylvania) for the detection of lipid phosphorous. To detect and separate alkylglycerols and 1′-alkenylglycerols, the unsaponifiables of total, neutral and phospholipid fractions from *C. antennarius* gills were separated by one-dimensional thin layer chromatography (TLC) using petroleum ether/diethyl ether/acetic acid (30:70:1, v/v/v) on Silica Gel G (17). The spots were located by spraying with 3% cupric acetate in 8% aqueous phosphoric acid (18) and careful charring; they were identified by comparison with authentic standards of cholesterol, 1-hexadecylglycerol, ceramide (obtained from sphingomyelin by the phospholipase C/saponification technique) and 1′-alkenylglycerols (from beef heart phospholipids, rich in plasmalogens [19], by the same technique).

An aliquot of the total lipids of *C. antennarius* gills was fractionated by column chromatography on silicic acid (Bio-Rad A, Bio-Rad Laboratories, Richmond, California)

into neutral lipids (eluted with 4 column vol of chloroform), glycolipids (collected in 4 vol of acetone) and the phospholipids (eluted last with 3 vol methanol) (20). Quantitative analysis of lipids was also accomplished with the Iatroscan TLC/FID (model TH-10, Mk. II) according to the procedure of Hakanson (21) using SI Chromarods. We spotted 20 μg total lipid in 1 or 2 μl of n-hexane. The rods were developed with hexane/diethyl ether/acetic acid (93:7:0.3, v/v/v) and scanned through the FID at 32 sec/rod; the hydrogen pressure was 1.2 kg/cm^2 and the air flow 2 l/min. From the electronically integrated FID signal the different lipid types were quantified using calibration curves for known compounds.

RESULTS

Table 1 presents the distribution of different lipids found in gills of crabs *Cancer antennarius* and *Portunus xantusi*. The principal lipids of both crustaceans are phospholipids (69–70% of total lipids) and sterols (18–21%, probably largely cholesterol [1,22]). Some minor components also occur, such as triglycerides, free fatty acids and cholesteryl esters; glycolipids were about 10% of total lipids by silicic acid column chromatography. The gill lipid composition of *P. xantusi* closely resembled that of *C. antennarius*.

Table 2 gives the amount of plasmalogens in gills, hepatopancreas and muscle of the two crabs. It is clear that the highest plasmalogen contents in both crabs were detected in gills (17.8–20.6%).

The composition of different classes of phospholipids isolated from gills (Table 3) is generally very similar in both species of Pacific crabs. The principal gill phospholipids are phosphatidylcholine (mainly diacyl forms) and phosphatidylethanolamine (essentially in the plasmalogenic form). This tissue is also rich in sphingomyelin and diphosphatidylglycerol.

TLC of the unsaponifiables of the gill total lipids from *C. antennarius* gave a distinct spot for 1′-alkenylglycerols with an approximate Rf value of 0.59 under our experimental conditions; this is higher than the Rf of 1-hexadecylglyceryl ether (0.42). Both alkyl and 1′-alkenyl ethers were found in the phospholipids, but the neutral lipids of gills contained only traces of alkylglycerols.

It was of interest to determine the total content of glyceryl ethers in gill phospholipids. The results for *C. antennarius* only are summarized in Table 4 and reveal a high concentration of ether lipids (16–21% of total phospholipids). When the fuchsin reagent was used, the values for plasmalogens (1.30 mg/g wet tissue) were not significantly different from the results obtained with the iodine uptake procedure (Table 2; 1.46 mg/g wet tissue).

nd, No data.

[a]Method of Blank et al. (15); total ether glycerols of total lipids. Assumes mol wt of 770 for in situ plasmalogens (10). Values are the mean of analyses of six individual animals.

[b]Method of Williams et al. (14); total 1′-alkenyl moieties of total lipids. Data of Tables 1 and 2.

[c]Method of Chapelle and Benson (11); choline plus ethanolamine plasmalogens only.

The alkylglycerol content (obtained by difference between total ether lipids and 1′-alkenyl forms) was also substantial, being about 0.78 mg/g of wet tissue, 11% of total phospholipids or 37.5% of the total ether lipids.

DISCUSSION

This investigation confirms that marine crustacean gills are a rich source of ether lipids (about 29% of total phospholipids in *C. antennarius*). Crab gills for the most part have phosphatidylethanolamines as principal plasmalogens (82.2–86.6% of total 1′-alkenylphosphoglycerols; Table 3). This agrees with our previously published data on gill plasmalogens for several different crustaceans (11). Phosphatidylethanolamine has been reported to be the principal plasmalogen in whole body lipids of arthropoda and many other marine invertebrates (8,23). We found no neutral plasmalogens ([1′-alkenyl]-diacylglycerols) in the gill lipids of *C. antennarius,* but estimate 1-alkyl-2-acyl phosphoglycerols to be about 11% of the phospholipids (Table 4).

1-Alkyl glyceryl ethers are widely distributed in marine organisms (8,23,24), but their occurrence as constituents of the phospholipids (i.e., as 1-alkyl-2-acyl-3-phosphoglycerols) is not well documented. The occurrence of neutral plasmalogens ([1′-alkenyl]-2,3-diacylglycerols) has been reported only for starfish (24,25) and ratfish liver (17).

Together with the literature, our results lead to the conclusions that in crustacean gills the phospholipids, although important sources of both alkyl and 1′-alkenyl ether phospholipids, contain more 1′-alkenyl than alkyl ether moieties and that neutral plasmalogens (i.e., [1′-alkenyl]-2,3-diacylglycerols) seem to be absent. The levels of plasmalogens in gill lipids of crustaceans are comparable to the content of these plasmalogenic substances in the lipids of mammalian heart and brain, with the latter

tissues being considered the most concentrated sources in vertebrates.

Extensive data document the role of gill membrane phospholipids and fatty acids in adaptation of aquatic invertebrates and vertebrates to environmental and salinity changes (7,26). We believe that similar studies of the response of gill membrane ether phospholipids (changes in the amounts of specific phospholipids and ether glycerophosphates and in the carbon chains of their fatty acids and 1-alkyl and 1′-alkenyl moieties) could offer additional parameters by which to investigate the role of ether phospholipids in biological systems.

ACKNOWLEDGMENTS

This work was supported through the Ecological Research Division, Office of Health and Environmental Research, Department of Energy. SC was supported by a NATO Fellowship. Animals were provided by Ron McConnaughey and the Scripps Aquarium.

[Received April 11, 1986]

Free and Esterified Sterols of Cotton Buds and Anthers

William R. Lusby*,[a], James E. Oliver[a], Gerald H. McKibben[b] and Malcolm J. Thompson[a]
[a]Insect and Nematode Hormone Laboratory, Agricultural Research Service, USDA, Beltsville, Maryland, and [b]Boll Weevil Research Laboratory, Agricultural Research Service, USDA, Mississippi State, Mississippi

Capillary gas liquid chromatography analyses were conducted on free and esterified sterol fractions of cotton (*Gossypium hirsutum* cv. Stoneville 213) floral buds and anthers. The free sterols of both cotton buds and anthers consist mainly of the common plant sterols sitosterol, stigmasterol and 24ξ-methylcholest-5-en-3β-ol. The composition of esterified sterols of cotton buds and anthers were similar, and consisted of pollinastanol, 31-norcycloartanol, cycloartenol, 31-norcycloartenol, 24-dehydropollinastanol and sitosterol. Desmosterol was also present in both the free and esterified sterols of anthers. The identities of the sterols were confirmed by gas chromatography–mass spectrometry analyses. Esterified sterols accounted for 46.7 and 88.7% of total sterols of cotton bud and anthers, respectively. The ratio of esterified sterol to free sterol per gram of tissue is about 8:1 in anthers. The Δ^5-sterols of the esterified sterols of cotton buds and anthers account for only 17 and 9.2% of the total sterols, respectively.
Lipids 22, 80–83 (1987).

The wax-sterol ester fraction of freeze-dried cotton buds or anthers has exhibited potent feeding stimulant activity for the cotton boll weevil (1). While demonstrating that certain waxes of the wax-sterol ester mixture were responsible for the feeding activity (1), it was observed that the composition of esterified sterols differed qualitatively and quantitatively from that of the free sterols and from results of a previous report (2). Most phytophagous insects are capable of converting the ubiquitous plant sterol sitosterol, as well as a variety of Δ^5-C_{28} and -C_{29} plant sterols, to cholesterol to obtain adequate quantities of this "essential" sterol (3). The fact that the boll weevil is capable of converting sitosterol, a major sterol of cotton buds, to cholesterol (4) and is stimulated to feed on and oviposit in cotton buds demonstrates an important host plant–insect relationship and the essential role of cotton buds in the life cycle of the cotton boll weevil. The composition of the esterified sterols suggests that the cotton boll weevil depends on the free sterols of cotton buds or anthers to satisfy its metabolic needs for sterols. The present paper describes the composition and identity of the free and esterified sterols of cotton buds and anthers.

MATERIALS AND METHODS

Instrumentation. Sterols and sterol acetates were analyzed by gas liquid chromatography (GLC). The GLC analyses were performed with a Varian model 3700 gas chromatograph equipped with a flame ionization detector and a 15 m × 0.32 mm DB-1 fused silica capillary column (0.25 μm film) at oven temperatures of 230 C and 240 C for free sterols and sterol acetates, respectively. Peaks, areas of peaks and retention times were automatically recorded by a Shimadzu model C-R1B recorder. Cholesterol, sitosterol and their acetates were used as standards. Electron ionization (70 eV) mass spectra were obtained with a Finnigan model 4500 gas chromatograph–mass spectrometer fitted with a 15 m × 0.25 mm DB-1 fused silica capillary column (0.1 μm film thickness). Data were analyzed by an on-line Incos data system. Thin layer chromatography (TLC) analyses were conducted on Anasil G Chromatoplates (Analabs, North Haven, Connecticut). Silver nitrate-impregnated Silica Gel H Chromatoplates (Analabs) were prepared as previously reported (5). Visualization of TLC spots was achieved by spraying with sulfuric acid followed by heating.

Extraction of cotton buds and anthers. Whole cotton (*Gossypium hirsutum* cv. Stoneville 213) floral buds with bracts were chopped in a blender and then freeze-dried. Anthers were dissected from buds and then freeze-dried whole. Twenty-five g of each freeze-dried material was extracted in a Soxhlet apparatus successively for 24 hr each with pentane, ethyl acetate, chloroform and methanol (1). The solvents were removed under reduced pressure at 50 C, and the resulting residues were analyzed by TLC on two separate plates; one was developed in toluene/hexane (1:1, v/v) and the other in toluene/ethyl acetate (9:1, v/v).

Free sterol and sterol ester isolation. After Soxhlet extraction, TLC analyses showed that the major portions of the unesterified sterols (free sterols) and wax-sterol ester mixtures were in the pentane extract with small quantities of each in the ethyl acetate extract. To remove the wax-sterol ester mixture and free sterols from more polar compounds in the ethyl acetate extract, the residue was partitioned between equal volumes of pre-equilibrated hexane and 70% aqueous methanol. The lower phase (70% aqueous methanol) was passed through a total of five funnels containing the hexane phase.

The hexane phase was washed twice with the lower phase. TLC analyses showed that there were neither free sterols nor sterol esters in the lower phase (70% methanol), and it was discarded. The combined upper phases, which contained the wax-sterol ester mixture and free sterols, were reduced to dryness under vacuum and combined with the pentane extract. The combined residues were chromatographed over 30 g of hexane-washed Merck Silica Gel (2.5 × 16 cm) by eluting with 150-ml volumes of 0 and 3% ether in hexane, with 100-ml volumes of 10, 25 and 50% ether in hexane, and finally with 100% ether. The wax-sterol ester mixture was present in the 3% ether in hexane fraction. The 25% and 50% ether-in-hexane fractions that contained a mixture of alcohols, sterols, diglycerides and fatty acids were combined.

Removal of fatty acids from sterol mixture. The combined 25% and 50% ether-in-hexane fractions were

Nomenclature—sitosterol: 24α-ethylcholest-5-en-3β-ol; 24ξ-methylcholest-5-en-3β-ol; stigmasterol: 24α-ethylcholesta-5,22E-dien-3β-ol; desmosterol: cholesta-5,24-dien-3β-ol; pollinastanol: 9β,19-cyclo-14α-methyl-5α-cholestan-3β-ol; 24-dehydropollinastanol: 9β,19-cyclo-14α-methyl-5α-cholest-24-en-3β-ol; cycloartenol: 9β,19-cyclo-4,4,14α-trimethyl-5α-cholest-24-en-3β-ol; 31-norcycloartanol: 9β,19-cyclo-4α-14α-dimethyl-5α-cholestan-3β-ol; 31-norcycloartenol: 9β,19-cyclo-4α,14α-dimethyl-5α-cholest-24-en-3β-ol; 24-methylenecholesterol: 24-methylcholesta-5,24(28)-dien-3β-ol.

reduced to dryness under vacuum, redissolved in ether and treated with an excess of diazomethane and a catalytic amount of methanol to esterify fatty acids. After the solvent was removed under vacuum, the residue was chromatographed on a silica gel column as before, and the fractions were monitored by TLC. The 10% ether-in-hexane fraction contained the fatty acid methyl esters. The 25% and 50% ether-in-hexane fractions containing the alcohols, sterols and diglycerides were combined and analyzed qualitatively and quantitatively by GLC.

Sterols from wax-sterol ester mixture. The 3% ether-in-hexane fraction, which contained the wax-sterol ester mixture, was saponified by refluxing with 5% potassium hydroxide in methanol/benzene (5:1, v/v) for 4 hr. Most of the solvent was removed under vacuum, and the mixture was diluted with water, acidified with dilute hydrochloric acid, and extracted three times with hexane. The hexane solution was washed with water and dried over sodium sulfate, and the hexane was removed under vacuum. The dried residue was dissolved in ether and treated with excess of diazomethane to esterify fatty acids. The ether was removed under vacuum and the residue was chromatographed over 30 g of silica gel (2.5 × 16 cm) as before in the removal of fatty acids from the sterol mixture. The column fractions were monitored by TLC.

Acetylation and argentation chromatography of esterified sterols. Since the compositions of the esterified sterols (from saponification of the wax-sterol ester fraction) from cotton buds and anthers were similar, they were combined and acetylated with acetic anhydride-pyridine overnight at room temperature. The sterol acetates were chromatographed on a 20% $AgNO_3$-Unisil column (1.5 × 27 cm), which was eluted with 50 ml of hexane followed by 50-ml volumes containing increasing amounts of ether in hexane (0.5 to 6.0%, in 0.5% steps). The fractions were monitored by GLC and TLC ($AgNO_3$-silica gel).

RESULTS

Free sterols from cotton buds and anthers. Extraction of cotton buds and anthers using successive solvents in a Soxhlet apparatus rather than the usual method, for example, with chloroform/methanol (2:1, v/v), yielded fractions that were less contaminated with more polar material. Both sterol esters and free sterols were completely extracted into pentane and ethyl acetate. The TLC and GLC analyses indicated that the 25% and 50% ether-in-hexane fractions from chromatography of the combined pentane and ethyl acetate extracts of both cotton buds and anthers, after removal of fatty acids, contained a mixture of sterols, a small quantity of other alcohols and (compared to our experiences with that of insect and plant tissues) an unusually large quantity of diglycerides. From 25 g of freeze-dried cotton buds, 53 mg of the alcohol-diglyceride-sterol mixture was obtained. The analysis of the mixture of sterols by GLC indicated a total of ca. 35 mg of sterols consisting mainly of sitosterol (87%) with lesser amounts of stigmasterol, 24ξ-methylcholest-5-en-3β-ol and detectable quantities of pollinasterol and cholesterol (Table 1).

Analogous fractions from 25 g of cotton anthers yielded 130 mg of the alcohol-diglyceride-sterol mixture, of which 32 mg was sterols. The free sterols of cotton anthers also consisted predominantly of sitosterol (78%) with lesser amounts of 24ξ-methylcholest-5-en-3β-ol, cholesterol, pollinastanol, stigmasterol and a detectable quantity of desmosterol (Table 1). The relative retention times (RRTs) (Table 1) and mass spectral data of the sterols were identical to those of authentic sterol standards.

Although column chromatography on silica gel did not separate the free sterols from the diglycerides, they were readily separated as their acetates. Acetylation of the sterol-diglyceride mixture followed by chromatography over 10 g of silica gel (2.5 × 6 cm) yielded the crystalline

TABLE 1

Relative Percentages of Total Free and Esterified Sterols of Cotton Buds and Anthers

		Cotton buds		Cotton anthers	
Sterols	RRT[a]	Free	Esterified	Free	Esterified
Sitosterol	1.65	87.0	17.0	78.4	5.7
Stigmasterol	1.42	7.0	—	3.6	—
24ξ-methylcholest-5-en-3β-ol	1.30	5.0	—	8.4	—
Pollinastanol	1.16	D[b]	26.0	4.3	29.5
Cholesterol	1.00	D	—	5.3	—
Cycloartenol	1.90 (1.77)	—	22.0	—	19.0
31-Norcycloartenol	1.51 (1.46)	—	16.0	—	17.6
31-Norcycloartanol	1.38 (1.34)	—	14.0	—	20.0
24-Dehydropollinastanol	1.28	—	5.0	—	4.0
Desmosterol	1.10	—	—	D	3.5
24-Methylenecholesterol	1.27	D	—	D	—
% of total sterol		53	47	11	89

[b]Detectable quantity.

sterol acetates in the 2% ether-in-hexane fraction; the diglyceride acetates were eluted from the column with 20% ether in hexane. TLC analyses and gravimetric quantitation of the acetate fractions from cotton anthers indicated 32 mg of sterol acetates and 81 mg of the diglyceride acetates; from cotton buds, 32 mg of sterol acetates and 14 mg of diglyceride acetates were obtained.

Interestingly, like triglycerides, the diglyceride acetates (R_f = 0.05) migrated only slightly from the origin on a TLC plate developed in toluene/hexane (1:1, v/v). The sterol acetates (R_f = 0.31), however, migrated nearly a third of the distance from the origin to the solvent front of the plate.

Esterified sterols from cotton buds and anthers. Saponification of the wax-sterol ester fractions isolated from cotton buds and anthers yielded about 85% sterols and 15% alcohols, which consisted of phytol, geranylgeraniol, dihydrophytol and a C_{18} alcohol with a double bond (1). The alcohols and sterols were eluted in the 25% and 50% ether-in-hexane fractions from a silica gel column. The 25% ether-in-hexane fraction showed two spots by TLC with R_f values of 0.25 and 0.31, which were higher than that of a 4-desmethyl sterol (R_f = 0.17). The 50% ether-in-hexane fraction showed two spots with R_f values of 0.18 (similar to that of a 4-desmethyl sterol) and 0.26. Since the aliphatic alcohols and the 4-methyl and 4,4-dimethyl sterols chromatographed similarly, to determine the total sterol composition the 25% and 50% ether-in-hexane fractions were combined and analyzed qualitatively and quantitatively by GLC. Thus, 25 g of freeze-dried cotton buds yielded 55 mg of semicrystalline material, of which 31 mg were sterols by GLC analysis. The common plant sterols sitosterol and 24ξ-methylcholest-5-en-3β-ol represented only 17% of the total sterols (Table 1). A far greater quantity of the wax-sterol ester mixture was obtained from 25 g of freeze-dried cotton anthers than from the same weight of cotton buds. The mixture from anthers, when quantified by GLC, contained 250 mg of sterols, which consisted of 4,4-dimethyl, 4-methyl and 4-desmethyl sterols (Table 1).

The compositions of esterified sterols from cotton anthers and buds were quite similar and consisted mainly of pollinastanol (1), 31-norcycloartanol (2), cycloartenol (5), 31-norcycloartenol (4), 24-dehydropollinastanol (3) (Scheme 1; Table 1) and sitosterol. (Previous investigations on higher plant sterols have shown that while 24-ethylcholest-5-en-3β-ol has the 24α-configuration, the 24-methylcholest-5-en-3β-ol is often a mixture of 24α- and 24β-epimers [6] and thus the 24ξ-methyl designation for the latter compound.)

(3) R = R' = H
(4) R = Me, R' = H
(5) R = R' = Me

SCHEME 1

In a previous study of the esterified sterols of cotton buds, cholesterol and sitosterol reportedly were found (2). In this study, however, the above-named sterols are the major esterified sterols of cotton buds and anthers, and sitosterol constitutes less than 6% of the total esterified sterols (Table 1). The esterified sterols of cotton anthers also contained demosterol. The sterol RRTs (Table 1) and mass spectral data were identical to those of authentic sterol standards.

With few exceptions, the RRT of a sterol vs cholesterol is identical to that of the corresponding sterol acetate vs cholesterol acetate (7,8). The exceptions are sterols with one or two methyl groups at C-4. For example, on an SE-30 column, the acetates of 31-norcycloartanol and cycloartenol gave RRTs of 1.35 and 1.75, respectively. The corresponding free sterols exhibited RRTs of 1.39 and 1.87, respectively (7,8). Surprisingly, on our 15-m DB-1 (a crosslinked and bonded dimethylpolysiloxane liquid phase) fused silica capillary column, the RRTs for the acetates of 31-norcycloartanol and cycloartenol were 1.34 and 1.77, respectively; the free sterol RRTs were 1.38 and 1.90, respectively (Table 1) and thus agree well with the RRTs obtained on an SE-30 coated column (7,8). The RRTs of the 4-desmethyl sterols were also similar to those previously reported (7,8). In order to have the RRT of a sterol vs cholesterol identical to that of a sterol acetate vs cholesterol acetate, the column temperature for analyses of the sterol acetate should not be more than 10 C higher than the column temperature for the free sterol.

Although 4-desmethyl sterols accounted for nearly 43% of the total esterified sterols from cotton anthers, the common 4-desmethyl sterols such as sitosterol and stigmasterol represented less than 6% of the total sterols. The composition of esterified sterols is quite similar in both buds and anthers, but the total quantity of sterols per gram of tissue is about eight times greater in anthers.

Argentation chromatography of the sterol acetates from the combined esterified sterols of cotton buds and anthers, followed by qualitative GLC analyses, was effective in separating the sterols on the basis of degree of unsaturation (Table 2). Fractions 5 and 6 contain the saturated steroids. Fractions 7–9 contain the steroids with one double bond whereas fraction 10 contains those with two double bonds. Since 4,4-dimethyl, 4-methyl and 4-desmethyl sterols are readily separated by chromatography over neutral alumina (8,9), it would be possible to obtain each of the steroids in Table 2 in high purity simply by saponification of the saturated and mono- and diunsaturated steroid fractions and subsequent chromatography on an alumina column. In fact, the argentation chromatography shows some degree of separation within the saturated, mono- and diunsaturated fractions on the basis of substituent at C-4 (Table 2).

DISCUSSION

The sterol composition of buds is similar to that for anthers. For either buds or anthers, however, the free sterols are qualitatively different from the esterified sterols (Table 1). Esterified sterols accounted for 47 and 89% of total sterols of cotton buds and anthers, respectively. By comparison, the esterified sterol fraction constituted 75% of the total sterols of mixed pollen (10). The

[a]Determined by GLC.
[b]In this fraction, 21.9% of the mass is the acetate of dihydrophytol.
[c]In this fraction, 5 and 6.5% of the mass are the acetates of dihydrophytol and phytol, respectively.
[d]In this fraction, 20% of the mass is the acetate of geranylgeraniol plus the acetates of two other alcohols or sterols representing 28% of total mass.

esterified sterol fraction of cotton anthers contained the least amount of sitosterol. Our results thus indicate that the composition of the free sterols is mainly the end products of sterol biosynthesis in these two tissues, whereas the esterified sterol fraction is composed of mainly precursors and intermediates in the biosynthetic pathway to sitosterol or other sterol end products of the cotton plant.

Pollinastanol (1) was first isolated from a pollen (11), and 24-dehydropollinastanol (3), 31-norcycloartanol (2) and 31-norcycloartenol (4) have also been isolated from a mixture of pollens (10). Since an anther is part of a stamen that develops and contains pollen, it is not surprising that pollinastanol was found in cotton buds and anthers. The esterified sterol fraction of cotton buds and anthers contains all of the above-named sterols except 24-dehydropollinastanol and affords a convenient and accessible source of cycloartenol, an intermediate in the production of the common Δ^5-sterols in green plants (6). Both cycloartenol and 31-norcycloartanol have been isolated from pollen of *Taraxacum officinale* (12). Interestingly, 24-methylenecholesterol, which is often the principal sterol in pollen from a number of plant species (10,13-15), was present at only detectable levels in the free sterol fraction of cotton buds and anthers.

Sterols play an important role as structural components of membranes and as precursors to hormones or other compounds having physiological functions. All subcellular particles studied have been found to possess sterols (6). Although esters and glycosides do occur, usually the sterol is primarily in the free form (6). It has also been suggested that sterols in crop plants may have multiple nonmetabolic roles (16). In this study, the cotton buds contained about equal amounts of free and esterified sterols. On the other hand, cotton anthers contained a far greater percentage of their total sterols in the esterified form. The content of major free sterols increased in sorghum during the first 20 hr of germination, and the amount of free sterol of the mature leaf blades increased from day 7 to day 48, then decreased (16). The amount of sterol esters and glycosides was relatively low until flowering (16). Similar changes occur in sterol composition throughout the life cycle of soybean and squash (17). Thus the type of tissue, its age, the state of development, etc., can influence the qualitative and quantitative nature of sterols that occur during plant growth. To better understand the mechanism of biosynthesis and functions of sterols and the interrelationship between free and esterified sterols and sterol conjugates in the plant and animal kingdoms, then, the free and esterified sterols as well as sterol conjugates in the tissues should be qualitatively and quantitatively determined.

Metabolism of Sterols of Varying Ring Unsaturation and Methylation by *Caenorhabditis elegans*

Ruben Lozano[a,*], **Thomas A. Salt**[b], **David J. Chitwood**[a], **William R. Lusby**[a] and **Malcolm J. Thompson**[a]
[a]Insect and Nematode Hormone Laboratory, Agricultural Research Service, USDA, Beltsville, Maryland and [b]Department of Botany, University of Maryland, College Park, Maryland

The metabolism of three dietary 4,4-desmethylsterols and two 4α-methylsterols was investigated in the free-living nematode *Caenorhabditis elegans*. Dietary cholestanol was converted mostly to lathosterol. Dietary lathosterol, 7-dehydrocholesterol, 4α-methylcholest-7-enol and 4α-methylcholest-8(14)-enol each remained largely unchanged. An absolute requirement for a substantial quantity of 7-dehydrocholesterol in *C. elegans* did not exist. *C. elegans* was unable to remove a 4α-methyl group or introduce a double bond at C-5 and also demonstrated the lack of a Δ^7-reductase. Its nutritional sterol requirement was satisfied by cholestanol, lathosterol or 7-dehydrocholesterol; growth was comparable to that obtained previously in media containing Δ^5-sterols. However, the two 4α-methylsterols appeared to be unsatisfactory sterol nutrients. The possible physiological importance of 4α-methylsterols is discussed briefly.
Lipids 22, 84–87 (1987).

Nematodes are incapable of de novo sterol biosynthesis (1–4) and require exogenous sterol for normal growth and development (5–8). Metabolism of these exogenous sterols by nematodes is of current interest due to findings that several compounds with nematicidal activity also disrupt sterol metabolism in the free-living nematode *Caenorhabditis elegans* (9–11).

We recently discovered a unique metabolic process involving nuclear methylation of sterols at C-4 that occurs in three free-living nematodes, *C. elegans* (12), *Turbatrix aceti* and *Panagrellus redivivus* (13), but has not yet been reported in any other organism. Cultures of *C. elegans* propagated in media containing one of several dietary 4,4-desmethylsterols were found to produce 4-methylsterols, predominantly 4α-methylcholest-8(14)-enol with smaller amounts of lophenol (4α-methylcholest-7-enol) (9–14). Disruption of this 4-methylsterol pathway could provide for the design of selective nematicides against plant- and animal-parasitic species. 4-Methylsterols were not detected in cysts of *Heterodera zeae*, the corn cyst nematode (15), although the possibility of their occurrence in other life stages of this or other parasitic nematodes is under investigation.

Previously, with the exception of stigmastanol (14), we had only utilized Δ^5-sterols in the media, which were subsequently metabolized by *C. elegans* to produce mostly 7-dehydrocholesterol. Given the predominance of this $\Delta^{5,7}$-sterol, it became of interest to determine how non-Δ^5-sterols (Δ^0, Δ^7, $\Delta^{8(14)}$) would be metabolized and whether the presence of 7-dehydrocholesterol was an absolute requirement for growth and reproduction of *C. elegans*.

In the present study, sterols were isolated and identified from *C. elegans* propagated in media containing either cholestanol, 7-dehydrocholesterol, lathosterol, lophenol or 4α-methylcholest-8(14)-enol. Utilization of these dietary sterols, selected for their variation in ring unsaturation as well as their postulated intermediacy to 4α-methylcholest-8(14)-enol (11,14,15), provided further insight into sterol metabolism in *C. elegans.*

MATERIALS AND METHODS

C. elegans was cultured axenically in semidefined aqueous media containing 25 mg/l sterol (10). Cholestanol (5α-cholestan-3β-ol) was obtained by catalytic reduction of cholesterol. 7-Dehydrocholesterol and lathosterol (5α-cholest-7-en-3β-ol) were commercial samples and were purified by column chromatography. Lophenol (4α-methylcholest-7-enol) and 4α-methylcholest-8(14)-enol were synthesized from lathosterol as described elsewhere (12). The purity of the dietary sterols (>98%) was assessed by capillary gas chromatography (GC).

Free and esterified sterols were isolated from lyophilized nematodes according to our earlier procedures (10, 14). Qualitative and quantitative analyses of sterols and their steryl acetate derivatives were performed by GC using both a glass column packed with 2.0% OV-17 liquid phase and a 15-m DB-1 capillary column. Final identifications were confirmed by capillary GC-mass spectrometry and UV spectroscopy (where applicable) and were in agreement with our previously described characteristics (14). Instrumental details have been supplied in an earlier paper (10).

RESULTS

C. elegans grew very well when propagated with either cholestanol, 7-dehydrocholesterol or lathosterol, as demonstrated by the population and dry weight values in Table 1, which are similar to those obtained previously when sitosterol was utilized as dietary sterol (10). Total lipid and sterol content values for these three desmethylsterol experiments (Table 1) did not differ appreciably from each other and are also similar to those obtained previously for a variety of dietary desmethylsterols including cholesterol, sitosterol and stigmasterol (9,14). Whether the dietary sterol was cholestanol, 7-dehydrocholesterol or lathosterol, most of the sterol from *C. elegans* was nonesterified; steryl esters comprised only 13–19% of the total sterol (Table 1).

By contrast, in the presence of either dietary 4-methylsterol, growth and reproduction of *C. elegans* were very poor. Dietary 4α-methylcholest-8(14)-enol resulted in population and dry weight values that were only 38% and 35%, respectively, of the average values yielded by the three dietary desmethylsterols. Reproduction was even poorer on lophenol, which yielded only 6% and 18% of the population and dry weight, respectively, obtained with desmethylsterol propagation. Although their total lipid contents were similar, the total sterol

[a]Stigmastanol data were reported previously (14).

content of 4-methylsterol-propagated cultures was greater than that of desmethylsterol-propagated cultures, possibly due to a greater uptake of the 4-methylsterols by *C. elegans*.

The compositions of free sterol and steryl ester fractions from *C. elegans* propagated with cholestanol, 7-dehydrocholesterol, lathosterol or stigmastanol (from a previous study [14]) are presented in Table 2. *C. elegans* propagated with cholestanol contained, excluding dietary sterol, predominantly lathosterol with lesser amounts of 4α-methylcholest-8(14)-enol and cholest-8(14)-enol, as it did similarly when propagated with another stanol, stigmastanol. The major sterol of *C. elegans* propagated with 7-dehydrocholesterol was dietary sterol with lesser amounts of cholesta-5,7,9(11)-trienol, 4α-methylcholest-8(14)-enol and lathosterol. Lathosterol-fed *C. elegans* contained mostly dietary sterol and smaller quantities of 4α-methylcholest-8(14)-enol and cholest-8(14)-enol. The free sterol compositions were generally similar to the esterified sterol profiles with the exception of 4α-methylcholest-8(14)-enol, which, in all cases, comprised a fairly large percentage of the ester fraction. This phenomenon has been observed in all of our previous sterol analyses.

Table 3 lists the total sterol compositions of *C. elegans* propagated with each of the two 4-methylsterols. Lophenol-propagated cultures contained predominantly dietary sterol and a small but significant percentage of 4α-methylcholest-8(14)-enol. *C. elegans* fed 4α-methylcholest-8(14)-enol contained almost exclusively dietary sterol.

DISCUSSION

In our previous studies (9,11,14), the nutritional requirement for sterols in *C. elegans* was satisfied by a number of Δ^5-sterols, which were subsequently metabolized to produce predominantly 7-dehydrocholesterol, a $\Delta^{5,7}$-sterol. In the present study, cholestanol and a Δ^7-sterol (lathosterol) each performed as well as the Δ^5-sterols in satisfying the nutritional requirement. Dietary cholestanol and stigmastanol were converted mostly to lathosterol, while dietary lathosterol remained largely unchanged. In *C. elegans* fed either cholestanol or lathosterol, we detected a very small quantity of 7-dehydrocholesterol, which was probably of exogenous origin rather than a metabolite of the supplemented cholestanol and lathosterol. Therefore, even though 7-dehydrocholesterol is the major metabolite in

TABLE 3

Relative Percentages of Total Sterols from *C. elegans* Propagated with Dietary 4-Methylsterols

Recovered sterol	Dietary sterol	
	4α-Methylcholest-7-enol	4α-Methylcholest-8(14)-enol[a]
Cholesterol	0.6	0.6
Cholest-8(14)-enol	0.2	0.4
Lathosterol	0.8	0.7
Campesterol	—	1.1
Sitosterol	0.6	0.7
4α-Methylcholest-7-enol	87.3	1.6
4α-Methylcholest-8(14)-enol	10.5	94.9

[a]Contained less than 1% 4α-methylcholest-7-enol by GC.

C. elegans fed Δ^5-sterols, *C. elegans* has no absolute requirement for a substantial quantity of 7-dehydrocholesterol. Its structural requirement for sterol can also be fulfilled by lathosterol. Much of the dietary 7-dehydrocholesterol remained unchanged. A relatively small amount of cholesterol was present in 7-dehydrocholesterol-fed *C. elegans,* whose origin may have been as a media contaminant rather than as a metabolite of the supplemented 7-dehydrocholesterol. It is most probable that *C. elegans* lacks both a C-5 dehydrogenase and a Δ^7-reductase. Some of the dietary lophenol was converted to its $\Delta^{8(14)}$-analog; most of the dietary 4α-methylcholest-8(14)-enol (or possibly all of it) was not metabolized. In each case, we found only small percentages of desmethylsterols, which probably were exogenous media contaminants not completely extracted in our media preparation. Therefore, *C. elegans* has little or no ability to demethylate either of these two 4α-methylsterols.

While a number of 4,4-desmethylsterols have been shown to fulfill the nutritional requirement of *C. elegans,* neither of the two 4α-methylsterols tested here appeared satisfactory. Failure could possibly be due to the inability of a 4α-methylsterol to function as a bulk membrane component in *C. elegans,* and perhaps this nematode biosynthesizes 4α-methylsterols for a more specific function such as a hormone, a pheromone or a precursor to these, as previously suggested (9). Alternatively, if the 4α-methylsterol could indeed fulfill the bulk membrane role, normal growth and reproduction might not occur if an insufficient quantity of 4-desmethylsterols were available to fill some critical role requiring a structure-specific sterol (e.g., 7-dehydrocholesterol or lathosterol). Evidence for such multiplicity of sterol functions has been demonstrated by sterol "sparing" effects in insects (16) and "sparking" effects in fungi (17-19). Failure to make indirect use of 4α-methylsterols stems from the inability of *C. elegans* to convert them to presumably functional 4-desmethylsterols.

The compositions of recovered sterols from *C. elegans* propagated with the various dietary sterols (Tables 2 and 3) substantiate our previously hypothesized metabolic pathways (20). Figure 1 summarizes the nuclear modifications leading toward the production of 4α-methylcholest-8(14)-enol in *C. elegans.*

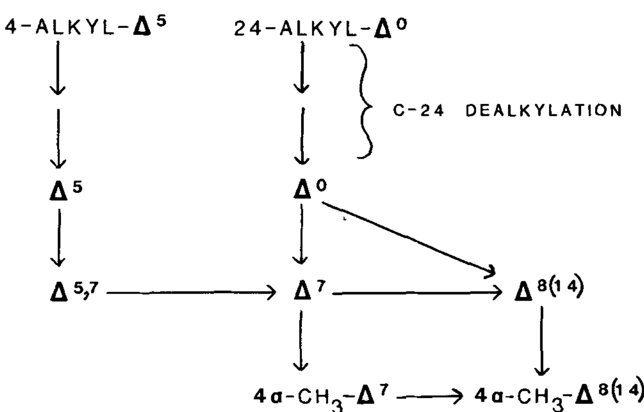

FIG. 1. Metabolic pathways to 4α-methylsterols in *C. elegans.*

[Received August 1, 1986]

The Effects of Fat-Free, Saturated and Polyunsaturated Fat Diets on Rat Liver and Plasma Lipids

Gary J. Nelson, Darshan S. Kelley, Perla C. Schmidt and **Claire M. Serrato**
Biochemistry Research Unit, Western Human Nutrition Research Center, Agricultural Research Service, U.S. Department of Agriculture, PO Box 29997, Presidio of San Francisco, CA 94129

The liver and plasma lipids and fatty acid composition of rats fed synthetic diets of differing fat type and content were studied. All animals were starved for 48 hr and then refed a high carbohydrate, fat-free diet for 48 hr. They were then divided into three groups and fed for an additional 48 hrs the following: group 1, the fat-free diet; group 2, a diet containing 44% of calories from corn oil; and group 3, a diet containing 44% calories from completely hydrogenated soybean oil. The total lipid concentration of the liver in the animals on the fat-free diet was elevated at 72 and 96 hr. The addition of either saturated or unsaturated fat in the diet at 48 hr prevented this accumulation. The total phospholipid and cholesterol concentrations of the liver were relatively uninfluenced by any diet in this study. Plasma total fatty acid concentration was elevated at 72 hr in the animals on a fat-free diet compared to those fed the stock diet, starved for 48 hr or fed the fat-containing diets. By 96 hr, however, plasma fatty acid concentrations in all groups were similar to those in animals fed only the stock diet. The release of de novo synthesized fatty acids into plasma from the liver was strongly inhibited by dietary fat, either saturated or polyunsaturated. With the fat-free diet there was a significant increase in the saturated and monounsaturated fatty acids in both liver and plasma. The addition of corn oil to the diet facilitated a reversion of the fatty acid composition in liver and plasma to that found in the animals fed the stock diet ad libitum, but saturated fat did not. No effect of diet on the fatty acid composition of the red cells was observed during the course of this study. Exogenous saturated fatty acids, although similar chemically to the fatty acids synthesized by the liver, may have physiological actions that differ from endogenously synthesized fat.
Lipids 22, **88–94 (1987).**

Dietary fat has profound effects on endogenous fat metabolism, and these effects differ depending upon the type of fat consumed (1–3). Fat-free diets in the rat stimulate liver fatty acid synthesis (2,4–6), while polyunsaturated fat in the diet strongly inhibits endogenous fatty acid synthesis (7–10). The effect of saturated fat in the diet on the suppression of endogenous fatty acid synthesis is still controversial (11–13).

This research was undertaken to elucidate how short-term changes in dietary fats influence endogenous fatty acid synthesis in the rat in vivo because of the marked effects observed in cultured rat hepatocytes (14,15). It was also of interest to determine how dietary fat composition affects the content and composition of tissue lipids. This report presents the effects of short-term fat feeding and type of dietary fat on liver and plasma lipid levels and the time course of changes in the fatty acid composition of the liver and plasma. In addition, release of de novo synthesized fatty acids into the plasma as a function of time and type of diet was determined.

MATERIALS AND METHODS

Materials, animals and diets. Male Sprague-Dawley rats, 100–150 g, were purchased from Bantin and Kingman (Fremont, California). They were fed a stock laboratory diet from Ralston-Purina (Richmond, Indiana) until they had grown to 400–500 g. At 120–140 days of age, the animals were segregated into three groups of 12 to 22 rats each, starved for 48 hr and refed a fat-free, high carbohydrate (FF) diet for 48 hr. After that, one group was continued on the FF diet for another 48 hr. A second group was placed on a synthetic diet in which 44% of the calories was supplied by corn oil (CO). The remaining group was fed a diet in which 44% of the calories was supplied by completely hydrogenated soybean oil (HSO) (a gift of Durkee Foods, Cleveland, Ohio) for 48 hr. The rats fed the stock diet were not starved and refed. The composition of the three diets is given in Table 1; that of the dietary fats is listed in Table 2. The vitamin and mineral mix (AIN-76) added to the synthetic diets was from Teklad Diets (Madison, Wisconsin). Animals had access to the diets ad libitum except initially, when all animals were given ca. 3 ml of the diet by stomach tube at the start of refeeding both the fat-free and fat-containing diets. All animals consumed approximately the same amount of calories regardless of diet group and appeared to find the diets quite palatable.

The animals were killed at 0, 3, 9, 24, 48, 51, 57, 72 and 96 hr after refeeding was begun. All animals received intraperitoneally ^3H_2O one hour before being killed (0.5 mCi/100 g body weight).

The liver and other tissues were removed and either extracted immediately or frozen at −20 C until they were extracted. Blood was drawn into heparinized syringes from the inferior vena cava. Red cells and plasma were separated by centrifugation at 3600 × g for 15 min. The red cells were washed (4×) with isotonic phosphate-buffered saline.

TABLE 1

Composition of Diets

Component	Wt % Fat-free diet	Corn oil diet	Hydrogenated soybean oil diet
Sucrose	70.5	43.0	43.0
Glycerol	5.0	—	—
Egg albumin	20.0	27.9	27.9
Mineral mix (AIN-76)	3.5	3.3	3.3
Vitamin mix (Teklad #40060)	1.0	1.0	1.0
Fat	—	24.8	24.8

Caloric distribution for the fat-free diet is the same as the weight %; that for fat-containing diets is 34% sucrose, 22% albumin and 44% fat.

20:4(n-6)	0.09	—
22:0	0.16	—
24:0	—	0.11
Sum of trace components	2.96	1.21

[a]Fatty acids are designated by the carbon chain length, number of double bonds and the position of the first double bond from the methylene end of the molecule.

All organic solvents were obtained from Burdick and Jackson (Muskegon, Michigan). Purified fatty acid methyl ester (FAME) reference standards were purchased from Nu-Chek-Prep (Elysian, Minnesota).

Lipid extraction. The lipid extractions were performed using $CHCl_3$-MeOH (2:1, v/v) by the procedures described previously (16,17) after lyophilization to remove all free and tritiated water. Hydroquinone was added to all samples. The purified total lipid extracts (TLE) were either prepared for transmethylation immediately or stored under nitrogen at −20 C until further processing.

Phospholipid analysis. The total phospholipid content (in mg) of the TLE was estimated from the mg of inorganic phosphate × 25 (18).

Cholesterol determination. Cholesterol was determined by a gas liquid chromatography (GLC) method. An aliquot of the TLE was dissolved in $CHCl_3$ to a concentration appropriate for direct injection onto a fused silica capillary column. The column was coated with a cross-linked methyl silicone polymer (Ultra-1 column, 25 m × 0.25 mm I.D., obtained from the Hewlett-Packard Corp., Palo Alto, California). The gas chromatograph was a Hewlett-Packard 5880A equipped with a Hewlett-Packard electronic integrator and data processor. Conditions were as follows: carrier gas, He at 14.5 psi; injection port temperature, 250 C; oven temperature, 280 C; FID temperature, 300 C; split ratio 50:1.

Under these operating conditions, cholesterol eluted from the column as a clean peak at 12.5 min. There was no interference from the other components in the TLE. Various peaks attributable to triglycerides, fatty acids and decomposition products of phospholipids appeared on the chromatogram, but always at retention times of 9 min or less under these chromatographic conditions.

Cholesterol was quantitated using peak areas compared to area obtained from a high purity cholesterol reference standard from Sigma Biochemicals (St. Louis, Missouri). The calibration was linear from 50 ng to 20 mg per μl of cholesterol. The cholesterol peaks showed some tailing at the higher concentrations, but this did not affect quantitation. Integration of peak areas, use of correction factors and calculation of the absolute amounts of cholesterol in the sample were performed automatically by the data station after calibration.

Tritium-labeled liver cholesterol samples were prepared for liquid scintillation counting by separation on thin layer plates (16), using pre-coated silica-gel plates obtained from E-M Science (Cherry Hill, New Jersey). The developing solvent was hexane/diethyl ether/acetic acid, (85:15:2, v/v/v). The cholesterol spot was located with iodine vapor and scraped into a scintillation vial without eluting the cholesterol from the absorbent. The presence of the adsorbent in the scintillation vial did not significantly interfere with the tritium counting.

Transmethylation. The transmethylations to obtain FAME were carried out using methanolic-HCl (7%, w/w) (14). FAME were diluted in hexane to an appropriate concentration and stored at −20 C until analyzed by GLC or by liquid scintillation counting of ^3H in their fatty acid moiety.

GLC of FAME. The FAME samples were analyzed as described previously (14) on fused silica capillary columns coated with SP-2340 (Supelco, Bellefonte, Pennsylvania). Samples were chromatographed on a Perkin-Elmer Sigma 2000 coupled to a P-E 7500 computer loaded with a Chrom 3 data analysis program.

The quantitative accuracy of the GLC procedures was evaluated by using either purified single FAME or reference mixtures selected to cover the range of FAME present in the experimental samples. Accuracy of the analysis was estimated to be within 5% for the major components (greater than 10% of the total FAME in the sample) and within 10% for the minor components in the samples.

The cholesterol extracted into the hexane washes of the transmethylation procedure was not separated from the FAME prior to injection of the samples in the chromatograph. However, cholesterol is largely decomposed during acidic transmethylation (19), and free cholesterol does not elute as a discrete peak from a SP-2340 column under the conditions in this work (14).

The composition (wt %) of the FAME in the rat samples were derived from the area percentages on the chromatograms (14). A chromatogram had between 40 and 80 discrete FAME peaks. Most minor peaks contributed less than 0.1% to the total area individually and were not identified with confidence. The major identified components usually comprised 95–97% of the total FAME present in the sample. For convenience, only selected major fatty acids are listed in the tables. The residue is collectively presented as "sum of trace components" and varies from approximately 4 to 12% of the total fatty acid present in the samples. Both identified and unidentified components are grouped in this category.

In some of the tables and figures, data are presented in terms of mg lipid/mg cellular protein because this allows the amounts to be compared in absolute terms rather than by the normalized values given by the usual wt % calculations. Proteins were analyzed by the method of Lowry et al. (20). The data were analyzed statistically using the two-tailed Student's t-test.

*Significantly different from the stock diet at $P < 0.05$.

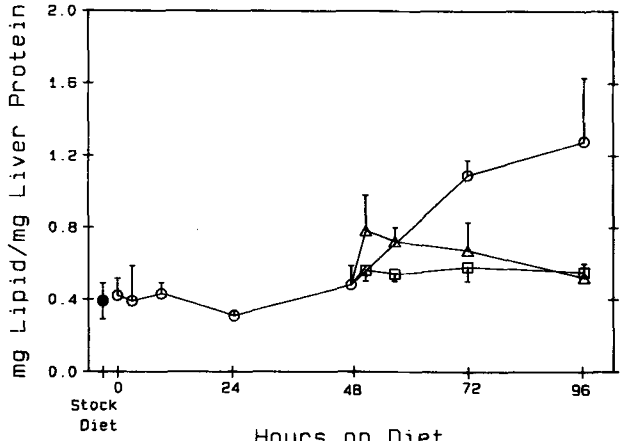

FIG. 1. The total lipid concentration (mg total lipid/mg liver protein) of liver for rats fed the various diets. ○, Fat-free, high carbohydrate diet; □, corn oil diet; △, hydrogenated soybean diet; ●, stock diet. Data shown are means ±S.D. for 3 to 6 animals. Only the 72- and 96-hr points for the animals on the fat-free diet are significantly different from the other points ($p < 0.05$ for the 72-hr point and $p < 0.01$ for the 96-hr point). Dietary protocols are given in the text.

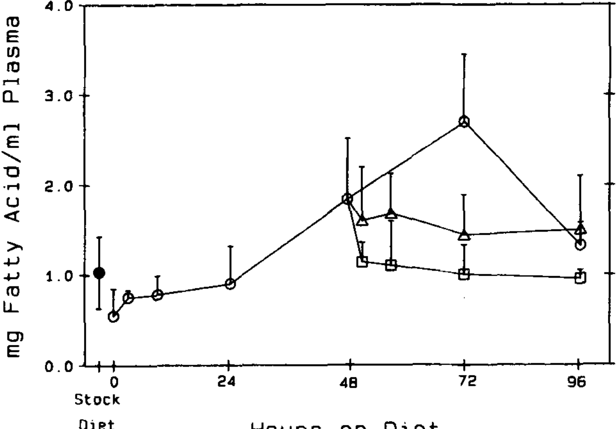

FIG. 2. Plasma total fatty acid concentration from rats on the three dietary treatments. ○, Fat-free, high carbohydrate diet; □, corn oil diet; △, hydrogenated soybean diet; ●, stock diet. Only the 72-hr data point for the animals on the fat-free diet is significantly different from the other data points ($p < 0.05$).

RESULTS

Table 3 lists average weights, percent lipid and protein per g of liver for the experimental animals on the various diets fed in this study. The wet weight of the liver decreased markedly after 48 hr of starvation and increased rapidly on the fat-free diet. The addition of either saturated or polyunsaturated fat to the diet caused a reversal of this trend and a return to the average wet weight found in the stock-fed animals. The percent lipid in the livers of these animals increased on the fat-free diet but decreased when either fat was added. The absolute amount of protein per cell varies little in these short-term feeding studies (14,15); hence, it is advantageous to present changes in the lipid content of the liver in terms of mg lipid/mg liver protein, as this value is relatively uninfluenced by changes in liver hydration and glycogen content that tend to confound percent weight calculations.

Figure 1 shows the time course of changes in the total lipid concentration of rat liver in mg lipid/mg liver protein as a function of the three dietary treatments. The liver lipids of animals on the fat-free diet show a significant elevation at 72 and 96 hr. The addition of fat to the diet after 48 hr of refeeding a FF diet prevented this increase in liver lipid concentration. This reduction was noted within 3 hr with the corn oil diet and within 24 hr with the saturated fat diet. By 48 hr on either fat-containing diet, the liver lipid level had equalized at about 8% of the liver wet weight, considerably below that found in the animals fed the FF diet.

Figure 2 presents the total fatty acid concentration of the plasma in the three groups. By 96 hr the plasma fatty acid content had reached a similar level (in mg fatty acid/ml plasma) in all three groups of animals, regardless of diet, in contrast to the liver lipid concentration, which demonstrated a marked difference between the fat-fed and fat-free diet groups at 96 hr. The animals on the fat-free diet did have elevated plasma lipid levels at 72 hr, while the plasma lipids in the fat-fed animals did not show a significant rise at this time. The slight elevation of the

plasma fatty acid in the animals fed unsaturated fat was not statistically significant.

Figure 3 displays the phospholipid concentration of the livers in the animals on the different diets. The ordinate in this figure is given in terms of mg phospholipid/mg of liver protein. Once again, the ordinate scale was chosen because this is approximately equivalent to a per-cell measurement unaffected by hydration or liver glycogen content (15). Expressed in these units, the phospholipid level of the liver changed only slightly during the starvation and refeeding periods and was relatively uninfluenced by the fat type or level in the diet.

Figure 4 shows the cholesterol concentration of the livers of the animals on the various diets during the feeding period. Similar to the phospholipids of the liver, cholesterol was not significantly influenced by the diets.

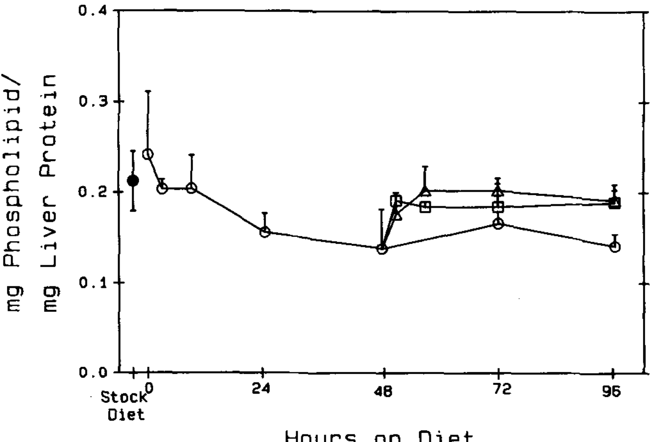

FIG. 3. Total phospholipid concentration of the livers from rats on the three dietary treatments. ○, Fat-free, high carbohydrate diet; □, corn oil diet; △, hydrogenated soybean diet; ●, stock diet. While a slight downward trend in the phospholipid content of the liver in animals on the fat-free diet was noted, no statistically significant differences were detected among the three dietary treatments.

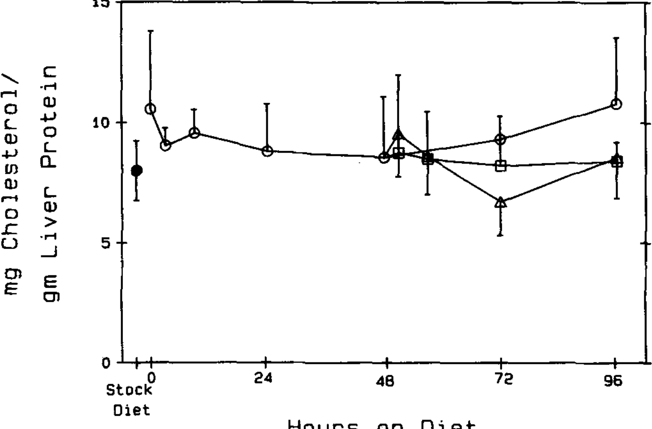

FIG. 4. Total cholesterol content of the liver in rats on the three dietary treatments. ○, Fat-free, high carbohydrate diet; □, corn oil diet; △, hydrogenated soybean diet; ●, stock diet. No significant differences in the liver cholesterol concentration were detected among the three dietary treatments.

In addition, when the cholesterol fraction of the liver was isolated and counted, no significant activity could be detected, indicating that very little de novo synthesis of cholesterol had occurred during the time the animals were receiving the experimental diets devoid of exogenous cholesterol.

Table 4 lists the fatty acid composition of the livers of the animals in the three dietary groups at 0, 24, 48, 72 and 96 hr. The fat-free and the saturated-fat diet groups had very similar fatty acid compositions in their livers during this study, markedly different from that observed in stock-fed animals. When corn oil was added to the diet, there was an immediate and marked change in the fatty acid composition of the liver—within 48 hr it reverted to that observed in the stock-fed animals.

Rat liver appears to show a marked preference for polyunsaturated fatty acids such as linoleic acid. In animals fed corn oil for 24 hr, the liver linoleic acid content increased from 2% to 15% and was approximately equal to that of the animals fed stock diet ad libitum. This would indicate a replacement of monounsaturated and saturated fatty acids by linoleic acid in the liver. Liver fatty acid composition was similar in animals fed saturated-fat and fat-free diets. Stearic acid accounted for approximately 40% of calories in the saturated fat diet, but little accumulated in liver.

Table 5 presents the fatty acid composition of plasma in the different dietary groups at 0, 24, 48, 72 and 96 hr. Ingested linoleic acid caused a rapid rise (within 3 hr) in the animals' plasma linoleic acid levels; stearic acid ingestion did not cause a marked rise in the plasma stearic acid levels. No major differences were observed between the fatty acid compositions of the plasma of the fat-free and the saturated-fat diet groups. After 3 hr on the 44% saturated-fat diet, the plasma stearic acid content rose only 3%; it increased by 6% after 48 hr. The palmitoleic acid content of the plasma was the most markedly affected by the corn oil diet; it decreased from 8.2% at the start of corn oil feeding to 0.8% after 48 hr. The levels of the other major fatty acids of the plasma were not as affected by the corn oil diet as the level of palmitoleic acid.

All percentages for the major fatty acids in liver and plasma for the various diet groups listed in Tables 4 and 5 were significantly different from those in the liver and plasma of animals in the group starved for 48 hr.

The fatty acid composition of the red blood cells in the animals in the three diet groups showed no significant changes during the course of this study (data not shown).

Figure 5 displays the activity (in DPM) of tritium-labeled fatty acids found in plasma of animals in the various dietary groups. The maximum release was achieved at 48 hr on the fat-free diet, and it decreased markedly by 96 hr. However, this release of de novo synthesized fatty acids into the blood was strongly inhibited by dietary fat. The amount of activity in the fatty acids in plasma after 3 hr on either the saturated fat or polyunsaturated fat diets was equally diminished. The apparent difference between the shape of the curve of the saturated and unsaturated diet groups is not statistically significant.

DISCUSSION

This report extends earlier studies on the effect of dietary fat on liver and plasma lipid and their fatty acid

[a]Fatty acids designated by chain length, number of double bonds and the position of the first double bond from the methylene end of the molecule.

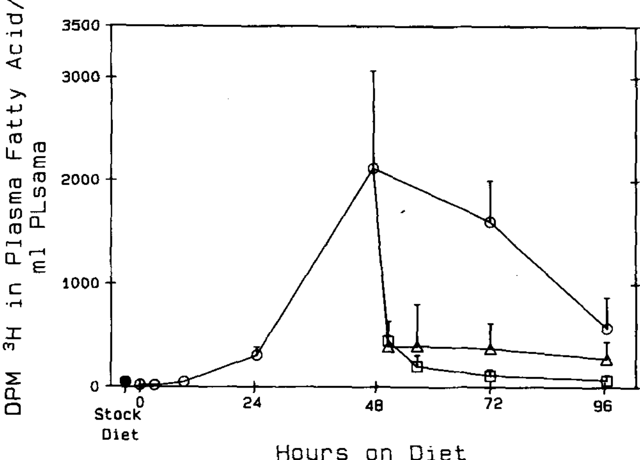

FIG. 5. Activity of ^3H of plasma fatty acid in DPM/ml plasma for rats on the three dietary treatments. ○, Fat-free, high carbohydrate diet; □, corn oil diet; △, hydrogenated soybean diet; ●, stock diet. The 48- and 72-hr points for the animals on the fat-free diet are significantly different from the other dietary groups (48 hr, $p < 0.05$; 72 hr, $p < 0.01$). The 96-hr point for the fat-free diet group did not reach significance at the 0.05 level. Refer to text for details of the experimental conditions.

compositions. It differs from previous studies in that the time course of changes during the first 96 hr of feeding are presented. These results indicate that refeeding a fat-free, high carbohydrate diet to animals starved for 48 hr causes an increase in the lipid concentration of the liver, as previously reported by ourselves (16) and others (6,11,21-23), which is almost exclusively in the triglyceride fraction of the liver lipids. Nace and Szepesi (6) reported that animals starved for 48 hr and refed fat-containing diets did not exhibit the increase in liver lipids observed in animals refed a FF diet after three days of refeeding. Those authors did not, however, refeed a fat-containing diet to animals that had first been refed a FF diet. The work reported here demonstrates that even after induction of active lipogenesis by a FF diet, addition of fat to the diet rapidly halts the increase in liver lipid accumulation.

In our work, the nutrient densities of the fat-free and fat-containing diets were quite different with respect to the vitamin and mineral content. However, it is unlikely that during the 96 hr of refeeding these differences would markedly influence any of the metabolic processes examined. Also, the digestibility of corn oil and hydrogenated soybean oil is very different. For this reason, diets with a high level of fat were deliberately chosen to insure that an adequate amount of the saturated fat would be absorbed and able to influence liver fatty acid metabolism. It is possible that some of the differences in fatty acid composition found among the tissues in animals consuming the two different diets are the result of this digestibility difference in saturated and unsaturated fatty acids. Nevertheless, our data suggest that dietary saturated and unsaturated fatty acids have similar influence on fat metabolism when consumed in appropriate amounts.

It should also be noted that the increases in wet weight and lipid content of the liver in our animals were somewhat greater than those reported by other investigators (6,12, 22). The animals used in this study were older and larger than rats of 150 to 200 g frequently used by others, which may well account for the differences.

The hydrogenated soybean oil diet contained mainly palmitic (11%) and stearic (86%) acids. These two compounds are also the primary products of fatty acid synthesis in rat liver (24,25) in animals on a fat-free diet, so there is no obvious reason why their addition to the diet should reduce liver lipid levels. Product feedback inhibition of the lipogenic enzymes by exogenous fatty acids may be the cause, but it should be noted that the livers in the animals fed the FF diet synthesize amounts of these compounds in excess of that reported to inhibit lipogenesis by dietary fatty acids (8,9,26), yet did not exhibit inhibition of fat synthesis. If the liver can distinguish synthesized from absorbed fatty acids, the mechanism is unknown. However, the absorption process in the intestines might provide appropriate signals to the liver, for example, the apoproteins, such as apoB-48 (27,28), synthesized in the intestines and incorporated into the chylomicrons and very low density lipoprotein (VLDL) during fat absorption (29,30).

Liver may accumulate triglycerides because of inadequate synthesis of phospholipids in the livers of animals fed a polyunsaturated fatty acid-deficient diet. Phospholipids are required for the formation of the phospholipoprotein coat (30,31) of the nascent VLDL particles that are secreted by the liver and transport de novo synthesized triglycerides to peripheral tissues (33,34). Dietary corn oil would provide polyunsaturated fatty acids for phospholipid synthesis but the hydrogenated soybean oil diet would not. Yet the liver seems to clear the accumulated triglycerides easily once saturated fatty acids are added to the diets. Thus, one may have to invoke the concept of signals from the intestine during fat absorption, as discussed above, to explain this phenomenon.

The phospholipid and cholesterol content of the liver in all three groups of animals showed little or no change during the course of the experiment. Reiser et al. (12) reported an increase in liver cholesterol in animals fed a diet containing safflower oil for two weeks, but they did not give a time course for this increase; presumably it occurred after 48 hr. Earlier work by Hill et al. (11) also indicated an increase in the synthesis of liver cholesterol in fat-fed rats but with a definite lag period, which is consistent with the observations reported here.

A rapid change in the fatty acid composition of liver in rats fed a FF diet after being starved for 48 hr was demonstrated previously (14). This work demonstrates that the pattern established at 48 hr does not change significantly when the animals are maintained on the FF diet for another 48 hr, except that the palmitic acid level increased from 26 to 31% of the total fatty acids.

The failure of the liver to accumulate stearic acid may have been due to its rapid desaturation to oleic acid (35-37), its conversion to glucose for energy metabolism (38,39), its malabsorption in the gut (see discussion of this point below) or a combination of these factors.

It is generally accepted that the fatty acid composition of the plasma reflects the composition of the fat consumed (30,40). In animals on a fat-free diet, the plasma fatty acid composition is similar to that found in the liver (14). The

plasma fatty acid composition of rats fed the saturated fat diet did not change substantially from that observed in animals fed a FF diet. It may be that because stearic acid is very poorly absorbed (41,42), the lack of marked changes in the stearic acid level reported here for both liver and plasma are indicative of malabsorption (43) rather than differences in the metabolism of the saturated fat. Examination of the feces of the animals on the saturated fat diet indicated appreciable fat was excreted unabsorbed, although the actual amount of fat absorbed by each animal was not measured. Food intake was recorded, and all animals consumed about the same number of calories.

The data presented here suggest that intestinal absorption and transport of exogenous fatty acids have an important role in the regulation of fatty acid metabolism in the liver. Further research, however, will be necessary to prove the existence of any intestinal involvement in the regulation of liver fatty acid metabolism.

[Received July 14, 1986]

The Effect of Mengovirus Infection on Lipid Synthesis in Cultured Ehrlich Ascites Tumor Cells

Helmut Schimmel[1] and **Peter Traub***
Max-Planck-Institut fuer Zellbiologie, Rosenhof, D-6802 Ladenburg/Heidelberg, Federal Republic of Germany

The concept of generally increased lipid synthesis during the initial 2/3 of picornaviral infectious cycles, held by several authors, needs differentiation. In mengovirus-infected Ehrlich ascites tumor cells, an increase in the rate of synthesis of phosphatidylcholine could be confirmed, but for phosphatidylethanolamine constant to decreasing rates of synthesis were found. Moreover, phosphatidylinositol was increasingly synthesized in the midst of the infectious cycle. The changes observed might have their functional expression in the proliferation of smooth cytoplasmic membrane systems that provide the structural framework for the replication of picornaviral RNA and virus assembly. The alterations in the labeling patterns of phosphatidylinositol, phosphatidylglycerol and diphosphatidylglycerol late in virus infection point to increased turnover of these compounds, possibly mediated by phospholipase D. The formation of lysophosphatidylcholine (cytolytic effect) and bis(monoacylglyceryl)phosphate in the final phase of the infectious cycle might be correlated with the liberation of lysosomal enzymes and the development of the cytopathic effect.
Lipids 22, 95-103 (1987).

Infection of susceptible animal cells with picornaviruses causes rapid inhibition of host protein and nucleic acid synthesis while viral RNA is replicated and translated (1). These macromolecular processes have been the subject of extensive studies, whereas the role of cellular membranes in the replicative cycle of picornaviruses has attracted comparably little attention.

Well-documented effects of picornaviral infections at the membrane level are stimulated incorporation of choline into phospholipids and extensive proliferation of smooth endoplasmic membranes (2-10), at a time postinfection when cellular macromolecular synthesis has largely been shut off (1,11,12).

Replication and translation of picornaviral RNA as well as maturation of virus particles are associated with cytoplasmic membranes (13-21). Studies performed by Caliguiri and Tamm (22-24) have identified smooth cytoplasmic membranes as the site of replication and rough cytoplasmic membranes as the site of translation of viral RNAs. Generally, the different phases of the infectious cycle of picornaviruses appear to be dependent on preexisting and newly synthesized cellular membranes.

This communication presents a more detailed investigation of the lipid metabolism of Ehrlich ascites tumor (EAT) cells infected with mengovirus.

MATERIALS AND METHODS

[^{32}P]Orthophosphoric acid was purchased from New England Nuclear (Dreieich, Federal Republic of Germany); [2-^{3}H]myoinositol (9.3 Ci/mmol), [2-^{3}H]glycerol (500 mCi/mmol) and [9,10(n)-^{3}H]oleic acid (2.1 Ci/mmol) were from Amersham Buchler (Amersham, United Kingdom). The solvents in which the radiochemicals were delivered were evaporated under nitrogen. [^{3}H]Glycerol was dissolved in minimum essential medium (MEMS) and [^{3}H]oleic acid was taken up in serum-free MEMS. Lipid standards were obtained from Fluka AG (Buchs, Switzerland), Serva (Heidelberg, Federal Republic of Germany), Sigma (St. Louis, Missouri) and Applied Science Europe B.V. (Oud-Beijerland, The Netherlands). Thin layer chromatography (TLC) and high performance TLC precoated plates (silica gel) as well as all solvents (analytical grade) and spray reagents were from Merck (Darmstadt, Federal Republic of Germany).

Growth of EAT cells and mengovirus. EAT cells were grown in suspension culture at 37 C, essentially according to the procedure described by Van Venrooij et al. (25) as modified by Egberts et al. (26). Mengovirus was grown in monolayers of L 929-cells as performed by Egberts et al. (26).

Mengovirus infection of EAT cells. At a cell density of 5 to 5.5 × 10^{5} cells/ml (logarithmic phase), EAT cell cultures were divided into halves, and the cells were harvested by centrifugation at 225 × g for 5 min at 37 C. The supernatants were saved and the pelleted cells resuspended in a fraction of the corresponding supernatants to result in 20-fold concentrated cell suspensions. Prewarmed mengovirus solution was added to one-half of the cell culture to yield a multiplicity of infection of 50 PFU/cell (unless otherwise stated). The other half was correspondingly mixed with virus-free medium (mock infection).

The mock- and mengovirus-infected cell suspensions were stirred at 37 C for 45 min. Both concentrates were then diluted, with the supernatants kept at 37 C during the time of virus adsorption. Incubation at 37 C was continued for various times when aliquots of the cell suspensions were withdrawn for the incorporation of radioactively labeled lipid precursors and the preparation of lipid extracts as indicated in the figures of the Results section. Lysis of infected cells was followed by the dye exclusion test with trypan blue (27) at 8, 12 (24) hr postinfection.

Incorporation of radioactively labeled precursors into the lipids of mock- and mengovirus-infected EAT cells. EAT cells from 1.2-l cultures were infected as described above. At various times postinfection, 25-ml portions were taken from the mock- and virus-infected cell cultures and centrifuged at 225 × g for 5 min at 37 C; 1.25-ml aliquots were withdrawn from 20-fold concentrated cultures at 0 and 30 min after infection. The cells were washed with 10 ml MEMS and resuspended in 1.25 ml MEMS lacking phosphate, inositol or fetal calf serum in case of labeling with radioactive orthophosphoric acid, myoinositol or oleic acid. For radioactive labeling, 250 μCi [^{32}P]orthophosphoric acid, 250 μCi [2-^{3}H]glycerol, 50 μCi [2-^{3}H]myoinositol and 50 μCi [9,10(n)-^{3}H]oleic acid, respectively, were added in 50-μl volumes to the cell suspensions, which

[1]Present address: Heumann-Pharma GmbH & Co., Biochemische Forschung, Heideloffstrasse 18-28, 8500 Nuernberg, Federal Republic of Germany.
*To whom correspondence should be addressed.

were incubated with shaking at 37 C for 15 min (labeling with [2-^{3}H]glycerol: 5 min). Thereafter, the cells were collected by centrifugation at 360 × g for 5 min at 0 C and, in the case of labeling with oleic acid, were washed three times with 20 ml cold, serum-free MEMS that was supplemented with 2.5 mg/ml bovine serum albumin. In the other cases, the cells were washed once with 20 ml cold phosphate-free, inositol-free and complete MEMS, respectively. Finally, the cells were washed twice with 20-ml and 7-ml portions of cold Tris-saline (0.01 M Tris-acetate, pH 7.5 [20 C], 0.15 M NaCl). After centrifugation at 800 × g and 0 C for 5 min, the pellets were stored at −80 C.

Extraction of lipids. Unless otherwise stated, all operations were carried out at 0-2 C. The pelleted cells were extracted three times with 20-vol portions of chloroform/methanol (2:1, v/v) according to Folch et al. (28). The organic phases were evaporated under reduced pressure at 37 C, and the lipids were taken up in chloroform/methanol (2:1, v/v). When EAT cells had been labeled with myoinositol, they were additionally extracted four times with ethanol/distilled water (50:50, v/v). After centrifugation at 2600 × g for 5 min at 4 C, the combined supernatants were evaporated under reduced pressure at 50 C, and the residues were redissolved in ethanol/distilled water (50:50, v/v).

Determination of lipid phosphorus and cholesterol. The method of Chen et al. (29) was modified to achieve quantitative lipid hydrolysis and a higher sensitivity of lipid detection, as described by Schimmel (30). The cholesterol content of lipid extracts was measured by means of a test combination (Boehringer Mannheim, Mannheim, Federal Republic of Germany) according to Röschlau et al. (31).

TLC separation of lipids. Neutral lipids were separated as described by Schimmel (32). By raising the polarity of the solvent system used by Skipski et al. (33) to chloroform/methanol/glacial acetic acid/distilled water (52.5:50:4:1, v/v/v/v), good separation of the phospholipid classes, including a reliable resolution of phosphatidylserine and phosphatidylinositol, was achieved. For the separation of diphosphatidylglycerol and phosphatidylglycerol, the basic solvent system chloroform/methanol/n-propylamine/distilled water (26:12:1.1:1.65, v/v/v/v) was used. The separation of phospholipids was usually performed on HPTLC plates (20 × 10 cm). Lipid classes were identified by cochromatography of extracts with standards in different solvent systems and by detection with specific spray reagents (34,35). Identification of individual lipids was carried out by two-dimensional TLC using combinations of different acidic and basic solvent systems. Lipids were routinely made visible by exposure of the TLC plates to iodine vapor.

Identification of bis(monoacylglyceryl)phosphate. A lipid extract from EAT cells (250 ml cell culture) pulse-labeled with [9,10(n)-^{3}H]oleic acid for 15 min at 7.5 hr postinfection was separated on two HPTLC plates (20 × 10 cm) in the modified solvent system described above. Bis(monoacylglyceryl)phosphate (R_f = 0.76) was eluted with chloroform/methanol (2:1 and 1:2, v/v). Half of the eluate was evaporated and the residue hydrolyzed according to Dawson (36, micromodification of method I). The water-soluble products were separated as described by Poorthuis and Hostetler (37). Glycerol and glycerol-3-phosphate as well as phosphatidylglycerol, diphosphatidylglycerol and the corresponding deacylated products (36) were used as reference substances. The residue of the other half of the eluate was taken up in 10 μl chloroform/methanol (2:1, v/v) and subjected to two-dimensional TLC according to Poorthuis et al. (38) with diphosphatidylglycerol as a reference.

Identification of polyphosphoinositides. EAT cells (450 ml cell culture) were pulse-labeled with 900 μCi [2-^{3}H]myoinositol for 15 min at 2 hr postinfection. After lipid extraction according to Folch et al. (28), the cell residues were additionally extracted with aqueous ethanol as described above. Following evaporation, the residue of the extract was taken up in 500 μl aqueous ethanol, and 400 μl of the resulting solution was separated semipreparatively on TLC plates using the solvent system described by Eberlein and Gercken (39). After localization of the compounds by means of a Beta-camera (Laboratorium Prof. Dr. Berthold, Wildbad, Federal Republic of Germany), they were successively eluted with chloroform/methanol (2:1, 1:1 and 1:2, v/v, respectively). The eluates were evaporated and the residues hydrolyzed (36). The deacylation products were separated by TLC according to Koch-Kallnbach and Diringer (40). Glycerophosphoinositol derived from phosphatidylinositol (36) was used as a reference compound. The remainder of the aqueous ethanol extract was separated in the solvent system described by Eberlein and Gercken (39) using phosphatidylinositol, phosphatidylinositol 4-phosphate and phosphatidylinositol 4,5-diphosphate for reference.

Sucrose density gradient centrifugation of cell homogenates. Two 1.2-l EAT cell cultures were mock- and mengovirus-infected (multiplicity of infection: 100 PFU/cell), and the cells were harvested at 6 hr postinfection. They were pulse-labeled with 246 μCi of [2-^{3}H]myoinositol for 5 and 15 min. Cell rupture and sucrose density gradient centrifugation of the homogenates were carried out essentially as described by Nelson et al. (41).

Measurement of radioactivity. Radioactivity was measured by liquid scintillation counting after adequate pretreatment of samples. Radioactively labeled lipids were localized on TLC plates by means of a Beta-camera (LH 290 HR, Berthold), by a TLC Linear Analyzer (LB 282, Berthold) and by autoradiography.

RESULTS

Figure 1 shows the incorporation of [2-^{3}H]glycerol into total lipids of mengovirus- and mock-infected EAT cells. In virus-infected cells, enhanced incorporation of the radiolabel was observed between 1.5 and 4.5 hr postinfection, followed by a sharp decrease, whereas incorporation in mock-infected cells increased in parallel with cell density.

It should be noted that for the comparison of lipid syntheses in virus- and mock-infected cells, in the latter case linearly growing cultures were used as controls. Since in the following the incorporations of radioactively labeled precursors into individual lipid species are expressed as percentage distributions, deviations from constancy during mock-infection should allow the detection of possible disturbances or inhomogeneities in the formation of these lipids. As demonstrated in Figures 2 to 5 and Figure 7, such deviations were not observed to any significant extent during the entire period of measurement. The averages of the relative incorporations of precursors into

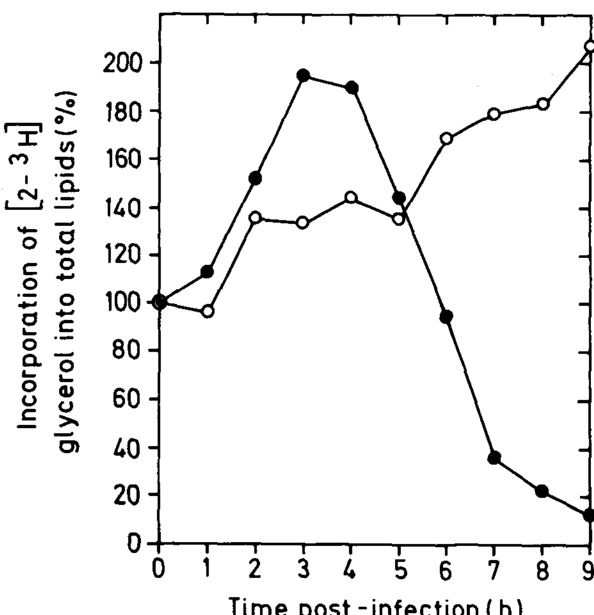

FIG. 1. Incorporation of [2-^{3}H]glycerol into total lipids of mock-infected (○) and mengovirus-infected (●) EAT cells (5 min pulse/25 min chase). Incorporation prior to infection is set equal to 100%. The values represent the means of two individual experiments. The analytical determinations were run as duplicates.

individual lipids at different time points of mock-infection should therefore serve as the most reliable controls.

The percentage distribution of the incorporation of [2-^{3}H]glycerol into various phospholipid classes of mock- and mengovirus-infected EAT cells is depicted in Figure 2. The rate of synthesis of phosphatidylcholine increased up to about four times the initial value until 3 hr postinfection and fell back to about this value until 9 hr postinfection. The rate of synthesis of phosphatidylethanolamine, however, decreased gradually during the infectious cycle as compared to the control. For phosphatidylinositol, a significantly enhanced rate of synthesis was found in the middle of the infectious cycle. The same results were obtained after labeling the phospholipids with [^{32}P]orthophosphoric acid (30).

However, phosphatidylglycerol and diphosphatidylglycerol showed different labeling patterns after incorporation of [2-^{3}H]glycerol and [^{32}P]orthophosphoric acid, respectively (30). Whereas labeling was increased late in the infectious cycle in the former case, it was reduced in the latter case. For both phospholipids, the possibility of multiple labeling has to be considered, especially when the labeling is carried out with glycerol. Labeling with [2-^{3}H]glycerol offered information about the synthesis of those phospholipid classes that did not show sufficient incorporation during labeling with [^{32}P]orthophosphoric acid. Increased synthesis was also observed for phosphatidylserine (with maxima at 1 and 8 hr postinfection) (Fig. 2d), whereas a continuously low incorporation was found for lysophosphatidylcholine (Fig. 2a) and for sphingomyelin (Fig. 2b). Although the latter compound is not a glycerophospholipid, its labeling can be explained by metabolization of glycerol. For bis(monoacylglyceryl) phosphate, an enhanced incorporation was noted in the second half of the infectious cycle (Fig. 2h).

A study of the incorporation of [9,10(n)-^{3}H]oleic acid into the lipids of mock- and mengovirus-infected EAT cells has shown that about 80% of the maximal labeling occurred during the initial 15 min after the addition of the radiochemical (30). Thus, a sufficiently high labeling was to be expected from the performance of pulse labeling for 15 min; this also made possible the analysis of the radioactively labeled neutral lipid- and glycolipid-fractions.

The percentage distribution of the incorporation of [9,10(n)-^{3}H]oleic acid into the phospholipid fractions of mock- and mengovirus-infected EAT cells, delineated in Fig. 3, essentially confirmed the results reported above. Again, constant incorporation rates were observed for the control cultures. The cultures infected with mengovirus revealed differentiated incorporation patterns for the different phospholipid classes. Oleic acid incorporation into phosphatidylcholine (Fig. 3c) was enhanced until 3 hr postinfection to an extent comparable to that observed with glycerol (Fig. 2c). Subsequently, the rate of synthesis dropped rather steadily until the end of the infectious cycle (insert, Fig. 2c). An incorporation only slightly diminished was observed for phosphatidylethanolamine (Fig. 3f), whereas the incorporation of [2-^{3}H]glycerol (Fig. 2f) and [^{32}P]orthophosphoric acid (30) into this phospholipid was substantially reduced. The increased production of phosphatidylinositol (Fig. 3e) observed between 4 and 6 hr postinfection correlated with the results obtained with [2-^{3}H]glycerol (Fig. 2e). Increased synthesis of this phospholipid between 4 and 5 hr postinfection could also be demonstrated by incorporation of phosphate label (30).

Bis(monoacylglyceryl)phosphate was determined together with diphosphatidylglycerol and phosphatidylglycerol, as in this series of experiments its localization on the chromatograms could not be achieved with confidence. Between 6 and 9 hr postinfection, an increase in the incorporation of radiolabel into the three phospholipids was observed (Fig. 3g) comparable to that found after labeling with [2-^{3}H]glycerol (Figs. 2g, 2h) with respect to its extent as well as its temporal appearance. The synthesis of lysophosphatidylcholine, sphingomyelin and phosphatidylserine (Figs. 3a, 3b, 3d) was slightly enhanced between 6 (or 7) and 9 hr postinfection.

The synthesis of most neutral lipids (2-monoacylglycerol, 1-monoacylglycerol, cholesterol, 1,3-diacylglycerol) was more or less increased after mengovirus infection or significantly decreased in the case of cholesterol esters (30). Because of the importance of 1,2-diacylglycerols and triacylglycerols as precursors of phospholipids, only their labeling characteristics are presented in Figure 4. The incorporation of [^{3}H]oleic acid into 1,2-diacylglycerols was decreased throughout the entire infectious cycle, whereas the formation of triacylglycerols was significantly enhanced from 0 to 4.5 hr postinfection.

The increased labeling of phosphatidylinositol with [^{32}P]orthophosphoric acid (30) and [2-^{3}H]glycerol (Fig. 2e) in the middle of the infectious cycle necessitated further examination, especially in consideration of the numerous publications dealing with increased turnover of phosphatidylinositol (e.g., 42–47). The incorporation of [2-^{3}H]myo-inositol into the lipids of mock- and mengovirus-infected EAT cells is shown in Figure 5. In mengovirus-infected cells, its incorporation into phosphatidylinositol increased

dramatically between 4.5 and 9 hr postinfection, up to about 14-fold as compared with the mock-infected controls at 7 hr postinfection. The label was not metabolized and thus was incorporated exclusively into phosphatidylinositol, as demonstrated by cochromatography of the lipid extracts with phosphatidylinositol standard in the acidic solvent system (30).

Nearly equal amounts of tritium label (mainly as myoinositol; compare ref. 40) were found within the initial 3 hr postinfection in the aqueous phases after lipid extraction (28) of mengovirus-infected EAT cells. The amount of tritium label diminished distinctly between 3 and 4 hr postinfection and remained at a nearly constant, low level (Fig. 6), indicating that uptake of inositol was drastically reduced after about 4 hr postinfection and/or that the polyalcohol was increasingly consumed in the process of phospholipid synthesis.

Extraction of the cell pellets with aqueous ethanol after removal of chloroform/methanol-soluble lipids yielded another fraction of phosphoinositides. By TLC separation of the ethanolic extracts, the following phosphoinositides could be characterized by their R_f values: phosphatidylinositol (PI), 0.48; unknown phosphoinositide (PI-X), 0.41; phosphatidylinositol-4-phosphate (PI-4-P), 0.28; lysophos-

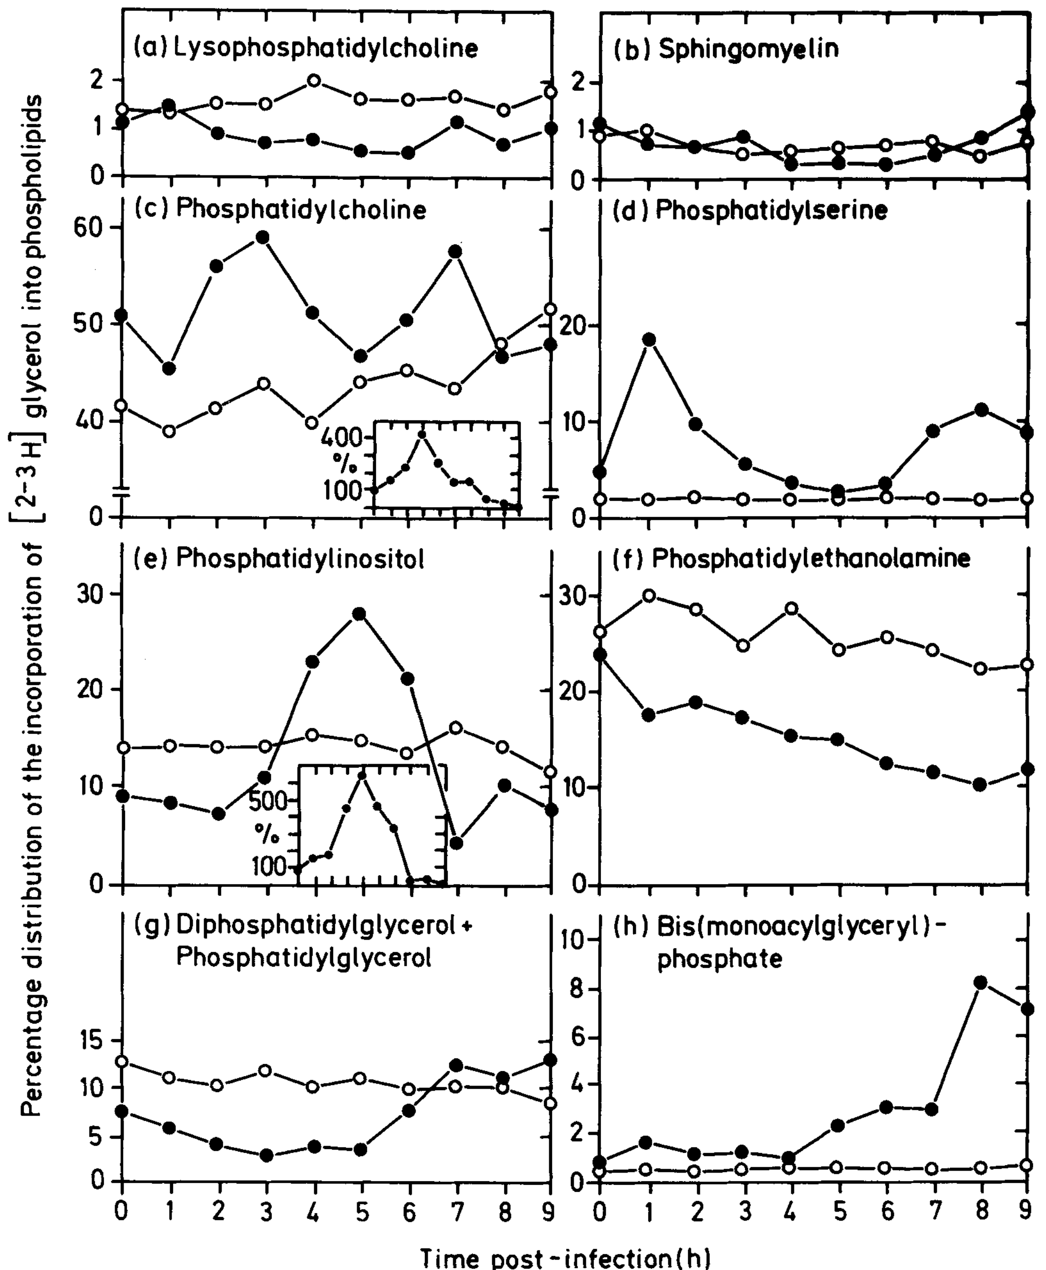

FIG. 2. Incorporation of [2-^{3}H]glycerol into the phospholipids of mock-infected (○) and mengovirus-infected (●) EAT cells (5 min pulse/25 min chase). The values represent the means of two individual experiments. The analytical determinations were run as duplicates. The inserts in panels c and e show the alterations of the respective incorporation rates (incorporation rates at 0 hr postinfection are set equal to 100%).

phatidylinositol; 0.21; phosphatidylinositol-4,5-diphosphate (PI-4,5-DP), 0.08. The R_f values of the deacylation products of PI, PI-X, PI-4-P and PI-4,5-DP were 0.30, 0.27, 0.20 and 0.09, respectively. In consideration of its chromatographic behavior, the unidentified component (PI-X) is assumed to contain a sugar moiety different from or in addition to inositol. Figure 7 illustrates that the incorporation of [2-^{3}H]myoinositol into ethanol/water-soluble phosphoinositides of mengovirus-infected EAT cells was increased about 22-fold at 2 hr postinfection as compared to mock-infected cells.

To gain information on the intracellular localization of

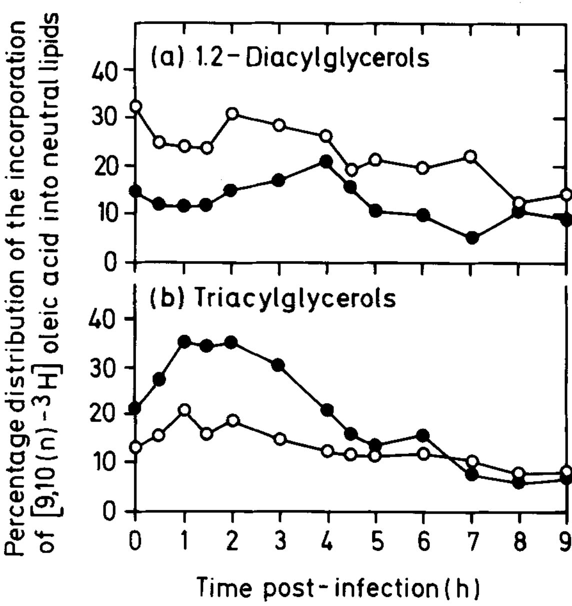

FIG. 4. Incorporation of [9,10(n)-^{3}H]oleic acid into the phospholipids of mock-infected (○) and mengovirus-infected (●) EAT cells (15 min pulse). Only the data obtained for 1,2-diacylglycerols and triacylglycerols are presented. The values represent the means of two individual experiments. The analytical determinations were run as duplicates.

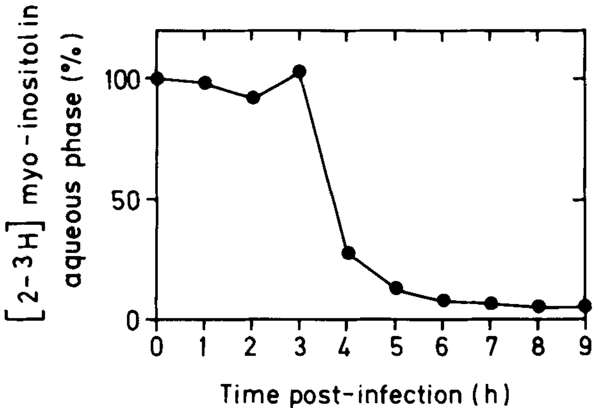

FIG. 6. Alterations of ^{3}H-label (mainly free inositol) in the aqueous phases of extracts (according to Folch et al., 28) of mengovirus-infected EAT cells after 15 min pulse-labeling with [2-^{3}H]myoinositol. The radioactivity in the aqueous phase (60 195 cpm from 0.5 ml cell suspension) measured at the beginning of the infection is set equal to 100%. The values represent the means of two individual experiments. The analytical determinations were carried out fivefold.

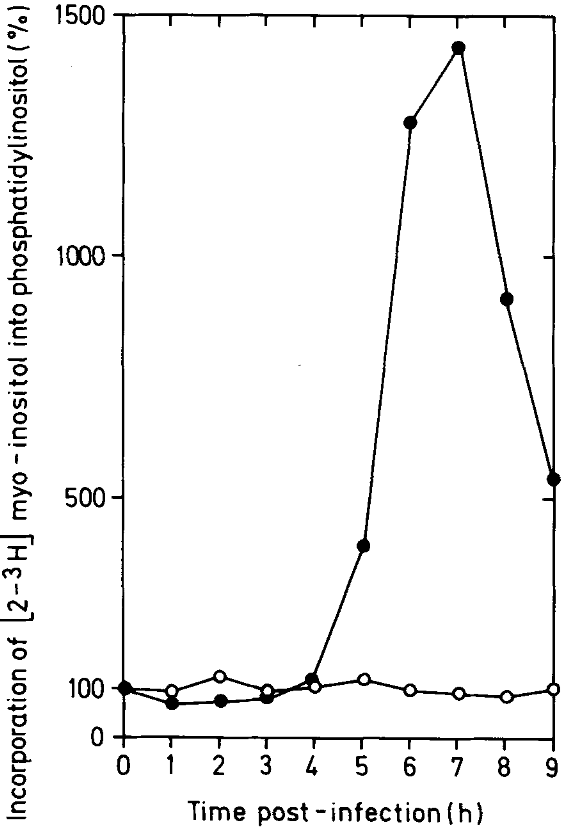

FIG. 5. Incorporation of [2-^{3}H]myoinositol into phosphatidylinositol of mock-infected (○) and mengovirus-infected (●) EAT cells (15 min pulse). Incorporation prior to infection is set equal to 100%. The values represent the means of two individual experiments. The analytical determinations were run as duplicates.

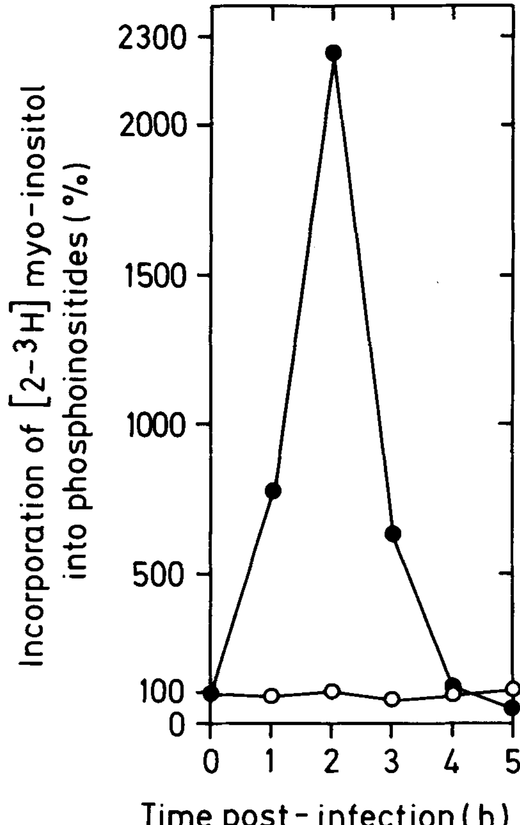

FIG. 7. Incorporation of [2-^{3}H]myoinositol into phosphoinositides of mock-infected (○) and mengovirus-infected (●) EAT cells (15 min pulse). After extraction according to Folch et al. (28) of the cells, the residues were extracted with aqueous ethanol.

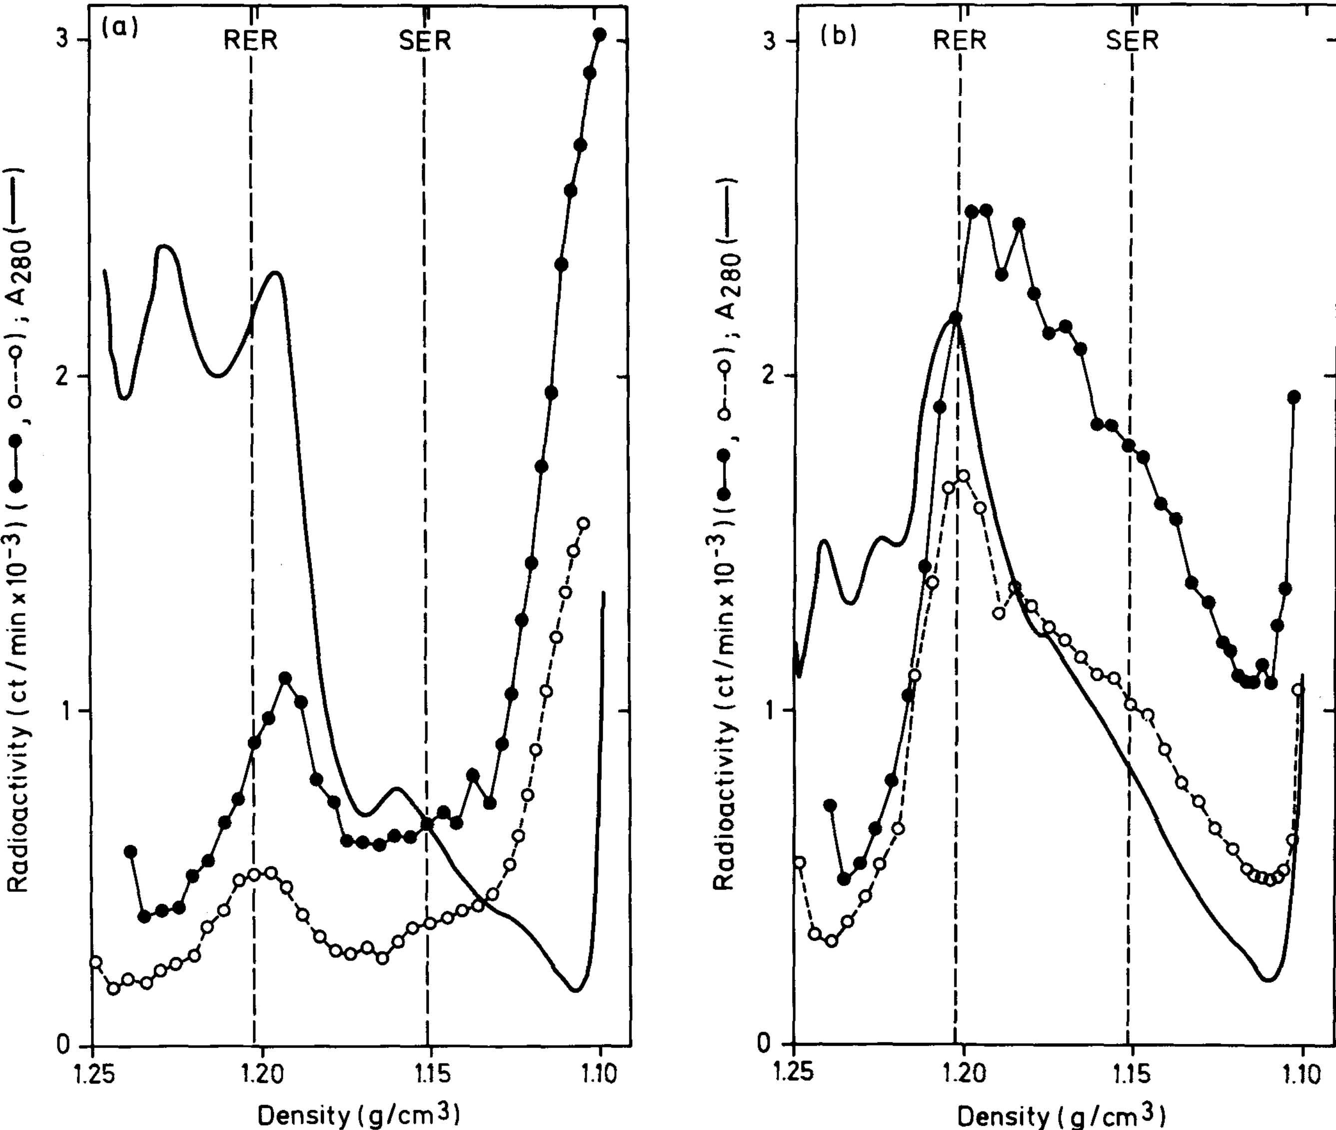

FIG. 8. Intracellular localization of the incorporation of [2-^{3}H]myoinositol into phosphatidylinositol of mock-infected (a) and mengovirus-infected (b) EAT cells. Mock- and mengovirus-infected EAT cells were homogenized in a hypotonic Tris buffer, pH 8, and the postnuclear supernatants were subjected to sucrose density gradient equilibrium centrifugation according to Nelson et al. (41). ○, 5 min pulse and ●, 15 min pulse of [2-^{3}H]myoinositol incorporation; ——, optical density at 280 nm. The specific densities for smooth endoplasmic reticulum (SER, 1.1504 g/cm^3) and rough endoplasmic reticulum (RER, 1.2020 g/cm^3) of EAT cells were taken from Nelson et al. (41).

the turnover of phosphatidylinositol, homogenates of mock- and mengovirus-infected EAT cells pulse-labeled with [2-^{3}H]myoinositol for 5 and 15 min, respectively, were subjected to sucrose density gradient equilibrium centrifugation. A comparison of Figures 8a and 8b shows increased incorporation of the label in virus-infected cells. The shape of the radioactivity profiles after pulse-labeling for 5 min did not differ significantly from that obtained after pulse-labeling for 15 min. The radioactivity profiles of the homogenates derived from mengovirus-infected EAT cells revealed a minor shoulder at the density of the smooth endoplasmic reticulum, however.

DISCUSSION

On the basis of the present results, the previously established concept of generally increased lipid synthesis during the course of picornaviral infections of mammalian cells (2,5–7,48,49) could be further differentiated. A study of the effect of mengovirus infection on lipid synthesis in EAT cells (50) has shown that in infected cells the lipid phosphate content increased steadily up to 6 hr postinfection to nearly 130% of the initial value, then dropped to about 90% within 1 hr and remained at this level. Similar results were obtained for the cholesterol content. Using [^{32}P]orthophosphoric acid, [2-^{3}H]glycerol and [^{3}H]oleic acid as radioactively labeled lipid precursors, this net increase in lipid synthesis was demonstrated to be differentially distributed among the most important phospholipid classes. During the first half of the infectious cycle, increased synthesis of phosphatidylcholine was observed, but for phosphatidylethanolamine constant to decreasing rates of synthesis were found. Phosphatidylinositol showed an enhanced rate of synthesis that was limited

to the middle of the infectious cycle between 4 and 5 hr postinfection. Increased incorporation of labeled myo-inositol into phosphatidylinositol was also shown to occur in poliovirus-infected human embryonic lung cells (50).

It is remarkable that increased new synthesis of phosphatidylinositol temporally coincides with the proliferation of smooth cytoplasmic membranes as observed by electron microscopy (23,24). It is known that replication of picornaviral RNA is associated with smooth internal membrane systems (17,22–24), while the synthesis of viral proteins is dependent on rough cytoplasmic membranes (23,24). In this connection, it is pertinent to note that mengovirus-infected EAT cells exhibit maximal viral RNA synthesis between 5 and 6 hr postinfection (Schimmel, H., and Traub, P., unpublished results). For comparison, viral protein synthesis reaches its maximum between 3 and 4 hr postinfection in this system (26). Interestingly, sucrose density gradient centrifugation of homogenates obtained from mengovirus-infected EAT cells revealed that newly synthesized phosphatidylinositol is eventually incorporated into membranes with the density of rough and smooth endoplasmic reticulum. The mengovirus-induced changes in lipid synthesis of EAT cells might also be correlated with the dramatic alterations in membrane permeability that set in 3 hr postinfection (51) and with the shut-off of host-specific protein synthesis in the first half of the infectious cycle (26).

Increased synthesis of bis(monoacylglyceryl)phosphate, a marker lipid of secondary lysosomes (52), was observed during the last third of the infectious cycle. This might be correlated with the liberation of lysosomal enzymes, as was found during the development of the cytopathic effect in different cell lines infected with picornaviruses (37,53,54). Furthermore, phosphatidylinositol, increasingly synthesized in the middle of the infectious cycle, is known to stimulate the formation of bis(monoacylglyceryl)phosphate from phosphatidylglycerol (55). The enhanced incorporation of glycerol and oleic acid labels, but not of phosphate label, into phosphatidylglycerol and diphosphatidylglycerol late in infection indicates an increased participation of these phospholipid species in turnover reactions; in this case, phospholipase D-catalyzed transfer reactions (56,57) might play an important role. It is reasonable to assume that the changes in lipid synthesis late in infection contribute to the destruction of the plasma membrane and thus to the release of progeny virus particles into the medium. Mengovirus-infected EAT cells start to become permeable to trypan blue 6 to 7 hr post infection (51). While intracellularly the first infectious mengovirus particles can be detected 5 hr postinfection, extracellularly the first virus particles appear 8 hr post-infection (51).

Another striking observation of the present investigation was the enhanced turnover of phosphatidylinositol late in infection. It could be shown to be localized to rough cytoplasmic membranes and to temporally coincide with the most active phase of virus assembly (51). Its mechanism appears different from that of phosphatidylinositol turnover in connection with virus-receptor interactions (58) and receptor-mediated endocytosis (46,47). In this case, as formulated by Michell (42,43), Nishizuka (46) and Berridge and Irvine (47), enhanced labeling with phosphate catalyzed by diglyceride kinase should have been expected, whereas in the late phase of mengovirus infection of EAT cells only the inositol moiety of phosphatidylinositol was exchanged. For the decomposition reaction, a phospholipase D activity has to be postulated. Enzyme activities of this type have been demonstrated in bacteria and plants (57), but only rarely in animal cells (45,46). However, a respective reaction sequence for phosphatidyl turnover has been discussed by Hokin-Neaverson (59).

Finally, the finding that 2 hr postinfection substantially increased incorporation of myoinositol into ethanol/water-soluble phosphatidylinositol occurs indicates the existence of a second cellular pool of the phospholipid in mengovirus-infected EAT cells. Two different cellular pools of phosphatidylinositol have already been demonstrated in synapses (60), in microsomal membranes of rat liver (61) and in a tumor cell line (62).

[Received July 11, 1986]

Measurement of Free and Bound Malondialdehyde in Vitamin E-Deficient and -Supplemented Rat Liver Tissues[1]

Hye-Sung Lee and **A. Saari Csallany***
Department of Food Science and Nutrition, University of Minnesota, 1334 Eckles Ave., St. Paul, MN 55108

The quantity of free malondialdehyde (MDA) in liver tissues of rats fed vitamin E-deficient or -supplemented diets for 43 wk was measured by a newly developed high performance liquid chromatographic (HPLC) method. Bound MDA was quantified by the same HPLC method after alkaline hydrolysis of tissue homogenates. Tissues from vitamin E-deficient animals showed levels of free MDA about 15 times higher but levels of bound MDA less than 2 times higher than the vitamin E-supplemented animals. Free MDA is the major form in vitamin E-deficient tissues, but bound MDA is predominant in vitamin E-supplemented tissues. Conventional thiobarbituric acid (TBA) test results revealed that the content of TBA-reactive substances expressed in MDA equivalents was much higher than the actual free MDA levels in all groups. Results indicate that free MDA level measured by HPLC is a more sensitive index than the TBA value for lipid peroxidation. Some other TBA-reactive substances seem to exist in liver tissue regardless of the dietary treatment.
Lipids 22, **104-107 (1987).**

Malondialdehyde (MDA), one of the most-studied products of lipid peroxidation, generally has been regarded as involved in causing cell damage and in the formation of lipofuscin age pigments (1-3). It is also well documented that MDA undergoes reactions with amino acids (4-7), proteins (8-14) and nucleic acids (15,16) and can be metabolized (17). The condensation product of MDA with the primary amino groups of biomolecules has been known to possess fluorescence due to a Schiff base-type structure. The crosslinking of biomolecules with MDA under physiological conditions is of great biochemical and physiological interest.

A common method to measure the degree of oxidative damage in biological and food systems is the thiobarbituric acid (TBA) test. It has been suggested by several investigators, however, that this colorimetric method is not specific for MDA, since other known and unknown compounds produce positive reactions (1,18-20). It is questionable, therefore, whether the TBA value can be used as a reliable index for lipid peroxidation. A high performance liquid chromatographic (HPLC) method (21) was recently developed in our laboratory that is specific and sensitive for the direct measurement of MDA in tissues.

There are many reports in the literature on the measurement of MDA using the TBA test for various peroxidizing conditions (20,22-24), but little is known about the actual quantity of MDA produced. In the present study, free MDA levels were measured by HPLC to assess the level of in vivo peroxidation in rat liver tissues from animals fed diets deficient in or supplemented with vitamin E for 43 weeks. Hydrolysis of tissue homogenates was carried out to estimate the amount of MDA generated from the bound form of MDA-biomolecule complexes. The actual MDA levels were compared to the conventional TBA test results.

MATERIALS AND METHODS

Animals and diets. Three groups of eight Sprague-Dawley female weanling rats were fed one of the following three diets for 43 weeks: 1) a modified basal vitamin E-deficient diet developed by Draper et al. (25), adequate in all respects except for vitamin E (−E group); 2) the basal diet supplemented with 30 mg/kg diet of RRR-α-tocopheryl acetate (1.36 IU/mg, type 3, Sigma Chemical, St. Louis, Missouri) (NE group); or 3) the basal diet supplemented with 300 mg/kg diet of RRR-α-tocopheryl acetate (+E group). Diets and water were provided ad libitum. Sodium salt of sulfamerazine (Sigma) was added to drinking water (1 g/3.8 l) to prevent pulmonary infection. After 43 weeks, the animals were killed and the tissues were removed, washed three times with cold physiological saline solution and blotted dry. The tissues were individually wrapped in parafilm and stored at −70 C.

Free MDA determination. A 10% (w/v) liver tissue homogenate in cold 0.01 M sodium phosphate buffer, pH 7.0, was prepared using a Brinkman homogenizer equipped with a PT20ST probe generator (Brinkman Instruments, Westbury, New York). An aliquot of the 4 ml homogenate was immediately filtered through a 50-ml Amicon cell equipped with a YC05 Diaflo ultrafiltration membrane (Amicon Corp., Danvers, Massachusetts) to remove compounds with a molecular weight greater than 300. The Amicon cell was operated under 35 psi pressure of nitrogen gas. The clear filtrate was used for HPLC analysis.

The HPLC separations were performed on a Spherogel-TSK 1000PW size exclusion column, 7.5 mm ID × 30 cm (Beckman Instruments, Berkeley, California) with a mobile phase of 0.1 M sodium phosphate buffer, pH 8.0, at a flow rate of 0.6 ml/min at ambient temperature. The absorbance was monitored at 267 nm.

Bound MDA determination. A 4-ml aliquot of 10% (w/v) liver tissue homogenate was taken into a 10-ml graduated centrifuge tube. The pH of the homogenate was adjusted to 13 using 100 μl of saturated NaOH solution and incubated in a 60 C water bath for 30 min. The hydrolyzed homogenate was neutralized to pH 8.0 with concentrated HCl and immediately subjected to ultrafiltration using the Amicon cell under nitrogen pressure. The clear filtrate was analyzed to quantify MDA by the previously described HPLC method. This value of MDA is referred to as the total MDA of liver tissues. The difference between MDA levels prior to and after hydrolysis is called bound MDA.

Preparation of MDA standard. MDA was prepared by hydrolysis of 1,1,3,3-tetraethoxypropane (TEP) (Aldrich Chemical Co., Milwaukee, Wisconsin) by a modification of the method of Kwon and Watts (26). One mmol of TEP was dissolved in 100 ml of 0.01 N HCl and heated in a 50 C water bath for 60 min. A standard solution of MDA (1×10^{-5} M) was prepared by diluting 0.1 ml of the hydrolyzed TEP solution to 100 ml with 0.01 M sodium phosphate buffer, pH 7.0. The absorption spectrum of MDA standard solution was obtained with a Beckman Model DU-8 spectrophotometer using a 1-cm quartz cell. The optical density of MDA solution at λmax (267 nm) was measured to verify the molar extinction coefficient and, thus, the purity of the solution.

TBA test. The measurement of TBA reactive substances (TBA-RS) in rat liver tissue was performed by a modified method of Uchiyama and Mihara (20). A 0.5-ml aliquot of 10% (w/v) tissue homogenate in cold 0.01 M sodium phosphate buffer, pH 7.0, was taken into a 20-ml screw-capped test tube. Three ml of 1% phosphoric acid and 1 ml of 0.6% TBA solution were added, and the mixture was heated for 45 min in boiling water bath. After cooling to room temperature, the reaction mixture was extracted with 4 ml of n-butanol. The butanol phase was separated by centrifugation at 2000 rpm for 10 min. The absorbance of the butanol phase was measured at 535 and 520 nm by a Beckman Model DU-8 spectrophotometer. The difference in absorbance was used for the calculation of the amount of TBA-RS. Various concentrations of MDA standard solution were subjected to the same TBA test procedure, and a standard curve for the TBA-MDA complex was prepared. The contents of TBA-RS in the sample tissues were calculated as MDA equivalents from the standard curve.

Tissue α-tocopherol determination. The HPLC method developed by Zaspel and Csallany (27) was used to measure the content of α-tocopherol in rat liver tissues. The HPLC separations were performed on a 10-μm Hibar II Lichrosorb RP-18 column, 250 × 4.6 mm (EM Reagents, Gibbstown, New Jersey), preceded by a guard column, 70 × 4.6 mm, packed with perisorb RP-18 (EM Reagents) with a mobile phase of 2% water in methanol at a flow rate of 2 ml/min. Tissue α-tocopherol was detected by fluorescence at an excitation wavelength of 295 nm and an emission wavelength of 340 nm using a Perkin-Elmer Model 650-10S fluorescence spectrophotometer (Perkin-Elmer Corp., Norwalk, Connecticut) equipped with a 20 μl capacity quartz flow cell. Tissue α-tocopherol concentrations were calculated from peak area responses using a standard curve prepared by chromatography of known amounts of pure d-α-tocopherol.

Statistical analysis of data. Comparisons of three group means were done by ANOVA and Tukey's multiple comparison test (28) and comparisons of two group means by Student's t-test.

RESULTS AND DISCUSSION

Animal body weights and hepatic tissue α-tocopherol concentrations of rats fed vitamin E-deficient or -supplemented diets are shown in Table 1. The vitamin E-deficient group started to show a gradual decrease in growth rate at 22 weeks on the experimental diet compared to the vitamin E-supplemented groups. By 43 weeks of age, when animals were killed, the vitamin E-deficient rats weighed only 76% of the vitamin E-supplemented rats. A significantly high accumulation of α-tocopherol was shown in the liver tissues of vitamin E-supplemented groups. A detectable amount of α-tocopherol was still found in the liver of the −E group after 43 weeks on the completely vitamin E-deprived diet. This small amount of α-tocopherol was derived from inborn tissue storage.

Free and bound MDA concentrations of rat liver tissues following 43 weeks of feeding diets deficient in or supplemented with vitamin E are also shown in Table 1. The amount of free MDA measured in tissues of the −E group was about 15 times higher than NE and +E groups. No difference in the free MDA level was seen between NE and +E groups, even though the +E group had been fed 10 times more vitamin E than the NE group. This seems to indicate that the protective effect of vitamin E against in vivo lipid peroxidation is not dose-dependent, and the normal dietary vitamin E level offers as much protection as the higher level.

Tissue homogenates were hydrolyzed to estimate the amount of MDA present in the bound form with biomolecules such as amino acids, proteins or nucleic acids. After hydrolysis, a considerable amount of MDA was released in all the groups regardless of the dietary treatment. The average amount of released MDA (referred to as bound MDA in Table 1) in the −E group was significantly higher than that in the +E group. No difference was shown between −E and NE groups. It has been found that bound MDA is a predominant form of MDA present in vitamin E-supplemented liver tissue. It is interesting to note that less MDA exists in the bound form than in a free form in the −E liver tissues, indicating

TABLE 1

Body Weights and Concentrations of α-Tocopherol, Free and Bound Malondialdehyde in Rat Liver

Group	Body weight (g) Wk 0	Body weight (g) Wk 43	α-Tocopherol (μg/g tissue)	Free MDA (μg/g tissue)	Bound MDA (μg/g tissue)
−E	56.6 ± 1.28	262.5 ± 14.19^a	3.20 ± 0.65^a	3.91 ± 0.35^a	2.66 ± 0.34^a
NE	52.8 ± 1.61	345.3 ± 7.35^b	36.54 ± 4.08^a	0.28 ± 0.04^b	2.29 ± 0.25^{a,b}
+E	53.7 ± 1.61	341.3 ± 16.19^b	138.38 ± 19.63^b	0.25 ± 0.06^b	1.49 ± 0.27^b

Values represent the mean ± S.E.M. for 8 animals per dietary groups. Means within each column not sharing a common superscript letter are significantly different ($p < 0.05$) by Tukey's multiple comparison test.

possible faster MDA production than the capability to be reactive with some other compounds. The fact that there is no significant difference in bound MDA levels between −E and NE groups in spite of a large difference in free MDA levels might indicate that the highly peroxidative −E tissue could clear toxic free MDA more efficiently than normal tissue by possibly increasing the activity of aldehyde dehydrogenase or by excreting it in the urine (29) as a defense system. Recently, Hjelle and Petersen (30) reported that rat liver contained at least three aldehyde dehydrogenases which oxidize MDA, two with relatively high affinity for MDA in cytosol and one with lower affinity in mitochondria. We have also found a significantly higher level of TBA-RS in vitamin E-deficient rat urine than in urine from supplemented groups (unpublished data).

Comparison of MDA levels to TBA-RS in liver tissues is shown in Figure 1. Free and total (free + bound) MDA concentrations were separately compared to the amount of TBA-reactive substances within each dietary group. Levels of TBA-reactive substances were significantly higher than free MDA in all the dietary groups and also significantly higher than total MDA levels in the −E and +E groups. The vitamin E-deficient group showed 3-4 times more TBA-RS than vitamin E-supplemented groups. The difference in the levels of TBA-RS among the three dietary groups is much less than that for free MDA levels. These results indicate the definite presence of some other TBA-RS that are not MDA in the liver tissues of all dietary groups.

The ratios of TBA-RS as an equivalent of MDA to free and total MDA were calculated (Table 2) to show the relationship between these two lipid peroxidation indices. It was found that the ratio of TBA-RS to free MDA in the −E group was much lower (3.0:1) than the ratios of NE and +E groups (12.9:1 and 12.2:1, respectively). However, the ratios of TBA-RS to total MDA in liver tissues were similar in all dietary groups. These results demonstrate that the proportion of free MDA in TBA-RS measured by the TBA test is much higher in the vitamin E-deficient liver tissues than in the vitamin E-supplemented tissues. However, similar proportions of total MDA exist in TBA-RS in both vitamin E-deficient and vitamin E-supplemented liver tissues, indicating that most of the MDA exists in a bound and not a free form in the vitamin E-supplemented state. The present study also demonstrates that the TBA test may be useful for measuring the peroxidative state of tissues but that it should not be equated with MDA levels.

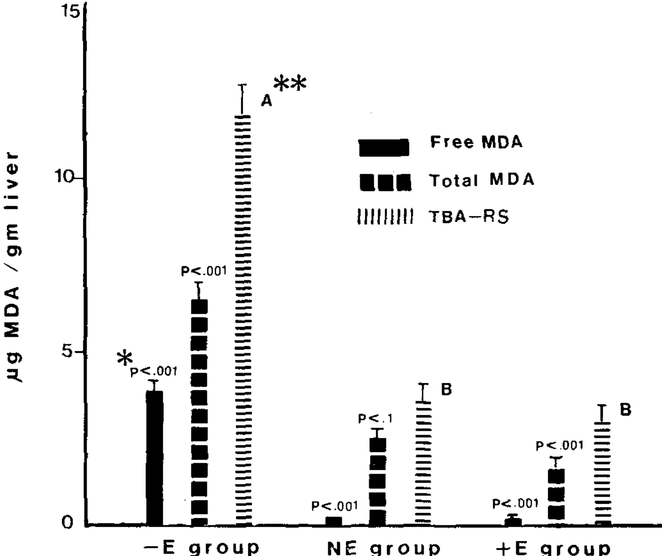

FIG. 1. Comparison of the levels of MDA and TBA-reactive substances. Values represent the mean ± SEM for eight animals for dietary group. *, P values at the top of the MDA bars indicate the results of Student's t-test between free or total MDA levels and the TBA-RS within each dietary group. **, Differences in TBA-RS levels among the dietary groups were tested by Tukey's multiple comparison method. Means not sharing a common letter are significantly different (p < 0.05).

TABLE 2

The Ratios of TBA-Reactive Substances to Free and Total Malondialdehyde[a]

Group	TBA-RS[b]/free MDA	TBA-RS/total MDA
−E	3.0	1.8
NE	12.9	1.4
+E	12.2	1.7

[a]Ratios were calculated from the mean values of each group.
[b]TBA-reactive substances calculated as MDA equivalents.

Cholesteryl Esterase Activities in Ventricles, Isolated Heart Cells and Aorta of the Rat

Hans Stam*, **Sietske Broekhoven-Schokker**, **Kees Schoonderwoerd** and **Willem C. Hülsmann**
Department of Biochemistry I, Medical Faculty, Erasmus University Rotterdam, PO Box 1738, 3000 DR Rotterdam, The Netherlands

Cholesteryl esterase activities were determined in homogenates of rat heart (ventricles), isolated, calcium-tolerant, cardiac myocytes and aortic tissue and were compared with acid and neutral triglyceride lipase activities in these fractions.

Using cholesteryl oleate/phosphatidylcholine/taurocholate emulsions and digitonin pretreatment of the enzyme fractions, acid and neutral cholesteryl esterase activities were measured in all tissue preparations. In contrast to the acid and neutral triglyceridase and acid cholesteryl esterase activity, the neutral cholesteryl esterase activity was subject to substrate inhibition. Upon isolation of cardiac myocytes, and in contrast with the recovery of neutral triglyceride lipase activity, only a small portion of the neutral cholesteryl esterase (6%) was recovered, suggesting that nonmyocyte neutral cholesteryl esterase activity markedly contributes to the relatively high activity detectable in whole ventricular homogenates. The recovery of large amounts of neutral cholesteryl esterase activity in the supernatant of collagenase-digested heart tissue, obtained during the isolation of myocytes, which is also markedly enriched in activities of two endothelial marker enzymes (5′-nucleotidase and angiotensine-converting enzyme) may indicate the predominant contribution of neutral cholesteryl esterase activity from coronary endothelial cells to this activity detectable in ventricular homogenates. Relative to the activity in ventricular and myocyte homogenates, aorta homogenates possessed the highest specific neutral cholesteryl esterase activity. We propose that in addition to coronary endothelium, smooth muscle cells also contribute to the neutral cholesteryl esterase activity in ventricular homogenates. Pretreatment of rats with carrageenan, an agent toxic to macrophages, lymphocytes and fibroblasts, induced a significant drop in myocardial neutral cholesteryl esterase and triglyceride lipase activity, suggesting that interstitially trapped macrophages may also contribute to lipolytic activities present in whole ventricular homogenates. Our data indicate that caution has to be taken upon extrapolation of experimental findings in heart homogenates to myocardial muscle cells.
Lipids 22, 108–115 (1987).

In rat heart homogenates, the presence of various lipolytic activities involved in the hydrolysis of exogenous and endogenous triglycerides and cholesteryl esters has been known for a long time (1–8). However, one cannot conclude from the presence of lipolytic activities in tissue homogenates that these enzymes are present in the cardiac myocytes, since these cells comprise only 12–20% of the total amount of heart tissue cells, although they represent the bulk of the tissue by mass (9). In addition to the myocytes, the heart contains cells of vascular origin (endothelial and smooth muscle cells), connective tissue cells and cardioadipocytes but probably also (occasional) interstitially trapped fibroblasts, lymphocytes, macrophages and neutrophils that have infiltrated the heart tissue. High acid and neutral triglyceride lipase and cholesteryl esterase activities have been described for aortic tissue and cultured macrophages, fibroblasts, lymphocytes and neutrophils (8,10–19). Furthermore, neutral triglyceride lipase activities, including lipoprotein lipase, have been described in isolated rat heart myocytes (20–23).

Recently, Goldberg and Khoo demonstrated for the first time the presence of a neutral cholesteryl esterase activity in mouse and rat heart homogenates and isolated rat heart cells (24). The present study was undertaken to reevaluate the cholesteryl esterase activities in rat heart (ventricular) homogenates, isolated rat heart myocytes and rat aortic tissue. The occurrence of cholesteryl esterase activities in the tissue preparations was compared with the presence of intracellular triglyceride lipase activities. In addition, the contribution of cholesteryl esterase activities present in interstitially occurring cells to overall heart homogenate activities was estimated after pretreatment of the rats with carrageenan, a polygalactan toxic for macrophages, lymphocytes and fibroblasts (25,26).

MATERIALS AND METHODS

Animals. Male Wistar rats of 200–250 g were used throughout the study. They had free access to control laboratory chow and water and were kept under an artificial light cycle of 12 hr (07.00–19.00 hr). Carrageenan (25 mg/kg body weight, suspended in sterile 0.9% [w/v] NaCl) was injected intraperitoneally under light ether anesthesia. Data obtained from the carrageenan-treated rats were compared with rats only receiving saline. The animals were killed 24 hr after carrageenan treatment. Carrageenan and saline injections did not affect the food consumption of the animals.

Perfusion protocol. Under light ether anesthesia the hearts were removed quickly from the thorax and immersed in ice-cold perfusion buffer. Subsequently, they were arranged for a non-recirculating Langendorff perfusion with a modified Tyrode buffer containing 11.1 mM glucose as described previously (5). Nonventricular tissue was removed as much as possible, and the hearts were electrically stimulated at a rate of 300 beats/min. After a 10-min preperfusion, heparin (5 U/ml) was included in the buffer to remove vascular lipoprotein lipase. Heparin perfusion continued for 30 min. No lipase activity could be detected in the effluent thereafter. Finally, a 5-min heparin washout perfusion was done. After perfusion, the hearts (ventricles) were minced finely, homogenized in a 1-mM phosphate buffer (pH 7.4) and, when indicated, a low speed supernatant prepared as described previously (5).

Preparation of isolated, calcium-tolerant cardiac myocytes. Myocytes were prepared from hearts of fed rats using a modification of the method described by Farmer et al. (27). We used a Tyrode buffer ($[Ca^{2+}]$ = 1.35 mM) instead of a Krebs-Henseleit buffer ($[Ca^{2+}]$ =

*To whom correspondence should be addressed.

2.5 mM). In addition, we included 0.01% (w/v) butylated hydroxytoluene, an antioxidant, during all incubations and washings. Briefly, after preperfusion with Tyrode buffer (step 1), a 5-min Ca^{2+}-free perfusion took place (step 2) followed by a 5-min perfusion with buffer containing 50 μM Ca^{2+}, 0.1% (w/v) collagenase, 0.1% (w/v) hyaluronidase and 0.1% (w/v) bovine serum albumin at a flow rate of 8 ml/min (step 3). Then the hearts were removed from the apparatus, two vertical slashes were made toward the apex of the heart and the tissue was incubated at 37 C with buffer supplemented with 50 μM Ca^{2+}, 0.1% (w/v) collagenase and hyaluronidase and 2% (w/v) bovine serum albumin (step 4). Then the disaggregated cells were collected by sieving through a 300-μ nylon mesh. The first cell suspension was discarded. After step 4 three successive 5-min incubations with the same medium were done followed by sieving (step 5). Thereafter, when almost the whole tissue was digested, the cells were collected by centrifugation (40 $\times$ g, 1 min) and washed three times with Tyrode buffer containing 50 μM Ca^{2+} and 2% (w/v) bovine serum albumin (step 6). The final cell pellet was suspended in control Tyrode buffer for characterization. In our lab, this method gives a 41.7 $\pm$ 0.58% (n = 8) cell yield on protein basis with a viability, as determined from 0.3% (w/v) trypan blue exclusion, of 70–80%. Sixty to 75% of the cells were rod-shaped; 10–20% of them were beating spontaneously. The myocytes were finally centrifuged, and the pellet was homogenized in a 1-mM phosphate buffer (pH 7.4) (step 7). When indicated, a low speed supernatant was prepared as described previously (5).

Aorta preparation. After removal of the heart for perfusion, the thoracic aorta was dissected free and stripped from nonarterial tissue. Aortas were washed thoroughly free of blood components using 0.9% (w/v) NaCl. All handlings took place in the cold room (4 C). Aortic tissue was finely minced, homogenized in a 1-mM phosphate buffer (pH 7.4) by two 30-second bursts of a Polytron tissue homogenizer (setting 5) and, when indicated, a low speed supernatant was prepared by centrifugation (5 min, 300 $\times$ g).

Determination of cholesteryl esterase activities (EC 3.1.1.13). Cholesteryl esterase activities in the various enzyme sources (homogenates or low speed supernatants) were initially tested using three different cholesteryl [1-^{14}C]oleate preparations. We used cholesteryl oleate/phosphatidylcholine/glycerol dispersions as described by Severson and Fletcher (8) (assay A), cholesteryl oleate/phosphatidylcholine/bile salt micelles according to Hajjar et al. (15) (assay B) and cholesteryl oleate/phosphatidylcholine/bile salt micelles after digitonin pretreatment of the enzyme preparations (0.025 mg/ml, 10 min, 4 C) according to Haley et al. (12) (assay C). All incubations were performed at 37 C for 30 min.

Assay A, final volume 100 μl, contained 50 μM [^{14}C]cholesteryl oleate (186 Becq/nmol), 320 μM phosphatidylcholine, 0.4% (w/v) bovine serum albumin (fatty acid-free), 1.25 M glycerol and 50 mM Tris-HCl/acetate buffer (pH range 3–9).

Assay B, final volume 125 μl, contained 50 μM [^{14}C]cholesteryl oleate (238 Becq/nmol), 200 μM phosphatidylcholine, 0.04% (w/v) bovine serum albumin, 100 μM sodium taurocholate and 100 mM potassium phosphate/acetate buffer (pH range 3–9).

Assay C, final volume 125 μl, contained 50 μM [^{14}C]cholesteryl oleate (359 Becq/nmol), 4.35 mM phosphatidylcholine, 2.0 mM sodium taurocholate and 125 mM Tris-HCl/acetate buffer (pH range 3–9).

Extraction of the liberated labeled fatty acids occurred as described elsewhere (8,12,15).

Cholesteryl esterase activity is expressed as nmol fatty acid released from the cholesteryl oleate substrate per hr per mg protein. The interassay variation of both cholesteryl esterase activities was less than 2%.

Determination of triglyceride lipase activities (EC 3.1.1.3). Triglyceride lipase activities in the various homogenates or low speed supernatants were determined at pH 4.8, 7.4 and 8.2, using a [^{3}H]triolein/gum acacia suspension as previously described (5). Neutral (or alkaline) triglyceride lipase activity was estimated in the absence and presence of 15% (v/v) rat serum, obtained from rats fasted overnight and preheated for 60 min at 56 C to remove its lipolytic activity. Triglyceride lipase activity is expressed as nmol fatty acid released from the triolein substrate per min per mg protein.

Determination of 5′-nucleotidase (EC 3.1.2.5) and angiotensine-converting enzyme activities (EC 3.4.15.1). The activities of 5′-nucleotidase and angiotensine-converting enzyme, marker enzymes for endothelial cells (28,29), were determined as described previously (29).

Immunotitration. Polyclonal antibodies against rat heart heparin-releasable lipoprotein lipase were obtained from female goats as described earlier (5,30). Twenty-five μl of the antibody preparation inhibited 10 mU of lipoprotein lipase activity. Triglyceride lipase and cholesteryl esterase activity in the various enzyme preparations were incubated with control and anti-lipoprotein lipase γ-globulins (90 min, 4 C). Thereafter the assay was started by the addition of the substrate.

Chemical assays. Protein content of ventricular, aorta and myocyte preparations was determined according to Lowry et al. (31) using bovine serum albumin as standard. Total cholesteryl ester contents of the tissue and cell preparations were determined, after organic extraction according to Bligh and Dyer (32) and drying, using a Boehringer test combination, based on methods described by Stähler et al. (31) and Trindler (32).

Reagents. Reagents and chemicals (all of analytical grade) were obtained from Merck (Darmstadt, Federal Republic of Germany) and Boehringer (Mannheim, Federal Republic of Germany). Bovine serum albumin (fraction V), collagenase (type I) and hyaluronidase (type II) were purchased from Sigma (St. Louis, Missouri). The albumin was freed from fatty acids by charcoal treatment. [9,10(n)-^{3}H]Glycerol triolein and cholesteryl [1-^{14}C]oleate were from Amersham International PLC (Amersham, United Kingdom), Instagel was from Packard (Downers Grove, Illinois) and heparin was from Organon (Oss, The Netherlands). Carrageenan was from Sigma and a gift from E. J. Schenkelaars from the Department of Pharmacology of our faculty.

Statistics. Most data are presented as mean values ($\overline{X}$) $\pm$ standard error of the mean (SEM), with n representing the number of experiments. Statistical significance of differences was calculated with Student's t-test (two-tailed). $P > 0.05$ was considered not significant (NS).

RESULTS

Validation of assays. The triolein, emulsified in gum acacia, is well established as a suitable substrate for the

assay of lipase activities in various tissue homogenates, and the activity of acid and neutral triglyceride lipase and lipoprotein lipase in heart tissue can be compared with data obtained with glycerol/triolein dispersions, ethanolic triolein substrates, [^{3}H]triolein-labeled chylomicrons and triolein/phosphatidylcholine micelles (3,35, 36). As demonstrated previously for low speed supernatants of whole heart homogenates (5), the triglyceride lipase activities in myocyte and aorta preparations also exhibited classical Michaelis-Menten kinetics (not shown). In addition, the lipase activities of all preparations were linear with time and increasing amounts of enzyme protein (not shown).

Previous work of Hajjar et al. (15) has indicated that the physical dispersion of cholesteryl oleate largely determines the actual rate of its hydrolysis by cholesteryl esterase. Figure 1 illustrates the pH dependence of cholesteryl esterase activity in low speed supernatants of ventricular homogenates using three different substrate preparations varying in their molar ratio of cholesteryl oleate, phosphatidylcholine and sodium taurocholate, preincubation of the enzyme fraction with digitonin, the stabilizing presence of glycerol and the presence of bovine serum albumin (assays A, B and C; see Materials and Methods). In all three assays, cholesteryl esterase activity exhibited two pH peaks, of which the actual rates and optima were different (see below). The highest acid cholesteryl esterase activity was measured using the glycerol-dispersed cholesteryl oleate/phosphatidylcholine micelles (assay A). However, using this preparation, only a low neutral cholesteryl esterase activity peak could be detected. By contrast, the use of sodium taurocholate yielded lower acid but higher neutral cholesteryl esterase activities. The substrate preparation described by Haley et al. (12) (assay C), using digitonin preincubation of the low speed supernatant, revealed a higher acid and neutral cholesteryl esterase activity compared with the substrate described by Hajjar et al. (15) applying cholesteryl oleate, phosphatidylcholine and taurocholate in a different ratio. Since this was also the case in low speed supernatants of aorta and myocyte homogenates, assay C was chosen for routine cholesteryl esterase determinations. As illustrated in Figure 2, the acid and neutral cholesteryl esterase activity of all enzyme preparations was linear with time for at least 40 min of incubation. Thereafter linearity was lost. During routine cholesteryl esterase assays we used an incubation period of 30 min. In addition, as presented in Figure 3, the acid and neutral cholesteryl esterase

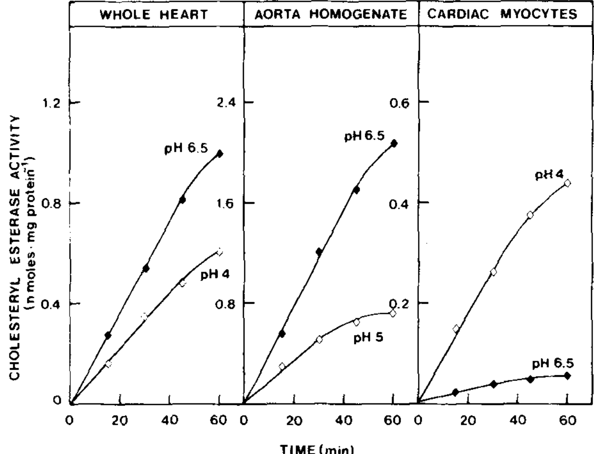

FIG. 2. Time dependency of acid and neutral cholesteryl esterase activity in low speed supernatants of homogenates prepared from whole rat heart (ventricles), aorta and isolated cardiac myocytes. For further details see Fig. 1 and Materials and Methods. Results are the mean values of two separate experiments.

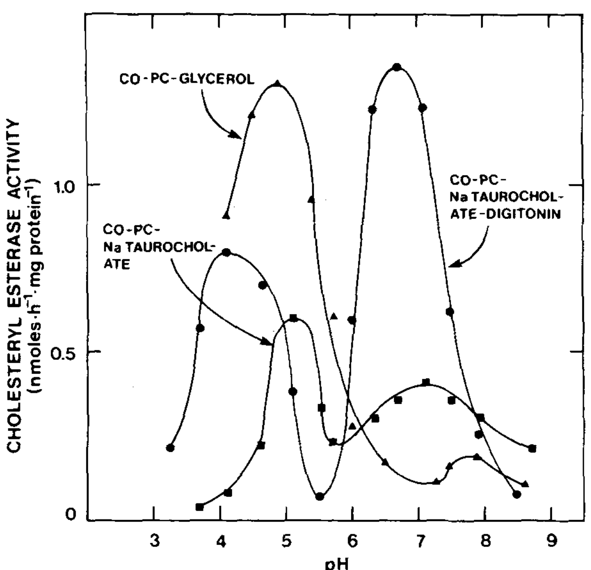

FIG. 1. The effect of substrate preparation on pH dependence of cholesteryl esterase activity in low speed supernatants of rat heart (ventricular) homogenates. Cholesteryl oleate (CO) substrate emulsions were prepared as described in Materials and Methods. The preparations were ▲: 50 μM CO, 320 μM phosphatidylcholine (PC), 1.25 M glycerol; □: 50 μM CO, 200 μM PC, 100 μM taurocholate; ●: 50 μM CO, 4.35 mM PC, 2.0 mM taurocholate after digitonin pretreatment of the enzyme fraction (0.025 mg/ml, 10 min at 4 C). The ● assay was used in routine determinations of cholesteryl esterase activity. The results are the mean value of two separate experiments.

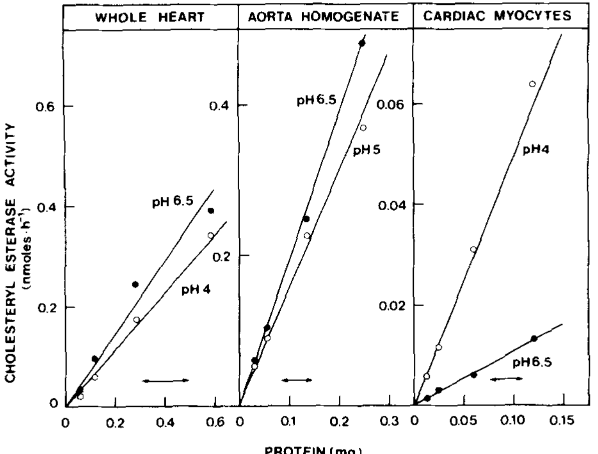

FIG. 3. Protein dependency of acid and neutral cholesteryl esterase activity in low speed supernatants of homogenates prepared from whole rat heart (ventricles), aorta and isolated cardiac myocytes. For further details see Fig. 1 and Materials and Methods. Results are the mean values of two separate experiments. The horizontal bars indicate the amount of protein in the low speed supernatant used during routine cholesteryl esterase assays.

activity of all tissue preparations was linear with increasing amounts of enzyme protein. The neutral cholesteryl esterase activity (pH 6.5; see below) in low speed supernatants of ventricular, aorta and myocyte homogenates was subject to substrate inhibition at cholesteryl oleate concentrations above 50 μM (Fig. 4). Acid cholesteryl esterase activity, in contrast, did not show this phenomenon in low speed supernatants of heart homogenates (activity peak at pH 4) and was only moderately inhibited at higher cholesteryl oleate concentrations in aortic and myocyte preparations (activity peak at pH 5 and 4, respectively).

Based upon the total endogenous cholesterol content of the used tissue preparations (7.3 μg/mg protein in ventricles, 33.2 in aorta and 6.3 in the myocyte preparations, of which less than 5% was in esterified form; $\bar{X}$, n = 2), we calculated that endogenous cholesteryl esters maximally enhanced the assay concentration by about 0.5%. Together with the protein linearity of the assay, we conclude that endogenous cholesteryl esters were not hydrolyzed in preference nor did they dilute the radioactivity of the added substrate significantly. The described substrate inhibition can therefore not be attributed to effects of endogenous cholesteryl esters.

Acid and neutral cholesteryl esterase activities in ventricular tissue, aorta and isolated myocytes compared with triglyceride lipase activities. As presented in Figure 5, the low speed supernatant fractions of whole ventricular, aortic and myocyte homogenates contain acid (pH 4.0, 5.0 and 4.2, respectively) and neutral (pH 6.5) cholesteryl esterase activity peaks. Aortic cholesteryl esterase activities were the highest on a mg protein basis. Strikingly, the neutral cholesteryl esterase activity in low speed supernatants of whole ventricular homogenates was recovered to only a small extent in the myocyte preparation. This difference in specific activity may indicate that the bulk of the heart enzyme was not associated with the myocytes but with other cell types present in the myocardial tissue.

The pH activity profiles of cholesteryl esterase in ventricular, aortic and myocyte preparations were compared

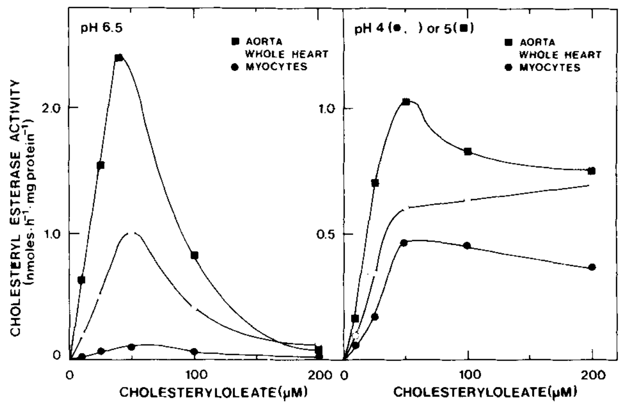

FIG. 4. The effect of increasing cholesteryl oleate concentrations on the activity of acid and neutral cholesteryl esterase in low speed supernatants of homogenates prepared from rat heart (ventricles) (O), aorta (■) and isolated cardiac myocytes (●). For further details see legend to Fig. 1 and Materials and Methods. Results are the mean values of two separate experiments.

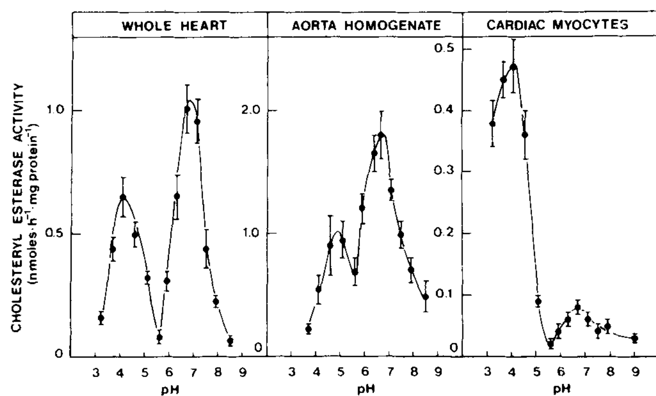

FIG. 5. pH dependence of cholesteryl esterase activities in low speed supernatants of homogenates from rat heart (ventricles), aorta and isolated cardiac myocytes. For further details see legend to Fig. 1 and Materials and Methods. Results are the mean values ± SEM of 4–8 experiments.

with those of the acid and neutral (or alkaline) triglyceride lipase activities. The low speed supernatants of ventricular, aorta and myocyte homogenates contain acid triglyceride lipase activity peaks of pH 4.8, 5.5 and 5, respectively. The ventricular neutral triglyceride lipase activity, determined in the absence of serum, peaked at pH 7.4. This activity was markedly stimulated during incubation in the presence of serum. In the aortic and myocyte preparation, the pH peak of serum-activated triglyceride lipase activity shifted to alkaline regions (pH 8.2).

In contrast to the basal and serum-stimulated neutral triglyceridase activity (5), the neutral cholesteryl esterase activity of all three preparations was not inhibited by preincubation with anti-lipoprotein lipase γ-globulins (not shown).

Two successive washings of the final myocyte preparation with heparin (5 U/ml) induced only a 11 ± 2% (n = 3) reduction of basal and serum-stimulated neutral triglyceride lipase activity and did not affect the neutral cholesteryl esterase activity. This suggests a predominant intracellular origin of the neutral triglyceridase activity in myocytes.

Table 1 summarizes the absolute recoveries of protein and lipolytic activities during the isolation of myocytes from rat hearts. Protein recovery in myocyte homogenates amounted to about 40%. Myocyte homogenate acid and neutral triglyceride lipase and acid cholesteryl esterase activities were recovered by about 30% relative to their activity in whole heart homogenates. The 10% difference may be a consequence of the presence of nonviable dead cells in our myocyte preparations (20–30%). Of the neutral cholesteryl esterase activity detectable in whole ventricular homogenates, only about 6% was recovered after isolation of the myocytes. The loss of neutral cholesteryl esterase activity upon myocyte isolation indeed suggests that its activity in homogenates is associated with other nonmyocyte cell types in the heart.

Acid and neutral cholesteryl esterase activity in fractions obtained during the isolation of calcium-tolerant myocytes from adult rat hearts. The low recovery of neutral cholesteryl esterase activity in the final myocyte fraction (Table 1) prompted us to study its recovery in other fractions obtained during the isolation of myocytes

TABLE 1

Recovery of Protein and Lipolytic Enzyme Activities After the Isolation of Calcium-Tolerant Myocytes from Adult Rat Hearts

	Ventricular homogenate	Myocyte homogenate
Total protein (mg)	198.3 ± 5.4 (100%)	82.7 ± 1.1 (41.7 ± 0.5%)
Acid triglyceride lipase (nmol/min)	42.1 ± 1.6 (100%)	7.1 ± 0.3 (16.9 ± 1.3%)
Neutral triglyceride lipase − serum (nmol/min)	23.9 ± 2.6 (100%)	6.3 ± 0.2 (26.4 ± 1.0%)
Neutral triglyceride lipase + serum (15% v/v) (nmol/min)	199.8 ± 9.4 (100%)	58.4 ± 0.6 (29.2 ± 0.3%)
Acid cholesteryl esteras (nmol/hr)	103.2 ± 1.7 (100%)	31.9 ± 1.3 (30.9 ± 1.3%)
Neutral cholesteryl esterase (nmol/hr)	126.5 ± 6.5 (100%)	7.2 ± 0.3 (5.7 ± 0.2%)

Adult rat hearts were preperfused with heparin and subsequently homogenized in a 1-mM phosphate buffer of pH 7.4. Cardiac myocytes were isolated from adult rat hearts and the final pellet was homogenized as above. Total protein content and lipolytic activities in ventricular and myocyte homogenates were measured. Protein content and lipolytic activities in ventricular homogenates were taken as 100%. Values obtained in the myocyte homogenate were expressed as percentages of values determined in the ventricular homogenates (see parentheses). Results represent the mean values ± SEM of 4-8 separate experiments. For further details, see Materials and Methods.

from adult rat hearts. The following fractions were collected and investigated for total activities of acid and neutral cholesteryl esterase and two endothelial enzyme markers, 5′-nucleotidase and angiotensine-converting enzyme (28,29): a) the myocardial effluent collected during collagenase- and hyaluronidase perfusion (step 3); b) the cell suspension from the first incubation of preperfused heart tissue with collagenase and hyaluronidase (step 4); c) the final supernatant of completely digested tissue after pelleting the myocytes by centrifugation (step 5); d) the combined supernatants obtained after the washing of the myocytes (step 6); and e) the final myocyte preparation. The percent distribution of cholesteryl esterases and markers between the collected fractions is presented in Table 2. Overall recovery of enzyme activities in the isolated fractions, compared with the total activity in whole heart homogenates, was 126.3% for the acid cholesteryl esterase, 94.7% for the neutral cholesteryl esterase, 104.3% for the 5′-nucleotidase and 107.3% for the angiotensine-converting enzyme.

From Table 2 we conclude that, in contrast to the acid cholesteryl esterase activity, a large part of the neutral cholesteryl esterase was recovered in the supernatant fraction obtained from the digested heart tissue by centrifugation (step 5). This fraction was also markedly enriched in both endothelial cell enzyme markers. Acid cholesteryl esterase activity was recovered predominantly in the final myocyte pellet. The endothelial contamination of this fraction is relatively small: from the recovery of the marker enzymes we estimate about 3-11%. In contrast to 5′-nucleotidase, the angiotensine-converting enzyme was also recovered in substantial amounts in the effluent collected during collagenase and hyaluronidase perfusion (step 3). This "release" may be a consequence of the loose binding of the enzyme to the endothelial cell membrane (37) and does not reflect the washout of endothelial cells, since the 5′-nucleotidase release was low.

Effect of carrageenan pretreatment of rats on myocardial cholesteryl esterase and triglyceride lipase activities. To investigate the contribution of lipolytic activites from other cell types (macrophages, lymphocytes and fibroblasts) to activities detectable in whole ventricular homogenates, we treated rats with carrageenan (intraperitoneally administered) and determined the lipolytic activity in whole ventricular homogenates 24 hr later. Carrageenan is proposed to possess a selective toxicity for macrophages and other (occasionally interstitial) cell types (fibroblasts, lymphocytes) throughout the body (25, 26). The dose of the intraperitoneally injected carrageenan (25 mg/kg body weight) and the duration of the treatment (24 hr) were chosen based on data from Fowler and Thomson (28). As demonstrated in Table 3, carrageenan treatment induced a small but statistically significant decrease in neutral triglyceride lipase and predominantly the neutral cholesteryl esterase activity. The small reduction in the activity of lysosomal lipolytic enzymes was not statistically significant. Since the interassay variation was much lower than the standard deviation of lipase and esterase activity in control and carrageenan-treated rats, the significant drop in both neutral enzymes induced by carrageenan truly reflects an effect of this drug.

DISCUSSION

Although isolated perfused organs and their homogenate or subcellular fractions are frequently used in metabolic studies, one must be aware that tissues are heterogenous and it may be difficult to extrapolate findings in fractionated tissue to the main cell type in such a tissue.

The presence of different metabolic tissue compartments in perfused rat hearts was demonstrated by us previously using a modified perfusion technique allowing the separate collection of interstitial fluid and coronary vascular effluent (39,40). The composition of both effluents was completely different, revealing that metabolites and enzymes from cardiac myocytes (glycerol, lactate, fatty acids, proteins, lactate dehydrogenase) were mainly recovered in the interstitial fluid, whereas products from vascular origin (prostaglandin E_2 and I_2, lysophosphoglycerides, lipid peroxidation products, lipoprotein lipase) were largely recovered in the coronary venous effluent.

In the present study, we have described and partially characterized cholesteryl esterase activities in low speed supernatants of homogenates of rat hearts, isolated cardiac myocytes and aortic tissue.

Our experiments again point out the importance of the mode of substrate preparation in the cholesteryl esterase assay (12-14). Using the preparation described by Haley et al. (12), acid and neutral cholesteryl esterase activities in all enzyme fractions could easily be detected. Using glycerol dispersions of cholesteryl oleate, a lower neutral cholesteryl esterase activity was detected. All tissue

TABLE 2

Distribution of Acid and Neutral Cholesteryl Esterase Activities and the Endothelial Marker Enzymes 5′-Nucleotidase and Angiotensine-Converting Enzyme Between Fraction Obtained During the Stepwise Isolation of Cardiac Myocytes from Adult Rat Hearts

Fraction (isolation step)	% Distribution of activity			
	Acid cholesteryl esterase	Neutral cholesteryl esterase	5′-Nucleotidase	Angiotensine-converting enzyme
Effluent from collagenase + hyaluronidase perfused hearts (step 3)	7.5 ± 1.3	10.3 ± 1.9	5.2 ± 2.2	29.5 ± 2.7
Discarded cells from the collagenase + hyaluronidase incubation of heart tissue (step 4)	3.9 ± 0.1	9.3 ± 1.6	5.3 ± 0.4	9.5 ± 0.2
Total supernatant of the digested heart tissue (step 5)	25.4 ± 1.2	52.5 ± 1.7	53.6 ± 2.4	46.1 ± 2.1
Total myocyte-washing supernatant (step 6)	21.4 ± 1.9	21.7 ± 0.3	22.4 ± 0.7	11.5 ± 0.7
Final myocyte preparation	41.8 ± 1.8	6.2 ± 0.4	13.5 ± 1.2	3.4 ± 0.3

In fractions obtained during the isolation of cardiac myocytes from adult rat hearts, total acid and neutral cholesteryl esterase, 5′-nucleotidase and angiotensine-converting enzyme activities were determined. The sum of the activities was taken as 100%. Results represent the mean values ± SEM of 4 separate experiments. For further details, see Materials and Methods.

TABLE 3

Effect of Carrageenan Pretreatment of Rats on Ventricular Cholesteryl Esterase and Triglyceride Lipase Activities

Enzyme	pH	Control	Carrageenan
Cholesteryl esterase (nmol/hr/mg)	4.0	0.66 ± 0.02 (13)	0.58 ± 0.11 (4)
Cholesteryl esterase (nmol/hr/mg)	6.5	1.02 ± 0.06 (13)	0.85 ± 0.05 (4)[a]
Triglyceride lipase (nmol/min/mg)	4.8	0.53 ± 0.04 (6)	0.45 ± 0.02 (4)
Triglyceride lipase (−) (nmol/min/mg)	7.4	0.56 ± 0.08 (6)	0.45 ± 0.03 (4)
Triglyceride lipase (+) (nmol/min/mg)	7.4	1.92 ± 0.05 (6)	1.76 ± 0.03 (4)[a]

Rats were intraperitoneally injected with carrageenan (25 mg/kg body weight) suspended in sterile 0.9% (w/v) NaCl. Control animals only received saline. Hearts were perfused with heparin (5 U/ml) 24 hr later to remove vascular lipoprotein lipase. Thereafter, the ventricles were homogenized and a low speed supernatant was prepared by centrifugation. Acid and neutral triglyceride lipase and cholesteryl esterase activities were measured at the indicated pH. Neutral triglyceride lipase activity was determined in the absence (−) and presence (+) of 15% (v/v) rat serum. The data are presented in mean values ± SEM. The number of experiments is given in parentheses. For further details, see Materials and Methods.

[a]$p < 0.05$ vs the control group.

preparations contained an acid cholesteryl esterase activity, probably from lysosomal origin. Our data with respect to the neutral cholesteryl esterase in rat heart homogenates confirms recent findings of Goldberg and Khoo (24) who, for the first time, described this neutral activity in mouse heart postmitochondrial fractions. The neutral cholesteryl esterase in rat heart homogenates, myocytes and aorta was subject to substrate inhibition. This phenomenon excludes meaningful application of conventional kinetic modeling and analysis. Substrate inhibition of neutral cholesteryl esterase activity was also observed in rat testis (41).

Aortic neutral cholesteryl esterase activity is probably associated with the vascular smooth muscle cells and involved in the mobilization of stored cytosolic cholesteryl esters (42). An intracellular localization is therefore conceivable. Upon isolation of myocytes from rat heart, a large part of the neutral cholesteryl esterase was lost. Only about 6% of total rat heart homogenate activity was recovered, whereas the acid cholesteryl esterase was recovered for 30.9%.

All enzyme preparations contained an acid triglyceride lipase, presumably of lysosomal origin (3,29). In accordance with earlier findings also, a neutral triglyceride lipase activity was present in all preparations. This lipase exhibited all characteristics of lipoprotein lipase (stimulation by serum, inhibition by 1 M NaCl and almost complete inhibition by anti-lipoprotein lipase antibodies). The presence of lipoprotein lipase in isolated myocytes and aorta confirms previous results (19–27,43). In addition, Ramirez et al. (21) and Goldberg and Khoo (24) have recently described a very low and labile activity of a

neutral lipase apparently distinct from lipoprotein lipase in isolated rat myocytes.

The recovery of the neutral triglyceride lipase and neutral cholesteryl esterase, both presumably intracellular enzymes, during the preparation of isolated myocytes was strikingly different (30% vs 6%, respectively). The overall recovery of acid triglyceride lipase, the acid cholesteryl esterase and neutral triglyceride lipase activity were 16.9, 30.9 and 26.4%, respectively. The rather dramatic loss of neutral cholesteryl esterase activity during the isolation of myocytes may be explained by a) a selective inactivation of this enzyme during the isolation procedure or b) its predominant localization in nonmyocardial cardiac tissue cells or interstitially occurring macrophages, lymphocytes and fibroblasts. There are no arguments at hand for a selective inactivation of the neutral cholesteryl esterase. The overall recovery of neutral cholesteryl esterase activity in fractions obtained during the isolation of myocytes was 95% compared with whole heart homogenates. This excludes the presence of an activator in whole tissue homogenates that is lost during myocyte isolation or selective inactivation of the enzyme in the myocyte fraction. Moreover, the 30% recovery of the rather labile intracellular neutral triglyceridase followed the overall recovery of viable cells on a protein basis.

A contribution of neutral cholesteryl esterase from other cell types in heart tissue is therefore more likely. The concomitant recovery of the bulk of the neutral cholesteryl esterase activity and the marker enzymes for endothelial cells (5′-nucleotidase and angiotensine-converting enzyme) in the supernatant of collagenase-treated heart tissue (step 4) indicated that coronary vascular endothelium may substantially contribute to the neutral cholesteryl esterase activity detectable in ventricular homogenates. Assuming that aortic tissue is a reliable marker for overall (coronary) vascular tissue, it is tempting to speculate on the additional contribution of neutral cholesteryl esterase activity from vascular smooth muscle cells to ventricular homogenates, especially since the aortic cholesteryl esterase has the highest specific activity compared to ventricular homogenates and isolated myocytes. In addition, our experiments using carrageenan, a sulfated polygalactose that is very toxic to macrophages, fibroblasts and lymphocytes, indicate that also neutral cholesteryl esterase and triglyceride lipase activities present in these carrageenan-sensitive cells contribute to overall ventricular homogenate activities. Unfortunately, there is no reliable enzymatic marker for the above cells, so it is not possible to evaluate the actual carrageenan action. Finally, myocardial adipocytes may contribute to all lipolytic activities in tissue homogenates, but this contribution is difficult to estimate in the experimental set-up used.

In conclusion, our experiments indicate the presence of acid and neutral cholesteryl esterase activity in rat ventricular homogenates, aortic tissue and isolated cardiac myocytes. The relatively high activity of neutral cholesteryl esterase in ventricular homogenates may largely be determined by activities from nonmyocyte tissue cells in the heart. We propose that cells from vascular origin, in particular endothelial cells, and interstitially occurring carrageenan-sensitive cells are good candidates. Extrapolation of enzymic findings in whole heart (or ventricular) homogenates to processes in cardiac myocytes may therefore easily lead to misinterpretation.

ACKNOWLEDGMENTS

[Revision received September 12, 1986]

Resolution of Radiolabeled Molecular Species of Phospholipid in Human Platelets: Effect of Thrombin

A. David Purdon*, D. Patelunas and J. Bryan Smith
Thrombosis Research Center, Temple University, 3400 N. Broad St., Philadelphia, PA 19140

Resolution of individual molecular species of human platelet 1,2-diradyl-*sn*-glycero-3-phosphocholines and 1,2-diradyl-*sn*-glycero-3-phosphoethanolamines by reverse phase high pressure liquid chromatography (HPLC) allowed a thorough analysis of those phospholipids labeled with [^{3}H]arachidonic acid. Approximately 54% and 16% of the total incorporated radiolabel was found in choline glycerophospholipids and ethanolamine glycerophospholipids, respectively, with ca. 90% of this being found in the 1,2-diacyl molecular species. Eighty percent of [^{3}H]-arachidonic acid incorporated into 1-acyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine in resting platelets was equally distributed between 1-palmitoyl-2-arachidonoyl and 1-stearoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine, while 70% of the radiolabel in 1-acyl-2-arachidonoyl-*sn*-glycero-3-phosphoethanolamine was found in 1-stearoyl-2-arachidonoyl-*sn*-glycero-3-phosphoethanolamine. Thrombin stimulation (5 U/ml for 5 min) resulted in deacylation of all 1-acyl-2-[^{3}H]arachidonoyl molecular species of 1-acyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine and 1-acyl-2-arachidonoyl-*sn*-glycero-3-ethanolamine. There was also a slight increase in 1-O-alkyl-2-[^{3}H]arachidonoyl-*sn*-glycero-3-phosphocholine and a significant increase in 1-O-alk-1′-enyl-2-[^{3}H]arachidonoyl-*sn*-glycero-3-phosphoethanolamine molecular species of over 300%. Thus, HPLC methodology indicates that arachidonoyl-containing molecular species of phosphatidylcholine and phosphatidylethanolamine are the major source of arachidonic acid in thrombin-stimulated human platelets, while certain ether phospholipid molecular species become enriched in arachidonate.
***Lipids 22,* 116–120 (1987).**

Analysis of 1,2-diradyl-*sn*-glycero-3-phosphocholine of human platelets has shown that 81% of the phospholipid mass consists of 1,2-diacyl-*sn*-glycero-3-phosphocholine (1,2-diacyl GPC) molecular species, while two ether phospholipid subclasses, namely 1-O-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (8.8%) and 1-O-alk-1′-enyl-2-acyl-*sn*-glycero-3-phosphocholine (9.2%), constituted the remainder (1). It also is known that over 60% of human platelet 1,2-diradyl-*sn*-glycero-3-phosphoethanolamine is 1-O-alk-1′-enyl-2-acyl-*sn*-glycero-3-phosphoethanolamine (i.e., plasmalogen) (1–3). Further analysis showed that only 3% of 1-radyl-2-acyl-*sn*-glycero-3-phosphoethanolamine was the 1-O-alkyl-2-acyl-*sn*-glycero-3-phosphoethanolamine subclass, with the remainder having the 1,2-diacyl-*sn*-glycero-3-ethanolamine structure (1,2-diacyl GPE) (1). Finally, 1,2-diradyl-*sn*-glycero-3-phosphoinositol (1,2-diradyl GPI) has been shown to contain 1% 1-O-alkyl-2-acyl-*sn*-glycero-3-phosphoinositol, with the rest being 1,2-diacyl-*sn*-glycero-3-phosphoinositol (1,2-diacyl GPI) (4).

Mahadevappa and Holub (5–7) have analyzed completely the diacyl molecular species of phospholipid from human platelets using snake venom phospholipase A_2 for release of *sn*-2 fatty acids and argentation thin layer chromatography; however, ether subclasses were not considered. High pressure liquid chromatography (HPLC) procedures are now available for separating a given phospholipid class into its individual molecular species of phospholipid (8). Studies by Kramer et al. (9) on the incorporation of radiolabeled 1-O-hexadecyl-2-lyso-*sn*-3-glycerophosphocholine into 1-O-hexadecyl-2-acyl-*sn*-3-glycerophosphocholine in human platelets utilized this methodology. This same approach had been shown to separate 1,2-diacyl, 1-O-alkyl-2-acyl and 1-O-alk-1′-enyl-2-acyl structural analogues of neutrophil phospholipid labeled with [^{3}H]arachidonic acid (10). Thus, we decided to analyze the individual molecular species of phospholipid radiolabeled with arachidonic acid in both unstimulated platelets and cells activated with thrombin to ascertain changes in individual molecular species of phospholipid.

MATERIALS AND METHODS

All chemicals were reagent grade or better. All solvents were HPLC grade (EM Science, Omnisolv) and were obtained from Bodman Chemicals (Media, Pennsylvania). Primulin dye was purchased from Sigma (St. Louis, Missouri). Silica Gel H thin layer chromatography (TLC) plates were obtained from Analtech (Newark, Delaware). Phospholipid standards were purchased from Serdary (London, Ontario, Canada) and Avanti (Birmingham, Alabama). Tritiated arachidonic acid (5,6,8,9,11,12,14,15,-^{3}H) was obtained from Amersham (Arlington Heights, Illinois) and had a specific activity of 137 Ci/mmol, while [^{14}C(U)]arachidonic acid (sp act 390 mCi/mmol) and [12,13-^{3}H]linoleic acid (sp act 49.0 Ci/mmol) were from New England Nuclear (Dupont, Boston, Massachusetts). Betafluor was a product of National Diagnostics (Somerville, New Jersey). The HPLC column was a 4.6 $\times$ 250 mm ultrasphere ODS (5 μm particle size) purchased from Beckman Instruments (Berkeley, California).

Isolation of human platelets. Blood was collected in 1/6 vol ACD (2.5 g trisodium citrate, 1.5 g citric acid, 2.0 g glucose/100 ml H_2O) solution and supernatant platelet-rich plasma (PRP) removed after centrifugation at 200 $\times$ g for 15 min at 22 C. Fifty ml PRP (pH 6.5) was centrifuged at 2600 $\times$ g for 15 min at 22 C, and the pellet was gently resuspended in 1/10 vol supernatant plasma. This was incubated with the appropriate radioactive fatty acid(s) (solvent evaporated) for 1 hr at 37 C. Labeling was done either with 50 μCi [^{3}H]arachidonic acid or for double labeling experiments 25 μCi [^{3}H]linoleic and 2 μCi [^{14}C]arachidonic. The PRP was allowed to cool to 22 C and gel was filtered on a Sepharose 2B column using Tyrodes buffer with an albumin concentration of 0.2% w/v as previously described (11). Platelet concentration was determined by Coulter counter (11) and then adjusted to 10^9 cells/ml.

Thrombin. Ten thousand units of thrombin (Parke-Davis, Detroit, Michigan) was dialyzed against 0.15 M

*To whom correspondence should be addressed.

NaCl for 12 hr to remove calcium, then diluted to a concentration of 100 units/ml and kept frozen.

Extraction and fractionation of phospholipids. Cellular lipids were extracted by the method of Bligh and Dyer (12). The choline- and ethanolamine-containing phospholipids were isolated by TLC on Silica Gel H plates using the solvent system of Skipski et al. (13). To determine the [^{3}H]arachidonic acid content in 1,2-diacyl-, 1-O-alkyl-2-acyl- and 1-O-alk-1′-enyl-2-acyl-, *sn*-glycero-3-phosphocholine (GPC) and *sn*-glycero-3-phosphoethanolamine (GPE), the TLC-resolved phospholipid classes of 1,2-diradyl-*sn*-glycero-3-phosphocholine and 1,2-diradyl-*sn*-glycero-3-phosphoethanolamine were treated for 12 hr with *Bacillus cereus* phospholipase C and acetylated as previously described (1,14). The 1,2-diradyl-glyceroacetates were resolved by TLC (14) and eluted from the silica gel, and the radioactivity was determined.

HPLC of intact phospholipid. The isocratic reverse phase system of Patton et al. (8), which uses 20 mM choline chloride in methanol/water/acetonitrile (90.5:7:2.5, v/v/v) as solvent at a flow rate of 1.0 ml/min, was used to resolve individual molecular species of a given class of phospholipid. This approach also resolves ether phospholipids from diacyl molecular species (10) and, for given structural analogues, the elution sequence is 1,2-diacyl, 1-O-alk-1′-enyl-2-acyl and 1-O-alkyl-2-acyl. The column was run at 37 C, and the sample was injected in a 1:1 solution of methylene chloride/methanol (10). Recovery of the applied phospholipid radioactivity was greater than 94%. In most experiments, the phospholipid from 3.3 × 10^8 cells for choline glycerophospholipids and 5 × 10^8 cells for ethanolamine glycerophospholipids was injected onto the column. To determine the elution of [^{3}H]arachidonate, 1-ml samples of eluate were collected and portions were counted to determine radioactivity. In other experiments, individual peaks were collected and total radioactivity was determined. Identification of individual peaks was done initially by comparison with the elution time of synthetic phospholipid standards and analysis of the fatty acid methyl esters of the phospholipid in individual peaks by gas liquid chromatography (GLC). 1-O-alkyl-2-arachidonoyl GPC standards were donated by R. Wykle (Department of Biochemistry, Bowman Gray School of Medicine, Winston-Salem, North Carolina). To verify identification, we used the procedures of this lab (1), Patton et al. (8), Mahedevappa and Holub (5), Kramer et al. (9) and Swendsen et al. (10). Generally, the Patton system gave some overlap of adjacent molecular species; however, most of the arachidonoyl-containing molecular species were well resolved. Phospholipid eluate was monitored at 206 nm.

GLC analysis of phospholipid. Eluate from the reverse phase column was evaporated to dryness and treated for 10 min with 2 M sodium methoxide at 50 C. The resulting fatty acid methyl esters were isolated and analyzed using a Hewlett-Packard chromatograph model 5730A as described elsewhere (11).

*Hydrolysis of 1-O-alk-1′-enyl-2-acyl-*sn*-glycero-3-phosphoethanolamine.* 1,2-Diradyl-*sn*-3-glycerophosphoethanolamine from platelets or material from individual eluate peaks obtained from HPLC was dissolved in chloroform/methanol (1:1, v/v) and dried so as to coat the inside of a 25-ml flask and then was exposed to HCl gas (1). The resulting 1-O-lyso-2-acyl-*sn*-3-glycero-phosphoethanolamine was separated from the intact 1,2-diacyl-*sn*-3-glycerophosphoethanolamine and 1-O-alkyl-2-acyl-*sn*-3-glycerophosphoethanolamine (only 3% of the total) by TLC (1). Subsequently, the lipid was eluted and compared with unhydrolyzed sample.

Following radioactive labeling and gel filtration, 1-ml samples (10^9 cells/ml) were incubated for 2 min at 37 C and time zero samples were taken. Coincidentally, thrombin was added to give a final concentration of 5 U/ml in duplicate samples for 5 min. Control samples were incubated in the absence of thrombin for the maximum time of the experiment. Samples were not stirred. Cells then were immediately added to chloroform/methanol (1:2, v/v) containing 0.01% butylated hydroxy toluene. This antioxidant also was present in all extraction and TLC solvents.

RESULTS

1,2-Diradyl GPC and GPE were isolated from cells incubated in the absence of thrombin for 5 min. In resting platelets, the [^{3}H]arachidonate radioactivity in 1-radyl-2-acyl GPC and GPE was 280,540 ± 22,580 cpm (mean ± SEM) and 81,522 ± 8,150 cpm per 10^9 cells (n = 6). This represented 54.3% and 15.8% of the total [^{3}H]arachidonate radiolabel incorporated into the cellular phospholipid. Analysis of diglyceride acetates gave the following contribution by subclasses to the total 1-radyl-2-acyl GPC: 1,2-diacyl, 93.4%; 1-alkyl-2-acyl, 5.6%; and 1-O-alk-1′-enyl-2-acyl, 1.0%. For 1-radyl-2-acyl GPE, the contribution for the same subclasses was 86.8%, 1.8% and 11.4%, respectively.

1,2-Diradyl GPC and GPE from resting human platelets radiolabeled with [^{3}H]arachidonic acid were subjected to reverse phase HPLC using the isocratic solvent system of Patton et al. (8). The elution profiles are shown in Figures 1 and 2. Figure legends describe identification of molecular species of phospholipid. The high amount of [^{3}H]arachidonate radioactivity in 1,2-diacyl GPC and GPE compared to ether lipid helped in identifying different molecular species. 1-O-alk-1′-enyl-2-acyl GPE molecular species (Fig. 2) were located by treatment of the plasmalogen with HCl gas (1).

The radioactivity in individual molecular species or separate peaks was determined for 1,2-diradyl GPC eluted from the reverse phase HPLC column. In control cells, radioactivity associated with peak 5 (18:2–20:4), peak 10 (16:0–20:4), peak 11 (18:1–20:4) and peak 20 (18:0–20:4) represented 5.9%, 8.9%, 39.4% and 37.7%, respectively, of the total radioactivity eluted from the column. As the relative contribution of 1,2-diacyl GPC to the total 1-radyl-2-acyl GPC radioactivity was known, the radioactivity contributed by a given molecular species could be determined. Such calculations were performed both for total 1-radyl-2-acyl GPC and GPE of control and thrombin-stimulated cells. Results for individual molecular species are shown in Table 1. In resting cells, 80% of the [^{3}H]arachidonate in 1,2-diacyl GPC was equally distributed between the molecular species 16:0–20:4 and 18:0–20:4 species, with the remainder being present in 18:1–20:4 and 18:2–20:4 GPC. Seventy percent of the [^{3}H]arachidonate in 1,2-diacyl GPE of resting cells was found in 18:0–20:4 GPE, with the remainder present in 18:1–20:4 and 16:0–20:4 GPE. Relatively little [^{3}H]arachidonate was observed in the three plasmalogen molecular

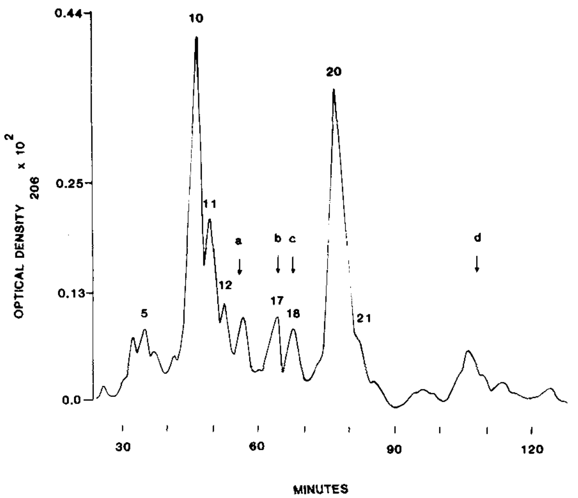

FIG. 1. Resolution of individual molecular species of 1,2-diradyl GPC by HPLC. The 1,2-diradyl GPC applied to the column was obtained from 3.3×10^8 resting platelets. Results in this and accompanying figures are representative of six separate experiments on different platelet preparations. 1,2-Diacyl molecular species are numbered according to Patton et al. (8). Letters over arrows indicate the elution position of known ether lipid standards determined by Swendsen et al. (10). Identification of 1,2-diacyl molecular species: peak 5, 18:2–20:4; 10, 16:0–20:4; 11, 16:0–18:2 (peak 11 is also coincident with 18:1–20:4, as shown in ref. 8); 12, 18:1–18:2; 17, 16:0–18:1; 18, 18:1–18:1; 20, 18:0–20:4; 21, 18:0–18:2. Identification of ether molecular species of 1,2-diradyl GPC: peak a, 16:0 alk-1′-enyl-20:4; b, 16:0 alkyl-20:4; c, 18:1 alkyl-20:4; d, 18:0 alkyl-20:4, as indicated by ref. 10.

TABLE 1

[^{3}H]Arachidonic Acid Individual Molecular Species of 1,2-Diradyl GPC and GPE in Control and Thrombin-Stimulated Human Platelets[a]

Molecular species	Control	Thrombin-stimulated
1,2-Diacyl PC		
18:2–20:4	16,770 ± 4,850	9,050 ± 3,900[b]
18:1–20:4	26,150 ± 2,510	13,430 ± 2,950[c]
16:0–20:4	114,100 ± 12,510	59,300 ± 7,820[c]
18:0–20:4	100,620 ± 13,150	53,700 ± 6,820[c]
1-O-alkyl-2-acyl GPC[d]	18,930 ± 2,330	21,550 ± 3,180[b]
1,2-Diacyl GPE		
18:1–20:4	9,060 ± 1,990	7,670 ± 2,350[b]
16:0–20:4	12,400 ± 1,910	10,290 ± 2,560[b]
18:0–20:4	49,530 ± 2,510	42,100 ± 2,100[e]
1-O-alk-1′-enyl-2-acyl GPE		
18:1–20:4	1,010 ± 350	3,330 ± 1,520[c]
16:0–20:4	3,530 ± 780	11,510 ± 1,530[c]
18:0–20:4	4,740 ± 350	15,440 ± 2,110[c]

[a]Results are expressed as mean ± S.E.M. for 10^9 platelets from three different donors.

[b]Results are not significantly different from control values.

[c]$P < 0.001$.

[d]Results are given only for the whole subclass.

[e]$P < 0.05$.

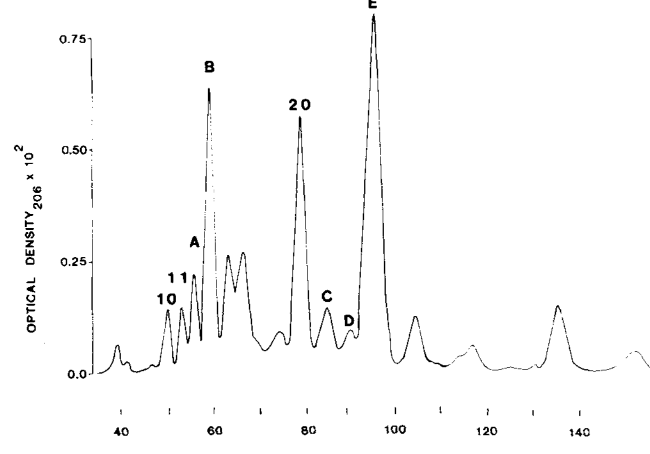

FIG. 2. Resolution of individual molecular species of platelet 1,2-diradyl GPE by HPLC. 1,2-Diradyl GPE obtained from 5×10^8 resting platelets was applied to the column. 1,2-Diacyl GPE peaks were labeled as in ref. 8. Identification of 1,2-diacyl molecular species: peak 10, 16:0–20:4; 11, 18:1–20:4; peaks between those labeled B and 20 are unidentified 1,2-diacyl molecular species; 20, 18:0–20:4. Identification of 1-O-alk-1′-enyl-2-acyl molecular species: peak A, 16:0 alk-1′-enyl-20:4; B, 18:1 alk-1′-enyl-20:4; peaks C and D not identified, E, 18:0 alk-1′-enyl-20:4.

species, alk-1′-enyl; 16:0–20:4, 18:1–20:4 and 18:0–20:4 GPE in resting platelets.

1,2-Diradyl GPC and GPE were also isolated from thrombin-stimulated cells. Following thrombin stimulation, the radioactivity in 1-radyl-2-acyl GPC decreased to 158,505 ± 16,513 (mean ± SEM, n = 6), or 56.5% of the starting value. The distribution in subclasses of 1-radyl-2-acyl GPC resolved as diglyceride acetates was 1,2-diacyl, 88.2%; 1-O-alkyl-2-acyl, 10.0%; and 1-O-alk-1′-enyl-2-acyl, 1.7%. For 1-radyl-2-acyl GPE, there was a significant increase of 15.1% in radioactivity from 81,522 ± 8,150 cpm to 93,750 ± 6,899 cpm ($p < 0.05$) after a 5-min treatment of the cells with thrombin. The distribution of radioactivity was 1,2-diacyl, 64.2%; 1-O-alkyl-2-acyl, 1.7%; and 1-O-alk-1′-enyl-2-acyl, 32.3%. In agreement with previous work, there was no change in 1,2-diradyl GPS while there was a substantial decrease in 1,2-diradyl GPI following thrombin stimulation, indicating that the response agonist included a net decrease in total [^{3}H]arachidonate content of platelet phospholipid (11,15,16).

The distribution of radioactivity in the arachidonoyl-containing molecular species of 1,2-diacyl GPC and GPE isolated from thrombin-stimulated cells and eluted by HPLC is shown in Figures 3 and 4 and Table 1. [^{3}H]-Arachidonate was decreased in all four molecular species of 1,2-diacyl GPC containing [^{3}H]arachidonate (Fig. 3 and Table 1). The 1-O-alkyl-2-arachidonoyl GPC-containing molecular species are also indicated in Figure 3 (as in Fig. 1) by small letters over arrows. The radioactivity associated with the 1-O-alkyl-2-[^{3}H]arachidonoyl molecular species of GPC (i.e., Fig. 3; b, c, d) was considerably less than that incorporated into 1-acyl-2-[^{3}H]-arachidonoyl GPC molecular species. Thrombin stimulation resulted in a very slight (not statistically significant) increase in the radioactivity of these molecular species of 1-O-alkyl-2-acyl GPC (Table 1). In thrombin-stimulated cells,

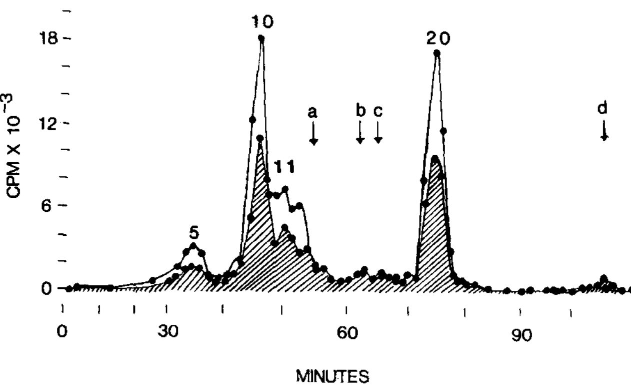

FIG. 3. Resolution of individual radiolabeled molecular species of 1,2-diradyl GPC from control or thrombin-stimulated (5 U/ml, 5 min, 37 C) platelets previously incubated for one hour at 37 C with [^{3}H]arachidonic acid. Shaded areas represent results from thrombin-stimulated platelets. Radioactivity was associated with peak 5, 18:2–20:4; 10, 16:0–20:4; 11, 18:1–20:4; and 20, 18:0–20:4. The level of incorporated [^{3}H]arachidonic acid in all these 1,2-diacyl arachidonoyl-containing molecular species is decreased by thrombin stimulation. Radioactivity in 1-O-alkyl-2-[^{3}H]arachidonoyl GPC molecular species (i.e., molecular species b, c and d of Figs. 1 and 3) is low and increases slightly following thrombin addition.

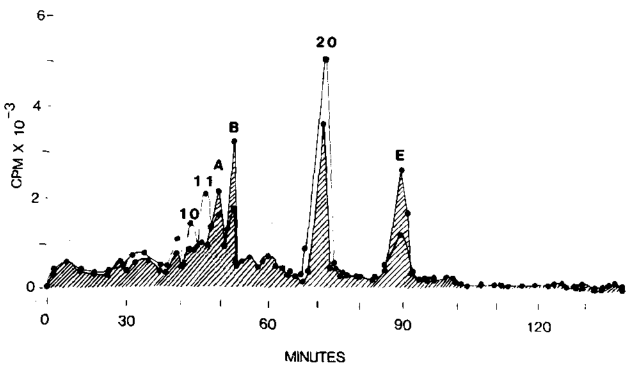

FIG. 4. Resolution of individual molecular species of 1,2-diradyl GPE from control and thrombin-stimulated (5 U/ml, 5 min 37 C) platelets previously incubated for 1 hr at 37 C with [^{3}H]arachidonic acid. Shaded areas represent thrombin results. Incorporated [^{3}H]arachidonoyl radioactivity was found in peaks 10, 11 and 20 (1,2-diacyl GPE); and A, B, and E (1-O-alk-1′-enyl-acyl GPE). There was a decrease in the radioactivity of peaks 10, 11 and 20 and a considerable increase in that of peaks A, B and E following thrombin stimulation.

the [^{3}H]arachidonate was decreased in 1,2-diacyl GPE arachidonoyl-containing molecular species (Fig. 4 and Table 1). The low level of radioactivity observed in 1-O-alk-1′-enyl GPE molecular species was increased over 300% following thrombin stimulation (Table 1 and Fig. 4).

In double labeling experiments using [^{14}C]arachidonic acid and [^{3}H]linoleic acid, the arachidonic acid was found to be incorporated into the same 1,2-diradyl GPC molecular species as seen previously (Figs. 1 and 3). [^{3}H]Linoleoyl radioactivity was found in peaks 5, 11, 12 and 21, which are the main linoleoyl-containing species of platelet 1,2-diacyl GPC, i.e., peak 5, 18:2–20:4; peak 11, 16:0–18:2; peak 12, 18:1–18:2; and peak 21, 18:0–18:2 GPC, respectively. Following thrombin addition, significant decreases were only found in the molecular species containing [^{3}H]arachidonate, as shown previously (data not shown). No significant incorporation of [^{3}H]linoleic acid into platelet 1,2-diradyl GPE was seen, in keeping with the low linoleic acid content of this phospholipid (1,2,5).

DISCUSSION

Liberation of arachidonic acid from its *sn*-2 linkage in membrane phospholipids is a necessary first step toward the production of thromboxane A_2 and lipoxygenase products in thrombin-stimulated human platelets (15,16). Previous workers have indicated that 1,2-diradyl GPI (11,17–19), 1,2-diradyl GPC (15,16,20) and 1,2-diradyl GPE (3,21) may all be considered potential sources of the arachidonic acid released for eicosanoid production.

Reverse phase HPLC was used in this study to resolve individual molecular species of phospholipid; it was effective in separating the various arachidonoyl-containing components. The incorporation of [^{3}H]arachidonic acid was highest in the 1,2-diacyl molecular species of both 1,2-diradyl GPC and 1,2-diradyl GPE. This agrees with previous results for human platelets (14) and, given the high radioactivity in 1,2-diacyl GPC and GPE molecular species, the identification of highly labeled molecular species was simplified. In general, the amount of incorporation was proportional to the mass of the molecular species within a given subclass, and these same phospholipids were those most rapidly deacylated after stimulation with thrombin. Ether phospholipids incorporated considerably less of the label in resting platelets, and the level of [^{3}H]arachidonate either increased slightly (1-O-alkyl-2-[^{3}H]arachidonoyl GPC; Fig. 3) or significantly (1-O-alk-1′-enyl-2-[^{3}H]arachidonoyl GPE; Fig. 4 and Table 1) following thrombin stimulation.

Previously we suggested that 1-O-alkyl-2-arachidonoyl GPC might be an important contributor of arachidonic acid in thrombin-stimulated cells (1). This had been shown for ionophore A23187-stimulated neutrophils (10). In view of the high specific activity of [^{3}H]arachidonate released by thrombin-stimulated platelets (22), the low acylation/deacylation of [^{3}Harachidonate in 1-O-alkyl-2-arachidonoyl GPC in resting or stimulated cells shown here and elsewhere (14) suggests that this ether lipid is not a significant source of arachidonic acid after addition of thrombin. Other workers have also demonstrated in other cells (23,24) and platelets (25,26) a more rapid uptake of arachidonic acid into 1,2-diacyl GPC and GPE compared to their ether subclasses. Ionophore-stimulated cells have shown a considerable decrease in 1-O-alkyl-2-[^{3}H]arachidonoyl GPC, and we have demonstrated the same for human platelets (14). However, there is no such decrease in thrombin-stimulated human platelets (14, and this work), although substantial deacylation of 1-O-alkyl-2-[^{3}H]arachidonoyl GPC does occur in thrombin-stimulated rabbit platelets (26).

The exact contribution of 1-O-alkyl-2-arachidonoyl GPC to the free arachidonate pool will be known only when mass changes in 1-O-alkyl-2-arachidonoyl GPC due to thrombin stimulation have been determined. 1-Acyl-2-arachidonoyl-*sn*-glycero-3-phosphoinositol is a minor contributor (15%) to the 30 nmol of arachidonic acid released from 10^9 thrombin-stimulated human platelets (11,27). In addition, only picomole levels of

platelet activating factor are generated by the same number of stimulated cells (28,29). Thus, we conclude that the pathway for the production of platelet activating factor, which involves deacylation of 1-O-alkyl-2-acyl GPC followed by acetylation, is not a significant source of arachidonic acid in human platelets (14). On the other hand, 1,2-diacyl molecular species of GPC and GPE appear crucial with respect to the release of arachidonic acid. Deacylation of the various molecular species of 1,2-diradyl GPC and GPE appears related to the rate of uptake in the resting cell and occurs most markedly in 1,2-diacyl phospholipids. Thus, 1-palmitoyl-2-arachidonoyl GPC, 1-steroyl-2-arachidonoyl GPC and 1-stearoyl-2-arachidonoyl GPE are the main molecular species involved in acylation with [^{3}H]arachidonic acid in resting cells, as well as deacylation in stimulated cells. The lack of deacylation in those molecular species of 1,2-diacyl GPC radiolabeled with linoleic acid but not [^{14}C]arachidonic acid argues for selectivity in the deacylation of arachidonoyl vs non-arachidonoyl-containing molecular species of 1,2-diacyl GPC.

In this study we found that the slight increase in total GPE radioactivity after 5 min of thrombin stimulation was due to an increase in 16:0, 18:1 and 18:0 alk-1′-enyl-2-[^{3}H]arachidonoyl GPE. Thus, the small increase in 1,2-diradyl GPE radioactivity represented a small decrease of radioactivity in 1,2-diacyl GPE (particularly 1-stearoyl-2-[^{3}H]arachidonoyl PE) and a greater increase in plasmalogen structures. Transacylation between 1,2-diacyl GPC and plasmalogen GPE of human platelets has been reported previously (30,31). The considerable increase in the radioactivity of 1-O-alk-1′-enyl-2-acyl GPE indicates that this ether phospholipid may also be a significant source of arachidonate.

It was not possible in this study to determine exact mass changes in individual molecular species of platelet phospholipid following addition of thrombin. A decrease in the optical density at 206 nm for 18:2-20:4 (peak 5), 16:0-20:4 (peak 10), 18:1-20:4 (peak 11) and 18:0-20:4 (peak 20) GPC was observed, while changes in other molecular species were not apparent. However, it is difficult to determine mass changes when one monitors unsaturation at 206 nm.

In summary, our work indicates arachidonoyl-containing molecular species of 1,2-diacyl GPC and GPE are the main source of [^{3}H]arachidonic acid liberated in thrombin-stimulated platelets, particularly compared to 1-O-alkyl-2-arachidonoyl GPC and probably 1-O-alk-1′-enyl-2-arachidonoyl GPE. The main action of endogenous acyl hydrolase is on the two main 1-acyl-2-arachidonoyl molecular species of GPC as well as on 1-stearoyl-2-arachidonoyl GPE. Transacylation involves mainly three molecular species, 16:0, 18:1, and 18:0 alk-1′-enyl-2-[^{3}H]arachidonoyl PE.

[Revision received October 9, 1986]

Oleic Acid Modulates the Partitioning of Cholesterol from Micellar Bile Salt Solution

Kazuo Chijiiwa
Department of Surgery 1, Faculty of Medicine, Kyushu University, Fukuoka 812, Japan

The effects of monounsaturated fatty acid (oleic acid) on cholesterol monomer activity and on the rate of cholesterol influx were studied in vitro. A polyethylene disc method was employed to determine cholesterol monomer activity in constant sodium taurocholate-cholesterol micellar solution containing different oleic acid concentration levels at pH 5.5, 6.5 and 7.2. In addition, the effect of oleic acid on the rates of cholesterol influx was determined using an everted rat jejunal sac technique.

At pH 5.5, increased oleic acid concentration from 5 to 10 mM resulted in significant decreased apparent cholesterol monomer activity (3.8 ± 0.21 nmol/disc vs 1.0 ± 0.08, $P < 0.001$). At pH 6.5, apparent cholesterol monomer activity was 2.3 ± 0.19 nmol/disc at 5 mM and 0.5 ± 0.09 at 16 mM oleic acid level ($P < 0.001$). Apparent monomer activity of cholesterol in micellar solutions at pH 7.2 used for the influx study at 5 and 15 mM oleic acid concentration level was 1.8 ± 0.14 and 0.7 ± 0.08 nmol/disc, respectively ($P < 0.001$). Thus there was a significant decrease in cholesterol monomer activity by the addition of oleic acid at each pH. The rate of cholesterol influx across the brush border membrane of the rat jejunum at 5 and 15 mM oleic acid concentration level was 3.2 ± 0.31 and 1.5 ± 0.21 nmol/100 mg dry weight tissues/min, respectively ($P < 0.001$).

It is concluded that the addition of oleic acid decreases both monomer activity and the rate of influx of cholesterol from micellar solution. This effect is primarily attributable to the inhibition of the release of cholesterol monomers from the mixed micelle.
Lipids 22, 121–124 (1987).

Despite the fact that the partitioning of cholesterol from micellar bile salt solution is modulated by the micellar constituents (1–5) and pH (6), little study has been done on the role of fatty acids in the physiology of cholesterol in micellar solution. Hollander and Morgan (3) showed that both oleic acid and lecithin inhibited cholesterol absorption in the rat in vivo. On the other hand, Thomson and Cleland (4) demonstrated that palmitic acid increased and inhibited cholesterol uptake in vitro when lecithin was absent and present, respectively. Thus, the effect of fatty acids on the physiology of cholesterol in micellar bile salt solution is still contradictory.

Since free fatty acids are present in bile (7) and in the intestinal bulk phase following lipolysis (8), it is important to evaluate the effect of fatty acids on the partitioning of cholesterol out of the micelle.

Accordingly, the aim of this study was to examine the effect of oleic acid, one of the predominant monounsaturated fatty acids, on the partitioning of cholesterol from micellar solutions at various physiological pH (pH 5.5, 6.5 and 7.2). In addition, the effect of oleic acid on the rate of influx of cholesterol across the brush border membrane was studied using the everted rat jejunal sac technique in vitro.

MATERIALS AND METHODS

Experimental design. Experiments were designed for two purposes. First, the effect of oleic acid on cholesterol monomer activity in 30 mM sodium taurocholate-0.1 mM cholesterol micellar solution was studied at pH 5.5 and 6.5. Polyethylene disc technique was used to determine the partitioning of cholesterol from micellar solution into the disc (apparent monomer activity). Second, the rates of influx of cholesterol from a similar micellar solution with 5 or 15 mM oleic acid concentration level, pH 7.2, were investigated to confirm the altering effect of oleic acid on the influx through the brush border membrane and compared the relationship between apparent monomer activity and the rate of influx of cholesterol. The rate of cholesterol influx was determined using an everted rat jejunal sac method in vitro.

Chemicals. Sodium taurocholate (NaTC) was purchased from ICN (K and K Laboratories, Plainview, New York). Oleic acid was obtained from Nu-Chek-Prep (Elysian, Minnesota) and cholesterol from Fisher Scientific (Springfield, New Jersey). [1,2-^{3}H]Cholesterol, 53.0 Ci/mol, was purchased from New England Nuclear (Boston, Massachusetts). All were >98% pure as judged by thin layer chromatography and were used without further purification. ^{14}C-Polyethylene glycol (PEG; MW 4,000; sp act 34.7 mCi/mmol) was obtained from Amersham (Arlington Heights, Illinois) and was used as supplied by the manufacturer. All other reagents were of analytical grade.

Micellar solutions. Three kinds of micellar sodium taurocholate solutions were prepared: a) 30 mM NaTC, 0.1 mM ^{3}H-cholesterol (sp act 1 μCi/μmol) and 5 or 10 mM oleic acid, final pH 5.5; b) 30 mM NaTC, 0.1 mM ^{3}H-cholesterol and 5 or 16 mM oleic acid in lactated Ringer having the composition 130 mEq/l Na^+, 4 mEq/l K^+, 3 mEq/l Ca^{++}, 109 mEq/l Cl^-, 28 mEq/l lactate$^-$, final pH 6.5. Ten and 16 mM oleic acid concentrations used were close to the maximal micellar solubility at each pH level (6); c) 30 mM NaTC, 0.1 mM ^{3}H-cholesterol and 5 or 15 mM oleic acid were prepared in 0.02 M phosphate buffer, pH 7.2, with 0.12 M NaCl. Since the fatty acid is present in the upper small intestine under these physiological conditions, the current experiments do not provide a fatty acid-free solution.

Apparent cholesterol monomer activity. The partitioning of cholesterol from the various micellar solutions described above was determined as previously reported (6) based on the method of Sallee (9). Briefly, polyethylene discs, 0.6 cm in diameter punched out from polyethylene film 0.006 inches thick, were a gift from Verney L. Sallee (Alcon Laboratories, Fort Worth, Texas). The discs were washed with methanol and distilled water and were dried before use. Partitioning of cholesterol into polyethylene discs from micellar solutions was determined after equilibration for 24 hr. Each disc was placed in 3 ml micellar solution in a 25 mm × 100 mm screw-capped tube and incubated at 37 C in a Dubnoff incubator at 100

oscillations/min. After an equilibration period, the disc was removed and rinsed thoroughly in the distilled water. The polyethylene disc was placed in the scintillation vial and 0.5 ml of distilled water was added; 0.5 ml of the original micellar solution was used to determine the specific activity of cholesterol. Discs and micellar solutions were counted simultaneously following the addition of 13 ml scintillation solution and partitioning of cholesterol into the disc was expressed as nmol/disc.

Effect of oleic acid on the rate of cholesterol influx. Male Wistar rats, 180–200 g, were fasted overnight and killed by decapitation. A section of proximal jejunum (ca. 25 cm from Lig. Treitz) was removed immediately and rinsed with ice-cold physiological saline. The intestine was everted immediately over a glass rod and gently filled with cold 0.02 M phosphate buffer, pH 7.2, with 0.12 M NaCl (0.5 ml/2.5 cm gut). Sacs, 2.5 cm long, were prepared by cutting double ligatures and were rinsed immediately with cold 0.02 M phosphate buffer with 0.12 M NaCl. The sacs were randomized and each was immersed in oxygenated micellar solution in an Erlenmyer flask. All flasks were gassed with 95% O_2 5% CO_2 and incubated at 37 C in a Dubnoff metabolic shaking incubator at 100 oscillations/min for 4 min. The incubation medium consisted of 10 ml of a bile salt micellar solution that contained 300 μmol of sodium taurocholate, 50 or 150 μmol of oleic acid and 1 μmol of ^{3}H-cholesterol with a tracer amount of ^{14}C labeled PEG (0.5 μCi/10 ml). At the end of the incubation period, sacs were removed and rinsed vigorously for 20 sec in iced 0.02 M phosphate buffer, pH 7.2, with 0.12 M NaCl and placed on moistened filter paper. The ends of the sacs were transected and the central cylinder of the intestine was dried overnight in an oven at 60 C. Part of the sac was preserved in buffered 10% formalin for histological examination. Dried sacs were weighed, placed in glass scintillation vials and dissolved in 0.5 ml of 1 N NaOH in an oven at 120 C for 30 min. After neutralization with 0.5 ml 1 N HCl, 13 ml scintillation solution (phase-combining system, New England Nuclear) was added to determine the radioactivity.

Preliminary validation experiments demonstrated that the water-soluble nonabsorbable marker (PEG) was homogeneously distributed in the adherent mucosal fluid layer after a 4-min incubation period and constant thereafter. Cholesterol influx (nmol/100 mg dry wt) was a linear function of the incubation time for at least the 4-min incubation period, and the intercept of the linear regression curve was nearly zero at 0 time for both high and low concentration of oleic acid. The cholesterol taken up by the tissue was not esterified during a 4-min incubation period. Accordingly, a 4-min incubation period was selected in the present study. The rate of cholesterol influx was calculated without correction for adherent mucosal fluid volume (10). Since the concentration of cholesterol in the adherent mucosal fluid layer was extremely low as the result of continuous uptake by the tissue, the correction was not necessary under the present experimental condition. The values were expressed as nmol/100 mg dry wt/min.

Effect of oleic acid on cholesterol solubility. In the fundamental study, 30 mM sodium taurocholate, an excess amount of cholesterol (3 mM) and 0, 5, 10 and 15 mM oleic acid were mixed in 0.02 M phosphate buffer, pH 7.2, with 0.12 M NaCl solution and incubated at 37 C for more than three days. These solutions were filtered through a sterile 0.2-μm filter (Nihon Millipore, Tokyo, Japan) and 0.5 ml of the filtrate was placed in a 10-ml volumetric flask. Coprostanol was added as an internal standard and filled up to 10 ml with methanol; 0.5 ml of this solution was evaporated, and trimethylsilyl (TMS) ether derivatization was made and subjected to gas liquid chromatography (Shimadzu Seisakusho, Kyoto, Japan) equipped with a Van den Berg's solventless injector, WCOT column, 25 m × 0.35 mm id, coated with SE-30 (LKB-Produktor, Stockholm, Sweden) and flame ionization detector. The temperature of the column and injection port was 280 C and 310 C, respectively, and the flow rate of helium carrier gas was 2 ml/min. Cholesterol was quantified by calculating a peak area ratio to internal standard.

Determination of radioactivity. Radioactivity was counted in a Beckman M52 scintillation counter and determined by means of an external standardization technique to correct for variable quenching of the two isotopes.

Statistics. Values were mean ± SEM for at least six observations. Student's t-test was used, and p values less than 0.05 were considered to be significant.

RESULTS

Apparent cholesterol monomer activity. Apparent cholesterol monomer activity in micellar solutions at pH 5.5 and 6.5 is depicted in Figure 1. Polyethylene discs were equilibrated after a 24-hr incubation period. The higher the cholesterol monomer activity after the equilibration period, the higher the monomer activity throughout the incubation period. Apparent cholesterol monomer activity in micellar solutions after equilibration is shown in Figure 2. Apparent cholesterol monomer activity in the constant micellar solution (30 mM NaTC, 5 mM oleic acid and 0.1 mM cholesterol) was significantly higher at pH

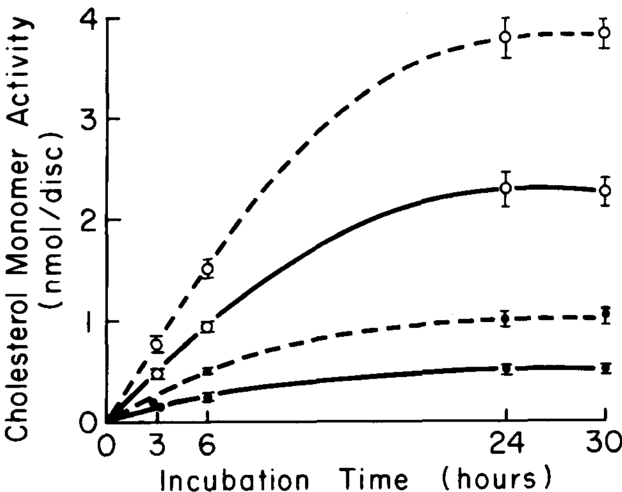

FIG. 1. Effect of oleic acid and pH on apparent cholesterol monomer activity in micellar solutions during various incubation periods. ○, Cholesterol monomer activity in 30 mM NaTC, 5 mM oleic acid and 0.1 mM cholesterol mixed micellar solution. ●, Monomer activities of cholesterol in similar micellar solutions except for oleic acid concentrations (10 mM at pH 5.5 and 16 mM at pH 6.5). – – –, pH 5.5; ——, pH 6.5. Values are mean ± SEM of 6 observations.

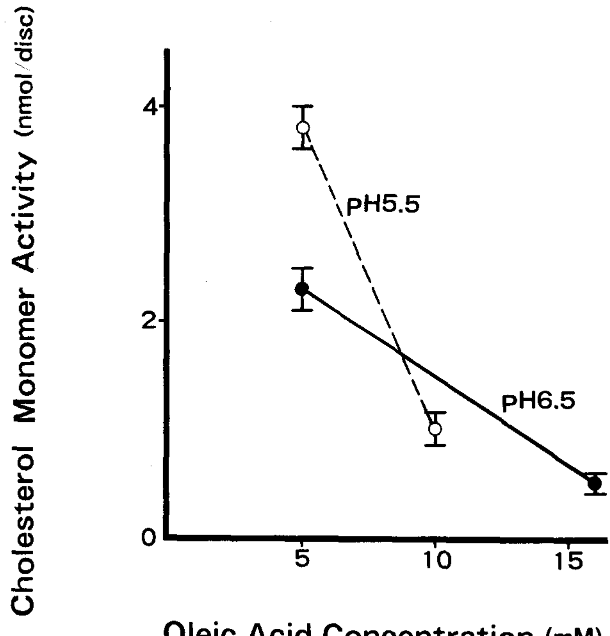

FIG. 2. Effect of oleic acid on apparent cholesterol monomer activity in micellar solution. Micellar solutions contained 30 mM NaTC, 0.1 mM cholesterol and oleic acid below its maximal micellar solubility at pH 5.5 and pH 6.5. ○, Apparent cholesterol monomer activity in micellar solutions with 5 mM and 10 mM oleic acid at pH 5.5 (– – –); ●, apparent cholesterol monomer activity at 5 and 16 mM oleic acid at pH 6.5 (——). Values represent mean ± SEM (n = 6).

5.5 than at pH 6.5 (3.8 ± 0.21 vs 2.3 ± 0.19 nmol/disc, $p < 0.001$), which confirmed our previous observations (6). Next, only oleic acid concentration was increased close to its saturation point at each pH level. At each pH, the higher the oleic acid concentration, the lower the monomer activity of cholesterol. At pH 5.5, increased oleic acid concentration from 5 to 10 mM decreased apparent cholesterol monomer activity from 3.8 ± 0.21 to 1.0 ± 0.08 nmol/disc ($p < 0.001$). Similarly, at pH 6.5, elevating oleic acid concentration decreased apparent cholesterol monomer activity significantly (2.3 ± 0.19 nmol/disc at 5 mM oleic acid and 0.5 ± 0.09 at 16 mM oleic acid concentration, $p < 0.001$). These results indicate that cholesterol monomer activity declines with increasing oleic acid concentration at constant cholesterol concentration level (Fig. 2).

In the second experimental series, apparent cholesterol monomer activity was determined in micellar solutions (30 mM NaTC, 0.1 mM ^{3}H-cholesterol with 5 or 15 mM oleic acid, pH 7.2) used for the following influx study to confirm the effect of oleic acid on apparent cholesterol monomer activity and on the rate of cholesterol influx. Apparent cholesterol monomer activity was 1.8 ± 0.14 nmol/disc at 5 mM oleic acid level and 0.7 ± 0.08 at 15 mM oleic acid level, respectively ($p < 0.001$). Again, the apparent monomer activity of cholesterol was significantly lower at the higher oleic acid concentration level.

Rate of cholesterol influx. The rates of cholesterol influx across the brush border membrane of rat jejunal sac exposed to the 30 mM NaTC-0.1 mM cholesterol micellar solution with 15 mM and 5 mM oleic acid were 1.5 ± 0.21 and 3.2 ± 0.31 nmol/100 mg dry weight tissue/min, respectively (Fig. 3). There was a significant difference ($p < 0.001$) and the rate of influx was higher at 5 mM oleic acid concentration level than at 15 mM oleic acid concentration. Histological examination following the exposure to the micellar solution showed no damage to the mucosa.

Effect of oleic acid on cholesterol solubility. Increased oleic acid concentration resulted in higher cholesterol solubility (Fig. 4); 0.2 ± 0.03 mM (SEM) cholesterol was solubilized in 30 mM NaTC solution without oleic acid. The cholesterol solubility was 0.5 ± 0.06 mM, 1.4 ± 0.19 mM and 2.6 ± 0.22 mM in micellar solutions containing 5, 10 and 15 mM oleic acid, respectively.

DISCUSSION

Cholesterol is passively taken up by the enterocyte as monomers in the intermicellar aqueous phase in equilibrium with micellar aggregate (11,12). Cholesterol monomer in the intermicellar aqueous phase is governed by its partition coefficient between aqueous phase and micellar aggregate.

This partition coefficient mainly depends on the constituents of the micelle. Phospholipid inhibits the uptake and the partitioning of cholesterol from micellar solution (1-3). The effect of fatty acid on the uptake of cholesterol by the enterocyte has been studied, and contrary results were reported. Thomson and Cleland (4) reported that palmitic acid enhances the uptake of cholesterol. On the other hand, Hollander and Morgan (3) demonstrated that oleic acid decreases cholesterol absorption.

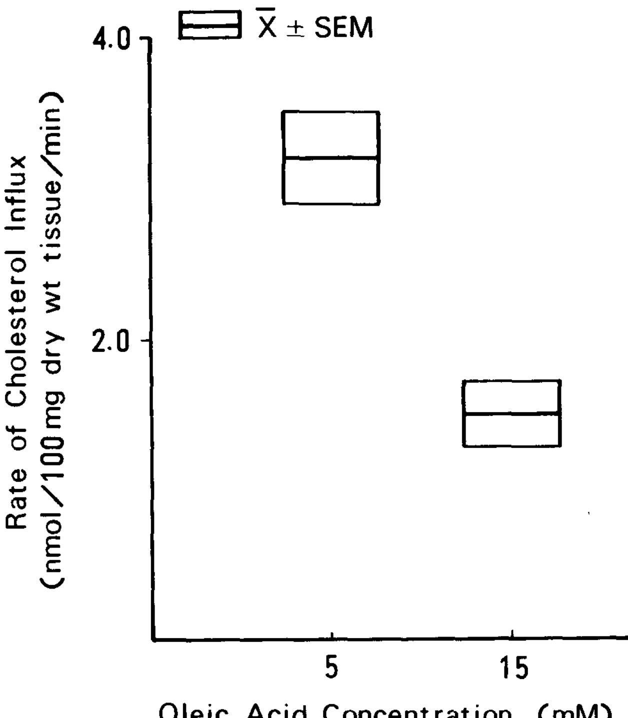

FIG. 3. Effect of oleic acid on the rate of cholesterol influx across the brush border membrane of everted rat jejunum in vitro. Everted sacs were exposed to micellar solution containing 30 mM NaTC, 0.1 mM cholesterol with 5 or 15 mM oleic acid at pH 7.2 and were incubated for 4 min.

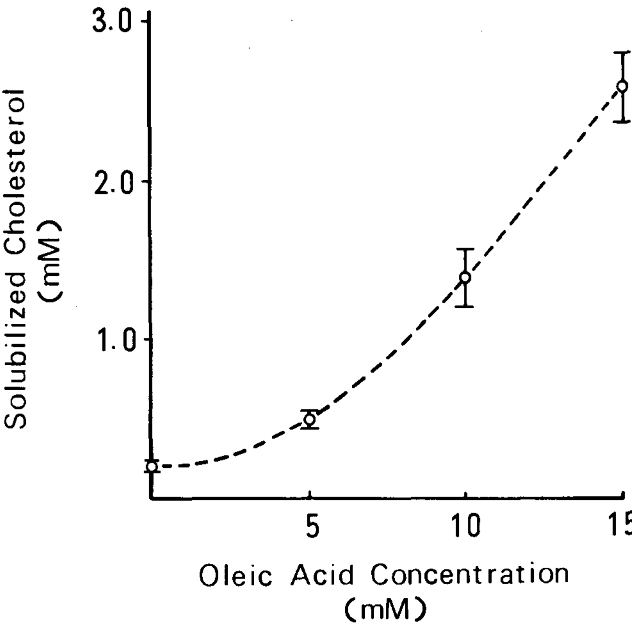

FIG. 4. Effect of oleic acid on maximal micellar solubility of cholesterol. Excess amounts of cholesterol were dissolved in 30 mM NaTC with 0, 5, 10 and 15 mM oleic acid at pH 7.2. Solutions were mixed well and incubated at 37 C for more than 3 days to reach equilibrium. Clear filtrate through the membrane (0.2 μm) was subjected to gas liquid chromatography. Values are mean ± SEM.

In the present study, two factors (micellar solubility and the size of the micelle) are possibly modulated by the presence of oleic acid. First, the addition of oleic acid enhanced the micellar solubility of cholesterol, as shown in the present experiment. In the additional study, the addition of small amount of oleic acid below 5 mM concentration level had no significant effect on the partitioning of cholesterol from micellar solutions. Increased micellar solubility by the addition of phospholipid (1) and by elevating the pH (6) resulted in lower monomer activities of fatty acids and cholesterol. The present study revealed the evidence that increased micellar solubility of cholesterol by the addition of oleic acid results in decreased apparent cholesterol monomer activity (partitioning of cholesterol) (Figs. 1 and 2). Apparent cholesterol monomer activity in the micellar solution at a constant cholesterol concentration level mainly depends on its partition coefficient between aqueous phase and micellar aggregate, which regulates cholesterol monomer concentration in the intermicellar aqueous phase. The lower monomer activity at the higher oleic acid concentration presumably can be ascribed to the lower partition coefficient by forming the mixed micelle, which can incorporate much more cholesterol inside the micelle. Thus, the addition of oleic acid in the sodium taurocholate-cholesterol micellar solution shifts cholesterol monomers away from aqueous phase to micellar aggregates.

Another possible factor is the size of the micelle. The addition of oleic acid increases the size of the micelle (13). Expanded micelles diffuse toward the brush border membrane at a slower rate, which declines the rate of cholesterol influx.

The current study was focused on the role of monounsaturated fatty acid (oleic acid) in the partitioning phenomenon of cholesterol in the micellar solutions. Increased oleic acid concentration levels resulted in the decreased apparent cholesterol monomer activity, which positively correlated with the rate of cholesterol influx across the brush border membrane in vitro. The overall effect of oleic acid on cholesterol absorption in vivo should be examined further, since fatty acids are efficiently absorbed (12) and affect the esterification and enhance the transport of cholesterol (5,14,15). The results support the observations by Hollander and Morgan (3), but are opposite to the report by Thomson and Cleland (4). This might be due to the difference in fatty acids, because Thomson and Cleland used palmitic acid. Study of the effect of fatty acid type on the partitioning of cholesterol out of micelle is in progress. Of particular interest is the modulating effect of free fatty acids on the partitioning of cholesterol from micellar solutions into the organic phase (polyethylene disc). Since free fatty acids are present in bile (7) and gallstone (16), the role of free fatty acids in the pathogenesis of gallstone might be deducible.

It is concluded from this study that the lowering effect of monounsaturated fatty acid (oleic acid) on the partitioning and rate of influx of cholesterol from micellar bile salt solution in vitro is mainly mediated by its enhanced micellar holding capacity for cholesterol, which would shift cholesterol monomers from aqueous phase to mixed micelles.

METHODS

Electrochemical Detection of Phospholipid Hydroperoxides in Reverse-Phase High Performance Liquid Chromatography

K. Yamada, J. Terao and S. Matsushita
Research Institute for Food Science, Kyoto University, Uji, Kyoto, Japan 611

Hydroperoxy derivatives of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) can be separated from their respective phospholipids by reverse-phase high performance liquid chromatography (HPLC). However, ultraviolet absorption due to conjugated diene cannot detect the hydroperoxy group. In this work, an electrochemical (EC) detector was first applied to the analysis of hydroperoxy phospholipids. Both the PC and PE hydroperoxides from rat liver were reduced quantitatively by the glassy carbon electrode at −300 mV vs Ag/AgCl. Since neither the hydroxy derivatives nor unoxidized phospholipids showed any response, it would seem this technique can be used to distinguish phospholipid hydroperoxides from their hydroxy derivatives. Thus, the reverse phase HPLC-EC detection method is proposed for the specific analysis of hydroperoxy phospholipids in biological tissues.
Lipids 22, 125–128 (1987).

In recent years, lipid peroxidation has attracted much interest in relation to the aging process, cancer development and other pathological conditions. To measure lipid hydroperoxides, the primary products of lipid peroxidation in the biological system, sensitive methods have been developed which use fluorescence (1), chemiluminescence (2,3), peroxidase (4,5) and cyclooxygenase activity (6).

Membrane phospholipids including phosphatidylcholine (PC) and phosphatidylethanolamine (PE) are assumed to be the main species responsible for hydroperoxide formation during lipid peroxidation in vivo. PC hydroperoxides can be separated from unoxidized PC by reverse-phase high performance liquid chromatography (HPLC) (7–10). Thus, reverse-phase HPLC seems to be useful as a direct method for determining lipid hydroperoxides. Previously, we succeeded in separating the PC and PE hydroperoxides of rat liver from their respective phospholipids by reverse-phase HPLC and applied the technique to measure the phospholipid peroxidation products of rat liver after carbon tetrachloride administration (11). However, we found it difficult to distinguish phospholipid hydroperoxides from their hydroxy derivatives on the chromatogram because the detection was based on UV absorption due to conjugated diene structure. A method that would specifically detect the hydroperoxy group was required in order to use the HPLC technique for the measurement of lipid hydroperoxides. Moreover, it may be essential to distinguish phospholipid hydroperoxides from the hydroxy derivatives because enzymatic reduction of PC hydroperoxides is implied in the cellular defense system against lipid peroxidation (12).

We previously conducted a polarographic study of triacylglycerol hydroperoxides and obtained polarographic reducing waves under a dropping mercury electrode (13,14). An electrochemical (EC) detector equipped with a glassy carbon electrode has recently been developed, a significant improvement since Kissinger et al. (15) first proposed combining HPLC with the EC detector. Therefore, we investigated the effectiveness of the HPLC-EC detector in detecting phospholipid hydroperoxides.

Results showed that phospholipid hydroperoxides could be detected quantitatively by the EC detector, while there was no response from the hydroxy derivatives and unoxidized phospholipids. Compared with the UV detector for phospholipid hydroperoxides, the EC detector seems to have a higher sensitivity.

EXPERIMENTAL

Materials. Male Wistar rats, 8 wk old, were used. Rats were anesthetized, and whole livers were removed and washed with normal saline and then kept at −80 C prior to lipid extraction. PC and PE were obtained from the liver lipid fraction according to the method described previously (16). Hydroperoxy and hydroxy derivatives of rat liver PC and PE were prepared from their respective photosensitized oxidation products by the procedure described previously (16). Hydroperoxy derivatives of egg yolk PC were obtained by the same method used for rat liver PC.

The amount of the sample used in the experiments was obtained by successive dilution of the original weighed sample.

Apparatus. A Shimadzu liquid chromatograph LC-4A with a YMC A-212-C-8 column (6 × 150 mm, 5 μm particle size; Yamamura Kagaku Co., Kyoto, Japan) was used for HPLC analysis. A Shimadzu SPD-2A variable-wavelength UV detector and an Irica E-502 amperometric detector (Irica Co., Kyoto, Japan), which contains a glassy carbon electrode, were used as the UV and EC detectors, respectively. The EC detector was connected in series behind the UV detector. The chromatograms were recorded by a Shimadzu Chromatopack C-R1B or C-R3A processor. The glassy carbon electrode was washed and polished after a run of ca. 40 hr. Before the analysis, a 2-hr run was necessary to stabilize the electrode.

Reverse-phase HPLC. The sample was dissolved in a mixture of methanol and chloroform (93:7, v/v), and 150 μl was injected into the HPLC column. The column was eluted with methanol/water/acetonitrile (90.5:7:2.5, v/v/v) containing 0.25 mM sodium perchlorate. The flow rate was kept at 1.8 ml/min. The eluent was monitored at 235 nm for UV detection and −300 mV vs Ag/AgCl for EC detection.

The mobile phase was kept free from oxygen by continuous bubbling through helium gas. No attempt was made to remove oxygen from the sample solution.

RESULTS

Figure 1 shows typical chromatograms of egg yolk PC hydroperoxides obtained by the UV and EC detectors.

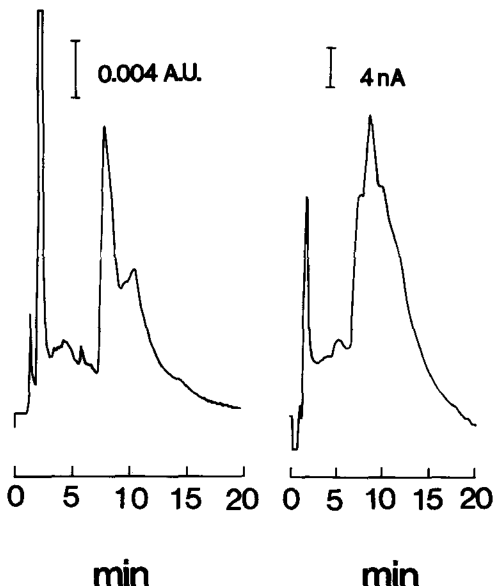

FIG. 1. Chromatograms of phosphatidylcholine hydroperoxides obtained by UV (A) and EC detection (B). The amount of PC hydroperoxides applied on the column was 50 nmol. The elution solvent contained 0.25 mM sodium perchlorate. Applied electrode potential was −400 mV vs Ag/AgCl. Wavelength of UV detector was adjusted at 235 nm.

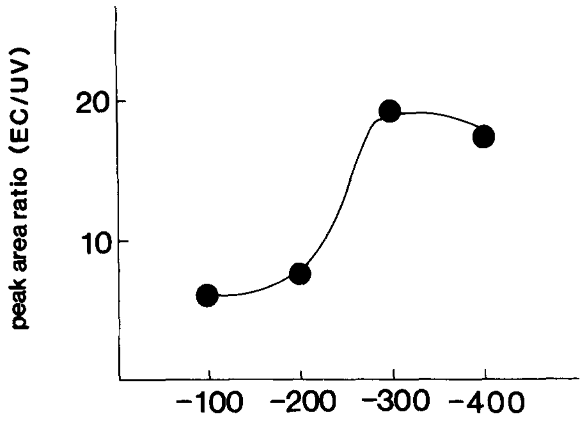

FIG. 2. Electric current-electrode potential curve. Experimental conditions were the same as those for Fig. 1, except the amount of phosphatidylcholine hydroperoxides applied on the column was 70 nmol and applied electrode potentials were changed. The electric current was represented as the ratio of the peak area obtained by EC detection against that obtained by UV detection at 235 nm.

In both chromatograms, the hydroperoxides appeared as overlapping peaks at a retention time of ∿7–10 min.

The ratio of the peak area obtained by EC detector to that obtained by UV detector was calculated at differing electrode potentials ranging from −100 to −400 mV vs Ag/AgCl, as shown in Figure 2. The EC detector was found to be the most sensitive at a potential of −300 mV vs Ag/AgCl in the above range. Figure 3 shows the effect of sodium perchlorate concentration on the sensitivity of

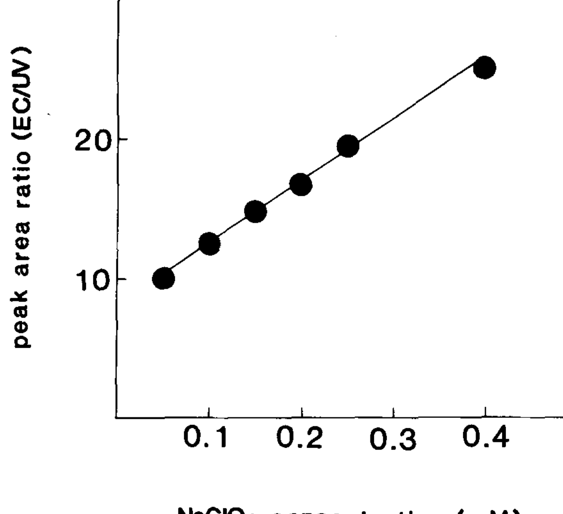

FIG. 3. Effect of concentration of supporting electrolyte on the sensitivity of EC detector. The experimental conditions were the same as those for Fig. 1, except the amount of phosphatidylcholine hydroperoxides applied was 70 nmol and the salt concentrations of the elution solvent were changed.

the EC detector. Sensitivity increased linearly with the increase in salt concentration. However, the higher concentration was found to generate large noises because the salt adhered to the surface of the electrode, and sudden lowering of the sensitivity in shorter periods resulted.

From the results of Figures 2 and 3, −300 mV vs Ag/AgCl and 0.25 mM were selected as the electrode potential and the supporting electrolyte concentration for the following experiments.

Under these analytical conditions, PC hydroperoxides of rat liver gave prominent peaks on the chromatogram monitored by the EC detector, similar to that of the UV detector (Fig. 4). Hydroxy derivatives of rat liver PC were eluted at almost the same position as the hydroperoxy derivatives. However, there were no peaks for the hydroxy derivatives on the chromatogram monitored by the EC detector. Unoxidized PC was eluted later than the hydroperoxy and hydroxy derivatives, as indicated on the chromatogram by the UV detector based on nonspecific end absorption (203 nm). Unoxidized PC was not detected by EC detection.

Similar results were obtained from rat liver PE and its hydroperoxy and hydroxy derivatives, but only the hydroperoxy derivatives gave prominent peaks on the chromatogram obtained by the EC detector (Fig. 5).

For both rat liver PC and PE, a linear relationship was observed between the amounts of their hydroperoxides and the peak areas in the chromatograms obtained by EC and UV detections in the range from 1 to 25 nmol (Figs. 6 and 7) (correlation coefficient: 0.990 for PC hydroperoxides by EC detection, 0.999 for PC hydroperoxides by UV detection, 0.823 for PE hydroperoxides by EC detection, 0.980 for PE hydroperoxides by UV detection). The slope of the regression lines indicates that the sensitivity of EC detection is more than 10 times higher than that of the UV detection for both phospholipid hydroperoxides. Conjugated diene isomers occupied more than 70% of the

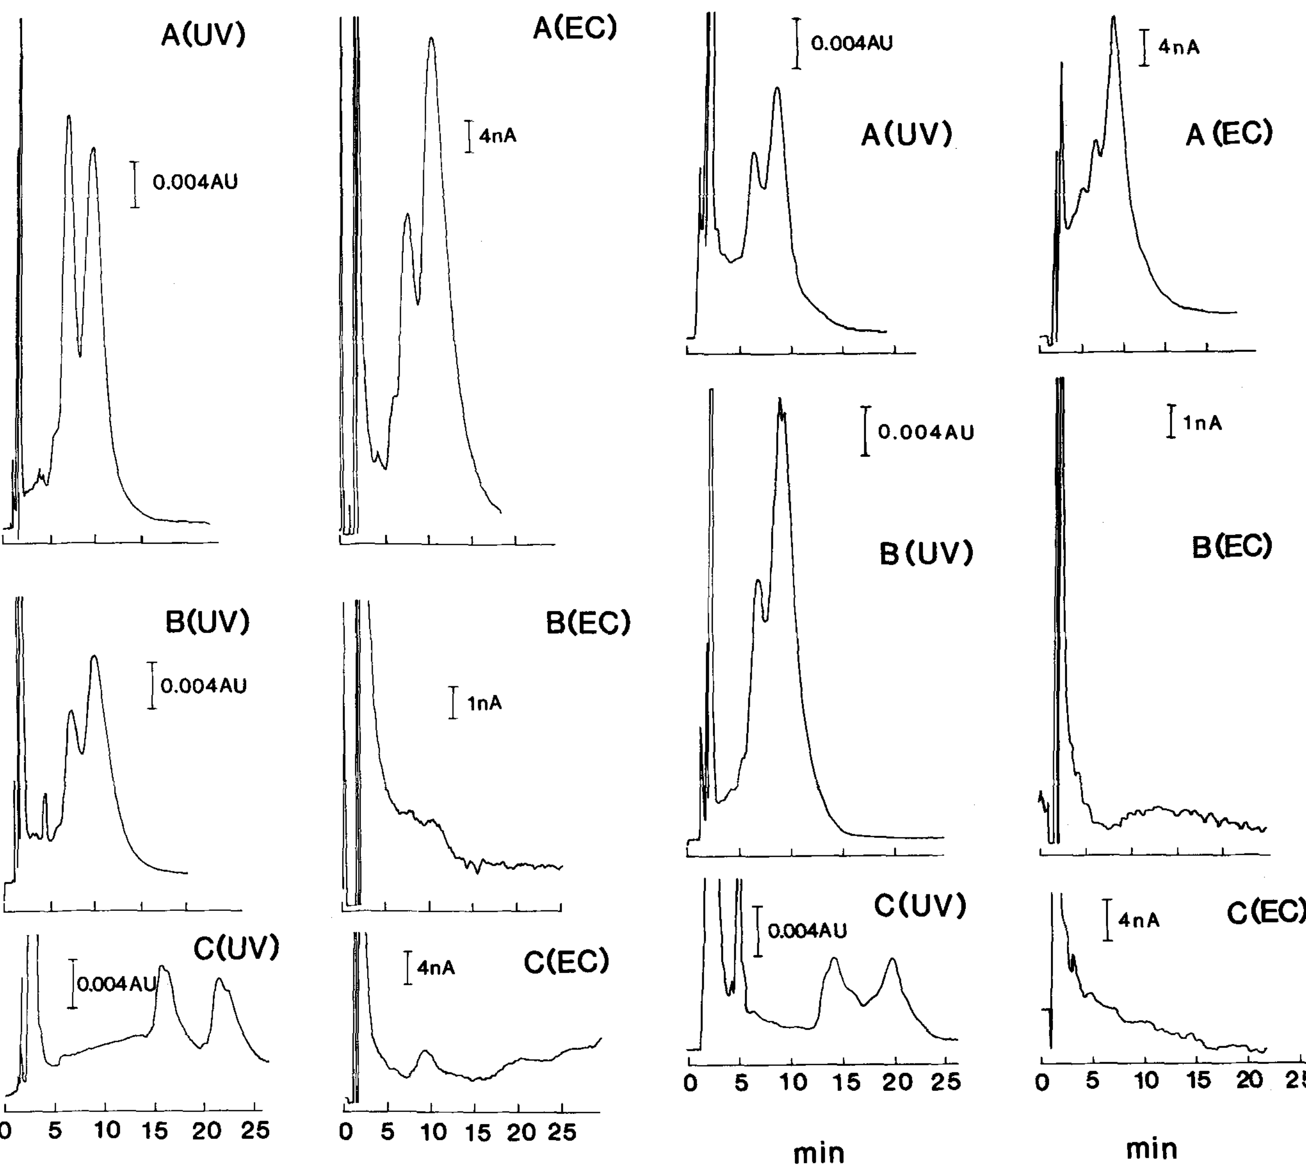

FIG. 4. Chromatograms of hydroperoxy and hydroxy derivatives of rat liver phosphatidylcholine (PC) and unoxidized PC. (A) Hydroperoxy derivatives (40 nmol), (B) hydroxy derivatives (20 nmol) and (C) unoxidized PC (20 nmol) were injected into the column. The eluting solvent contained 0.25 mM sodium perchlorate. Applied electrode potential was −300 mV vs Ag/AgCl. The UV detector was adjusted at 235 nm for hydroxy and hydroxy derivatives, and 203 nm for unoxidized PC.

FIG. 5. Chromatograms of hydroperoxy and hydroxy derivatives of rat liver phosphatidylethanolamine (PE) and unoxidized PE. (A) Hydroperoxy derivatives (20 nmol), (B) hydroxy derivatives (60 nmol) and (C) unoxidized PE (20 nmol) were injected into the column. Experimental conditions were the same as those for Fig. 4.

preparations used for standard phospholipid hydroperoxides (16), although they involved nonconjugated diene isomers, which might be undetectable by the absorption at 235 nm. Therefore, the scales of the peak area obtained by the UV absorption in Figures 6 and 7 were corrected by assuming that the conjugated diene isomers exclusively existed in the sample. The lowest detectable level of the EC detector was determined to be 200 pmol for PC hydroperoxides and 200 pmol for PE hydroperoxides.

DISCUSSION

Many attempts have been made to detect biological materials using the EC detector with HPLC, a combination that was proposed by Kissinger et al. (15). However, there are only a few studies on the use of the EC detector for the oxidized form of hydrophobic compounds. We previously found the reduction of lipid hydroperoxides by polarography (13,14) and thus were motivated to investigate the effectiveness of the EC detector for HPLC analysis of lipid hydroperoxides. The analytical capability of the EC detector seems to be limited when this detector is applied to hydroperoxy phospholipids. A higher concentration of salt, which would strengthen the supporting electrolyte, might elevate the response of the detector. However, we used a lower concentration of salt for this analysis because the electrode could not be stabilized for a long time. On the other hand, a higher electrode potential (−300 mV vs Ag/AgCl) was chosen because the lower electrode potential overlapped with that of oxygen.

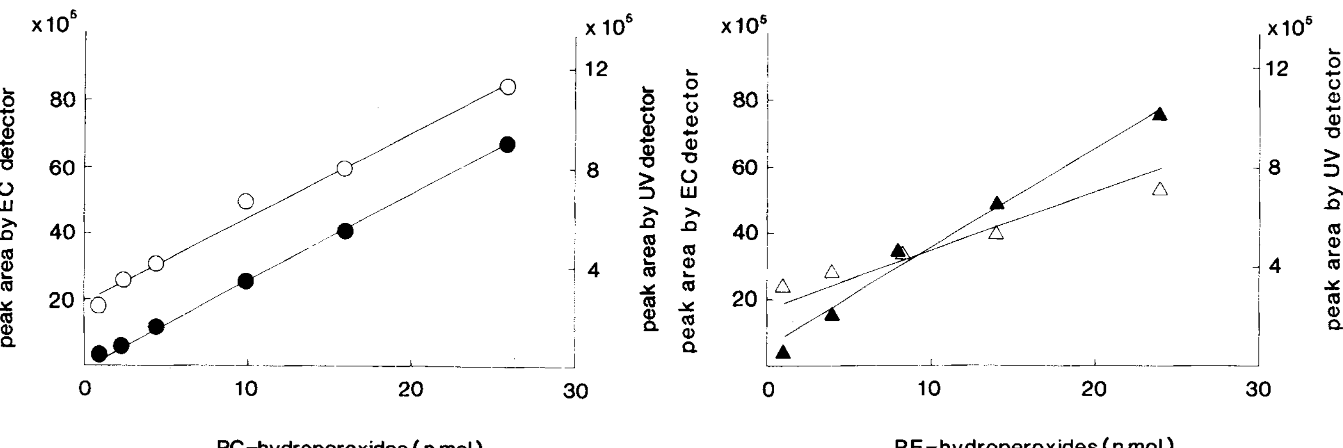

FIG. 6. Calibration curves for PC hydroperoxides. Experimental conditions were the same as those for Fig. 4. The scale of UV absorption was adjusted as the amount of conjugated diene isomers in the sample was estimated to be 74% (16). ●, UV detection; ○, EC detection.

FIG. 7. Calibration curves for phosphatidylethanolamine hydroperoxides. Experimental conditions were the same as those shown in Fig. 4. The scale of the UV absorption was adjusted as the amount of conjugated diene isomers in the sample was estimated to be 76% (16). ▲, UV detection; △, EC detection.

In our preceding work (11), the separation of phospholipid hydroperoxides from unoxidized phospholipids was achieved by reverse-phase HPLC using a C-18 column. This column was replaced by a C-8 column to elute the phospholipid hydroperoxides and unoxidized phospholipids in a shorter time without increasing the flow rate during the analysis. Thus, the HPLC condition described here may be more suitable for practical use.

It has been suggested that hydroperoxy phospholipids can be removed by reduction of the hydroperoxy group directly (12) or after release of the hydroperoxy free fatty acids by reaction with phospholipase A_2 (17,18). Hydroxy derivatives may accumulate instead of the hydroperoxides in membrane phospholipids when lipid peroxidation proceeds in vivo. Thus, the specific detection of the hydroperoxy group is required when phospholipid hydroperoxides are determined by reverse-phase HPLC, because phospholipid hydroperoxides and their hydroxy derivatives are not separated from each other. The EC detector seems able to detect hydroperoxides selectively under HPLC analysis. Furthermore, the EC detector in this condition is more sensitive than the UV detector, based on conjugated diene absorption as shown in Figures 6 and 7.

In conclusion, the combination of reverse-phase HPLC and the EC detector can serve as a sensitive and specific method for the quantitative analysis of phospholipid hydroperoxides. The application of this method to lipid peroxidation products in vivo will be reported in a following paper.

[Received August 15, 1986]

Effects of Parenteral Nutrition with High Doses of Linoleate on the Developing Human Liver and Brain

Manuela Martínez* and **Angel Ballabriga**
Autonomous University of Barcelona, School of Medicine, Hospital Infantil Vall d'Hebron, 08035 Barcelona, Spain

The developmental changes in the fatty acid composition of ethanolamine phosphoglycerides (EPG) and choline phosphoglycerides (CPG) were studied in the liver and brain of 18 newborn infants with gestational ages ranging from 20 to 44 wk. A small group of five newborns receiving total parenteral nutrition (TPN) with high doses of linoleic acid (18:2ω6) was also studied and compared to controls of the same gestational age to look for effects on the developmental fatty acid patterns of liver and brain EPG and CPG. TPN with Intralipid 20% was given for 4–12 days, the total fat intake being 14.7–90 g (mean ± S.D. = 47.1 ± 29.8 g). The main developmental changes in the liver and brain of the control group were an increase in 22:6ω3 (docosahexaenoic acid) at the end of gestation and a linear decrease in 20:4ω6 (arachidonic acid) and 18:1ω9 (oleic acid) in EPG and CPG. A very good correlation in the percent values of these fatty acids in the brain and liver tissues was obtained. Very significant changes in the fatty acid composition of liver EPG and CPG could be found in the infants receiving TPN with Intralipid–mainly an increase in 18:2ω6, a decrease in the linoleate elongation/desaturation to longer members of the series and a decrease in the 22:6ω3 levels of liver EPG and CPG. In the brain, only an increase in the 18:2ω6 value of CPG, not accompanied by any increase in the longer ω6 fatty acids, could be detected. Possible adverse effects of high doses of 18:2ω6 on the tissue levels of long chain polyunsaturated fatty acids (PUFA), especially of 22:6ω3, are discussed.
Lipids 22, 133–138 (1987).

Neural tissues are by far the richest in polyunsaturated fatty acids (PUFA), and a remarkable constancy in the fatty acid composition of the brain, despite widely different dietary intakes of essential fatty acids (EFA) has been well documented (1–3). In contrast, the liver is much more readily influenced by differences in the diet (3,4). Dietary EFA are chain elongated and desaturated in the liver to form long chain PUFA, which are preferentially taken up by the brain, especially during development. A progressive increase in the fatty acid length and degree of unsaturation from maternal liver to placenta, fetal liver and fetal brain has been found (5). Direct incorporation of dietary long chain PUFA into the developing brain has also been demonstrated (6).

Besides being influenced by diet, the fatty acid composition of body organs changes with development. Special attention has been focused on developmental changes of the brain fatty acid patterns (7–11), but few data are available on the fatty acid composition of the mammalian liver during development (12,13). Clandinin et al. (14,15) have applied a quantitative approach to the study of total fatty acid accretion in the developing human liver and brain as a means of estimating neonatal dietary needs for ω6 fatty acids but, to our knowledge, a systematic study on the developmental fatty acid patterns of the main phosphoglycerides of human liver and brain is lacking.

For many years it has been general practice in pediatrics to supplement milk formulas with substantial amounts of linoleic acid (18:2ω6). Linoleate supplementation has even been extended to cases in which oral feeding is not possible, and several parenteral formulas highly enriched in 18:2ω6 have appeared. The content and proportion of α-linolenic acid (18:3ω3) have relatively been disregarded in most of these formulas. There is an increasing concern for the metabolic effects of such unphysiological EFA supplies, and some effects on the levels of arachidonic acid (20:4ω6) (16,17), long PUFA with 22 carbon atoms (17,18) and prostaglandin production (19) have been published. However, there is little information on the effects of total parenteral nutrition (TPN) with high doses of 18:2ω6 on the fatty acid composition of human tissues during development (19).

The aim of the present work was twofold: first, to correlate the fatty acid patterns of the main phosphoglycerides in the liver with those in the brain during normal human development and, second, to study the effects of a high supply of linoleic acid, a widely used formula (TPN with Intralipid) administered intravenously, on the developmental fatty acid patterns of human liver and brain. Some preliminary accounts of this work have appeared elsewhere (20,21).

MATERIALS AND METHODS

Developmental study. The developmental study comprised 18 newborn infants with gestational ages between 20 and 44 wk. Gestational ages were determined by maternal history and clinical examination; only those cases with body weights appropriate for gestational age according to Lubchenco's grid (22) were included. Those cases with any kind of neonatal problem that could affect cerebral integrity were excluded. The cause of death, occurring during the first 48 hr of life, was immaturity and/or acute respiratory disease.

Study on TPN. Five infants who received TPN and died during the neonatal period due to major surgical problems were studied. Four were full-term neonates (gestational ages between 37 and 43 wk) and the fifth had been born slightly premature (35 wk). Body weight was appropriate for gestational age in all cases. All infants had to be administered TPN because of multiple congenital defects requiring major surgery (two cases of esophagus atresia and tracheoesophageal fistula, one associated to duodenal obstruction; one case of myelomeningocele plus diaphragmatic hernia and arthrogryposis; one case of intestinal malrotation and duodenal stenosis; and one case of imperforate anus). TPN was infused immediately after operation, performed during the first 24 hr of life. Total fluid intake was 156 ml/kg/day, and total calories ranged from 85.5 to 102 kcal/kg/day. The intravenous infusion

contained amino acids (1.5–2.5 g/kg/day), glucose (11.2–12.9 g/kg/day), electrolytes and minerals (Na, 2.2 meq/kg/day; K, 1.8 meq/kg/day; Cl, 2.0 meq/kg/day; Ca, 2.5 meq/kg/day; Mg, 0.5 meq/kg/day; P, 2 mmol/kg/day) and vitamins (A, 1000 IU; D, 100 IU; E, 0.5 mg; B_1, 5 mg; B_2, 1.4 mg; B_6, 1.5 mg; C, 50 mg; niacin, 10 mg; pantothenic acid, 2.5 mg). Fat was administered as Intralipid 20% (Vitrum AB, Stockholm, Sweden). A progressive amount of lipids was infused, increasing from 1.0 g to 4.0 g per kg per day in the course of 7 days. The infants died from various complications at 5–13 days after birth, having received TPN for a minimum of 4 days and a maximum of 12. This represented a total fat intake of 14.7–90 g (means ± S.D. = 47.1 ± 29.8 g). According to the analysis of our batch of Intralipid 20%, the total supply of 18:2ω6 ranged from 6.7 g to 41 g (21.5 ± 13.59 g) and that of 18:3ω3 from 1.2 g to 7.3 g (3.8 ± 2.41 g).

All the bodies were refrigerated at 4 C immediately after death. Autopsy, which was done within 12–36 hr of death, did not reveal any brain or liver anomalies. A cerebral hemisphere and the liver were removed, wrapped in double bags of aluminum foil and polyethylene, and stored frozen at −20 C until analysis.

Analytical procedures. All solvents and reagents were of highest purity, purchased from Merck (Darmstadt, Federal Republic of Germany). Just before lipid extraction, the complete hemisphere and the whole liver were homogenized in a Sorvall Omnimixer (Norwalk, Connecticut) to avoid regional differences. Brain and liver homogenates were diluted with an equal volume of water, and total lipids were extracted with 20 vol of chloroform/methanol (1:2, v/v) as specified elsewhere (23). Ethanolamine phosphoglycerides (EPG) and choline phosphoglycerides (CPG) were separated from aliquots of the lower phase by thin layer chromatography (TLC) in two different ways. In order to have a high fatty acid/impurities ratio, as much as 40 μg of lipid P were spotted on a precoated Silica Gel G plate (Chromatoplate, Merck) for the separation of EPG. For CPG, on the other hand, only 20–25 μg of lipid P were spotted on a 0.25-mm-thick Silica Gel G plate prepared manually in the laboratory, because this procedure was shown to give best separation between choline and serine phosphoglycerides. In both cases, the solvent system was chloroform/methanol/water (65:25:3.5, v/v/v). The individual phosphoglycerides were recovered from the plates by scraping off the spots, and the fatty acid methyl esters were obtained directly from the dried silica by cold methanolysis with 2 ml of 0.1 N sodium methoxide in dry methanol, according to Svennerholm (24). After neutralization with 1 N acetic acid, the fatty acid methyl esters were extracted three times with 2 ml of very pure petroleum ether (40–60 C), washed twice with water and dried with anhydrous sodium sulfate. After evaporation with N_2, the fatty acid methyl esters were dissolved in a small volume of hexane and injected into the gas chromatograph.

A Perkin Elmer 900 gas chromatograph was used, equipped with flame ionization detectors (FID) and a 10-ft, 1/8 inch OD, stainless steel column, packed with 15% ethylene glycol succinate (LAC 4R 886) on Chromosorb W 100–120 mesh, acid-washed and dimethyldichlorosilane-treated. The carrier gas was N_2, and the column was operated on a temperature program from 160 C to 195 C, at a rate of 3 C/min. A relatively high volume (10 μl) was injected so that the descending effect of the solvent tail compensated for the column bleeding, and a good base line was obtained despite the use of a single column. The peak areas were measured with an Autolab electronic computer-integrator, system IV model, and the results were expressed as area percentages, which were essentially equivalent to weight percentages within the range of fatty acids studied. The statistical analyses were effected with an electronic programmer (Olivetti, 203 model). For the study on normal development, regression analysis was used, either linear or quadratic depending on the developmental trend. All cases were analyzed individually, with gestational ages plotted on the X axis against corresponding fatty acid values on the Y axis (for correlation between liver and brain, the fatty acid value for the liver was plotted on the X axis against the corresponding value for the brain of the same child on the Y axis, as shown in Figs. 1–3). The levels of significance of the regression coefficients are indicated in Results. On

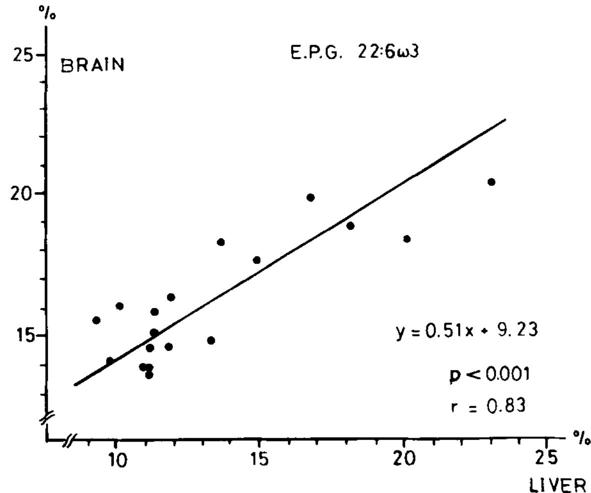

FIG. 1. Brain against liver percent values of docosahexaenoic acid in ethanolamine phosphoglycerides of a group of newborn infants with gestational ages from 20 to 44 wk.

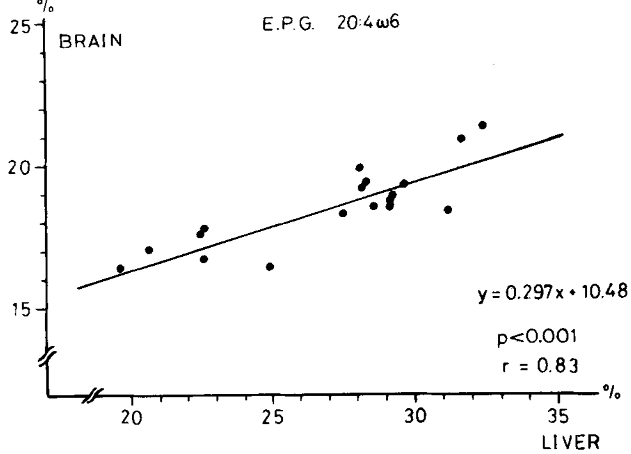

FIG. 2. Brain against liver percent values of arachidonic acid in ethanolamine phosphoglycerides of a group of newborn infants with gestational ages from 20 to 44 wk.

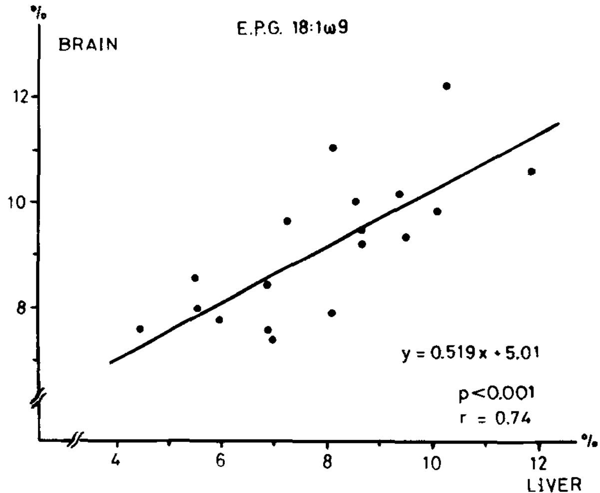

FIG. 3. Brain against liver percent values of oleic acid in ethanolamine phosphoglycerides of a group of newborn infants with gestational ages from 20 to 44 wk.

the other hand, for the study on the effects of TPN on tissue fatty acid composition, all cases were distributed into three age groups (see Results and Tables 1 and 2). This allowed us to compare the cases receiving TPN to controls of the same age. The differences observed were validated by means of Student's t-tests for independent variables, and the levels of significance are given in the tables.

RESULTS

Normal development. Under "controls," Tables 1 and 2 summarize the developmental changes in the fatty acid composition of the main phosphoglycerides of the human liver and brain during the second half of gestation. For the sake of simplicity, Tables 1 and 2 show all the cases distributed into three age groups: a very immature group, ranging from 20–25 wk of gestational age; an immature group in a developmental stage just before the beginning of the "chemical spurt" (23), 28–31 wk; and a full-term group, with gestational ages from 37 wk onward. However, for statistical analysis, all control data were considered individually (by means of regression lines) and not by groups, so that the developmental changes could find a more real statistical expression.

Confirming previous data (10,11), the main developmental changes in the brain were an increase in 22:6ω3 (docosahexaenoic acid) at the end of gestation and a quite linear decrease in 18:1ω9 (oleic acid) and 20:4ω6 in EPG. The elongation/desaturation of arachidonic acid to its products 22:4ω6 (docosatetraenoic or adrenic acid) and 22:5ω6 (docosapentaenoic acid), expressed by the index (22:4ω6 + 22:5ω6)/20:4ω6, increased linearly with gestational age in brain EPG, and the ratio 22:4ω6/22:5ω6 increased with maturation in EPG and CPG as shown before (10). All these changes were very significant statistically ($p < 0.001$).

Very similar changes could be observed in the liver, with 22:6ω3 increasing markedly at the end of gestation in both phosphoglycerides. A linear decrease in 18:1ω9

All values represent wt % of each fatty acid (mean values, for the number of cases indicated, *n*) ± S.D. The statistically significant changes for the children receiving TPN are signaled by letters according to the following levels of significance (based on Student's t-test with 9 degrees of freedom): *a*, <0.1; *f*, <0.001.

*, (20:3ω6 + 20:4ω6 + 22:4ω6 + 22:5ω6)/18:2ω6; **, (22:4ω6 + 22:5ω6)/20:4ω6.

and 20:4ω6 was also found in EPG and CPG, significant at the 0.001 level. The 22:4ω6/22:5ω6 ratio, on the other hand, did not show significant variations with age, these fatty acids being quantitatively less important in the liver than in the brain due to a poorer elongation/desaturation of arachidonate [see the index (22:4ω6 + 22:5ω6)/20:4ω6 in the tables]. As for the parent ω6 fatty acid, 18:2ω6, it is present only in very low amounts in brain because of its very active elongation and desaturation to the higher members of the family. In liver, on the other hand, it is an important constituent of phosphoglycerides, and it increased slowly with maturation in EPG ($p < 0.05$) and CPG ($p < 0.01$), at the same time as its elongation/desaturation slowed down in both phosphoglycerides ($p < 0.001$). As a consequence of these maturational changes, the ratio 18:2ω6/18:1ω9 increased linearly and very significantly ($p < 0.001$) in liver EPG and CPG.

The striking similarity of some fatty acid profiles in the liver and the brain was emphasized by plotting the brain values against the corresponding liver values. This resulted in a very significant ($p < 0.001$) positive correlation between the brain and liver values of 22:6ω3 (Fig. 1), 20:4ω6 (Fig. 2) and 18:1ω9 (Fig. 3). Although only a minor constituent, 20:3ω9 was also studied for its significance in relation to nutrition and showed a parallel decrease with maturation in EPG of liver ($p < 0.001$) and brain ($p < 0.01$) and in liver CPG ($p < 0.001$).

Influence of TPN on fatty acid patterns of liver and brain. The fatty acid composition of liver and brain EPG and CPG in a group of full-term infants receiving TPN with Intralipid is shown in Tables 1 and 2 beside the normal patterns corresponding to controls of the same age, so that the effects of TPN can be easily detected. It can be seen that there was a threefold increase in linoleic acid in the two phosphoglycerides of liver and a twofold increase in brain CPG, all very significant statistically (a t-test was applied between the two full-term groups, control and TPN-treated; see tables for levels of significance). This increase in 18:2ω6, however, was not accompanied by any parallel increase in the long members of the family. On the contrary, 20:3ω6 (dihomo-γ-linolenic acid) decreased very significantly in liver EPG and CPG, and 20:4ω6 decreased markedly in liver CPG (although not in EPG). The longer ω6 PUFA, 22:4ω6 and 22:5ω6, showed a tendency to decrease in liver EPG. It can be deduced, therefore, that the elongation/desaturation of 18:2ω6 was significantly decreased in both phosphoglycerides of the liver, leading mainly to reductions in 20:4ω6 in CPG and in the 22 carbon atom members in EPG.

The ratio of 18:2ω6 to 18:1ω9, which increased slowly with maturation in the liver of the normal child, was much more augmented in the liver phosphoglycerides of infants receiving TPN. Palmitic (16:0) and palmitoleic (16:1ω7) acids were slightly reduced in the liver of the TPN-treated group, more significantly in CPG than in EPG, but 18:0 (stearic acid) did not show any significant variation, and 18:1ω9 slightly increased in liver EPG and showed a nonsignificant tendency to decrease in liver CPG.

A most interesting finding was the very significant decrease in the 22:6ω3 level of the liver, which was reduced to about half the normal value at this age in liver EPG and CPG. As a consequence, the ω3/ω6 ratio was also greatly reduced in the liver of children receiving TPN.

It is interesting to note that the only change in the brain of the parenterally nourished infants was the abovementioned increase in 18:2ω6 in brain CPG. A consequence of this was a very significant reduction of the 18:2ω6 elongation/desaturation and an increase in the 18:2ω6/18:1ω9 ratio in brain CPG. The rest of brain CPG fatty acids, however, were totally within normal limits, and no variation at all could be found in brain EPG.

DISCUSSION

The developmental changes in the fatty acid composition of the main phosphoglycerides in the human brain confirm our previous data on a larger number of cases (10,11), i.e., there is a significant increase in the 22:6ω3 level of the brain EPG and CPG after 32 wk of gestational age and a linear decrease in the 20:4ω6 and 18:1ω9 values during the second half of gestation, mainly in brain EPG.

The present data show an excellent correlation between the main developmental fatty acid changes in the brain and the liver during early human development. In other words, docosahexaenoate increases in the human liver also in a parabolic manner, whereas arachidonate and oleate decrease in a linear way in the two main phosphoglycerides, mainly in EPG. During this crucial stage of brain development the percentage of 22:6ω3 in the liver EPG is almost as high, or even a little higher toward the end of gestation, as that in the brain EPG, indicating that during this period elongation and desaturation of ω3 fatty acids in the human liver is very active and capable of providing the high levels of long ω3 PUFA required by the developing brain.

Upon comparison of fatty acid patterns in the infants receiving TPN with controls of the same age, the decrease in the docosahexaenoate level in both liver phosphoglycerides is striking. Such a decrease in 22:6ω3 has not even been described in rats receiving high doses of 18:2ω6 intravenously (17), in which a similar reduction was noted in liver CPG, but not in liver EPG.

A significant decrease in liver 20:4ω6 has been found in rats (16,17) and humans (19) receiving TPN with high doses of 18:2ω6. In our study, this decrease was only significant in liver CPG, the levels of arachidonate in liver EPG being totally within normal limits for the age. On the other hand, we found a very important increase in 18:2ω6 in both phosphoglycerides of the liver and even in brain CPG, which has not been described in the experimental animal; as a consequence, the ratio of 20:4ω6 to 18:2ω6 (or, as we prefer, the elongation/desaturation of linoleate expressed by the index [20:3ω6 + 20:4ω6 + 22:4ω6 + 22:5ω6]/18:2ω6) was greatly reduced, even much more so than in the rat receiving a large supply of parenteral 18:2ω6 (16).

For many years, studies on EFA have focused mainly on the linoleate (ω6) family. On the other hand, the essentiality of α-linolenic acid (18:3ω3) has been questioned (25), because no signs of ω3 deficiency could be discovered in laboratory animals subjected to ω3-deficient diets. However, from a quantitative point of view, the main long chain PUFA of the ω3 series, docosahexaenoic acid (22:6ω3), is a very important component of neuronal and retinal membranes. Although its functions are still not fully understood, 22:6ω3 seems to be an important factor in membrane fluidity of neurons and outer segments of the retina, probably enhancing the various movements of rhodopsin (26). Docosahexaenoate may even play a role in neurotransmission, as indicated by its preferential accumulation in synaptic membranes (27). Furthermore, another member of the ω3 family, eicosapentaenoic acid (EPA, 20:5ω3), plays an important role in platelet aggregation (28–31), and the supply of ω3 fatty acids is now recommended in the prevention of thromboembolic disorders (32–35).

Recently, clinical evidence of ω3 deficiency, caused by a poor supply of α-linolenic acid, has been presented in the human (36) and in the monkey (37). The present results suggest that a relative deficiency of ω3 fatty acids can also be produced by a different mechanism. It is very possible that the exclusive concern for the ω6 fatty acids and the very high doses of linoleate used in many milk formulas and most forms of TPN has caused the natural preference of the Δ6-desaturase system by the ω3 family (38,39) to be overcome and displaced towards the predominant ω6 fatty acids. Thus, even if a ω3 fatty acid deficiency is spontaneously very rare, if possible at all, because of the abundance of these fatty acids in nature, their small minimum requirements and the enzyme preferences for the linolenate family, our results show that it is possible to artificially produce a relative deficiency in ω3 fatty acids by supplying a great excess of ω6 fatty acids, as has also been shown in the rat brain and retina (40) and liver (17). It seems advised, therefore, to warn clinicians, mainly pediatricians, against the use of excessive amounts of linoleic acid in the diet, especially during early development.

Our cases received TPN only for a short period (4–12 days), and this was enough to produce important alterations in the fatty acid composition of the main liver phospholipids and even a significant increase in 18:2ω6 in brain CPG. The brain's resistance to changing its fatty acid composition despite dietary manipulation is well known (1,2,41,42), and we could not find any alteration in the brain long chain PUFA in our cases receiving TPN. However, it is possible that a more prolonged diet with large doses of 18:2ω6 could affect these fatty acids, as has been shown in the experimental animal (40). In any case, a diet capable of reducing the level of liver EPG and CPG docosahexaenoate to half its normal value during a critical developmental stage should certainly be proscribed. In agreement with very recent data in the rat (17), our results indicate that a correct ratio of linoleate to linolenate is not the only relevant factor in devising an EFA diet, especially when the nutrient has to be administered intravenously. An excess of 18:2ω6, even if a theoretically correct ratio of 18:2ω6 to 18:3ω3 is maintained, should be avoided if the balance of long chain PUFA is to be kept unaltered, an aim particularly important during brain development.

[Received July 14, 1986]

Time Course of Incorporation of 20-Carbon Polyunsaturated Fatty Acids in a Human Keratinocyte Cell Line

Kari Punnonen[a,1], **Tapio Puustinen**[a,1] and **Christer T. Jansén**[b]
Departments of [a]Physiology and [b]Dermatology, University of Turku, 20520 Turku, Finland

Human keratinocytes (NCTC 2544) in culture were labeled with equal amounts of either ^{14}C-arachidonic acid, ^{14}C-dihomo-γ-linolenic acid or ^{14}C-eicosapentaenoic acid. At various time points, the incubations were stopped and the distribution of the ^{14}C-fatty acids was analyzed. All these eicosanoid precursor fatty acids were effectively incorporated into the cellular lipids of the keratinocytes, and the major radiolabeled individual lipid fraction was phosphatidylethanolamine. The distributions of arachidonic acid and dihomo-γ-linolenic acid within cellular lipids were rather the same. However, less eicosapentaenoic acid than either arachidonic acid or dihomo-γ-linolenic acid was incorporated into the phospholipids and, correspondingly, more eicosapentaenoic acid was incorporated into the nonphosphorus lipids. In the phosphatidylinositol + phosphatidylserine fraction, there was significantly less eicosapentaenoic acid than either arachidonic acid or dihomo-γ-linolenic acid. The present study suggests that these eicosanoid precursor fatty acids are effectively incorporated into the human keratinocytes and that the pattern of incorporation and distribution of eicosapentaenoic acid appears to differ slightly from that of either arachidonic acid or dihomo-γ-linolenic acid.
Lipids 22, 139–143 (1987).

Eicosanoids, derivatives of the 20-carbon polyunsaturated fatty acids (1), play an important role in both physiological and pathophysiological reactions of human skin (2,3). The precursor fatty acids for the eicosanoids are dihomo-γ-linolenic acid, arachidonic acid and eicosapentaenoic acid, respectively. The initial step in the formation of eicosanoids is obviously the release of the precursor fatty acids from the cellular lipid stores (4). Dietary factors may affect the formation of eicosanoids by altering the tissue levels of different precursor fatty acids, and, notably, the biological activities of the metabolites derived from each of these fatty acids may differ considerably (5–7). Recently, it has been demonstrated that the distribution and release of arachidonic acid in human keratinocytes may be affected by certain physical and chemical factors (8–10).

When considering the possibilities of dietary alterations in modifying the production of eicosanoids, for example, in inflammatory reactions, one must know if their precursor fatty acids (i.e., dihomo-γ-linolenic acid, arachidonic acid and eicosapentaenoic acid) are equally incorporated and distributed in the cellular lipids. In the present study, the time course of incorporation and subsequent distribution of arachidonic acid, dihomo-γ-linolenic acid and eicosapentaenoic acid into the lipids of human keratinocytes in culture have been investigated.

MATERIALS AND METHODS

Chemicals. ^{14}C-Arachidonic acid (sp act 58 mCi/mmol), ^{14}C-dihomo-γ-linolenic acid (sp act 56 mCi/mmol) and ^{14}C-eicosapentaenoic acid (sp act 58.6 mCi/mmol) were purchased from Radiochemical Centre (Amersham, England). Radioactive fatty acids were converted to their sodium salts and added to cell cultures in 100 μl of 0.9% NaCl. Unlabeled reference compounds for the thin layer chromatograms were purchased from Sigma Chemical (St. Louis, Missouri).

Cell culture. In this study a human keratinocyte cell line NCTC 2544 from Flow Laboratories (Rickmansworth, England) was used. This cell line originates from a clone of skin cells derived from a male Caucasian (8). On the basis of both phase contrast microscopy and transmission electron microscopy this cell line has been classified as epithelial (9). Several lines of evidence indicate that the NCTC 2544 cells are nonmalignant: the cells form a monolayer in culture and exhibit growth inhibition, and by light microscopy the nuclei have been found not to appear malignant (9). Moreover, the cells have been found not to grow in soft agar as most malignant cells have been reported to do (9). These cells do not demonstrate complete keratinization, and apparently they are more like the basal than the stratified cells of epidermis. Cytokeratins have been demonstrated using mouse monoclonal anticytokeratin antibodies (DakoPatts, CK-1) in combination with immunofluorescence staining (goat anti-mouse IgG, Vector Laboratories, Burlingame, California). The cells were cultured (40×10^6 cells per flask) in a medium of 40 ml containing 90% RPMI 1640 (KC Biological) and 10% swine serum (Flow Laboratories). In swine serum, arachidonic acid, dihomo-γ-linolenic acid and eicosapentaenoic acid comprised approximately 4.5%, 1.5% and 0.5%, respectively, of total fatty acids. At the start of labeling, 360,000 cpm (0.16 μCi, ca. 2.8 nmol) of the ^{14}C-fatty acid was added to the cell culture. After a labeling period of 30 sec, 12 min, 1 hr, 6 hr, 24 hr or 48 hr, respectively, the labeling medium was removed and the amount of unincorporated radioactivity in the medium was measured by liquid scintillation counting. The experiments of 30 sec are referred to as the 0-hr time point. After the labeling, the cells were washed with a small volume of Hank's buffered salt solution and detached from the culture flasks by gentle mechanical rubbing without trypsin. For the following lipid analysis, the cells were transferred from the culture flasks into glass tubes in a small volume of methanol.

Distribution of ^{14}*C-fatty acids in cellular lipids.* The cells were homogenized by vigorous vortexing in 10 ml of chloroform/methanol (2:1, v/v) containing 0.01% of α-tocopherol to prevent oxidation. Homogenates were filtered through glass wool and mixed with 0.2 vol of 0.12 M KCl (13,14). The upper phases were removed and the organic phases were evaporated into dryness. Six ml of acetone saturated with $MgCl_2$ was added to the residue, and the tubes were stored overnight at −20 C. The tubes were centrifuged, and the supernatants (containing the

neutral lipids) were removed. The neutral lipids were thereby separated from the precipitated phospholipids. After acetone was evaporated into dryness, both the neutral lipid and phospholipid fractions were redissolved in chloroform.

Neutral lipid fractions were further analyzed by thin layer chromatography (TLC) (DC-Alufolien Kieselgel 60, Merck 5553) in hexane/diethyl ether/acetic acid (60:40:1, v/v/v) (13,14). Phospholipids were analyzed in a two-dimensional system (13,14). The plates were first developed in chloroform/methanol/13 N ammonia/water (70:30:4:1, v/v/v/v), dried in air flow and developed in the second direction in chloroform/methanol/acetic acid/water (75:45:12:3, v/v/v/v). In this chromatography, phosphatidylinositol (PI) migrated on the same area as phosphatidylserine (PS). For the separation of PI and PS, the corresponding area was scraped from the TLC plate and extracted with chloroform/methanol/acetic acid/water (50:39:1:10, v/v/v/v) (15). The samples were then rechromatographed using a solvent system of chloroform/methanol/acetic acid/formic acid/water (45:10:1:5:1, v/v/v/v/v) (10,16). The lipid fractions were identified by unlabeled standards that were visualized by exposure to iodine vapor. The distribution of radioactivity on the TLC plates was determined by autoradiography of the TLC plates, and the amount of radioactivity on the TLC plates was further determined by liquid scintillation counting.

Statistical analysis. To test the statistical significance of observed differences between fatty acids, the data was following inverse sine (arscine) transformation subjected to two-way analysis of variance. If two-way analysis showed that differences existed, the comparisons of the fatty acids to each other were performed using Bonferroni's test (Tables 1 and 2).

Data indicates differences in the time course of the incorporation of radiolabeled arachidonic acid, dihomo-γ-linolenic acid and eicosapentaenoic acid, respectively, into various lipid subclasses in human keratinocytes. The data was subjected to two-way analysis of variance and the pairwise comparisons of the various fatty acids to each other at the various time points were performed using Bonferroni's test: *, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$; NS, not significant; 20:3, dihomo-γ-linolenic acid; 20:4, arachidonic acid; 20:5, eicosapentaenoic acid. PE, phosphatidylethanolamine; PC, phosphatidylcholine; PI + PS, phosphatidylinositol + phosphatidylserine; SM, sphingomyelin; PA, phosphatidic acid; TG, triacylglycerols; DG, diacylglycerols; CE, cholesteryl esters.

RESULTS

Radiolabeled arachidonic acid (20:4n-6), dihomo-γ-linolenic acid (20:3n-6) and eicosapentaenoic acid (20:5n-3) were effectively incorporated into the cellular lipids of human keratinocytes (NCTC 2544) in culture. The amounts of the ^{14}C-fatty acids (360,000 cpm, 2.8 nmol) incorporated increased continuously up to 24 hr when 87.1 ± 0.4%, 84.2 ± 0.5% and 82.4 ± 0.1% of ^{14}C-arachidonic acid, ^{14}C-dihomo-γ-linolenic acid and ^{14}C-eicosapentaenoic acid, respectively, was taken up by the cells. The bulk of the ^{14}C-fatty acids was recovered in different phospholipids, and at 48 hr the amount incorporated into nonphosphorus lipids was ca. 5%, 5% and 12% for arachidonic acid, dihomo-γ-linolenic acid and eicosapentaenoic acid, respectively (Fig. 1). At 6 hr and later, there was more ^{14}C-eicosapentaenoic acid than either ^{14}C-arachidonic acid or ^{14}C-dihomo-γ-linolenic acid within the nonphosphorus lipids. After 6 hr the amount of ^{14}C-arachidonic acid or ^{14}C-dihomo-γ-linolenic acid in the triacylglycerols showed only slight increments, whereas the amount of ^{14}C-eicosapentaenoic acid still showed an increasing tendency at 48 hr.

The major radiolabeled phospholipid fraction was phosphatidylethanolamine (PE), in which ca. 50%, 50% and 40% of arachidonic acid, eicosapentaenoic acid and dihomo-γ-linolenic acid, respectively, were recovered. Two other significant radiolabeled fractions were phosphatidylcholine (PC) and PI + PS. Less ^{14}C-eicosapentaenoic acid than either ^{14}C-arachidonic acid or dihomo-γ-linolenic acid was consistently recovered in the PI + PS fraction. The separation of PI and PS from each other was carried out from the samples of the time point of 24 hr. The rechromatography revealed that of the total of ^{14}C-dihomo-γ-linolenic acid, ^{14}C-arachidonic acid and ^{14}C-eicosapentaenoic acid in the PI + PS fraction, only ca. 10%, 5% and 10%, respectively, were associated with PS.

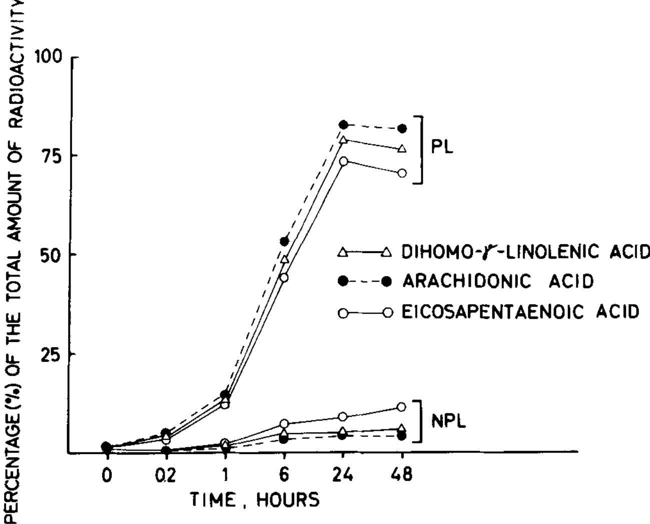

FIG. 1. Time course of the incorporation of radiolabeled arachidonic acid, dihomo-γ-linolenic acid and eicosapentaenoic acid, respectively, into phospholipids (PL) and nonphosphorus lipids (NPL) of human keratinocytes in culture. At the time points indicated, the incubations were stopped and the distribution of radiolabel in cellular lipids was analyzed. Values are expressed as percentage of the total amount of radiolabel in each incubation. The values at 0 hr are means of two experiments; values at other time points are means of three (SEM always less than 2%).

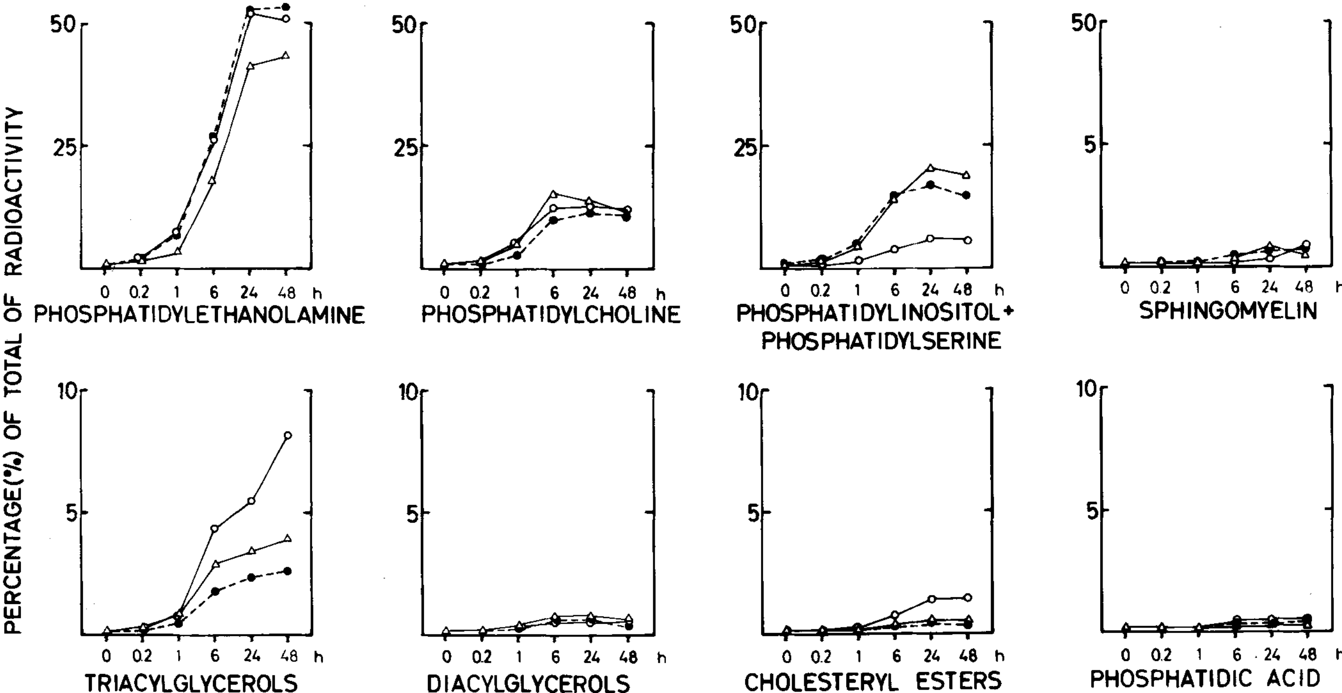

FIG. 2. Time course of the incorporation of radiolabeled arachidonic acid, dihomo-γ-linolenic acid and eicosapentaenoic acid, respectively, into various lipids in human keratinocytes. The cells were incubated with 360,000 cpm (ca. 2.8 nmol) of ^{14}C-dihomo-γ-linolenic acid, ^{14}C-arachidonic acid or ^{14}C-eicosapentaenoic acid, respectively. At the time points indicated, the incubations were stopped and the distribution of radiolabel within cellular lipids was analyzed. Results are expressed as percentage of the total amount of radiolabel in each incubation. The values at 0 hr are means of two experiments; values at other time points are means of three (SEM always less than 1%).

Between 6 hr and 24 hr there was a notable increase in the total amount of incorporated radioactivity and this was accompanied by a twofold increase in the amount of radioactivity in PE. After 6 hr the labeling of the PI + PS fraction by either ^{14}C-arachidonic acid or ^{14}C-dihomo-γ-linolenic acid was also increased slightly, but the dominant change in the distribution of the fatty acids was the significant increase in the amount of radioactivity associated with PE (Fig. 2).

DISCUSSION

Arachidonic acid, dihomo-γ-linolenic acid and eicosapentaenoic acid were effectively incorporated into the cellular lipids of the human keratinocytes (NCTC 2544). The bulk of the incorporated fatty acids was recovered in various phospholipids. In the nonphosphorus lipids, the amount of eicosapentaenoic acid at either 24 hr or 48 hr was about twofold that of arachidonic acid or dihomo-γ-linolenic acid. The present study, together with previous findings (14), suggests that eicosapentaenoic acid is incorporated less effectively than arachidonic acid or dihomo-γ-linolenic acid into the phospholipids as a whole, and correspondingly more efficiently into the nonphosphorus lipids.

The two major features in the labeling of the phospholipids of keratinocytes were the effective incorporation of all these fatty acids into PE and the poor incorporation of eicosapentaenoic acid into the PI + PS fraction. Since at 24 hr, only minor amounts of radioactivity were recovered in PS, it is apparent that the incorporation of ^{14}C-fatty acids into PI was mainly responsible for the total of ^{14}C-label in the PI + PS fraction. After 6 hr, the labeling of PE showed considerable increments, whereas only slight changes were detected in the labeling of the other phospholipid fractions. This finding is apparently related to the phospholipid composition of the keratinocytes, as PE comprises ca. 40% of the total amount of phospholipids in this cell line (14). It is thus evident that PE has the highest capacity to incorporate eicosanoid precursor fatty acids. The preferential incorporation of arachidonic acid into the PI + PS fraction may be related to the selective acylation of arachidonoyl-CoA or the effective synthesis of arachidonoyl-CoA by specific arachidonoyl-CoA synthetase (17,18). In the present study, the results concerning incorporation and distribution of ^{14}C-arachidonic acid are in relatively good agreement with a previous report on ^{14}C-arachidonic acid incorporation into murine keratinocytes in culture (19). Also with respect to the amount of eicosapentaenoic acid in the PI + PS fraction the present data are fairly consistent with the previous studies (16,20–22), although results of another kind have also been reported (23).

The kinetics and the underlying mechanisms of the acylation of dihomo-γ-linolenic acid and eicosapentaenoic acid into membrane lipids are only poorly understood. In the present study, the patterns of incorporation of arachidonic acid and dihomo-γ-linolenic acid were similar, suggesting that dihomo-γ-linolenic acid could well compete with arachidonic acid for the same binding sites in the cellular lipids. Eicosapentaenoic acid was also effectively incorporated into the keratinocytes, although relatively minor amounts were recovered in the PI + PS fraction. Arachidonic acid and dihomo-γ-linolenic acid thus seem to be the preferential 20-carbon fatty acids in the PI + PS fraction of human keratinocytes. This may be of importance under conditions associated with the stimulated breakdown of inositol-containing phospholipids, which are closely related to the release of eicosanoid precursor fatty acids (23).

Modifications in the dietary fatty acid composition have been shown to alter the fatty acid composition of body tissues; furthermore, at least in some tissues, such modifications have been shown to induce changes in the formation of eicosanoids (6,25,26). The biological activities of the eicosanoids of the 1-, 2- and 3-series may differ considerably. As the eicosanoids of the different series may also interfere with the biosynthesis of other eicosanoids, it is possible that changes in the fatty acid composition of tissues could interfere with the formation of lipid-derived inflammatory mediators (5,27–30). As a conclusion from the present findings, arachidonic acid, dihomo-γ-linolenic acid and eicosapentaenoic acid are effectively incorporated into the cellular lipids of human keratinocytes during short-term culture. The practical implications of the present study remain to be elucidated.

[Received July 22, 1986]

The Formation of Lysophosphatidylinositol Phosphate in Human Platelet Microsomes

L.M. Thomas and **B.J. Holub***
Department of Nutritional Sciences, University of Guelph, Guelph, Ontario, Canada N1G 2W1

The formation of lysophosphatidylinositol phosphate (lysoPIP) from lysophosphatidylinositol (lysoPI) via kinase activity was studied in microsomal preparations from human platelets. For this purpose, [^{3}H]lysoPI or [^{3}H]phosphatidylinositol ([^{3}H]PI) was prepared and incubated in the presence or absence of ATP, $MgCl_2$ and Triton X-100, and the appearances of radioactivity in [^{3}H]lysoPIP and [^{3}H]phosphatidylinositol phosphate ([^{3}H]PIP), respectively, were monitored using thin layer chromatography. Both lysoPI and PI phosphorylations were completely dependent upon the presence of ATP and $MgCl_2$ in the incubation medium; Triton X-100 addition stimulated both reactions, with the stimulation of PI conversion being considerably greater than that for lysoPI conversion. The present results demonstrate that lysoPI can be converted to lysoPIP by phosphorylation in human platelet microsomes. The potential significance of this enzymatic reaction in stimulated cells is discussed in relation to the generation of inositol-1,4,5-trisphosphate, an important intracellular second messenger.
Lipids 22, 144–147 (1987).

Extensive research has been done on the metabolism of polyphosphoinositides. This has included investigations on phosphatidylinositol (PI) and phosphatidylinositol-4-phosphate (PIP) kinase activities as well as the actions of phosphodiesterases and phosphomonoesterases in mammalian cells (1–8). However, by comparison, very little work has been done investigating the metabolism of the lysophosphoinositides. Of the studies performed, most pertain to lysophosphatidylinositol (lysoPI) and its acylation to PI via microsomal acyltransferase activity (9–11); little information is available on the metabolism of the lysopolyphosphoinositides, lysophosphatidylinositol-4-phosphate (lysoPIP) and lysophosphatidylinositol-4,5-bisphosphate (lysoPIP$_2$). With respect to these latter lipids, Palmer (12) has shown that they are not reacylated when incubated with radioactive arachidonic acid, but do undergo a rapid dephosphorylation to lysoPI when incubated with rat brain or liver microsomes. He also concluded that neither the lysopolyphosphoinositides nor the lysoPI derived from them were degraded by acyl hydrolases or phosphodiesterases. Recently, Murase and Okuyama (13) have reported a membrane-bound phospholipase C in porcine platelets with an apparent specificity for lysoPI.

The stimulation of platelets with thrombin, collagen or Ca^{2+} ionophore (14–16) results in the production of lysoPI via the phospholipase A_2-mediated breakdown of PI. Based on previous work in mammalian cells, the fate of the newly formed lysoPI could involve reacylation to PI (9–11), deacylation to glycerophosphorylinositol (17) or degradation by phosphodiesterase activity (13). Since PI is interconvertible with PIP and PIP$_2$ via a phosphorylation-dephosphorylation cycle, it was of interest to determine if another potential metabolic fate might involve the enzymatic phosphorylation of lysoPI to lysoPIP. For this purpose, radiolabeled lysoPI was prepared and incubated with platelet microsomes. Parallel incubations containing radiolabeled PI were conducted for comparison.

MATERIALS AND METHODS

Materials. [2-^{3}H]Glycerol (200 mCi/mmol) was obtained from New England Nuclear Corp. (Boston, Massachusetts). Phospholipase A_2 (*Crotalus adamanteus* snake venom), Triton X-100, adenosine triphosphate (ATP) and lipid standards were purchased from Sigma Chemical Co. (St. Louis, Missouri). Blood collection bags were from Travenol Canada (Mississauga, Ontario, Canada). Precoated thin layer chromatography (TLC) plates (silica gel 60) were purchased from E. Merck, associate of BDH Chemicals Canada Ltd. (Toronto, Ontario, Canada). All chemicals and solvents were of analytical grade. Siliconized glassware was used during the isolation and incubation of platelets.

Preparation of substrates. For the preparation of [^{3}H]PI, blood samples were drawn from the antecubital vein of human donors into blood collection bags containing 63 ml of an anticoagulant solution (2.0 g dextrose, 1.7 g sodium citrate, 206 mg citric acid, 140 mg monobasic sodium phosphate, 17 mg adenine). The blood was centrifuged at 250 × g for 7 min at 22 C. The platelet-rich plasma (PRP) was removed and 100 mM Na_2EDTA was added (10 ml per 150–180 ml PRP obtained from each donor). After the PRP was spun at 2000 × g for 15 min at 22 C, the platelets from each donor were resuspended in 15 ml of platelet-poor plasma and incubated with [2-^{3}H]glycerol (2.0 mCi) for 3.5 hr at 37 C. The tubes were cooled on ice and centrifuged at 2000 × g for 15 min at 4 C. The platelets were then resuspended in a Tris/saline buffer (2 mM Na_2EDTA, 0.15 M NaCl, 0.02 M Tris hydroxy methyl aminomethane, pH 7.4) and recentrifuged at 2000 × g for 15 min at 4 C. The final platelet pellet was resuspended in a glucose buffer (134 mM NaCl, 15 mM Tris hydroxy methyl aminomethane, 5 mM glucose, pH 7.4) before extraction of the lipids by the method of Bligh and Dyer (18). After removal of the lower chloroform phases, the remaining upper phases were reextracted with additional chloroform and the extracts were combined. The lipid extracts were dried under N_2 to smaller volumes, spotted on precoated silica gel 60 plates and developed in chloroform/methanol/acetic acid/water (50:37.5:3.5:2, v/v/v/v) to separate the individual phospholipids. The plates were sprayed with 2′,7′-dichlorofluorescein in methanol/water (50:50, v/v) and exposed to ammonia vapor followed by acetic acid vapor before lipid bands were viewed under UV light. The [^{3}H]PI band was scraped from the plate and eluted by the method of Arvidson (19). The specific activity was determined by taking aliquots for scintillation counting and gas liquid chromatographic analysis of the derived fatty acid methyl esters in the presence of an internal standard (20).

*To whom correspondence should be addressed.

Unlabeled PI was obtained from rat liver extract (obtained by the method of Folch et al. [21]) using the above isolation and elution methods.

The [^{3}H]lysoPI was obtained by incubating [^{3}H]PI with a phospholipase A_2 solution. An aliquot of [^{3}H]PI was added to a tube and dried under N_2. After the addition of 15 µl phospholipase A_2 (5 mg/ml of 50 mM Tris-HCl, 5 mM $CaCl_2$, pH 7.4) and 1.5 ml anhydrous ether, the tube was shaken on a metabolic shaker for 4 hr at 22 C. The reaction was stopped by drying under N_2 and adding 100 µl chloroform/methanol (2:1, v/v). The [^{3}H]lysoPI was isolated by the phospholipid TLC method described previously and eluted by a modification of the Bligh and Dyer method (18) as described by Allan and Michell (22). After removal of the chloroform phase, the remaining upper phase was reextracted twice with additional chloroform and the three extracts were combined. The specific activity of the [^{3}H]lysoPI was determined as for [^{3}H]PI. Similar procedures were performed to obtain unlabeled lysoPI from rat liver PI.

Preparation of microsomes. The isolation and washing of platelets from human donors was performed as described above. The final platelet suspension was placed in an ice-cooled container and sonicated at 100 watts three times for 30 sec (with cooling on ice for 15-sec intervals). The sonicated platelets were centrifuged at 3000 × g for 30 min at 4 C to remove the unbroken cells. The supernatant so obtained was spun at 105,000 × g for 60 min at 4 C. The microsomal pellet was homogenized in a sucrose buffer (0.25 M sucrose, 0.01 M Tris hydroxy methyl aminomethane, pH 7.5), quick frozen using acetone and dry ice, and stored at −80 C until needed for the incubations. Protein concentration was determined on the platelet microsomes by the method of Lowry et al. (23), using bovine serum albumin (Calbiochem, La Jolla, CA) as the standard.

Enzyme assays. Unless indicated otherwise in the text, the standard incubation mixture contained 50 mM Tris hydroxy methyl aminomethane (pH 7.4), 25 nmol substrate ([^{3}H]PI or [^{3}H]lysoPI; 50,000 cpm), 3 mg microsomal protein, 2 mM ATP, 30 mM $MgCl_2$ and 0.25% Triton X-100 in a final volume of 3 ml. The substrates were appropriate mixtures of labeled and nonlabeled compounds. [^{3}H]PI or [^{3}H]lysoPI and Triton X-100 in Tris buffer were preincubated for 5 min at 30 C before initiating the reactions by the addition of microsomal protein, ATP and $MgCl_2$. Incubations were normally conducted for 12 min at 30 C, unless otherwise stated, in a shaking water bath. After stopping the reactions with 11.25 ml chloroform/methanol/concentrated HCl (100:200:5, v/v/v), the lipids were extracted as described earlier for [^{3}H]-lysoPI. The lipid extracts were dried under N_2 to 25–30 µl, spotted on precoated silica gel 60 plates and developed in chloroform/methanol/8 M ammonium hydroxide/water (45:35:8:4, v/v/v/v) for the separation of the polyphosphoinositides and their lyso derivatives. The lipid bands were detected as before and scraped into scintillation vials to which 1.5 ml water and 13.5 ml Aquasol-2 (New England Nuclear) were added prior to counting using a Beckman LS7800 scintillation counter (Beckman, Irvine, California). When calculated, the percent conversions of PI and lysoPI to their corresponding phosphorylated products were determined based upon the radioactivities in the substrate regions of the TLC plate from control (zero-time) incubations and the increased radioactivities found in the product regions of the TLC plate from 15-min incubations.

RESULTS

The distributions of radioactivity among the polyphosphoinositides of human platelet microsomes incubated with either [^{3}H]PI or [^{3}H]lysoPI are given in Table 1. With ATP, $MgCl_2$ and Triton X-100 in the incubation medium, the formation of PIP and lysoPIP occurred when PI and lysoPI, respectively, were the substrates. There was an

[a]PI, phosphatidylinositol; lysoPI, lysophosphatidylinositol; PIP, phosphatidylinositol phosphate; lysoPIP, lysophosphatidylinositol phosphate; PIP_2, phosphatidylinositol bisphosphate; lysoPIP_2, lysophosphatidylinositol bisphosphate. Each incubation (3 ml) contained 25 nmol substrate, 3 mg microsomal protein and, where indicated, 2 mM ATP, 30 mM $MgCl_2$ and 0.25% Triton X-100. Incubations were performed at 30 C for 15 min. Results are from a single experiment.

[b]A zero-time incubation served as control.

11.1% and 2.7% conversion of PI and lysoPI, respectively, to their phosphorylated products under the specific conditions used. In separate experiments with 25 nmol PI or 22 nmol lysoPI, the conversions to PIP or lysoPIP were 12.3% and 2.4%, respectively (data not shown). These results indicate that PI conversion to PIP was at least four times greater than that of lysoPI to lysoPIP. Both the PI and lysoPI kinase reactions were completely dependent upon the presence of ATP and $MgCl_2$ in the incubation medium. The detergent Triton X-100 exhibited a stimulatory effect on both reactions, as evidenced by the decreased formations of PIP and lysoPIP when Triton X-100 was removed from the medium. The stimulation of PIP formation by Triton X-100 was four times greater than the stimulation of lysoPIP formation. Without Triton X-100 in the incubation medium, there was an equal amount of PIP and lysoPIP formed (0.307 nmol and 0.305 nmol, respectively) from PI and lysoPI.

Figure 1 shows the time course for the synthesis of PIP and lysoPIP by PI kinase and lysoPI kinase activities, respectively. In general, PIP and lysoPIP formations increased steadily with reaction times up to 30 min, with the latter apparently approaching a plateau at 12 min. Based on these results, incubation times of 12 min were used routinely for studying the effect of microsomal protein and substrate concentrations.

The influence of microsomal protein concentration on the formation of PIP and lysoPIP is shown in Figure 2.

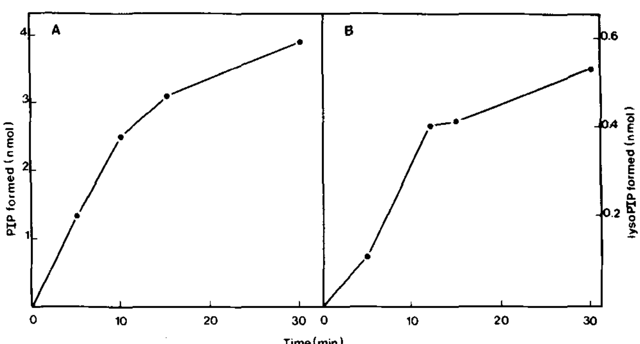

FIG. 1. Effect of incubation time on PIP (A) or lysoPIP (B) synthesis. Standard assay mixtures (as described in Materials and Methods) were incubated for 0–30.

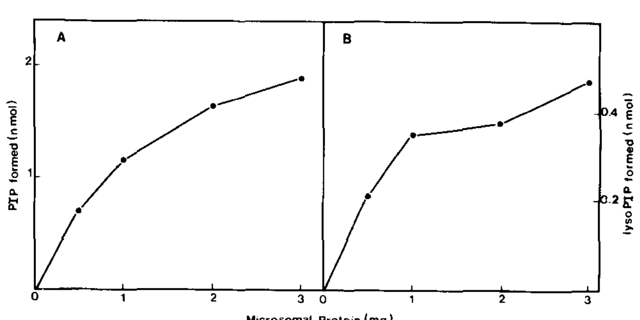

FIG. 2. Effect of microsomal protein concentration on PIP (A) or lysoPIP (B) synthesis. Assay procedures were as described in Materials and Methods except that incubations were performed using 0–3 mg microsomal protein.

The synthesis of PIP and lysoPIP increased progressively with microsomal protein concentrations up to 3 mg. Figure 3 shows the effect of increasing substrate concentration on product formation. There was a linear increase in the production of PIP with increasing PI concentrations, while there was a steady but nonlinear increase in lysoPIP synthesis as lysoPI concentrations increased. Even at the highest substrate concentrations, PIP and lysoPIP formations did not reach a plateau.

DISCUSSION

Previous reports have demonstrated the activity of PI kinase in a number of cell types (1–4). In the present work, we have demonstrated the conversion of lysoPI to lysoPIP in human platelet microsomes via a kinase activity with an obligatory dependency upon ATP and $MgCl_2$. This is of interest since little information is available on the presence of lysoPIP in tissues. In addition, our results indicate the presence of PI kinase activity in platelet microsomes.

The detergent, Triton X-100, exhibited stimulatory effects on the conversions of both PI and lysoPI to their corresponding phosphorylated products (Table 1). This is in agreement with previous work utilizing membranes from liver (24) or plant cells (25) where PIP formation was stimulated by the addition of Triton X-100 and exogenous PI. Without Triton X-100, there was an equal formation of PIP and lysoPIP from their respective substrates, but when Triton X-100 was included in the incubations, PI phosphorylation was stimulated to a much greater extent than lysoPI phosphorylation. This may reflect differences in the solubilities of the substrates, the accessibility to the membrane-bound enzyme and/or the solubilization(s) of enzyme and substrate. It is interesting that upon addition of PI or lysoPI to the microsomal preparation in the absence of Triton X-100, there was a net positive change in the radioactivity associated with the PIP_2 and $lysoPIP_2$ regions, respectively. With Triton X-100 included in the incubation medium, these changes in radioactivity were not observed. Previous studies (3,26) have demonstrated an inhibitory effect of Triton X-100 on PIP phosphorylation to PIP_2. The increased radioactivity in $lysoPIP_2$ in the incubation without Triton X-100 was

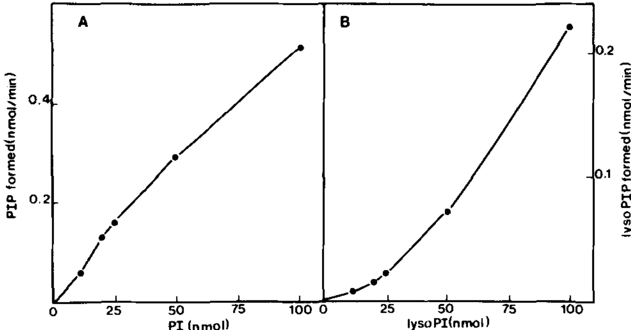

FIG. 3. Effect of substrate concentration on the rate of synthesis of PIP (A) or lysoPIP (B). Assay procedures were as described in Materials and Methods except that incubations were performed using substrate concentrations of 12–100 nmol. Substrates were incubated for 7 or 12 min to determine reaction rates. Zero-time and zero-protein incubations served as controls.

small and insignificant. Whether incubating microsomes with lysoPIP, under conditions favoring PIP_2 synthesis, would result in the formation of $lysoPIP_2$ remains to be determined.

It remains to be studied whether separate kinase enzymes are involved in the phosphorylations of PI and lysoPI. The kinetics of both reactions (Figs. 1-3), although similar, differed in some respects. It may be that the PI kinase enzyme acts on lysoPI as well as PI, but possesses different characteristics toward each substrate. In this regard, Palmer (12) has shown that brain and liver microsomes dephosphorylate the lysopolyphosphoinositides, $lysoPIP_2$ and lysoPIP, and has speculated that the phosphatases responsible are most likely the PIP_2 and PIP phosphatases, respectively. In the case of phospholipase C, separate enzymes appear to act on PI and lysoPI, based upon recent work in porcine platelets (13).

The formation of lysoPIP from lysoPI is a potentially important finding. It has been shown in platelets stimulated with thrombin, collagen or the Ca^{2+} ionophore, A_{23187} (14-16), that the lysoPI level increases, presumably due to a phospholipase A_2-mediated breakdown of PI. From the work reported herein, it can be speculated that some of the newly formed lysoPI could be phosphorylated to lysoPIP. If lysoPIP were formed in intact platelets or mammalian cells, it may be phosphorylated to $lysoPIP_2$ by kinase activity. Subsequent degradation of $lysoPIP_2$ via a phospholipase C activity, analagous to that reported toward lysoPI (13), would result in the formation of monoacylglycerol and inositol-1,4,5-trisphosphate (IP_3). IP_3 has been implicated as a second messenger (27,28) in the mobilization of intracellular Ca^{2+} following agonist stimulation of a variety of cell types, including platelets (29,30), and the subsequent phospholipase C-mediated breakdown of PIP_2. Alternative fates for lysoPIP could include dephosphorylation to lysoPI (12), hydrolysis via phospholipase C to monoacylglycerol and inositol-1,4-bisphosphate, or deacylation/reacylation reaction(s).

In conclusion, we have shown that lysoPI can be converted to lysoPIP by enzymatic phosphorylation in platelet microsomes. The presence and importance of lysoPIP formation in other stimulated and unstimulated mammalian cell types remains to be investigated.

[Received August 22, 1986]

Effect of Hypothyroidism on the Lipid Composition of Rat Plasma and Erythrocyte Membranes

F.M. Ruggiero*, G.V. Gnoni and E. Quagliariello
Department of Biochemistry and Molecular Biology and C.N.R. Unit for the Study of Mitochondria and Bioenergetics, University of Bari, Bari, Italy

The effect of hypothyroidism on plasma and erythrocyte membrane lipid components has been investigated. This pathological state is accompanied by a) a cholesterol increase of about 60% in plasma, and at the same time a 22% reduction in erythrocyte membranes; b) 44% and 30% phospholipid level decreases in both plasma and red cell membranes, respectively; and c) almost unaffected phospholipid and fatty acid compositions of both plasma and erythrocyte membranes. All changes were corrected by treatment of the hypothyroid rats with triiodothyronine for two days. These findings suggest that in hypothyroid rats a reduced transfer of cholesterol from plasma to erythrocyte membrane probably takes place. This could explain, at least in part, the increased hematic cholesterol level observed in hypothyroid animals. In red cell membranes, the simultaneous decrease in cholesterol and phospholipid levels does not alter the cholesterol/phospholipid molar ratio, thus avoiding their abnormal function.
***Lipids 22,* 148–151 (1987).**

Lipids are essential structural components in the membranous structure of cells. The cholesterol to phospholipid (C/P) ratio in the erythrocyte membrane is usually regulated to maintain proper membrane fluidity for normal functioning of the cell. Since erythrocytes have a relatively insignificant degree of cholesterol synthesis (1), the exchange of cholesterol between plasma and erythrocytes is very active both in vivo and in vitro (2). Recently Lange et al. (3,4) have reported a new effect of cholesterol in determining the stability of membrane contour so as to prevent endocytosis.

In biological membranes, phospholipids are asymmetrically arranged, and their exchange between plasma lipoproteins and red cell membranes is very active (5). It has been reported that thyroid hormones affect both plasma cholesterol concentration, hepatic metabolism and cholesterol synthesis (6–8). Recently we have shown the alteration induced by hyperthyroidism on the lipid composition of plasma and erythrocyte membranes (9) as well as on rat liver mitochondria and microsome lipid pattern (10).

The present study was designed to investigate the effects of 6-n-propyl-2-thiouracil (PTU)-induced hypothyroid state on the lipid pattern in both plasma and erythrocyte membranes. The data obtained indicate that in plasma from hypothyroid rats there is an increased cholesterol concentration and a phospholipid decrease. In erythrocyte membranes of the same animals the decrease of cholesterol content, accompanied by a decrease of phospholipids, does not significantly alter the C/P molar ratio. All of the changes were corrected by treatment of the hypothyroid rats with triiodothyronine (T_3) to render them euthyroid. The phospholipid composition as well as the pattern of total fatty acids both in plasma and in erythrocyte membranes is unchanged by propylthiouracil treatment. These results add insight into the role of thyroid hormones in regulating the cholesterol and phospholipid levels in plasma by the active change taking place between plasma and erythrocyte membranes.

MATERIALS AND METHODS

Animals. Male Wistar rats (200–250 g) fed ad libitum with a standard diet were used and divided into three groups: group 1, normal rats (euthyroid); group 2, rats made hypothyroid by adding PTU (0.1% in tap water) for 3–4 weeks (11) (hypothyroid); group 3, rats made hypothyroid injected intraperitoneally with 3,3′,5-L T_3 (25 μg/100 g body weight) dissolved in 0.9% NaCl/propyleneglycol (40:60, v/v) twice daily to render them euthyroid (treated-hypothyroid) (12). The animals were killed by decapitation, and the blood was collected in a beaker with EDTA as anticoagulant and centrifuged at 750 × g for 7 min. Erythrocytes were washed four times with a buffer containing 140 mM NaCl, 5 mM KCl, 1 mM $MgSO_4$, 1 mM $CaCl_2$, 1 mM NaH_2PO_4, 10 mM Tris and 5 mM glucose, pH 7.4. Hemoglobin-free erythrocyte membranes were prepared according to the method of Dise et al. (13) by hypotonic hemolysis in 80 ml of 10 mM Tris, pH 7.4, isolated by centrifugation and washed four times with the same buffer.

High pressure liquid chromatography (HPLC) analysis of cholesterol, phospholipids and fatty acids. Cholesterol, phospholipids and fatty acids were analyzed by HPLC, using a Beckman 344 gradient liquid chromatography equipped with a Perkin-Elmer LC-55B spectrophotometric detector.

To determine cholesterol (free and total), the chromatographic column was Altex ultrasphere-ODS, reverse phase (4.6 × 250 mm) from Beckman (Palo Alto, California). Free cholesterol was determined in plasma by the method of Duncan et al. (14). The mobile phase was 2-propanol/acetonitrile/water (60:30:10, v/v/v) at a flow rate of 1 ml/min. For total cholesterol determination, both plasma and erythrocyte ghosts were saponified with alcoholic KOH for 60 min at 45 C and extracted with hexane. Then the extract was evaporated and the residue dissolved in 2-propanol, an aliquot of which was injected into the column. The mobile phase was 2-propanol/acetonitrile (50:50, v/v) at a flow rate of 1 ml/min (14).

For fatty acid analysis, both plasma and erythrocyte membranes were saponified for 15 min at 90 C with 5 ml of 5% KOH in 50% aqueous methanol. The solution was then acidified and extracted with chloroform, taken to dryness and esterified with m-methoxy-phenacyl bromide (15). The chromatographic column was Altex ultrasphere-ODS, reverse phase (4.6 × 250 mm) from Beckman. The mobile phase was tetrahydrofuran/acetonitrile/water (45:25:35, v/v/v) at a flow rate of 2 ml/min. For estimation of a single fatty acid concentration, the calculated

peak areas were compared with areas of each fatty acid standard solution.

Total lipids from plasma and erythrocyte membranes were extracted with chloroform/methanol by the procedure of Bligh and Dyer (16). A portion of this extract was digested at 180 C with perchloric acid, after which lipid phosphorus content was determined by the Nakamura method (17). Phospholipids were separated by the HPLC method previously described (10) with an Altex ultrasil-Si column (4.6 × 250 mm) from Beckman. The chromatographic system was programmed for gradient elution using two mobile phases: solvent A, hexane/2-propanol (6:8, v/v) and solvent B, hexane/2-propanol/water (6:8:1.4, v/v/v). The percentage of solvent B in solvent A was increased in 15 min from 0% to 100%. Flow rate was 2 ml/min and detection was at 206 nm. The quantitative estimation of single phospholipid species was carried out by comparing the calculated peak areas with those of each phospholipid standard solution.

RESULTS

The effect of PTU-induced hypothyroidism on plasma free and esterified cholesterol is illustrated in Table 1. The data reported show that both plasma free and esterified cholesterol are increased by about 60% in PTU-treated rats with respect to euthyroid animals. The table also reports plasma concentration of total phospholipids in euthyroid and hypothyroid rats. In the latter, a 44% total phospholipid decrease with respect to euthyroid animals can be observed. The increase of both free and esterified cholesterol and the decrease of phospholipids in hypothyroidism all reverted to normal after two days of T_3 therapy.

Table 2 reports the concentration of total cholesterol and phospholipids in erythrocyte membranes of euthyroid, hypothyroid and treated-hypothyroid rats. From this table, both cholesterol and phospholipids can be seen to decrease by about 22% and 30%, respectively. After T_3 treatment, these changes reverted to normal. It is worth pointing out that the similarity in percentage decrease of both compounds allows the C/P molar ratio to remain almost unchanged in erythrocyte membranes of hypothyroid rats.

Table 3 shows that the individual plasma phospholipids decreased in an approximately parallel manner so that the phospholipid composition was not significantly altered by the hypothyroid state. As observed in plasma, the erythrocyte membrane phospholipid composition is unaffected by PTU treatment.

Lastly, Table 4 reports the mol % distribution of each fatty acid both in plasma and in erythrocyte membranes. It can be seen that the pattern of fatty acids in plasma and in erythrocyte membranes is similar in both euthyroid and hypothyroid rats.

DISCUSSION

It has been shown that administration of PTU to rats reduces the circulating thyroid hormone concentration by about 90% (6). To clarify the influence of the thyroid state on lipid components of plasma and erythrocyte membranes,

TABLE 1

Effect of Propylthiouracil Administration on Cholesterol and Phospholipid Content in Rat Plasma

Animals	Free cholesterol[a]	Increase (%)	Esterified cholesterol[a]	Increase (%)	Phospholipids[a]	Decrease (%)
Euthyroid	0.82 ± 0.12	—	1.85 ± 0.30	—	1.35 ± 0.22	—
Hypothyroid	1.33 ± 0.14[b]	62.2	3.06 ± 0.24[b]	65.4	0.75 ± 0.17[b]	44.4
Treated-hypothyroid	0.85 ± 0.14	—	1.90 ± 0.29	—	1.30 ± 0.20	—

[a]Each value represents the mean ± S.E. obtained for 6 experiments with 5 rats each. Free and esterified cholesterol are expressed as μmol/ml; phospholipids are expressed as μmol lipid Pi/ml. P values vs euthyroid rats were calculated by Student's t-test.

euthyroid, hypothyroid and treated-hypothyroid rats have been used. In agreement with other authors (6,7), we have found that PTU-induced hypothyroidism enhances rat plasma cholesterol content. On the contrary, in erythrocyte membranes of the same animals, there is a significant decrease of both cholesterol and phospholipid contents. As is well known, the exchange of cholesterol between lipoproteins and erythrocytes is very active both in vivo and in vitro (2,18). Recently we have reported that following T_3 administration to rats, a major cholesterol transfer from plasma to erythrocytes takes place (9). The results reported here confirm our previous hypothesis that the rate of cholesterol transfer from plasma to erythrocytes could depend on, among other factors, circulating thyroid hormone level, i.e., it increases in hyperthyroid rats but is inhibited in the PTU-treated ones. Correction of this cholesterol transfer following two days of thyroid hormone therapy adds further support to this hypothesis.

Another interesting result that emerges from the present work is the decrease in phospholipid content observed both in plasma and in erythrocyte membranes of hypothyroid rats (see Tables 1 and 2). This could probably be attributed to a reduced availability of fatty acids to their decreased hepatic synthesis (19), as well as to an association between the regulation of phospholipid synthesis and the assembly and release of lipoproteins from the liver (20). These data further confirm our earlier studies (9) showing a divergence in the metabolic response to thyroid hormones between phospholipids and cholesterol. A similar difference between plasma cholesterol and triglycerides has also been observed in hypothyroid rats and was found to be connected to a decrease in plasma very low density lipoproteins (VLDL) and to an increase of low density lipoproteins (LDL) and high density lipoproteins (HDL), while intermediate density lipoproteins (IDL) remain constant. Since plasma and erythrocyte phospholipids are in equilibrium, due to the active exchange between the two pools of compounds (22), the lower erythrocyte phospholipid content of hypothyroid rats depends on their reduced plasma concentration.

Distribution of cholesterol within the various lipoprotein classes has been reported by Dory and Roheim (6). These authors have found the greatest increase in cholesterol concentrations in LDL and HDL, although VLDL and IDL also contained higher concentrations,

whereas the decrease in plasma phospholipid concentrations is primarily due to a decrease of phospholipids in HDL fraction (data not reported).

Finally, our results show that an altered circulating thyroid hormone level induces only quantitative changes in the lipids of rat blood. These changes imply that thyroid hormones, or a lack of them, affect both the metabolism process and the lipid distribution.

[Received May 23, 1986]

Role of the Lymphatic System in the Transport of Absorbed 7,12-Dimethylbenzanthracene in the Rat

J.M. Laher and **J.A. Barrowman***
Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3V6

To determine the role of the intestinal lymphatic system in the absorption of a polycyclic aromatic hydrocarbon, 7,12-dimethylbenzanthracene, a radiolabeled preparation of the compound was given by intraduodenal infusion to rats in doses of 10 μg, 10 mg and 20 mg in olive oil solution. The hydrocarbon appeared to be absorbed from the intestine in a fractional manner, ca. 20% of the administered radioactivity being recovered totally in bile and intestinal lymph in 24 hr at all three dose levels. Biliary radiolabel accounted for 75–82% of combined recovery of radioactivity in bile and lymph with all three doses. The recovery of significant amounts of radiolabel in bile before the appearance of isotope in lymph, together with the fact that the biliary radiolabel greatly exceeded at all times the lymphatic recovery of isotope, suggests that an alternative pathway, presumably the portal venous route, is of major importance in the transport of the absorbed hydrocarbon.
Lipids 22, 152–155 (1987).

Polycyclic aromatic hydrocarbons (PAH), composed of three or more fused benzene rings, form a class of highly lipophilic substances of considerable toxicological interest. Among the members of this class are several compounds such as benzo(a)pyrene, 3-methylcholanthrene and 7,12-dimethylbenzanthracene, which on metabolic conversion become potent carcinogens. These compounds are found in significant amounts in certain foods, such as smoked meats and fish (1,2). They are readily absorbed by the gastrointestinal tract, metabolized by phase I and II reactions and excreted mainly by the biliary route as water-soluble forms (3–7). These biliary metabolites are substantially reabsorbed in the intestine and re-excreted; thus, there is a considerable enterohepatic circulation of the metabolites of absorbed PAH (6–8). Because of their high lipophilicity and their administration in lipid meals in studies of absorption in animals, it has been considered that a major route for their transport is as solutes in the liquid triglyceride core of lymph chylomicrons (9–14). However, since the 1960s, the intestine has been known to have a considerable capacity for metabolism of PAH (15), and metabolites formed during the absorptive step are known to be transported in the portal vein (16).

The relative importance of the two routes of transport, portal venous vs lymphatic, for PAH absorbed from the intestine is not known, nor is it known whether the proportions of the absorbed compound transported by these routes vary with the load of compound presented for absorption. The route of transport may be important in the ultimate disposition of these compounds in the body since lymphatic transport affords access to the systemic circulation bypassing the liver.

The present study was undertaken to examine the importance of the lymphatic route in the absorption of 7,12-dimethylbenzanthracene (DMBA) and to determine whether a fixed or variable proportion of the absorbed PAH is transported by the lymphatic route.

MATERIALS AND METHODS

Preparation of test meals. DMBA (98% pure) was obtained from Sigma Chemical (St. Louis, Missouri). (G-^{3}H)-DMBA (43 Ci/mmol; 92.4% pure by thin layer chromatography) was purchased from Amersham Corp. (Oakville, Ontario, Canada). Olive oil, obtained from Diamond Brand Manufacturers (St. John's, Newfoundland, Canada), was found by gas liquid chromatography to be composed primarily of glycerides of oleic (80%), linoleic (9%) and palmitic acids (10%).

Toluene solutions of ^{3}H-DMBA and DMBA were combined in glass vials protected from light and were evaporated to dryness under nitrogen. Olive oil was added to DMBA preparations to achieve final DMBA concentrations of 10 μg (12.5 μCi ^{3}H), 10 mg (12.5 μCi ^{3}H) or 20 mg (12.5 μCi ^{3}H) per ml of oil. Olive oil was chosen as the vehicle since this carrier triglyceride preparation had been used in our previous studies of DMBA absorption (8). The solutions were kept in the dark for 18 hr and examined visually for undissolved hydrocarbon, then were combined with pooled rat bile to yield a final oil to bile ratio of 2:1 (v/v). These mixtures were vortexed to emulsify the preparations, and aliquots of each were taken for liquid scintillation counting. Volumes of 1.5 ml were drawn up into syringes that were weighed prior to and following test meal administration.

Animal surgery. Male Sprague-Dawley rats (275–325 g) were purchased from Charles River Breeding Laboratories (St. Constant, Quebec, Canada) and maintained with free access to food (Purina Rat Chow) and water under standard light and temperature conditions.

After a ventral midline abdominal incision was made under ether anesthesia, the main mesenteric lymphatic duct was exposed and cannulated with vinyl tubing (Dural Plastics and Engineering, Dural N.S.W., Australia; external diameter 0.80 mm, internal diameter 0.50 mm) by the method of Turner and Barrowman (17). The accessory intestinal lymph vessel was obliterated by cutting and application of cyanoacrylate glue to ensure complete collection of intestinal lymph. The common bile duct was cannulated above its confluence with the pancreatic ducts using polyethylene tubing (Clay Adams, Parsippany, New Jersey; PE-10, external diameter 0.61 mm, internal diameter 0.28 mm) and was secured with ligatures of 4 × 0 surgical silk as previously described (8). A saline-filled premature infant nasogastric feeding tube (size 5F, C.R. Bard Ltd., Mississauga, Ontario, Canada) was used to cannulate the duodenum by the method of Laher et al. (8). The lymphatic and biliary catheters were exteriorized through stab wounds in the right flank, while the duodenal catheter was exteriorized through the abdominal wound. The incision was then closed in two layers with silk sutures.

*To whom correspondence should be addressed.

Immediately following surgery, the animals were placed in restraining cages in a warm room (23 C) for overnight recovery. During this time they were infused intraduodenally with 0.9% NaCl at 2.5 ml/hr. Bile was collected during the first 5 hr and kept under refrigeration. If normal bile and lymph flow, as judged from values obtained in a large series of animals, were not achieved by the end of the 20-hr recovery period, an animal was rejected from the study. Normal flows for lymph and bile were considered to be approximately 1 ml/hr and 0.4 ml/hr, respectively.

Experimental procedure. Thirty-min control samples of bile and lymph were collected into preweighed vials (those for lymph contained sodium citrate to prevent clot formation). Each animal then received a 1.5-ml test meal (containing 10 μg, 10 mg or 20 mg DMBA and 12.5 μCi ^{3}H-DMBA) by intraduodenal infusion at a rate of 1.5 ml/hr. The residual mixture in the catheter was flushed in with a pulse of 0.5 ml bile and followed by an infusion of bile/saline (1:5, v/v) over the next 6 hr at a rate of 4.8 ml/hr. From the beginning of the control period, bile and lymph vials were changed every 30 min, weighed and analyzed for radioactivity. Over the following 17 hr, one collection was performed, during which time an intraduodenal saline infusion of 2.5 ml/hr was given. Following one additional 30-min collection period, the animals were killed by an anesthetic overdose and examined for patency of catheters.

Sample analysis. The volumes of lymph and bile obtained were calculated from their weight using a specific gravity of 1.00 for each. Duplicate 50-μl aliquots of both fluids were mixed with 10 ml Aquasol-2 scintillation cocktail (New England Nuclear, Lachine, Quebec, Canada) and counted in a Beckman LS8100 liquid scintillation counter. Quench was corrected using an external standard.

After removal of samples for analysis, the initial 7-hr lymph collections were pooled from two rats that had received the 20-mg dose of DMBA. The samples were diluted 3:1 with normal saline, and aliquots were removed for scintillation counting. The mixtures were then ultracentrifuged for 30 min in a Beckman 75Ti rotor at 30,000 rpm in a Beckman L2-65B ultracentrifuge. Following gentle aspiration of the creamy lipid layer, samples of the clear infranatant were taken for liquid scintillation counting.

To determine the proportion of radiolabel in the supernatant lipid layer, recovery of hydrocarbon was assessed by liquid scintillation with no differentiation between DMBA or its metabolites.

Statistical analyses were performed using an ANOVA and also Student's t-test for unpaired values where appropriate with significance established to be $p < 0.05$.

RESULTS

Figure 1 shows the appearance of radiolabel in lymph and bile for a 7-hr period following intraduodenal administration of a lipid test meal containing 12.5 μCi ^{3}H-DMBA and 10 μg, 10 mg or 20 mg of DMBA. Little radiolabel could be detected in lymph within 60 min of administration, in contrast to a significant presence of isotope in bile during the same time period. The figure shows the recoveries of radiolabel for each 30-min collection period. In the three groups, bile and lymph flows were similar (results not shown). By 2 hr post-administration, lymphatic radiolabel concentrations increased rapidly, although actual recoveries never exceeded those of bile for any dose of hydrocarbon. The 2-hr lag time in the appearance of significant lymphatic radiolabel coincides with the appreciable appearance of lipid-laden chylomicrons and an increase in lymph volume that follows the administration of fat. Lymphatic transport of tritium began to decline before peak biliary radiolabel was attained with the two smaller doses (Fig. 1). Peak radiolabel concentrations following 10 μg, 10 mg or 20 mg DMBA correspond to 32 ± 6 ng/ml, 36 ± μg/ml and 49 ± 16 μg DMBA equivalents per ml of lymph, respectively, while respective peak biliary radiolabel values represent 271 ± 62 ng/ml, 164 ± 22 μg/ml and 370 ± 80 μg DMBA equivalents per ml of bile.

Figure 2 illustrates the cumulative recovery of radiolabel in lymph and bile from all three doses. The rates of recovery from the lymph (given as a percentage of the

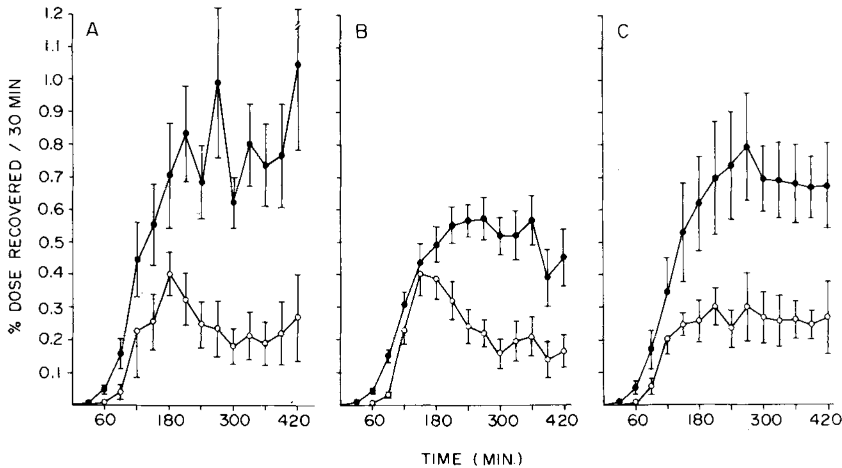

FIG. 1. Total recovery of radiolabel in bile and lymph over 7 hr as a percentage of administered radiolabel (^{3}H-DMBA) for doses of 10 μg (A), 10 mg (B) and 20 mg (C). Closed symbols, bile; open symbols, lymph. Each point represents the mean and SEM for six animals for the 10-μg and 10-mg doses and four animals for the 20-mg dose.

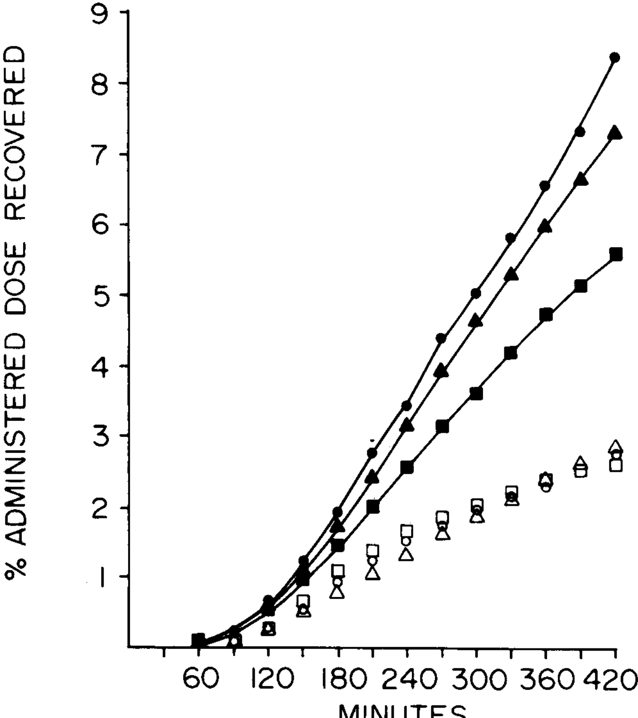

FIG. 2. Cumulative recovery of radiolabel over 7 hr in lymph (open symbols) and bile (closed symbols) for three doses of DMBA. Circles, 10 μg (six animals); squares, 10 mg (six animals); triangles, 20 mg (four animals).

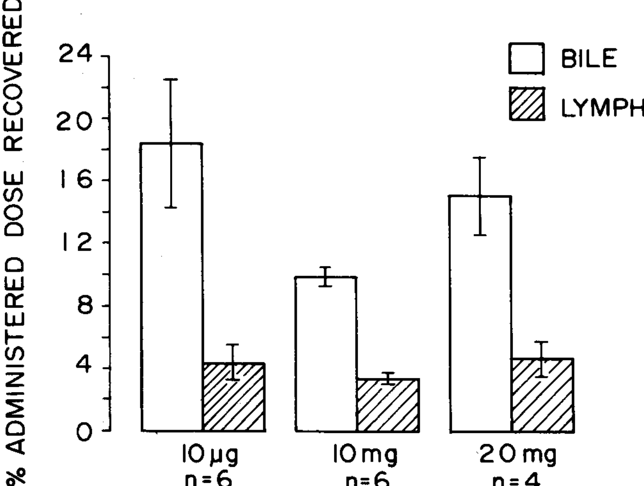

FIG. 3. Total 24-hr recovery of radiolabel in lymph and bile for three doses of DMBA (means and SEM).

administered dose) were nearly identical for all time points throughout the 7-hr study period. Radiolabel appeared in the bile at an approximately constant rate for each dose. These rates exceeded the corresponding lymphatic rates of transport of DMBA. The highest fractional rate of biliary radiolabel recovery occurred with the 10-μg DMBA dose.

The total biliary and lymphatic recovery of radiolabel in the 24 hr following test meal administration are given in Figure 3. Total percentage recoveries were not significantly different among the three doses by analysis of variance ($p > 0.05$), although recovery from the 10-mg dose as compared to the 10-μg and 20-mg doses was somewhat less ($p < 0.01$). Biliary radiolabel accounted for the greatest proportion of retrieved radiolabel, yielding bile to lymph ratios of 4.85 $\pm$ 0.75, 3.05 $\pm$ 0.22 and 3.53 $\pm$ 0.43 for the 10-μg, 10-mg and 20-mg dosages, respectively. The 10-μg dose exhibited a significantly higher bile to lymph ratio and percentage of recovered dose present in the bile than did the 10-mg dose of DMBA ($p < 0.05$), whereas values obtained from the 20-mg dose were not significantly different from either the 10-μg or 10-mg test meals of hydrocarbon ($p > 0.05$).

Significant levels of lymph radioactivity were only obtained once the lymph became turbid with particulate lipid. Following removal of this lipid from pooled lymph by ultracentrifugation, only 14.0 $\pm$ 1.3% of the original radiolabel remained in the infranatant.

DISCUSSION

PAH are lipophilic compounds with very low aqueous solubilities; for example, DMBA has a water solubility of 0.061 mg/l (18). PAH are relatively well absorbed from the gastrointestinal tract when presented in solution in nutrient lipids (9–14) or a solvent such as ethanol (16). Following absorption, DMBA is metabolized in the liver, excreted chiefly in the bile as glucuronide-conjugated metabolites (4,5) and ultimately eliminated in the feces. From the intestine, the compound is partially reabsorbed and reexcreted by the liver (8) in an enterohepatic circulation, which delays its elimination from the body.

There is evidence that following intestinal absorption, PAH are transported in both portal venous blood and lymph, but the proportions of the compounds carried by these two routes are not known. In one recent study of benzo(a)pyrene absorption in sheep, it was shown that the amounts of the compound appearing in systemic blood following intragastric administration in corn oil solution were negligible in animals with intestinal lymph fistulae; this was taken to indicate that lymph is of paramount importance in the transport of absorbed benzo(a)pyrene (14). However, systemic blood concentrations may be an unreliable index of absorption by the portal venous route if hepatic extraction of the compound or its metabolites is efficient. There are many studies that document the appearance of absorbed PAH in intestinal lymph (9–14), and the portal venous transport of metabolites of absorbed PAH is well established. For example, Bock et al. (16), using rat jejunum in situ, found that within 30 min of intraluminal instillation of benzo(a)pyrene dissolved in ethanol, portal blood contained 40% of administered radioactivity; more than 90% was in the form of metabolites.

It is of some importance to know the proportions of the compounds transported via the lymphatic route, since this affords access of the substance to the systemic circulation and extrahepatic tissues. Furthermore, it has been suggested that important interactions may occur between absorbed PAH and lymphoid cells during the passage of these compounds through the lymph and lymph nodes (14). Of interest also is the ultimate disposition of PAH that reach the systemic circulation via the lymph. These compounds might be deposited in peripheral tissues

during lipolysis of chylomicron triglyceride or might be transported to the liver for metabolism and excretion.

The present study was designed to determine what proportion of absorbed DMBA is transported in lymph and whether this is a fixed proportion or is variable and dependent on the mass of compound presented for absorption. The model used is an indirect means of assessing portal venous vs lymphatic transport and takes biliary excretion of metabolites in the presence of complete intestinal lymph diversion as a rough index of portal venous transport. This approach has been used to determine the relative importance of portal venous and lymphatic transport of absorbed nutrient lipids such as retinol in rats (19).

Our data show that over a 2000-fold range of dose of DMBA, the proportions of the compound (or its metabolites) leaving the intestine by the lymphatic route are relatively constant at about 20% of the total amount recovered in lymph and bile. Thus another pathway, presumably portal venous transport, appears to be more important. A recent study has come to a similar conclusion for absorbed benzo(a)pyrene (20). The factors determining the partition between lymph and portal venous blood are presently unknown. It has long been known that the intestinal epithelium can metabolize PAH and that the resulting metabolites are transported in portal venous blood (15,16). In intestinal lymph, the parent compound, DMBA, can be demonstrated as a solute in chylomicrons (unpublished results). The present study, however, has not attempted to determine the chemical form of DMBA or its derivatives in portal venous blood or lymph.

If the predominant form of DMBA in lymph were parent compound and in portal venous blood were in the form of more polar metabolites, one might have expected the compound's partition between portal venous blood and lymph to alter with increasing DMBA loads as the metabolic capacity of the enterocyte was exceeded, but such an effect was not observed in the present experiments. The situation, however, may be very complex, since it is possible that during the hours absorption was being studied the hydrocarbon may have induced the metabolizing enzymes of the enterocyte (21). Another factor remaining to be investigated is the role of the mass of carrier triglyceride, fixed at 1 ml in the present study, in determining the partition of DMBA between lymph and portal venous blood.

Results in the present study suggest that the absorption of DMBA over the large dosage range may be of fractional character, ~20% of the administered radioactivity being recovered in bile and lymph over 24 hr. It is presumed that the 80% unaccounted for represents unabsorbed material. Fractional absorption is observed with certain other lipids, such as sterols. Sylven and Borgström (22) found that an almost constant fraction (about 0.4) of various cholesterol doses, ranging from a trace to 100 μmol, is recovered in thoracic duct lymph. β-Sitosterol is absorbed in a similar fractional fashion (23). The explanation for this type of absorption is not presently known.

Nonenzymatic Hydrolysis of Phosphatidylcholine Prepared as Liposomes and Mixed Micelles

Rodney J.Y. Ho*, Mark Schmetz and David W. Deamer
Department of Zoology, University of California, Davis, CA 95616

Nonenzymatic hydrolysis of phosphatidylcholine was investigated at several pH ranges in liposomes and mixed micelles. Phosphatidylcholine was stable to hydrolysis for 140 hr at pH 4, 7 and 10, but slowly hydrolyzed at pH 1 with a half-time of 50 hr. We conclude that phosphatidylcholine is not significantly degraded by hydrolysis under conditions typical for liposome preparation methods.
Lipids 22, 156–158 (1987).

Although liposomes are increasingly used as model membrane systems in basic and applied research, relatively little is known about their chemical stability. Noncatalyzed hydrolysis of ester bonds linking fatty acyl groups to glycerol would be expected to be fairly slow, yet at least two earlier reports (1,2) have noted a rapid degradation of lipids upon exposure to ultrasonic irradiation. Furthermore, no systematic study has been done to determine long-term chemical stability of liposome in buffered solutions.

Products of degraded lipids such as fatty acids and lysophosphatides can increase bilayer permeability (3). Such alterations may be particularly important for clinical testing of liposome-based therapy (4) and immunoassays, since successful storage of encapsulated material is likely to depend on the stability of lipid.

It is generally agreed that liposomes are sufficiently stable to hydrolysis at neutral pH ranges, so that for most purposes the amount of hydrolysis occurring during preparation and storage times of several hours is negligible. However, in some procedures, lipid may be exposed to aqueous solutions for more than 24–48 hr, for instance, during preparation of liposomes by detergent dialysis (5,6). In other experiments, lipids in the form of planar lipid membranes (7) or liposomes (8) have been exposed to pH values ranging from 1 to 10 for periods of a few minutes to several days.

It is clearly important to know the relative extent of lipid hydrolysis under normal and extreme conditions. To address this question, we have exposed lipid in several physical states (small and large unilamellar liposomes, and mixed micelles in octylglucoside) to different pH ranges and monitored the appearance of hydrolysis products over time. We chose 1-palmitoyl-oleoyl-*sn*-glycerophosphorylcholine as the lipid because phosphatidylcholine is a commonly used lipid in model membrane systems. Furthermore, the presence of specific acyl groups permitted an estimate of the relative rates of hydrolysis at the 1- and 2-positions. Conditions of pH were chosen to represent the extreme values in the literature and included ranges near 1, 4, 7 and 10.

EXPERIMENTAL METHODS

Liposome preparation. 1-Palmitoyl 2-oleoyl phosphatidylcholine (POPC) was purchased from Avanti (Birmingham, Alabama). Large unilamellar vesicles (LUV) were prepared by the methods of Mimms et al. (5). In a typical experiment, 10 μmol POPC was solubilized with 100 μmol octylglucoside in the buffer to a final volume of 10 ml, then passed through a Bio Gel P6 column. Vesicles prepared by this method range around 0.1 μ in diameter. To prepare SUV, the LUV were sonicated in a bath sonicator for 10 min. For lipid in the form of mixed micelles, 10 μmol POPC was solubilized with 100 μmol octylglucoside in the appropriate buffer to a final volume of 10 ml.

We chose to use potassium phosphate solutions for the buffer, because phosphate has useful buffer capacity in the pH ranges used in the study. Stock solutions of the buffer were produced by appropriate mixtures of 0.1 M K_2HPO_4 and phosphoric acid. This provided the same initial conditions for extraction of all samples and placed free fatty acids in their acid (neutral) form to aid extraction. The samples were immediately extracted with 2 ml chloroform/methanol (2:1, v/v) containing myristic acid (50 μg/ml) as an internal standard. The samples were stirred by vortexing, followed by centrifugation (5 min, 1000 × g) to separate the chloroform phase. The upper aqueous phase was carefully removed and discarded, and the chloroform extract was stored at −10 C until analysis.

Before methylation of the free fatty acids, phospholipid was removed from the chloroform extract by filtration through small silicic acid columns (HiFloSil, BioRad) prepared in Pasteur pipettes. The fatty acids were eluted by passing two volumes of chloroform/methanol (1 ml each) through the column, and the eluates were taken to dryness under nitrogen. Methylation was carried out with boron trifluoride/methanol. Methyl esters were extracted from the methylation mixture with 2 ml diethyl ether. One ml of the ether extract was taken to dryness under nitrogen, and 100 μl of carbon disulfide was added to dissolve the esters. One-μl aliquots of the carbon disulfide solution were analyzed by gas liquid chromatography using a 10% SP-2330 Chromosorb column. The amount of each fatty acid present was determined from the ratio of peak areas to the internal standard peak area, followed by comparison with predetermined values to known peak ratios of the fatty acids.

One experimental series was designed to measure appearance of lysophosphatidylcholine (LPC) as a hydrolysis product. In this, POPC liposomes were prepared in 0.1 M K_2SO_4 by octylglucoside dialysis (5), then adjusted to pH 1.0 with 0.1 M phosphate buffer to a final lipid concentration of 1.0 mM. At increasing time intervals, 1-ml aliquots of the suspension were extracted with 2 ml of chloroform/methanol (2:1, v/v), and the chloroform layer was taken to dryness under nitrogen. The lipid was then dissolved in 150 μl of chloroform, and 2 μl was applied to a Chromarod, developed in chloroform/methanol/water (65:25:4, v/v/v) and analyzed with an Iatroscan instrument (9). The amounts of the separated lipid species were determined by comparison of integrated peak areas with known standards of POPC, LPC and fatty acids.

RESULTS AND DISCUSSION

Effect of pH and physical state on hydrolysis rates. The lipid dispersions were surprisingly stable to hydrolysis in the pH range of 4-10. At the start of the incubation period, ca. 1% of the total fatty acid was present as free fatty acid, and after 140 hr this figure had not significantly increased (Fig. 1). However, significant hydrolysis was observed at pH 1, and about 20% of the total fatty acid ester had been hydrolyzed after 140 hr. The physical state of the lipid did not markedly affect the hydrolysis rate, although there was a trend for lipid dispersed as micelles to be hydrolyzed at a slightly faster rate. Similar hydrolysis rates were also observed at pH 10 with egg phosphatidylethanolamine and bovine brain phosphatidylserine in the form of mixed micelles, LUV and SUV.

Effect of acyl chain position on hydrolysis rates. Figure 2 shows results for relative hydrolysis rates of acyl chains at the *sn*-1 and *sn*-2 positions. Within experimental error, we were unable to distinguish any differences in relative lability to hydrolysis at the two positions. It was possible that LPC was more labile to acid hydrolysis than POPC and that the lack of specificity of hydrolysis rate with respect to acyl chain position was simply due to rapid hydrolysis of LPC to glycerophosphorylcholine. Therefore, the accumulation of LPC at pH 1 was also monitored as described in Methods. We found that as POPC was hydrolyzed, both LPC and fatty acid accumulated at approximately equal rates (Fig. 3). We concluded that the appearance of fatty acid from the *sn*-1 and *sn*-2 positions did, in fact, reflect a nonspecific hydrolysis mechanism.

Comparison with earlier investigations. This report has established that POPC liposomes are reasonably stable to hydrolysis within pH ranges and incubation times (up to six days) used by other investigators. Only near pH 1 was significant hydrolysis observed, and this occurred

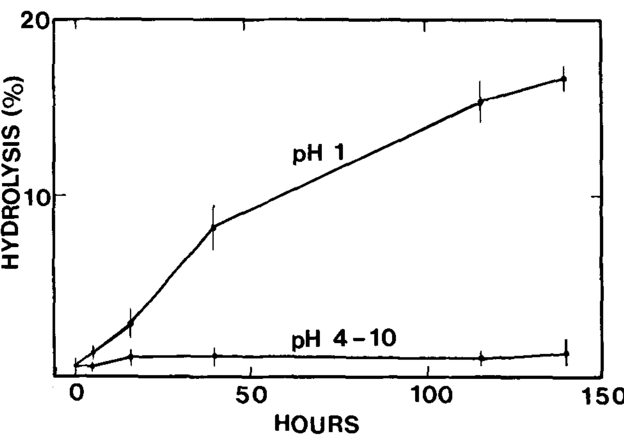

FIG. 1. Dependence of hydrolysis rate on pH. Phosphatidylcholine was dispersed as mixed micelles in octylglucoside and as small and large unilamellar liposomes, as described in Methods. The dispersions were incubated at pH ranges near 1, 4, 7 and 10 for periods up to 140 hr, and hydrolysis was monitored by the appearance of free palmitic and oleic acid in the medium. Since there were no significant differences for hydrolysis rates of lipid in different physical states, the data are summed and presented as mean ± S.D. Little hydrolysis was observed between pH 4 and 10 (lower line). At pH 1, significant hydrolysis occurred, and about 16% of the the total fatty acid was hydrolyzed after 140 hr incubation.

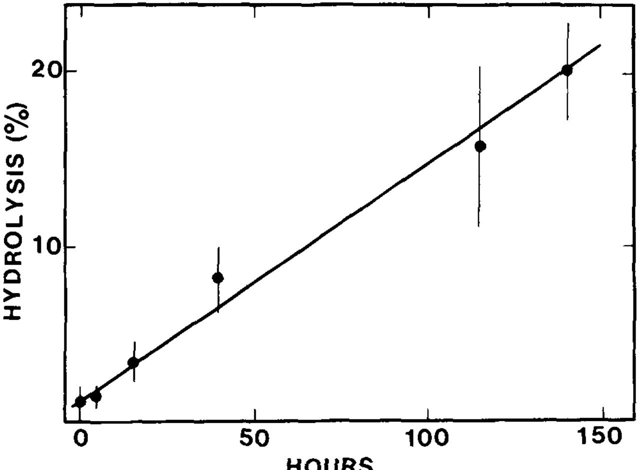

FIG. 2. Hydrolysis rates of palmitic and oleic acid from POPC. Figure shows summed data for palmitic and oleic acid present as mixed micelles of phosphatidylcholine, large unilamellar liposomes and small unilamellar liposomes at pH 1. There were no significant differences for hydrolysis rates of palmitic and oleic acid in the *sn*-1 and *sn*-2 positions, respectively, nor for physical state of the phosphatidylcholine, so each data point represents the mean ± S.D. of six different experiments. The data is presented as percentage of hydrolysis of each fatty acid, rather than as percentage of total fatty acid, as in Fig. 1.

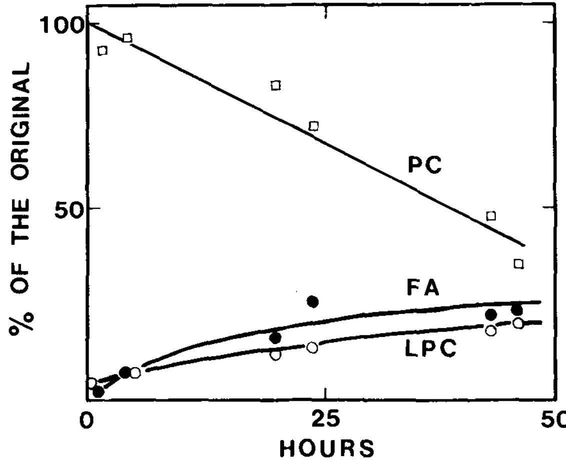

FIG. 3. Rates of POPC disappearance and appearance of LPCFA. In one experiment, both phosphatidylcholine and hydrolysis products were monitored during hydrolysis at pH 1. As phosphatidylcholine was hydrolyzed, fatty acids and lysophosphatidylcholine (LPC) appeared in the medium at approximately 1:1 stoichiometries, suggesting that LPC was not significantly more labile to hydrolysis than phosphatidylcholine.

randomly at the *sn*-1 and *sn*-2 positions. The hydrolysis rate was not markedly affected by the physical state of the lipid at this pH, and small and large unilamellar vesicles, as well as lipid dispersed as mixed micelles in octylglucoside, underwent hydrolysis at similar rates.

Two earlier studies reported results for nonenzymatic hydrolysis of phospholipid. These were not directed at establishing chemical stability of lipid dispersions, but rather to study reaction mechanisms. For instance, Wells (10) and Kensil and Dennis (11) used highly alkaline

conditions to study the effect of aggregation state on hydrolysis rates. In the latter report, lipid was dispersed as monomers, small and large unilamellar vesicles, multilamellar vesicles and mixed micelles in Triton X-100. The lipids were then subjected to alkaline hydrolysis near pH 12.7 (0.132 M NaOH) and the hydrolysis products were analyzed by thin layer chromatography. Possible positional specificity of hydrolysis was also determined by using dipalmitoyl phosphatidylcholine labeled with ^{14}C-acyl chains in the *sn*-2 position. Acid hydrolysis of phospholipid has also been reported (for a review see ref. 12).

Our results for acyl position hydrolysis agree with those of Kensil and Dennis, who observed no significant differences in rates of hydrolysis at the *sn*-1 and *sn*-2 positions. These investigators did find that the alkaline hydrolysis rate in lipid dispersed as micelles was seven- to 11-fold faster than in vesicles, whereas our results for acid hydrolysis did not show this effect. Finally, the rate constants for alkaline hydrolysis were much higher than those for acid hydrolysis in the pH 1 range. For instance, Kensil and Dennis reported $K_1 = 1.4 \times 10^{-3} s^{-1} M^{-1}$, for hydrolysis of egg PC in vesicles at pH 12.7, while our results for hydrolysis of POPC in the range of pH 1 is 5.3×10^{-6}, about 300-fold slower.

In summary, we conclude that phosphatidylcholine is sufficiently stable in the pH range of 4–10 so that liposome preparations and experiments carried out over time intervals of a few hours to several days should not produce significant hydrolytic degradation. At extreme pH ranges in the range of 1 and 12, hydrolysis can occur at significant rates, with half-times from 20 min (Kensil and Dennis) to 50 hr (this report). It is possible that other phospholipids have different hydrolysis rates under certain conditions; this remains to be tested.

Platelet Changes after a Saturated Fat Meal and Their Prevention by Dazmegrel, a Thromboxane Synthetase Inhibitor

J.J.F. Belch*, A.R. Saniabadi, K. McLaughlin and C.D. Forbes
University Department of Medicine, Royal Infirmary, 10 Alexandra Parade, Glasgow G31 2ER, Scotland

A saturated fat meal was given to 10 normal males both before and after pretreatment with UK38,485, a thromboxane synthetase inhibitor (Dazmegrel, Pfizer Central Research, Sandwich, Kent, United Kingdom). Following the fat meal at 2 and 4 hr there was laboratory evidence of platelet activation. Dazmegrel lowered baseline platelet activity and lessened platelet activation following the fat meal. This drug should be investigated further as a potential antithrombotic agent.
Lipids 22, 159-162 (1987).

Epidemiological studies (1,2) indicate that a diet rich in saturated fats has a distinct negative influence on coronary artery disease, whereas a polyunsaturated diet might have protective effects (3). In other conditions associated with thrombosis and arterial disease, platelet behavior is influenced by alterations in dietary lipids (4), and it has been well documented that alimentary hyperlipidemia alone may create platelet activation (5-7). That this may be linked to clinical disease is suggested by the work of Regan et al. (8) and Kuo and Joyner (9), who demonstrated decreased oxygen delivery to the myocardium and an increased frequency of angina attacks in fat-fed patients with ischemic heart disease. The mechanism by which a saturated fat diet produces this platelet activation is thought to be related to an alteration in prostanoid production, in particular an increase in production of thromboxane A_2 (TxA_2), the potent platelet aggregant and vasoconstrictor (10). If the effects on platelets are mediated through an increase in TxA_2, it might be reasonable to suggest that its selective inhibition might be an alternative for normalizing platelet behavior in these hyperlipidemic patients.

Dazmegrel (Pfizer Central Research, Sandwich, Kent, United Kingdom) is an imidazole derivative that has been shown to inhibit thromboxane synthetase (11). In addition, this drug may preserve prostacyclin (PGI_2) production (11,12), whose antiplatelet vasodilator effects should further protect against thrombosis.

The aim of our study was to investigate the effects of a saturated fat meal on platelet behavior before and after pretreatment with Dazmegrel. As there is also some work suggesting that acute fat feeding may decrease blood fibrinolysis (13,14), this was also studied.

SUBJECTS AND METHODS

Ten healthy male volunteers (mean age 28 ± 8 yr) were enrolled after informed consent was obtained. Permission for the study was obtained from the regional Ethical Committee. Subjects were fasted for 12 hr overnight and, after baseline blood samples had been taken, ingested 150 ml of double cream (fatty acid content g/100 g cream, shown in Table 1). Further blood tests were taken by separate venipuncture 2 and 4 hr later and after an overnight fast, at 24 hr. Following a one-month washout period, the procedure was repeated. On each occasion, the subjects were pretreated with either placebo or 100 mg of Dazmegrel at 24, 12 and 1 hr prior to the ingestion of cream. The dose of Dazmegrel used has been shown to decrease significantly thromboxane production (12).

TABLE 1

Fatty Acid Composition of Double Cream

Saturated	28.8 g/100 g cream
Monounsaturated	15.4 g/100 g cream
Polyunsaturated	1.3 g/100 g cream

Reference 6.

Blood tests: platelet aggregation (PA). Nine ml of blood was anticoagulated with 1 ml (3.8%) trisodium citrate, and PA was carried out using the conventional aggregating agents adenosine 5′-diphosphate (ADP) and collagen. Two techniques were used: in the first, PA in platelet-rich plasma (PRP) to 2 μm ADP and 2 μg/ml collagen was measured using the established turbidometric technique (15) (Malins photometric aggregometer). Plasma becomes turbid after a fat meal; as this interferes with the light transmission used with PRP aggregation, studies at 2 and 4 hr using this method were not carried out. In the second, PA in whole blood at 37 C was estimated using the Ultraflo 100 Whole Blood Platelet Counter (Clay Adams). To estimate whole blood PA the single platelet count is measured prior to the addition of the aggregating agents (2 μm ADP and 0.5 μg/ml collagen) and again at peak fall in platelet count (1 min for collagen, 3 min for ADP). The initial platelet count will fall as the platelets aggregate. This can be recorded as a percentage of baseline. If the drug protects the platelets against the aggregating agents, then the percentage fall from baseline is less.

Platelet count and volume, white cell count. The Ultraflo whole blood platelet counter was used to measure the number of single platelets. Counts were carried out immediately, the sample was rotated for 5 min at 37 C and the count was repeated. This measures the rate of spontaneous aggregation of platelets with time. A Coulter S Plus was used to measure platelet volume and white cell numbers.

Fibrinogen and fibrinolysis. Nine ml of blood was anticoagulated with 1 ml of 3.8 trisodium citrate. Measurements were made of plasma fibrinogen (16), plasminogen (17) and plasminogen activator (fibrin plate) (18).

Cholesterol and triglyceride. Serum lipids were measured in the routine biochemistry laboratory.

RESULTS

Baseline. When one looks at the two fasting baseline results, the first without pretreatment with Dazmegrel and the second after 100 mg × 3, it can be seen that PA

*To whom correspondence should be addressed.

in whole blood after addition of both ADP and collagen is significantly decreased after pretreatment with Dazmegrel, although there is no change in the PA in PRP (Table 2). Neither is there any alteration in the platelet count, although the drug does appear to protect the platelets against spontaneous aggregation over 5 min. There is no effect on plasma fibrinogen or fibrinolysis.

Post-fat feeding. When one looks at the effects of fat feeding on the tests, it can be seen that there is a significant increase in triglyceride at 2 and 4 hr (Table 3) but no change in PA in whole blood. There is a significant decrease in platelet count at 2 hr that is not seen after pretreatment with Dazmegrel. Interestingly, the platelet count significantly increases again by 4 hr, a change also abolished by Dazmegrel. There is also a significant increase in platelet volume and total white cell count at both 2 and 4 hr, changes that again are not seen after pretreatment with the drug (Table 4).

Plasma fibrinogen and plasminogen were unchanged by the fat meal, although plasminogen activator activity was significantly increased at 2 and 4 hr with and without Dazmegrel.

DISCUSSION

In this study we have shown that treatment with Dazmegrel significantly protects the platelets against spontaneous PA and against PA induced by ADP and collagen in whole blood. PA to ADP and collagen in PRP, however, was not altered by Dazmegrel. It is possible that there is an increase in production of antiaggregatory prostaglandins from the white blood cells present in the whole blood aggregation system (12). This may explain the discrepancy between whole blood aggregation and PA in PRP. Other thromboxane synthetase drugs have also failed to lower dramatically baseline PRP aggregation

(19), and it may be that the antiplatelet effects of a drug may not be fully appreciated if work is carried out only in PRP.

Dazmegrel in the dose given does not appear to affect fibrinogen or the measurements of fibrinolysis carried out in this study.

When one looks at the effects of fat feeding on the platelets it can be seen that there is a degree of activation as shown by the fall in platelet count (6) and the increase in platelet volume (7). These changes, however, did not occur after pretreatment with Dazmegrel, demonstrating further protection by the drug.

It was interesting that, despite a fall in platelet count and an increase in platelet volume, PA was unchanged. However, this does agree with the work of Moolten et al. (20) and Bohl et al. (21), who also looked at normal volunteers. In previous work suggesting platelet activation in normal volunteers after a fat meal, two groups used circulating platelet aggregates as their measure of activation (5,6) and platelet stickiness to glass beads (20), and these may be more sensitive tests in this situation. Only animal studies have shown an increase in rate of PA but larger equivalent doses of fat were used in these experiments (22).

We have also shown in this study a significant increase in white blood cell count 2 and 4 hr post-fat meal. The reason for this is not clear, as ingestion of 1.2 l of milk failed to increase either total or differential counts in humans (23). That it could be due to stress is a possibility; however, the subjects experienced no discomfort following the meal. In a previous experiment in our laboratory (24), in subjects smoking three cigarettes in 20 min, which certainly appeared more stressful, the white cell count did not change. Obviously more work is required in this field to determine what types of cell increase and if their behavior is altered. This is of interest, as it is becoming generally accepted that white cells may be more important in the process of thrombosis than was previously thought. Interestingly, whatever the mechanism of the increased white cell count, it seems to have been inhibited by pretreatment with Dazmegrel.

Finally, we could demonstrate no decrease in fibrinolysis using the tests described in this study. This is in contrast to the work of Dubber et al. (13), who studied Europeans, but agrees with Ferguson et al. (14), who looked at an African population. Indeed we detected an increase in plasminogen activator activity, which probably reflects a change from the fasting to nonfasting state. Again it may be of interest to investigate the role of the white cell in this context. However, to assess accurately the effects of fat on fibrinolysis, a nonfat meal should be given as control.

ACKNOWLEDGMENTS

Dazmegrel and matching placebo capsules were supplied by H. Tyler, Pfizer Central Research. The authors received a grant (no. 86/72) from the British Heart Foundation.

Biokinetics of and Discrimination Between Dietary *RRR*- and *SRR*-α-Tocopherols in the Male Rat[1]

Divisions of [a]Chemistry and [b]Biological Sciences, National Research Council of Canada, Ottawa, Ontario, Canada K1A OR6

The net rates of uptake of the natural (2*R*,4′*R*,8′*R*) diastereoisomer of α-tocopherol (α-T) and the biodiscrimination relative to its 2*S*-epimer (2*S*,4′*R*,8′*R*) have been measured, in two experiments, for the blood and 21 tissues of male Sprague-Dawley rats fed over a period of several months diets containing deuterium-substituted forms of the α-T acetates. Gas chromatography–mass spectrometry was used to measure the amount of deuterated tocopherols taken up relative to the amount of nondeuterated tocopherol remaining. The measurements were performed at different times after the rats, placed for one month on a basal diet containing nondeuterated, natural α-T acetate, were switched to a diet containing the same total quantity of deuterated forms of either natural α-T acetate or a mixture of the acetates of the 2*R*- and 2*S*-epimers (i.e., *ambo*-α-T acetate). In experiment 1 the source of vitamin E in the replacement diet was trideuterio-2*R*,4′*R*,8′*R*-α-T acetate. The data obtained provide the first direct measure of the rate at which natural vitamin E is replaced and augmented in the tissues of growing animals under normal laboratory dietary conditions. There are dramatic differences in the tissue kinetics; for example, the apparent half-life of vitamin E, i.e., the time at which the total amount of ingested trideuterio-α-T taken up is the same as the amount of nondeuterated α-T remaining, varies from ca. 1 wk for the lung to ca. 11 wk for the spinal cord. In experiment 2 the vitamin E in the replacement diet was an equimolar mixture of trideuterio-2*S*,4′*R*,8′*R*- and hexadeuterio-2*R*,4′*R*,8′*R*-α-T acetates. The results show that there is a preferential uptake of the natural diastereoisomer of α-T by all tissues (except the liver during the first month). Examination of fecal material reveals that the biodiscrimination begins in the gut; the incomplete hydrolysis of the acetates shows clearly that this reaction proceeds to a greater extent with the natural diastereoisomer. The greatest discrimination of all the tissues examined was found to occur in the brain. After five months, the level of the deuterated natural diastereoisomer was more than five times that of the deuterated 2*S*-epimer. These results have potential implications for human nutrition.
Lipids 22, 163–172 (1987).

Vitamin E appears to owe its bioactivity mainly or entirely to its ability to inhibit lipid peroxidation in vivo (1). This it does by "trapping" the chain-carrying lipid peroxyl radicals, thus "breaking" the free-radical chain process (for concise reviews of the mechanism of lipid peroxidation and its prevention by antioxidants, see refs. 2 and 3). The major component of natural vitamin E, 2*R*,4′*R*,8′*R*-α-T (*RRR*-α-T; Scheme 1) has long been known to show in various animal bioassays a greater activity than synthetic 2*RS*,4′*RS*,8′*RS*-α-T (*all-rac*-α-T), which is an equimolar mixture of all of the eight possible stereoisomers (1).

More recently, it has been shown that the acetates of each of the eight diastereoisomers of α-T all have different activities in the rat fetal gestation-resorption assay, with the natural diastereoisomer, i.e., *RRR*-α-T, being the most active form (4). The differences in biopotencies of the α-T diastereoisomers appear to originate largely from the difference in the chirality at carbon atom 2 (5–10). Thus, the four diastereoisomers with the 2*R* configuration are generally more active than their corresponding 2*S* epimers (in which the CH_3 group and $C_{16}H_{33}$ phytyl group at position 2 are interchanged). Also, single dose experiments in which radioactively labeled 2*R*,4′*RS*,8′*RS*-α-T and 2*S*,4′*RS*,8′*RS*-α-T (or *RRR*-α-T and 2*S*,4′*R*,8′*R*-α-T [*SRR*-α-T]) have been administered to rats (11,12) and chicks (13,14) show that the uptake of the 2*R*-diastereoisomers into tissues is greater than for the 2*S* compounds, strongly suggesting that this is the reason for their greater bioactivity.

We have conducted the first experiments that measure the long-term uptake under normal laboratory dietary conditions of deuterium-substituted *RRR*-α-T and *SRR*-α-T into rat tissues, either singly (*RRR*-α-T only) or competitively (i.e., *RRR*-α-T vs *SRR*-α-T), using diets in which the acetates of these compounds were the only source of vitamin E.

MATERIALS AND METHODS

Materials. [5-CD_3]-2*R*,4′*R*,8′*R*-α-T (d_3-*RRR*-α-T) and [5,7-$(CD_3)_2$]-2*R*,4′*R*,8′*R*-α-T (d_6-*RRR*-α-T) were prepared by the $SnCl_2$-catalyzed deuteriomethylation with perdeutero-

HO, H_3C, CH_3, 5, 7, 2, O_1, 4′, 8′, H, CH_3 — *RRR*-α-T

paraformaldehyde of natural (2R,4'R,8'R) γ- and δ-tocopherols, respectively (15). [5-CD_3]-2S,4'R,8'R-α-T (d_3-SRR-α-T) was obtained after repeated recrystallization of an approximate 80:20 mixture of SRR- and RRR-[5-CD_3]-α-T-p-phenylazobenzoates produced by the $ZnCl_2$-catalyzed cyclization of [5-CD_3]-α-T quinol (16). The quinol was obtained by the $NaBH_4$ reduction of [5-CD_3]-α-T quinone, which in turn was obtained by the $FeCl_3$-catalyzed oxidation (17) of deuteriomethylated 2R,4'R,8'R-γ-T (15). Natural γ-T and δ-T were obtained from soybean oil concentrate. The chiral purity of the deuterated RRR- and SRR-tocopherols was confirmed by measurement of the optical rotation of the potassium ferricyanide oxidation product mixture (16). Tocopherol acetates were prepared by reaction with sodium acetate in acetic anhydride.

Methods. Two experiments were conducted. In both experiments, nine 3-wk-old male Sprague-Dawley rats bred at the NRCC specific pathogen-free facility and housed in individual wire cages were placed for four weeks on a standard AIN-76 diet (major components: 50% sucrose, 20% casein, 15% cornstarch and 5% tocopherol-stripped corn oil) (18) that contained extra menadione [10 times the level in the original diet (19,20)] and 36 mg of 2R,4'R,8'R-α-T acetate (d_0-RRR-α-T-Ac) per kg of diet. After four weeks, the rats were switched to diets in which the (nondeuterated) α-T was replaced by a nominally equivalent amount of either 36 mg of d_3-RRR-α-T acetate (d_3-RRR-α-T-Ac; experiment 1) or a combination of 18 mg of d_6-RRR-α-T acetate (d_6-RRR-α-T-Ac) and 18 mg of d_3-SRR-α-T acetate (d_3-SRR-α-T-Ac) per kg of diet (experiment 2; this combination of diastereoisomers is known as *ambo*-α-T). (All three diets were prepared at NRCC and the tocopherols were incorporated—along with the recommended amount [18] of butylated hydroxytoluene—into each diet after dissolving them in tocopherol-stripped corn oil.)

Blood samples and tissues were obtained from animals after 1, 2, 4, 8, 16, 31–32 and 64–65 days (and 154 days in experiment 2) on the diets containing the deuterated tocopherols.

The blood samples (1 ml), obtained by heart puncture with animals under halothane anesthesia, were withdrawn from one to seven animals (fasted for at least 4 hr) on each of the specified days. The blood was placed in microcentrifuge tubes coated with disodium ethylenediaminetetraacetate and spun at 2000 rpm for 3/4 min in an Eppendorf microcentrifuge. The plasma was removed and stored frozen at −50 C. The red blood cells (RBC) were washed by resuspending them in ice-cold phosphate-buffered saline (5 mM, pH 8.0), spinning for 30 sec, removing the supernatant and repeating the whole procedure twice. The washed RBC were resuspended in the same buffer containing fresh sodium ascorbate (1 mg per ml of buffer) and stored frozen at −50 C. (The ascorbate was added to protect the α-T from oxidation by hemoglobin-derived iron during storage, thawing and extraction.)

Rapid extractions of α-T into heptane were performed on the plasma immediately after thawing by the usual ethanol/heptane procedure (21,22). Typically, 200 μl of ethanol was added to and mixed with 200 μl of plasma followed by 250 μl of heptane. The heptane extracts were stored at −50 C as 2 × 100 μl samples for the purpose of performing replicate analyses.

RBC were extracted using a modified version of the sodium dodecyl sulfate (SDS) method (22). Although volumes and hematocrits varied with each sample, the average volume of RBC suspension in the phosphate/saline/ascorbate buffer used in each extraction was 700 μl, and the average hematocrit was 25% (i.e., 175 μl of packed RBC). The following is an example of a typical extraction: the RBC suspension (700 μl), thawed in ice water, was transferred to a 30-ml glass centrifuge tube. The vial that contained the frozen cells was rinsed with 300 μl of the phosphate/saline/ascorbate buffer, and the rinsings were added to the RBC suspension in the centrifuge tube. SDS (0.1 M; 1.8 ml; 10 × volume of packed RBC) was added to the RBC and mixed briefly on a vortex stirrer, followed by absolute ethanol (2.8 ml, equal to the total aqueous volume), which was also briefly vortex-stirred. n-Heptane (1.0 ml) was added, and the mixture was vortex-stirred for 1 min and centrifuged for 1–2 min. A large fraction (0.8 ml) of the heptane extract was carefully removed and concentrated down under a stream of nitrogen to a volume of less than 200 μl.

Tissues were obtained from rats that had been killed either by decapitation (experiment 1) or by perfusion of saline into the anesthetized animals (experiment 2). The effect of perfusion of the tissues upon the measured ratios of deuterated and nondeuterated tocopherols was determined by using both methods on the two rats that were killed on day 4 in each experiment. All tissues were stored at −50 C. Vitamin E was extracted from aqueous homogenates of the tissues using the SDS method (22). The concentration of the SDS solution used was 0.1 M unless noted otherwise.

All extracts (including those from plasma and RBC) were purified, and the total α-T was quantitated by high performance liquid chromatography (HPLC) (Varian model 5000) using a Lichrosorb Si 60 column (5 μ; Merck, Darmstadt, Federal Republic of Germany) eluted with hexane/t-butylmethyl ether (3%)/2-propanol (0.05%) at 2 ml min^{-1}. 2,2,5,7,8-Pentamethyl-6-hydroxychroman was used as the internal standard (22). Often, the collected fraction containing the α-T was purified further by a second "pass" through the HPLC after being concentrated under a stream of nitrogen. Some modifications of the extraction and purification procedures were necessary depending on the type and amount of the particular tissue.

Liver, lung, kidney, heart, brain, testes, small intestine (duodenum), biceps femoris (1–2 g of each) and spleen (ca. 0.75 g) were homogenized in 6 ml of water (2 × 15 sec using a Brinkmann/Kinematic Polytron PT 10/35 equipped with an anaerobic generator). (In light of the known differences in uptake of vitamin E by different regions of the rat brain [23], the whole brain was homogenized.) A carefully measured volume (2.0 ml) of the homogenate was placed in a 30-ml glass centrifuge tube. SDS (2.0 ml), ethanol (4.0 ml) and n-heptane (2.5 ml) were each added to the homogenate in succession and vortex-mixed briefly (except n-heptane, which was mixed for 1 min). The mixture was centrifuged (1–2 min), and 2 × 1.0 ml of the heptane extract was carefully removed and placed in separate vials. One sample was concentrated to ca. 200 μl under a stream of nitrogen and injected onto the HPLC column after the addition of the internal standard. The other sample was stored at −50 C for a replicate analysis later, if desired.

Epididymal, inguinal and retroperitoneal white adipose tissue (1–2 g of each) were homogenized in a mixture of water (5.5 ml) and SDS (0.5 ml). SDS (1.5 ml), ethanol (6.0 ml) and *n*-heptane (2.5 ml) were each added in succession to the homogenate (4.5 ml) with vortex-mixing in the manner already described. The heptane extract was divided into two 1.0 ml samples. Preliminary HPLC analysis indicated a lot of interference in the region of the α-T peak. Therefore, the sample was subjected to an alkaline hydrolysis to reduce the possibility of interference by ion fragments from other species in the subsequent gas chromatography–mass spectrometry (GC-MS) analysis of the isotopically substituted tocopherols. The sample (1.0 ml) was placed in a 15-ml glass tube equipped with a teflon-lined screw cap, blown down to dryness under a stream of nitrogen and redissolved in ethanol (2 ml) containing sodium ascorbate (1%). Anhydrous sodium methoxide (0.5 M, 4 ml) was then added and the mixture heated at 80 C for 20 min. After the mixture cooled, glacial acetic acid (200 μl) was added followed by water (6 ml) and *n*-heptane (2.5 ml). The mixture was then vortex-stirred for 1 min. A portion (2.0 ml) of the heptane extract was removed, concentrated down to 200 μl under a stream of nitrogen and injected onto the HPLC column. The α-T fraction was collected and blown down, and the residue was subjected to a second alkaline hydrolysis. Again, the heptane extract was passed through the HPLC column and the α-T fraction collected and concentrated.

Interscapular brown adipose tissue (0.4 g) was treated essentially in the same manner as white adipose tissue. Homogenization was performed in water (4 ml), and the entire homogenate was extracted with SDS (2 ml), ethanol (6 ml) and *n*-heptane (2.5 ml). The extract (1 ml) was hydrolyzed and purified twice by HPLC using the method already described.

Diaphragm, soleus, tensor fascia latae and tibialis anterior muscle tissues (0.2–0.6 g) were cut into small pieces with scissors, homogenized in a mixture of water (3 ml) and SDS (0.5 ml, 20 sec) and extracted in the usual manner by adding a further amount of SDS (0.5 ml) followed by ethanol (4 ml) and *n*-heptane (2.5 ml). A portion (1 ml) of the recovered heptane extract (2.0 ml) was purified by HPLC in the usual way.

Aorta (40 mg) was homogenized with a mixture of water (0.5 ml) and SDS (0.2 ml). The probe/generator of the homogenizer was rinsed with water (ca. 1.3 ml) to bring the final aqueous volume to 2 ml. The entire homogenate was treated in the usual way with ethanol (2 ml) and *n*-heptane (2 ml), and the heptane extract (1.8 ml) was purified by HPLC in the normal manner.

Skin (0.4–0.7 g) was cut into small pieces and converted to a powder by cooling with liquid nitrogen and grinding the mixture in a stainless steel mortar and pestle. The powder was homogenized first with water (5 ml, 10 sec) and then with added SDS (0.5 ml, 10 sec). The entire homogenate was extracted in the usual way by adding more SDS (0.5 ml) followed by ethanol (6 ml) and *n*-heptane (2.5 ml). A fraction (1.0 ml) of the recovered extract (2.0 ml) was purified by HPLC.

Fecal pellets (ca. 0.5 g), recovered from the lower part of the large intestine, were homogenized with water (4 ml). A sample of the homogenate (2 ml) was extracted with SDS (2 ml), ethanol (4 ml) and *n*-heptane (2.5 ml). A portion (1.0 ml) of the recovered extract (2.0 ml) was injected onto the HPLC column. The α-T fraction was collected as well as an earlier eluting fraction containing α-T acetate. The latter fraction was blown down to dryness under a stream of nitrogen and the α-T acetate hydrolyzed by heating the residue at 70 C for 30 min with sodium methoxide (0.5 M) in methanol (2 ml) plus methanol (1 ml) containing sodium ascorbate (1%). Glacial acetic acid (100 μl) was added to the cooled mixture followed by SDS (2 ml) and *n*-heptane (2 ml), which were vortex-mixed. The heptane extract recovered after centrifugation was injected onto the HPLC column and the α-T fraction was recovered.

The content and composition of α-T acetate in each diet were checked after saponification of the food to extract the α-T. The diet (0.5 g) was made into a slurry with water (0.5 ml) and warmed at 70 C for 2 min, with a 2% solution of sodium ascorbate in ethanol (2 ml). Saturated aqueous potassium hydroxide (1 ml) and ethanol (1.5 ml) were added, and the mixture was heated at 70 C for 40 min. Water (2 ml) and hexane (6 ml) were added to the cooled mixture and vortex-stirred. A sample (1 ml) of the hexane layer that separated after centrifugation of the mixture for 2 min was removed and concentrated down to 200 μl under a stream of nitrogen (after the addition of an internal standard). The α-T in the concentrated sample was then simultaneously quantitated and purified for GC-MS by the usual HPLC method.

The relative proportions of d_0-, d_3- and d_6-α-Ts were determined by GC-MS of their trimethylsilyl ethers (24). Although the free tocopherols could be successfully analyzed by GC-MS, the trimethylsilyl ether derivatives were used because there was no "tailing" of the peaks. This feature was considered desirable for obtaining more accurate peak area integrations.

The tocopherol trimethylsilyl ethers were prepared by evaporating the purified extracts of α-T in heptane down to dryness under a stream of nitrogen, adding pyridine (100 μl) and N,O-bis(trimethylsilyl)trifluoroacetamide (BSTFA) with 1% trimethylchlorosilane (TMCS) (50 μl; Pierce, Rockford, Illinois) and heating at 65 C for 15 min. After cooling, the mixture was blown down to a small volume (ca. 20 μl). A sample (2 μl) was injected onto a Hewlett Packard Ultra 1 fused silica capillary column (10 m × 0.2 mm ID, OV-101 type, cross-linked, bonded phase) maintained at 275 C in a Hewlett Packard 5790A Series GC, which was connected to a Hewlett Packard 5970A Series Mass Selective Detector set up to monitor continuously the 502 (d_0), 505 (d_3) and 508 (d_6) molecular ions. The peak area data for the 505 and 508 ions were corrected for the contribution (2.37%) from the M+3 ions originating from d_0-α-T and d_3-α-T, respectively.

RESULTS

Table 1 indicates the high degree of purity of the deuterium-substituted α-T. It is clear that by using three mass units separation to distinguish the different α-Ts, the M+3 contributions to the next highest molecular ion are very small and in good agreement with the contribution (2.37%) expected from natural abundance isotopes.

GC-MS analysis of α-T extracted from the saponified diets containing deuterated tocopherols confirmed the absence of the nondeuterated form in each diet and verified that the d_6-*RRR*-α-T-Ac/d_3-*SRR*-α-T-Ac ratio was 1.0 in the diet used in experiment 2.

TABLE 1

Relative Ion Intensities, Measured as Peak Areas by Single Ion Monitoring, of the 502, 505 and 508 Ions Obtained from the Gas Chromatography–Mass Spectrometry of the Trimethylsilyl Ethers of d_0-α-T, d_3-*RRR*-α-T, d_3-*SRR*-α-T and d_6-*RRR*-α-T[a]

Compound	502	505	508
d_0-*RRR*-α-T	100.00	2.25	<0.01
d_3-*RRR*-α-T	1.30	100.00	2.17
d_3-*SRR*-α-T	0.26	100.00	2.22
d_6-*RRR*-α-T	0.13	1.70	100.00

[a]The ion intensities for each compound are expressed as a percentage of the parent molecular ion, which is arbitrarily set at 100%.

32	—	347
64	—	480
65	485	—
65	459	—
154	—	499

[a]Number of days after 7-wk-old rats were switched to diet containing deuterated α-tocopherol acetate.

Table 2 shows for each experiment the weights of the rats at the time they were killed for tissue analysis.

We will use the symbol ∅ to describe the ratio of total deuterated α-T [$\Sigma(d_x$-α-T); x = 3,6] to nondeuterated α-T, i.e., ∅ = $\Sigma(d_x$-α-T)/(d_0-α-T), which is d_3-*RRR*-α-T/d_0-*RRR*-α-T in experiment 1 and (d_6-*RRR*-α-T + d_3-*SRR*-α-T)/d_0-*RRR*-α-T in experiment 2. The complete set of data are presented in Table 3. (Note that the data presented for plasma and RBC are average values.) A comparison of the results from animals that were perfused with saline with those that were not (day 4 in both experiments) indicates that the results were not affected by the presence of blood in the tissue.

In both experiments, plots of ∅ vs time were linear for almost all tissues. This result was not anticipated and seems remarkable considering the fact that each point in the plots was obtained from a different animal. Some examples of these plots are shown in Figure 1.

In view of the demonstrated linearity of ∅ with time, the data were fitted by the method of least squares to the equation ∅ = kt, where t is time and k is a proportionality constant, the value of which depends on the tissue, diet, etc. The results are shown in Table 4.

The two k values obtained for each tissue in experiment 2 (i.e., with or without inclusion of the final point for day 154) are in satisfactory agreement except in the case of lung. If this tissue is excluded from consideration, with only one or two exceptions the k values derived from experiment 2 are somewhat lower than the k values derived from experiment 1. This means that the rate of uptake of α-T by the rats is smaller when the vitamin is provided as the mixture of two stereoisomers in experiment 2 than when it is provided as the natural stereoisomer in experiment 1.

The reciprocal of each k value listed for experiment 1 in Table 4 yields the apparent half-life, $t_{1/2}$, in days for natural *RRR*-α-T in each tissue; $t_{1/2}$ is the time it takes for the net amount of ingested deuterated *RRR*-α-T taken up by a tissue to equal the amount of the nondeuterated *RRR*-α-T remaining. This time is shortest for the lung ($t_{1/2} \approx 7$ days, experiment 1), liver and small intestine and is longest for the brain, testes ($t_{1/2} \approx 30$ days, experiment 1) and spinal cord ($t_{1/2} \approx 76$ days, experiment 1).

Figure 2 shows the time dependence of the discrimination in the net uptake of d_6-*RRR*-α-T vs d_3-*SRR*-α-T in plasma, RBC, liver and brain of rats fed the diet containing equal amounts of the acetates of these diastereoisomers (experiment 2). After a single day there is a 1.4-fold enrichment of d_6-*RRR*-α-T in the plasma, the enrichment increasing to ca. 2.5 over the 5-mo duration of this experiment. The RBC consistently show a higher enrichment in d_6-*RRR*-α-T than the plasma throughout the experiment; the enrichment ratio, i.e., $(RRR/SRR)_{rbc}/(RRR/SRR)_{plasma}$ has a mean value of 1.35 ± 0.13 (standard deviation for 30 values).

Three remarkable results are also shown in Figure 2. First, the liver, in contrast to all the other tissues, shows an initial excess, by a factor of two, of d_3-*SRR*-α-T. This lasts for ca. 3 wk until eventually the liver begins to show a slight excess of d_6-*RRR*-α-T. The initial excess of the *SRR*-epimer is similar to the result reported from an early experiment by Weber et al. (12), in which fasted rats received single doses of either 2*S*,4′*RS*,8′*RS*-α-T or 2*R*,4′*RS*,8′*RS*-α-T radioactively labeled acetates. In that experiment, the average level of the 2*S*-diastereoisomers found in the liver half an hour after the doses were orally administered was approximately twice that of their 2*R*-epimers (12). However, after two hours the situation was reversed and the 2*R*-diastereoisomers exceeded their 2*S* counterparts by a small margin. Although in our own experiment the rats were deprived of food for at least four hours before their livers were removed, it is very likely that some food was still present in the gut at the time they were killed. There will, therefore, have been a continuing infusion of vitamin E into the animals. This may explain why our liver data appear to be similar to the trends noted in the very early stages of the single dose experiment (12).

Second, the brain shows an extraordinary, progressive discrimination in favor of natural *RRR*-α-T, especially after one month, with the *RRR/SRR* ratio exceeding a value of five after five months and showing no sign of leveling off. This result has been confirmed in subsequent related experiments. In one experiment, two rats were placed on the diet used in experiment 2 (i.e., 1:1 d_6-*RRR*-α-T/d_3-*SRR*-α-T acetates) immediately after weaning and were found to have in their brains d_6-*RRR*-α-T/d_3-*SRR*-α-T ratios of 5.7 and 4.8 after 120 and 128 days, respectively. In a second experiment in which two weanling rats

[a]Ratios of the deuterated to nondeuterated forms, d_3-*RRR*-α-T/d_0-*RRR*-α-T (experiment 1) and (d_6-*RRR*-α-T + d_3-*SRR*-α-T)/d_0-*RRR*-α-T (experiment 2), respectively, are given for various times after switching the rats to the diets containing the deuterated α-tocopherols. In experiment 1, only the animal corresponding to the data for the first set of day 4 results was perfused with saline. In experiment 2, all animals were perfused except the animal corresponding to the second set of day 4 results.

[b]Mean values for blood drawn from several rats (except day 154): number of rats (day no.)—4 (1), 7 (2), 6 (4), 4 (8), 3 (16), 2 (31), 2 (32), 2 (64), 2 (65). Single values for day 111 (experiment 2 only) were 5.94 and 10.35 for plasma and red blood cells, respectively.

[c]ND, not determined.

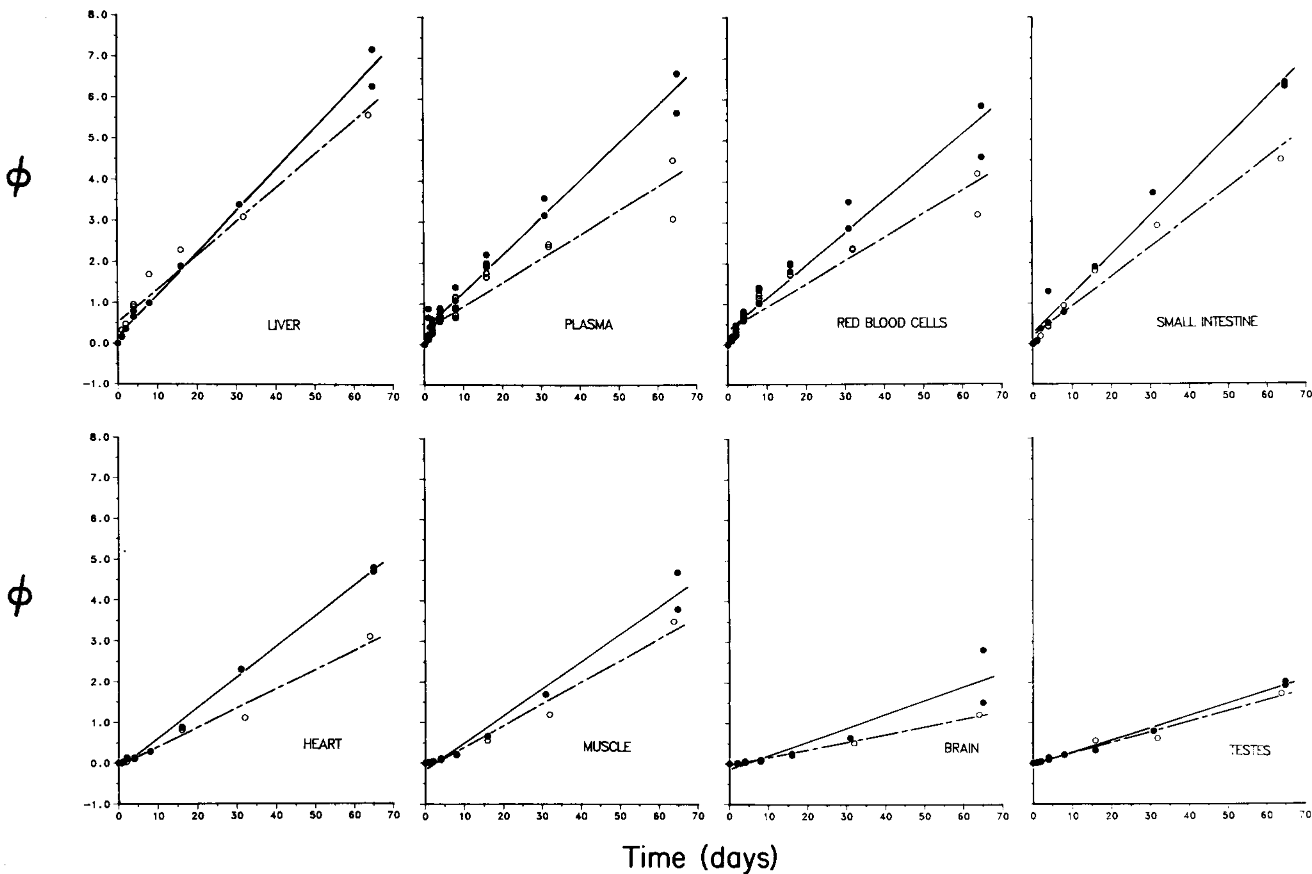

FIG. 1. Plots of ∅ [ratio of the total amount of deuterated to nondeuterated α-tocopherols, $\Sigma(d_x\text{-}\alpha\text{-T})/(d_0\text{-}\alpha\text{-T})$] vs time for liver, plasma, red blood cells, small intestine, heart, muscle (soleus), brain and testes. Each graph includes data points from experiment 1 (d_3-*RRR*-α-T/d_0-*RRR*-α-T; solid line) and experiment 2 [(d_6-*RRR*-α-T + d_3-*SRR*-α-T)/d_0-*RRR*-α-T; broken line)]. Lines were obtained by a least squares fit of the data collected over a 64–65 day period for each experiment. The data ponts are from single rats (9 and 8 points for each tissue in experiments 1 and 2, respectively, and 30 data points for plasma and red blood cells in both experiments).

[a]Obtained by least squares analysis of data fit to the equation ∅ = kt, where ∅ is the ratio of (total) deuterated to nondeuterated α-tocopherols and t is time in days. Units are day^{-1} (± standard deviation) for k and days for $t_{1/2}$.

[b]Duration of experiment.

[c]Results obtained by excluding the one additional data point for day 154.

[d]Calculated from the reciprocal of the k values from experiment 1.

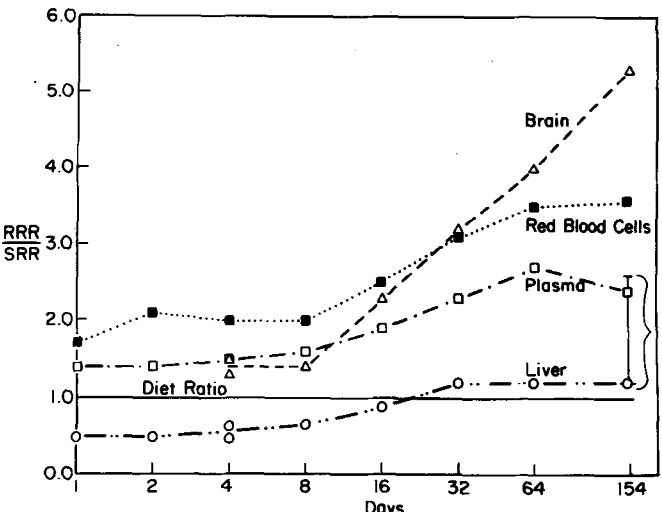

FIG. 2. Time-dependence of the discrimination in the net uptake of deuterated *RRR*- and *SRR*-α-tocopherols (d_6-*RRR*-α-T/d_3-*SRR*-α-T) into plasma, red blood cells, liver and brain of male rats fed a diet containing equal amounts of the corresponding tocopherol acetates (experiment 2). Points for plasma and red blood cells represent mean values from two or more animals (except for day 154). The points for liver and brain are from single animals. The bar at 154 days represents the full range in the *RRR/SRR* ratio found at 154 days for all of the other tissues examined (see Table 4).

were placed on a diet with a d_6-*RRR*-α-T/d_3-*SRR*-α-T acetate ratio of 0.5, the d_6-*RRR*-α-T/d_3-*SRR*-α-T ratios in the rats' brains were 2.2 and 2.5 after 64 days; that is, relative to the dietary ratio, the enrichments of d_6-*RRR*-α-T to d_3-*SRR*-α-T were 4.4 and 5.0, respectively.

Third, all the other tissues examined (except brain, RBC, liver and spinal cord; see Table 5 for complete data) show discriminations that after one month lie between that of plasma on one hand and liver on the other (see bar at day 154 in Fig. 1).

Analysis of fecal material from the large intestine (Table 6) reveals that the hydrolysis of the dietary tocopherol acetates in the gut was incomplete, particularly in experiment 2. It is also very clear that *RRR*-α-T-Ac underwent hydrolysis to a greater extent than *SRR*-α-T-Ac. This latter observation is probably the reason why the amount of fecal d_6-*RRR*-α-T was generally larger than the amount of d_3-*SRR*-α-T, and the ratio of α-T-Ac to α-T was generally higher in experiment 2 than in experiment 1.

The data in Table 6 also show that the original, non-deuterated tocopherol persists in the gut longer than would be expected after switching the animals to a diet containing 100% deuterated tocopherol. From the GC-MS data provided in Table 1, the apparent limiting ratio of d_3-*RRR*-α-T to d_0-*RRR*-α-T in experiment 1 can be calculated to be 100/1.3 = 76.9. Similarly, the apparent limiting ratio in experiment 2 (i.e., for a 1:1 mixture of

d_3-*SRR*-α-T and d_6-*RRR*-α-T) can be calculated to be (100 + 100)/(0.26 + 0.13) = 513. It is evident that these limits are not attained in either experiment.

DISCUSSION

The advantage of using deuterium-labeled α-T in conjunction with GC-MS for studies of relatively long-term uptake and discrimination of vitamin E is evident from the present results. Our two experiments have yielded remarkably consistent results for the net rates of uptake of deuterated α-T by various tissues. The plots of Ø vs time for the tissues and blood show an unexpected and surprising degree of linearity. Even though there is a steady influx of vitamin E from the diet, this fact alone is not sufficient to explain the linearity. Nevertheless, the empirically observed linearity of Ø has allowed us to obtain the first comprehensive picture of the biokinetics in the tissues and blood of α-T acquired under normal dietary conditions. Particularly noteworthy is the large range in the rates of net uptake of deuterated α-T into different tissues. This is dramatically illustrated by the α-T half-lives ($t_{1/2}$), which range from 8 days in the lung to 76 days in the spinal cord (see Table 4). Of course, the animals underwent significant growth during the experiment (see Table 2) and therefore the total quantity of tocopherol was increasing in many organs and tissues because the size of the organs and tissues was increasing. Growing tissue would be expected to take up more tocopherol than it loses, and the new cells would be expected to contain mainly the deuterated (i.e., new) α-T. Growth would therefore have the effect of increasing the Ø values compared to the values that might be obtained in mature animals of stable weight. In growing tissues, the $t_{1/2}$ values will therefore tend to underestimate somewhat the actual time for a 50% turnover of α-T.

It is interesting to note that the Ø values were higher in lung, liver and small intestine than in plasma. This is easy to understand for the small intestine, since it is here that the new (deuterated) α-T is being absorbed from food containing only deuterated α-T. We suggest that the Ø values for the other two organs are higher than in plasma because uptake of α-T occurs most rapidly soon after feeding, when both the total α-T concentration and the Ø ratio in the plasma are temporarily elevated (25). This enhanced rate of absorption at elevated α-T levels in plasma may be combined with a fairly rapid cell turnover in these tissues (i.e., the death of old cells with "old" d_0-*RRR*-α-T and the birth of new cells with "new" d_x-α-T).

For organs whose weights remained essentially the same or increased only marginally during the experiment (e.g., brain, testes and heart), $t_{1/2}$ must correspond quite closely to the time it took for 50% of the natural α-T to be lost from a tissue by all chemical and physical processes. It remains to be seen to what extent the rate of turnover is determined by chemical consumption (by, for example, oxidation of α-T by lipid peroxyl radicals, which is not repaired by ascorbate or other water-soluble reducing agents [2; 26 and references cited therein]) and by physical loss (e.g., cell death, exchange into plasma or lymph).

A second major aspect of this work is that it provides direct information regarding the pattern of tissue discrimination between two of the eight diastereoisomers of α-T. This gives us new insights into the reasons for the different bioactivities of individual stereoisomers, including, for example, the difference between natural and *all-rac*-α-T.

The results obtained from fecal material suggest that discrimination in favor of the natural compound begins with the hydrolysis of the α-T acetates in the gut, i.e., before there has even been any absorption of the free phenol into the lymph. The simplest explanation for this would be that *RRR*-α-T-Ac is more rapidly hydrolyzed than *SRR*-α-T-Ac, presumably because of the chirality of the active enzymes in the pancreatic juice (e.g., carboxyl ester hydrolase) or the bile salts that are necessary for hydrolysis to occur (25,27) or to both. However, this explanation is not consistent with the result obtained by Weber et al. (12), which showed that the 2*S*-diastereoisomers are absorbed more rapidly within the first half-hour after dosing. A possible explanation that reconciles the results from both experiments is that the hydrolysis of

the 2*S*-diastereoisomers is faster but is more susceptible to inhibition by free tocopherol. The effects of inhibition and chiral discrimination upon the in vitro enzymic hydrolysis of α-T acetates are currently being investigated.

Our discovery that a small percentage of the α-T present in the fecal material is undeuterated after two months (experiments 1 and 2) and even after five months (experiment 2; see Table 5) suggests that α-T is "returned" to the gut from at least some tissues in the body of the rat. We presume that this return occurs by transport in the plasma and lymph with eventual excretion in the bile (experiments underway).

RBC exhibit a moderate chiral selectivity, relative to plasma, in favor of *RRR*-α-T [$(RRR)/(SRR)_{rbc}/(RRR)/(SRR)_{plasma}$ = 1.35, see Fig. 2]. We presume that chiral discrimination by the (chiral) phospholipids, cholesterol, proteins, etc., will be accentuated by the more structured lipid environment of the RBC membranes compared with the more "relaxed" environment of the plasma lipoproteins. In this regard, attempts to measure chiral effects in model phospholipid vesicles by various nuclear magnetic resonance methods have not been successful (28).

The unique behavior of the liver, in which there is an initial discrimination in favor of the unnatural *SRR*-α-T for ca. 3 wk, suggests that it possesses a mechanism by which *SRR*-α-T is selectively extracted from the lymph (25) and/or a mechanism that selectively "exports" *RRR*-α-T into lipoproteins that enter the blood plasma. Lipid "export" from the liver is known to involve the very low density lipoproteins (VLDL) and is likely to be accompanied by vitamin E "export." Indeed, an α-T transport protein, which is present in rat liver cytosol but not in other tissues (29–32), has been identified and shown to be fairly specific for the natural stereoisomer (31). We therefore suggest that this protein is active in transporting *RRR*-α-T into the lipoproteins synthesized in the liver, i.e., *RRR*-α-T is selectively "exported." There is, presumably, also some mechanism for the removal of *SRR*-α-T from the liver. However, it appears to take some weeks to become fully activated.

The very strong long-term discrimination by rat brain in favor of (natural) *RRR*-α-T and the very slow uptake of α-T into spinal cord have potential consequences for human nutrition and the treatment of neurological diseases associated with vitamin E deficiency (33,34). The high degree of discrimination implies that the rat brain will take up less of the *ambo*-α-T than *RRR*-α-T from diets that contain the same amount of both. The biokinetic data support this. The difference between the k values for experiments 1 and 2 is most marked for the brain (see Table 4). This result strongly suggests that a diet (dose) of natural α-T will be significantly more "available" to the brain than an equivalent diet (dose) of synthetic *all-rac*-α-T.

It seems likely that the high discrimination shown by the brain and to a lesser extent by the spinal cord is a result of the "blood-brain barrier." Possibly, α-T enters these tissues by passive diffusion across several membranes. This would be slow, and by analogy to the RBC, would tend to favor the natural stereoisomer.

The other tissues show no enhancement of the *RRR/SRR* ratio relative to plasma. This is probably because α-T uptake by tissue occurs in conjunction with the uptake of other lipidic material, there being, therefore, little chance of chiral discrimination at the point of entry of the tocopherol into the cell. Thus, α-T is known to be present in all lipoprotein fractions, and two mechanisms have been identified by which α-T is transferred from human lipoproteins to tissue. First, the specific, high affinity, low density lipoprotein (LDL) receptor mechanism (35) has been shown to be involved in the delivery of vitamin E from human LDL to human fibroblast cells (36,37). Second, α-T present in human chylomicrons has been shown to transfer to human erythrocytes and fibroblasts during the hydrolysis of triglycerides by lipoprotein lipase, and for this transfer to occur the lipase must itself bind to the cell membrane (38). The second of these two mechanisms is probably the more important in the rat (39); the *RRR/SRR* ratio in most tissue should at least parallel the *RRR/SRR* ratio in the plasma. The mechanism by which α-T is transferred to or from tissue by the high density lipoproteins (HDL) has not apparently been identified, although α-T in human HDL has been shown to transfer readily to human erythrocytes (40).

Finally, our results raise serious questions regarding the validity of and reliance upon current animal bioassays for evaluating the biopotencies of different tocopherols. As far as the stereoisomers of α-T are concerned, it would seem that both the duration of the test period and the tissue(s) that give the observed symptoms of deficiency and cure could affect the derived biopotency.

ACKNOWLEDGMENTS

The Association for International Cancer Research partially supported this work. E. Lusztyk, M. Slaby, B. E. Nadeau and S.W.Y. Ma gave valuable help, T. F. Slater and N. Cohen lent advice and encouragement and the Central Soya Corp., Fort Wayne, Indiana, donated soybean concentrate.

[Received May 26, 1986]

Studies of Lipoproteins and Fatty Acids in Maternal and Cord Blood of Two Racial Groups in Trinidad

G. Oladunni Taylor[a], John J. Albers[b,*], G. Russell Warnick[c], Janet L. Adolphson[c], H. McFarlane[d], D.R. Sullivan[e], C.E. West[f], V. Sri-Hari[g] and R. Edwards[g]

[a]Department of Chemical Pathology, University of Ibadan, Ibadan, Nigeria, [b]Departments of Medicine and Pathology, University of Washington School of Medicine and Northwest Lipid Research Clinic, Seattle, Washington, [c]Department of Medicine and the Northwest Lipid Research Clinic, Harborview Medical Center, University of Washington, Seattle, Washington, [d]Departments of Chemical Pathology and Immunology, General Hospital, Port of Spain, Trinidad and Tobago, West Indies, [e]Department of Clinical Biochemistry, Royal Prince Alfred Hospital, Caperdown, NSW 2050, Australia, [f]Department of Human Nutrition, Agricultural University Wageningen, The Netherlands, and [g]County General Hospital, Sangre Grande, Trinidad and Tobago, West Indies

The high mortality rate from coronary heart disease (CHD) among Indians compared to Negroes in Trinidad led us to test plasma lipid profiles to see whether dietary or genetic factors might be involved. There were no interracial differences in the composition of plasma cholesterol ester fatty acids of the tested women and neonates. This finding suggests that dietary fat does not account for the interracial difference in CHD, nor does the cause appear to be due to genetic differences in lipid profiles, as there was no significant difference between values for plasma triglycerides, total cholesterol, high density lipoprotein (HDL) cholesterol, apo-I, apo-II, apo B or cholesterol ester fatty acids in the cord blood of each racial group.

Blood samples were collected from 69 nonpregnant and 71 postpartum, fasted Negro and Indian women. Also taken were 71 umbilical cord blood samples. The mean triglyceride level was significantly lower in the Negro nonpregnant and postpartum women than in the Indians. HDL cholesterol and apo-I values were lower in the Indian women. There were no significant differences in the total cholesterol and apo B measurements. The triglyceride values for postpartum women were higher than those of the nonpregnant Negroes and Indians (75% and 47%, respectively), whereas the total cholesterol and HDL cholesterol, apo A-I and apo A-II ranged from 9% to 29% higher in the postpartum women. Apo B was about 40% higher postpartum in both ethnic groups.

The high CHD rate of Indians in Trinidad cannot be explained by dietary factors, plasma total cholesterol or fatty acid composition. However, the lower level of HDL cholesterol and plasma A-I could play a role in the higher CHD rate in Indians.
Lipids 22, 173–177 (1987).

Coronary heart disease (CHD) risk increases with increasing concentration of total or low density lipoprotein (LDL) cholesterol and decreases with an increased high density lipoprotein (HDL) cholesterol concentration (1,2). Elevated plasma triglycerides and very low density lipoprotein (VLDL) levels have also been associated with an increased CHD risk, but this association may be related to the effect of other lipoproteins, such as the reduction of HDL (3–5). However, a reduced level of HDL cholesterol is found in some populations where the incidence of ischemic heart disease is rare (6,7). It has been suggested that the prediction for CHD risk could be improved by simultaneous determination of lipoproteins and apoproteins (8).

CHD is the highest single cause of mortality in Trinidad (9). The difference between the rates of CHD for the Negro and Indian populations has been attributed to the high prevalence of diabetes mellitus and to the elevated concentrations of serum cholesterol evident in Indians in Trinidad and elsewhere (10,11). A 1982 study by Miller et al. (12) confirmed that Indian men in Trinidad have an unfavorable lipoprotein profile, with an elevation of VLDL and LDL triglycerides and cholesterol and a reduction in HDL cholesterol. But Miller's 1985 study (13) on serum HDL subclasses, testosterone and sex-hormone-binding globulin did not offer any explanation for a lower serum HDL level in Indians compared with Negroes in Trinidad.

Dietary and genetic factors may explain the differences in mortality rate from CHD between these two racial groups. The quantity and composition of dietary fat affect serum lipids and lipoproteins. One usually associates a high serum cholesterol level with populations consuming high dietary fat (14). However, the only food survey (15) carried out in Trinidad showed that Indians purchase more cereals, grains, vegetables and fish and less milk, dairy products, oil and fat than other racial groups in Trinidad. To date, these data have not been substantiated with detailed studies of dietary consumption. Analysis of the fatty acid composition of plasma cholesterol esters provides a limited assessment of both the composition (16) and quantity (17) of consumed dietary fat. Reduced concentration of dienoic fatty acid in plasma cholesterol esters has also been associated with development of myocardial infarction (18).

This study investigates the differences in plasma lipids, lipoproteins, apoproteins and fatty acid composition of plasma cholesterol ester in normal women of Negro and Indian descent in Trinidad. The comparative study was extended to include plasma from cord blood and from women after delivery, to see if there were differences in lipid profile at birth. While marked differences in the fatty acid composition of cholesterol esters of maternal and cord blood samples have been found within races (19), the difference between races has not been studied.

SUBJECTS AND METHODS

The postpartum subjects for this study were all women who came for delivery during the month of April 1984 at the Sangre Grande County General Hospital, Trinidad. This hospital serves the entire St. Andrews area, where the major ethnic groups are Negroes and Indians. The ethnicity of each participant was defined by the race of the subjects' grandparents ("Indian" or "Negro" if three of four grandparents were purely of that race). The study

---

had the permission of the Government Chief Medical Officer, and participants gave informed consent to all procedures.

Participants were free of gestational complications, and delivery occurred between 37 and 40 wk. Patients fasted from 10 to 13 hr prior to delivery, and blood was collected by antecubital venipuncture within 15 min postpartum. Cord blood was drained from the placental end of the umbilical cord immediately after transection. The blood samples were anticoagulated with EDTA (1 mg/ml) and kept on ice until plasma could be separated by a 15-min centrifugation at 1500 × g. This was accomplished within an hour of collection, after which samples were kept frozen at −20 C and shipped to participating laboratories.

Blood was also obtained from fasted nonpregnant women who were attending the Family Planning Clinic at Sangre Grande, after the purpose of the study had been explained to them. They were not on any contraceptive pill at the time of the study.

All subjects were interviewed, and details of age, occupation of spouse, dietary habits, sources and amounts of dietary fat, alcohol use, tobacco use, reproductive history and gestational history were recorded on a standard questionnaire. Physical parameters recorded included adult height and weight (antepartum of mothers) and neonatal weight, sex, length and head circumference.

Determination of total HDL cholesterol and triglycerides. The procedure used was that described in the Lipid Research Clinics Program Manual (20). For HDL cholesterol determination, 0.15 ml of 1 M $MnCl_2$ and 0.12 ml of 35 mg/ml heparin (Riker Laboratories, Northbridge, California) were added to a 3-ml aliquot of plasma.

Cholesterol of the supernatant fraction and the plasma triglyceride was analyzed with a Technicon Auto Analyzer II (Technicon Instruments Corp., Terrytown, New York) (20). For cholesterol analysis, the coefficient of variation was 2%. For triglyceride analysis, they were 3% and 4%, respectively.

Determination of apo A-I and A-II. The method used was as described by Albers et al. (21) and Cheung and Albers (22). Plasma aliquots were diluted with an equal volume of 8.4 M, 1,1,3,3-tetramethylurea (TMU) and mixed. The TMU plasma mixture was diluted with Tris-Urea and incubated at room temperature. Agarose radial immunodiffusion plates were prepared as described (23). From each sample, 0.4 μl was drawn and added to duplicate wells chosen in different quadrants of the plates. The plates were placed in a humid chamber at 37 C until the precipitate rings attained their final size, which was usually after 48 hr. The precipitate rings were measured and, using the square of the diameter of the precipitate ring and the concentration of the standard, the values for apo A-I and apo A-II for each sample were computed. The coefficient of variation for the assay was 7% for apo A-I and 6–10% for apo-II.

Determination of apo B. Apo B was quantified by the double antibody immunoassay technique described by Albers et al. (24). Briefly, 10 μl of plasma was diluted with 90 μl of RIA buffer (20 mM borate, 150 mM NaCl, 1 mM disodium EDTA, 6% bovine serum albumin, pH 8.0) followed, in order, by addition of 100 μl of ^{125}I-LDL (65 μg/ml) and 100 μl of anti-LDL (about 1:240 dilution). The mixture was incubated for 24 hr at 4 C. Then, 100 μl of diluted (about 1:50) normal rabbit serum and 300 μl of sheep anti-rabbit IgG were added to each tube, mixed, and incubated for 14–18 hr at 4 C. The samples were centrifuged, the supernatant was decanted and the precipitate was washed twice with RIA buffer. A set of standards and quality control samples were also included in the assay. Radioactivity in all tubes was determined. The percentage ^{125}I-LDL bound was calculated, and the relationship between antigen bound and log dose was linearized by unweighted least square regression of the logit of the percentage antigen bound vs log dose.

Fatty acid determination. The fatty acid composition of five samples of dietary oil, collected from the city of Sangre Grande, as well as cholesterol esters from 33 pairs of maternal and cord sera were determined. Lipids were extracted by the method of Folch et al. (25) and separated by thin layer chromatography on 0.5-mm silica gel H plates (E. Merck, Darmstadt, Federal Republic of Germany); the solvent system comprised petroleum ether (B.P. 40–60 C), diethyl ether and glacial acetic acid (160:30:5, v/v/v). Lipid fractions were localized with rhodamine G, scraped into extraction tubes and extracted into chloroform. Cholesterol esters were hydrolyzed, and the fatty acids were methylated with BF_3 in methanol. After extraction with petroleum ether, the fatty acid methyl esters were separated using a gas chromatograph (Model 427, Packard Instruments International, Talstrasse 39, Zurich, Switzerland) with a flame ionization detector. The chromatograph was fitted with 180 cm × 2 cm glass column packed with Chromabsorb W-AW (100–120 mesh) coated with 10% (w3w) Silar 5 CP. The proportions of the six principal fatty acids (C16:0, C16:1, C18:0, C18:1, C18:2, C20:4) were calculated on the basis of the mass of their methyl esters. Accuracy of estimation of an internal standard ranged from 0.33% to 1.5% for major fatty acids (C16:0, C18:1, C18:2) and from 1.9% to 3.3% for minor fatty acids.

Statistical analysis. Mean and standard deviation of mean were calculated by standard methods. Because the distributions of values for plasma triglycerides and HDL cholesterol were skewed, a logarithmic transformation was carried out before statistical analysis. Linear regression coefficients were calculated and used to determine relationships between the parameters. Student's t-test was used to compare the mean values, and values with $p < 0.05$ were regarded as significant.

RESULTS

As shown in Table 1, there were no significant interracial differences in the mean value of plasma cholesterol for postpartum women, nonpregnant women or neonates. The transformed mean values for the plasma triglyceride for both nonpregnant and postpartum women were significantly higher ($p < 0.005$) in the Indians than in the Negroes. However, there was no significant difference in triglycerides between Negro and Indian neonates.

The geometric mean values for the HDL cholesterol were significantly lower ($p < 0.001$) in the nonpregnant Indian women than in their Negro counterparts, but the difference in these levels in the postpartum women did not reach statistical significance. There was no difference in the values for the neonates. The ratio of HDL cholesterol to total cholesterol for the neonates was almost double the value for the women. There were no significant

HDL, high density lipoproteins; chol, cholesterol.

differences in the values of the ratio between the adults of the two ethnic groups.

The mean apo A-I value for the nonpregnant Negro women was significantly higher ($p < 0.005$) than the mean for the nonpregnant Indian women (Table 2). This difference was absent in the postpartum women and the neonates. There were no significant differences in the value of apo A-II for the paired groups of nonpregnant women, postpartum women or neonates. Similarly, there were no significant differences in the mean value of apo B for each of the paired groups. The ratio of apo A-I to apo A-II was not significantly different in the nonpregnant and postpartum women, but this ratio was significantly lower for the neonates than the values for the adult Negro and Indian women ($p < 0.025$). Similarly, the ratio of HDL cholesterol to apo A-I + apo A-II was not significantly different in the Negroes and Indian nonpregnant and postpartum women. The value of this ratio for the neonates was significantly smaller compared with values for nonpregnant and postpartum Negro women ($p < 0.02$) and for nonpregnant Indian women ($p < 0.025$). The differences in the total cholesterol to apo B ratio between the Negroes and Indians in each group were not significant, but the mean ratios for nonpregnant women were higher than the values for postpartum women. The differences in this ratio between postpartum women and neonates were significant ($p < 0.001$).

Although dietary description was not sufficient to typify the dietary habits of the different racial groups, analysis of the five types of cooking oil used, as recorded on questionnaires, revealed that the oils were nearly identical in composition and had P/S ratios between 3.8 and 4.5.

DISCUSSION

Nonpregnant women. In the present study, it has been confirmed that in Trinidad nonpregnant Indian women in the age group of 20 to 30 yr have high plasma triglycerides and low HDL compared with values for Negro women of the same age. Until now, plasma apoproteins and cholesterol ester fatty acid composition have not been

investigated in Indians and Negroes. Indian nonpregnant women had a geometric mean plasma triglyceride value about 50% higher than Negroes, a lower HDL cholesterol geometric mean and lower plasma apo A-I and apo A-II levels. The mean plasma total cholesterol and apo B values were not significantly different. Mean values of 81 mg/100 ml for plasma triglycerides and 44 mg/100 ml for HDL cholesterol in the nonpregnant Negro women in the present study were not significantly different from the values found by Miller and Gibson (26) for Negroes in rural Caribbean communities. Our value of 135 ± 28 mg/100 ml for apo A-I in the nonpregnant Negro women is significantly higher than the value of 119 ± 28 mg/100 ml for the Indian nonpregnant women.

In agreement with other studies (21,22,27,28) the apo A-I was significantly correlated with HDL cholesterol in both Negroes and Indians, but the correlation between total cholesterol and apo B was only significant for the nonpregnant women. The values of apo B, 98 ± 28 mg/100 ml and 100 ± 35 mg/100 ml for the nonpregnant Negroes and Indians, respectively, are similar to the Lowry protein value of 100 ± 23 mg/100 ml obtained for apo B for Caucasian women of the age range 20–29 years (24). The ratio of HDL cholesterol/total cholesterol that has been suggested to be a useful factor in assessing risk of atherosclerosis (29,30) was recently shown to be related to age, sex, race and gonadal hormone use (30). In the present study, there were no significant differences in this ratio for the two ethnic groups; however, the value of this ratio was much lower than the value obtained for African women in a similar study (31).

Postpartum women. The hypertriglyceridemic and hypercholesterolemic effect of pregnancy is a well-known characteristic (32,33), but there appears to be some variation in the degree of hyperlipidemia in different communities. In the present study, the main differences between nonpregnant Negro and Indian women persisted in pregnancy, although to a lesser extent when the absolute values of triglycerides and HDL cholesterol were considered. The most prominent change in pregnancy was in the plasma triglyceride geometric value, with an increase of 75% and 45% over the values for nonpregnant Negroes and Indians, respectively, while the increase in total cholesterol, HDL cholesterol, apo A-I and apo A-II was from 9% to 29%. In a similar study (31) of African women of the same income status, a much higher increase in triglycerides, total cholesterol and HDL cholesterol was observed. The ratios of HDL cholesterol/total cholesterol, apo A-I/apo-II and HDL cholesterol/(apo A-I + apo A-II) for both pregnant and nonpregnant women were not significantly different, which suggests similarity in HDL composition. This finding confirms an earlier report of Hillman et al. (34).

The hypertriglyceridemia in pregnancy is due to an enhanced entry of triglyceride-rich lipoproteins into the circulation rather than to a diminished removal (35). This physiological adaptation would serve to make triglyceride fatty acid available to all tissue, including the placenta and the fetus. Although there is evidence to support the hormonal basis for the hyperlipidemia of pregnancy, a recent study has shown that the hypercholesterolemia in pregnancy could be ameliorated with a reduction in dietary cholesterol intake (36). A comparison of values obtained for plasma total cholesterol and triglycerides in two previous studies among Nigerian women showed a further increase in their levels during delivery compared with the value for the third trimester of pregnancy (37). This increase could be due to the effect of stress of labor during delivery.

Neonates. The cord blood samples were studied to detect any interracial differences that might exist at birth. Any such findings might suggest genetic rather than environmental causes for the differences between races. No significant differences were observed in plasma values of triglycerides, total cholesterol, HDL cholesterol, apo A-I, apo A-II or apo B, but their concentrations were below the values for the nonpregnant women. The total cholesterol values were similar to those reported by Glueck et al. (38) in their study of 1800 babies. A reported range of 54–66% of the adult apo A-I concentration in neonates (17,36) was slightly below the 71% and 76% obtained in the present study. The mean plasma HDL cholesterol in neonates was more than 50% of the nonpregnant mean, and it constituted more than 40% of the plasma total cholesterol of the neonates.

So far, there are few reports on the composition of lipoprotein classes in the cord blood. It has been shown that the composition of LDL and HDL of human umbilical cord serum is similar to that of the adult, but that the VLDL of cord blood is lower in triglyceride and higher in protein content than that from adults (39,40). It has also been shown that the composition of VLDL has no simple correlation with birth weight, sex or gestational age (40). While it is reported that the distribution of lipoproteins is different in cord blood compared with that of the adult (41), the significance of the high ratio of HDL cholesterol to total cholesterol and its decline to the adult level has not been fully investigated. It is of interest to note that the value of this ratio obtained in the present study is not different from that obtained by Taylor et al. (31) in a similar study of Africans. In the present study, the ratios of HDL to apo A-I + apo A-II and apo A-I to apo A-II for the neonates were significantly different from the values for adults, with the relative percentages of these ratios ranging from 80% to 90% of the values for the nonpregnant women.

The high prevalence of diabetes mellitus among Indians compared to Europeans (42), Negroes (10) and Africans (43) has been suggested to be the main predisposing factor in explaining the high mortality rate of CHD among Indians. However, it has been reported that diabetes mellitus was less common among Indians before the age of 25 (42) and that juvenile diabetes was also rare among Indians (43). The mean age of the Indian subjects in the present study is about 25. It is therefore probably not likely that the high prevalence of diabetes mellitus among the Indians could explain the lipid profile of this group of subjects. Moreover, no specific factor has been found to explain the high prevalence of diabetes mellitus among Indians.

In an attempt to exclude dietary factors, the plasma lipids, lipoprotein, apoprotein and cholesterol ester fatty acid composition of maternal and cord were studied, but the results did not provide any evidence of differences in lipid profile of Indians and Negroes at birth (Table 3). Thus, it appears that, as in a recent study of diet and CHD in Asian residents of London (44), the high CHD rate of the Indians in Trinidad cannot be explained by

TABLE 3

dietary factors, plasma total cholesterol or fatty acid composition. However, the lower level of HDL cholesterol and plasma apo A-I could play a role in the higher CHD rate in the Indians.

ACKNOWLEDGMENTS

Useful suggestions and assistance were given by the Chief and Deputy Matrons and the nursing staff of the Labor Ward of Sangre Grande General Hospital; the staff of the Health Centre Sangre Grande; V. Wilson of the Department of Immunology, General Hospital, Port of Spain, Trinidad and Tobago; the staff of the Core Lipoprotein Laboratory of the Northwest Lipid Research Clinic, Harborview Medical Center, University of Washington, Seattle, Washington. This study was partially supported by a grant from U.S. National Institute of Health (HL 30086).

[Received May 19, 1986]

Membrane Fatty Acid Modification in Tumor Cells: A Potential Therapeutic Adjunct[1]

C. Patrick Burns and **Arthur A. Spector***
Departments of Internal Medicine and Biochemistry, University of Iowa, Iowa City, IA 52242

The fatty acid compositions of several tumors have been modified sufficiently to alter some of their properties and functions. These modifications were produced in culture by adding specific fatty acids to the growth medium or by feeding fat-supplemented diets to tumor-bearing mice. The phospholipid fatty acid composition of the plasma membrane was modified, but there were no changes in membrane phospholipid or cholesterol content or in phospholipid head group composition. Each of the most abundant membrane phosphoglyceride fractions exhibited some degree of fatty acid modification. Electron spin resonance measurements with nitroxystearate spin probes indicated that the fatty acid modifications were sufficient to alter the physical properties of the plasma membrane. The K'_m for methotrexate uptake was reduced when the L1210 leukemia cells were enriched in linoleic acid. Even when the kinetics of uptake at 37 C were not altered, such as for melphalan and phenylalanine uptake, the temperature transition of transport was modified, indicating that these transport systems also are responsive to the membrane fatty acid modifications. Enrichment with highly polyunsaturated fatty acid did not affect either the growth rate or radiosensitivity of the L1210 leukemia. However, the sensitivity of the L1210 cells to the cytotoxic effects of Adriamycin and hyperthermia was increased. These findings suggest the possibility that fatty acid modification of tumors may be a useful adjunct to certain currently available therapeutic modalities.
Lipids 22, 178–184 (1987).

The fatty acid composition of cultured cells can be modified extensively by changing the type and amount of lipid contained in the growth medium (1). This is due to the fact that when fatty acids are available in the extracellular fluid, they are utilized preferentially, and de novo fatty acid synthesis is suppressed (2). Tumors also derive most of their fatty acid from the extracellular fluid when an adequate supply of lipid is available (3). Therefore, as in the case of nonmalignant cells, it seemed likely that the membrane fatty acid composition of tumor cells also might be susceptible to fairly extensive modification. We have explored this approach because of the possibility that certain lipid modifications might make a tumor more sensitive to clinically useful therapeutic modalities. This review summarizes the types of lipid modifications that we have been able to produce, both in culture and in the tumor-bearing host, and the effects of these manipulations on the properties and function of the tumor cells.

EXPERIMENTAL METHODS

The L1210 murine leukemia was grown in male DBA mice (4), and the Ehrlich ascites tumor was grown in male CBA mice (5). In the dietary modification studies, the mice were given a basal fat-deficient mixture supplemented with either 16% coconut oil (saturated fat) or 16% sunflowerseed oil (polyunsaturated fat). These diets were fed to the mice for 4 wk prior to intraperitoneal inoculation of the tumor, and the diet was continued during tumor growth (4,5). The L1210 leukemia and Ehrlich ascites carcinoma cells also were maintained in culture (6,7). Additional studies were done with cultured Y-79 retinoblastoma cells (8), Friend erythroleukemia cells (9) and hepatoma 7777 cells (10).

Transport studies were done with intact cells using radioactive isotopes and rapid separation procedures for removing the incubation medium (4,5,8). Growth rate was measured by counting the cells or following the incorporation of [^{3}H]thymidine (11). Electron spin resonance was assayed with either the 12- or 5-nitroxystearate probes incorporated into isolated plasma membrane fractions prepared from the L1210 or Ehrlich ascites cells (4,7). Phospholipids were separated by thin layer chromatography, and fatty acids were assayed by gas liquid chromatography after transmethylation (5). In the radiation sensitivity study, cells were irradiated at room temperature with a GE Maxitron x-ray machine at 250 kVp and 20 mA. The hyperthermia studies were done using a circulating water bath in which the temperature was maintained within ±0.02 C (12). Cell survival was assessed with a soft agar clonogenic assay at 37 C for 1 wk in a medium containing 20% horse serum (12).

RESULTS AND DISCUSSION

Membrane fatty acid modifications. Considerable changes in the fatty acid composition of tumor cells can be achieved, either by growth of the tumor in animals fed different fat-supplemented diets (13,14) or in culture by varying the lipids added to the medium (7,8,12). Table 1 summarizes the changes that occur in the plasma membrane of L1210 murine leukemia cells and Ehrlich ascites carcinoma cells when they are grown in mice fed a diet rich in saturated fat, as compared with polyunsaturated fat. When exposed to saturated fat, the L1210 membrane contained twice as much monoenoic, but only half as much polyenoic, fatty acid. The saturated fatty acid content was essentially unchanged. These changes were associated with a large increase in oleic acid (18:1; number of carbon atoms:number of double bonds) and a large decrease in linoleic acid (18:2). There was little or no change in the content of the other major membrane fatty acids—palmitic (16:0), stearic (18:0) or arachidonic (20:4). Similar fatty acid modifications were produced in the plasma membranes of Ehrlich ascites carcinoma cells grown in mice fed these diets. In both cases, the effects were confined to the membrane fatty acid composition, and there was no change in membrane phospholipid content, cholesterol content or phospholipid head group composition (4,15). Therefore, what occurs is a substitution of fatty acyl groups within the same phospholipid framework of the membrane.

22:6	1.1 ± 0.3	2.9 ± 0.1	0.6 ± 0.1	1.2 ± 0.2

[a]Cells were grown in mice fed the semipurified diet supplemented with either 16% coconut oil (saturated fat) or 16% sunflowerseed oil (polyunsaturated fat). Each value is the mean ± SE of results from three separate membrane preparations.

[b]These values do not add up to 100% because only the most prevalent fatty acids are listed.

[c]Refers to the fat contained in the diet fed to the tumor-bearing mice.

[d]Trace, <0.2%.

TABLE 2

Fatty Acid Composition of Membranes Obtained from Tumor Cells Grown in Culture

	Membrane composition (%)[a]				
	L1210 leukemia[b]		Y-79 retinoblastoma[c]		
Fatty acid	Control[d]	Docosahexaenoic acid[e]	Oleic acid[f]	Arachidonic acid[f]	Docosahexaenoic acid[f]
16:0	13.4 ± 1.8	20.0 ± 3.0	19.7	25.3	24.2
16:1	4.8 ± 0.9	3.4 ± 1.4	4.9	7.9	6.6
18:0	14.0 ± 0.4	16.7 ± 0.4	15.0	12.1	16.3
18:1	56.3 ± 1.7	25.2 ± 1.2	36.9	22.7	25.0
18:2	3.2 ± 1.2	2.3 ± 0.2	0.1	0.8	0.5
20:4	3.2 ± 1.4	1.7 ± 0.7	8.1	14.0	6.6
22:6	0.3 ± 0.2	23.4 ± 3.7	4.0	3.2	14.8

[a]Values do not add up to 100% because only the most prevalent fatty acids are listed.

[b]The growth medium contained 5% fetal bovine serum, RPMI 1640 and 40 μg/ml gentamicin sulfate. Each value is the mean ± SE of results obtained from three separate membrane preparations, each obtained from different cultures.

[c]The growth medium contained 10% fetal bovine serum, RPMI 1640, 294 μg/ml glutamine, 100 U/ml penicillin and 100 μg/ml streptomycin. Each value is the average of two determinations that differed by less than 15%.

[d]No fatty acid supplement was added to the growth medium.

[e]Growth medium was supplemented with 32 μM 22:6 for 48 hr before the cells were harvested.

[f]Growth medium was supplemented with 30 μM of these fatty acids for 72 hr before the cells were harvested.

All of the major phospholipids contained in the Ehrlich cell plasma membrane were modified, although the extent of the modification was different in each fraction (15). The fatty acid compositions of the Ehrlich cell nuclear membrane and endoplasmic reticulum also were modified using this approach (16,17). Similar to these findings with ascites tumors, changes in dietary fat intake also produce alterations in the membrane lipid composition of solid mammary tumors (18–21).

Extensive changes in membrane fatty acid composition of tumor cells also can be produced by supplementing the medium with specific fatty acids during growth in culture (Table 2). When the medium of one set of L1210 leukemia cultures was supplemented with 32 μM docosahexaenoic acid (22:6), there was a 250% elevation in the polyenoic fatty acid content of the membrane, accounted for primarily by an increase in the 22:6 content. This was compensated for by a 57% decrease in monoenoic fatty acids, primarily 18:1. Enrichment with 22:6 also was associated with a 35% increase in the membrane saturated fatty acid content.

Similar modifications in membrane fatty acid composition have been produced in cultured human Y-79 retinoblastoma

cells (1,8). Table 2 illustrates the differences in membrane fatty acid composition that occurred when the medium in which the Y-79 cells are grown was supplemented with 30 μM of oleic, arachidonic or docosahexaenoic acid. As noted in the L1210 membranes, the saturated fatty acid content of the membranes increased to a small extent when the Y-79 cells were enriched with the polyunsaturated fatty acids. Compared to membranes from cells supplemented with oleic acid, those grown in the medium supplemented with arachidonic acid contained considerably less 18:1 and 73% more 20:4. Likewise, the membranes from cells supplemented with docosahexaenoic acid contained less 18:1 and 270% more 22:6 than those from the cells supplemented with oleic acid.

These types of membrane fatty acid modifications also have been produced in cultured Ehrlich ascites carcinoma cells (7), Friend erythroleukemia cells (9) and hepatoma 7777 cells (10). The advantage of this method, as opposed to the use of fat-supplemented diets, is the enrichment with the higher polyunsaturates such as 20:4 and 22:6 that can be produced in culture.

Membrane physical properties. Using electron spin resonance with fatty acid spin probes, we find that the physical properties of the plasma membrane lipids are altered by these kinds of phospholipid fatty acid replacements. Arrhenius plots of temperature dependence of the approximate rotational correlation time with nitroxystearate spin probes indicated that the membranes have two major temperature transitions, one at about 20 C and the other at 31.5 C. Results obtained with L1210 leukemia and Ehrlich ascites carcinoma plasma membranes are consistent (4,7,22). Changes in the fatty acid composition of the plasma membrane had essentially no influence on the 31.5 C transition, but they caused the lower transition to vary from 18.5-22 C in the L1210 plasma membrane and from 19-24.5 C in the Ehrlich membrane when the modifications were produced by feeding different fats to the tumor-bearing mice (4,22). In agreement with these findings, fatty acid substitutions in culture caused the lower transition in the Ehrlich ascites cell plasma membrane to vary between 20.5 C and 26 C (7). Enrichment with polyenoic fatty acids lowered this transition temperature, while higher values were obtained with saturated fatty acids.

The electron spin resonance order parameter, S, also was influenced by membrane fatty acid modifications produced either by diet or in culture (4,7,22). This parameter is a measure of phospholipid fatty acyl chain mobility; hence, the packing of these hydrocarbon chains in the lipid bilayer. The effect of fatty acid modification of the L1210 plasma membrane was similar with both the 5- and 12-nitroxystearate probes (Fig. 1). The value of S was lower at each temperature when the cells were grown in the mice fed the diet rich in polyunsaturated fat, which increased the polyenoic fatty acid content of the L1210 membrane phospholipids. Decreases in the plasma membrane S values also were noted when Ehrlich ascites carcinoma and L1210 leukemia cells were enriched with polyunsaturated fatty acids in culture (7,12,22). Further work indicated that the changes in S values were not due to the trapping of cytoplasmic lipid droplets in these membrane preparations (23).

Throughout the temperature range tested, the value of S was always higher with the 5-nitroxystearate compared

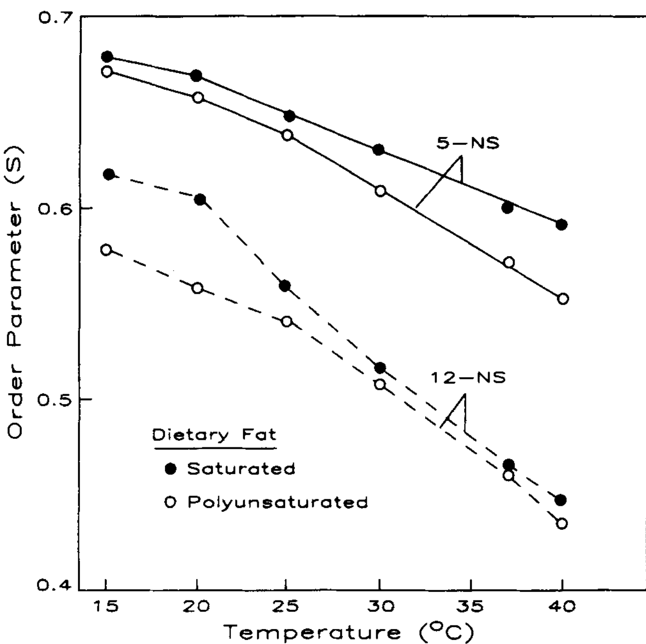

FIG. 1. Effect of changes in plasma membrane saturation of L1210 leukemia cells on the order parameter (S) measured by electron spin resonance. One group of cells was grown in mice fed the saturated diet, the other the polyunsaturated fat diet. After the plasma membrane fraction was isolated from the cell homogenate, the spin label was incorporated into the membrane by incubation with a solution containing 5% serum albumin. The abbreviations refer to the spin probes that were incorporated into the membranes: 5-NS, 5-nitroxystearate; 12-NS, 12-nitroxystearate.

to the 12-nitroxystearate probe (Fig. 1). It is assumed that these fatty acid spin probes enter the membrane lipid bilayer and are oriented parallel to the phospholipid fatty acid chains. In such orientation, the fatty acid carboxyl group would be at the surface of the phospholipid bilayer in the same plane as the polar head groups of the phospholipids, and the 5-nitroxide group would be located closer to the membrane surface than the 12-nitroxide group. The higher S value with the 5-nitroxystearate probe suggests that fatty acyl chain motion is more restricted closer to the membrane surface, near the ester linkage with the phospholipid head group, than deeper with the hydrocarbon phase.

These findings suggest that the lipid modifications produced in the intact tumor cell are sufficient to alter the physical properties of the plasma membrane lipid bilayer, i.e., to produce a membrane fluidity change. Since neither the cholesterol nor phospholipid content of the membrane changes, the fluidity effect results entirely from the fatty acid modifications. Because the differences in the values of S at 37 C are very small, the physiologic effects of the fluidity changes probably are fairly limited.

Carrier-mediated transport. To determine whether the lipid modifications actually can have an effect on membrane function, we investigated the uptake of a number of substances that are transported by carrier-mediated processes. As shown in Table 3, changes were noted in the K'_m of high-affinity uptake in several cases. The K'_m for the uptake of methotrexate, a chemotherapeutic drug, was reduced by 30% at 37 C when L1210 leukemia cells

TABLE 3

Effect of Fatty Acid Modification on the K'_m for High-affinity Transport[a]

Compound	Cell	K'_m (μM) Saturated fat	Polyunsaturated fat
Methotrexate	L1210	4.1 ± 0.1	2.9 ± 0.4
Melphalan	L1210	0.9 ± 1.8	1.2 ± 0.5
α-Aminoisobutyrate	Ehrlich	2300 ± 200	900 ± 200
Phenylalanine	Ehrlich	120 ± 30	140 ± 100
Choline	Y-79	2.2 ± 0.1	1.1 ± 0.2
Taurine	Y-79	37 ± 6	20 ± 1
Glycine	Y-79	34 ± 3	136 ± 27
Glutamate	Y-79	27 ± 1	28 ± 6
Leucine	Y-79	95 ± 19	72 ± 8

[a]The murine L1210 leukemia cells and the Ehrlich ascites carcinoma cells were modified by diet as indicated in Table 1. The human Y-79 retinoblastoma cells were modified in culture using a growth medium containing 10% fetal bovine serum. No fatty acid supplement was added to the growth medium of the Y-79 cultures for the column headed "saturated fat." In the case of the column headed "polyunsaturated fat," the growth medium of the Y-79 cultures was supplemented with 30 μM 22:6. Each value is the mean ± SE of results obtained from at least four separate experiments.

were enriched with polyunsaturated fatty acid by propagation in mice fed the diet supplemented with sunflowerseed oil (4). In Ehrlich cells, enrichment with polyunsaturated fatty acid in this way resulted in a 60% reduction in the K'_m for Na^+-dependent α-aminoisobutyrate uptake at 37 C (5). When human Y-79 retinoblastoma cells were enriched with polyunsaturated fatty acids in culture, the K'_m for choline and taurine transport at 37 C also was lowered (8,24), but that for glycine was increased (25). Table 3 shows the results for the Y-79 cells enriched with 22:6; qualitatively similar changes were obtained when the cells were enriched in culture with other polyunsaturated fatty acids (8,24,25).

As opposed to these positive findings, no statistically significant change in the high-affinity K'_m at 37 C was observed with melphalan (a phenylalanine mustard alkylating agent) in L1210 cells (26), phenylalanine in Ehrlich cells (27) or glutamate and leucine in Y-79 cells (8). In two of these cases, however, melphalan in L1210 cells and phenylalanine in Ehrlich cells, the transition temperature of the transport system was lower when the cells were enriched with polyunsaturated fatty acid (26,27).

No statistically significant change in V'_{max} occurred in those cases where the K'_m for transport at 37 C was reduced—methotrexate in L1210 cells (4), α-aminoisobutyrate in Ehrlich cells (5) or choline and taurine in Y-79 retinoblastoma cells (8,24). By contrast, the V'_{max} for glycine transport was increased three- to fivefold when the Y-79 retinoblastoma cells were enriched with polyunsaturated fatty acids (25).

These findings indicate that a number of carrier-mediated transport systems in several kinds of tumor cells, including a human tumor, are affected by the types of membrane fatty acid modifications that can be produced in the intact cell. Since the K'_m of the transport process is altered, the mechanism probably involves lipid structural effects on the conformation of the membrane carrier that are sufficient to influence the binding of the substrate. The effects on transport kinetics at 37 C, however, are not uniform for all substances, suggesting that the mechanism is more complex than a general response to changes in bulk membrane fluidity. Even in those cases in which no kinetic changes are evident at 37 C, the carrier appears to be sensitive to the membrane lipid microenvironment, as evidenced by the changes in the transition temperature.

Growth rate. Studies with the L1210 leukemia indicate that the growth of the tumor is not changed significantly when the cells are enriched with polyunsaturated fat in vivo, as compared to saturated fat (11). Cell counts obtained on days 5, 6 and 7 following intraperitoneal inoculation of the tumor were not different in the two dietary conditions. Likewise, [^{3}H]thymidine incorporation by the cells was unchanged. Consistent with our findings, dietary fat modifications also had no effect on the growth of the MT-W9B rat mammary tumor (28). These results suggest that there is unlikely to be any direct beneficial effect of these types of lipid modifications on tumor growth. Therefore, we directed our attention to the possibility that the lipid modifications may facilitate other treatment modalities.

Adriamycin cytotoxicity. Studies on lipid composition of Adriamycin-resistant P388 cells (P388/Adr) have revealed a decrease in the phosphatidylcholine to sphingomyelin ratio (29) and a higher degree of membrane lipid structural order (30). Similarly, studies on a series of sublines of Sarcoma 180 with different degrees of sensitivity to Adriamycin showed a correlation between drug resistance and membrane fluidity (31). These observations suggest that membrane lipids may have important implications regarding Adriamycin therapy. Therefore, we examined the effects of lipid modifications on the sensitivity of the L1210 and P388/Adr tumor cell lines to Adriamycin cytotoxicity.

L1210 cell survival in culture after treatment with Adriamycin was reduced when the cells were enriched with polyunsaturated fatty acids (6). Most of this work was done with 22:6 enrichment to maximize the increase in polyunsaturation. Increased cytotoxicity occurred at all of the Adriamycin concentrations tested (Fig. 2). In this study the cells were grown for 48 hr in either control medium or a medium supplemented with 32 μM 22:6. After removal of this medium, the cultures were exposed to various concentrations of Adriamycin for 2 hr, and the percentage of surviving cells was determined by a clonogenic assay based on colony formation in soft agar (6). Additional studies indicated that the amount of Adriamycin cytotoxicity increased as increasing quantities of 22:6 were incorporated into the cell lipids (6). The clonogenic assay measures the ability of single cells to generate daughter cells for more than 2-3 mitotic divisions. This is an appropriate measure of the cytotoxic effect of an antineoplastic therapy, since it is the reproduction of surviving cells that perpetuates the tumor.

The augmented cytotoxicity is due to an enhanced effect of Adriamycin toward 22:6-enriched L1210 cells and is not simply the result of greater polyunsaturation alone. We have previously demonstrated that the culture doubling time for L1210 cells grown in 22:6-supplemented medium is 10.0 ± 0.3 hr, which is not different from that

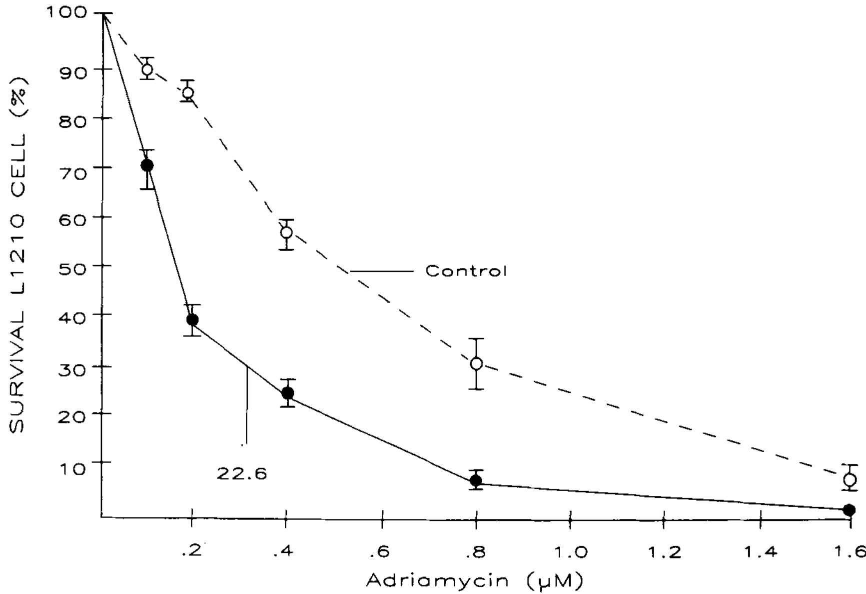

FIG. 2. Effect of phospholipid fatty acid saturation on the cytotoxicity of Adriamycin in L1210 leukemia cells. The growth medium contained RPMI 1640 and 5% fetal bovine serum. In one set of cultures, the medium was supplemented for 48 hr with 32 μM 22:6. Each point is the mean ± SE of 4 determinations.

of L1210 cells grown in unsupplemented medium, 9.2 ± 0.9 hr (6). Likewise, the soft agar cloning efficiency of cells enriched in 22:6 is not different (6).

The enhanced cytotoxicity was associated with an increase in the accumulation of Adriamycin in the L1210 cells (32). No difference in Adriamycin release from the cells occurred, however, indicating that the greater accumulation did not result from an inhibition of Adriamycin efflux. Binding and lipid partitioning studies also indicated that the greater intracellular accumulation is not due to increased Adriamycin adsorption to the polyunsaturated fatty acid-enriched membranes. At present, the mechanism responsible for the greater accumulation is unknown.

We have also investigated whether polyunsaturated fatty acid enrichment would confer Adriamycin sensitivity to a tumor that normally was resistant to this drug, the murine P388/Adr lymphoma. P388/Adr cells were enriched in culture with either 32 μM 18:1 or 22:6 and then exposed to 0.4 μM Adriamycin for up to 4 hr (Fig. 3). No cytotoxicity differences were observed in a subsequent assay, indicating that a large increase in polyunsaturation will not cause an otherwise resistant tumor cell to become Adriamycin-sensitive.

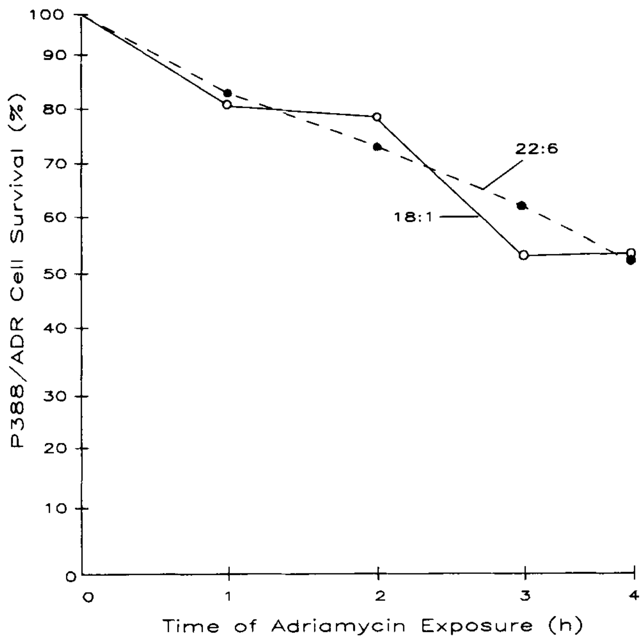

FIG. 3. Effect of changes in phospholipid fatty acid saturation on the cytotoxicity of Adriamycin in P388/Adr lymphoma cells. The growth medium of the cultures was enriched with either 18:1 or 22:6.

Radiation sensitivity. Polyunsaturated fatty acid enrichment did not affect the sensitivity of the L1210 leukemia cells to ionizing radiation (33). L1210 cells grown in mice fed the diets rich in either saturated or polyunsaturated fat were irradiated with increasing doses of x-rays, and cytotoxicity was assessed subsequently with a soft agar clonogenic assay. No difference in cytotoxicity was observed (Fig. 4). A similar negative result was obtained when the polyunsaturation of the human Y-79 retinoblastoma cell line was raised in culture by supplementation of the medium with 22:6.

Sensitivity to hyperthermia. There is considerable evidence documenting the cytotoxic effect of elevated temperatures on tumors in vitro (34) and in vivo (35). In our studies, the thermosensitivity of the L1210 leukemia increased when the cells were enriched with polyunsaturated fatty acid (Fig. 5). In this study, the cultures were grown in media containing 40 μM of the supplemental fatty acid for 10 days, removed from this medium and then heated at the designated temperatures. Cytotoxicity was assessed by a soft agar clonogenic assay (12). At 42 C, the D_0 values (minutes of heating required to reduce

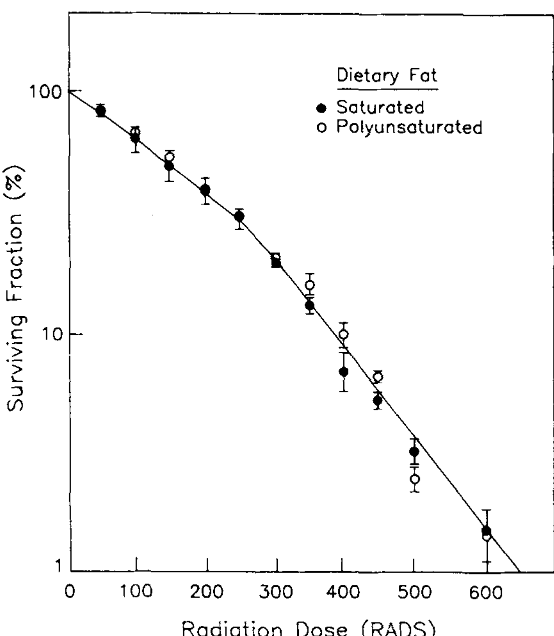

FIG. 4. Effect of changes in phospholipid fatty acid saturation on the cytotoxicity of x-ray exposure in L1210 leukemia cells. The cells were grown in mice fed either the saturated or polyunsaturated fat diets. Each point is the mean ± SE of 3 determinations.

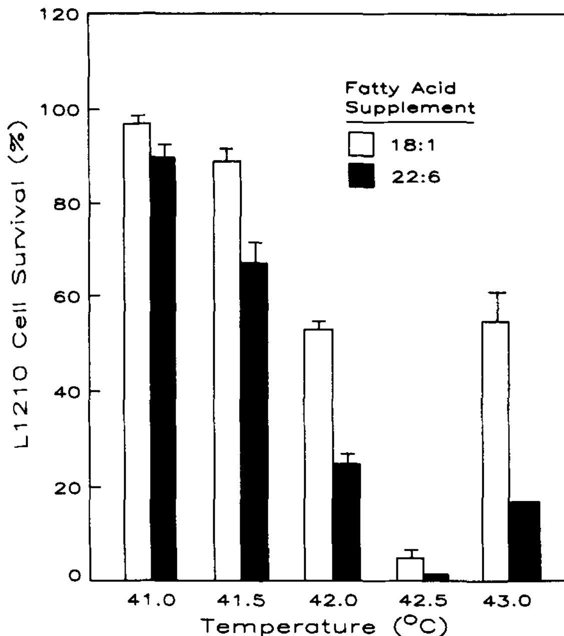

FIG. 5. Effect of changes in phospholipid fatty acid saturation on the thermosensitivity of L1210 leukemia cells. The growth medium of the cultures contained 5% fetal bovine serum and was supplemented with either 40 μM 18:1 or 22:6. Each bar is the mean ± SE of 4 determinations. Cells were heated for 90 min at the temperatures of 41.0-42.5 C. At 43 C, no cell survival was detected at 90 min; the study therefore was done at 30 min.

cell survival on the exponential portion of the curve by 63%) for cells enriched with 18:1 and 22:6 were 46.2 ± 1.6 min and 18.7 ± 0.4 min, respectively. Additional studies in which the cultures were heated for 2 hr at 42 C indicated that thermosensitivity increased as the 22:6 content of the cell lipids was raised (12). Therefore, changes in fatty acid saturation cause the L1210 cell to respond differently to various kinds of radiation. Although the response to ionizing radiation is not affected, the sensitivity to thermal radiation becomes enhanced.

Conclusions. These findings demonstrate that it is possible to change the fatty acid composition of an intact tumor cell sufficiently to alter the physical properties of the plasma membrane and to affect certain cellular responses. The growth rate of the tumor in vivo is not affected by these changes. This suggests that if such lipid modifications have any therapeutic benefit, it probably is as an adjunct to other treatment modalities rather than as an independent form of treatment. Since functionally significant lipid modifications can occur as the result of changing the dietary fat intake of a tumor-bearing host, the possibility of applying this approach to humans is feasible. Moreover, for localized tumors, it may be possible to produce specific fatty acid modifications such as those that have been achieved in cell culture by using a localized perfusion technique.

The diets that were used alter the lipid composition of many organs in the mouse (36). Therefore, the changes are not tumor-specific, raising the possibility that this approach may also increase the toxicity of some therapeutic modalities. Another concern is that high fat diets, particularly those that are rich in essential polyunsaturated fatty acids, enhance the development of certain tumors (37-43), apparently by facilitating tumor promotion (44-46). While these concerns must be considered, the strikingly positive responses obtained with Adriamycin and hyperthermia suggest that the approach of utilizing membrane lipid modification in conjunction with existing forms of therapy merits further exploration.

Biochemical Characterization of Acetyl-CoA:1-Alkyl-2-Lyso-*sn*-Glycero-3-Phosphocholine Acetyltransferase in Rat Spleen Microsomes

Kuniaki Seyama and **Teruo Ishibashi***
Department of Biochemistry, Hokkaido University School of Medicine, Sapporo 060, Japan

Acetyl-CoA:1-alkyl-2-lyso-*sn*-glycero-3-phosphocholine (lyso-PAF) ultrasonic disruption in the presence of 25% glycerol from rat spleen microsomes. About 26% of the enzymatic activity was recovered in the 225,000 × g supernatant by this treatment, although the specific activity was slightly decreased compared with the original microsomes. The solubilized enzyme was remarkably susceptible to various kinds of metal ions. Sulfhydryl reagents such as p-chloromercuribenzoate and N-ethylmaleimide significantly inhibited the enzyme reaction, suggesting that the enzyme is an SH enzyme. Based on the sedimentation pattern in sucrose density centrifugation, the isoelectric point, the kinetic characteristics and the sensitivity to tryptic digestion of microsomes, it appears that acetyl-CoA:lyso-PAF acetyltransferase does not differ from the acetyltransferase responsible for the transfer of acetate from acetyl-CoA to 1-acyl-2-lyso-*sn*-glycero-3-phosphocholine.
Lipids 22, 185–189 (1987).

Platelet-activating factor (PAF) is a potent phospholipid mediator capable of promoting numerous biological effects, including platelet activation, hypotension and bronchoconstriction (1,2). Neither the 1-acyl-linked analog nor the nonacetylated analog was active at comparable doses of PAF (3–5). Specific enzymatic reactions involved in the biosynthesis of PAF have been documented in recent reports. These reactions include an acetyl-CoA:1-alkyl-2-lyso-*sn*-glycero-3-phosphocholine (lyso-PAF) acetyltransferase (EC 2.3.1.67) (6–8) and a CDP-choline:1-alkyl-2-acetyl-glycerol cholinephosphotransferase (9). Both enzymatic activities are present in various rat tissues (6,9), human polymorphonuclear leucocytes (8,10), murine macrophages (11–13) and rabbit platelets (14). However, the activity of acetyltransferase is induced up to 10-fold when polymorphonuclear leucocytes are treated with opsonized zymosan (10). Under these conditions, the activity of cholinephosphotransferase is not affected (10). Furthermore, modulation of acetyltransferase activity by treatment of various cell types with different factors is accompanied by a parallel change in the amount of PAF released into the media (11,13,15). These results suggest that acetyltransferase is an important regulatory enzyme in the biosynthesis of PAF. It is not yet known how various stimuli regulate the biosynthesis of PAF.

Wykle et al. (6) found that a significant amount of acetyltransferase activity occurred in the microsomal fraction of the rat spleen. However, actual attempts to remove the enzyme from its membrane environment have not been performed. This paper describes for the first time an effective procedure for solubilization and partial characterization of acetyltransferase. In addition, we have investigated whether the enzyme reactions introducing the acetyl moiety into the c-2 position of lyso-PAF and 1-acyl-2-lyso-*sn*-glycero-3-phosphocholine (LPC) are catalyzed by the same enzyme.

MATERIALS AND METHODS

Chemicals. Chemicals were obtained from the following commercial sources: acetyl-CoA, p-chloromercuribenzene sulfonic acid (p-CMBS), phenylmethylsulfonic acid (PMSF), trypsin (bovine pancreas), trypsin inhibitor (soybean) and phospholipase C *(Bacillus cereus)* were from Sigma (St. Louis, Missouri); diisopropyl fluorophosphate (DIPF) was from Fluka (Tokyo, Japan); lyso-PAF (1-O-hexadecyl-2-lyso-*sn*-glycero-3-phosphocholine) was from Bachem Feinchemikalien (Budendorf, Switzerland); and LPC (1-palmitoyl-2-lyso-*sn*-glycero-3-phosphocholine) was from Nippon Shoji (Osaka, Japan). PAF was prepared semisynthetically from rat fish *(Hydrolagus colliei)* liver oil as described previously (16). The chemical 1-O-hexadecyl-2-acetyl-*rac*-glycerol was synthesized starting from 1-O-hexadecyl-*rac*-glycerol (chimyl alcohol) (17,18). N-ethylmaleimide (NEM) was obtained from Wako (Tokyo, Japan); carrier Ampholite (pH 3.5–10) was from LKB (Uppsala, Sweden); and [1-^{14}C]acetyl-CoA (55 Ci/mol) was from Amersham (Arlington Heights, Illinois). The specific activity was adjusted to 2.5 Ci/mol by the addition of unlabeled acetyl-CoA. All other chemicals were reagent grade.

Preparation of microsomes. Spleens were excised from Wistar rats (200–300 g) after they were killed by decapitation. Microsomal fractions were prepared according to the procedure described by Lenihan and Lee (19) and were suspended in 0.25 M sucrose/20 mM Tris-HCl buffer (pH 7.4)/1 mM dithiothreitol (10–15 mg of protein/ml).

Enzyme assay. Acetyl-CoA:lyso-PAF acetyltransferase activity was determined by the method described by Wykle et al. (6), with several modifications. The incubation mixture consisted of 100 μM [1-^{14}C]acetyl-CoA, 30 μM lyso-PAF or LPC, 0.1 M potassium phosphate buffer (pH 6.9) and enzyme protein (20–100 μg) in a final volume of 0.25 ml. After incubation for 10 min at 37 C, the enzymatic reaction products were extracted by the method of Bligh and Dyer (20). The radioactivity was measured by liquid scintillation counting. Results were collected with backgrounds without added lyso-PAF or LPC.

Analytical methods. Protein was determined by either the method of Bensadoun and Weinstein (21) or the Bio-Rad protein assay kit, using bovine serum albumin as a standard.

RESULTS

Solubilization of acetyltransferase. In an effort to solubilize acetyltransferase from rat spleen microsomes, we first tried various detergents, including Triton X-100,

TABLE 1

Solubilization and Partial Purification of Acetyltransferases from Rat Spleen Microsomes

Procedure	Protein (mg)	Total activity (nmol/min)		Specific activity (nmol/min/mg)		Yield (%)	
		Lyso-PAF	LPC	Lyso-PAF	LPC	Lyso-PAF	LPC
Microsomes	23.8	38.5	35.6	1.62	1.50	100	100
Solubilization	8.8	10.2	6.3	1.16	0.72	26.5	17.7
Sepharose 6B	3.0	8.3	5.9	2.74	1.96	21.6	16.6

Lyso-PAF, 1-alkyl-2-lyso-*sn*-glycero-3-phosphocholine; LPC, 1-acyl-2-lyso-*sn*-glycero-3-phosphocholine.

Tween 80, octylglucoside, Lubrol, Briji, Miranol HM2 and cholate derivatives. However, the enzyme activity was remarkably inhibited by these detergents in spite of their low concentration (below 0.2%). Finally, we were able to solubilize the enzyme using the following steps: Glycerol (a final concentration of 25%) was added to the microsomal suspension, and the mixture was subjected to an ultrasonic disruption in a Branson sonifier equipped with a microtip at 0 C for three 1.5-min periods. The mixture was centrifuged at 225,000 × g for 1 hr, and the resultant supernatant was the source of the solubilized enzyme, in which ca. 26% of the acetyltransferase activity was recovered (Table 1). Then the solubilized enzyme was applied to a Sepharose 6B column (1.5 × 75 cm) previously equilibrated with 0.25 M sucrose/10 mM potassium phosphate buffer (pH 7.4)/1 mM dithiothreitol/10% glycerol. The active fractions eluting near the void volume were pooled and used in all the subsequent experiments as partially purified enzymes. Enzymes were partially purified ca. 1.7-fold with a 21% yield. The final enzyme preparation was extremely labile, and ca. 50% of the activity was lost after 24 hr at 4 C.

On the other hand, rat spleen microsomes also catalyzed the transfer of acetate to LPC. The LPC acetyltransferase activity was solubilized and partially purified by the same procedures used for lyso-PAF acetyltransferase. The results were similar to those obtained with lyso-PAF acetyltransferase.

Enzymatic properties of lyso-PAF acetyltransferase and LPC acetyltransferase: sucrose density gradient centrifugation. Both lyso-PAF and LPC acetyltransferases appeared in almost the same fraction near the top of the centrifuge tube, although lyso-PAF acetyltransferase activity showed a shoulder on the right-hand side (Fig. 1).

Isoelectric focusing. The isoelectric point of lyso-PAF and LPC acetyltransferase was a single peak at pH 4.25 (Fig. 2).

Effect of various chemicals. As shown in Table 2, there was no significant difference in the effects of various reagents on either form of acetyltransferase. Both EDTA and EGTA inhibited the enzyme activities, but the inhibition did not appear related to a divalent metal ion requirement. Divalent cations inhibited the activity of both forms of transferase to various degrees. Mn^{2+} showed an especially striking inhibition. On the other hand, p-CMBS and NEM remarkably inhibited the enzyme activity, indicating that the enzymes are SH enzymes. DIPF and PMSF, however, had no effect.

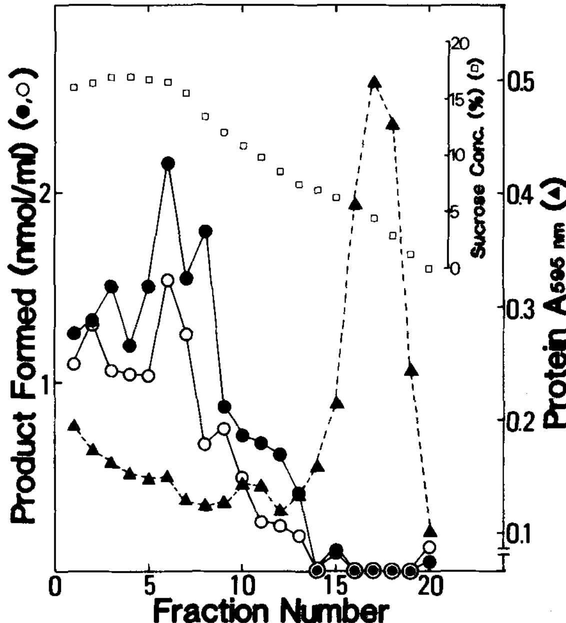

FIG. 1. Sucrose density gradient centrifugation. The solubilized enzyme (4.8 mg of protein) was applied to the top of a linear sucrose gradient (0–20%) in a 50-mM potassium phosphate buffer (pH 7.4)/1 mM dithiothreitol/10% glycerol that was prepared in a 10-ml centrifuge tube and centrifuged at 11,700 × g for 14 hr at 4 C using a Hitachi RPS-40T rotor. After centrifugation, fractions of 555 μl each were collected from the bottom of the tube. The protein was determined in 10 μl of an aliquot using the Bio-Rad protein assay kit. ●, Lyso-PAF acetyltransferase; ○, LPC acetyltransferase; ▲, protein. Sucrose concentrations (□) were measured by a refractometer.

Kinetics. The transferase activity was linear with protein concentrations up to 50 μg and throughout 25 min of incubation (data not shown). The optimum concentrations of both lyso-PAF and LPC were ca. 50 μM (Fig. 3). Lyso-PAF or LPC concentrations above 50 μM reduced the enzyme reactions strikingly, possibly due to the detergent effects of lysophospholipids (6,23). An apparent Km value for acetyl-CoA was the same (196 μM) with both lyso-PAF and LPC acetyltransferase.

Effect of tryptic digestion of microsomes. The enzyme activity in the intact microsomes was susceptible to tryptic digestion, and lyso-PAF and LPC acetyltransferase activity were inactivated in a parallel manner in relation to incubation time (Fig. 4).

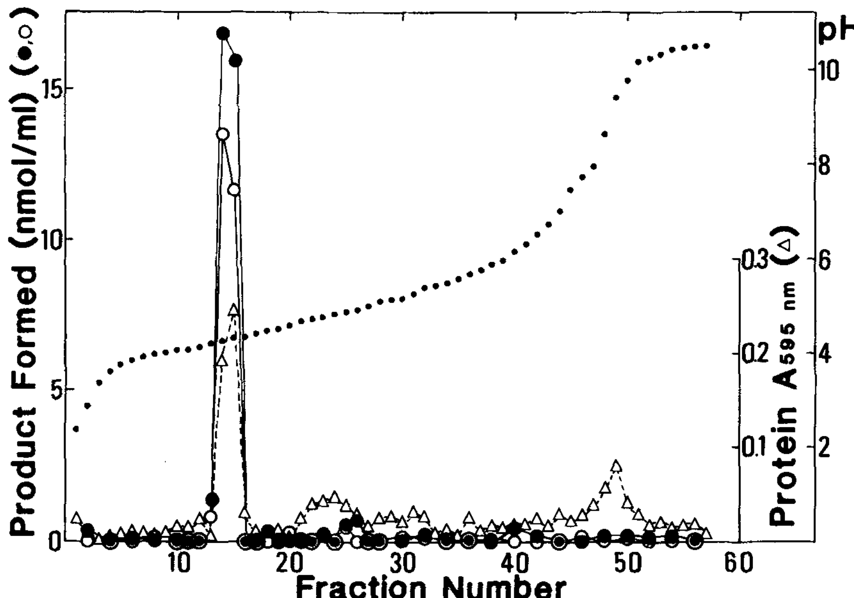

FIG. 2. Isoelectric focusing. The solubilized enzyme (2.8 mg of protein) was subjected to a column (110 ml) containing 1% Ampholine carrier ampholyte solution, over a pH range of 3.5-10, with a step-wise sucrose gradient at 500 V for 48 hr, according to the method of Vesterberg (22). The column content was collected separately in 1-ml fractions each at a flow rate of 80 ml/hr. The pH of fractions was measured in an ice-cold bath. Protein was determined in 10 μl of an aliquot using the Bio-Rad protein assay kit. ●, Lyso-PAF acetyltransferase; ○, LPC acetyltransferase; △, protein.

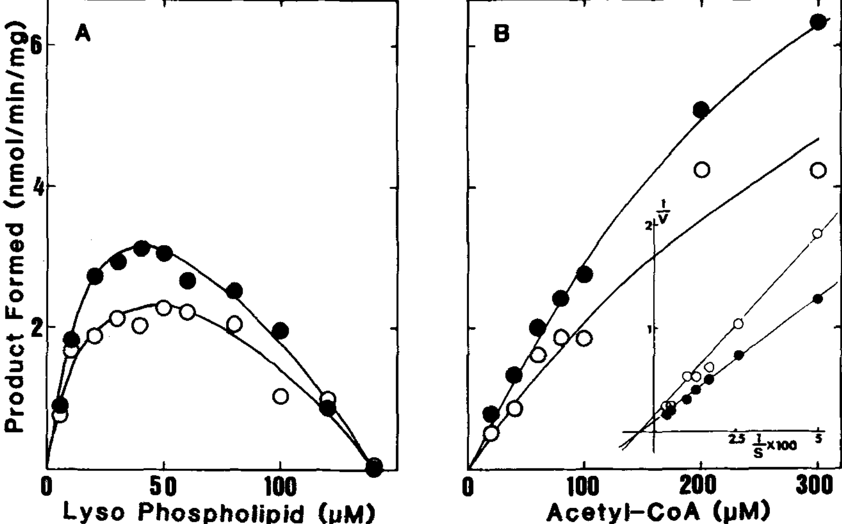

FIG. 3. Kinetic studies. Enzymatic activity was determined as described in Materials and Methods, except that the substrates were changed as indicated and 24 μg of protein was used. A, Effect of lysophospholipid concentration; B, effect of acetyl-CoA concentration; ●, lyso-PAF acetyltransferase; ○, LPC acetyltransferase.

Product identification. The following steps were carried out to identify the reaction product: (a) The reaction product was hydrolyzed with phospholipase C and acetylated with acetic anhydride. The chemically modified radioactive product was chromatographed by TLC. The reaction product had exactly the same mobility as that of authentic 1-alkyl-2,3-diacetyl glycerol when lyso-PAF was used as a substrate (Fig. 5). When LPC was used as a substrate, on the other hand, 1-acyl-2,3-diacetyl glycerol was the major reaction product. However, a small amount of reaction product was detected even though lysophospholipids were not added exogenously, which suggests that either endogenous lyso-PAF or LPC may be used as an acetyl acceptor. (b) The reaction product elicited a significant platelet aggregation in a dose-dependent manner when lyso-PAF was added as a substrate (Fig. 6).

TABLE 2

Effect of Various Reagents on Acetyltransferase Activities

Reagents added	Concentration (mM)	Relative activity (%)	
		Lyso-PAF	LPC
None	—	100	100
EDTA	1	14	12
EGTA	1	28	22
$CaCl_2$	10	42	44
$MgCl_2$	10	76	76
$MnCl_2$	10	4	6
NaCl	200	29	36
KCl	200	26	33
p-CMBS	0.5	0	0
NEM	1	11	14
DIPF	1	96	117
PMSF	5	116	92

Lyso-PAF, 1-alkyl-2-lyso-*sn*-glycero-3-phosphocholine; LPC, 1-acyl-2-lyso-*sn*-glycero-3-phosphocholine; p-CMBS, p-chloromercuribenzene sulfonic acid; NEM, N-ethylmaleimide; DIPF, diisopropyl fluorophosphate; PMSF, phenylmethylsulfonyl fluoride.

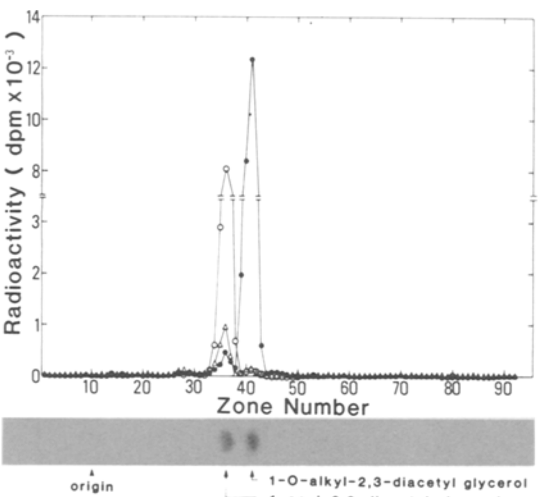

FIG. 5. Thin layer chromatographic identification of the reaction product. The enzymatic reaction products of several incubations with identical substrates were pooled and applied to thin layer plate developing with chloroform/methanol/acetic acid/water (50:25:8:4, v/v/v/v). Radioactive products with the same mobility as authentic PAF were extracted and hydrolyzed with phospholipase C (28), followed by acetylation with acetic anhydride (29). The reaction product was chromatographed on a thin layer plate, which first was developed 7 cm from the origin with hexane/ethyl ether/acetic acid (50:50:1, v/v/v) and then 15 cm from the origin with toluene. The silica gel plate was scraped in 2-mm sections, and the radioactivity was determined by liquid scintillation counting. ●, Lyso-PAF acetyltransferase; ○, LPC acetyltransferase; △, no lysophospholipid added.

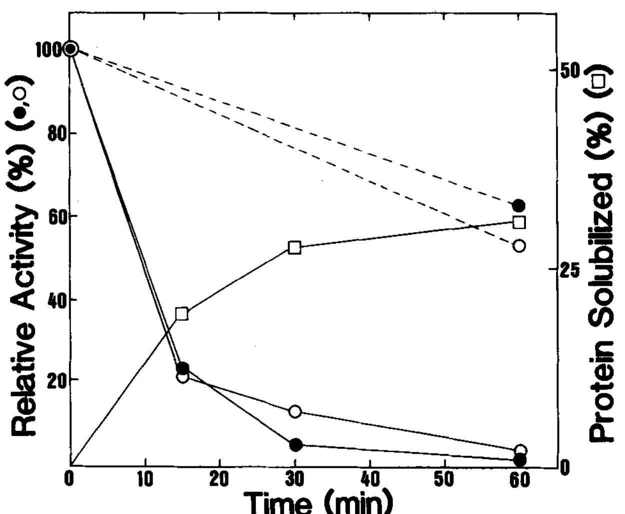

FIG. 4. Effect of tryptic digestion of rat spleen microsomes. Microsomes (10 mg of protein) were digested with trypsin (5 mg) at 30 C, and the reaction was stopped at the indicated time by adding a trypsin inhibitor (7.5 mg). The trypsin-treated microsomes were isolated by centrifugation at 105,000 × g for 1 hr. ●, Lyso-PAF acetyltransferase; ○, LPC acetyltransferase; □, protein solubilized. Dotted line represents an untreated control.

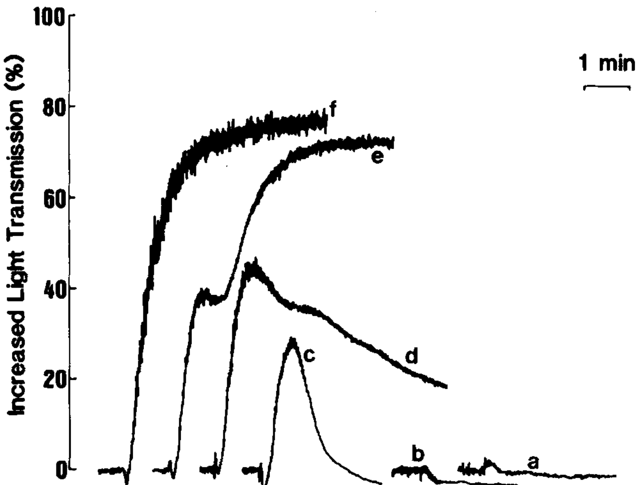

FIG. 6. Platelet aggregation by the enzyme reaction product. The radioactive product was pooled as described in Fig. 5, and the biological activity was assessed by platelet aggregation (30). Human venous blood was drawn from healthy volunteers and added to 1/10 volumes of 3.8% citrate anticoagulant. Platelet-rich plasma (PRP, $5 \times 10^5/mm^3$) was prepared by centrifugation at 250 × g for 15 min. Platelet aggregation was measured by the turbidimetric method using an aggregometer (31). The reaction was started by the addition of the sample to 200 μl of PRP maintained at 37 C with continuous stirring. The radioactive product was prepared from an incubation mixture containing the following lysophospholipids as substrates: None (a), LPC 476 nM (b), lyso-PAF 48 nM (c), 91 nM (d), 176 nM (e) and 244 nM (f).

However, the reaction product showed no platelet aggregation when LPC was used as a substrate.

DISCUSSION

Solubilization of membrane-bound enzymes without loss of activity has been achieved in the past by the use of nondenaturating detergents such as Triton X-100. The acetyltransferase under investigation here, however, was completely inactivated by these detergents. One possible explanation for such inactivation is that the detergents replace membrane-phospholipids and that the association

of these membrane-phospholipids with the enzyme may be essential for enzyme activity. In these experiments, we were able to solubilize effectively the acetyltransferase from rat spleen microsomes by ultrasonic disruption in the presence of 25% glycerol. However, it is possible that the activity is still associated with small membrane vesicles that failed to sediment. By a similar procedure, phosphatidylglycerol phosphatase (EC 3.1.3.27) was solubilized from rat liver mitochondria (32).

Wykle et al. (6) reported the presence of an acetyltransferase activity in rat spleen microsomes. The product of the reaction was identified by TLC, but its biological potency in platelet aggregation tests was not documented. Satouchi et al. (33) reported that acyl-type PAF, 1-acyl-2-acetyl-*sn*-glycero-3-phosphocholine, was produced concomitantly with PAF by stimulated rabbit polymorphonuclear neutrophiles. This correlation may suggest that the enzymes involved in the steps of deacylation and acetylation in PAF synthesis (34) do not have strict selectivity for linkage at the *sn*-1 position of choline phosphoglyceride. In fact, an acyl analog of lyso-PAF, LPC, can serve as a substrate (6). In addition, Mueller et al. (35) detected the synthesis of acyl-type PAF (13.0–25.7%) when polymorphonuclear leucocytes were incubated with [^{3}H]acetate in the presence of various stimuli. Therefore, acetyltransferase may contribute to the formation of acyl-type PAF in the cells. These results suggest that the same acetyltransferase was responsible for the transfer of [^{3}H]-acetate from [^{3}H]acetyl-CoA to lyso-PAF or LPC, respectively. Therefore, the availability of lyso-PAF and LPC in vivo may exert a regulatory influence on the production of PAF. An interesting problem for future study is whether the acyl-type PAF has a different role from PAF.

Recently, Lee et al. (36) demonstrated that microsomal rat spleen preparations can synthesize alkyl-acetyl-glycerol by an acetyl-CoA:alkyl-lyso-*sn*-glycero-3-phosphate acetyltransferase and that this intermediate is subsequently dephosphorylated by an alkyl-acetyl-*sn*-glycero-3-phosphate phosphohydrolase to generate alkyl-acetyl-glycerol. Furthermore, they found that the acetyltransferase differs from the acetyltransferase responsible for the transfer of acetate from acetyl-CoA to lyso-PAF. The biosynthesis of these unique diglyceride analogs that possess a short chain acyl group at the *sn*-2 position could have important ramifications other than just in the formation of PAF, since in some systems oleoyl-acetyl-glycerols (37) and alkyl-acetyl-glycerols (38) can exert potent biological effects, such as the activation of protein kinase C and the induction of cellular differentiation, respectively. However, no definitive conclusion can be reached until the enzymes are purified and the properties studied.[1]

ACKNOWLEDGMENTS

This investigation was supported by a Grant-in-Aid from the Ministry of Education, Science and Culture of Japan and by a grant from the Eisai Science Foundation.

[1]After submission of this manuscript, a paper on the partial purification and characterization of 1-O-alkyl-2-lyso-*sn*-glycero-3-phosphocholine:acetyl-CoA acetyltransferase from rat spleen was published (Gomez-Cambronero, J., Velasco, S., Sanchez-Crespo, M., Vivanco, F., and Mato, J.M. (1986) *Biochem. J. 237* 439–445); the activity in the presence of LPC was about 12% of that observed with lyso-PAF.

[Received September 19, 1986]

Two New Icosapentaenoic Acids from the Temperate Red Seaweed *Ptilota filicina* J. Agardh

Albert Lopez and **William H. Gerwick***
College of Pharmacy, Oregon State University, Corvallis, OR 97331

Two new fatty acid metabolites, 5(Z),7(E),9(E),14(Z),17(Z)-icosapentaenoic acid and 5(E),7(E),9(E),14(Z),17(Z)-icosapentaenoic acid, have been isolated from the temperate red marine alga, *Ptilota filicina* (Ceramiales, Rhodophyta). The structures of these new compounds, isolated as their methyl ester derivatives, have been deduced from detailed ^{1}H nuclear magnetic resonance (NMR), ^{13}C NMR and 2D-NMR analyses as well as comparisons to known compounds.
Lipids 22, 190–194 (1987).

The widespread occurrence of ω3 fatty acids in marine organisms is a unique feature of marine-derived lipids with considerable health and economic consequences (1–6). Further, relatively simple biochemical modifications of arachidonic and icosapentaenoic acids results in molecules possessing important hormonal and bioregulatory functions in mammalian systems (7–9). Hence, we have been interested in examining metabolites of fatty acid origin from Oregon coastal seaweeds as part of our evaluation of the biomedicinal potential of these marine plants. The lipid extract of *Ptilota filicina* was identified in our survey efforts as strongly antimicrobial to gram-positive and -negative bacteria and possessed several unique secondary metabolites by thin layer chromatographic (TLC) analysis. A series of subsequent large-scale recollections have yielded, following extensive purification work, several new and uniquely functionalized 20 carbon fatty acids. The structures of two of these—5(Z),7(E),9(E),14(Z),17(Z)-icosapentaenoic acid (1) and 5(E),7(E),9(E),14(Z),17(Z)-icosapentaenoic acid (3)—are reported here (Scheme 1).

Other species of the genus *Ptilota* from elsewhere in the world have been examined previously for new biomedicinal agents. From *P. pectinata* collected from Norway, the amino acid taurine was identified (10); from *P. plumosa* from the coast of Great Britain, a potent hemagglutinin activity with human B cells has been described (11–13). *P. filicina* from the Soviet Union has been examined as a possible food source due to reported high concentrations of essential amino acids (14). However, Oregon coastal seaweeds have not been previously examined in detail, presumably due to the combination of adverse collection conditions and fewer reports of unique terpenoid natural products from temperate zone algae. Hence, the natural products of *P. filicina* from Oregon were unstudied prior to this work.

EXPERIMENTAL METHODS

Ultraviolet spectra were recorded on an Aminco DW-2a UV-Vis spectrophotometer and infrared spectra (IR) on a Perkin-Elmer 727 spectrophotometer. Nuclear magnetic resonance (NMR) spectra were recorded on Varian EM 360, FT-80A and Bruker AM 400 NMR spectrometers, and all shifts are reported relative to an internal TMS standard. Low resolution mass spectra (LRMS) were obtained on a Varian MAT CH7 spectrometer, while high resolution mass spectra (HRMS) were obtained on a Kratos MS 50 TC. High performance liquid chromatography (HPLC) was done using a Waters M-6000 pump, U6K injector and R 401 differential refractometer, while thin layer chromatograms were made using Merck aluminum-backed TLC sheets (silica gel 60 F_{254}). All solvents were distilled from glass prior to use.

P. filicina was collected from exposed intertidal pools (−0.5 to +0.5 m) at Marine Gardens on the Oregon coast in June 1985. Voucher specimens are on deposit at the Department of Botany Herbarium at Oregon State University. The seaweed was preserved by freezing until workup, at which time the defrosted alga (1.522 kg dry weight) was homogenized in warm $CHCl_3$/MeOH (2:1, v/v). The mixture was filtered and the solvents were removed in vacuo to yield a residue that was partitioned between $CHCl_3$ and H_2O. The $CHCl_3$ was dried over $MgSO_4$, filtered and reduced in vacuo to yield 17.3 g of a dark green tar. The crude extract was fractionated by silica gel chromatography in the vacuum mode (10 cm × 9 cm, Merck TLC-grade Kieselgel), and metabolites were

*To whom correspondence should be addressed.

progressively eluted with increasingly polar mixtures of isooctane and EtOAc. Those eluting with 25–45% EtOAc/isooctane yielded a mixture of fatty acids containing compounds 1 and 3. Treatment of a portion of these fractions with CH_2N_2 afforded a mixture of methyl esters (696 mg), which was subsequently chromatographed on a gravity-driven silica gel column (2.5 cm × 55 cm, Woelm Kieselgel 70–230 mesh) using isocratic conditions (EtOAc/isooctane, 1:9, v/v). This yielded a simplified mixture of 2 and 4 (296 mg) from which each could be isolated by normal phase HPLC (Alltech Si Gel column, 25 cm × 10 mm, 2.0% EtOAc/isooctane) to give 71.5 mg of 2 and 44.3 mg of 4, both as colorless oils.

Methyl 5(Z),7(E),9(E),14(Z),17(Z)-icosapentaenoate (2). Compound 2 was a colorless mobile oil showing the following: UV (MeOH) λ_{max} 253, 262, 273 nm (ε = 56,880; 74,570; 56,370); IR ($CHCl_3$) ν 3010, 2925-2875, 1735, 1450, 1000, 920 cm^{-1}. For ^1H NMR and ^{13}C NMR data, see Table 1.

Methyl 5(E),7(E),9(E),14(Z),17(Z)-icosapentaenoate (4). Compound 4 was also isolated as a colorless mobile oil and showed UV (MeOH) λ_{max} 258, 268, 279 (ε = 45,000; 57,000; 44,000); IR ($CHCl_3$) ν 3015, 2930-2870, 1735, 1440, 1000 cm^{-1}. For ^1H NMR and ^{13}C NMR data, see Table 1.

N-Icosa-5(E),7(E),9(E),14(Z),17(Z)-pentaenoyl pyrrolidine (5). The pyrrolidide derivative 5 was obtained via the following literature procedure (15): At 0 C, freshly distilled pyrrolidine (1 ml) was added to a partially pure sample of 4 (12.2 mg), glacial acetic acid (0.1 ml) was added and the solution was maintained at 20 C. After 24 hr, the reaction was terminated by quenching with water, and the products were repetitively extracted with $CHCl_3$ (3 × 25 ml). The $CHCl_3$ layer was first washed with 1 M HCl (3 × 25 ml) and then with H_2O (3 × 25 ml); it then was evaporated in vacuo to obtain 9.2 mg of crude product. Final purification of compound 5 (ca. 1.8 mg) was achieved using HPLC (Waters μ-Porasil 8 mm × 50 cm, 40% EtOAc in isooctane) and showed the following: ^1H NMR (bz-d-6) δ0.91 (3H, t, J=7.7 Hz), 1.21 (4H, m, N-CH_2*CH_2*), 1.39 (2H, p, J=7.4 Hz), 1.93 (4H, m), 2.03 (4H, q, J=7.2 Hz), 2.16 (2H, q, J=6.9 Hz), 2.65 (2H, t, J=6.5 Hz, N-*CH_2*), 2.79 (2H, bt, J=6.3 Hz), 3.38 (2H, t, J=6.4, N-*CH_2*), 5.45 (4H, m), 5.60 (2H, m), 6.18 (4H, m). Low resolution electron impact mass spectrometry (LR EIMS) m/z (rel. intensity): 356 (M^+)+H (1.7), 355 (M^+) (6.7), 340 (0.2), 326 (0.3), 312 (0.4), 300 (0.3), 286 (1.8), 272 (0.5), 260 (0.3), 246 (1.4), 232 (1.0), 218 (1.1), 2.04 (0.6), 192 (0.6), 178 (0.6), 166 (1.4), 152 (2.4), 140 (1.8), 126 (5.9), 113 (100), 98 (19.3), 70 (26.2), 55 (46.1); HR EIMS m/z, obs. 356.2969 (M^+)+H, $C_{24}H_{38}NO$ requires 356.2955.

RESULTS AND DISCUSSION

The red seaweed *P. filicina* (Ceramiales) grows abundantly in the mid-intertidal zone along the central Oregon coast (16). Based on the results of our survey for biomedicinals from Oregon seaweeds, a large recollection was made in June 1985 and maintained frozen until extracted for its lipids using standard methodology. Conventional silica gel vacuum chromatography of this dark green oily tar gave several fractions containing a brown charring, UV active compound. By infrared (IR) and ^{13}C NMR analyses, these fractions were a mixture of carboxylic acids that were rendered separable following derivation to the corresponding methyl esters (CH_2N_2). Final purification of these derivatives was achieved using silica gel column chromatography followed by HPLC and yielded two unstable colorless oils (2 and 4), the structures of which were deduced from spectroscopic data as outlined below.

It was recognized early in the structure elucidation process that 2 and 4 were geometrical isomers of one another, due to the similarity in spectroscopic properties of the two molecules and the spontaneous room temperature conversion of 2 and 4, monitored by HPLC. Further, the characteristic ultraviolet absorptions for a *c,t,t* triene functionality (λ_{max} = 253, 262, 273) in 2 were replaced in the absorption spectra of 4 with those characteristic for a *t,t,t*-triene (λ_{max} = 258, 268, 279) (17). Hence, the greater instability of 2 was explained by its propensity to double bond isomerization as well as autoxidation and presumed polymerization (18–20).

As neither 2 nor 4 gave meaningful mass spectral information (electron impact, chemical ionization), the more stable metabolite derivative, 4, was converted into the corresponding pyrrolidide (5) (21). Derivative 5 was characterized by LR EIMS (obs. M^+ 355 [6.7%]) and HR EIMS (obs. [M^+]+H) to yield a molecular formula of $C_{24}H_{37}NO$. Hence, the corresponding molecular formula

[b]Assignments by comparison with values determined for 4 and with several model compounds (24,25,27).

[c]Assignments from a ^1H-^{13}C heteronuclear 2D shift correlation spectroscopy experiment and by comparisons with model compounds (24,25,27).

[d]Carbons assigned by comparison to model *c,t,t* and *t,t,t* conjugated trienes (27).

for both natural products (1 and 3) was $C_{20}H_{30}O_2$, yielding six degrees of unsaturation.

Further structure elucidation efforts were conducted with derivative 2, principally because most of its protons were clearly resolved in its high field ^{1}H NMR spectrum (Table 1). The ^{13}C NMR spectrum of 2 showed one ester carbonyl, confirmed by a characteristic stretch at 1735 cm^{-1} in the IR, and 10 olefinic carbon atoms, thus accounting for all six degrees of unsaturation. Other than these olefin and ester carbons, the ^{13}C NMR spectrum was composed of one methyl ester carbon, one aliphatic methyl carbon and eight methylene carbons. Hence, 2 was deduced to be a methyl ester derivative of an icosapentaenoic acid containing a conjugated *c,t,t* triene as well as two nonconjugated double bonds.

The linear array of these methylene and olefinic groups in 2 was conveniently given by a ^{1}H-^{1}H 2D shift correlation spectroscopy (COSY) experiment (Fig. 1) (22). The C-2 protons, identified by their characteristic chemical shift (δ2.33) and triplet multiplicity (23), were correlated to a 2H signal at δ1.73 (H_2-3), which was further correlated to another 2H signal appearing at δ2.23 (H_2-4). The allylic nature of these latter protons was indicated by both their chemical shift and a clear correlation to an olefin proton at δ5.33. As this latter signal overlapped four other protons at this chemical shift, observation of the continuity of this linearly related spin system was afforded by detection of allylic coupling between H_2-4 and H-6 (δ6.04). The H-6 proton was correlated both to the H-5 proton at δ5.33 and the H-7 proton at δ6.35. The H-7 signal was, in turn, correlated to H-8 (δ6.15), H-8 to H-9 (δ6.10) and H-9 to H-10 (δ5.71). Coupling constant analysis (Table 1) of this C-5 to C-10 olefin constellation reconfirmed the *c,t,t* nature of the triene, as well as fixing its orientation relative to the carboxyl group.

A correlation between H-10 and two protons of a 6H multiplet at δ2.09 identified the allylic protons at C-11. This latter multiplet was coupled in the upfield region only to the terminal methyl group and a 2H signal at δ1.46. This latter signal must, therefore, be H_2-12. In turn, these C-12 protons were coupled exclusively to the 6H multiplet at δ2.09, and therefore, H-13 must also be allylic. Further, since the 6H multiplet was only coupled in the olefin region to one proton at δ5.71 (H-10) and to two of five overlapping protons at δ5.33, H-14 must be located in this latter multiplet.

At the other end, the terminal methyl group (δ0.97) was correlated to the 6H multiplet of overlapping allylic protons at δ2.09 and thus must contain, in addition to H_2-11 and H_2-13, H_2-19. In analogy to the reasoning used to

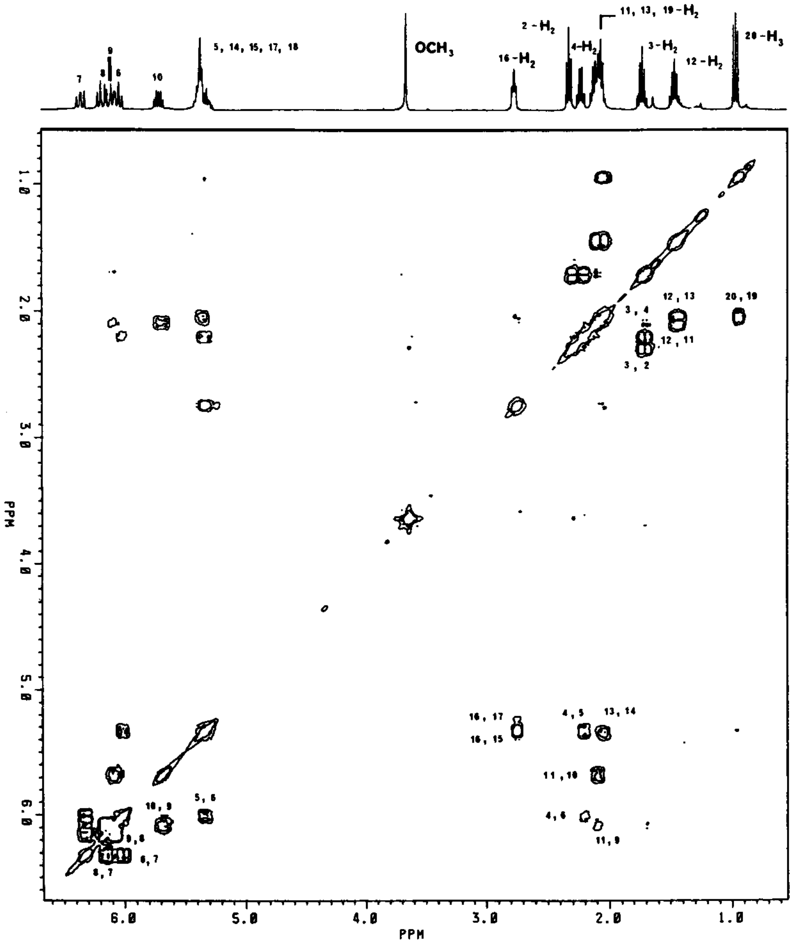

FIG. 1. ^{1}H-^{1}H correlation spectroscopy (22) of methyl 5(Z),7(E),9(E),14(Z),17(Z)-icosapentaenoate (2) showing correlations between coupled protons (ca. 7 mg of 2 in 0.4 ml $CDCl_3$ with 0.3% TMS, 5-mm tube, 400 MHz).

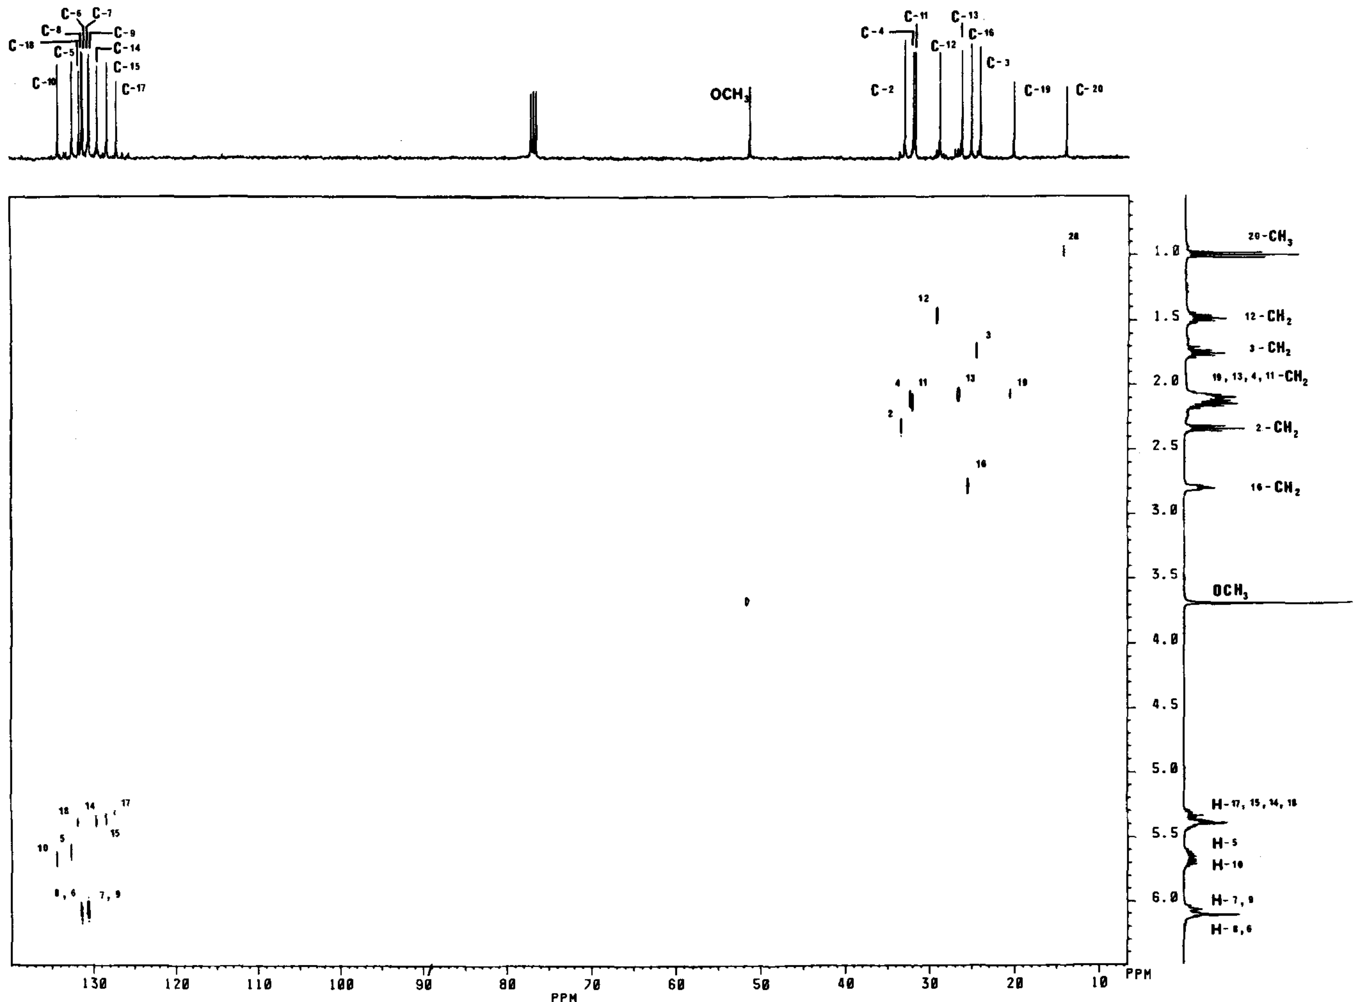

FIG. 2. ^1H-^{13}C heteronuclear 2D shift correlation spectroscopy (22) of methyl 5(E),7(E),9(E),14(Z),17(Z)-icosapentaenoate (4) showing one bond coupling (^1J) correlations between carbons and their respective protons (ca. 20 mg of 4 in 0.4 ml $CDCl_3$ with 0.3% TMS, 5-mm tube; ^1H NMR at 400 MHz, ^{13}C NMR at 100 MHz).

identify the H-14 chemical shift, the H-18 proton must also be in the 5H multiplet at δ5.33.

A third partial structure for derivative 2 was identified beginning with a bisallylic methylene, identified as such by its characteristic chemical shift (δ2.77) and multiplicity (t, J=6.1 Hz) (23). In the COSY experiment, these protons were exclusively correlated to two of the five olefin protons occurring as an multiplet at δ5.33. By a ^1H-^{13}C heteronuclear 2D shift correlation spectroscopy experiment (Fig. 2) (22), the carbon shift of the bisallylic methylene was identified as δ25.56; hence, via comparison with all four geometrical isomers of the model compound, methyl-12,15-octadecadienoate, both olefins were of the Z geometry (24).

Consideration of these three partial structures with regards to the molecular formula and number of olefins in 2 required two of the olefins to be duplications. With two connections to be made between these three partial structures, and with the middle fragment being symmetrical, only one structure, 2, was possible.

The structure of derivative 4 was developed by comparison of its spectroscopic properties with those of derivative 2 (Table 1). In most respects, the major structural features present in 2 were also present in 4, as was suggested by the facile conversion of 2 into 4. The major difference was that the *c,t,t* triene in 2 was replaced in 4 by a *t,t,t* triene. This was evidenced by UV (see experimental), ^1H NMR ($J_{5\text{-}6}$ = 14.4 Hz, $J_{9\text{-}10}$ = 14.4 Hz) and ^{13}C NMR data (6 olefin carbon signals greater than 130 ppm) (25).

It is likely that both natural products 1 and 3 are derived by isomerization of the $C_{8\text{-}9}$ and $C_{11\text{-}12}$ olefins in 5(Z),8(Z),11(Z),14(Z),17(Z)-icosapentaenoic acid to the $C_{7\text{-}8}$ and $C_{9\text{-}10}$ positions. Metabolites 1 and 3 were shown to be true natural products of *P. filicina* by nearly identical TLCs for the lipid extracts obtained by standard extraction methodology and by a procedure described to inhibit extraction artifacts resulting from enzyme-catalyzed degradation of complex lipids (26).

ACKNOWLEDGMENTS

Harry Phinney of the Department of Botany at Oregon State University helped in the collection and identification of the *Ptilota filicina*. Roger Kohnert assisted in obtaining NMR data on the OSU Department of Chemistry's Bruker AM 400 spectrometer, purchased in part through grants from the National Science Foundation (CHE-8216190) and the M. J. Murdock Charitable Trust. Brian Arbogast

and Don Griffin helped with the low and high resolution mass spectra through the mass spectral facility in the OSU College of Agricultural Chemistry. The high resolution instrument, a Kratos MS 50 TC, was purchased with grants from the National Institutes of Health Division of Resources (DRR 1S10RR01409). The reviewers of this manuscript gave constructive comments. This work was supported by the Oregon Sea Grant Program (R/PD-47).

METHODS

Analysis of Volatile Fatty Acids in Biological Specimens by Capillary Column Gas Chromatography

S.E. Fleming[1], **H. Traitler*** and **B. Koellreuter**
Nestle Research Department, Nestec Ltd., 1800-Vevey, Switzerland

A method was developed to analyze and quantify volatile fatty acids (VFA) such as acetic, propionic, butyric, isobutyric, valeric and isovaleric acids in biological specimens. To obtain good sample transfer into the chromatographic system an organic solvent had to be used together with an aqueous milieu, thus improving wetting properties of the liquid sample plug introduced into the column. Sample preparation was carried out under alkaline conditions in order to exclude or minimize sample losses due to sample transfer during the extraction and work-up procedure. A cold on-column injection was applied to avoid irregular discrimination of the various acids due to sample splitting and an automatic injection technique was used to accommodate the large number of samples generated from biological origin. Connection of a pre-column of wide internal diameter (0.53 mm) to the analytical column (0.32 m) was optimized and adapted to the nature of the injection solvent mixture consisting of acetonitrile, water and hydrochloric acid. To obtain well-separated and correctly quantifiable gas chromatographic peaks, it was essential to perform the chromatography under acidic aqueous conditions. Standard resolution conditions and response factors were evaluated. The chromatographic results of applying this method to biological specimens from both rats and humans are provided.
Lipids 22, 195–200 (1987).

Volatile fatty acids (VFA) include components such as acetate, propionate, butyrate, isobutyrate, valerate and isovalerate. These components are described as being volatile since they can be steam distilled under acidic conditions, but they are also classified as short chain fatty acids due to their low molecular weights. Some of these compounds are produced during the normal metabolic processes, while all of them are produced in the large intestines of mammals, including humans, via fermentation pathways. It is this latter route of production that includes our research interest. VFA are produced when dietary components such as fibers, α-galactosides and unabsorbed starch and sugars are fermented. Recent evidence indicates that there are several potentially beneficial physiological effects of VFA production and absorption. These include their abilities to serve as an energy source (1,2) and their influence on the differentiation and growth of colonic epithelial cells (3,4). To study these effects, it is necessary to have a rapid, sensitive and accurate method for analyzing these constituents in biological specimens such as intestinal tissues, plasma and saliva.

Separation, identification and quantification of these volatile fatty acids have most commonly been done using gas liquid chromatography. However, the stationary phase of columns must be sufficiently polar to separate the acids without exhibiting excessive retention of the constituents, and it must also be efficient at low temperatures so that pyrolysis and decomposition of the constituents or of the stationary phases do not occur (5). A primary difficulty with this method of analysis, in the case of packed columns, has been the interaction between the acids and the column packing, which results in tailing of peaks (reversible adsorption) and retention of the acids on the column (irreversible adsorption). With subsequent injections, these constituents may be released, and this phenomenon has been referred to as "ghosting" or "memory effect." This type of absorption has been reduced by using glass columns in preference to stainless steel columns (5), by incorporating phosphoric acid into the packing materials (5) and by incorporating formic acid into the carrier gas stream (6). To some extent, these problems have been overcome by using capillary column chromatography (6). Recently, these constituents were reported to be separable by employing a fused silica capillary column coated with OV-351, which is a Carbowax nitroterephthalic acid polymer, and a split injection mode chromatography procedure (6). A similar technique has been used by others to analyze these constituents in human urine (7). Other workers (8) reported quantifying both volatile and nonvolatile organic acids as the t-butyldimethylsilyl derivatives following capillary chromatography using OV-17, a coating material of intermediate polarity.

A cold, on-column mode injection system and an immobilized phase composed of polar coating material were used in developing an alternate procedure for separating and quantifying VFA using capillary column chromatography. With this procedure, accurate and reproducible analyses of VFA were performed in extracts prepared from biological samples including plasma, saliva, intestinal contents and intestinal tissues.

MATERIALS AND METHODS

Materials. Routine separations of the acids were made using a standard mixture containing acetic, n-propionic, isopropionic, n-butyric, isobutyric, n-valeric and isovaleric acids (WFA-2, Supelco, Gland, Switzerland). Isocaproic acid (Fluka AG, Switzerland) was added to this mixture and served as an internal standard for purposes of quantification. Acetonitrile (Romil Chem., Shepshed, England; HPLC grade) was used without further purification, and it was necessary to use a high-purity grade solvent so that there was no measurable contamination with acetic acid. Hydrochloric acid, methanol, acetone, hexane (all from Merck, Darmstadt, Federal Republic of Germany),

tridecane (Fluka) and sodium chloride (Merck) were used as supplied. Water was deionized and distilled.

Apparatus. A fused-silica capillary column (25 m × 0.32 mm ID) was coated with Carbowax 20M (Applied Science Labs., State College, Pennsylvania) using a procedure fully described elsewhere (9), and a desired film thickness was 0.30 μm. A fused-silica (1 m × 0.53 mm ID) precolumn was also utilized after applying a procedure in which it was washed, using suction, with a solution of 5% (w/v) γ-glycidoxypropyltrimethoxysilane (Union Carbide, New York, New York) in methanol. The Carlo Erba Mega HRGC 5160 chromatograph used was equipped with an automatic liquid on-column injector (Carlo Erba AS-550). Data were generated and acquired using a Spectra-Physics 4700 integration system.

In general, the chromatography was conducted using hydrogen as carrier gas at a flow of 2.5 ml/min and a pressure of 0.6 kPa. The precolumn was connected to the analytical column by means of a purged-butt connector that facilitated entrance of hydrogen as a make-up or auxiliary gas to flush the union, and the analytical column was inserted into the precolumn by at least 1 mm. The flame ionization detector was operated at 300 C with gas flows of 300 ml/min for air and 30 ml/min for hydrogen. Nitrogen (ca. 20 ml/min) was used as make-up gas. The injector block was air-cooled and was equipped with a secondary cooling system. The injection was made directly into the column at the point that it entered the oven.

Use of a precolumn was found to be necessary to extend the lifetime of the analytical column. This fused silica precolumn was of 0.53 mm id and was treated prior to being installed with a silane monomer (9) followed by washing with ca. 10 ml of the acidic/aqueous/organic solvent mixture. Furthermore, we were able to intermittently remove the precolumn from the chromatograph, and to flush the precolumn with this solvent mixture so that accumulated impurities and salts could be removed. This precolumn and its treatment significantly extended the lifetime of the analytical column.

Sample preparation and assay procedure. Standard curves were derived by the addition of analytes and internal standard (isocaproic acid) to the solution composed of the desired solvent:water/HCl ratio. The calibration ranges were from 0–800 nmol/ml for each acid. The ratios of the integrated areas for the seven VFA were calculated as a percentage of the integrated areas for 400 nmol of internal standard, and these ratios were plotted against concentration of the analyte to generate the standard curves. Linear regression analysis was then used to determine the quantity of VFA in a sample to which had been added 400 nmol of internal standard. The extractions of VFA from biological specimens were performed using the alcoholic extraction procedure of Remesy and Demigne (5), except that KOH was used to alkalinize the extracts in place of NaOH, and the ratio of ethanol:water was increased from 5:1 to 8:1.

RESULTS

Fused silica columns coated with Carbowax 20M to desired film thicknesses ranging from 0.20–0.50 μm were prepared. Those columns with film thicknesses of 0.20–0.30 μm were found to give the best separations of the six VFA and the internal standard (isocaproic acid), and the peak shapes tended to be sharper, which allowed more accurate quantification. In our experience, better resolution of these seven components was achieved with immobilized Carbowax 20M as a coating material than with OV-351.

The choice of solvent had a significant effect on the general appearance of the solvent front and baseline as well as the resolution of the compounds. Six solvents—acetone, acetonitrile, hexane, methanol, tridecane and water—were evaluated. None provided acceptable results when used in a single solvent system. Solvent peaks tended to be broad for methanol and acetone, and this interfered with elution of the components of interest. However, when a solvent/water mixture was used, the characteristics of the solvent peak were tremendously improved.

Solvent. Water mixtures of 8:2 were generally found to produce the most desirable results. Of the six solvent systems evaluated, acetone/water and acetonitrile/water were found to be the most favorable, since they provided excellent characteristics in showing a rapid return to baseline following the elution of the solvent, and the seven compounds were fully resolved. By contrast, resolution of the components was poor when methanol/water was used as solvent; the immiscibility of some of these solvents with water precluded their use. When water was used as the sole solvent, the peak shapes of the acids were generally poor.

The degree of acidification had a marked effect on the chromatography of the acids. Without adequate acidification, the compounds failed to elute as distinct, quantifiable peaks. Additionally, ghosting, or the appearance of components from one injection during subsequent injections, and retention time shifts were serious problems. These problems were overcome by adjusting the acidity so that the peaks were discrete and unchanged by further addition of acid. In general, we found that using 1 N HCl in the presence of 80% of the other organic solvent provided excellent results. Nonetheless, it was necessary to add additional HCl if samples were stored for more than 18 hr prior to their analyses. It should be emphasized, however, that there were no observable undesirable consequences of "overacidifying" since no further changes were detected in peak shape or area ratios of the acids to internal standard once the critical, but minimum, quantity of acid had been added.

Temperature programming was used in all analyses. We found that the characteristics of the solvent peaks were best when initial temperatures of 60–75 C were used. At higher starting temperatures, the solvent peak was excessively large. Following a time lag of 2 min at the initial temperature, a constant increase at 8 C/min was found to provide optimum resolution of the components. Under these conditions, the compound of highest molecular weight, isocaproic acid, was eluted within 10–12 min. Nonetheless, continuous high quality resolution was only achieved if the oven temperature was cycled to 180–200 C and held at that temperature for at least 5 min.

A typical chromatogram showing the separation of the six VFA and isocaproic acid as internal standard is provided in Figure 1. The seven components are distinctly separable. Reproducibility of duplicate injections were

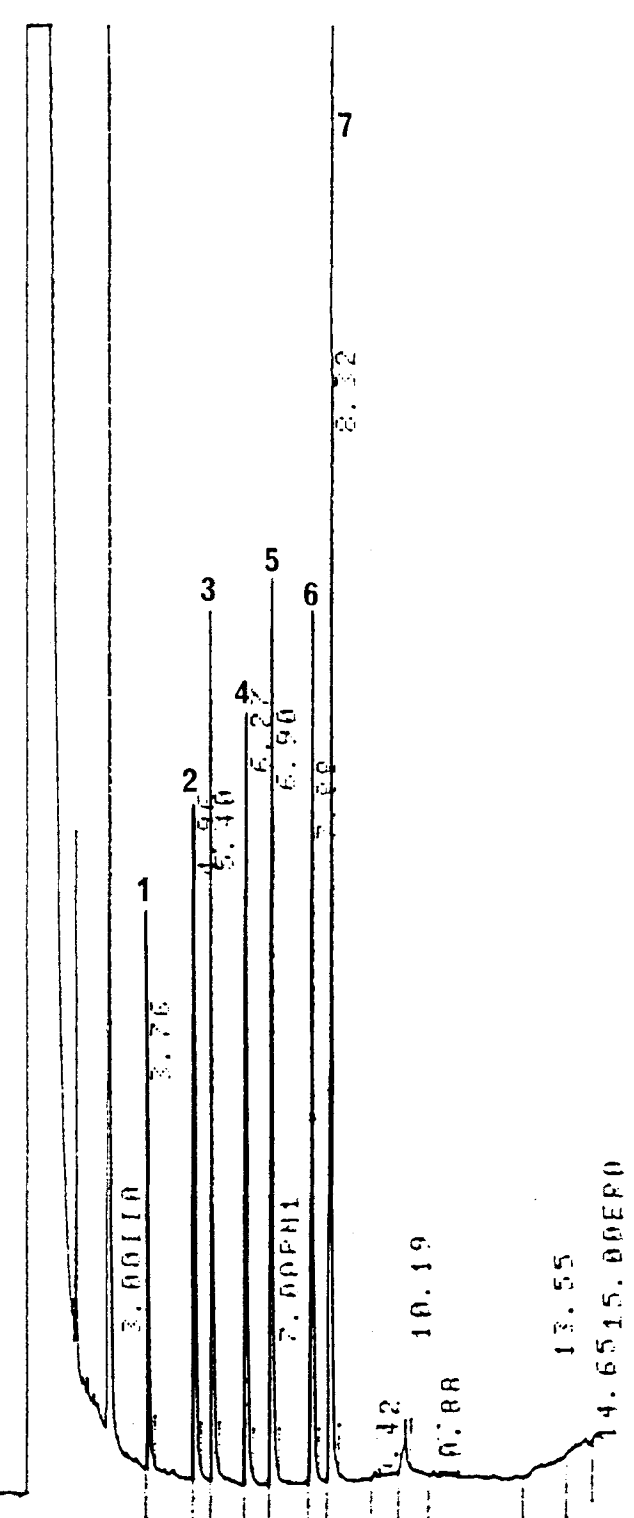

FIG. 1. Chromatogram of standard VFA (WSFA-2, Supelco Inc.) with isocaproic acid as internal standard. Peak identifications: 1, acetic acid; 2, propionic acid; 3, isobutyric acid; 4, n-butyric acid; 5, isovaleric acid; 6, n-valeric acid; 7, isocaproic acid. Solvent: acetonitrile/H_2O; temp. prog: 65–145 C; injector: cold, on-column; detector: FID, 300 C.

found to be within 5%, when the area ratios of the VFA:internal standard were calculated. Additionally, the response was found to be linear between the range of at least 0–800 nmol/ml when a 1 μl injection was made (Fig. 2), and this linearity may have continued although higher concentrations were not evaluated. We estimate that the lower limits of detection were in the range of 20 nmol/ml and that the lower limits for quantification were in the range of 50 nmol/ml. The identity of the component that corresponded to the sharp peak that eluted before peak 1 (Fig. 1) was not determined but, since the purity of the WSFA-2 solution was not indicated, it is likely that this peak could have been formic acid.

The reproducibility with which we could analyze VFA in biological specimens closely approximated the reproducibility of our standards. In particular, the coefficients of variation of replicate injections for standard VFA, which had not undergone any of the routine extraction procedures necessary as part of the analytical procedure used to quantify VFA in biological specimens, ranged from 2–5%. When these same standards were subjected to the alcoholic extraction procedure, the coefficients of variation were unchanged. When biological specimens were similarly extracted and repeat injections made, the coefficients of variation ranged from 3–6% for specimens including plasma, cecal contents and cecal tissue of rats, and plasma and saliva from humans. Typical chromatograms of extracts prepared from these biological specimens are shown in Figure 3. It is worth noting that in

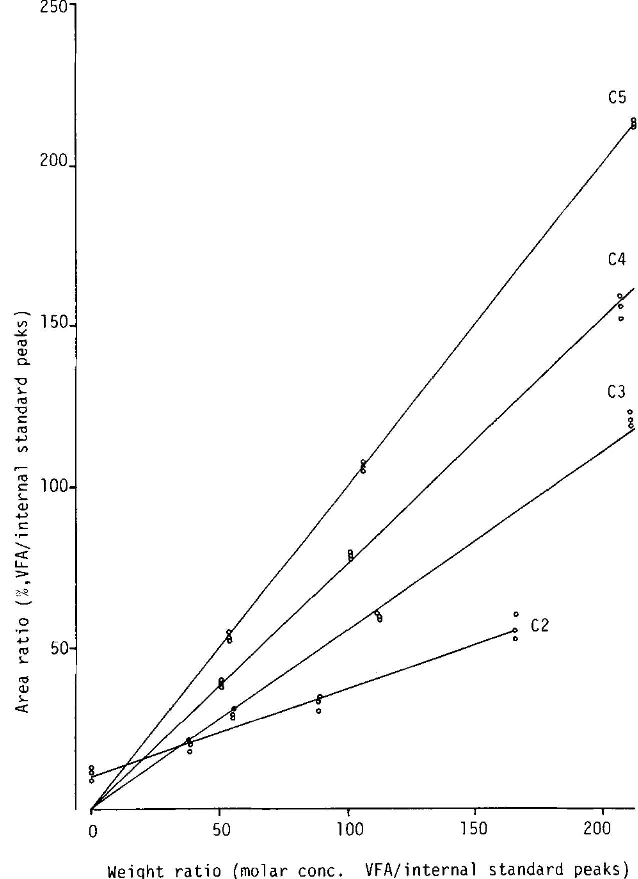

FIG. 2. Area ratio of VFA: internal standard peaks vs weight ratio of VFA: internal standard. Values were determined at 4 weight ratios for each of 4 standard VFA. Triplicate analyses were made on three days using newly prepared solutions.

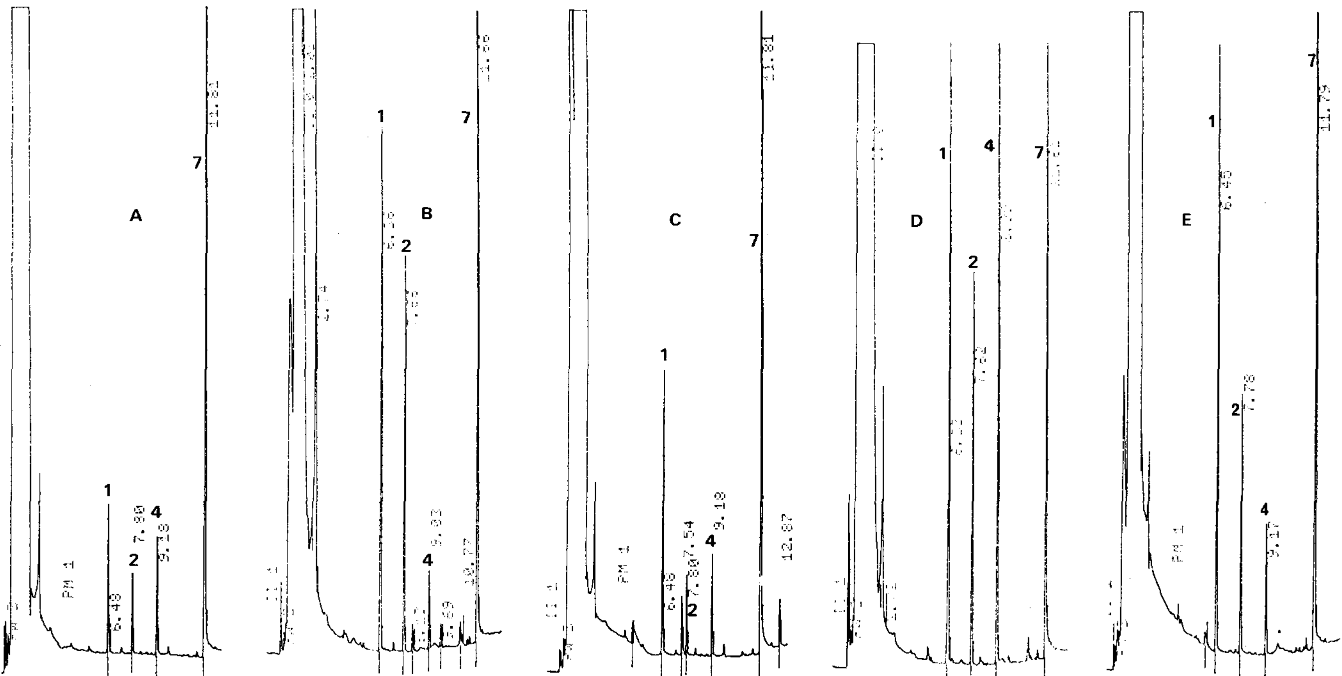

FIG. 3. Chromatograms of VFA in alcoholic extractions of biological specimens including human plasma, 300 mg (A); human saliva, 100 mg (B); rat portal plasma, 200 μl (C); rat cecal contents, 100 μl, 1:10 dilution (D); and rat cecal tissue, 100 μ, 1:10 dilution (E). Each chromatogram is shown in the presence of ca. 400 nmol of isocaproic acid as internal standard.

some of these biological specimens some higher molecular weight constituents were observed, but these did not interfere with further chromatographic analyses.

DISCUSSION

The objective of this research was to develop a capillary chromatography system to analyze volatile fatty acids in large numbers of biological specimens. Thus, we needed to have readily quantifiable chromatograms and columns that would remain functional during many analyses. Additionally, it was necessary to be able to perform each analysis quickly and with a minimum of preparation. To meet these objectives, we wished to avoid derivatization. This necessitated performing the chromatography in a solvent matrix consisting of water/hydrochloric acid together with an organic solvent.

Although other workers have reported using a polar phase such as OV-351 to separate the volatile fatty acids and their isomeric constituents (6), we found that these constituents were better resolved on a stationary phase of the polyethylene glycol type. Previously, we have reported using immobilized Carbowax 20M columns for the analyses of such lipids as methyl esters of long chain fatty acids and prostanoids (10–12). To prepare these columns, we used a technique in which silane monomers are grafted onto the polymer chains followed by cross-linking between the grafted units, which effected phase immobilization as previously reported (9). This polymer was found to be sufficiently stable to withstand repeated loads of the acidic/aqueous/organic solvent mixture used in the solubilization of underivatized volatile fatty acids, and it could also withstand large sample volumes of up to 10 μl without phase stripping effects. Additionally, this phase proved to be efficient and durable, since we were able to make more than 1000 analyses on a single column over a period of ca. 3 months using an automatic injection mode.

Due to the volatile nature of these acids, consideration was given to the nature of the injection system. An on-column injection mode was thought to be desirable since it avoids the discrimination of constituents, which may occur with the split-injection technique and a septum purge. Additionally, the on-column injection mode reduces the potential for degradation of the highly polar compounds, which may occur in an acidic medium if a flash evaporation technique is used such as occurs in a heated injector.

Given the desirability of using a direct injection system and a precolumn, it was necessary to use a precolumn that had a larger diameter (0.53 mm) than that of the analytical column (0.32) to accommodate the injection needle (ca. 0.4 mm). The precolumn had another positive side effect. Creating, by definition, a retention gap (13,14), this helped to avoid possible peak splitting, which otherwise could have occurred. The two columns were connected via a purged butt connector, using a technique that avoided dead volumes and backflush. In addition to the usual connection mode, a restricting valve can be installed in this gas line for precisely adjusting the auxiliary gas flow relative to the precolumn length. The conformation of the system is diagrammatically presented in Figure 4. The degree to which the pressure is restricted by this valve distinctly influences gas chromatographic performance, and this can most easily be observed by monitoring the elution shape of the solvent, as is shown by the examples of an incorrectly and a correctly purged butt connector (Fig. 5). Efficient flushing of this connector is also

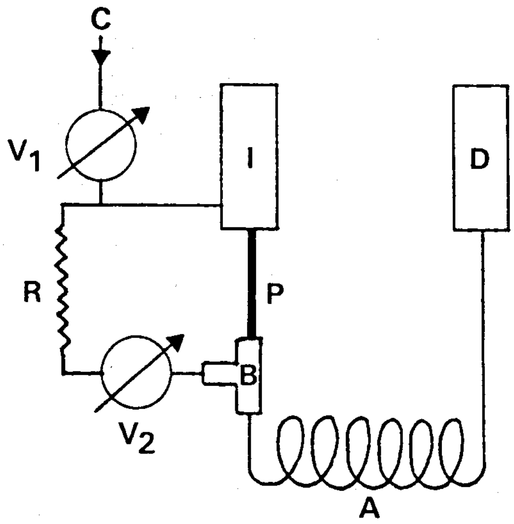

FIG. 4. Physical conformation of the analytical column, precolumn and carrier gas streams. A, analytical column; B, butt connector; C, carrier gas inlet; D, detector; I, injector; P, precolumn; R, restriction; V_1, carrier gas valve; V_2, fine metering valve.

essential in order to avoid the deposition or accumulation of noneluted and partially degraded compounds on the column. This would lead to rapid deterioration of column performance.

The optimum initial oven temperature for resolution of the VFA contained within this solvent system was found to be between 60-75 C. At these temperatures, peak resolutions were excellent, acetic acid was clearly separated from the solvent peak system and the overall speed of analysis was acceptable. At higher initial temperatures of ~80 C, an excessively large solvent peak was observed, and this interfered with the quantification of VFA; at lower initial temperatures of ~50 C, the speed of analyses was unnecessarily slow. The initial temperature was maintained for 1-2 min to allow elution of the solvent peaks, and this was followed by temperature programming at 8 C/min to 140 C. At this temperature, all VFA were eluted, but the column was still found to contain impurities that could be eluted by more rapidly heating the column to 200 C and maintaining this temperature for at least 5 min. Thus, the column was "purged" prior to the next injection, and the impurities were not allowed to accumulate. Nonetheless, we found that impurities collected

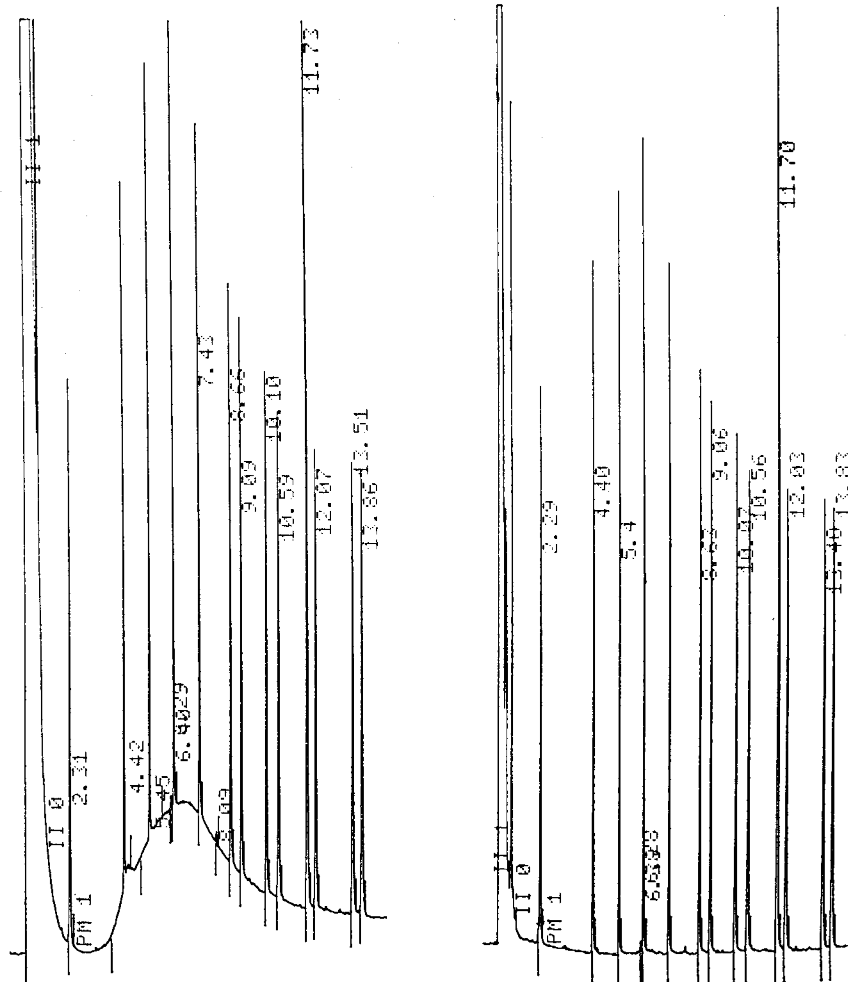

FIG. 5. Influence of proper purging of the butt connector on the elution shapes of the solvent peaks. Left chromatogram unpurged; right chromatogram purged. Peaks correspond to fatty acid methyl esters C8-C17.

in the precolumn over time, and this necessitated cleaning by cutting away an initial section or by rinsing with the injection solvent mix. These cleaning procedures were repeated roughly every 100 injections, and the total number of injections which could be made on one length of precolumn varied from 400–500. By caring in this way for the precolumn, we were able to make more than 1000 injections on a single analytical column. Thus, our experiences showed that the immobilized Carbowax columns were highly resistant against water, acid and solvent stripping.

Various solvent systems were evaluated, and the choice was based on extraction of VFA from biological specimens and consideration of the underivatized character of the acids. Thus it was necessary to avoid solvents that would favor dissociation of the acids that would cause peak broadening and reduce the accuracy of quantification. Water as the sole solvent was found to cause excessively broad peaks, and it appeared to cause the formation of an intermediate pseudo-stationary film that interacted in the chromatographic process. Thus, since water could not be used alone as solvent for the analyses of the underivatized acids, it was necessary to use solvents that could function as a co-solvent with this aqueous phase. Thus, water served as the primary solvent for the free acids, and the organic phase had primary importance in sample transfer and in determining chromatographic resolution. VFA would not disperse in hexane or ether, and the immiscibility of these solvents with the acidified aqueous phase precluded their use. When methanol was used as solvent, we observed a remarkably low response. Acetone or acetonitrile, in combination with an acidified aqueous phase, provided excellent resolution of the VFA, high responses and identical chromatographic performance. However, acetone could not be found in an absolutely acetic acid-free quality, and since the degree of contamination was not constant, quantification of acetic acid in biological specimens was impeded. Thus, acetic acid-free acetonitrile was taken as the preferred solvent. However, since acetic acid or a co-eluting component was found to be generated within this solvent system over long periods of time, it was necessary to simultaneously prepare and analyze calibration standards and samples so that this change could be eliminated from the calculated results. When this was done, the quantification of acetic acid in biological specimens was found to be constant over at least a 3-day storage period. Thus, the final composition of the injection sample consisted of acetonitrile, water and aqueous hydrochloric acid in proportions that could be variable within the limits previously described. Samples injected in such a medium gave sharp, quantifiable peaks (Fig. 3) with highly reproducible results.

[Received August 6, 1986]

The Use of Iodine Staining for the Quantitative Analysis of Lipids Separated by Thin Layer Chromatography

Giuseppe Palumbo* and **Fulvio Zullo**
Cattedra di Chimica Fisiologica, Facolta' di Medicina e Chirurgia, Universita' degli Studi di Reggio Calabria, Via S. Brunone di Colonia, Catanzaro and Centro di Endocrinologia ed Oncologia Sperimentale del C.N.R., Via S. Pansini, 5 80131 Naples, Italy

The method described for quantitative estimation of lipids separated on thin layer chromatography plates exploits the observation that most lipids can be stained by iodine vapor and that, in "controlled" conditions, the intensity of this staining is proportional to the actual amount of lipid in the spot. The method consists of i) exposing the developed plate to iodine vapor; ii) spraying it with a suitable solvent to prevent halogen evaporation; iii) collecting the stained lipids by scraping the spots off the plate; and iv) determining by a rate-sensing method the absorbed iodine. The final determination is performed by measuring spectrophotometrically (at 410 nm) the rate of decolorization of a solution of Ce(IV) by As(III) in strong acidic conditions. The reaction rate, which is positively related to the concentration of iodine, is derived from the slope of the absorbance change plotted vs time.

Providing that standards and samples are stained simultaneously, a quantitative estimation of lipid components of a mixture is possible in a reasonable time with excellent accuracy and reproducibility. In our hands, the method has been successfully applied to several common phospholipids, long chain fatty acids, cholesterol and deoxycholate, and triacylglycerols, in the range of 5–60 μg.
Lipids 22, 201–205 (1987).

Quantitation of lipid spots on thin layer chromatography (TLC) plates involves two steps: visualization of lipids and quantitative (chemical or densitometric) analysis.

One of the most widely used visualization procedures is the exposure of the developed plate to iodine vapor (1). Due to the hydrophobic character of both the halogen and lipids, samples adsorb iodine and readily appear on plates as brownish spots.

Early observations and our present experience (1,2) indicated that molecules as phospholipids, long chain fatty acids, triacylglycerols and cholesterol derivatives adsorb iodine proportionally to the amount of lipid material (up to 60 μg) on the TLC plate. This is true, however, only if iodine evaporation from the plate is immediately blocked and the exposure of plates is not exceedingly long. Under these conditions, a staining procedure widely used for qualitative purposes may become useful also for quantitative determinations.

It must be pointed out that the method described here allows a significant time savings, since it requires less than 30 min of effective work and uses common laboratory equipment and reagents.

This method has not been tailored for routine chromatographic measurements or for very specialized laboratories devoted to lipid chemistry. Rather, this procedure is proposed for investigators who might have occasional need of a rapid and suitable quantitative analysis of lipids.

MATERIALS AND METHODS

Egg yolk sphingomyelin (containing primarily palmitic acid), cardiolipin (pig heart), phosphatidylinositol (containing primarily linoleic and palmitic acids), dipalmitoylphosphatidylserine, linoleic, oleic and elaidic acids, cholesterol and sodium deoxycholate were purchased from Sigma (St. Louis, Missouri); triolein (glycerol trioleate) was from BDH (Deventer, The Netherlands). All these substances were used without further purification and were solubilized or diluted in chloroform or chloroform/methanol (2:2, v/v) to give final concentrations (gravimetrically assessed) of 2.5 mg/ml.

Precoated silica gel 60 TLC plates with or without fluorescent indicator (0.2 mm thick) were obtained from Merck (Darmstadt, Federal Republic of Germany). The spotting solvent was chloroform or chloroform/methanol (2:1, v/v).

Equipment consisted of an Eppendorf microfuge, a chromatographic tank (22 × 10 × 22 cm) and a Beckman UV 5230 spectrophotometer with a built-in strip-chart recorder. Readings were taken at 410 nm. Normally, full scale was set at O.D. 2 and the chart speed at 2 inches/min.

For the arsenious acid reagent, sodium arsenite (Baker, Poole, England) was dissolved (with heating and stirring) in 0.15 M sulfuric acid to give a final concentration of 0.01 M. After cooling, the solution was divided into small aliquots and stored in the refrigerator. These solutions are stable for long periods. Before analysis the arsenite reagent was diluted 20-fold with 0.15 M sulfuric acid; this solution is hereafter referred to as solution A.

For the ceric-ammonium sulfate reagent, ceric sulfate and ammonium sulfate (Baker) were dissolved (with heating and stirring) together in 2.8 M sulfuric acid to give final concentrations of 0.05 and 0.15 M, respectively. The solution was centrifuged and the clear deep yellow supernatant decanted and divided into small aliquots. These solutions (referred to as solution B) are stable for several months at room temperature.

Commercial TLC plates are available with or without fluorescent indicators and may contain several other substances as binders or salts. Because it cannot be assumed that all these substances do not affect the reactions described below, plates, different in type and source, should not be considered necessarily interchangeable.

Preliminary experiments should be performed to assess the possibility of using the various types of commercially available plates. Most of our studies were performed on Merck Silica gel 60 plates (20 × 20 cm) with or without fluorescent indicator. However, a few experiments carried out with similar plates from different commercial sources gave essentially the same results.

Lipids were dissolved in suitable solvents (chloroform or chloroform/methanol). Amounts ranging from 5 to 60 μg were spotted on TLC plates with the aid of a small glass syringe with a Teflon tip fitted with a micrometric device (Radiometer SBU1A). Any device for precise and reproducible delivery of solutions on plates may be used.

Iodine crystals were placed in a round plastic dessiccator and allowed to vaporize at room temperature until the jar was saturated with iodine vapor. The plate was quickly put in the dessiccator horizontally with its four corners based on the inner round edge of the container. The gel side was toward the transparent cover of the jar to allow a rapid inspection of the staining.

Several durations of exposure of the plates to iodine vapors were tried, but 90 sec was found to be satisfactory for most of the tested substances. Some lipids (e.g. phosphatidylinositol, phosphatidylethanolamine), however, required a longer exposure (120 sec), especially at minimal concentrations of lipids. The lipids appear as brown spots on a white background (after longer exposure the background tends to become yellowish).

Densitometric measurements were performed using a Shimadzu CS 920 densitometer.

The principle of the assay method has been discussed extensively in a previous paper (3). In brief, the assay is based on the ability of iodine to act as catalyst in the ceric arsenite reaction (4). Since the formation of the reaction product (CeIII) results in a dramatic decrease in the absorption of the solution at 410 nm, the kinetics of this process may be easily measured by monitoring the rate of decolorization. The change in absorption at 410 nm follows zero order kinetics and may be conveniently monitored spectrophotometrically (the use of a strip-chart recorder is advisable). The initial velocity (initial reaction rate) is proportional to iodine concentration, which is, in turn, proportional to the amount of lipid in the spot. The lipid concentration in an unknown sample may be easily estimated by comparison with a standard curve prepared simultaneously with the same material. In a typical assay, a mixture of lipids (the amount of each component should not exceed 60 μg) is spotted on the left corner (ca. 2 cm from the bottom) of a chromatographic plate and developed as needed. At the end of the run, the plate is removed from the tank and let to dry at room temperature. With the aid of a micrometric device, scalar volumes of standards are regularly placed on the large area of the plate that has not been used for the chromatographic separation. After drying, the plate is moved into a jar containing iodine crystals and stained by exposure (normally 90 sec) to iodine vapor (Fig. 1). The plate is removed and immediately sprayed with glacial acetic acid. All the round brown areas are marked with a glass tip, carefully scraped off the plate and transferred into plastic Eppendorf vials (1.5 ml). After addition of 1 ml of 1.8 M sulfuric acid, the samples are vigorously shaken on a vortex (1-2 min) and, finally, centrifuged on a microfuge (5 min). Blanks consisting of background areas (having approximately the size of the broader sample spot) are similarly treated. The supernatants (0.8 ml) are collected in small capped tubes, where they can be stored for 48 hr or more. In fact, iodine determinations performed at various times on the same samples gave essentially similar results after a few minutes to up to 60 hr (Fig. 2). To perform the final iodine quantitation, the samples (e.g., 50 μl) are diluted fivefold with 1 M sulfuric acid. This dilution diminishes the chances of accidental transfer of silica gel particles in the optical cuvette, thus preventing possible artifactual interferences. Furthermore, if the lipid amount in the sample is rather small, the dilution step may be skipped or proportionally reduced. Two-hundred-and-fifty μl of this diluted solution is transferred directly to a cuvette (plastic disposable cuvettes are convenient to use).

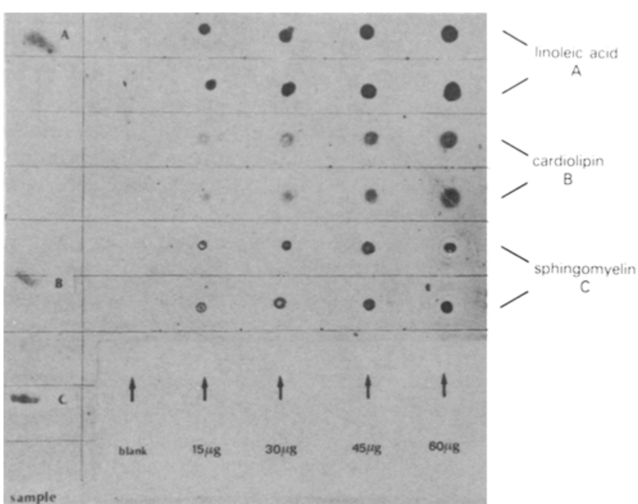

FIG. 1. An example of quantitative assay of a simple lipid mixture. Left side: linoleic acid, 25 μg (A, top), pig heart cardiolipin, 25 μg (B, middle) and egg yolk sphingomyelin (containing primarily palmitic acid), 30 μg (C, bottom), after their chromatographic separation on a silica gel 60 plate (chloroform/methanol/water [67:25:3, v/v/v]). Right side: Scalar amounts of each of the above substances. Arrows indicate the relative quantities. Standards have been loaded on the gel immediately after the sample separation and before the exposure to iodine vapor. By this procedure, staining of samples and standards is accomplished simultaneously under identical conditions.

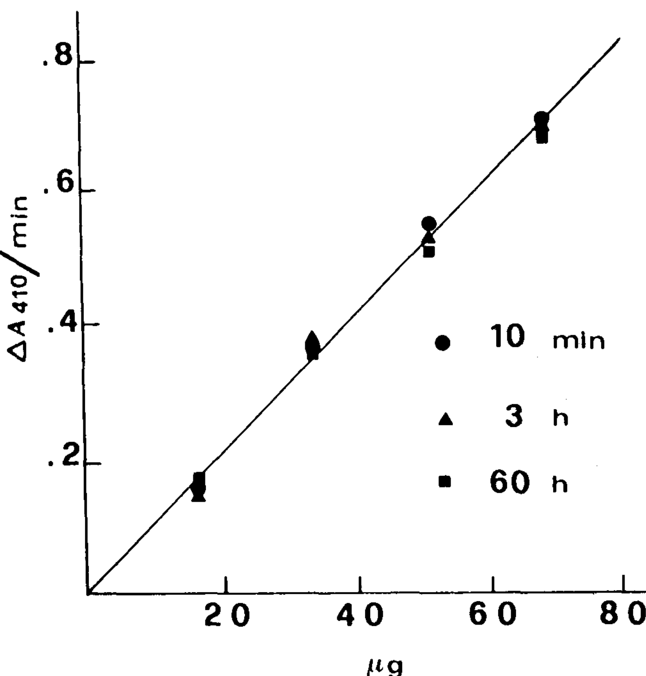

FIG. 2. Acetic acid prevents evaporation of iodine from stained plates. Quantitative determinations of dipalmitoyllecithin performed at various intervals of time (10 min-60 hr) after spraying the iodine-stained plate. Essentially the same reaction rate is observed in all determinations.

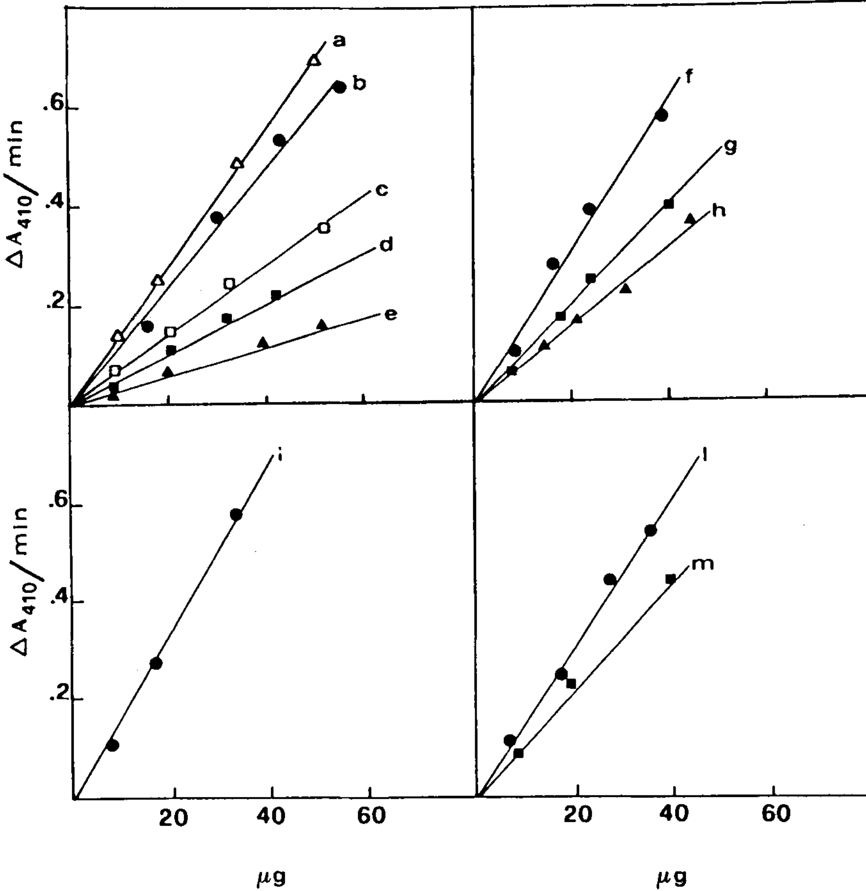

FIG. 3. Standard curves (in the range 5–60 μg) obtained with various lipids: a, egg yolk sphingomyelin (containing primarily palmitic acid); b, cardiolipin (from pig heart); c, phosphatidylinositol (containing primarily linoleic and palmitic acids); d, dipalmitoyllecithin; e, dipalmitoylphosphatidylserine; f, linoleic acid; g, oleic acid; h, elaidic acid; i, triolein (glycerol trioleate); l, sodium deoxycholate; m, cholesterol.

Six-hundred μl of solution A (arsenite) and 60 μl of solution B (ceric-ammonium sulfate) are then sequentially poured in the same cuvette. After rapid mixing by inversion, the cuvette is placed in the spectrophotometer, set at 410 nm for reading. The calibration curve is obtained by plotting the initial rate (i.e., the slope of the change in absorbance vs time) expressed as ΔA/min vs the lipid (iodine) content of standards. The actual amount of lipid in a mixture is readily obtained by reading the values off this curve, the amount corresponding to the measured rate (ΔA/min).

Figure 3 shows several standard curves obtained using different types of lipid molecules. It seems clear that the response is correlated to lipid saturation (linoleic acid > oleic acid > elaidic acid). Specific details are given in the figure legend.

Precision of the assay was evaluated as between-day or day-to-day precision using lipid extracts from three amniotic fluids containing increasing amounts of lecithin (palmitoyl lecithin was used as standard) for a period of 15 days (Table 1). The procedure for lipid extraction and separation was that of Gluck et al. (5).

TABLE 1

Precision of Assay

Sample	μg of lecithin		
	1	2	3
Precision between day	18.0 ± 1.2	31.1 ± 1.8	46.2 ± 1.7
Precision day to day	17.2 ± 1.4	31.5 ± 2.0	46.9 ± 2.4

Precision has been assessed over a period of 15 days. Samples 1, 2 and 3 are three amniotic fluids containing three different levels of lecithin. The extraction of lecithin and its separation has been performed according to Gluck et al. (5).

The same three amniotic fluids used for determining precision were used for accuracy. It was assessed by comparing our procedure with a well accepted method (6). In this case, the ratio of lecithin to sphingomyelin (μg/μg) was densitometrically measured according to the original

TABLE 2

Accuracy

Sample	1	2	3
R_1 (μg/μg)	1.2	2.3	2.8
R_2 (μg/μg)	1.4	2.5	2.7

R_1 indicates the ratio of lecithin to sphingomyelin in three amniotic fluids determined by means of our method; R_2 is the same ratio densitometrically determined according to Gluck et al. (6).

paper (5) and compared with the ratio obtained by making use of our method (Table 2).

DISCUSSION

A variety of methods for the quantitative estimation of lipids separated by TLC are today available. The lipids are usually visualized and subsequently quantitated by either charring or staining, followed by either direct densitometric (or planimetric) measurement or by scraping the spots off the plate for chemical wet analysis.

Charring simply involves spraying the TLC plate with sulfuric acid or with sulfuric acid containing a strong oxidizing agent, followed by heating at high temperature for various times. Although this method appears to be generally suitable, nevertheless it is known that staining by charring is sensitive to lipid saturation, is influenced by the silica gel and is dependent on the time and temperature of heating. Moreover, when present, the oxidizing agent may affect the result because of the possible loss of carbon by conversion to CO_2.

Dye staining, a nondestructive method, usually allows recovery of material from the plates, so that scraped spots may be used for further analysis. Different types of staining have been proposed over the years. Some have general application (2,7-10), while others make use of more specific reagents and are used when the lipid molecules contain phosphorus, choline, sialic acid or other groups of particular reactivity (11-16). Even in these instances, however, there are frequent problems with background discoloration or fading of spot colors, especially when the spots have to be read by densitometry or directly evaluated by planimetry.

Various other problems have been described after spraying plates with ammonium sulfate, bismuth subnitrates (6,17), etc.

Another widely applied method of staining lipid molecules on TLC chromatographic plates is the exposure of the plate to iodine vapor in a sealed tank. This method is extremely simple, sufficiently sensitive and almost universally applicable. Also in this case, however, staining is dependent on the nature of the lipid molecule (i.e., some molecules stain more than others) and is dependent on the time of exposure to the halogen vapor. Furthermore, once the plate is removed from the container, the brown spots begin to fade within a few minutes and more or less rapidly tend to disappear.

The method presented in this paper makes use of iodine staining by introducing a simple procedure to hinder the evaporation of the halogen. Under controlled conditions and within a relatively wide range of concentrations, it appears that the amount of trapped iodine is linearly related to the amount of adsorbing lipid. The subsequent estimation of iodine is performed by exploiting a rate-sensing method developed in our laboratory a few years ago (3): by this technique we have successfully applied the procedure to various lipid molecules, by making use of appropriate calibration curves, prepared from standards placed on the same plate where the chromatographic separation has taken place.

The method has proved to be largely reliable and reproducible with several test substances, providing that evaporation of iodine from the plates is effectively hindered. After several attempts, we have found that uniform spraying with acetic acid, a solvent in which iodine is highly soluble, is the most effective treatment for this purpose.

The observation that various lipid molecules, even in the same quantity, stain quite differently, does not represent a serious problem. To circumvent this obstacle, in fact, it is possible to reduce up to fivefold the preliminary dilution (see Methods) of the sample before the final spectrophotometric measurement. The assay is performed in a reasonable time, is not particularly cumbersome, does not require special attention or skills and, most important, is highly reproducible. Another important advantage comes from the fact that the assay is a rate-sensing method: the superior accuracy of true kinetic methods over others is generally recognized and, in regard to iodine determination, has been extensively discussed in a previous paper (3).

It must be emphasized that since the response (the change in the absorption of cerium) is correlated with the lipid saturation (see standard curves of Fig. 3), the quantitation of unknown samples is impossible unless the same material is available for calibration curves. However, the linearity of the response observed with synthetic and natural mixtures of lipids indicates the possibility of using such mixtures as standards of a total lipid in tissue or biological fluid extracts, providing that the approximate lipid composition is known.

Bearing in mind such restrictions, the present method may be conveniently used when the occasional need of lipid analysis does not justify the acquisition of dedicated optical devices, such as densitometers, and when turnaround time may be critical for the immediate prosecution of the research work.

[Received May 12, 1986]

Measurement of Lipid Peroxidation In Vivo: A Comparison of Different Procedures

Alfonso Pompella, Emilia Maellaro, Alessandro F. Casini, Marco Ferrali, Lucia Ciccoli and Mario Comporti*
Istituto di Patologia Generale dell'Università di Siena, Via Laterino 8, 53100 Siena, Italy

A study was undertaken to investigate whether some of the methods commonly used to detect lipid peroxidation of cellular membranes in vivo correlate with each other. The study was performed with the livers of bromobenzene-intoxicated mice, in which lipid peroxidation develops when the depletion of glutathione (GSH) reaches a threshold value. The methods tested and compared were the following: i) measurement of the malondialdehyde (MDA) content of the liver; ii) detection of diene conjugation absorption in liver phospholipids; iii) measurement of the loss of polyunsaturated fatty acids in liver phospholipids; and iv) determination of carbonyl functions formed in acyl residues of membrane phospholipids as a result of the peroxidative breakdown of phospholipid fatty acids. Correlations among the values obtained with these methods showed high statistical significances, indicating that the procedures measure lipid peroxidation in vivo with comparable reliability. Analogously, the four methods appeared also to correlate when applied to in vitro microsomal lipid peroxidation.
Lipids 22, 206–211 (1987).

During the past 30 years, a great deal of experimental evidence has accumulated suggesting that lipid peroxidation in cellular membranes is implicated in a variety of pathological conditions. These include liver cell injury by a number of toxins (CCl_4 and other halogenated hydrocarbons [1–6]; the effect of bromobenzene and other aryl halides acting as glutathione [GSH] depleting agents [7–9], injury due to other hepatotoxins, probably including ethanol [10]); lung damage after exposure to nitrogen dioxide (11) and ozone (12) or intoxication with the herbicide paraquat (13); increased red blood cell permeability and hemolysis associated with vitamin E deficiency (14); retrolental fibroplasia (15); paroxysmal nocturnal hemoglobinuria (16); abetalipoproteinemia (17); cell damage caused by ionizing radiation (18); and several aspects of oxygen toxicity (19).

Because of the growing importance of lipid peroxidation in the biomedical field, an increasing need for reliable methods to detect these processes has been perceived. Many methods are available to measure the extent of lipid peroxidation, but most are based upon the measurement of the products originating from the process at different stages. These methods include (20) i) the classic thiobarbituric acid (TBA) reaction to measure malondialdehyde (MDA) (21); ii) detection of the UV absorption characteristic of conjugated dienes (22); iii) fluorescent analysis of lipid peroxidation products (23); iv) measurement of ethane and pentane formation (24,25); v) detection of chemiluminescence (26); vi) measurement of oxygen uptake (27); vii) measurement of the loss of polyunsaturated fatty acids in membrane phospholipids (28); viii) the detection of lipid hydroperoxides (29); and ix) measurement of specific aldehydes such as alkenals (30).

*To whom correspondence should be addressed.

The detection of lipid peroxidation in biological systems in vitro is relatively simple since, when the reaction has been blocked, it is conceivable that the measurement of a certain product in the sample represents a reliable estimation. On the other hand, when detection of lipid peroxidation in vivo is attempted, many problems arise: the oxidation product may be rapidly metabolized or removed from the tissue under study; it may have interacted with different cellular substances so that it cannot be found in the free form; or it may be formed as an artifact during sampling of the tissue and other technical procedures. For these reasons, the detection of lipid peroxidation in vivo has often puzzled the biochemical pathologist who is primarily concerned with understanding the in vivo events. The present work was undertaken to determine whether the methods more commonly used in various laboratories to detect lipid peroxidation in vivo correlate and to test the reliability of each individual method. The study was performed with the livers of bromobenzene-intoxicated mice, in which lipid peroxidation develops when the depletion of GSH reaches a threshold value (9). Bromobenzene hepatotoxicity represents a good model for the study of in vivo lipid peroxidation, since in this experimental condition the level of detectable lipid peroxidation is far greater than in the case of CCl_4 or $BrCCl_3$ hepatotoxicity (9,31).

The following methods were compared: i) measurement of the MDA content of the liver; ii) detection of diene conjugation absorption in liver phospholipids; iii) measurement of the loss of polyunsaturated fatty acids in liver phospholipids; and iv) measurement of the carbonyl functions formed in the acyl residues of membrane phospholipids as a result of the peroxidative breakdown of phospholipid fatty acids. The latter method was recently developed in our laboratory (32).

MATERIALS AND METHODS

Male NMRI albino mice (Ivanovas GmbH, Federal Republic of Germany) weighing 20–30 g and maintained on a pellet diet (Altromin-Rieper, Bolzano, Italy) were used.

In vivo experiments. The animals were fed a liquid glucose (20%) diet for two days before intoxication, according to the protocol of Wendel et al. (33), to decrease the hepatic GSH content. This regimen decreased hepatic GSH by about 50% as compared to laboratory chow-fed animals and increased the frequency of occurrence of lipid peroxidation in liver phospholipids.

Bromobenzene (C. Erba, Milano, Italy) mixed with two volumes of mineral oil was administered intragastrically under light ether anesthesia, at a dose of 15 mmol/kg body weight. Control mice received mineral oil alone. All animals were fasted after intoxication.

Eighteen hr after intoxication, the animals were killed by exsanguination under ether anesthesia, and the livers were quickly removed, rinsed in ice-cold saline, weighed, and divided into two portions. The first portion was

extracted with 24 vol of chloroform/methanol (2:1, v/v) according to the method of Folch et al. (34), and the extract was used for i) detection of diene conjugation absorption in liver phospholipids; ii) determination of the amount of carbonyl functions in liver phospholipids; and iii) determination of the fatty acid pattern of phospholipids.

The diene conjugation absorption of liver phospholipids was measured as described by Casini and Farber (35), after precipitation of the phospholipids with acetone according to Borgström (36). Typical UV spectra and the difference spectrum (intoxicated − control animal) are reported in Figures 1A and 1B, respectively.

The amount of carbonyl functions originating from the peroxidative breakdown of unsaturated fatty acids in cellular phospholipids was measured according to Benedetti et al. (32). Briefly, carbonyl functions were detected after derivatization with 2,4-dinitrophenylhydrazine (DNPH) and separation of phospholipids from neutral lipids and unreacted DNPH. The absorption spectrum of DNPH derivatives of liver phospholipids from the intoxicated animals is similar to that obtained with a mixture of dinitrophenylhydrazones of standard aldehydes (Fig. 1D, dashed line). Figure 1C shows the typical absorption spectra of DNPH-treated liver phospholipids from control and bromobenzene-treated animals 18 hr after poisoning. From the difference spectrum (intoxicated − control animals) obtained (see Fig. 1D, solid line), the content of carbonyl functions in liver phospholipids can be estimated using an average molar extinction coefficient of 25500 (37–39).

The decrease of polyunsaturated fatty acids (arachidonic and docosahexaenoic acids) was measured by determining the whole fatty acid pattern of acetone-precipitated liver phospholipids (36). Fatty acid methyl esters were prepared and purified as reported by Benedetti et al. (40). They were analyzed by gas liquid chromatography in a Fractovap apparatus Model GI (C. Erba) using a spiral glass column (2 m × 2 mm internal diameter) packed with 20% diethyleneglycol succinate on Chromosorb W. Other conditions were as reported previously by Benedetti et al. (41).

The second portion of each liver was used for determination of the tissue content of MDA, which was measured as follows: tissue samples were homogenized in ice-cold trichloroacetic acid (TCA) (1 g tissue + 1 ml 10%, w/v, TCA, plus 8 ml 5%, w/v, TCA, or equivalent amounts) in an Ultra Turrax homogenizer. After centrifugation, a volume of the supernatant was added to an equal volume of 0.6%, w/v, TBA, and the mixture was heated to 100 C for 10 min. The absorption spectrum was then recorded over the range of 480–600 nm. As can be seen in Figure 1, the spectra obtained (Figs. 1E and 1F, solid lines) were quite similar to that obtained with a MDA standard produced by acid hydrolysis of 1,1,3,3-tetraethoxypropane and run under the same conditions. The MDA concentration was calculated from the absorption at 532 nm (absorption maximum) of the difference spectrum (intoxicated − control animals) using a molar extinction coefficient of 1.56×10^5, as reported by Jordan and Schenkman (28); this was also recalculated from our own standards.

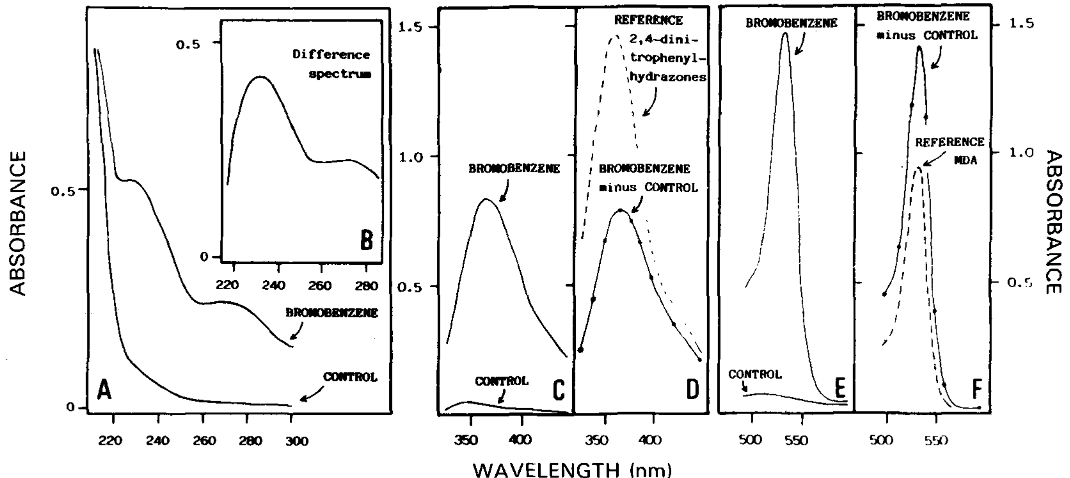

FIG. 1. A: Diene conjugation absorption in liver phospholipids derived from a control and a bromobenzene-poisoned mouse. The mice were killed 18 hr after intoxication (15 mmol/kg body weight, by mouth). Phospholipid concentration = 0.5 mg/ml in cyclohexane. B: Difference spectrum calculated from the spectra of panel A by subtracting the spectrum of the control sample from the one of the sample of the intoxicated animal. C: Absorption spectra of DNPH-treated liver phospholipids derived from a control and a bromobenzene-poisoned mouse (same animals as in A). The phospholipid concentration of the sample in chloroform was 0.5 mg/ml. The spectra of DNPH-treated samples were recorded against the corresponding blank samples in the reference cuvette. The blank samples contained the same phospholipid concentration, but were not treated with DNPH. See text and Benedetti et al. (32) for additional explanations. D: Solid line, difference spectrum calculated from the spectra of panel C by subtracting the spectrum of the control sample from the spectrum of the sample of the intoxicated animal. Dashed line, absorption spectrum obtained with a mixture of 2,4-dinitrophenylhydrazones of various aldehydes (4-hydroxynonenal, hexadecanal and decyl aldehyde, 20 nmol/ml for each aldehyde). E: Absorption spectra of the chromogen derived from the reaction of TBA with the TCA extracts of the livers derived from a control and a bromobenzene-poisoned mouse (same animals as in A). See text for additional explanations. F: Solid line, difference spectrum calculated from the spectra of panel E by subtracting the spectrum of the control sample from the spectrum of the sample of the intoxicated animal. Dashed line, absorption spectrum of the reaction product of TBA with standard MDA in TCA (6 nmol/ml).

The same TCA homogenate was also used for the determination of the tissue content of GSH according to Sedlak and Lindsay (42).

In vitro experiments. Mice were fasted overnight before use. The preparation of the microsomal fraction and the incubation of the microsomes were carried out as described by Benedetti et al. (32). The concentration of $FeSO_4$ in the incubation mixture was 60 μM. At the end of each incubation time, aliquots were drawn and divided into two portions: one was used for detection of the MDA formed as previously described (43); the other was extracted with 24 vol of chloroform/methanol (2:1, v/v) according to the method of Folch et al. (34). The lipid extract was then used for the detection of diene conjugation absorption, for the measurement of carbonyl functions in phospholipids and for the determination of the fatty acid pattern.

Other procedures. Protein content was determined according to the method of Lowry et al. (44). Serum glutamate-pyruvate transaminase (SGPT) activity was determined by an optimized UV enzymatic method (C. Erba).

RESULTS AND DISCUSSION

Table 1 shows the hepatic GSH depletion, liver necrosis (as assessed by the SGPT levels) and lipid peroxidation (measured by the hepatic MDA content, the diene conjugation absorption, the amount of carbonyl functions and the loss of polyunsaturated fatty acids in liver phospholipids) in the bromobenzene-intoxicated animals used in the present study. As was noted in previous studies (9), a large variation was observed in the sensitivity of individual animals to bromobenzene. There was, however, a readily evident relationship between the different parameters of the response to bromobenzene when the values for the individual animals were graphed together. As shown in Figure 2, a good correlation ($P < 0.001$) was found between the log of SGPT and the log of carbonyl functions, indicating that in each intoxicated animal lipid peroxidation is associated strictly with liver necrosis. The fact that 18 hr after the intoxication some animals showed high levels of lipid peroxidation while others revealed only minor values gave us the opportunity to study the relationships among the different methods for detecting lipid peroxidation in vivo. Figure 3 shows the correlations between (A) the hepatic content of MDA and the amount of carbonyl functions in liver phospholipids; (B) the hepatic content of MDA and the absorption of conjugated dienes in liver phospholipids; (C) the amount of carbonyl functions and the absorption of conjugated dienes in liver phospholipids; and (D) the hepatic content of MDA and the loss of polyunsaturated fatty acids (arachidonic and docosahexaenoic acids). All correlations showed high statistical significance, indicating that the methods

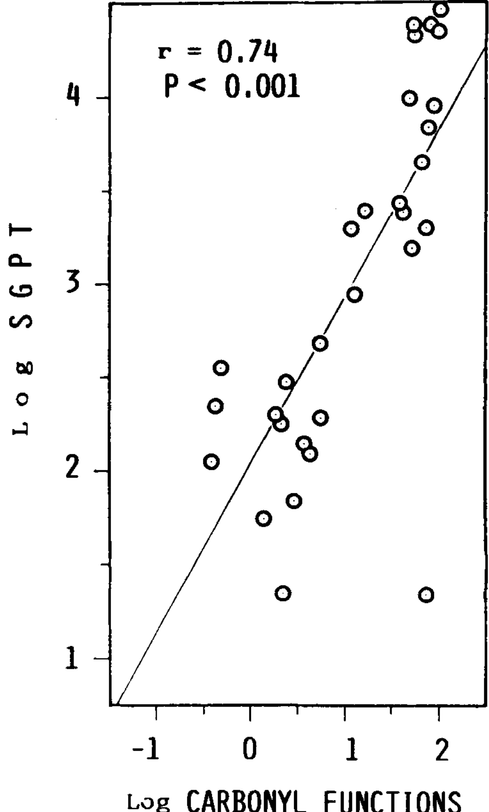

FIG. 2. Correlation between lipid peroxidation (as measured by the amount of carbonyl functions in liver phospholipids) and liver necrosis (as measured by SGPT levels). The parameters were expressed as log of the values obtained 18 hr after bromobenzene poisoning (15 mmol/kg body weight).

TABLE 1

Hepatic GSH Depletion, Liver Damage (SGPT Levels) and Lipid Peroxidation in Bromobenzene-Poisoned Mice[a]

	GSH (nmol/mg protein)	SGPT (U/l)	MDA (pmol/mg protein)	Diene conjugation absorption[b] ($\Delta A_{233\ nm}$)	Carbonyl functions (nmol/mg phospholipids)	PUFA (relative %) 20:4	PUFA (relative %) 22:6
Control	30.3±3.1 (8)	7±3 (6)	—	—	—	19.0±0.7 (7)	10.1±0.4 (7)
Bromobenzene-treated	1.8±0.2 (36)	1709±451 (36)	518.7±173.8 (23)	0.341±0.076 (30)	24.2±5.1 (43)	16.3±0.6[c] (32)	8.9±0.2[c] (32)

Values reported are means ± SEM. The number of animals is given in parentheses. Control values for MDA, diene conjugation absorption and carbonyl functions were subtracted from those of the intoxicated animals.

[a]MDA content of the liver, diene conjugation absorption, carbonyl functions and loss of polyunsaturated fatty acids (PUFA) in liver phospholipids.

[b]Phospholipid concentration: 1 mg/ml in cyclohexane.

[c]Significantly different from control, $P < 0.05$.

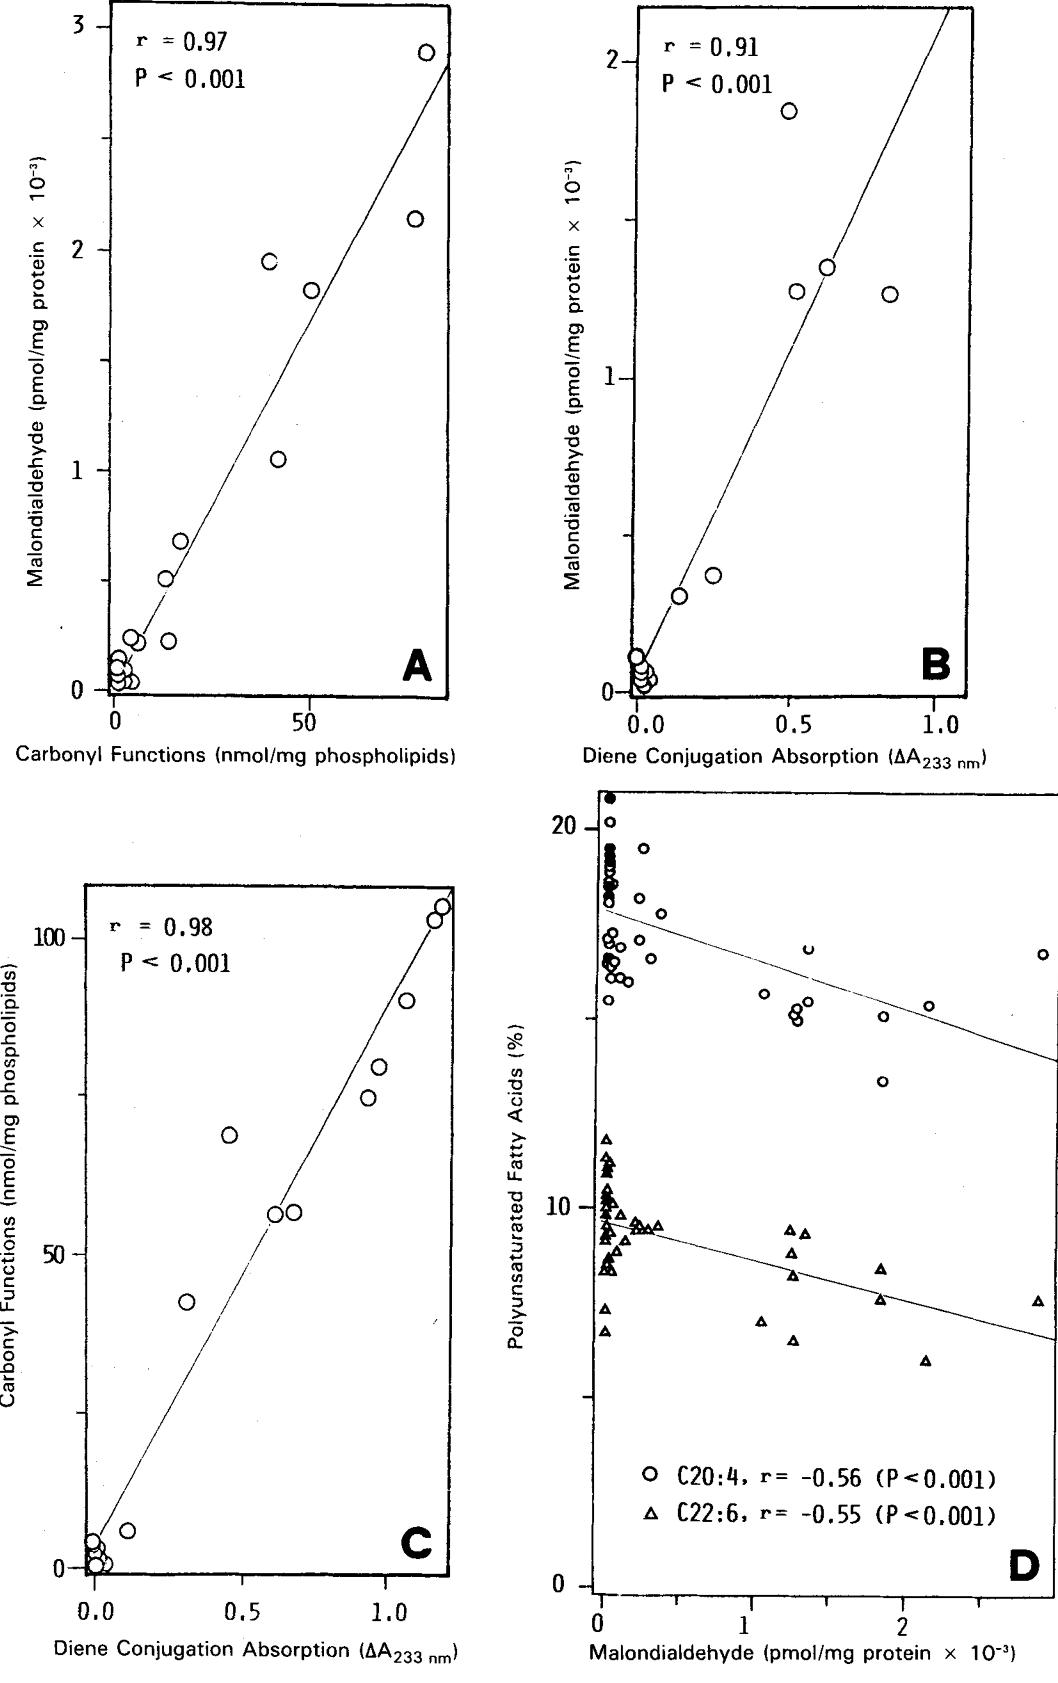

FIG. 3. In mice intoxicated with bromobenzene (15 mmol/kg body weight, by mouth), correlations between: A, hepatic content of MDA and carbonyl functions in liver phospholipids (PL); B, hepatic content of MDA and absorption of conjugated dienes in liver PL; C, carbonyl functions and absorption of conjugated dienes in liver PL. D, correlation between hepatic content of MDA and relative percentage of arachidonic (○) and docosahexaenoic (△) acids in liver PL from control mice (closed symbols) and mice intoxicated with bromobenzene (open symbols; same conditions as in panel A).

TABLE 2

MDA Release, Diene Conjugation Absorption, Amount of Carbonyl Functions and Decrease in Arachidonic and Docosahexaenoic Acids in Phospholipids of Liver Microsomes Incubated in an NADPH-Fe^{2+}-Dependent System

Time of incubation (min)	MDA (nmol/mg protein)	Diene conjugation absorption ($\Delta A_{233\ nm}$)[a]	Carbonyl functions (nmol/mg phospholipids)	Arachidonic acid (nmol/mg phospholipids)	Docosahexaenoic acid (nmol/mg phospholipids)
0	—	—	—	375 ± 49	189 ± 28
5	2.83 ± 0.97	0.158 ± 0.070	36.8 ± 1.8	323 ± 59	160 ± 31
15	7.48 ± 1.04	0.400 ± 0.035	43.1 ± 6.2	302 ± 32	143 ± 9
30	10.21 ± 0.50	0.817 ± 0.216	72.6 ± 14.2	237 ± 23	120 ± 14

Values reported are means ± SEM of 3 experiments. Control values (0 min of incubation) for MDA, diene conjugation absorption and carbonyl functions were subtracted from values for later times of incubation. Correlations among the parameters were as follows: MDA and diene conjugation absorption, $r = .967$, $P < 0.01$; MDA and carbonyl functions, $r = .940$, $P < 0.01$; carbonyl functions and diene conjugation absorption, $r = .941$, $P < 0.01$; MDA and loss of arachidonic acid, $r = -.959$, $P < 0.01$; MDA and loss of docosahexaenoic acid, $r = -.981$, $P < 0.001$.
[a]Phospholipid concentration: 1 mg/ml in cyclohexane.

measure lipid peroxidation in vivo with comparable reliability. However, the polyunsaturated fatty acid levels, due to their large dispersion, give somewhat less sensitive measures of lipid peroxidation in individual animals.

Table 2 shows the results of an in vitro study of lipid peroxidation of liver microsomes incubated in the NADPH-Fe dependent system. These experiments, essentially similar to those reported by several other investigators (45-48), were performed to examine, in an in vitro system, the relationships among the aforementioned methods to detect lipid peroxidation. As can be seen in Table 2, the correlations among the four methods examined showed high statistical significances, as in the case of in vivo lipid peroxidation.

The good agreement among the results obtained by the different methods to detect lipid peroxidation in vivo and in vitro not only assures good reproducibility, but also reaffirms confidence in each of the procedures. However, caution is needed in using the decrease of arachidonic acid as the sole index of lipid peroxidation, because conditions exist under which loss of polyunsaturated fatty acids is unrelated to lipid peroxidation, such as inhibition of the chain elongation-desaturation system, essential fatty acid deficiency and other dietary changes.

Hepatic Lipid Abnormalities in a Chemical/Viral Mouse Model for Reye's Syndrome

We have examined hepatic lipid profiles in a mouse model for Reye's Syndrome (RS) in which young animals are exposed to nontoxic doses of an industrial pesticide emulsifier and subsequently are infected with sublethal doses of mouse-adapted human Influenza B (Lee) virus (FluB). The purpose of this study was to determine whether liver lipid content was altered in the mice, the time course of any changes, and whether lipid changes were consistent with liver pathology. Neonatal mice exposed dermally to the emulsifier, Toximul MP8 (Tox), had significantly elevated levels of hepatic cholesterol, with otherwise normal lipid composition. Subsequent inoculation of the mice with FluB significantly increased mortality rate. The combined Tox + FluB treatment had several significant effects on liver lipids, including a transient increase in phospholipid (PL) content, a reduction in neutral glycerides and persistently high cholesterol levels. Abnormalities in fatty acid profiles included an apparent elevation in medium chain fatty acids and increased ratios of PL arachidonic to docosahexaenoic acids. Histologically, there was no evidence of fat accumulation in the liver; however, hepatic mitochondria had severe structural abnormalities characteristic of RS. These studies demonstrate that chemical-dependent enhancement of viral virulence is associated with significant alterations of hepatic lipids. We believe that these abnormalities are related to mitochondrial structural damage in RS despite the absence of hepatic steatosis.
Lipids 22, 217-223 (1987).

Reye's Syndrome (RS) is a potentially fatal disease of children that is characterized by abnormal serum lipid profiles (1-3), fatty infiltration of the liver (4-7), hepatic mitochondrial damage (8), hyperammonemia (9) and brain edema (9). Abnormalities in serum and hepatic lipids are believed to reflect the key metabolic defects in RS; however, the factors that lead to and perpetuate these abnormalities are not known. It has not been possible to study the time courses of development of lipid and other abnormalities in RS patients, since these changes occur either before and/or during an associated prodromal viral-like illness. Accordingly, it has become necessary to examine these changes using appropriate animal models.

We have demonstrated previously that suckling mice exposed dermally to nontoxic doses of an industrial pesticide emulsifier, Toximul MP8 (Tox), and subsequently infected with encephalomyocarditis virus (EMC) (10) or mouse-adapted human Influenza B (Lee) virus (FluB) (11) developed many of the features characteristic of RS, including hyperammonemia, abnormal urea-cycle enzyme activities and abnormal hepatic mitochondrial structure and function (Table 1). Recently we reported that combined Tox/FluB treatment also induced abnormal serum lipid profiles in the mice (12), which were manifested as hypopanlipidemia (including hypocholesterolemia), a feature of human RS. However, unlike in RS, the mice did not exhibit serum freefattyacidemia.

The purpose of this study was to examine hepatic lipid profiles in the mouse model to determine (i) whether there were quantitative and/or qualitative changes associated with the different treatment modalities (emulsifier alone, virus alone, emulsifier plus virus), and, if so, whether they were similar to those seen in patients with RS; (ii) the time course of evolution of these changes; and (iii) whether any abnormalities determined analytically were consistent with histological changes in the mouse livers.

EXPERIMENTAL PROCEDURES

Chemical/viral mouse model. Details regarding the chemical/viral mouse model for RS have been described previously (11,12). Briefly, newborn Swiss white CFW mice (bred from animals obtained from Canadian Biobreeding Farms, St. Constant, Quebec, Canada) were pooled at 24 hr of age and randomly assigned to nursing females (7 pups/mother). Each mother and her pups were housed in a separate cage. Twenty-four hr later, half of the animals received abdominal applications of the industrial emulsifier Tox (Charles Tennant Co., Toronto, Canada; lot #9-30162) in corn oil (Tox/corn oil, 1:100, v/v); the control animals received corn oil alone. This application was continued daily for 10 days. For the first five days, 8.6 ± 2.6 mg of Tox (in solution) was painted on each mouse with a small brush; during the last five days the dose was increased to 25.8 ± 9.0 mg per animal. Forty-eight hr following discontinuation of dermal application (experimental day 13), half of each experimental group received intranasal inoculations of FluB under light ether anesthesia. The remaining animals received anesthetic alone. Deaths were recorded each morning throughout the experiment. On days 8, 12 (one day before viral infection), 15, 16 and 17, six live animals were removed from each of the four groups (control, Tox, virus, Tox + virus) for liver lipid analysis and morphological examination. Immediately after the animals were killed by decapitation, the livers were excised, wrapped in acetone-rinsed aluminum foil and flash-frozen for lipid studies. Samples for histological examination were prepared as described below. Each sample was coded, and samples were analyzed at random before being decoded.

Lipid extraction and analysis. Livers were homogenized and lipids extracted according to Folch et al. (13) with chloroform/methanol (C/M, 2:1, v/v) containing the antioxidant butylated hydroxytoluene (5 μg/ml). Lower phases were washed with 0.25 volumes of 0.88% KCl and then with methanol/H_2O (1:1, v/v). The lower organic phases were filtered, dried under a gentle stream of N_2 and

reconstituted in 1 ml C/M (2:1, v/v). Aliquots were taken for determination of phospholipid phosphorous (14) and cholesterol (Sigma Kit #351). The remains were dried under N_2, reconstituted in a small volume of solvent and spotted on a sheet of silicic acid-impregnated glass fiber paper (Gelman Scientific Co., Montreal, Ontario, Canada). Lipid classes were separated by instant thin layer chromatography (ITLC) using petroleum ether/diethyl ether/glacial acetic acid (90:10:1, v/v/v) as the solvent system. After drying, the paper was sprayed with 2′,7′-dichlorofluorescein (0.1%, by vol, in ethanol), and spots were identified under ultraviolet light by comparison with authentic standards. Areas corresponding to triglyceride (TG), free fatty acid (FFA) and phospholipid (PL) were extracted from the papers with chloroform, chloroform and C/M (2:1, v/v), respectively, with a recovery rate greater than 95%. A known amount of heptadecanoic acid (17:0) was added as the internal standard, and the samples were transmethylated with 10% BF_3 in methanol at 100 C for 45 min (15). Fatty acid methyl esters (FAME) were extracted with petroleum ether, extracts were dried under N_2 and the residues were reconstituted in small volumes of iso-octane (2,2,4-trimethylpentane). FAME were separated on a Sigma 3B gas liquid chromatograph (Perkin-Elmer, Ottawa, Ontario, Canada) equipped with a 30-m SP 2330 fused silica capillary column (Supelco Canada, Oakville, Ontario, Canada). The initial oven temperature (110 C for 3 min) was increased to 210 C at 3 C/min. Final temperature was held for 10 min. FAME were identified by comparison with authentic standards and quantitated by comparison with the internal standard, using an LCI 100 Laboratory Computing Integrator (Perkin-Elmer).

Fatty acid standards were purchased from Supelco Canada Ltd., Sigma Chemical Co. (St. Louis, Missouri) or Serdary Research Laboratories (London, Ontario, Canada). All solvents were high performance liquid chromatography grade.

Statistical analysis. Data represent the means of values obtained from a minimum of three animals. Data were analyzed using an analysis of variance (ANOVA) and differences were judged to be significant when $p < 0.05$.

Histological examination. Morphological examination was carried out on livers from control, Tox-, FluB- and Tox + FluB-treated animals to determine whether hepatic structure was consistent with the biochemical findings. We also examined the relationship between hepatic morphology and fat accumulation and the nature of the infecting virus, by comparing the morphological features seen with FluB with those determined in earlier studies with EMC (previously unpublished). The procedures used for oil-Red-O fat staining and electron microscopic analysis were described previously (11).

RESULTS

The animals were breastfed throughout the experiment, and milk was present in the stomachs of all at the time of death. There were no significant differences in body weights between the four experimental groups. As we have demonstrated previously (11), the group of neonatal mice given topical applications of Tox for 10 days and subsequently inoculated with FluB had a significantly higher mortality rate than did the other three experimental groups (Table 2). The reason for the deaths of four of the 33 control animals on day 16 is not known, as there are usually no deaths in either this group or the group that receives Tox alone. (Some deaths occur as a result of ether anesthesia; however, these are confined to the 24-hr period immediately following anesthetic administration.) Differences in mortality rates between the different experimental groups first became apparent on day 17 of the experiment, and by day 18, few animals had survived combined exposure to Tox + virus.

Total lipid content of the mouse livers (Fig. 1) was calculated as the sum of the PL and neutral lipid (TG, FFA, total cholesterol) fractions. Values obtained from day 12 of the experiment indicated that abdominal application of Tox for 10 days did not alter appreciably the total lipid content of the livers. On day 15, values for total lipid in the animals given Tox, FluB and Tox + FluB were significantly increased relative to control animals; however, the values obtained for the controls had fallen between days 12 and 15. This difference between control and treatment groups did not persist through day 17, the time when differences in mortality first became apparent (Table 2).

On day 15 of the experiment (48 hr after FluB and/or anesthetic), only those livers from mice treated with Tox alone exhibited increased levels of TG and FFA, and these values had returned to normal by day 17 (Fig. 2). Animals inoculated with virus alone did not have altered levels of these liver lipid components. However, the TG content of livers from mice that received combined Tox + FluB treatment was significantly lower than that of either control or Tox-treated animals at day 15. The reduction persisted to day 17, when values for TG in the combined treatment animals were significantly lower than all other treatment groups. Hepatic FFA content was not alterec.

TABLE 2

Cumulative Mortality Rates in Neonatal Mice Exposed to Tox and/or Infected with Mouse-adapted Influenza B (Lee) Virus and in Control Mice that Received Anesthetic Alone

[a]Data represent the percentage of animals in each group alive on the experimental day indicated, relative to the number (N) that survive the 24-hr period following virus inoculation and/or anesthesia.

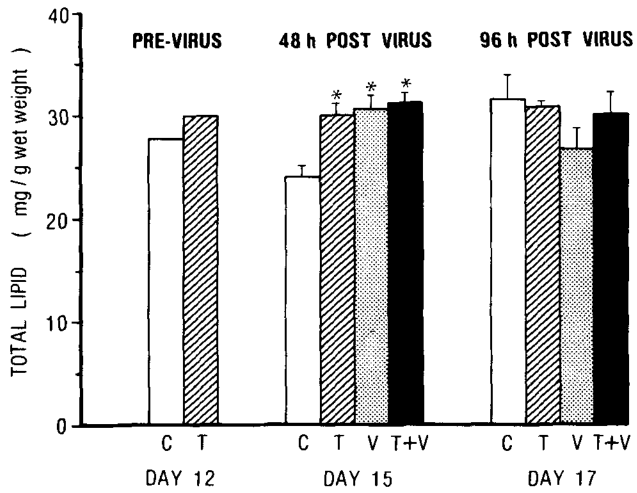

FIG. 1. Effects of Tox and/or FluB on liver total lipid content (mg/g wet weight) in the mouse model for Reye's Syndrome. Neonatal mice were given dermal applications of Tox (T) or corn oil (C) daily from experimental days 2 to 11. On day 13, half of the mice from each group received FluB under light ether anesthesia (V, T + V), and the other half received anesthetic alone. The animals were killed at the times indicated; livers were excised and lipids extracted and analyzed as described in the text. Data for total lipid are the sum of values obtained for the phospholipid, triglyceride, free fatty acid and cholesterol fractions. *, $p < 0.05$ relative to control animals.

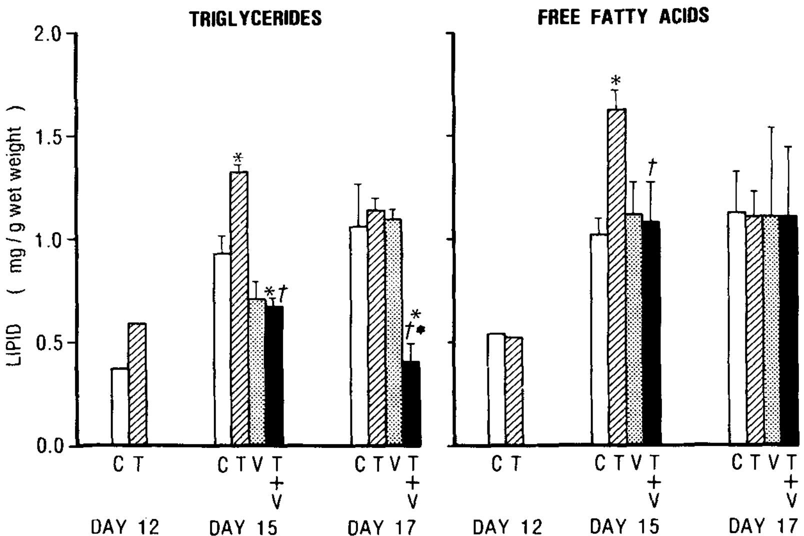

FIG. 2. Developmental changes in lipid class profiles in the mouse model for Reye's Syndrome. The experimental paradigm was as described in the legend to Fig. 1. Animals were killed on the days indicated, and livers from each of the four treatment groups were extracted. Triglyceride and free fatty acid fractions were separated and quantitated by gas liquid chromatography as described in the text. *, $p < 0.05$, relative to control animals; †, $p < 0.05$, relative to Tox-treated animals; ★, $p < 0.05$, relative to FluB-infected animals.

in FluB- or Tox + FluB-treated mice on any of the days examined.

PL constituted the major proportion (>85%) of the total lipid of livers from all four animal groups at each time point analyzed (Fig. 3). The only PL differences observed were increases at day 15 in livers from the three experimental groups; values had returned to normal by day 17.

Ten days' abdominal application of Tox resulted in a significant increase in the total cholesterol content of neonatal mouse livers (Fig. 4). Values for cholesterol gradually returned to normal in those animals that had received only Tox; however, levels were elevated on both days 15 and 17 in animals that received FluB, whether or not they had been preexposed to Tox.

We examined fatty acid composition of the PL, TG and FFA fractions of the mouse livers to determine whether shorter chain fatty acids (<C_{12}) accumulated under any of the experimental conditions and/or whether there was any evidence of abnormalities in the metabolism of hepatic polyunsaturated fatty acids. As shown in Table 3, there were apparent increases in the medium chain fatty acids in the TG and FFA fractions of livers from the Tox, virus and Tox + virus groups, with the greatest increase observed in the combined-treatment animals. They were not seen in all animals, which precluded statistical analysis. This probably reflects the fact that the analytical conditions were not optimized for quantitative recovery of these acyl constituents. Shorter chain fatty acids were not detected in the PL fraction of any animals.

Examination of the fatty acid composition of the liver PL revealed significant, time-dependent increases in the

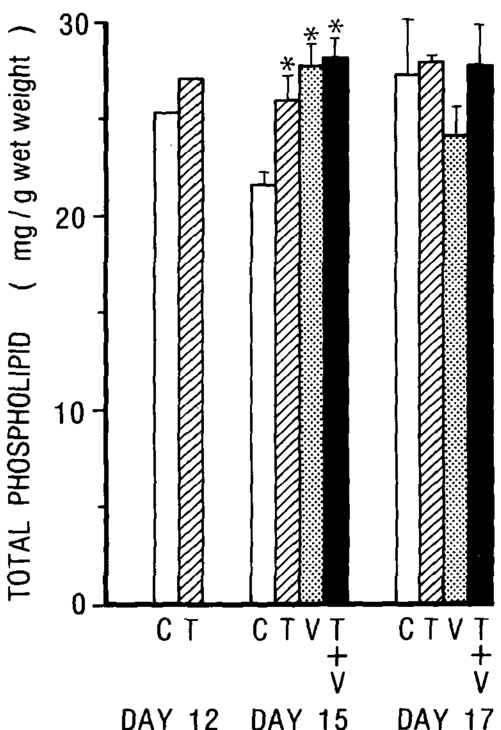

FIG. 3. The effect of chemical/viral treatment on liver phospholipid (PL) content in the mouse model. The experiment was carried out as described in the legend to Fig. 1. On the days indicated, livers were extracted and analyzed for PL phosphorus as described in Experimental Procedures. *, $p < 0.05$ relative to control animals.

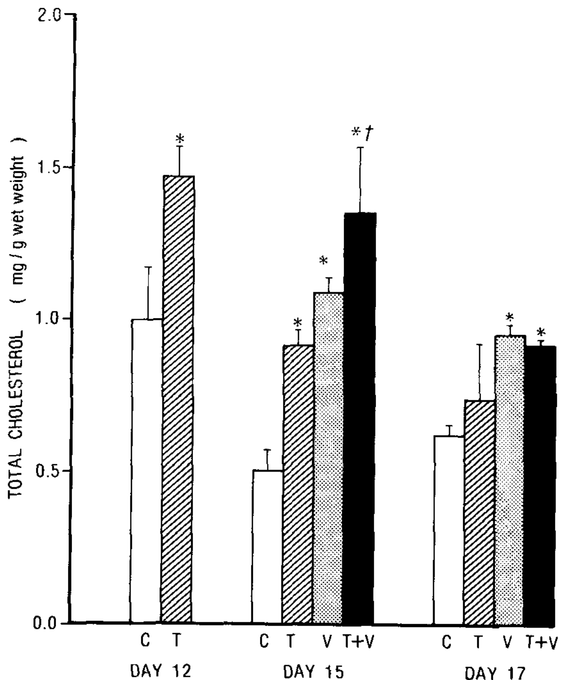

FIG. 4. Changes in liver cholesterol content in the mouse model. The experimental protocol is described in the legend to Fig. 1. Aliquots of the liver lipid extract were analyzed for cholesterol content as described in Experimental Procedures. *, $p < 0.05$, relative to control animals; †, $p < 0.05$, relative to Tox-treated animals.

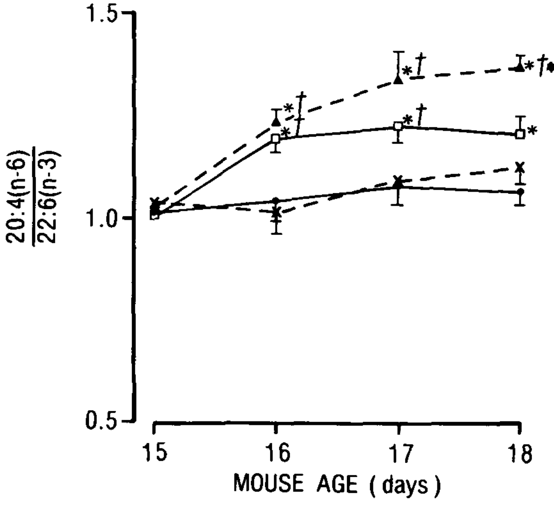

FIG. 5. Ratios of hepatic phospholipid (PL) arachidonic (20:4n-6) to docosahexaenoic (22:6n-3) acids in the mouse model for Reye's Syndrome. The experiment was carried out as described in the legend to Fig. 1. Lipid was extracted from livers from each of the four treatment groups (●, control; x, Tox; □, FluB; ▲, Tox + FluB) and the lipid classes were separated by instant thin layer chromatography. PL were transmethylated and fatty acid methyl esters were separated and identified by capillary gas liquid chromatography as described in the text. The data represent the means (± SEM) of the ratios of proportions of arachidonic (20:4n-6) to docosahexaenoic (22:6n-3) acids in the PL fraction. *, $p < 0.05$, relative to control animals, †, $p < 0.05$, relative to Tox-treated animals; ★, $p < 0.05$, relative to FluB-infected animals.

relative proportions of arachidonic (20:4n-6) to docosahexaenoic (22:6n-3) acids in the animals that received either FluB alone or Tox + FluB (Fig. 5). The altered ratios reflected increases in 20:4 and a decreased 22:6 content. By day 18 of the experiment, when few animals in the combined-treatment groups remained alive, the hepatic 20:4n-6/22:6n-3 ratio in these animals was significantly higher than that of any other group.

Light microscopic examinations were performed on 10 livers from each of the four treatment groups on day 17 of the experiment. Routine hematoxylin and eosin (H&E) stains revealed no evidence of necrosis, and oil-red-O staining showed no evidence of microvesicular fat accumulation (Table 4). This was in marked contrast to our earlier experiments in which treatment with the Tox and the natural mouse pathogen EMC resulted in panlobar hepatic microvesicular steatosis in 30–40% of the animals (Table 4).

Electron microscopic analysis of four livers from each group indicated that mice treated with Tox + FluB had severe hepatic mitochondrial structural abnormalities, including increases in the number and size of the mitochondria, with flocculation and focal rarefaction of their matrices (Fig. 6B). The mitochondrial cristae were detached and degenerated, with only a few recognizable abnormal cristae present. Similar mitochondrial abnormalities had been observed in our earlier studies with Tox + EMC exposure. The hepatocytic mitochondria of mice infected with FluB only or exposed to Tox only (Fig. 6A), showed mild pleomorphism, but there was no evidence of damage to their cristae or matrices. FluB was not detected in the livers of infected animals, and there was no evidence of cell inflammation or necrosis.

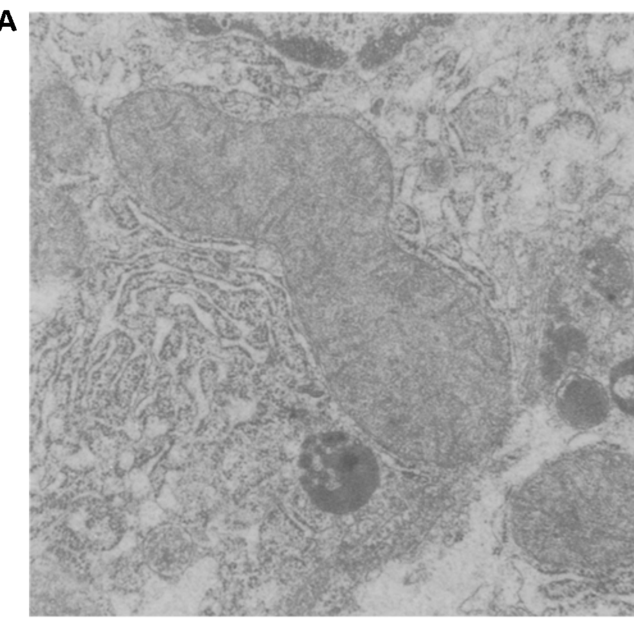
[b]0, Absent; 3+, Severe.

DISCUSSION

Children who develop RS exhibit several prominent abnormalities in hepatic lipid metabolism, including increases in TG levels (4,5,17) generally accompanied by an apparent reduction in PL content (4,5,17). Reports of effects of the disease on hepatic FFA and cholesterol levels are inconsistent.

In our animal model for RS, suckling mice exposed to the industrial emulsifier Tox and subsequently infected with Influenza B virus showed no evidence of fatty infiltration of the liver by either chemical analysis (Fig. 1) or morphological examination (Fig. 6) at the time when the mortality rate in this group began to increase (Table 2). There are several possible explanations for the apparent lack of hepatic steatosis in the mouse. First, fat production may require specific virus-species interactions, and although FluB is one of the most common viruses

A



B

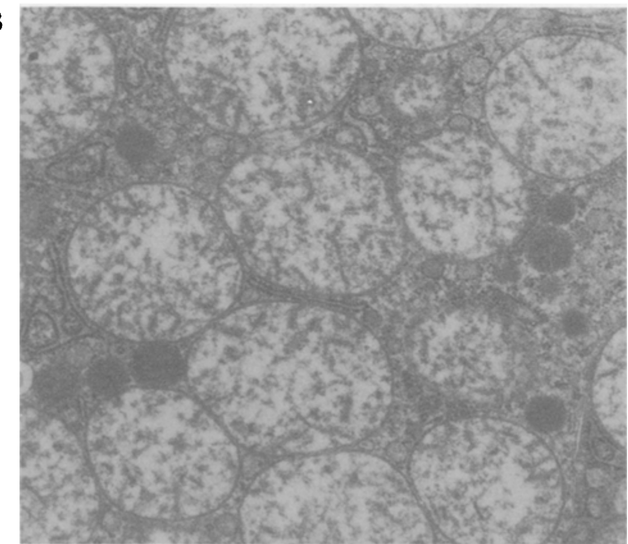


FIG. 6. The effects of chemical/viral treatment on the mitochondrial structure of neonatal mouse liver. On day 17 of the experiment (see legend to Fig. 1), livers were processed for electron microscopy as described in Experimental Procedures. The photomicrographs are of livers from animals that received (A) Tox or (B) Tox + FluB treatment. The liver from the combined treatment group shows marked swelling of mitochondria with extensive disintegration of the cristae. A few detached but still recognizable cristae are present. Focal rarefaction of the mitochondrial matrices and loss of dense bodies are evident. The micrographs show normal peroxisomes and no apparent lipid accumulation (30,000× magnification).

associated with development of RS in humans, it may not be appropriate for inducing fatty liver in animal models when the virus is not native to the species. This possibility is supported by the fact that hepatic steatosis did occur in our earlier studies with the mouse model, when the infecting pathogen was the native mouse virus EMC (10; Table 4). The constituents of the hepatic lipid obtained with Tox + EMC were not determined. A second possible explanation for lack of hepatic steatosis in our present model is that by taking samples for analysis 48 hr after viral infection, we may have missed a narrow time span during which levels were elevated. Our observation that hepatic lipid in the Tox, FluB and Tox + FluB groups were significantly higher (relative to control animals) in the samples analyzed at 48 hr (experimental day 15) suggest that levels may have been even higher in the first 24 hr following infection. However, TG levels were not elevated at any of the times tested, which is in contrast to the apparent increase in this fraction in patients with RS. Interestingly, several investigators have questioned the essentiality of a fatty liver in the pathogenesis of human RS (18,19); to our knowledge this question has not been fully resolved.

Perhaps one of the most important features of this study is the observation that, regardless of whether there was fat accumulation in animals given combined chemical/virus treatment, severe mitochondrial degeneration was seen consistently in this treatment group. Human RS is widely accepted to involve mitochondrial injury specifically, as reflected in morphological and biochemical anomalies of the liver and changes in blood chemistry (20). As is the case in humans, the mechanisms involved in mitochondrial injury in the Tox + FluB mice are unknown.

The mechanisms by which exposure to Tox and/or FluB altered PL, TG and cholesterol content in the neonatal mice are matters of conjecture at present. There have been few coordinated studies of the effects of viral infections on lipid metabolism in mammals, and the results of these have been complex and frequently contradictory in nature. Reports have documented inhibition (21-23) as well as stimulation (23,24) of lipid synthesis subsequent to viral infections. This probably reflects variations in the type of virus and the species infected; furthermore, changes can be transient in nature, with the result that data obtained may depend upon the duration of the infection (25). Clearly, liver lipid status at any given time reflects the net result of availability of precursors, relative synthetic and catabolic activities and intraorgan transport. For example, it has been suggested but not confirmed that decreased transport of TG from the liver due to impaired production of very low density lipoprotein is responsible for hepatic steatosis in RS patients (4). Our next goals are to determine whether enzymes involved in TG and cholesterol metabolism are altered as a result of the different treatment regimes and whether transport functions of the various lipid classes are abnormal in the model.

In addition to changes in lipid classes in the mouse livers, we observed distinct changes in fatty acid profiles (Table 3, Fig. 5). Other investigators have described virus-specific increases in the content of saturated (26,27) or unsaturated (28) fatty acids in host lipids. Changes in the proportions of these constituents may have deleterious effects on cell structure and dynamic properties, including the host's immune status (29). One consistent fatty acid modification that we observed was a significant time-dependent increase in the ratio of PL arachidonic (20:4n-6) to docosahexaenoic (22:6n-3) acids in the animals given combined Tox + FluB treatment (Fig. 5). Arachidonate is a precursor of the diene series of prostaglandins and leukotrienes, and increases in its proportions could alter

the synthesis and availability of these physiologically and pharmacologically active compounds, and as well, alter the concomitant production of superoxide anions. Abnormalities in arachidonic acid metabolism have been suggested to be involved in the pathogenesis of RS (3); however, whether these occur during the viral enhancement phase in the mouse model remains to be determined.

The apparent increase in the medium chain saturated fatty acids in the TG and FFA fractions of livers from the experimental animals is difficult to interpret, since they were not sufficiently consistent to allow statistical analysis. Nevertheless, their apparent increase could reflect impaired mitochondrial β-oxidation, which may be related closely to specific disorganization and dysfunction of this organelle (7).

One of the major questions raised by this study is whether there is a relationship between changes in cellular lipid content and viral enhancement. In the mice, the only significant effect of 10 days' exposure to Tox was an increase in hepatic cholesterol levels (Fig. 4), which was associated with a concomitant decrease in serum cholesterol (12). Reports of clinical studies have suggested generally that hepatic total cholesterol is not altered in patients with RS, although examination of the data in at least one report indicated that levels were elevated (17). Furthermore, serum cholesterol content is significantly reduced in RS (2), as it is in the mice. Interestingly, several groups of investigators have demonstrated that susceptibility to infection by and the virulence of several viruses, including Coxsackie-virus (30), Semliki Forest (31) and Sindbis (32) viruses increase with increasing membrane cholesterol content. Since we have not yet been able to isolate virus from the mouse livers, an association between Tox-dependent elevations in cholesterol and hepatic viral penetration appears unlikely. However, as suggested by Campbell et al. (30), it is possible that elevated cholesterol is related indirectly to defects in the nonspecific immune response, which are of primary importance in determining resistance to an invading pathogen. We have shown previously that interferon production is significantly reduced in mice exposed to the emulsifying agent (33).

In summary, we have found that neonatal mice given nontoxic topical applications of an industrial surfactant and subsequently infected with sublethal doses of virus develop a severe metabolic disease accompanied by an increased mortality rate and abnormal hepatic lipid metabolism. We have demonstrated a surfactant-dependent increase in hepatic cholesterol content, which may be related to increased susceptibility to viral infection (30–32). Once the animals are infected, there are distinct changes in liver lipid content, and depending upon the nature of the virus, there may be fat accumulation. However, even in the absence of hepatic steatosis, combined chemical/viral treatment of the young mice produces dramatic mitochondrial abnormalities that we believe to be closely related to the increased mortality associated with viral enhancement.

[Received October 3, 1986]

Mass Spectra of the Picolinyl Esters of Isomeric Mono- and Dienoic Fatty Acids

W.W. Christie*,[a], E.Y. Brechany[a] and R.T. Holman[b]
[a]The Hannah Research Institute, Ayr, Scotland KA6 5HL and [b]The Hormel Institute, Austin, Minnesota

The picolinyl ester derivatives of the complete series of isomeric octadecenoates, methylene-interrupted octadecadienoates, and of octadec-9-ynoate have been subjected to gas chromatography-mass spectrometry. A fused-silica capillary column, coated with a cross-linked methyl silicone, was used for the separation. Electron impact spectra were determined at 70 eV. Earlier observations with a limited series of model compounds were confirmed, and it was shown that the picolinyl ester derivatives were of almost universal value in the location of double bonds in such isomers. Difficulties of interpretation arose mainly when the double bonds were close to the carboxyl group.
Lipids 22, 224–228 (1987).

Analysts have approached the problem of the location of double bonds in fatty acids by means of mass spectrometry (MS) in two ways (reviewed comprehensively elsewhere [1,2]): either the double bonds are fixed by adding some form of substituent group that gives a characteristic fragmentation pattern, or certain amide or related derivatives of the carboxyl group are prepared that appear to stabilize in the mass spectrometer the ions containing double bonds. The latter method is inherently more elegant and convenient, when it can be applied. Harvey, for example, showed that the picolinyl ester derivatives of certain model fatty acids gave characteristic spectra, which permitted unambiguous determination of the positions of double bonds (3–5). Derivatives of this kind, prepared from natural samples such as cod liver oil and pig testis lipids, were readily separated by gas chromatography (GC) on fused-silica capillary columns coated with nonpolar methyl silicone phases (6). GC-MS identification was accomplished for all components that were resolved and in sufficient abundance (>0.5% of the total fatty acids). However, the interpretations were based on a set of simple rules derived from spectra of a relatively limited number of model compounds in which the double bonds tended to be located in central positions in the fatty acyl chains. It is uncertain how applicable these rules are when double bonds are located at the proximal or terminal ends of the molecule. The electron impact mass spectra of the picolinyl ester derivatives of the complete series of isomeric *cis*-octadecenoic acids and of methylene-interruped *cis,cis*-octadecadienoic acids were therefore obtained, and they are described below.

MATERIALS AND METHODS

Most of the isomeric *cis*-octadecenoic acids, octadec-9-ynoic acid (7) and the isomeric methylene-interrupted *cis,cis*-octadecenoic acids (8) had been prepared earlier by total synthesis. 2-*Trans*-octadecenoic acid was a gift from F. D. Gunstone (Department of Chemistry, The University of St. Andrews, Scotland). The picolinyl ester derivatives were prepared as described previously (i.e., by reaction of the mixed anhydride of trifluoroacetic acid and the fatty acid with 3-(hydroxymethyl)-pyridine [6]). The GC-MS conditions were also as described previously (6). In brief, a fused-silica capillary column (25 m × 0.2 mm) coated with a cross-linked methyl silicone, with helium as carrier gas, was temperature-programmed from 60 C to 220 C at 50 C/min, then to 260 C at 1 C/min. The column outlet was connected directly to the ion source of a Hewlett-Packard 5970 mass selective detector, operated at an ionization energy of 70 eV.

RESULTS AND DISCUSSION

Picolinyl octadecenoates. Most of the fatty acids were more than 95% pure as judged by the total ion current trace from the mass spectrometer, and spectra were taken of the component eluting at the center of each peak, so the spectra should be representative. The spectra for each of the isomeric picolinyl octadecenoates are obviously distinctive; data for some of the ions of diagnostic value are listed in Table 1. The spectra for the 9- and 11-isomers resemble closely those published by Harvey, although his were obtained at an ionization potential of 25 eV, which was claimed to give better results (3). A definitive explanation for the discrepancy is not possible, but it may be related to differences in instrumentation. In each instance, a substantial molecular ion (M, m/z = 373) was observed, and the magnitude of the $(M-1)^+$ ion increased with the distance of the double bond from the carboxyl group. The base peak was generally at m/z = 92, but occasionally was at m/z = 93, representing an ion containing the pyridine ring and its methylene group. Other ions containing the pyridine ring at m/z = 108, 151 (cleavage between C2 and C3 of the aliphatic chain) and 164 (cleavage between C3 and C4 of the aliphatic chain) are almost always prominent. For example, the magnitude of the ion at m/z = 108 tends to increase with the distance of the double bond from the carboxyl group. The exception is the 2-isomer, where this ion is the base peak. Although this is the 2-*trans* isomer, none of the *cis* isomer being available, the configuration of the double bond is unlikely to affect the spectrum; certainly no difference was found between configurational isomers of the 9- and 11-octadecenoates (data not shown). The ion at m/z = 151 containing the picolinyl moiety is the base peak for the 4-isomer, and that at m/z = 164 is abundant for all but those isomers where the double bond is close to the carboxyl group.

In all the spectra, there are ions diagnostic for the positions of the double bonds. The points where characteristic fragmentations occur are shown for picolinyl octadec-9-enoate in Figure 1a. Doublets of prominent ions 14 atomic mass units (amu) apart representing cleavage on the distal side of the double bond were earlier found to be of special value in the identification of unknown fatty acids (6). In the spectrum of the 10-isomer illustrated in Figure 2 (as

noted above, spectra for the 9- and 11-isomers have already been published [3]), these ions are at m/z = 302 and 288. They were rationalized in terms of initial abstraction of allylic hydrogens on either side of the double bond with formation of a relatively stable conjugated diene system (3). These peaks are easily picked out in the mass spectra of most of the isomers. They are not, of course, seen in the spectra of those isomers where the double bond is close to the terminal methyl group, as shown in Figure 3, in which the spectrum of the 16-isomer is illustrated, because the proposed mechanism cannot operate here. The doublet is particularly pronounced with the 2-isomer, where a conjugated dienoic ion would also interact with the carbonyl function, but it is less prominent with the 3- and 4-isomers, as is evident from Figure 4, which illustrates the spectrum of picolinyl 3-octadecenoate. It is recognizable even with the latter isomers, however, as it is in regions of the spectrum where other ions are less abundant.

Distinctive fragmentation at the double bond is also apparent for each isomer. For example, to consider the 10-isomer (Fig. 2) once more, a regular series of ions 14 amu apart is seen in the high mass region, corresponding to fragmentations between each of the successive methylene groups, i.e., at m/z = 358 (M-CH_3), 344, 330, 316, 302, 288 and 274. There is then a gap of 26 amu to m/z = 248 (at points C and D on Fig. 1a), for the double bond carbons, followed by a further series of ions 14 amu apart at m/z = 234 (ion E in Fig. 1a), 220, 206, 192, 178 and 164. For some of the isomers, the gap of 26 amu is not always immediately obvious, but the gap of 40 amu between ions C and E is almost always readily identifiable. In addition to the other diagnostic ions, ions representing cleavage at C, D and E are evident in the spectra of the 5- to 17-isomers, as were the series of ions 14 amu apart that originate from either side of the double bond (other than from the 17-isomer, of course). The exceptions are the 2-, 3- and 4-isomers. With these, the fact that the double bond must be close to the carboxyl group can be recognized from the fact that only a single regular series of ions 14 amu apart is evident from the molecular ion downward, the doublet ions (A and B in Fig. 1a) being diagnostic and standing out from the surrounding ions. The 4-isomer can also be recognized because its base peak is at m/z = 151 rather than at m/z = 92, in addition to the doublet peaks (A and B).

Picolinyl octadec-9-ynoate. The spectrum of a single monoacetylenic ester was obtained, i.e., for picolinyl octadec-9-ynoate ("stearolate"). This resembled the spectrum of the corresponding monoene, in that there was a prominent doublet on the distal side of the triple bond (at m/z = 272 [45%] and 286 [46%]), and a gap of 24 amu from m/z = 258 (14%) to 234 (25%) for fragmentations on either side of the triple bond. The doublet ions may

[a]Expressed as a percentage of the base ion.
[b]In parentheses.
[c]Points of cleavage of ions A to E can be seen by reference to Figure 1b.

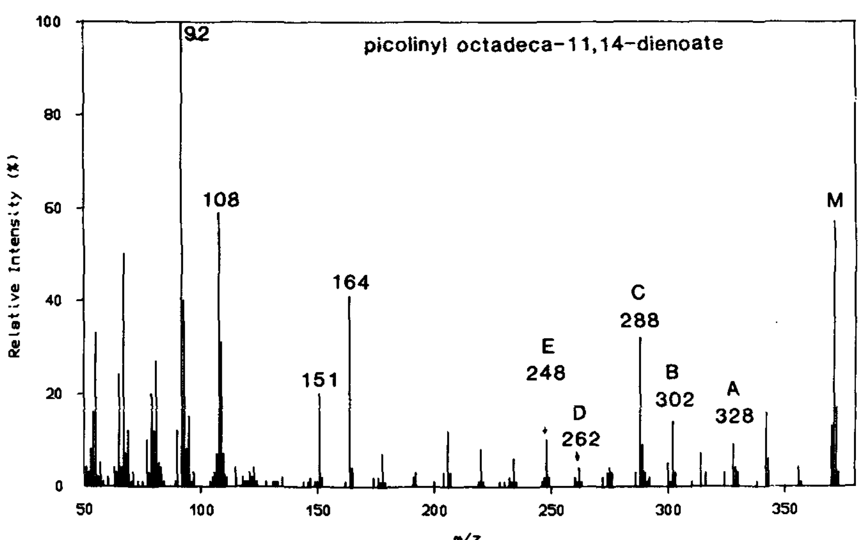

FIG. 5. The mass spectrum of picolinyl octadeca-11,14-dienoate. Ions A to E correspond to cleavage at the corresponding points relative to the double bond in Fig. 1b.

have arisen by abstraction of allylic hydrogens with formation of a conjugated double bond system, as with the monoenes (3). The ions characteristic of the picolinyl moiety are as expected. General rules on fragmentation cannot be derived from a single isomer, and the data are described simply as a guide for future work.

Picolinyl octadecadienoates. The ions in the mass spectra of the picolinyl 2,5- to 14,17-octadecadienoates of value for identification purposes are listed in Table 2. A substantial molecular ion (M) is always found (m/z = 371), and once more the abundance of the ion at $(M-1)^+$ tended to increase with the proximity of the double bonds to the terminal methyl group. As for most other picolinates, the base peak is at m/z = 92 (or 93), and the ions at m/z = 108, 151 and 164 are particularly prominent. Only for the 2,5- and 3,6-isomers is the ion at m/z = 164 less abundant.

There are also a number of ions that are diagnostic of the positions of the double bonds, and the positions of these are illustrated with reference to the naturally occurring 9,12-isomer in Figure 1b. As the spectrum of this compound has been published (5), that of the 11,14-isomer, which is also found in nature, is reproduced here in Figure 5 as an example of an isomer with centrally located double bonds. With the latter, a series of ions

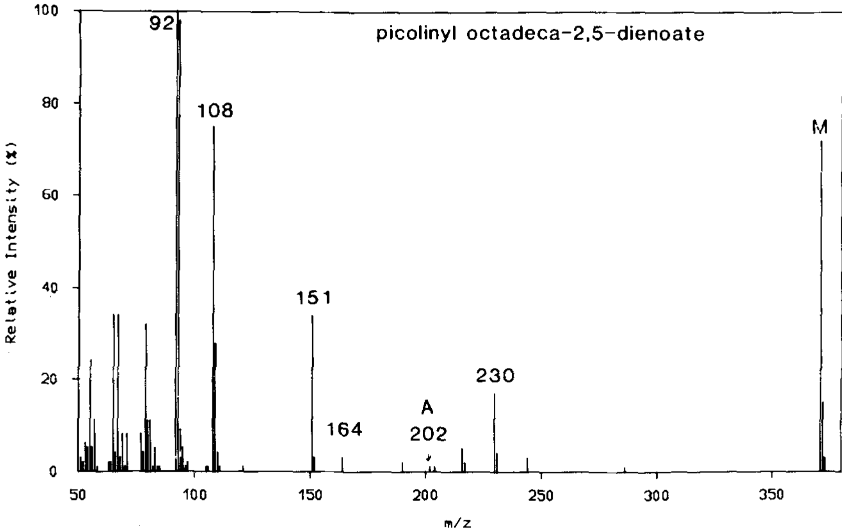

FIG. 6. The mass spectrum of picolinyl octadeca-2,5-dienoate. Ion A corresponds to cleavage at the corresponding point relative to the double bond in Fig. 1b.

14 amu apart is seen representing cleavage between successive methylene groups from the methyl end (at m/z = 356, 342 and 328 [ion A]). There is then a gap of 26 amu for the terminal double bond to m/z = 302 (ion B), followed by one of a further 14 amu to m/z = 288 (ion C) and a gap of 26 once more for the proximal double bond to m/z = 262 (ion D). As for the spectra of the monoenes, gaps of 40 amu between m/z 328 and 288 and between m/z = 288 and 248 (ion E) are usually easier to pick out than the gaps of 26 amu. A second series of relatively abundant ions 14 amu apart commences at m/z = 248 and continues until the carboxyl group is reached. Analogous ions to these are seen in the spectra of the picolinyl esters of the 3,6- to the 14,17-isomers, and ions A to E especially can be used to identify immediately the positions of the double bonds (as detailed in Table 2).

Only the spectrum of the 2,5-isomer defied immediate interpretation in these terms. It was remarkably devoid of ions in the high mass region, apart from the molecular ion itself, which is relatively more abundant than for any of the other isomers. There is an additional abundant ion at m/z = 230 (17%), which presumably represents cleavage between carbons 8 and 9 in the chain, although why such a fragmentation should be favored is not immediately obvious. The spectrum of this compound is illustrated in Figure 6 for reference purposes.

Conclusions. All the picolinyl esters were successfully chromatographed on a column of fused silica coated with a cross-linked methyl silicone phase. The retention times were determined over a period of several weeks, when small variations in the elution conditions could have occurred, so the data are not recorded here. On the other hand, it was apparent that for each series, the retention times follow a broadly sinusoidal relationship, very similar to that reported earlier for the methyl ester derivatives (9,10). Isomers with double bonds located approximately centrally are generally separable when these are 2 carbons apart (e.g., the 7-, 9- and 11-octadecenoates could be resolved). Such isomers are often found together in natural samples, as in those fractionated earlier (6). When the double bonds are near either end of the molecule, adjacent isomers are separable.

It is confirmed that the picolinyl esters of mono- and dienoic fatty acids are almost universally useful for locating double bonds. Problems arise in the interpretation of the mass spectra in terms of the positions of the double bonds only when they are close to the carboxyl group. Our experience has been that these derivatives are of equal value for polyunsaturated components, and fatty acids with up to six double bonds, methyl branches and as many as 24 carbon atoms have been separated and identified in this way.

ACKNOWLEDGMENTS

The Guest Professorship Program of the Hormel Institute, University of Minnesota, provided funding and facilities to WWC to initiate this work. It was also funded in part by Program Project Grant HLB 08214 from the National Institutes of Health and by the Hormel Foundation. F. Pusch gave technical assistance.

Characterization of Feline Omentum Lipids

Robert H. McCluer[a,*], James E. Evans[a], Marcia Williams[a], Ann L. Griffith[b] and Nicholas Catsimpoolas[b]
[a]Biochemistry Department, Eunice Kennedy Shriver Center, Waltham, Massachusetts, and [b]Department of Biochemistry, Boston University School of Medicine, Boston, Massachusetts

Feline omental lipid extracts, previously reported to be angiogenic in the cornea of rabbits, were fractionated and the major lipid components characterized. Approximately 97% of the chloroform/methanol extract consisted of triglycerides containing primarily 16:0, 18:0, 18:1 and 18:2 fatty acids. Trace quantities of free fatty acids, cholesterol, di- and monoglycerides were also detected. The phospholipid fraction, obtained by solvent partition and Unisil column chromatography and characterized by high performance liquid chromatography (HPLC)-mass spectrometry, was found to consist of phosphatidylcholine, sphingomyelin, phosphatidylethanolamine and phosphatidylserine. The neutral glycolipids, isolated by solvent partition and Unisil column chromatography and identified by high performance thin layer chromatography and HPLC of their perbenzoylated derivatives, were found to consist of glucosyl- and galactosylceramides, galabiosylceramide, lactosylceramide, globotriaosylceramide and globotetraosylceramide. The complex glycolipid fraction, obtained from Folch upper phase solvent partition, was found to consist primarily of Forssman glycolipid and gangliosides GM_3 and GD_3. Smaller amounts of GM_1 and other unidentified gangliosides were also present.
Lipids 22, 229-235 (1987).

A lipid extract of feline omentum has been shown (1-6) to produce excellent angiogenic activity after a single injection into the central cornea of rabbits and to produce increased perfusion in a standardized wound as measured by in vivo nuclear imaging techniques with Technetium-labeled erythrocytes (7). Angiogenesis and chemical factors that mediate or inhibit the angiogenic processes have important implications in major diseases, and polypeptide and small molecular weight angiogenic factors have been purified from various pathological sources and from normal tissue in small quantities (9-18). Thus, tissues available in large quantities that contain angiogenic activity provide opportunities for isolation, structural analysis and extensive animal and clinical studies.

The lipid composition of omental tissue has received little attention. Rabinowitz et al. (19) reported on the lipid composition of human omental tissue, but only nonpolar lipids and phospholipids were studied. Neutral glycosphingolipids and particularly gangliosides have recently been shown to be associated with a variety of cellular responses and to modulate the activity of several growth factor receptors (20). The purpose of this study has been to determine the lipid composition of feline omentum and to assess the angiogenic activity of the lipid fractions with the chick embryo chorioallantoic membrane (CAM) assay. The CAM activity data will be presented elsewhere.

MATERIALS AND ANALYTICAL PROCEDURES

Materials. High performance liquid chromatography (HPLC) grade methanol and other reagent grade solvents and chemicals were obtained from Fisher Chemical Scientific (Fairlawn, New Jersey); Iatrobeads 6RS-8060 and 6RS-8010 were from Iatron Industries (Tokyo, Japan); DEAE-Sephadex (A-25) was from Pharmacia Fine Chemicals (Piscataway, New Jersey); Unisil was from Clarkson Chemical Co. (Williamsport, Pennsylvania); and high performance thin layer chromatography (HPTLC) plates were obtained from E. Merck (Darmstadt, Federal Republic of Germany). BondElut C18 reversed phase cartridges were obtained from Analytichem International (Harbor City, California). Ganglioside and glycolipid standards were prepared as previously described (21,22). Vibrio cholerae neuraminidase was obtained from Sigma Chemical Co. (St. Louis, Missouri).

Neuraminidase treatment of gangliosides. Purified gangliosides were dried under nitrogen, and 300 μl of 0.05 M sodium acetate buffer, pH 5.5, containing 0.025% $CaCl_2$ was added. Vibrio cholerae neuraminidase (100 μl, 0.1 units) was added and the sample was incubated for 3 hr at 37 C. The reaction was stopped by the addition of 2 ml of chloroform/methanol (C/M) (2:1, v/v); the mixture was placed over a C18 reversed phase cartridge (BondElut) and the nonlipid components were eluted with water. Any remaining gangliosides and lipid reaction products were eluted with methanol and C/M and examined by HPTLC.

Sugar and fatty acid analysis. For sugar and fatty acid analysis, the glycolipids were subjected to methanolysis in anhydrous 0.75 N HCl in methanol as described (23,24). The fatty acid methyl esters were analyzed by gas liquid chromatography (GLC) on an 8 ft × 2 mm ID coiled column packed with 3% OV-1 on 80-100 mesh Supelcoport with a Hewlett-Packard model chromatograph equipped with a flame ionization detector. The column oven was programmed from 160-250 C at 2 C/min. The methyl glycosides were analyzed as their trimethylsilyl derivatives on the same OV-1 column as described (25,26). For HPLC analysis of the lower phase neutral glycolipids, the fraction was perbenzoylated with benzoyl chloride in pyridine, and the benzoylated glycosphingolipids were separated and quantitated by HPLC on a column packed with Zipax with gradient elution and 230 nm detection as previously described (21). For direct probe mass spectrometry, glycolipid or ganglioside samples (5-50 μg) were trimethylsilylated by heating at 80 C for 60 min in 25 μl of pyridine/hexamethyldisilane/trimethylchlorosilane/N,O-bistrimethylsilyl/trifluoroacetamide (4:2:1:1:1, v/v/v/v/v). One to 5 μl of the sample was placed in a sample

*To whom correspondence should be addressed at E. K. Shriver Center, 200 Trapelo Rd., Waltham, MA 02254.

The abbreviations and nomenclature used for glycosphingolipids are those recommended by IUPAC (1976), *Lipids 12,* 455-468: GlcCer, glucosylceramide; GalCer, galactosylceramide; LacCer, lactosylceramide; $GaOse_2Cer$, galabiglycosylceramide, Gal(α1-4)Gal(β1-1)Cer; $GbOse_3Cer$, globotriglycosylceramide, Gal(α1-4)Gal(β1-4)Glc(β1-1)Cer; $GbOse_4Cer$, globotetraglycosylceramide, GalNAc(β1-3)Gal(α1-4)-Gal(β1-4)Glc(β1-1)Cer; $GalNAcGbOse_4Cer$, Forssman glycolipid. The ganglioside nomenclature is according to the system of Svennerholm (*J. Neurochem. 10,* 613-623, 1963).

cup, and the probe was heated from 100 to 440 C at a rate of 30 C/min. The mass spectra were obtained with a Finnigan model 4500 quadrupole mass spectrometer equipped with Teknivent, model 56K data system. It was operated with an ionizing current of 0.5 ma and an ionizing voltage of 70 eV. The ionizer temperature was 150 C. Repetitive scans of the mass range from 100 m/e to 950 m/e were acquired at 17-sec intervals.

Immunochromatography. Glycolipids were chromatographed on aluminum-backed HPTLC plates (Merck) with C/M/water (60:35:8, v/v/v), dried, then dipped in 0.05% polyisobutyl methacrylate in hexane as described by Brockhaus et al. (27). The plates were then soaked in phosphate-buffered saline (PBS) containing 1% bovine serum albumin for 2 hr before similar exposure to antibody for 2 hr at 4 C. The plate of upper phase neutral glycolipid was treated with Forssman monoclonal antibody IgM, purchased from American Tissue Culture Collection T1B 121. The TLC plates of the disialoganglioside fraction were treated with GD_3 monoclonal antibody IgM prepared in this laboratory. After washing in PBS, the plates were exposed to goat anti-mouse IgM conjugated to horseradish peroxidase for 2 hr at 4 C. After washing in PBS, the plates were developed with 33 mM 4-chloronaphthol in 0.02 M Tris-HCl buffer containing 20% methanol and 0.025% H_2O_2.

HPLC-mass spectrometry (LC-MS) of phospholipids. LC-MS of phospholipids was performed by methods developed in this laboratory (28). Briefly, HPLC was performed with a Spectra Physics (model 8700) gradient pump and a Brownlee cartridge, 6 cm × 2.0 mm ID, spherical silica (5 μm) column. The column was eluted with a linear gradient of solvent A, dichloromethane/methanol/water (93:6.5:0.5, v/v/v) and solvent B, dichloromethane/methanol/water/15 M NH_4OH (65:31:4:0.2, v/v/v/v), from 12% B to 45% B in 10 min and programming to 100% B in 2 min, at a flow rate of 0.5 ml/min. The sample to be injected was dissolved in dichloromethane/methanol/15M ammonia (1:1:0.01, v/v/v) at a concentration of about 1 μg phospholipid per 1 μl. The HPLC eluant was applied as a fine stream to the moving belt of a Finnigan LC-MS interface to achieve an even coating. The sample evaporator heater was at 330 C, and the cleanup heater was set at 210 C. A Finnigan model 4500 mass spectrometer was used with ammonia (0.75 torr) as the chemical ionization (CI) reagent gas. The ion source was at 150 C. Positive ion spectra were obtained by the system under the control of a Teknivent model 56K MS data system. MS data were collected from m/z 100–900 with 7-sec scans.

FRACTIONATION METHODS AND RESULTS

Fractionation of omentum extracts. Omentum from adult female cats were excised and minced as previously reported (6). The omentum preparations were homogenized in cold PBS and centrifuged at 4 C for 20 min in 2150-ml plastic bottles at 1,600 × g. After centrifugation, the lipid cake was removed and homogenized in 20 vol C/M (2:1, v/v). The extract was centrifuged at 200 × g for 10 min to remove particulate matter, and the clear supernatant was evaporated to dryness in vacuo to obtain the C/M fraction (CMFr), which was further fractionated as shown in Figure 1.

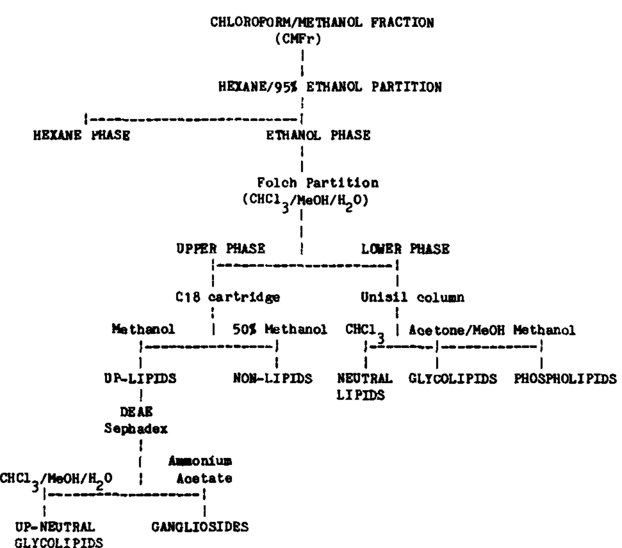

FIG. 1. Flow diagram for the fractionation of feline omentum chloroform/methanol extract.

TABLE 1

Weight Percent Distribution of Fractions from Feline Omentum Chloroform/Methanol Fraction (CMFr)

Fraction	Percent of CMFr	Percent of ethanol phase
CMFr	100	
Hexane	85	
Ethanol	15	100
Folch lower phase	13	86
Unisil column		
Neutral lipids	12	80
Glycolipids	0.03	0.17
Phospholipids	0.09	0.61
Folch upper phase	2	14
Nonlipid	0.27	1.9
Lipid		
Neutral glycolipids	0.18	1.25
Gangliosides		
Monosialo	0.007	0.05
Disialo	0.002	0.01
Polysialo	0.003	0.02

The CMFr was dissolved in hexane (ca. 60 ml/10 g of extract), and 0.66 vol of 95% ethanol was added. The phases were thoroughly mixed and allowed to separate. The lower phase was removed and the upper phase (hexane layer) reextracted with 95% ethanol. The lower phases were combined and reextracted with a fresh volume of hexane, and the hexane phases were combined. The phases were then taken to dryness in vacuo to obtain hexane upper phase material (hexane-UP) and ethanol lower phase material (ethanol-LP).

The hexane phase contained ca. 85% of the material in the CMFr and was shown to consist primarily of triglycerides as determined by HPTLC (weight distribution of the fractions from the omentum C/M extract is shown in Table 1). Alkaline methanolysis and gas chromatography

(GC)/MS analysis of the resulting fatty acid methyl esters revealed that 14:0 (1%), 16:0 (20%), 17:0 (1%), 18:0 (24%), 18:1 (44%) and 18:2 (10%) were the major triglyceride fatty acids. Small quantities of material migrating on HPTLC as free fatty acids, cholesterol, diglycerides and monoglycerides were also present in the hexane phase.

The ethanol-LP material was dissolved in C/M (2:1, v/v) (20 ml/g); 0.2 vol of water was added and phases were thoroughly mixed and allowed to separate as described by Folch et al. (29). The upper phase was removed, and the lower phase was washed with 0.4 vol of methanol/water (1:1, v/v). The upper phases were combined and both phases were taken to dryness in vacuo to obtain Folch-UP and Folch-LP material.

Folch-LP material was dissolved in chloroform and subjected to chromatography on a silicic acid (Unisil) column (30). The Unisil column was eluted successively with 20 column volumes of chloroform, acetone/methanol (9:1, v/v) and methanol to obtain the neutral lipid, glycolipid and phospholipid fractions, respectively. The neutral lipid fraction recovered from the Unisil column also consisted primarily of triglycerides, and small amounts of free fatty acids, cholesterol, di- and monoglyceride were detected by TLC analysis. The acetone/methanol glycolipid fraction was examined by TLC; components migrating as monohexosylceramides, lactosylceramide, globotriaosylceramide and globoside were present. Quantitative analysis of these glycolipids by HPLC is described below. The methanol phospholipid fraction was examined by TLC; components migrating as phosphatidylethanolamine, phosphatidylserine, phosphatidylcholine and sphingomyelin were present. Further characterization of phospholipids by LC-MS is described below.

HPLC analysis of the lower phase glycolipids. The lower phase glycolipids were examined by HPTLC with C/M/water (60:35:8, v/v/v) as the developing solvent and visualized with the orcinol spray reagent (31). They were also benzoylated with benzoyl chloride in pyridine, and the perbenzoylated derivatives were analyzed by HPLC with 230 nm detection as previously reported (32). The results are shown in Figure 2. These data show that the percent distribution of glycolipids in this fraction as GlcCer (Nfa), 26%; GalCer (Nfa), 9.6%; GlcCer (Hfa) + GalCer (Hfa) + $GaOse_2Cer$ (Nfa), 12%; LacCer, 11%; $GbOse_3Cer$, 10%; $GbOse_4Cer$, 26%.

LC-MS analysis of phospholipids. Aliquots of the phospholipid fraction were analyzed by LC-MS (28). Briefly, an aliquot containing at least 5 μg of each major phospholipid, was injected onto a column packed with spherical silica as described in Materials and Analytical Procedures. The column was eluted with a solvent gradient consisting of dichloromethane/methanol/ammonia with increasing concentrations of methanol and ammonia. The column effluent was applied to the Finnigan moving belt interface, solvent was removed under vacuum, and the chromatographic components were transported into the vaporization chamber and the lipids were volatilized into the ion source of the mass spectrometer. Positive ion mass spectra were continuously collected in the CI mode, with ammonia as the reagent gas. Figure 3 shows the total ion current chromatogram and selected ion plots specific for the phospholipid bases: serine (m/z 105), phosphoethanolamine (m/z 141) and phosphocholine (m/z 142). These data provide definitive identification and relative concentrations along with information on the fatty acid or ceramide composition of the different phospholipids. In order of decreasing concentrations, the following phospholipids were identified; phosphatidylcholine, sphingomyelin, phosphatidylethanolamine and phosphatidylserine. Trace quantities of phosphatidylinositol were also observed.

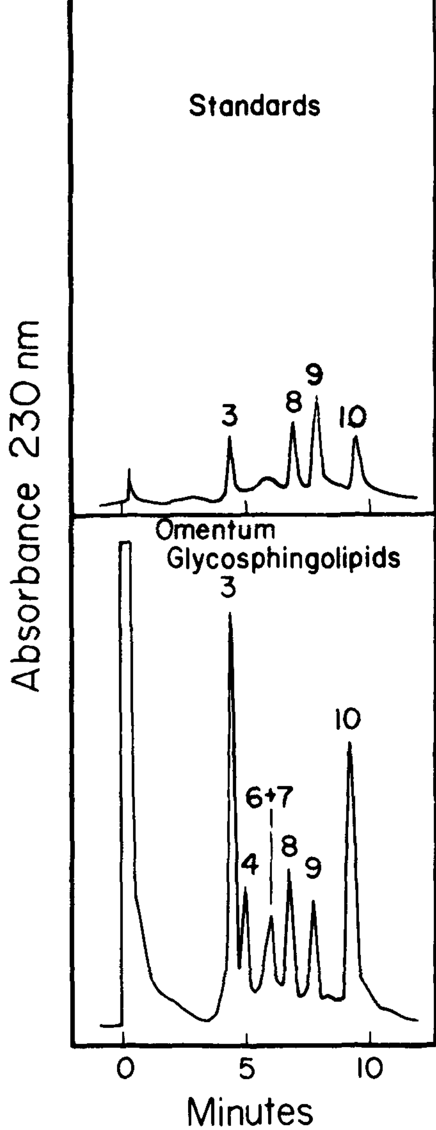

FIG. 2. High performance liquid chromatography of perbenzoylated neutral glycosphingolipids from feline omentum. A Zipax column with detection at 230 nm was used with a 13-min linear gradient of 1–20% dioxane in hexane at a flow rate of 2 ml/min. Peak numbers—3: GlcCer-NFA, glucosylceramide; 4: GalCer-NFA, galactosylceramide; 6: CMH-HFA, ceramide monohexoside with HFA (GlcCer and GalCer with hydroxyl fatty acids); 7: galabiosylceramide; 8: Lac-Cer, lactosylceramide; 9: CTH, ceramide trihexoside (globotriaosylceramide); 10: globotetraosylceramide (globoside).

Folch-UP material. Approximately 20% by weight of the ethanol-phase material was recovered in the Folch-UP. The Folch-UP was made 0.1 M with respect to KCl and applied to a C18 reversed phase cartridge (BondElut) (33), which was then washed with 4 vol of methanol/water (1:1, v/v) followed by elution with 4 vol of C/M (2:1, v/v).

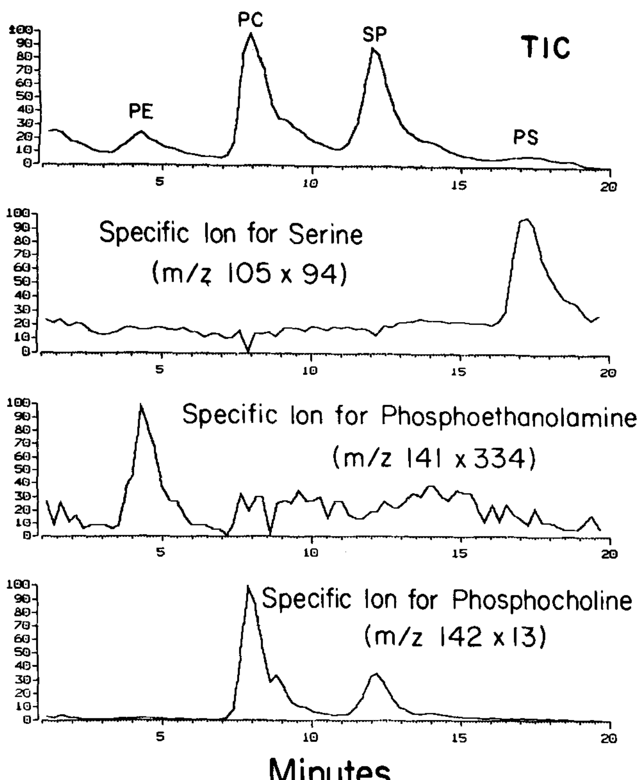

FIG. 3. Reconstructed plots of total ion current (a) and various specific ions monitored after high performance liquid chromatography (HPLC)-chemical ionization mass spectrometry (CIMS) of feline omentum phospholipids. An aliquot of the omentum phospholipid fraction equivalent to about 25 μg of total phospholipid was injected on a Brownlee silica gel (5 μm) cartridge HPLC column and eluted as described in the text. The eluate was applied to the moving belt of a Finnigan HPLC-MS interface. The solvent was removed under vacuum and the phospholipids were transported into the vaporization chamber and volatilized into the ion source (150 C) of the mass spectrometer. Positive ion mass spectra from m/z 100–900 were continuously collected every 7 seconds in the CI mode with ammonia as the reagent gas. The multiplication factor (*) for each plot is provided under each panel.

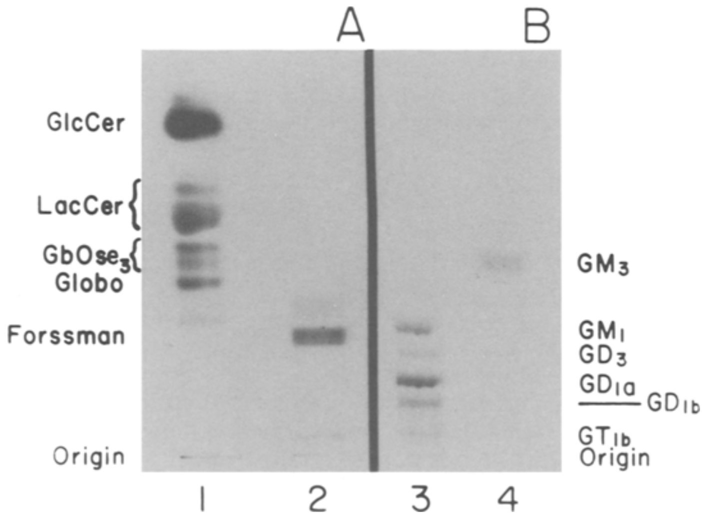

FIG. 4. High performance thin layer chromatography of feline omentum ganglioside and neutral lipid upper phase glycolipid fraction. Plate A was developed with chloroform/methanol/water (60:35:8, v/v/v), and the spots were visualized with orcinol spray reagent. The component migrating just above Forssman glycolipid is unidentified but migrates like paragloboside (nLcOse$_4$Cer). Plate B was developed with chloroform/methanol/0.25% $CaCl_2$ (55:45:10, v/v/v), and the spots were visualized with resorcinol spray reagents.

The two washes were separately collected and evaporated to dryness in vacuo to obtain nonlipid-UP material and lipid-UP material, respectively.

Nonlipid material. The nonlipid-UP fraction was taken to dryness and extracted with methanol. The majority of material was not methanol-soluble, and the suspension was centrifuged and the supernatant removed. The methanol-insoluble material was readily soluble in water. These fractions were examined by TLC, and the water-soluble fraction showed only one ninhydrin positive band. The bulk of this water-soluble material appeared to be salt. The methanol-soluble material contained at least six orcinol and ninhydrin positive components; GC/MS analysis, after trimethylsilylation, indicated this material was a complex mixture of sugars, amino acids, peptides and glycopeptides.

Lipid-UP. The lipid-UP material was dissolved in methanol and applied to a DEAE-Sephadex (acetate) column (31). The column was eluted with 10 vol of the same solvent to obtain the neutral lipid-UP fraction and then with 0.5 M ammonium acetate in methanol to obtain the ganglioside fraction. The fractions were evaporated to dryness in vacuo. The ganglioside fraction was desalted with a C18 reversed phase cartridge (BondElut) as described above.

Characterization of UP complex neutral glycolipids. The neutral lipid-UP fraction was found to constitute 40% of the lipid-UP material. Upon examination by HPTLC, this fraction was seen to consist primarily of an orcinol positive material migrating slightly slower than the globoside standard and small amounts of 3–4 more polar orcinol positive components (see Fig. 4). Immunoblotting with Forssman and SSEA-1 antibody indicated the major component was Forssman positive, and no SSEA-1 positive components were present. The major component was further purified by chromatography on an Iatrobead column (1 × 50 cm, 60 μ) eluted with hexane/isopropanol/water mixtures (23,26) and subjected to methanolysis and component analysis by GC/MS. Hexose ratios were found to be Glc/Gal/GalNAc (1.0:1.9:1.9). The fatty acids present were primarily 16:0, 18:0, 20:0, 22:0 and 24:0 with small amounts of the monounsaturated analogs, as shown in Table 2. The purified Forssman glycolipid appeared as four distinguishable bands when examined by HPTLC; these bands were isolated by preparative HPTLC and shown to contain different fatty acids, with the lowest band containing almost exclusively 16:0 and 18:0 fatty acids. The intact glycolipid was also silylated and examined by direct probe mass spectrometry. The spectra, shown in Figure 5, indicated the presence of terminal hexosamine, internal hexose residues, the presence of C18 sphingosine and fatty acids consistent with the data shown in Table 2. Taken together, these data indicate that the glycolipid is the Forssman pentaglycosylceramide (GalNAcGbOse$_4$Cer). Although position and configuration of linkages have not been directly determined, the antibody reactivity and glycolipid analytical data strongly support this structure.

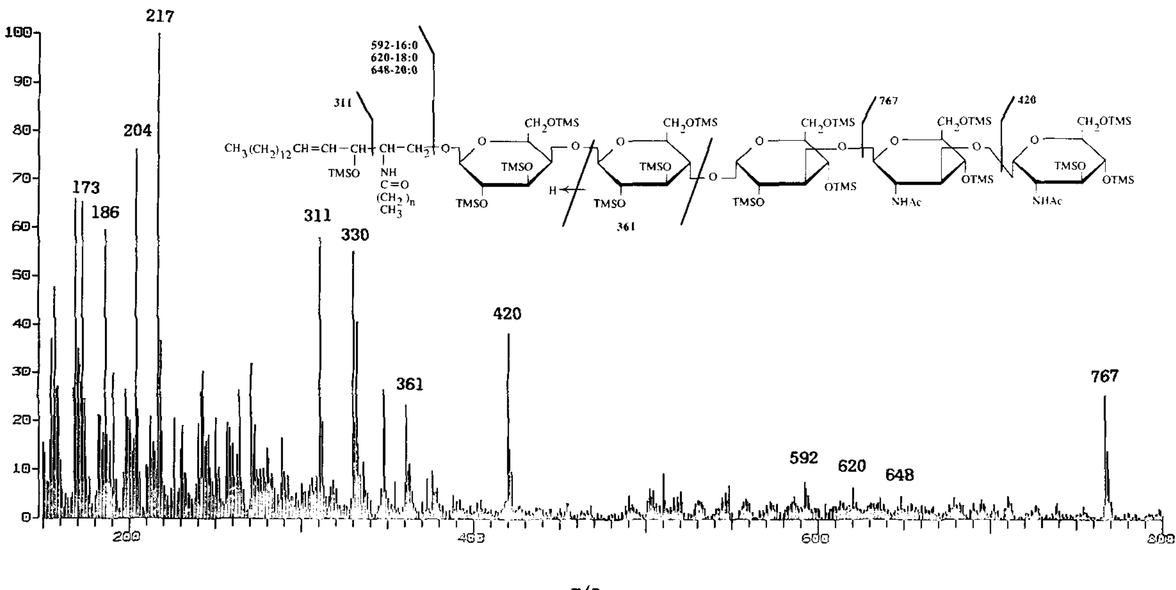

FIG. 5. Direct probe mass spectra of silylated pentaglycosylceramide from cat omentum extract. The signal at m/z 420 indicates the presence of terminal hexosamine while m/z 361 indicates internal hexose residues. The absence of an ion at m/z 451 indicates that no terminal neutral hexose is present, and the ion at m/z 767 is indicative of a terminal disaccharide consisting of two N-acetylhexosamine residues. These data are consistent with the presence of three neutral hexose and two hexosamine residues as in Forssman glycolipid (GalNAcGbOse$_4$Cer). The presence of C-18 sphingosine is indicated by the m/z 311 ion. Ions at m/z 592, 620 and 648 are indicative of 16:0, 18:0 and 20:0 fatty acid containing ceramides, respectively. These data are consistent with the fatty acid composition obtained by methanolysis and gas chromatography/mass spectrometry analysis of the methyl esters, as shown in Table 2.

TABLE 2

Percent Distribution of Fatty Acids in the Major Glycosphingolipids from Feline Omentum

Fatty acids	Forssman glycolipid	GM_3	GD_3
16:0	25.5	14.0	12.9
18:1	11.8	6.3	8.5
18:0	11.2	11.8	5.9
20:0	9.4	17.1	3.4
22:0	8.0	13.9	6.9
23:0	5.0	9.5	—
24:1	9.6	14.0	46.0
24:0	10.2	12.6	16.4

Only fatty acids present at concentrations greater than 2% are reported.

Characterization of omentum gangliosides. Examination of the ganglioside fraction by HPTLC revealed the presence of resorcinol positive components migrating as GM_3, GD_3 and minor amounts of GM_1, GD_{1a} and other polysialoganglioside components (see Fig. 4). The ganglioside fraction was treated with 0.25 N sodium hydroxide in methanol for 2 hrs at 37 C, neutralized with glacial acetic acid and desalted with a C18 reversed phase cartridge (Bond Elut). The alkali-treated ganglioside fraction was then subjected to chromatography on a DEAE-Sephadex column and eluted with 0.02 M, 0.08 M and 0.5 M ammonium acetate in methanol to obtain mono-, di- and polysialoganglioside fractions, respectively (24). The ganglioside fractions were separated into individual components by chromatography on a 0.4 × 50 cm, 10 μM particle, Iatrobead column eluted with C/M/water (65:35:8, v/v/v). Fractions of 1.2 ml were collected, aliquots were examined by HPTLC and fractions containing single components were appropriately pooled.

The monosialoganglioside fraction was shown by HPTLC to consist primarily of components migrating as a triplet of bands corresponding to the mobility of the GM_3 standard and a small amount of material migrating as GM_1. The monosialoganglioside fraction was further purified by chromatography on an Iatrobead column, and the fractions containing only components migrating as GM_3 were pooled. This material was treated with neuraminidase, and the lipid product was characterized as lactosylceramide by HPTLC and direct probe MS. The liberated sialic acid was shown by GC to consist only of N-acetylneuraminic acid. The intact ganglioside was subjected to methanolysis, and the sugars and fatty acids were examined by GC. The ratio of Glc/Gal was found to be 1.0:0.96; the fatty acids consisted primarily of 16:0, 18:0, 18:1, 20:0, 22:0, 23:0, 24:0 and 24:1, as shown in Table 2. The preparation was also examined by direct probe MS as the trimethylsilyl ether derivative. A mass spectra similar to that given by ganglioside GM_3 standard, sialyl(α2-3)galactosyl(β1-4)glucosyl(β1-1)ceramide, was obtained.

The disialoganglioside fraction was shown by HPTLC to consist primarily of a component migrating as GD_3. This material was further purified by chromatography on an Iatrobead column, and the fractions containing only a single component migrating as GD_3 were pooled. The preparation was subjected to methanolysis, and the methyl glycosides and fatty acid methyl esters were examined by GC/MS. The ratio of Glc/Gal was found to be 1.0:1.0, and the major fatty acid components were 16:0, 18:0, 18:1, 24:0 and 24:1, as shown in Table 2. The

material was treated with neuraminidase, and the lipid product was identified as lactosylceramide by HPTLC and direct probe MS. The liberated sialic acid was shown to consist only of N-acetylneuraminic by GC. Direct probe MS of the TMS derivative gave spectra consistent with GD_3. The material was also shown by immunoblotting to react with a monoclonal antibody prepared in this laboratory with demonstrated reactivity with GD_3.

The polysialoganglioside fraction was shown to contain components migrating on HPTLC as ganglioside GD_{1a}, GT_{1b}, but insufficient quantities were obtained for further analysis.

DISCUSSION

Omental tissue consists to a large extent of white adipose fat cells embedded in an extracellular matrix of collagen and elastin. According to Hodel (34), the fat droplets of the omental fat cells can reach diameters of 100 μm in well-fed animals. Quantities of macrophages are also usually present, sometimes visible grossly as "milky spots" (34-36). The cell types found in the omentum and especially in milky spots include fibroblasts, reticular cells, mesenchymal cells, histiocytes, macrophages, lymphocytes, plasma cells, mast cells, eosinophilic leukocytes and polymorphonuclear leukocytes (37). The tissue has long been known to be highly responsive to injury and infection (38,39). The studies by Rabinowitz et al. (19) on the lipid composition of human omentum showed that patients under caloric restriction showed a reduction in their total triglyceride content, a reduction in the content of unsaturated fatty acyl groups and a relative increase in phospholipid contents. Other factors such as injury and infection must also affect the lipid composition of this tissue. Species differences also exist, as we have shown in studies to be reported elsewhere, that the complex neutral glycolipids and gangliosides of porcine and bovine omentum are distinctly different from those found in this study of feline omentum.

The data reported here are the first on feline omental lipids and omental glycolipids. The triglyceride fatty acid composition of feline omentum resembled that reported by Rabinowitz et al. (19) for their control human omental tissue, except for the higher content of stearic acid. The phospholipid species found and their relative concentrations in the feline tissue also closely paralleled those reported for human tissue. The significant amounts of glycolipids found in the feline omental tissue are of interest. The presence of mono- and diglycosylceramides and globoseries glycolipids as well as gangliosides could possibly relate to the biological activity observed for the lipid extracts. Although some glycolipids may be characteristic of omentum, it is clear from ongoing studies of porcine and bovine that the glycolipid patterns are species-specific. It is anticipated that the identification of the lipid species reported here will be useful in characterizing the biologically active components. Recently Niinikoski et al. (40) reported that a hexosylceramide fraction from calf blood exerted an accelerating effect on wound-healing angiogenesis, and Gullino (41) reviewed reports on factors that can trigger angiogenesis and provided evidence that heparin, fibronectin and gangliosides are involved in the mobilization of capillary endothelium.

ACKNOWLEDGMENTS

This work was supported by Angio-Medical Corp. Hamdy Abdel-Maksoud performed HPLC-MS analyses of the phospholipids, and Denise Brescia assisted in preparation of the manuscript.

Phospholipid Studies of Marine Organisms: 14. Ether Lipids of the Sponge *Tethya aurantia*[1]

Glenn M. Smith and **Carl Djerassi***
Department of Chemistry, Stanford University, Stanford, CA 94305

The novel unesterified alkyl glycerol monoethers, (2S)-1-(hexadecyloxy)-2,3-propanediol (*1*), (2S)-1-(16-methylheptadecyloxy)-2,3-propanediol (*2*) and (2S)-1-(15-methylheptadecyloxy)-2,3-propanediol (*3*) were isolated from the marine sponge *Tethya aurantia* and were characterized by spectroscopic methods. These three saturated ethers as well as a series of alk-1′-enyl glycerol monoethers were also encountered in the phospholipids of the same sponge after reduction with $LiAlH_4$. Incorporation experiments with dissociated cells of *T. aurantia* indicated that [1-^{14}C]-hexadecanol was incorporated into the unesterified alkyl glycerol monoethers.
Lipids 22, 236–240 (1987).

Sponges are the most primitive of the multicellular animals and have been found to be rich sources of many unusual compounds (1,2), including lipids (3). Recently, a number of reports have appeared on the direct isolation of alkyl and alk-1′-enyl glycerol monoethers from marine sponges (4–7). To date, such compounds have only been isolated in the unesterified form from marine sponges, although glycerol ethers in the esterified form are commonly encountered in a wide variety of organisms (8).

Our interest in *Tethya aurantia* stems from studies currently underway in this laboratory concerning the biosynthesis of unusual fatty acids found in this sponge (9). Here we report the direct isolation of novel alkyl glycerol monoethers from *T. aurantia* without any prior hydrolysis. Alkyl and alk-1′-enyl glycerol monoethers were also found in the phospholipids of *T. aurantia* after reduction with $LiAlH_4$. Incorporation experiments utilizing [1-^{14}C]-hexadecanol were carried out to establish whether the glycerol monoethers were of dietary origin or were biosynthesized in the sponge. The possible role of the unesterified alkyl glycerol monoethers is also discussed.

MATERIALS AND METHODS

Materials. [1-^{14}C]Hexadecanoic acid was obtained from Amersham Corp. (Arlington Heights, Illinois) and 1-O-hexadecyl-glycerol from Sigma Chemical Co. (St. Louis, Missouri).

General methods. T. aurantia was collected from Carmel River Beach, Carmel, California, in February and April, 1986, at depths of 5 to 10 m. After freeze-drying, the sponges were extracted by the method of Folch et al. (10), and the resulting lipid extract was fractionated by flash chromatography (11) by elution with hexane/ether mixtures, acetone and methanol. The unesterified alkyl glycerol monoethers, which were eluted in the ether fraction by flash chromatography, were purified further by normal phase high performance liquid chromatography (HPLC), which was performed on a Waters Associates HPLC system (M-45 pump, R-401 differential refractometer) using an Altex Ultrasil-Si column (25 cm × 10 mm ID) with hexane/ether (3:7, v/v) as the mobile phase at 2 ml/min. The methanol-eluting fraction from flash chromatography, containing the phospholipids, was reduced with $LiAlH_4$ as described previously (12). The resulting mixture, which consisted predominantly of fatty alcohols and glycerol ethers, was separated by normal phase HPLC as described above.

^{1}H nuclear magnetic resonance (NMR) spectra were recorded on a Nicolet NT 300 WB (300 MHz) spectrometer using 5 mm ID spinning sample tubes. All samples were recorded in $CDCl_3$ and are expressed as ppm downfield from tetramethylsilane (TMS), the primary reference being chloroform, which resonates at 7.26 ppm relative to TMS.

Gas chromatography/mass spectrometry (GC/MS) analyses were performed with either a Ribermag R10-10 quadrupole mass spectrometer connected to a Carlo Erba series 4160 Fractovap chromatograph or a Hewlett Packard 5970 quadrupole mass spectrometer coupled to a Hewlett Packard 5890 gas chromatograph.

The identity of the alkyl glycerol ether hydrocarbon side chains (Fig. 1) was determined by GC/MS of both the nitrile and the pyrrolidide derivatives generated from the corresponding alkyl iodides after cleavage of the ether linkage. The cleavage was accomplished by refluxing the alkyl glycerol ethers with concentrated hydriodic acid for 3 hr (13) and by converting the resulting iodides to the nitriles by heating for 30 min at 90 C with NaCN in dimethylsulfoxide (14). The nitriles were hydrolyzed by refluxing in 6% KOH/ethanol for 16 hr, and the resulting acids were transformed into the methyl esters by refluxing with HCl/methanol for 30 min. The pyrrolidides were then synthesized by heating the methyl esters with pyrrolidine/acetic acid (10:1, v/v) at 100 C for 30 min (15).

The identity of the hydrocarbon side chains of the alk-1′-enyl glycerol monoethers (Fig. 2) was established by GC/MS of the resulting pyrrolidide derivatives after hydrolysis of the alk-1′-enyl ether linkage and derivatization. The vinyl ether linkage was hydrolyzed with

concentrated HCl for 2 min (16), and the resulting aldehydes were oxidized to the corresponding acids with Jones reagent (17). The methyl esters and pyrrolidides were synthesized from the resulting acids as described above.

Gas liquid chromatography (GLC) was carried out using a Hewlett Packard (HP) 5790 Series gas chromatograph equipped with an HP Ultra 2 (5% Ph Me Silicone) capillary column (25 m × 0.2 mm), temperature-programmed from 170 to 300 C at 5 C/min. Peak areas were calculated using an HP 3392A integrator.

Infrared spectra were recorded on a Perkin-Elmer 1310 infrared spectrophotometer.

Incorporation experiments. [1-^{14}C]Hexadecanol was synthesized byLiAlH$_4$ reduction of [1-^{14}C]hexadecanoic acid. Biosynthetic incorporation experiments were carried out using both intact sponges and dissociated sponge cells. [1-^{14}C]Hexadecanol (10 μCi in 0.25 ml 95% ethanol) was incorporated into intact sponges (ca. 6 cm in diameter) by injection and aquarium incubation in a minimum volume (ca. 200 ml) of seawater with aeration for 24 hr. The aquarium was then flushed continually with filtered seawater, with aeration, for a further 6 or 16 days, after which time the sponge was processed.

Dissociated sponge cells were produced by initially cutting the sponge into small pieces (ca. 1 cm × 1 cm), which were then pressed through a fine nylon cloth. To the filtrate (ca. 75 ml) was added [1-^{14}C]hexadecanol (10 μCi in 0.25 ml 95% ethanol), and the cell suspension was incubated in a 250-ml flask closed with a cotton plug, with shaking at 15 C for 16 hr. Isolation and analysis of the glycerol ethers were carried out as described above. Small aliquots (usually 1/100 or 1/50) of the ^{14}C samples were dissolved in 10 ml of organic counting scintillant, and the radioactivity was measured with a Beckman LS 7500 liquid scintillation counter. All results were corrected for background radiation and calculated as dpm by using a ^{14}C standard solution.

Identification of compounds: unesterified alkyl glycerol monoethers (Fig. 1). ^{1}H NMR (300 MHz, CDCl$_3$) of the alkyl glycerol ethers (s, d, t and m indicate singlet, doublet, triplet and multiplet): δ/ppm: 3.84 (1H, m, H-2), 3.70 (1H, dd, J = 3.5 Hz, J = 11 Hz, H-3a), 3.63 (1H, dd, J = 5 Hz, J = 11 Hz, H-3b), 3.50 (2H, t, J = 3.5 Hz, H-1a,1b), 3.44 (2H, dt, J = 1 Hz, J = 6 Hz, H-1′), 1.55 (2H, m, CH$_2$CH$_3$), 1.23 (s, CH$_2$), 0.85 (m, CH$_3$).

Mass spectra (GC/MS) of the nitrile derivatives of the hydrocarbon side chains: m/z [CH$_3$(CH$_2$)$_{15}$CN]: 251 (M$^+$, 1%), 236 (9%), 222 (36%), 208 (44%), 194 (31%), 180 (24%), 166 (24%), 152 (24%), 138 (35%), 124 (58%), 110 (83%), 96 (78%), 82 (56%), 68 (14%), 55 (100%); m/z [(CH$_3$)$_2$CH(CH$_2$)$_{14}$CN]: 265 (M$^+$, 1%), 250 (23%), 236 (3%), 222 (40%), 208 (19%), 194 (18%), 180 (18%), 166 (18%), 152 (21%), 138 (24%), 124 (41%), 110 (70%), 96 (55%), 82 (42%), 68 (10%), 55 (100%); m/z [CH$_3$CH$_2$CH(CH$_3$)-(CH$_2$)$_{13}$CN]: 265 (M$^+$, 1%), 250 (7%), 236 (51%), 222 (5%), 208 (15%), 194 (16%), 180 (29%), 166 (33%), 152 (32%), 138 (32%), 124 (34%), 110 (42%), 96 (40%), 82 (33%), 68 (10%), 55 (100%).

Mass spectra (GC/MS) of the pyrrolidide derivatives of the hydrocarbon side chains: m/z [CH$_3$(CH$_2$)$_{15}$CONC$_4$H$_8$]: 323 (M$^+$, 2%), 308 (1%), 294 (1%), 280 (1%), 266 (1%), 252 (1%), 238 (1%), 224 (1%), 210 (1%), 196 (1%), 182 (2%), 168 (3%), 154 (1%), 140 (3%), 126 (19%), 113 (100%); m/z [(CH$_3$)$_2$CH(CH$_2$)$_{14}$CONC$_4$H$_8$]: 337 (M$^+$, 2%), 322 (2%), 308 (<1%), 294 (2%), 280 (1%), 266 (1%), 252 (1%), 238 (1%), 224 (1%), 210 (1%), 196 (1%), 182 (2%), 168 (3%), 154 (1%), 140 (3%), 126 (20%), 113 (100%); m/z [CH$_3$CH$_2$(CH$_3$)-CH(CH$_2$)$_{13}$CONC$_4$H$_8$]: 337 (M$^+$, 2%), 322 (1%), 308 (2%), 294 (<1%), 280 (2%), 266 (<1%), 252 (<1%), 238 (1%), 224 (1%), 210 (1%), 196 (1%), 182 (2%), 168 (3%), 154 (2%), 140 (3%), 126 (19%), 113 (100%).

Alk-1′-enyl glycerol monoethers (Fig. 2). ^{1}H NMR (300 MHz, CDCl$_3$) of the alk-1′-enyl glycerol monoethers derived after reduction of phospholipids with LiAlH$_4$: δ/ppm: 5.94 (1H, d, J = 6 Hz, H-1′), 5.39 (t, J = 5 Hz, CH=CH), 4.41 (1H, q, J = 6 Hz, J = 10 Hz, H-2′), 3.92 (1H, m, H-2), 3.80 (2H, dd, J = 2 Hz, J = 5 Hz, H-1a,1b), 3.74 (1H, q, J = 3 Hz, J = 12 Hz, H-3a), 3.66 (1H, q, J = 6 Hz, J = 12 Hz, H-3b), 2.02 (m, CH$_2$CH=CHCH$_2$), 1.27 (s, CH$_2$), 0.88 (3H, t, J = 6 Hz, CH$_3$).

Mass spectra (GC/MS) of the pyrrolidide derivatives of the hydrocarbon side chains: m/z [CH$_3$(CH$_2$)$_{14}$CONC$_4$H$_8$]: 309 (M$^+$, 1%), 294 (1%), 280 (1%), 266 (1%), 252 (1%), 238 (1%), 224 (1%), 210 (1%), 196 (1%), 182 (1%), 168 (2%), 154 (1%), 140 (3%), 126 (20%), 113 (100%); m/z [CH$_3$(CH$_2$)$_{16}$CONC$_4$H$_8$]: 337 (M$^+$, 2%), 308 (1%), 294 (1%), 266 (1%), 252 (1%), 238 (1%), 224 (1%), 210 (1%), 196 (1%), 182 (2%), 168 (3%), 154 (2%), 140 (3%), 126 (19%), 113 (100%); m/z [CH$_3$(CH$_2$)$_7$CH=CH(CH$_2$)$_7$CONC$_4$H$_8$]: 335 (M$^+$, 2%), 278 (1%), 264 (1%), 250 (1%), 236 (2%), 222 (1%), 208 (1%), 196 (1%), 182 (2%), 168 (1%), 154 (1%), 140 (3%), 126 (70%), 113 (100%); m/z [CH$_3$(CH$_2$)$_2$CH=CH(CH$_2$)$_4$CH=CH(CH$_2$)$_6$CONC$_4$H$_8$]: 333 (M$^+$, 2%), 276 (1%), 264 (1%), 250 (1%), 236 (1%), 222 (1%), 208 (1%), 194 (1%), 182 (1%), 168 (1%), 154 (1%), 140 (2%), 126 (60%), 113 (100%).

IR (CCl$_4$) of the alk-1′-enyl glycerol ethers: ν_{max} = 3400, 2920, 2860, 1660, 1460, 1120.

RESULTS AND DISCUSSION

Alkyl glycerol monoethers were isolated after flash chromatography and HPLC of total lipid extracts of *T. aurantia,* without any prior derivatization or hydrolysis

steps, and represented 2% of the total lipid and 0.02% of the sponge dry weight.

The free alkyl glycerol monoethers were identified by a combination of ^{1}H NMR, GC/MS and chemical derivatization. ^{1}H NMR experiments indicated the presence of the glycerol monoether moiety (see Fig. 1). A multiplet at 3.84 ppm assignable to the H-2 proton was coupled to two double doublets at 3.70 and 3.63 ppm that are assignable to the two H-3 protons and also to a triplet at 3.50 ppm assignable to the H-1 protons. A double triplet at 3.44 ppm assignable to the H-1′ protons was coupled to the methylene resonance at 1.55 ppm. The ^{1}H NMR spectrum was consistent with the ^{1}H NMR spectrum of commercial 1-0-hexadecylglycerol and with earlier literature data (18). The ^{1}H NMR methyl resonance was observed as a complex multiplet, which was suggestive of methyl branch points on the hydrocarbon side chain.

Mass spectroscopy (direct insertion) of the intact alkyl glycerol monoethers and GC/MS of the isopropylidene derivatives identified three species of glycerol ethers with hydrocarbon chains corresponding to 16:0 (**1**) and 17:0 (**2** and **3**). The mass spectra of the isopropylidene derivatives gave a characteristic base peak at m/z 101, which is supportive of the glycerol monoether structure (19). The mass spectra, however, did not give any information on the existence or position of any methyl branching in the hydrocarbon side chain.

To establish the position of methyl branching, the ether linkage was cleaved and the resulting alkyl iodide was derivatized to the pyrrolidide derivative for mass spectral determination of the branch position(s). N-Acylpyrrolidides have been shown to be suitable derivatives for the mass spectral localization of methyl branches and unsaturation in fatty acids (15,20). GC/MS of both the nitrile and the pyrrolidide derivatives produced diagnostic fragments indicating the presence and position of the methyl branching. The three hydrocarbon chains were identified as 17:0, 18:0 iso and 18:0 anteiso, an extra carbon atom having been added during the transformation via the nitrile derivative. Thus, the hydrocarbon side chains of compounds **1**, **2** and **3** correspond to 16:0, 17:0 iso and 17:0 anteiso, respectively (Fig. 1). The position of the methyl branch was indicated by fragments of higher intensity 14 amu above and below a low intensity fragment. The mass spectra of the nitrile derivatives, however, proved to be superior to those of the pyrrolidides, showing significantly larger intensity differences between the diagnostic fragments. For example, the 17:0 iso nitrile derivative gave fragments of mass 250 (23%), 236 (3%) and 222 (40%), while the pyrrolidide derivative showed 322 (2%), 308 (0.05%) and 294 (2%). The mass spectra of aliphatic nitrile compounds have been described previously (21).

Quantification of the individual species was achieved by GLC of the isopropylidene derivatives of compounds **1**, **2** and **3**; the results are shown in Table 1.

The specific rotation, $[\alpha]^{20}_{598}$ + 2.9°, of the alkyl glycerol monoether mixture is in numerical agreement with that found for other natural glycerol monoethers (4,22,23), all of which possess the (2S)-absolute configuration.

The reduction of phospholipids with $LiAlH_4$ or $NaAlH_2(OCH_2OCH_3)_2$ has been suggested (24) as an efficient method of isolating alkyl and alk-1′-enyl glycerol monoethers from complex lipids. In view of the presence of the unesterified glycerol monoethers in *T. aurantia*, it was of interest to examine the presence of glycerol ethers in the phospholipids of this sponge.

Reduction of *T. aurantia* phospholipids with $LiAlH_4$ allowed the isolation of both alkyl and alk-1′-enyl glycerol monoethers, which were identified by ^{1}H NMR, GC/MS and chemical derivatization. The compositions of the alkyl glycerol monoethers derived from the phospholipids were found to be identical to the unesterified alkyl glycerol monoethers. The proportion of the three species, however, was markedly different, as shown in Table 1.

The alk-1′-enyl glycerol ether moiety (see Fig. 2) was identified by ^{1}H NMR (23). A doublet at 5.94 ppm was assigned to the H-1′ proton and a quartet at 4.41 ppm to the H-2′ proton. The chemical shift and coupling constant of the H-1′ are consistent with the *cis* isomer and similar to other naturally occurring alk-1′-enyl glycerol ethers (25). The resonances between 4.0 ppm and 3.6 ppm were assignable to the protons of the glycerol moiety. Specifically, a multiplet at 3.92 ppm was assigned to the

TABLE 1

Composition of Glycerol Ethers Isolated from *T. aurantia*

	Unesterified[a]	Phospholipids[b,c]	Phospholipids[b,d]
16:0	44	92	52
17:0 iso	32	6	—
17:0 anteiso	24	2	—
18:0	—	—	30
18:1	—	—	10
18:2	—	—	8

[a]Isolated directly without any prior chemical step. Represent 2% of the total lipids of the sponge.

[b]Isolated after reduction of phospholipids (40% of total lipids of the sponge) with $LiAlH_4$.

[c]Represent 32% of *T. aurantia* phospholipids.

[d]Represent 26% of *T. aurantia* phospholipids.

H-2 proton, the double doublets at 3.80 ppm were assigned to the H-1 protons and the two quartets at 3.74 and 3.68 ppm were assigned to the H-3 protons. Assignment of the glycerol protons was confirmed by acetylation of the mixture, which resulted in a downfield shift of ca. 1 ppm of the proton resonance(s) attached to the O-acetylated carbons. A triplet at 5.39 ppm indicated additional unsaturation in the alk-1′-enyl hydrocarbon side chain, while the methyl resonance was a clean triplet indicating no detectable methyl branching.

From the quantities of the compounds isolated, the proportions of the three species of phospholipid—diacyl, monoalkylacyl and monoalk-1′-enylacyl glycerides—were 42%, 32% and 26%, respectively. Thus, about half of the phospholipids in *T. aurantia*, which represent 40% of the total lipids extracted, contain an ether linkage.

To establish the identities of the hydrocarbon side chains of the alk-1′-enyl glycerol ethers, the ether bond was hydrolyzed with HCl to yield aldehydes and glycerol (16). The aldehydes were then oxidized to the corresponding acids and subsequently transformed into pyrrolidides. GC/MS of the pyrrolidide derivatives and GLC of the methyl esters enabled identification and quantification of the hydrocarbon side chains as 16:0, 18:0, 18:1 and 18:2 (see Fig. 2 and Table 1). The positions of unsaturation were identified by GC/MS by an interval of 12 amu in the fragmentation instead of the regular 14 amu spacing and suggested the unsaturation positions to be Δ^{9}-18:1 and $\Delta^{8,14}$-18:2. For example, Δ^{9}-18:1 showed characteristic fragments at m/z 222, 208, 196 and 182, while the $\Delta^{8,14}$-18:2 acid displayed characteristic fragments at m/z 276, 264 and 250 and at 208, 194, 182 and 168. The suggested unsaturation positions at $\Delta^{8,14}$-18:2 are to our knowledge previously unknown. Insufficient material was available to provide more secure evidence for the location of these double bonds.

Incorporation experiments were carried out with *T. aurantia* using both intact sponges and dissociated sponge cells. Different incorporation results were obtained using [1-^{14}C]hexadecanol with the two systems. Significant incorporation (1.1% of the total activity added) into the unesterified alkyl glycerol monoethers was obtained with dissociated sponge cells, whereas the esterified (i.e., phospholipid-derived) alkyl and alk-1′-enyl glycerol ethers contained essentially no radioactivity (<0.03% of the total activity added).

The incorporation experiments with intact sponges resulted primarily in the oxidation of the [1-^{14}C]hexadecanol to the acid and incorporation of the acid into the phospholipids; thus 1.7% and 1.1% of the total activity added was recovered, after 7 and 17 days, respectively, as fatty alcohols after reduction of the phospholipids. The incorporation of fatty alcohols primarily into complex lipids after being oxidized has also been observed for various mammalian tissues (26). The glycerol ether fractions contained essentially no radioactivity (<0.08% of the total activity added).

Screening a number of marine sponges of the class Demospongiae—*Aplysina fistularis* (Order Verongida), *Microciona prolifera* (O. Poecibsclerida), *Pseudaxinyssa* sp., Australian Museum Specimen #Z4988 (O. Axinellida) and *Reneira* sp. (O. Haplosclerida)—did not uncover any detectable level of unesterified alkyl glycerol monoethers, thus showing that this type of ether lipid is not widely distributed among sponges. No evidence of any di- or triglycerides of any form was obtained.

The unesterified alkyl glycerol monoethers 2 and 3, isolated from *T. aurantia*, are novel compounds. The ether 1, although previously reported, so far has not been encountered in unesterified form. Their biosynthesis can be explained on the basis of known enzymatic pathways (27) and represents a branch of the usual biosynthetic pathway to esterified glycerol ethers. The hydrocarbon side chains of the alkyl glycerol ethers, especially the 17:0 iso and anteiso chains, and possibly 16:0, are probably of bacterial origin, being either assimilated from dietary sources, which consist largely of bacteria (28), and/or contributed from the presumably symbiotic microorganisms residing in the sponge matrix. (*T. aurantia* contains numerous microorganisms as shown by electron microscopy; unpublished results.) Recently it has been shown that short-chain straight and branched fatty acids are elongated and desaturated by the sponges *Jaspis stellifera* (29) and *Aplysina fistularis* (30). The ^{14}C incorporation experiment with dissociated sponge cells suggests that the unesterified alkyl glycerol monoethers are, however, biosynthesized by *T. aurantia* and are not of dietary origin. The difference between the hydrocarbon side chain composition of the esterified alkyl and alk-1′-enyl glycerol monoethers (see Table 1) is surprising in view of the fact that alkyl glycerol ethers are considered (26) to be the precursors of the alk-1′-enyl glycerol ethers.

Alkyl glycerol monoethers have been found to possess potent antimicrobial activity, affecting both glycerolipid and lipoteichoic acid biosynthesis in *Streptococcus mutans* (31). Thus, it is possible that the alkyl glycerol monoethers isolated from *T. aurantia* may play a defensive role as antimicrobial agents.

ACKNOWLEDGMENTS

Ivan Stoilov gave valuable discussions and collected sponge samples, Janice Thompson collected sponge samples, Annemarie Wegmann-Szente recorded mass spectra and Robert D. Simoni contributed use of a scintillation counter. Financial support was provided by NIH grants GM-06840 and GM-28352. Use of the 300 MHz ^{1}H NMR facility at Stanford was made possible by NSF grant CHE81-09064. The Hopkins Marine Station at Monterey, California, provided facilities for the incorporation experiments.

[Received November 3, 1986]

Influence of Environmental Medium on Fatty Acid Composition of Human Cells: Leukocytes and Fibroblasts

B. Delplanque and **B. Jacotot**
Unité de Recherches sur les Dyslipidémies et l'Athérosclérose, INSERM U 32 Hôpital Henri-Mondor, F 94010 Créteil Cedex, France

Fibroblasts in culture and leukocytes have been widely used to study fatty acid and lipoprotein cellular metabolism. The present investigations were designed to study the role of nutritional and environmental factors on lipid metabolism in these two types of cells. Leukocytes freshly isolated from human blood and fibroblasts cultured in media enriched in human serum (HS) have relatively similar fatty acid distributions. However, more important differences are observed in fibroblasts cultured in media enriched with HS or with fetal bovine serum (FBS). It is obvious that the quantity and quality of fatty acids are very different in FBS and HS, but intracellular regulation ensures relative homogeneity of saturated (SFA) and monounsaturated fatty acids (MUFA) in the cells, particularly in phospholipids.

The first modifications induced by different media (FBS or HS) are detected on cellular growth; the differences seem to be due more to the fatty acid (FA) quantitative supply than to the FA quality of each culture medium. The major modifications in FA composition induced by different culture media concern the polyunsaturated fatty acids (PUFA) of phospholipids, especially the n-6 family. The intracellular linoleic acid level depends on the level in the medium, but intracellular n-6 metabolite levels depend both on the level in the medium and on the growth state of the cells. The n-3 family seems to be less affected by the quality of the medium in our experiment, and the cells maintain a stable docosahexaenoic acid (22:6n-3) level. A higher content of the n-3 family in the medium induces a higher level of eicosa- or docosapentaenoic acid, rather than docosahexaenoic acid itself.

Finally, the FA quality of the medium influences the cellular PUFA content but, with a low FA quantitative supply, the FA quality of the medium has less influence on the cellular PUFA quality, and apparently has no effect on the SFA content of phospholipids. Modification of the quantitative supply of the medium and of the quality of the cells (strain and growing state) are more important for the distribution of SFA and MUFA in the neutral lipids of the cells.
Lipids 22, 241-249 (1987).

Fibroblasts in culture and leukocytes have been widely used to study the cellular metabolism of fatty acids and lipoproteins. Recently, such systems have furthered the understanding of the mechanism of dyslipoproteinemias and diseases induced by lipid metabolism disturbances (1-3).

Cell cultures have provided a good system for studying lipid metabolism; indeed, in vivo studies on whole animals are often too complex or give conflicting results. However, in vitro cell studies are infrequently used to evaluate the role of dyslipidemic situations or various nutritional states on the cellular fatty acid metabolism (4,5).

Two major problems were encountered using cell cultures to study fatty acid (FA) metabolism: First, by comparing the results obtained in other laboratories, it became evident that single, minor modifications in the quality and the quantity of the medium can induce major differences in the results. For example, endothelial cells only express Δ5 and Δ6 FA desaturase activities in a poorly enriched serum medium (5,6). Second, because many experiments performed with massive amounts of a single free fatty acid (FFA) added to the medium have resulted in accumulation of toxic phenomena, which would probably never be encountered in whole organisms (7,8), it seems important to reproduce these physiological conditions as closely as possible. Valuable information can be gained from studies on the possible FA modifications obtained with culture media resembling human serum or interstitial fluid.

Another suitable tissue for lipid metabolic analysis is the leukocyte, because of its accessibility. It has been found to reflect a wide range of metabolic disturbances observed in numerous diseases affecting carbohydrate and lipid metabolism (1,9). In comparison with in vitro cultured cells, leukocytes, like fibroblasts, could be considered to represent an ex vivo steady state.

The present study was designed to examine whether, by using intact leukocytes as experimental tissue, it was possible to demonstrate the in vivo state of cellular FA composition, and whether this model could be related to the FA composition of fibroblasts cultured in vitro with human serum (HS)-enriched medium, instead of the fetal bovine serum (FBS)-enriched medium conventionally used. The importance of nutritional conditions in relation to cellular type and culture conditions on cellular FA composition is discussed.

MATERIALS AND METHODS

Materials. Human blood samples, leukocytes and skin fibroblasts were obtained from healthy female and male normolipemic subjects between 25 and 35 years of age, with total cholesterol between 180 and 220 mg/dl and triglycerides between 80 and 150 mg/dl. For culture medium, FBS was purchased from Eurobio (Paris, France); for in vitro isolation of leukocytes, Ficoll-paque was obtained from Pharmacia (Bois d'Arcy, France). The different FA used as standards for gas chromatography (GC) were obtained from Sigma (St. Louis, Missouri) and NuChek Prep (Elysian, Minnesota).

Cell cultures. Stock cultures of fibroblasts were maintained in 75 cm^2 flasks containing 30 ml of RPMI 16/40 supplemented with penicillin (100 μg/ml), streptomycin (100 μg/ml), Fungizone (5 μg/ml), 1% (v/v) L-glutamine (200 mM) and 10% (v/v) FBS.

Cells were maintained at 37 C in a humidified atmosphere of air/CO_2 (95:5). For all experiments, cells between five and 13 passages and 7-day cultures in 25 cm^2 flasks containing 10 ml of RPMI generally supplemented with 10% FBS or 10% HS were used.

A single batch of FBS was used in all experiments, and seven different human sera were tested. The FA

percentage compositions of FBS and HS were established (Table 1), as well as estimations of FA quantities (μg/ml medium) to determine the relative FA values of 10% FBS and HS culture media. When modified serum concentrations and culture durations were tested, this was indicated in the text and the tables.

Leukocyte preparation. Blood obtained by venipuncture (35 ml) was anticoagulated with heparin from fasting healthy donors (four female and one male), and leukocytes were isolated using the classical Ficoll-paque isolation procedure (10). Leukocyte preparations were washed three times with Puck EDTA solution (8 g NaCl, 0.4 G KCl, 1 g glucose, 0.35 g $NaHCO_3$, and 0.2 g EDTA per liter). Each experiment was performed on 3×10^6 cells (the smallest number of cells permitting FA analysis).

GC in glass capillary column. Methyl esters of FA from total lipids, phospholipids (PL), FFA, triglycerides (TG) and cholesteryl esters (CE) of each fraction were treated with methanol/benzene/sulfuric acid (100:0.2:2, v/v/v) for 3 hr at 80 C. The methyl esters were agitated for 1 min with a mixture of heptane/water (v/v), and the heptane phase was removed and evaporated.

FA analysis was performed on a Hewlett-Packard gas chromatograph 5880 A fitted with a hydrogen flame ionization detector and a 25-m glass column of butane diol-succinate (BDS) provided by the Society Lesieur-Cotelle. The oven was programmed from an initial phase of 4 min at 160–190 C for 17 min with a progression rate of 2 C/min. The peaks were identified by comparison of the retention times with those of known standards. Quantitation was performed using heptadodecanoic acid (17:0) as an internal standard introduced before transmethylation, and relative quantities of individual FA were expressed as a percentage of the total by comparison of peak areas using a Hewlett-Packard 3380 A integrator.

FA extraction and quantitation. Monolayer cell cultures were washed three times with Dulbecco phosphate buffered saline (pH 7.2) and covered for several minutes at

[a]FA, fatty acid; FBS, fetal bovine serum; HS, human serum; SFA, saturated FA; MUFA, monounsaturated FA; PUFA, polyunsaturated FA; met, metabolites. n, Number of serum tested or number of analyses of the same lot of fibroblasts. Each experiment was done in triplicate. Total FA were quantified using heptadecanoic acid (17:0) as a standard.

37 C by a trypsin film (0.05%) in Puck EDTA solution until detachment of the cells occurred. The fibroblasts were then isolated from the suspension by sedimentation at 1200 G for 5 min, and the pellet was resuspended in 2 ml of distilled water before being disrupted by seven freeze-thaw cycles; 0.5 ml was removed for protein determination by the method of Lowry et al. (11), and 2.7 ml of chloroform/methanol (2:1) was added to the remaining preparation (1.5 ml) for lipid extraction by the procedure of Folch et al. (12). Two other extractions of the aqueous phase were performed under the same conditions, and the pooled organic phases were evaporated to dryness under a stream of nitrogen.

Bursting and extraction of leukocytes were performed in the same manner from a suspension of 3×10^6 cells/ml of distilled water.

For thin layer chromatography, the extracted material was resuspended in 50 μl of chloroform and spotted on methanol prewashed Silica Gel G plates (250 μm thick; 1505/LS 254 from Schleicher-Schul), and then developed in petroleum ether/diethyl ether/acetic acid (90:30:1, v/v/v). Lipid spots were visualized by vaporization of a rhodamine 6G solution in ethanol (0.05%) and identified by comparison with known standards. Each lipid class was scraped off with silica gel before transmethylation.

Results were expressed as percentages to evaluate the variations in the FA distribution and in nanograms of FA per unit of cellular protein (μg) to appreciate the absolute quantitative differences or similarities in the cell FA for each type of culture. The amount of protein in each flask was closely related to the number of cells, but there were different coefficients for different cell types (leukocytes or fibroblasts). Analyses were performed in triplicate on 3×10^6 leukocytes or 25 cm^3 flask culture for fibroblasts and on 50 μl of HS and FBS.

RESULTS

FA composition of fibroblasts cultured in HS-enriched medium and of freshly isolated human leukocytes. The FA composition of freshly isolated leukocytes (expressed in percentage of total FA) was quite similar to the composition of fibroblasts cultured for seven days in 10% HS-enriched medium. Analysis of the two essential PUFA families, n-6 and n-3, showed some minor quantitative variations in these two cell types. The higher levels of n-6 FA in leukocytes compared to fibroblasts seems to be due to 18:2 FA metabolites (essentially arachidonic acid) more than to linoleic acid itself, unlike the n-3 family, which showed a decrease in the last metabolite (22:6n-3 docosahexaenoic acid).

These differences were demonstrated by calculating the n-6/n-3 ratio and 18:2n-6 metabolites/18:3n-3 metabolites ratio, which were increased in leukocytes compared to fibroblasts cultured in HS. No other major differences in FFA, TG, CE or PL were observed between leukocytes and fibroblasts cultured in HS (Tables 2 and 3). However, the arachidonic acid level was slightly higher in leukocyte neutral lipids than in fibroblasts.

FA composition of fibroblasts cultured in FBS or HS (Tables 2 and 3). Cells cultured over the same time period in a medium enriched with 10% HS or 10% FBS showed differences in polyunsaturated fatty acids (PUFA). Cells cultured in FBS showed a considerable reduction of PUFA; the most marked differences were in the n-6 family with a decrease of 50% and a corresponding increase of 30% in the n-3 family (the difference being more important for 22:5n-3 than for 22:6n-3). However, each member of the n-6 family was not altered to the same extent, and the discrepancies observed for each metabolite of 18:2n-6 were not as important as for 18:2 itself, which was three times less ($p < 0.01$) in FBS-cultured fibroblasts. On the other hand, 18:3n-6 derived from Δ6-desaturation of 18:2n-6 was increased by a factor of 2.5. The next link of this metabolic chain, 20:3n-6, was equally represented, but arachidonic acid (20:4n-6) was also reduced in FBS-cultured fibroblasts, together with 22:4n-6 ($p < 0.05$). The n-6/n-3 ratio reflected these differences, as the n-6/n-3 ratio was twice as high in cells cultured in HS than in FBS-cultured cells.

Although the distribution of FA differed to a certain extent in FBS- and HS-cultured fibroblasts, it must be

FA, fatty acid; FBS, fetal bovine serum; HS, human serum; SFA, saturated FA; MUFA, monounsaturated FA; PUFA, polyunsaturated FA; met, metabolites.

[a](n), Number of determinations.

noted that the cell growth was also different after seven days of culture, being half with FBS compared to HS cultures (estimated by the procedure of Lowry et al.). Lower growth was generally accompanied by a small increase in the ratio of total FA per unit of cellular protein related to the FA triglyceride content (40 to 75% more).

Analysis of the FA pattern in lipid classes (PL, TG, CE, FFA) of the two forms of cultured fibroblasts (Table 3) showed no striking differences in neutral lipids, which were essentially 90% saturated or monounsaturated chains.

FA pattern of culture medium and fibroblast FA composition. The FA compositions of HS and FBS were studied to explain differences observed in the FA composition of fibroblasts cultured in media enriched by different additives.

Table 1 shows the distribution of FA expressed as a percentage and also an estimation of FA quantities provided to the cells at the beginning of the culture (in μg FA/ml of medium enriched with 10% FBS or HS). It is obvious that the quality and quantity of FA is very different in FBS and HS. Qualitatively HS is poorer in saturated fatty acids (SFA) and monounsaturated fatty acids (MUFA) and richer in PUFA, but the distribution of n-6 and n-3 families is quite different, i.e. 18:2n-6 is well represented in HS and 18:2n-6 metabolites are equally represented. The n-3 family in HS is one-half of that of FBS, which results in a very different n-6/n-3, but the n-6/n-3 metabolite ratio does not differ to the same extent.

Moreover, quantitatively, it must be noted that FBS has one-half the protein content of HS and 4–5 times lower total FA content. Apart from differences due to the distribution of FA, this results in different contributions of culture media usually enriched with 10% HS or FBS. When 10% HS is used instead of 10% FBS, the cultured cells bathe in a medium containing 30 times more 18:2n-6

and four times more 18:2n-6 metabolites (with apparently the same percentage in FBS and HS) and twice as much n-3 (with apparently half the quantity expressed in %).

Medium sera concentrations and FA pattern of fibroblasts. As described above, culture in 10% FBS or HS does not provide the same FA qualitative and quantitative supply to cells. To determine how the serum FA level introduced into the culture medium can modify the quality of cellular FA, we added FBS or HS at different concentrations to the medium, in order to give approximately iso FA quantitative supply to the cells with each kind of serum (20% FBS and 5% HS, or 10% FBS and 2.5% HS) (Table 4).

Results show that the cellular PUFA increased with the HS content of the medium and remained stable with the FBS medium. Moreover, a global enrichment of the medium with the same serum, without changing the quality of FA (unchanged n-6/n-3 ratio), induces a selective modification of the cellular PUFA quality. HS-enriched culture showed more n-6 metabolites (+50%), more 18:2n-6 (+20%) and a blockade of Δ6 (−75% 18:3n-6), but minor modifications in the n-3. In FBS-cultured cells we observed similar findings, but to a lesser degree. These modifications in PUFA of total FA are corroborated by the analysis of cellular phospholipids, which showed minor modifications of SFA or MUFA. Finally, an identical FA quantitative supply, even with different FA quality for medium enrichment (using FBS or HS), reduces the differences in PUFA quality of cultured cells, especially with low quantitative supply (compare FBS 20% and HS 5% or FBS 10% and HS 2.5%). Differences in PUFA result mainly in a greater cellular enrichment of 18:2n-6, related to its concentration in the medium.

It must be noted that cell growth is related to FA quantitative supply, independent of the serum type (compare iso FA supply, FBS 10% and HS 2.5%). Doubling each serum concentration in the medium induces a 60–100% increase in the quantity of cellular protein for a 7-day culture. Reciprocally, the level of fatty acids per unit of protein was reduced, and this was linked to a loss of neutral lipids (essentially triglycerides in FBS cultured cells), leading to a reduction in SFA and MUFA. Modifications were not as clear or as systematically observed in FBS as in HS cultured cells.

Cellular growth and FA pattern of fibroblasts cultured in FBS and HS (Table 5). To verify whether the differences previously observed were simply related to growth state, the FA compositions of fibroblasts at different culture times were compared at days 4 and 6 in 10% FBS or HS. For the cells obtained in FBS, due to the lower supply contribution of the medium, growth was already stabilized at day 4 (measured by the protein content); for cells cultured in HS, the growth increased by 75% between day 4 and day 6 and then stabilized. Here also, the growth appeared related to a decrease in SFA and MUFA (20% in the cells cultured in HS).

We noticed that, using these two different media, only minor differences in n-6 and n-3 metabolites were found, with more enrichment in n-3 for FBS cultures (75%) and in n-6 for HS cultures (+33% for 20:4n-6); major differences in cellular PUFA were still due to the 18:2n-6 levels related to the composition of the medium.

Stability of cells cultured successively in different media. After seven days of culture, the medium was removed and cells were refed with the same type of medium (HS or FBS) and were harvested five days later. We observed that cellular protein did not change, but that the cells continued to be enriched in n-6 metabolites, essentially in 20:4n-6, without appreciable differences in the n-3 family.

In another experiment, after seven days of culture in 10% FBS or HS, the medium was changed with replacement of FBS by HS medium and vice versa. Five days later, FA modifications were almost complete for FBS

[a]A, 7 days fetal bovine serum (FBS); B, 7 days human serum (HS) + 5 days FBS; C, 7 days FBS + 5 days HS; D, 7 days HS. FA, fatty acid; met, metabolites. After a seven-day culture in 10% FBS (A) or HS (B), the medium is changed with inversion of FBS for HS culture (C) and vice versa (B). FA analysis is compared to normal culture in HS (D) or FBS (A).

culture secondarily bathing in HS (Table 6; A,C,D) except for 22:5n-3, which did not reach values generally obtained in cultures in HS (about one-third of its initial level in FBS). Modifications obtained in cells first cultured in HS and then in FBS were not as complete, and intermediary levels of FA were generally obtained when compared to cells cultured for seven days in FBS (Table 6; D,B,A). With each culture type, for the n-3 family, there were no modifications in the last metabolite 22:6n-3.

Influence of fibroblast strains and individual HS on FA distribution in fibroblasts. In all experiments, apart from the fibroblast strains, certain variations were observed in the distribution of FA in different cellular lipid classes, showing higher levels of cellular neutral lipids with a lower cellular protein content in the 7-day culture (Table 7).

As expected, the use of individual control HS with different FA composition for culture medium led to different distributions of cellular FA, especially of PUFA. For example (Table 8), two control sera differing only in some n-6 and n-3 fatty acids were used to culture the same fibroblast strain in 10% HS-enriched medium. The cellular level of each FA was related to its level in the serum used. However, the cellular 22:6n-3 was more stable regardless

[a]Control serum A: cholesterol, 240 mg/dl; triglycerides, 0.90 mg/dl. Control serum B: cholesterol, 240 mg/dl; triglycerides, 1.10 mg/dl. Total FA analyses were performed in triplicate with serum sample and on three different flasks for each fibroblast total FA analysis, and three other different flasks for each fibroblast phospholipid FA analysis (not reported here).

of the level of this FA in the serum used in the culture medium. These observations were most marked in PL.

DISCUSSION

The present investigations were designed to study the role of nutritional and environmental factors on lipid metabolism in two cell types: cultured fibroblasts and fresh leukocytes. Although all cells can synthetize FA de novo, this synthesis is inhibited when FA are present in the culture medium (13); thus the cells preferentially use preformed FA from the medium (14,15). In addition, FA generally incorporated in cells are not altered (16), and elongation and desaturation rates are rather slow compared to the esterification rate (17). This was extensively reviewed by Spector et al. (18).

The analysis of freshly isolated cells such as leukocytes compared with fibroblasts shows that the culture medium greatly influences the FA composition of cells. Many studies have been performed on leukemic cells (9,19,20) and on FA of control leukocytes or lymphocytes, but generally under immune stimulation (21-25). However, our results are in good agreement with their control cellular PL FA analysis.

As a matter of fact, leukocytes freshly isolated from human blood and fibroblasts cultured in medium enriched in HS present a relatively similar FA distribution, even when the drastic difference in their lipid/protein ratios is unexplained. The former contain only slightly more arachidonic acid in their PL. It is obvious that this particular FA composition of cells bathing in similar media but isolated from different tissues can be related to in vivo cellular functions; arachidonic acid can be related to prostaglandin precursors, present in large amounts in immune cells, as this was also observed in endothelial cells richer in arachidonic acid (26).

However, more important differences are obtained in normal fibroblasts cultured in medium enriched in HS or FBS. The same observation was reported with endothelial cells (27), which differed widely in FA composition when cultured in FBS or freshly isolated from the human umbilical cord. It is obvious that the quantity and quality of FA are very different in FBS and HS, i.e., compared to HS, FBS has half as much protein and five times less FA, and it contains less linoleic acid and n-6 metabolites, but is enriched in the n-3 family, SFA and MUFA.

However, even with a different medium, intracellular regulation results in a similar distribution of SFA and

MUFA in the cells and essentially in PL. This is also verified for PUFA, which present some qualitative differences, but a great stability of the n-3 family. This cellular regulation allows a modulation of the incorporation of FA present in the medium, in that cells always present a higher level of SFA than in the medium (FBS or HS), even if the medium contains different concentrations. Cells also always incorporate less linoleic acid than the quantity present in the medium, but inversely they in some way "concentrate" n-6 metabolites. However, the cells essentially reproduce the quantitative and qualitative variations of the medium.

First of all, the modifications induced by different media are detectable on cellular growth, i.e., growth is different following enrichment of the medium with 10% HS or FBS. This should be related first to the HS enrichment in PUFA, which influences the fluidity of cellular membranes and the ability of culture to develop. However, in our study, the difference seems to be due more to the quantity of FA supply than the FA quality of each culture medium. This was demonstrated by comparing cells cultured with iso FA quantity supply (given by HS or FBS) and by analyzing the changes of cultured cells after different periods of growth. Differences observed in the level of FA per unit of cellular protein also seem to be due to the growth state of the cells, since less FA were found in rapidly growing cells, and much less SFA and MUFA. The decrease is detected in neutral lipids, essentially triglycerides. The relative stability of phospholipids in quality and quantity of SFA and MUFA, when the medium is largely modified, has also been observed by other authors, the modification always being more marked in neutral lipids (16,28–31). From the correlative enrichment of cells in FA triglycerides with lower growth (at the beginning of the culture or with medium poorly enriched in serum), it can be hypothesized that this is linked to a rapid uptake of lipid from the medium and that these cells should accumulate in TG pool. This can be secondarily reconverted in another lipid class (in PL) as shown by others (32). The extent of this conversion depends on the cell requirement for growth or different metabolism. TG- or CE-rich lipid droplets were observed in cells cultured with hyperlipemic sera-enriched medium (33–35) or with an excess of FFA or very low density lipoproteins (VLDL) (16,36). As for us, we never found this form of lipid accumulation in our cells cultured with normolipemic sera, even when the medium was 20% enriched. Although quantitative lipid modifications of the medium influence the cellular growth, the growth state of the culture does not influence the capacity of cells to be modified in their FA composition by the medium, since confluent fibroblasts and rapidly growing cells can be modified in the same way (Table 6) when the medium is changed. This suggests a rapid but incomplete FA turnover as shown by other authors on leukemic cells (37,38), fibroblasts (39) and endothelial cells (7).

The major modifications in FA composition induced by different culture media occur in PUFA of PL and essentially in the n-6 family. The n-3 family seems to be less modified by the quality of the medium, and the cells maintain a stable level of docosahexaenoic acid (22:6n-3). A higher ratio of the n-3 family in the medium induces a higher level of eicosa- or docosapentaenoic acid rather than docosahexaenoic acid itself, and vice versa. This was clearly shown by our inversion of the medium on confluent culture cells (Table 6) and by others in the case of essential FA deficiency (40) or FA metabolism analysis of astroblasts (41). This can be related to a blockade of Δ4-desaturase.

Concerning the n-6 family, linoleic acid must be isolated, because its intracellular level depends on the level in the medium, but intracellular n-6 metabolite levels depend on both the level in the medium and the growth state of the cells. Cells show higher levels of n-6 metabolites when grown in media rich in n-6 metabolites and also with a longer bathing in these media. We observed at the same state of growth a relative stability of arachidonic acid levels, regardless of the level in the medium (HS or FBS). But FA resulting from elongation and desaturation of arachidonic acid, docosatetraenoic (22:4n-6) and docosapentaenoic (22:5n-6) acids show levels directly related to their levels in the medium and to the growth state of the culture. The relative stability of cellular arachidonic acid level correlated with the higher level of elongation product (22:4n-6) when the medium was enriched in arachidonic acid was also reported under different culture conditions (16). Since human fibroblasts contain elongation enzymes, it was postulated that some FA taken up from the medium can be elongated when higher levels are available (42). We also observed that the blockade of Δ6-desaturase (lower level of cellular γ-linolenic acid) related to a higher level of linoleic acid induces an elongation process conducing to an enrichment of 20:2n-6 in cells bathing in HS medium. Similar results were obtained with endothelial cells (43) or fibroblasts (16) supplemented with individual FA. These cells apparently express a very low Δ6-desaturase activity when grown in a lipid-rich medium (5,6).

Finally, the quality of FA in the medium influences the cellular PUFA content but, with a low FA quantitative supply, the quality of FA in the medium has a lesser influence on cellular PUFA quality and apparently no influence on SFA content of PL, the major part being located in cellular membranes, which remain very stable under these conditions. Modification of the quantity of FA supply of the medium and also of the cell qualities (strain and growing state) are more important for the distribution of SFA and MUFA in the neutral lipids of cells.

Short-term Biological Reproducibility of Serum Fatty Acid Composition in Children

Teemu Moilanen
Department of Biomedical Sciences, University of Tampere, PO Box 607, SF-33101 Tampere, Finland

To assess the biological day-to-day reproducibility of the fatty acid composition in serum lipid fractions in children on their habitual diets, fasting serum specimens were collected from healthy 8- to 9-year-old boys at 2-day (n = 21) or 7-day (n = 19) intervals. Percentage compositions of fatty acids in serum cholesteryl esters (CE), triglycerides (TG), free fatty acids (FFA) and phospholipids (PL) were analyzed by gas chromatography. The reproducibility was estimated by calculating linear correlation coefficients between the values obtained at the two time-points. Generally the correlations were higher in CE and PL than in TG and FFA. In CE the 7-day correlations of major fatty acids were only slightly lower than the 2-day ones. In PL the impairment of correlations was somewhat greater than in CE, but in TG and FFA there was a marked drop in reproducibility from 2- to 7-day intervals. The 2-day correlation coefficients of the percentages of linoleate, dihomo-γ-linolenate, arachidonate and eicosapentaenoate in CE were 0.95, 0.84, 0.91 and 0.92, respectively. In PL, the respective values were 0.86, 0.82, 0.95 and 0.90. The present results indicate high short-term biological reproducibility of fatty acid composition in serum CE and PL and clearly lower in those of TG and FFA.
Lipids 22, 250–252 (1987).

Dietary survey methods applicable to large population studies generally do not produce data accurate at the individual level, because of inaccuracy of these methods and a large day-to-day variation in dietary intake of most free-living individuals (1,2). To overcome these problems, analyses of the fatty acid (FA) composition of adipose tissue (3,4), serum or plasma lipids (5), red cell membrane (6) and even cheek cell phospholipids (PL) (7) have been used for estimation of the average FA composition of the diet. The composition of FA in serum lipid fractions is altered when the FA composition of dietary fats is changed in intervention studies (8–10), and it has also been found to correlate with the composition of dietary fat in cross-sectional population surveys (11,12). A change in the ratio of polyunsaturated to saturated FA (P/S ratio) of dietary fats induces rapid alterations in the composition of FA in triglycerides (TG) and free fatty acids (FFA), whereas changes in cholesteryl esters (CE) and PL occur more slowly (13–17).

When using single determinations of FA composition as estimates of the composition of dietary fats in free-living subjects or as a measure of adherence to given instructions in dietary interventions (18,19), it is of interest to know the biological day-to-day variation in the FA composition of different serum lipid fractions. In the present work, the FA compositions in serum CE, TG, FFA and PL were analyzed at 2- or 7-day intervals in children on their habitual diets.

SUBJECTS AND METHODS

Venous blood samples were drawn from antecubital vein into Vacutainer tubes from healthy 8- to 9-year-old schoolboys after an overnight fast (12 hr). The sampling was repeated in 21 subjects after a 2-day interval and in 19 subjects after a 7-day interval. After clotting at room temperature, serum was separated, and the aliquots were stored at −70 C until analyzed.

The serum specimens were collected in Turku, Finland, as an extension of the Finnish Multicenter Study on Atherosclerosis Precursors in Children (see ref. 20). The study protocol was approved by the local school board, and an informed consent was obtained from the parents. No dietary advice was given.

Analysis of FA. Lipids were extracted from 0.5-ml aliquots of serum with chloroform/methanol and purified (21). The extract was fractionated on 0.25-mm Silica Gel G thin layer chromatography (TLC) plates using n-hexane/ethyl ether/acetic acid (85:15:1, v/v/v) as developing solvent. The fraction corresponding to PL was located in UV-light, scraped off and transesterified immediately. After removal of PL, the TLC plates were stained with Rhodamin 6-G, and the fractions corresponding to FFA, TG and CE were scraped off. CE were saponified with KOH/ethanol at 85 C for 1 hr, and the FA in all four lipid fractions were esterified with H_2SO_4/methanol at 85 C for 2 hr.

The methyl esters of FA were analyzed in an HP-5880 gas chromatograph using an OV-351 fused silica open tubular capillary column (Nordion Instruments, Helsinki, Finland) and two-step temperature programming from 100 to 240 C. The temperature in the injector and detector was 270 C. A splitless injection technique was used. The results were expressed as percentages of the total area of identified FA from 14:0 to 22:6. Methodological reproducibility was measured by extracting duplicate aliquots of serum and running them through the entire analysis in different batches. The coefficients of variation for individual FA in CE and PL ranged between 0.8% and 10% for most FA (Table 1). In TG and FFA, the coefficients of variation were poorer, and varied between 3% and 20% for most of the fatty acids (Table 2).

RESULTS

The mean percentage compositions of FA in all serum lipid fractions in the total study population of 40 subjects at day 0 are shown in Tables 1 and 2. The mean compositions remained unchanged during the 2- and 7-day intervals (data not shown). The biological reproducibilities of FA percentages were estimated as correlation coefficients between the values measured at the two time-points.

Correlations between the time-points were highest for polyunsaturated and most saturated FA in serum CE and PL (Table 3). In CE the correlations of the major FA decreased only slightly from 2- through 7-day intervals.

The decrease was somewhat greater in PL, although most of the r-values remained highly significant even at the 7-day interval. The correlation coefficients for linoleic (18:2) and arachidonic (20:4) acids in CE were 0.95 and 0.91 at the 2-day and 0.80 and 0.90 at the 7-day interval, respectively. The respective values for 18:2 and 20:4 in PL were 0.86 and 0.95 at the 2-day and 0.61 and 0.83 at the 7-day interval. There was a trend toward lower correlations in saturated and monounsaturated fatty acids in comparison to polyunsaturated fatty acids; the lowest reproducibilities were for 14:0, 16:0 and 16:1.

The 2-day correlations of polyunsaturated FA in TG were only slightly lower than those in CE or PL, but declined more with time from the 2- to the 7-day period (Table 4). The reproducibilities of saturated and monounsaturated FA in TG were generally low and, especially at the 7-day interval, mostly statistically nonsignificant. With the exception of the 18:2 percentage, most of the correlations of the fatty acids in the FFA fraction were poor already at the 2-day interval and showed no consistent correlations from 2 through 7 days (Table 4).

DISCUSSION

Although the composition of FA is different in each of the four lipid fractions in serum, during constant dietary intake of fats the proportion of a given FA in one fraction is in certain equilibrium with its proportion in other

fractions and in other tissues as well. This is demonstrated by high correlations of the percentages of FA in serum CE with the same FA in other lipid fractions in serum (11,22) or platelet lipids (23). In free-living subjects, however, the diet is never constant. For instance, the P/S ratio of the diet may range from 0.05 to 1.30 between days in an individual's diet during a one-week period (24).

The present results show that the day-to-day variation of FA composition is fairly small in serum CE and PL, but substantially higher in TG and FFA. According to dietary intervention studies, a change in dietary P/S ratio can be demonstrated in serum TG and FFA fatty acids within a few days, whereas the alterations in CE and PL fatty acids occur slowly over a period of one to two weeks (13–17). Thus a substantial part of the observed differences in reproducibility between the lipid classes may be attributable to the insensitivity of CE and PL FA composition to the daily fluctuation in dietary fat intake.

The methodological reproducibility of FA analyses in TG and FFA was poorer than in CE and PL and corresponds to results of other authors (25). Even though the coefficients of variation for the major FA in TG and FFA were satisfactory, the reproducibilities of these FA were of the same general magnitude as the other fatty acids in these fractions, and it seems unlikely that the present low correlations in TG and FFA were due to methodological errors. The concentrations as well as the FA compositions in serum TG and FFA are known to be affected by fasting- vs nonfasting-state differences (26,27). In the present study the subjects fasted for 12 hr before each sampling, but it cannot be ruled out that fasting-state differences contributed to the poor reproducibility in TG and FFA.

The short-term reproducibilities of CE FA percentages in the present study fit well with data from earlier studies on their long-term tracking. The corresponding correlations for 18:2 and 20:4 in CE measured from 18 individuals at a 5-mo interval were 0.76 and 0.74 (22), and the correlations from 805 children and adolescents measured at a 3-year interval were 0.59 and 0.61 (5), respectively.

The respective short-term reproducibilities of serum total cholesterol and TG concentrations in the present study population (n = 54) were 0.82 and 0.47 (28). Thus the reproducibilities of CE FA were of the same magnitude as those of their parent lipid. The slightly better correlations for FA composition than for total concentration of TG are probably caused by the expression of the composition of FA as percentages, which is insensitive to alterations in absolute concentrations.

The present results show a fairly high short-term reproducibility of FA compositions in serum CE and PL and a markedly lower one in TG and FFA. The better reproducibility in CE and PL suggests that these lipid fractions should be preferred when single FA determinations are used as indicators of the composition of dietary fats in free-living subjects or in dietary interventions.

Effects of Aging on the Composition and Metabolism of Docosahexaenoate-Containing Lipids of Retina

N.P. Rotstein, M.G. Ilincheta de Boschero, N.M. Giusto and M.I. Aveldaño*
Instituto de Investigaciones Bioquímicas, Universidad Nacional del Sur and Consejo Nacional de Investigaciones Científicas y Técnicas, 8000 Bahía Blanca, Argentina

The amount of docosahexaenoate (22:6n-3)-containing phospholipid species decreases with aging in the rat retina. Most lipids, but especially choline and serine glycerophospholipids, show a significant fall in 22:6n-3, which is not compensated by increases in other polyenoic fatty acids. The decrease not only affects 22:6 but also various very long chain n-3 hexaenoic fatty acids which, in phosphatidylcholine, have up to 36 carbon atoms, and which are probably synthesized by successive elongations of 22:6n-3. The in vitro incorporation of [2-^{3}H]glycerol into retinal lipids indicates that the de novo biosynthetic pathways are not impaired by aging. The incorporation of [1-^{14}C]docosahexaenoate is significantly stimulated into all lipids of aged retinas, but to the largest extent in those showing the largest decreases in 22:6, especially in choline glycerophospholipids. The results indicate that the decreased levels of 22:6 with aging are due not to an impaired activity of the enzymes involved in the synthesis and turnover of phospholipids but to a decreased availability of this polyene in the retina. It is suggested that this may stem from a defect in some of the enzymatic steps that lead to the synthesis of 22:6n-3, probably that catalyzed by Δ_4 desaturase, the effect on longer hexaenes being secondary to the decreased synthesis of 22:6.
Lipids 22, **253–260 (1987).**

Alterations of the ratios between phospholipid headgroup classes as well as in the quality and proportions of their fatty acyl moieties are known to bring about dramatic changes in the physicochemical properties of biological membranes, along with many of their functions (1). Qualitative or quantitative changes of this type, affecting lipids, may play an important role among the biochemical causes of the insidious deterioration that many cell functions undergo during the process of aging, since lipids make the matrix where a variety of enzymes, receptors and transport systems work. Polyunsaturated fatty acid–containing lipids are especially likely to be involved, since the synthesis of their polar and nonpolar moieties—particularly that of long chain polyenoic fatty acids—needs the concurrence of, and delicate equilibrium between, many enzymatic activities. The retina is an excellent model to study these problems in mammals because its lipids are characterized by a high proportion of such polyunsaturates. The most abundant fatty acids in visual cells of vertebrates are polyenes of the n-3 series, the major representative being 4,7,10,13,16,19-docosahexaenoate (22:6n-3). The retina also contains a whole variety of tetra-, penta- and hexaenoic fatty acids along with 22:6. These include familiar polyenes like 20:4n-6 or 22:5n-3 and various polyenes whose chain lengths range from 24 to 36 carbon atoms (2,3). The latter are highly concentrated in dipolyunsaturated molecular species of phospholipids of photoreceptor membranes, specifically in phosphatidylcholine (PC) (2). This paper is concerned with the effects of aging on compositional and metabolic aspects of retina phospholipids. It is shown that the levels of docosahexaenoate as well as of other n-3 hexaenes are decreased in aged retina glycerophospholipids, especially in those of choline and serine. The in vitro labeling of retina lipids with [2-^{3}H]glycerol and [1-^{14}C]docosahexaenoate is also compared in young and aged animals. The incorporation of this polyenoic fatty acid is shown to be markedly stimulated with aging in most retina lipid classes, but especially in those showing the largest decreases in 22:6 levels.

MATERIALS AND METHODS

Wistar rats kept under constant environmental conditions and fed for various generations the same pelleted standard chow diet were used for the present experiments. No sex-related differences were found in the effect of aging on lipids. Rats aged 2–3 and 26–27 mo were killed by decapitation, their eyes were rapidly enucleated, and their retinas were dissected under a magnifying glass. Some of the retinas were immediately homogenized with chloroform/methanol and were destined to lipid and fatty acid composition analysis. Others were incubated with [2-^{3}H]glycerol and 4,7,10,13,16,19-[1-^{14}C]docosahexaenoic acid ([^{14}C]22:6) to determine the labeling of their lipids with these precursors. For this purpose, the retinas were preincubated for 5 min at 37 C in 0.8 ml of a bicarbonate-based ionic medium, pH 7.4, containing 2 mg/ml of glucose (4), after which 0.2 ml of the same medium containing the precursors (5 nmol[^{14}C]22:6 and 0.16 nmol [^{3}H]glycerol) was added, and incubations (37 C) proceeded for the periods indicated in Results. At the end of incubations, 9 ml of ice-cold medium was added and the tubes containing the retinas were centrifuged (10 min at 10,000 rpm). After supernatants were discarded, the pellets were extracted with chloroform/methanol. Protein was determined according to the method of Lowry et al. (5).

The extracts from labeled and unlabeled samples were partitioned and washed according to Folch et al. (6), and the lipids were resolved by means of thin layer chromatography (TLC) (7). After development, the lipid spots were located by exposing the plates to I_2 vapors and subjected to phosphorus analysis (7). The spots containing [^{3}H]- and [^{14}C]-labeled lipids were scraped from TLC plates and transferred to vials containing 0.4 ml water. Ten ml of a solution containing 0.4% Omnifluor (New England Nuclear, Boston, Massachusetts) and 20% Triton X-100 in toluene was then added, and radioactivity was measured by liquid scintillation counting. The [2-^{3}H]glycerol used (sp act 10 Ci/mmol) was from New England Nuclear, and the [1-^{14}C]docosahexaenoate (sp act 40 μCi/μmol) was provided by H. Sprecher, Ohio State University (Columbus, Ohio).

For fatty acid analyses, the lipids were isolated as before, the spots were located under UV light after spraying with dichlorofluorescein, and methyl esters were prepared (under N_2) by BF_3-catalyzed methanolysis (8). The latter were analyzed by gas liquid chromatography (GLC). Two glass columns (2 m × 2 mm id) packed with 15% OV-275 on 80–120 Chromosorb WAW (Varian, Sunnyvale, California) were connected to two flame ionization detectors operated in the dual-differential mode. A linear (5 C/min) temperature program, starting at 160 C and ending at 220 C, was used, and the injector and detector temperatures were 220 C and 230 C, respectively. To obtain the data in Table 3, after reaching 220 C the oven temperature was held constant at that value for 45 min to permit the analysis of very long chain polyenoic fatty acids (2).

RESULTS

Effects of aging on retina phospholipids. The concentration of phospholipids, expressed as the amount of lipid phosphorus per mg of retina protein, was lower by a factor of about 20% in retinas from aged rats than in those from young animals (Table 1). Such a difference in total lipid content was not significant statistically, as when the levels of individual phospholipids were considered. The average amounts of protein were 0.70 ± 0.11 and 0.64 ± 0.11 mg per retina in samples from young and aged retinas, respectively, while those of total phosphorus in lipid extracts from the same samples were 250 ± 34 and 189 ± 25 nmol, respectively. While the average decrease of 8% in protein was not statistically significant, that of 24% in lipid phosphorus was $P < 0.05$. Hence, the contents expressed as lipid/protein ratios in Table 1 show no large differences in lipid concentration because both protein and lipid are affected by aging, but it is apparent from the above results that lipids tend to be decreased relatively more than proteins. When the phospholipid composition (%) was analyzed, again no significant differences due to aging were readily apparent (Table 1). However, some interesting trends were observed by calculating the ratios between individual phospholipids. Most of the age-related differences in total phospholipid concentration were contributed by decreases in the three major phospholipids: phosphatidylcholine, ethanolamine glycerophospholipids (EGP) and phosphatidylserine (PS), which resulted in changes of certain phospholipid ratios. Among choline phospholipids, for instance, the amount of PC was decreased to a larger extent than that of sphingomyelin (Sph, unchanged), giving rise to a significantly lower PC/Sph ratio in aged retinas. Among acidic phospholipids, PS was more decreased than phosphatidylinositol (PI), which also resulted in a significant difference in the PS/PI ratio with age. The PC/PS ratio was similar in control and aged retinas, indicating that both were diminished to the same extent, and the PC/EGP ratio was increased. The fatty acid composition of retina glycerophospholipids was next examined in search for the possible involvement of polyenoic fatty acids in these effects, since it was apparent that the largest decreases affected those lipids that contribute the largest amounts of the most highly unsaturated fatty acids to retinal membranes.

Fatty acids of retina glycerophospholipids. The most conspicuous effect of aging on the fatty acid composition of lipids was a general tendency to a decreased proportion of 22:6n-3 (Table 2). Its percentage was about 30%, 10% and 13% lower in PC, EGP and PS, respectively, in aged than in young animals. If one considers that the amounts of these phospholipids were also lower (Table 1), it may be estimated that the amount of 22:6 per mg of protein decreased by about 42%, 31% and 30% as a consequence of the changes in such lipids (Table 4). It is evident from Tables 2–4 that no fatty acid was synthesized in retina to compensate for this decrease in 22:6, the slight increases observed in the percentages of some fatty acids being only relative to this diminution. The average unsaturation of lipids tended to decrease (Table 2), the most significant effect ($P < 0.05$) being observed for PC and PS.

The fatty acid composition of PC is expanded in Table 3

PC, phosphatidylcholine; EGP, ethanolamine glycerophospholipids; PS, phosphatidylserine; PI, phosphatidylinositol; PA, phosphatidic acid; Sph, sphingomyelin; DPG, diphosphatidylglycerol. The figures depict the amount of phospholipid as nmol/mg protein. The percentage composition is given in parentheses. Both are presented as mean values ± S.D. from 4 samples (each containing 6–8 retinas) from control (2.5 mo) and aged (26.5 mo) rats. Lipids were separated by two-dimensional thin layer chromatography. The ratios between lipids were calculated for individual samples and then averaged. *, Significant differences with respect to controls ($P < 0.05$ or lower).

Lipids were preparatively isolated by means of thin layer chromatography and their fatty acid composition was analyzed by gas liquid chromatography of fatty acid methyl esters. Results are presented as mean values ± S.D. from 3 samples, each containing 6–8 retinas. Average unsaturation represents the average number of double bonds in fatty acids per mole of lipid. *, Signiaficant effects of aging ($P < 0.05$ or less). Phosphatidic acid was analyzed after combining the three samples of each group.

VLCPUFA, very long chain polyunsaturated fatty acid. Methyl esters from the phosphatidylcholine samples whose composition is shown in Table 2 were combined and injected in a concentrated form to facilitate detection and quantitation of VLCPUFA. Total VLCPUFA is the sum of C_{24} to C_{36} polyenes.

[a,b,c]Coelute with minor amounts of 24:4n-6, 26:4n-6 and 28:4n-6, respectively.

to show the series of very long chain polyenoic fatty acids that elute after 22:6 (2). C_{24}–C_{36} polyenoic fatty acids made up 2.4% of the fatty acid weight of PC from rat retina. This may seem a minor proportion, but such very long chain polyenes are specifically esterified to some of the PCs (the dipolyunsaturated molecular species of the phospholipid) present in photoreceptor membranes (which in turn are a small fraction of the total membranes of entire retina) (2). Hence, the proportion of very long chain polyenes in the entire retina PC is small because they are "diluted" with the PCs from many cell membranes that do not contain such fatty acids. Even so, some very long chain polyenes, like 32:6 and 34:6, occur in higher proportions than some of the polyenes listed between 20:4n-6 and 22:6n-3 shown in Table 3.

The sum of very long chain polyenoic fatty acids of PC decreased in aged retinas, but some of them contributed more than others to this effect (Table 3). Thus, consistent with the effect observed for the "shortest" hexaene (22:6n-3), all longer n-3 hexaenes were also decreased. Very long chain (n-3) pentaenes and (n-6) tetraenes were less affected, as was also the case for the shortest polyenes of the respective series, such as 20:5n-3 and 20:4n-6. This fits into the general tendency observed for the polyenoic fatty acids of all retinal glycerophospholipids, which are summarized in Table 4: a) the ratio between n-3 and n-6 polyenes decreased with age, not due to an increase in n-6, but to a decrease in n-3 polyenes; b) among n-3 polyenes, the n-3 hexaene/pentaene ratio decreased with age, due primarily to a decrease in n-3 hexaenes; c) the absolute amounts of total polyenes as well as their percentages in lipids decreased with age, showing that no polyene was synthesized to substitute for the depleted 22:6; d) the effect on polyenes mainly accounted for the

PC, phosphatidylcholine; EGP, ethanolamine glycerophospholipids; PS, phosphatidylserine; PI, phosphatidylinositol; PA, phosphatidic acid. Total polyenes is the sum (mol%) of all polyenes detected in fatty acid composition analyses. The fatty acids were grouped as indicated to calculate the ratios. *, Significant effects of aging ($P < 0.05$ or less).

[a]Amounts estimated as (nmol fatty acid(s)/nmol lipid) × (nmol lipid/mg protein).

tendency shown by the major phospholipids to decrease their concentrations in aged retinas (Table 1), since other fatty acids were affected to lower extents. The incorporation of [1-^{14}C]docosahexaenoate in retina lipids was then studied to determine whether the age-dependent defect in 22:6 was due to an impairment of the enzymes involved in the turnover of their 22:6-containing species and was compared to that of [2-^{3}H]glycerol in search for possible effects of aging on the de novo synthesis of such lipids.

General features of the incorporation of [^{3}H]glycerol and [^{14}C]docosahexaenoate in retina lipids. After incubating retinas with these precursors, the incorporation of [^{14}C]22:6 was faster and more efficient than that of [^{3}H]glycerol (Table 5). One of the important factors determining this result was that the fatty acid was likely to be present in much larger concentrations in the tissue than glycerol, simply because it is relatively more "soluble" in the retinal lipid membranes than in the medium, as opposed to the water-soluble precursor. In the present experiments, the concentration of free [^{14}C]22:6 in the incubation medium was indeed higher than that of glycerol (5 vs 0.16 nmol, respectively, were offered to the tissue). To account for this difference in the concentration of precursors, the amount of incorporated glycerol was in all cases multiplied by a factor of 31.25, but even after this correction the ^{14}C/^{3}H ratios were always greater than 1 (Tables 5–7). Such correction, of course, cannot level off the possible differences in intracellular concentrations attained (which are ignored) nor the possible differences in compartmentation.

The incorporation of [^{3}H]glycerol into rat retina lipids followed the general routes through which the de novo synthesis of glycerol-containing lipids occurs in most vertebrate tissues. Thus, at early incubation times (10 min), phosphatidate was the lipid concentrating most of the label, followed by diacylglycerols and phosphatidylinositol (PI) (Table 6). While PI rapidly attained a plateau, the synthesis of PC continued throughout the incubation interval, this lipid being the predominant product at long

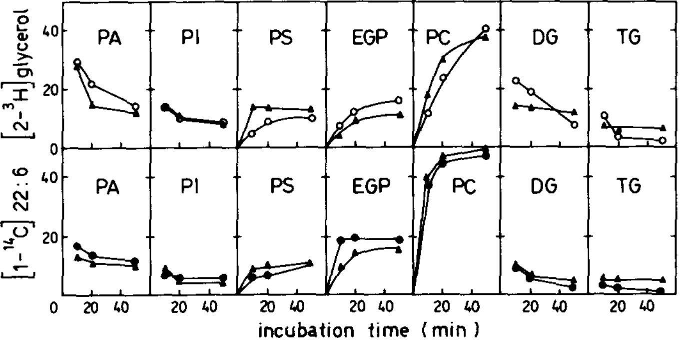

FIG. 1. Comparison of the time-course of the distribution of [^{3}H]-glycerol and [^{14}C]docosahexaenoate among lipids of control (circles) and aged (triangles) retinas. Results are percentages of the total incorporated activity in each case, calculated from the mean values in Tables 5 and 6. PA, phosphatidic acid; PI, phosphatidylinositol; PS, phosphatidylserine; EGP, ethanolamine glycerophospholipids; DG, diacylglycerols; TG, triacylglycerols.

incubation times. Most of the difference in total [^{3}H]-glycerol incorporated between 20- and 50-min incubations (Table 5) was accounted for by the labeling of PC (Table 6). The relationships between the various lipids are readily apparent when represented on a relative basis (Fig. 1). The contribution of phosphatidate and diacylglycerols to the total label in lipids decreased with time, in favor of the final products.

A large proportion of the total free [^{14}C]22:6 added to the media was recovered in the (comparatively very small volume of) tissue after incubations (Table 5). The esterification of free 22:6 by the retina was highly efficient, as indicated by the fact that a large proportion of the total label in the tissue was recovered in lipids (Table 5). In contrast to the redistributions observed for the [^{3}H] label among lipids (Fig. 1), [^{14}C]22:6 was predominantly incorporated in PC at all incubation times analyzed (40–50% of the esterified label). This indicates that most of the

The incorporations are expressed as pmol [^{14}C]22:6 or [^{3}H]glycerol in lipids/mg of retinal protein (mean values ± S.D. from 3 samples, each containing the two retinas of a rat). Control and aged retinas were 2.5 and 26.5 months old, respectively. The retinas were incubated for the specified intervals with both precursors, added simultaneously. The amount of incorporated [2-^{3}H]glycerol was multiplied by a factor of 31.25 to account for the difference in the amounts of [^{14}C]22:6 and [^{3}H]glycerol added to the incubation media (5 and 0.16 nmol, respectively).

Lipids labeled in the retina with both radioactive precursors were separated by thin layer chromatography. The figures represent the incorporation into each lipid class (pmol/mg retinal protein). Details as in Table 5.

available 22:6 was incorporated directly into preexisting PC molecules through acyl exchange reactions, rather than through the slower neobiosynthetic reactions. However, label from the fatty acid was in all glycerolipids, including phosphatidate (PA) and diacylglycerol, for part of the label in major phospholipids, particularly at long incubation times, may be contributed by (the incorporation of) these labeled intermediates. The specific radioactivity of PA was the highest among phospholipids with either glycerol or 22:6 (Table 7), which supports this possibility.

The differences in rates of incorporation of both precursors become even larger in favor of 22:6 if one takes into account that while [^{3}H]glycerol is introduced in the skeleton of all kinds of lipid molecular species from disaturated to dipolyunsaturated (9), [^{14}C]22:6 only labels

[b]The specific radioactivity of each lipid class was calculated as (fmol ^{3}H or ^{14}C in lipid/mg protein)/(amount of lipid/mg protein).
[c]Specific radioactivities of 22:6-containing species within each lipid class, calculated as (fmol [^{14}C]22:6/nmol lipid [fmol ^{3}H or ^{14}C in lipid/mg protein])/(nmol of 22:6/nmol lipid).

the 22:6-containing species of each retinal lipid (namely hexaenoic and dipolyunsaturated species [10]). The highest specific radioactivities, whether expressed per mole of lipid or per mole of 22:6 in lipid (Table 7), were attained by PA and PI with both precursors. Among the three major membrane phospholipids (PC, EGP and PS), the highest turnover rates of 22:6 (i.e., the exchange of labeled for unlabeled fatty acid) were attained by docosahexaenoate-containing species of PC. This is noteworthy, since both PS and EGP are richer in 22:6 than PC (Table 2).

Effects of aging on retinal lipid labeling with [^{3}H]-glycerol and [^{14}C]22:6. In the presence of equal amounts of free [^{14}C]22:6, retinas from aged rats incorporated about twice as much fatty acid in their lipids than those from young animals (Table 5). The labeling of all lipids by the fatty acid was stimulated (Tables 6 and 7), but PC and PS showed the largest increases in relation to other lipids (Fig. 1).

The incorporation of [^{3}H]glycerol was much less affected by aging than that of [^{14}C]22:6 (Table 5). No significant differences were observed in the total glycerol incorporated after 20- and 50-min incubation, even though a stimulation was apparent at short incubation times (10 min). This may have been provoked by the presence of unesterified [^{14}C]22:6 in the tissue since, coincidentally, the lipids whose labeling with [^{3}H]glycerol was most stimulated (especially early on) were also PC and PS (Table 6, Fig. 1). Of the two zwitterionic phospholipids, synthesis of PC was relatively more stimulated than that of EGP (see the PC/EGP ratios in Table 6). Similarly, of the two acidic phospholipids, labeling of PS increased more than that of PI (note that the labeled PS/PI ratios were 0.4, 0.9 and 1.1 for controls and 1.0, 1.2 and 1.6 for aged retinas after 10-, 20- and 50-min incubations, respectively, with glycerol). Such changes were not due to a depressed synthesis of EGP or PI (Tables 6 and 7) but to a relatively faster formation of PC and PS.

The specific radioactivities of [^{14}C]22:6-labeled lipids were in all cases larger in the retinas from the aged rat group (Table 7). The selective stimulation of the turnover of 22:6 in PC and PS became even more apparent when the specific radioactivities were expressed as fmol [^{14}C]-22:6 incorporated per mole of 22:6 in each lipid (Table 7), since the latter tended to decrease in all lipids of aged retinas (Table 2) but especially in these two phospholipid classes.

DISCUSSION

A marked decrease in the levels of 22:6n-3 along with other polyenoic fatty acids occurs in the glycerophospholipids of retina as a consequence of aging (Table 4). The phospholipids containing the largest percentages of docosahexaenoate (PC, EGP and PS) are those that exhibit the largest quantitative decreases of this fatty acid (Tables 2–4). This is apparently not compensated by increases in other fatty acids and is manifested in the tendency these phospholipids show to decrease their concentrations when they are expressed as nmol lipid/mg of retinal protein (Table 1). Phospholipids like PI and DPG, which contain much lower levels of 22:6 and other n-3 polyenoic fatty acids, are virtually unchanged, as is also the case with Sph (Table 1), which does not contain any polyenes. It is apparent that aging decreases the ability of retina to make 22:6-containing species of phospholipids. When retinas are incubated with [1-^{14}C]docosahexaenoate, however, it is observed that the esterification of the fatty acid into lipids is markedly stimulated with aging (Table 5). The lipids whose labeling is most stimulated are PC and PS (Tables 6 and 7), precisely the classes undergoing the largest decreases in 22:6n-3, as well as in longer n-3 hexaenoic fatty acids (Tables 2 and 3).

The incorporation of [^{3}H]glycerol and [^{14}C]22:6 into lipids shows that the de novo biosynthetic machinery as well as the enzymatic mechanisms involved in the turnover of 22:6 in preexisting phospholipid molecules are not responsible for the observed decreases in docosahexaenoate. On the contrary, aged retinas seem to work as

though they were more "avid" for 22:6 than their younger counterparts (Tables 5–7), i.e., as though they had developed a higher affinity for the fatty acid. The results allow us to conclude that the levels of 22:6-containing species of lipids are decreased during aging simply because there is less 22:6 available in the retina, since when the fatty acid is provided such enzymes work to attain, and even surpass, their fullest capacity.

That the decrease of 22:6 in lipids is not due to phospholipase A_2 activation during aging is supported by the fact that the levels of free fatty acids did not differ between young and aged retinas. The total free fatty acid pool size in the retinas whose composition is shown in Tables 1 and 2 was 16.2 ± 3.1 and 17.9 ± 3.7 nmol/mg of protein, respectively, of which only 1.8 ± 0.2% and 2.3 ± 1.1% was 22:6n-3, and 4.3 ± 1.4% and 1.7 ± 0.4% was 20:4n-6, respectively (mol% of the total unesterified fatty acids). Even when these are not strictly "endogenous" levels and percentages of free fatty acids, since these are known to be quickly released from excitable tissue lipids due to postdecapitation ischemia (11), no significant effect of age was observed, i.e., no accumulation of polyunsaturated fatty acids occurs in aged retinas, which may account for the decreases observed in phospholipids. Therefore, neither the synthetic nor the degradative processes of phospholipids themselves are responsible for the decreased levels of polyenoic fatty acids displayed in their composition.

There are at least two possibilities to explain the decreased levels of polyenoic fatty acids in lipids of aged retinas: either they are destroyed at higher rates, or they are synthesized less efficiently. Concerning the first alternative, reactions leading to the formation of several peroxidation products and free radicals from polyunsaturated fatty acids may be involved. In fact, these deleterious products do accumulate in senescent tissues, and a debilitation of the defense mechanisms of cells to dispose of them has been proposed to be an important factor contributing to the process of aging (12–14). The susceptibility of lipids to peroxidation runs parallel to their content in polyenoic fatty acids, which makes brain, and especially retina, lipids particularly prone to such damaging reactions. Docosahexaenoate is highly labile, since the larger the number of double bonds, the larger the number of possible hydroperoxides that may be produced, and the greater the rate constants of the reactions leading to free radical formation (15). Products of lipid peroxidation in turn may react with many cell molecules (13,16), giving rise to lipid-lipid, lipid-protein and protein-protein crosslinking. Such crosslinked products may contribute to the decrease in fluidity observed in many cell membranes during aging (17,18). Interestingly, the microviscosity of synaptosomal cortex membranes increases with age, the increase being higher for the hydrophobic than the hydrophilic region of the membrane, which supports this possibility (19). It is obvious at present that many chemical processes of completely differing natures may contribute during aging, with effects that are all translated as a change in this bulk physical property of membranes, including increases in cholesterol content, decreases in unsaturated fatty acids, alterations in phospholipid headgroup ratios, formation of crosslinked products and others.

Concerning the second possibility, i.e., that decreased levels of polyenoic fatty acids in retinal lipids may result from a decreased rate of synthesis of these highly unsaturated acyl moieties, two possibilities may be considered: first, that the enzymes that synthesize them (from essential fatty acids of the n-3 and n-6 series) work normally, but lower amounts of such precursors are available, and second, that such precursors are available, but some of the enzymatic steps involved in their further conversions are impaired. It is well established that the synthesis of 22:6n-3 follows the route 18:3n-3 $\xrightarrow{1}$ 18:4n-3 → 20:4n-3 $\xrightarrow{2}$ 20:5n-3 → 22:5n-3 $\xrightarrow{3}$ 22:6n-3. Similarly, the synthesis of 22:5n-6 follows the route 18:2n-6 $\xrightarrow{1}$ 18:3n-6 → 20:3n-6 $\xrightarrow{2}$ 20:4n-6 → 22:4n-6 $\xrightarrow{3}$ 22:5n-6. Steps 1, 2 and 3 are catalyzed by Δ_6, Δ_5 and Δ_4 desaturase systems, respectively, the other reactions being elongations. Much more is known on the regulation of Δ_6 and Δ_5 than of Δ_4 desaturases (20), but there is strong evidence that the desaturations rather than the elongations are rate-limiting steps in the sequences (21,22).

[1-^{14}C]20:5n-3 is readily transformed into [^{14}C]22:5n-3 and this into [^{14}C]22:6n-3 in the retina in vivo a few minutes after the injection of the precursor into the eye (23). This indicates that the retina does not rely on other organs (e.g., the liver) for the supply of 22:6, but is able to synthesize its own 22:6 from other (n-3) fatty acids (which, of course, must be available). The levels of n-3 pentaenes in retina lipids were much less affected by aging than n-3 hexaenes (Table 4), indicating that there was no defect in the availability of essential n-3 fatty acid precursors like 18:3n-3. Moreover, there is an important difference between the effect of aging shown here and that of essential fatty acid deficiency (24). Thus, during 18:2n-6 deficiency, 20:4n-6 is decreased in tissue lipids, but replaced by 20:3n-9 (made from oleate). During 18:3n-3 deficiency, 22:6n-3 decreases in lipids, being replaced by 22:5n-6 (made from linoleate). None of these compensatory mechanisms was observed in the aged retina. Moreover, the retina is known for the tenacity with which it holds 22:6 in its lipids, since generations of n-3 fatty acid precursor–deficient diets must elapse before a significant decrease of 22:6 can be observed in retina, as opposed to the rapid "adaptation" of liver, kidney and brain (25, 26). When the deficiency is eventually achieved, however (after at least two generations), the decreased 22:6n-3 is quantitatively replaced by 22:5n-6 (26–28). This is not the case with the aged retina, where both 22:6n-3 and 22:5n-6 decrease (Tables 2 and 3). It is quite coincidental that the two fatty acids whose synthesis is catalyzed by Δ_4 desaturase are the ones that undergo the most significant and consistent decreases, as illustrated in Table 8 by the ratios between the amounts (in nmol/mg protein) present in aged vs control retinas, as calculated from the data in Tables 1 and 2. This strongly suggests that, rather than a decreased availability of 18:3n-3 (and 18:2n-6) in the retina, an impairment of the Δ_4 desaturase system is probably responsible for the decreased levels of 22:6n-3 (and 22:5n-6) observed in retina lipids as a consequence of aging.

It is noteworthy that, in addition to 22:6n-3, other n-3 hexaenoic fatty acids are also decreased in aged retinas. This is clearly evident for PS (24:6n-3, Table 2) and for PC (Table 3), which contains a whole series of polyenoic fatty acids ranging from 24 to 36 carbons. The very long chain polyenes of PC fit into the general tendency observed

TABLE 8

Ratios Between Amounts (in nmol/mg Protein) of Fatty Acids in Aged vs Control Retinas (Calculated from Data in Tables 1 and 2)

PC, phosphatidylcholine; EGP, ethanolamine glycerophospholipids; PS, phosphatidylserine; PI, phosphatidylinositol.

for other polyenes, namely, that n-3 hexaenes (as 22:6n-3) decrease, and that they do so to a larger extent than n-3 pentaenes (as 20:5 and 22:5n-3) and n-6 tetraenes (as 20:4 or 22:4n-6). Very long chain tetraenes of vertebrate retina belong to the n-6 series and hexaenes to the n-3 series, and there are very long chain pentaenes from both the n-3 and n-6 families (2,3). The latter are in negligible amounts in rat retina but occur in larger proportions in rabbit and chicken retina PC (2). In chickens, it was observed that very long chain (n-6) pentaenes increase while very long chain (n-3) hexaenes decrease under dietary conditions that lead to an increased 22:5n-6/22:6n-3 ratio (2). The concomitant decrease of very long chain hexaenes and 22:6 observed here in rat retina PC is consistent with the idea that less 22:6 is produced during aging, since the impact is felt in the "shortest" hexaene as well as in the subsequently longer hexaenes that are synthesized by successive elongations of 22:6 (Rotstein, N.P., and Aveldaño, M.I., unpublished work). This fits into what is known on the synthesis of polyenoic fatty acids, i.e., that the rate-limiting steps are those catalyzed by desaturases, rather than those involving elongations, which mainly depend on the availability of the respective precursors (21), in this case 22:6. If the decrease in polyenes were exclusively due to increased rates of peroxidation during aging, one would probably not observe such trends of selectivity toward hexaenes and, especially, there would be no apparent reason for a decrease in 22:5n-6 much larger than that of 22:5n-3, since both fatty acids have identical number of carbons and double bonds.

It is evident from the [^{14}C]22:6 incorporation experiments that if docosahexaenoate is available, it is efficiently taken up by the aged retina, and it is most actively introduced into the phospholipid classes that show the largest decreases, not only of 22:6n-3 but of longer n-3 hexaenes. These observations are interesting from a functional point of view, since there is evidence that n-3 polyunsaturated fatty acids are necessary for the normal electrical response in visual excitation. Thus, a decrease of retina 22:6n-3 attained by dietary manipulation results in a change of the component of the electroretinogram that is generated by photoreceptors (27). Docosahexaenoate (27) as well as very long chain polyenoic fatty acids (2) are highly concentrated in the lipids of photoreceptor membranes. Therefore, a decrease in these fatty acids, which is observed even when the lipids of the entire retina are analyzed, must play an important role among the causes of vision impairment, which almost invariably accompanies senescence. The avidness with which aged retinas incorporate [^{14}C]22:6 in their 22:6-depleted lipids suggests the exciting possibility that an adequate supply of this fatty acid in the diet (rather than of its precursors) might help prevent, or at least delay, one of the many biochemical alterations that set in with aging.

[Revision received November 20, 1986]

Calmodulin Antagonists Suppress Cholesterol Synthesis by Inhibiting Sterol Δ^{24} Reductase

Ivan Filipovic* and **Eckhart Buddecke**
Institute of Physiological Chemistry, University of Muenster, Waldeyerstrasse 15, D-4400 Muenster, Federal Republic of Germany

Preincubation of hepatoma cells and human skin fibroblasts in the presence of the calmodulin antagonists trifluoperazine and N-(6-aminohexyl)-5-chloro-1-naphthalene sulfonamide resulted in a dose-dependent suppression of [^{14}C]mevalonolactone incorporation into cholesterol. At a calmodulin antagonist concentration of 25 μmol, the incorporation of [^{14}C]mevalonolactone into cellular cholesterol was suppressed to about 30% (hepatoma cells) and 10% (human skin fibroblasts) of control values. When the total nonsaponifiable [^{14}C]lipids were separated and analyzed by two-dimensional thin layer chromatography, an accumulation of [^{14}C]desmosterol was observed along with reduced formation of [^{14}C]cholesterol. However, when cells were preincubated in the presence of [^{14}C]dihydrolanosterol, [^{14}C]cholesterol formation was not inhibited by the calmodulin antagonists. About 25% of the cell-associated dihydrolanosterol radioactivity was converted to cholesterol in both control and calmodulin antagonist-pretreated cells. The data suggest that calmodulin antagonists prevent the conversion of desmosterol into cholesterol by inhibiting sterol Δ^{24} reductase and that the enzymes catalyzing sterol ring modifications are not affected by the inhibitors.
Lipids 22, 261-265 (1987).

Inhibitors of cholesterol biosynthesis are valuable tools for studying the regulation of cholesterol metabolism in cultured cells. Compactin (1), 3β-[2-(diethylamino)ethoxyl]-androst-5-en-17-one hydrochloride (U18666 A) (2,3), 4,4,10β-trimethyl-*trans*-decal-3β-ol (TMD) (4) and 1-[p-(β-diethylaminoethoxy)-phenyl]-1-(p-tolyl)-2-(p-chlorophenyl)-ethanol (MER 29, Triparanol) (5) have been found to inhibit cholesterol biosynthesis by acting at the level of 3-hydroxy-methylglutaryl coenzyme A (HMG CoA; EC 1.1.1.34) reductase (1-3), 2,3-oxidosqualene cyclase (EC 5.4.99.7) (2,4) and sterol Δ^{24} reductase (desmosterol reductase, EC 1.3.1.?) (5), respectively. The results obtained with these inhibitors suggest that oxysterols derived from squalene 2,3:22,23 dioxide may also act as physiological regulators of HMG CoA reductase (3).

Recently, the specific calmodulin antagonists N-(6-aminohexyl)-5-chloro-1-naphthalene sulfonamide (W-7) and trifluoperazine have been shown to suppress the cholesterol synthesis in human skin fibroblasts. A concomitant stimulation of low density lipoprotein receptor synthesis was found to be an independent effect (6). The present investigation describes the inhibitory effect of the calmodulin antagonists W-7 and trifluoperazine on the cholesterol synthesis in hepatoma cells and human skin fibroblasts. An analysis of the intermediates of cholesterol synthesis accumulated under the influence of calmodulin antagonists gives evidence for a preferential inhibition of the conversion of desmosterol to cholesterol by blocking sterol Δ^{24} reductase.

*To whom correspondence should be addressed.

MATERIALS AND METHODS

W-7 was obtained from Seikagaku Kogyo Co. (Tokyo, Japan). Trifluoperazine was purchased from Sigma (Taufkirchen, Federal Republic of Germany). 25-Hydroxycholesterol was obtained from Steraloids Inc. (Wilton, New Hampshire). Lanosterol, cholesterol, squalene and desmosterol were products of Sigma. Lanosterol was purified from contaminating dihydrolanosterol according to ref. 8. [2-^{14}C]Mevalonic acid lactone and [26,27-^{3}H]25-hydroxycholesterol were purchased from NEN (Dreieich, Federal Republic of Germany). All other chemicals and organic solvents were from reputable sources and of analytical grade.

Squalene-2,3-oxide and squalene-2,3:22,23-dioxide were synthesized according to Chang et al. (4) and Field and Holmlund (7). [^{14}C]Dihydrolanosterol was synthesized enzymatically from [^{14}C]mevalonolactone according to the procedure described by Gibbons and Mitropoulos (8). Products of synthesis were acetylated and purified by thin layer chromatography (TLC) on silver nitrate-impregnated silica gel plates and visualized by radiofluorography. Acetyldihydrolanosterol was saponified, and the resulting dihydrolanosterol was extracted with hexane and purified by TLC. [^{3}H]Desmosterol was synthesized from [^{3}H]25-hydroxycholesterol according to the method of Svoboda and Thompson (9).

Cells. Human fibroblasts from skin explants of healthy donors were cultured as described elsewhere (6). Hepatoma cell line HepG2 was a gift of A. Schwarz, Department of Pediatrics, Harvard University (Boston, Massachusetts). Cells were grown in minimal essential medium supplemented with essential amino acids and 10-20% fetal calf serum. All experiments were performed with cells grown to confluency (2.5-3.0 × 10^{6} cells/25 cm^{2} flask).

Incubation conditions. Cells were preincubated for 24 hr in lipoprotein-deficient medium and 12 hr in the presence of the calmodulin antagonists prior to the addition of the radioactive metabolic precursors [^{14}C]mevalonolactone or [^{14}C]dihydrolanosterol in absolute alcohol (0.1% by vol). The incubation was stopped by extensive washing of cell layers with ice-cold buffered saline. Cells were scraped from the culture vessels with a rubber policeman and harvested by centrifugation.

Total lipids were obtained by three cycles of vortexing the cells in chloroform/methanol (2:1, v/v), extracted for 8 hr and saponified at 80 C for 30 min with 1 M KOH in methanol/benzene (4:1, v/v). Water was added, and the nonsaponifiable lipids were extracted with hexane. The solvent was evaporated using a stream of N_2. Lipids were solubilized in small volumes of chloroform/methanol (2:1, v/v) and submitted to two-dimensional TLC as described by Sexton et al. (2). Radioactive lipid (-containing) spots were visualized by radiofluorography, scraped into vials containing scintillation fluid and counted for radioactivity. When individual lipid fractions were further analyzed by TLC, the radioactive spots were scraped into vials

containing chloroform/methanol (2:1, v/v) and extracted. Synthetic products were tentatively identified by cochromatography using known nonradioactive reference substances. The positions of the lipids were ascertained by radiofluorography followed by spraying the plates with concentrated sulfuric acid and incubation at 120 C. To establish unequivocally the identity of individual sterol fractions, the radioactive lipids were acetylated (8) and cochromatographed together with correspondingly acetylated reference substances on 10% silver nitrate-impregnated silica gel plates in hexane/benzene (50:50, v/v).

In vitro assay of sterol Δ^{24} reductase. Microsomes and postmicrosomal fractions were prepared from rat liver homogenates according to the method described by Dempsey (10). Microsomal pellets were washed twice with 0.1 M potassium phosphate buffer, pH 7.3, and recentrifuged for 30 min at 105,000 × g. Incubation mixtures contained 1 ml of microsomes (about 10 mg protein) suspended in 0.1 M potassium phosphate buffer, pH 8.3, 2.5 ml (18 mg/ml) of 105,000 × g supernatant and 85 × 10^3 cpm (1.5 μg) of [^{3}H]desmosterol in 150 μl of propylene glycol. Following the addition of 1 μl/ml of 25 mM trifluoperazine or W-7 in dimethylsulfoxide (1 μl/ml), the mixture was incubated for 15 min at 37 C. The enzymatic reaction was started by adding NADPH in a small volume of incubation buffer to a final concentration of 0.45 mM. The incubation was terminated after 2 hr by adding 15 ml chloroform/methanol (2:1, v/v) and extraction of lipids. The extraction procedure was repeated three times. The lipid extracts were pooled and the organic solvents were evaporated under vacuum. The total lipids were acetylated (8) and extracted in hexane, and aliquots were submitted to separation on 10% silver nitrate-impregnated silica gel plates in hexane/benzene (50:50, v/v). Radioactive spots were visualized by radiofluorography, scraped into scintillation fluid-containing vials and counted for radioactivity.

RESULTS

Calmodulin antagonists W-7 and trifluoperazine prevent conversion of desmosterol to cholesterol. Hepatoma cells incorporated ^{14}C radioactivity from [2-^{14}C]mevalonic acid lactone during a 6-hr pulse period preferentially into cholesterol. Intermediates of cholesterol synthesis (lanosterol, dihydrolanosterol and desmosterol) were detectable as minor components, which were, however, converted to cholesterol during an 18-hr chase period (Fig. 1A).

Preincubation of the cells in 25 μM W-7 or trifluoperazine led to an accumulation of [^{14}C]desmosterol (spot no. 6 of Figs. 1B and 1C). In addition, squalene 2,3-oxide and 2,3:22,23 squalene dioxide, an oxygenated by-product of sterol synthesis, accumulated within nonsaponifiable lipids. In a pulse-chase experiment, W-7 and trifluoperazine partially or almost completely prevented the conversion of desmosterol to cholesterol (Figs. 1B and 1C).

Desmosterol and cholesterol (spot numbers 6 and 5 of Fig. 1) were identified as acetyl derivatives. To do this, spots 6 and 5 were recovered from TLC plates, acetylated with acetic anhydride and cocrystallized with authentic acetyl derivatives of cholesterol and desmosterol in various solvent systems. In all systems, radioactive, acetylated material from the spots cochromatographed

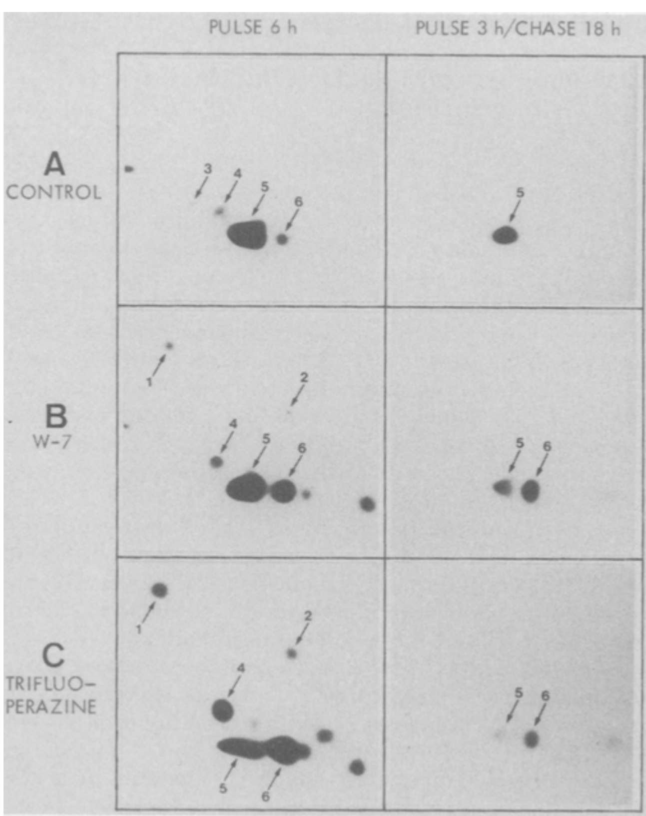

FIG. 1. Effect of N-(6-aminohexyl)-5-chloro-1-naphthalene sulfonamide (W-7) and trifluoperazine on sterol synthesis in HepG2 cells. Cells were preincubated for 12 hr in the presence of 25 μM W-7 or trifluoperazine prior to addition of 5 μCi/ml of [2-^{14}C]mevalonolactone, and the incubation continued for 6 hr. In pulse-chase experiments the incubation in the presence of the radioactivity was terminated after 3 hr by discarding the radioactive medium. Cell layers were washed three times with fresh nonradioactive medium and then maintained for 18 hr either in the presence or absence of the indicated concentrations of the calmodulin antagonists. Total lipids of harvested cells were extracted with chloroform/methanol (2:1, v/v) several times and processed as described in Materials and Methods. The nonsaponifiable lipids were submitted to separation on silica gel plates by two-dimensional thin layer chroamtography as described in Materials and Methods. Radioactive spots were identified by radiofluorography. Identified lipids are as follows: 1, squalene-2,3-oxide; 2, squalene-2,3:22,23-dioxide; 3, dihydrolanosterol; 4, lanosterol; 5, cholesterol; 6, desmosterol.

with reference acetyl derivatives. Figure 2 shows fluorograms of [^{14}C]acetylcholesterol and [^{14}C]acetyldesmosterol, which were found in positions virtually identical to those of the nonradioactive reference substances made visible with concentrated sulfphuric acid (not shown).

Quantitative data on the effect of W-7 and trifluoperazine on cholesterol synthesis in hepatoma cells and skin fibroblasts are given in Table 1. While the synthesis of total nonsaponifiable lipids in hepatoma cells was suppressed by calmodulin antagonists to only 75-80% of control values, the ratio of cholesterol to desmosterol decreased from 29.6 (control) to 0.54 (W-7) and 0.33 (trifluoperazine) under the influence of these agents. As demonstrated in Figure 3, the inhibition of cholesterol synthesis by trifluoperazine is dose-dependent.

Analogous results were obtained for human skin fibroblasts (Table 1). The ^{14}C radioactivity incorporated into

W-7, N-(6-aminohexyl)-5-chloro-1-naphthalene sulfonamide. Cells grown to confluency were preincubated for 24 hr in lipoprotein-deficient medium and 12 hr in the presence of the indicated concentrations of the calmodulin antagonists prior to the addition of 5 μCi/ml (HepG2 cells) and 10 μCi/ml (fibroblasts) of [2-^{14}C]mevalonic acid lactone. Incubation with the radioactive precursor was terminated after 6 hr by removing the medium and by extensive washing of the cell layers with Hank's solution. Fresh lipoprotein-deficient medium was then added, and the cells were scraped off the culture vessels and collected by centrifugation 18 hr later. Extraction, saponification and separation of radioactive sterols were as described in Materials and Methods. Values are means of two experiments made in duplicate.

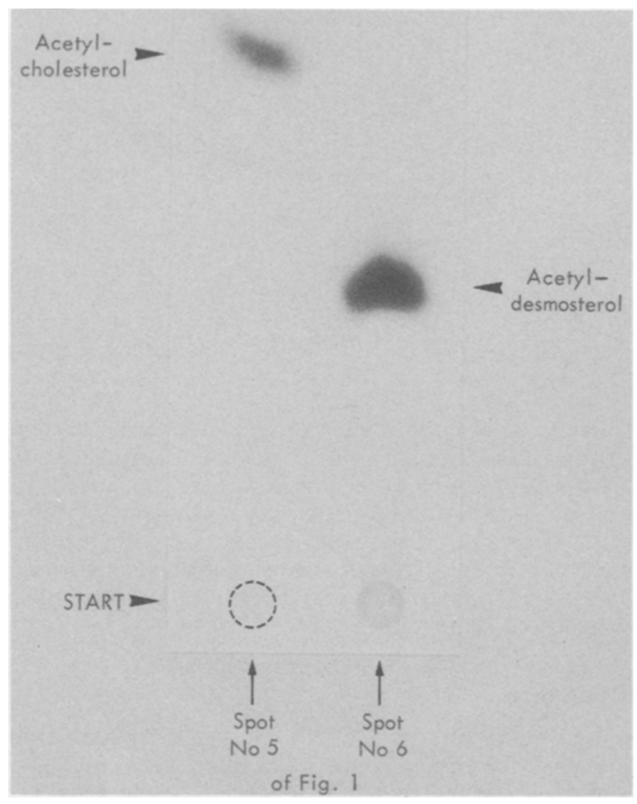

FIG. 2. Identification of synthetic products accumulated in HepG2 cells during a pulse-chase experiment in the presence of trifluoperazine. Radioactive spots designated 5 and 6 in Fig. 1 from pulse-chased and trifluoperazine-pretreated cells were scraped off into vials containing chloroform/methanol (2:1, v/v). The extracted lipids were acetylated and chromatographed on silver nitrate–impregnated silica gel G plates (Materials and Methods). Nonradioactive acetylcholesterol and acetyldesmosterol were cochromatographed. The positions of lipids on developed plates were determined by radiofluorography and by spraying the plates with concentrated sulphuric acid.

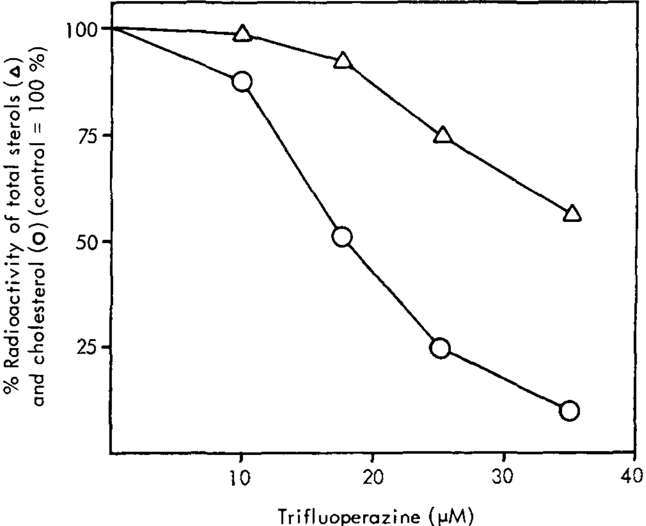

FIG. 3. Inhibition of sterol synthesis in HepG2 cells relative to trifluoperazine concentration. Cells were preincubated for 24 hr in lipoprotein-deficient medium and 12 hr in the presence of the indicated concentrations of trifluoperazine. Following incubation for 3 hr with 5 μCi/ml [2-^{14}C]mevalonolactone, the lipids were extracted from the cells as described in Materials and Methods and Fig. 1. Lipids were separated by two-dimensional thin layer chromatography. Total sterol synthesis was estimated by counting an aliquot of nonsaponifiable lipids.

the total nonsaponifiable lipids of fibroblasts was two to three times less than that incorporated into the lipids of hepatoma cells. Furthermore, the shift in the ratio of cholesterol to desmosterol under the influence of calmodulin antagonists was remarkable; the formation of [^{14}C]cholesterol dropped from 100% (control) to 3–6% (calmodulin antagonists), which caused desmosterol to accumulate.

Calmodulin antagonists inhibit sterol Δ24 reductase. The conversion of desmosterol to cholesterol is catalyzed by sterol Δ24 reductase. This enzyme has been reported to be present in various cholesterol-producing tissues and to reside in the microsomal fraction (11), but has not yet been characterized in detail. Rat liver microsomes were used to study the effect of W-7 and trifluoperazine on sterol Δ24 reductase activity in vitro. The data given in Table 2 demonstrate that in control experiments about 60% of the [^{3}H]desmosterol is converted within 2 hr to

TABLE 2

In Vitro Effect of W-7 and Trifluoperazine on Sterol Δ²⁴ Reductase of Isolated Rat Liver Microsomes

Additions	μM	^{3}H radioactivity Desmosterol (cpm)	Cholesterol (cpm)	% of Substrate converted
None	—	11240	18760	62.5

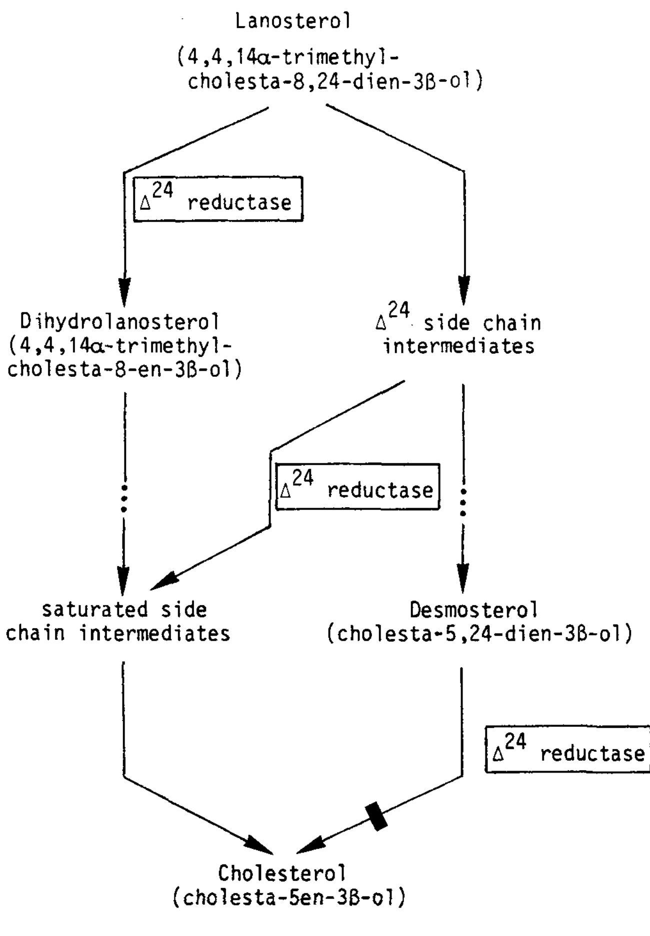
W-7, N-(6-aminohexyl)-5-chloro-1-naphthalene sulfonamide. Cells were preincubated for 24 hr in lipoprotein-deficient medium and 12 hr in the presence of 25 μM W-7 or trifluoperazine. Then [^{14}C]dihydrolanosterol (2.5 × 10^5 cpm/ml) in absolute alcohol (10 μl/ml) was added, and incubation was continued for 6 hr. After extensive washing with buffered saline the cells were scraped from the culture vessels and harvested by centrifugation. Lipids were extracted, and aliquots with equal amounts of radioactivity were submitted to separation on paraffin oil-impregnated silica gel G plates using acetone/water saturated with paraffin (85:15, v/v) as solvent. Radioactive lipids were detected by fluorography, recovered and counted. The identity of lipid fractions was ascertained by comparison with cochromatographed nonradioactive dihydrolanosterol and cholesterol. Values are means of two experiments made in duplicate.



SCHEME 1

[^{3}H]cholesterol by rat liver microsomes in the presence of NADPH. Under these conditions, W-7 and trifluoperazine significantly inhibited the enzymatic reduction of desmosterol to cholesterol (30% of control values).

Enzymatic conversion of dihydrolanosterol to cholesterol is not inhibited by calmodulin antagonists. The enzymatic conversion of lanosterol to cholesterol is comprised of several reactions: reduction of the Δ²⁴ double bond, removal of three methyl groups and shift of the nuclear double bond from the Δ⁸ to the Δ⁵ position. Calmodulin antagonists inhibit predominantly the reduction of the Δ²⁴ double bond, because when cells were incubated in the presence of [^{14}C]dihydrolanosterol, nearly equal amounts of ^{14}C radioactivity were incorporated into cholesterol in both control and calmodulin antagonist-pretreated HepG2 cells (Table 3). Dihydrolanosterol has been found to be a sterol intermediate in the biosynthesis of cholesterol and to be convertible to cholesterol (12,13). However, the reaction sequence dihydrolanosterol → cholesterol seems to be bypassed in HepG2 cells; only 25% of the internalized [^{14}C]dihydrolanosterol was converted to cholesterol by these cells.

DISCUSSION

The present study indicates that the calmodulin antagonists W-7 and trifluoperazine suppress the biosynthesis of cholesterol by blocking sterol Δ²⁴ reductase. The enzymatic reduction of the Δ²⁴ double bond is one of the necessary reactions during cholesterol synthesis. Reduction of the bond may occur at any of several points during transformation of lanosterol to cholesterol. Thus, sterol Δ²⁴ reductase may catalyze an initial conversion of lanosterol to 24,25-dihydrolanosterol, which has been found to be convertible to cholesterol (13). An alternative metabolic pathway leads via a series of Δ²⁴ side chain intermediates from lanosterol to desmosterol, which is finally converted to cholesterol by sterol Δ²⁴ reductase (see Scheme 1). The finding that the calmodulin antagonists used in this study do not inhibit the conversion of [^{14}C]24,25-dihydrolanosterol to cholesterol (Table 3), but cause an accumulation of desmosterol (Table 1), suggest

a) that calmodulin antagonist-induced inhibition of sterol Δ^{24} reductase is relatively specific and b) that the enzymes catalyzing sterol ring modifications are not affected by the inhibitors.

Calmodulin antagonists are reported to be potent and specific inhibitors of calmodulin-mediated reactions and calmodulin-dependent enzyme activities (14). Such inhibition appears to result from conformational restrictions conferred upon calmodulin by the bond antagonist (15). Our results, however, do not allow any conclusion as to whether sterol Δ^{24} reductase is a calcium calmodulin-regulated enzyme. In this regard, the conversion of [^{3}H]-desmosterol to [^{3}H]cholesterol by isolated rat liver microsomes under in vitro conditions was found to be inhibited by the calmodulin antagonists (Table 2), but the calcium calmodulin concentration of the microsomal fraction was not determined. Furthermore, no information is available to indicate whether the activity of sterol Δ^{24} reductase is controlled by calcium calmodulin-dependent protein-kinases or by phosphoprotein phosphatases. In view of the previously reported inhibition of sterol Δ^{24} reductase by U18666 A (2,3). TMD (4) and triparanol (16), the enzyme seems to be highly sensitive to agents with disparate chemical structure.

[Received November 11, 1986]

Liver Parenchymal Cells Differ from the Fat-storing Cells in Their Lipid Composition

Henk F.J. Hendriks*[,a], Pieter J.A.M. Brekelmans[a], Rien Buytenhek[b], Adriaan Brouwer[a], A. Margreet de Leeuw[a] and Dick L. Knook[a]
[a]TNO Institute for Experimental Gerontology, Rijswijk, The Netherlands and [b]TNO Gaubius Institute, Leiden, The Netherlands

The neutral lipid and phospholipid compositions of purified sinusoidal (fat-storing, endothelial and Kupffer) cells, parenchymal cells and liver homogenates were determined by thin layer chromatography. In addition, the retinoid content of the same purified cell populations was determined by high performance liquid chromatography. From each cell type, both a lipid droplet fraction and a pellet fraction (containing the majority of the remaining cell organelles) were prepared by differential centrifugation. Electron microscopic analysis showed that lipid droplets isolated from fat-storing cells were larger (up to 8 μm) than those isolated from parenchymal cells (up to 2.5 μm). Moreover, the parenchymal lipid droplets seemed to be surrounded by a membranous structure, while the fat-storing lipid droplets seemed not to be. Both fat-storing and parenchymal cells contained high concentrations of neutral lipids, 57.9 μg and 71.0 μg/10^6 cells, respectively, while endothelial and Kupffer cells contained only 8.6 μg and 13.8 μg/10^6 cells of neutral lipids, respectively. Sixty-five percent of fat-storing cell lipid droplet fractions comprised esters of retinol and cholesterol. This combined ester fraction contained mainly retinyl esters. In addition, considerable quantities (20%) of triglycerides were present. Parenchymal cell lipid droplet fractions comprised triglycerides (62%) and cholesteryl esters (up to 30%). The pellet fractions prepared from all four cell types consisted mainly of cholesterol (41-67%) and free fatty acids (20-28%). The phospholipid content was much higher in parenchymal cells than in the sinusoidal liver cell types. The relative proportions of the four major phospholipid classes were comparable in all liver cell types analyzed. It is concluded that parenchymal cell lipid droplets comprised mainly triglycerides and cholesteryl esters, which is in agreement with the function of parenchymal cells in lipid metabolism. Fat-storing cell lipid droplets consisted of retinyl esters and triglycerides, which correlates well with their function in retinoid storage and metabolism.
Lipids 22, 266-273 (1987).

Lipids found in liver cells are located mainly in membranes or in lipid droplets. Liver lipid droplets are almost exclusively observed in two different liver cell types, parenchymal and fat-storing cells. Fat-storing cells contribute considerably to the total lipid droplet volume in the liver (1,2).

It is well established that liver parenchymal cells have a function in triglyceride and cholesterol synthesis and metabolism (3). Fat-storing cells, on the other hand, have been shown to be important in retinoid storage (4,5) and metabolism (6). It is unknown whether these different functions in lipid metabolism are reflected in the cellular lipid composition. Limited information is available on some details of the lipid content of two of the liver cell types (7,8). In this study, neutral lipids and phospholipids present in a total liver homogenate and in isolated parenchymal and fat-storing cells, as well as in two other major liver cell populations, Kupffer and endothelial, were determined. Neutral lipids were also determined in the lipid droplets prepared from these cell types.

MATERIALS AND METHODS

Animals. Female Brown Norway/Billingham Rijswijk (BN/BiRij) rats aged 12 mo and weighing 180 ± 10 g were used. All rats were fed standard laboratory chow ad libitum (Diet AM II, Hope Farms, Woerden, The Netherlands) and were not fasted before the experiment. The chow contained 5.5 mg retinyl acetate and 72 g fat per kg diet, of which 17 g was derived from animal fats. Specific pathogen-free derived rats were maintained under "clean conventional conditions" (9). The status of this strain of rats has previously been characterized with regard to liver vitamin A status and serum concentrations of triglycerides, cholesteryl esters and retinoids (4).

Chemicals and solvents. All chemicals and solvents were of reagent grade or high performance liquid chromatography (HPLC) grade, if required. The solvents of reagent grade used for the extraction and chromatography of lipids were distilled twice to exclude any fatty contamination. Vitamins D_2, D_3 and E, cholestenon, cholestane-3β,6α-diol, cholesterol, cholestane-3β,5α,6β-triol and bovine serum albumin were purchased from Sigma (St. Louis, Missouri).

Isolation of liver cells and lipid droplets. Nonparenchymal cell suspensions were prepared by perfusion and incubation of the liver with pronase and collagenase as described previously (10). Kupffer, endothelial and fat-storing cells were purified by density centrifugation (4) and centrifugal elutriation (11). Parenchymal cell suspensions were prepared at 37 C by perfusion and incubation of the liver with collagenase (4) and were further purified by centrifugal elutriation (4).

Lipid droplet fractions were prepared from the various isolated cell preparations by freeze-thawing followed by ultrasonification using an MSE 150 Watt Ultrasonic disintegrator. Sonification was continued until more than 95% of the cells were homogenized, as judged by light microscopy. Cell homogenates were centrifuged in a 0.25 M sucrose solution for 7.9×10^6 $g_{1/2}$.min. The top layer (containing the lipid droplets) was separated from the pellet by cutting the centrifuge tube in a tube-slicing apparatus.

Cell counts were performed for the yield of the cell fraction. The purity of the cell preparations and the lipid droplet fractions was determined by electron microscopy (12). Cells were fixed for electron microscopy using a 2% glutaraldehyde solution in 0.15 M cacodylate buffer (pH 7.4) (6), while lipid droplets were fixed using a freshly mixed 0.7% glutaraldehyde and 1% osmium tetroxide solution in 0.15 M cacodylate buffer (pH 7.4) and processed for electron microscopy as for isolated cells.

*To whom correspondence should be addressed.

Protein content of the isolated cell preparations was determined by the method of Lowry et al. (13) with bovine serum albumin as a standard.

The total liver homogenate was prepared from a liver perfused in situ with Gey's balanced salt solution for several minutes at a flow rate of 10 ml/min. After perfusion, the liver was weighed and cut into small pieces of about 1 mm^3 with razor blades.

Analysis of lipids and retinoids. Lipids were extracted from liver homogenates, cell preparations and isolated lipid droplets as described by Bligh and Dyer (14). Neutral lipids were separated using thin layer chromatography (TLC). Internal standards cholestane-3β,6α-diol and cholestane-3β,5α,6β-triol were added to allow the quantitation of neutral lipids and phospholipids, respectively. Lipid extracts were spotted on glass microscope slides coated with a layer of ±0.1 mm of Silica DO (Camag, Switzerland) in a thin line at a concentration of 2 mg/ml in chloroform. The slides were developed in small chromatography cylinders (height 100 mm, diameter 45 mm).

Neutral lipids were chromatographed using chloroform/methanol (95:5, v/v) up to half of the height of the slide. The slides were then dried and lipids were further developed using hexane/chloroform (60:25, v/v) up to the top of the slide (15).

Phospholipids were separated on the same type of slides, developed with methanol/chloroform/water (75:25:4, v/v/v) up to the top of the slide and dried. The slides were then developed for a further 10 min in the same solution and dried again.

Both neutral lipids and phospholipids were visualized by wetting the slides with sulphuric acid (10%, v/v) and charring by a two-step heating procedure. The first heating at 100 C allows the identification of cholesterol and cholesteryl esters by the red color of their bands. Retinyl esters were already charred at 100 C. The second heating at 200 C for 15 min charred all lipids and resulted in black bands. The intensity of the charred lipids was quantified after the second heating by photodensitometry and the use of a Shimadzu data module (CS 910). As the number of densitometric units per μg lipid is dependent on the percentage of carbon in a lipid class, densitometric values of each lipid class were multiplied by a correction factor (15). Correction factors for cholesterol and retinol were the same as were those for cholesteryl esters and retinyl esters.

Equivalent volumes of cell-free medium were run as blanks and subtracted as background values. Background values never made up more than 2% of the total amount of lipid detected. Free retinol and free cholesterol cochromatographed in the TLC system. Retinyl esters and cholesteryl esters could not be calculated as separate classes using densitometry due to an incomplete separation. The two-step heating procedure did, however, allow the identification of these two lipid classes. Moreover, the major constituent present within each specific band (either as retinyl esters or as cholesteryl esters) could be estimated because retinyl esters were quantified separately in each cell preparation by HPLC (see below). Phosphatidylserine and phosphatidylinositol cochromatographed with phosphatidylcholine.

Peak identification of both neutral and phospholipids was achieved using normal rat serum as a standard in a parallel run. All materials that would be in contact with the extracted lipids were rinsed twice before use with distilled chloroform to wash off contaminating lipids.

Retinoids, including retinol, retinyl oleate, retinyl palmitate and retinyl stearate, were analyzed and quantified by reverse phase HPLC using retinyl acetate as an internal standard as described previously (4). Retinoids were analyzed in liver homogenates and cell preparations after lyophilization and overnight extraction at 4 C with methanol/diisopropylether/water (31.7:63.3:5, v/v/v) containing 50 mM ethylenediaminetetraacetic acid and butylated hydroxytoluene (50 μg/ml) (4).

The extraction procedures for TLC (14) and HPLC (4) were evaluated by quantitating the lipid classes by TLC. The quantities of neutral lipids determined in a liver homogenate were significantly higher when the extraction method described by Bligh and Dyer (14) was used (25.0 ± 2.6 mg/g wet weight [n = 4] and 12.1 ± 1.0 mg/g wet weight [n = 2] for TLC and HPLC extraction procedures, respectively). The only exception was the combined retinyl ester/cholesteryl ester fraction, which was equally well extracted in the two extraction procedures (2.6 ± 0.0 mg/g wet weight [n = 2] and 2.5 ± 0.2 mg/g wet weight [n = 4], respectively).

Extraction and separation of lipids and retinoids were performed under an atmosphere of nitrogen to prevent lipid oxidation. Since retinoids are photosensitive, all procedures were performed in reduced (red) light or, when possible, in the dark.

RESULTS

Characteristics of isolated cells and lipid droplets. Isolated parenchymal, Kupffer, endothelial and fat-storing cells were obtained with good viability (80–90%). The purity of all cell preparations was determined by electron microscopy; the average purity varied from 72% for fat-storing cells to 98% for parenchymal cells (Table 1).

Lipid droplets were isolated from each cell preparation. Representative micrographs of lipid droplets from fat-storing cells and parenchymal cells are shown in Figures 1a and 1b. Lipid droplets isolated from parenchymal cells had diameters up to 2.5 μm. Lipid droplets from fat-storing cells tended to be larger than parenchymal cell lipid droplets; their sizes varied up to 8 μm. Isolated lipid droplets from parenchymal cells seemed to be surrounded by a limiting membrane (Fig. 1b, inset). Fat-storing cell lipid droplets were surrounded by a thin thread of cytoplasm, but not by a limiting membrane (Fig. 1a, inset).

TABLE 1

Characterization of Cell Preparations Used for Lipid Analysis[a]

Cell fraction	n	Purity (%)	Protein content (μg/10^6 cells)	Total retinoids (μg/10^6 cells)
Fat-storing cells	5	72 ± 7	96 ± 7	85.6 ± 14.8
Endothelial cells	5	80 ± 3	50 ± 4	2.2 ± 1.2
Kupffer cells	5	80 ± 2	106 ± 6	1.1 ± 0.4
Parenchymal cells	3	98 ± 1	1267 ± 280	2.2 ± 1.2

[a]Values represent the mean ± SEM.

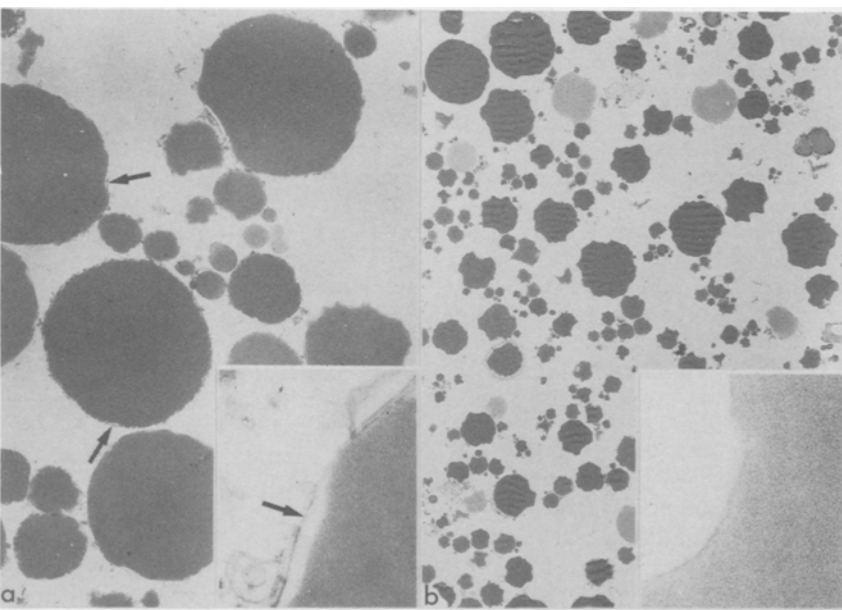

FIG. 1. Transmission electron micrograph of representative lipid droplet fractions. (a) Fat-storing cell-derived lipid droplet fraction. Lipid droplets of homogenous density and of variable diameter are shown (3,925×). Lipid droplets are surrounded by a thin thread of cytoplasm (arrows) but not by a limiting membrane (inset, 41,420×). (b) Parenchymal cell-derived lipid droplet fraction. Lipid droplets of variable density and size are shown (3,925×). Lipid droplets seem to be surrounded by a unilamellar membrane (inset, 93,740×).

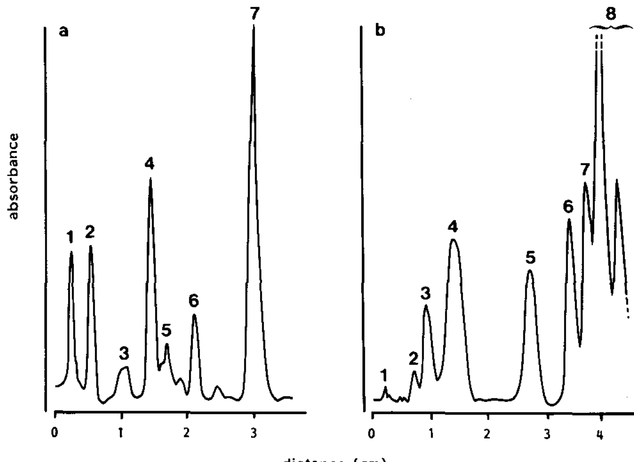

FIG. 2. TLC of extracts of fat-storing cell preparations. (a) Separation of neutral lipids. Peak identification: 1, sample origin containing phospholipids and cholestane-3β,5α,6β-triol; 2, cholestane-3β,6α-diol; 3, free fatty acids; 4, cholesterol/retinol; 5, ?; 6, triglycerides; 7, retinyl esters/cholesteryl esters. (b) Separation of phospholipids. Peak identification: 1, sample origin; 2, lysophosphatidylcholine; 3, sphingomyelin; 4, phosphatidylcholine, including phosphatidylserine and phosphatidylinositol; 5, phosphatidylethanolamine; 6, cholestane-3β,5α,6β-triol; 7, cholestane-3β,6α-diol; 8, neutral lipids.

All lipid droplet preparations were slightly contaminated with structures derived from mitochondria, lysosomes and ribosomes.

The yield and purity of the lipid droplet fractions derived from preparations of Kupffer and endothelial cells were low.

The pellet fractions of the cell lysates obtained after ultracentrifugation contained hardly any lipid droplets (results not shown). These pellets consisted mainly of cell organelles and a few intact cells.

Identification of lipid classes by TLC. Neutral lipids and phospholipids were separated using TLC. A representative chromatogram of neutral lipids present in a fat-storing cell preparation is shown in Figure 2a.

The main neutral lipid classes identified were free fatty acids, free cholesterol, triglycerides and esters of both cholesterol and retinol. Preparations of all isolated liver cell types, as well as the total liver homogenate, contained all these lipid classes. Vitamin E cochromatographed with the triglycerides, and vitamins D_2 and D_3 cochromatographed with cholesterol (not shown). The peaks that could be identified accounted for more than 80% of the total peak area, from which the phospholipids, carbohydrates and internal standards had been excluded. Other minor unidentified peaks were present, e.g., peak 5 (Fig. 2a). Peak 5 was detected in all cell fractions, but higher concentrations were found in fat-storing (Fig. 2a) and Kupffer cell preparations (not shown). In both cases, it accounted for 10–12% of the total peak area, again excluding phospholipids, carbohydrates and internal standards.

A representative chromatogram of the phospholipids present in isolated fat-storing cells is shown in Figure 2b. The main phospholipid classes identified in liver homogenates and in the four cell preparations were phosphatidylcholine, including phosphatidylserine and phosphatidylinositol, phosphatidylethanolamine, sphingomyelin and lysophosphatidylcholine. Together, these lipids accounted for more than 90% of the total phospholipids present.

[a]TLC, thin layer chromatography. Values are expressed as μg lipid per 10^6 cells and represent the mean ± SEM. Values differ significantly ($p < 0.01$) from values for *f*, fat-storing cells; *e*, endothelial cells; *k*, Kupffer cells; and *p*, parenchymal cells. Values were tested for significance using the unpaired *t*-test (two-tail).

Neutral lipid content of serum and total liver. Using the TLC method described above, the neutral lipid contents of serum and liver homogenate were determined to assess the lipid status of the rats used in this study (Table 2). Serum and total liver contained concentrations of triglycerides and free fatty acids, which were on the same order of magnitude as those previously reported in the literature (16–20; Table 2).

HPLC analysis of serum retinoids showed them to be almost exclusively retinol. Retinyl esters were not detectable or were present in very low concentrations. Consequently, the cholesteryl/retinyl ester fraction in serum detected by TLC consisted of cholesteryl esters only.

HPLC analysis of liver retinoids showed that retinol was present in a concentration of only 50.3 ± 1.9 μg/g wet weight (data not shown). The majority of the retinoids present in a liver homogenate were retinyl esters (97%; see Table 2). Therefore, a major contribution of retinol to the cholesterol/retinol peak detected by TLC could be ruled out. On the other hand, retinyl esters were a major part of the total cholesteryl/retinyl ester fraction of the liver.

Neutral lipid composition of isolated cell preparations. TLC analysis showed that parenchymal cells contained high amounts of neutral lipid per 10^6 cells, as did fat-storing cells (Table 3). Kupffer and endothelial cells, however, contained low amounts of neutral lipids. Kupffer cell fractions contained significantly more neutral lipid than endothelial cells. When calculated per mg cell protein (Tables 1 and 3), fat-storing cells contained significantly more neutral lipid (603 μg/mg protein) than parenchymal cells (56 μg/mg protein).

Free fatty acids were present in relatively high concentrations in both fat-storing cells and parenchymal cells as compared to Kupffer and endothelial cells (Table 3). In all cell types, free fatty acids accounted for only about 10% of the total neutral lipids present (Fig. 3). The percentage of free fatty acids present in liver homogenates (32%) was considerably higher than that in any of the isolated cell fractions (6–12%).

Very small amounts of retinol were present in fat-storing cell preparations (0.1 ± 0.0 μg/10^6 cells) as determined by HPLC. Thus, retinol did not make a major contribution to the cholesterol/retinol fraction.

The concentration of cholesterol, a major component of cell membranes, was significantly higher in the parenchymal cells (Table 3) than in the three other cell types. Fat-storing cells contained significantly more free cholesterol than did endothelial or Kupffer cells. Cholesterol made up a major part of the neutral lipids present in both endothelial cells and Kupffer cells (Fig. 3).

Parenchymal cells contained the highest concentration of triglycerides (Table 3). Triglycerides accounted for 62% of the total amount of neutral lipids present in the parenchymal cell fractions, which is higher than the percentages present in the other cell types (Fig. 3).

Esters of cholesterol and retinol were present in high concentrations in fat-storing cells (Table 3). These two classes of esters together accounted for most of the lipids in the fat-storing cells (51%; Fig. 3). The two-step heating procedure showed that the esters already charred at 100 C, indicating that the majority of these esters were retinoids, which was confirmed by HPLC analysis (Table 1).

The concentration of cholesteryl and retinyl esters was

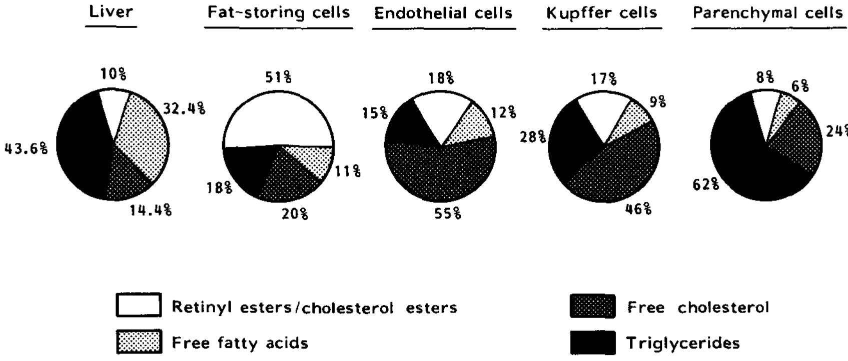

FIG. 3. Diagrams showing the neutral lipid composition of fat-storing, endothelial, Kupffer and parenchymal cells and liver homogenates, expressed as percentage of the total amount of neutral lipids determined. Neutral lipid classes identified and included are free fatty acids, cholesterol, triglycerides and esters of cholesterol and retinol. The number of experiments is indicated in Table 3.

TABLE 4

Estimated Distribution of Neutral Lipids in Fat-storing, Endothelial, Kupffer and Parenchymal Cells Calculated on the Basis of Data Determined by TLC and HPLC[a]

	TLC					HPLC
Cell fraction	Free fatty acids	Free cholesterol	Triglycerides	Retinyl/cholesteryl esters	Total neutral lipid	Retinyl esters
Fat-storing cells	15	8	3	37	10	83
Endothelial cells	3	4	1	3	2	2
Kupffer cells	2	3	1	2	1	1
Parenchymal cells	80	85	95	58	87	14

[a]TLC, thin layer chromatography; HPLC, high performance liquid chromatography. Values represent the estimated percentage distribution of the total amount of each component in each of the four types of isolated liver cells/g liver (or in the total liver). Values were tested for significance using the unpaired t-test (two-tail).

significantly lower in parenchymal cells and even more so in Kupffer and endothelial cells (Table 3 and Fig. 3). In all these cell types retinyl esters were only a minor component (Table 1).

The best estimates for the number of each cell type present per gram of liver in 12-mo-old female BN/BiRij rats are 108×10^6 parenchymal cells, 16×10^6 fat-storing cells, 19×10^6 endothelial cells and 9×10^6 Kupffer cells (4,6). On the basis of these data, it was calculated that the recoveries of the neutral lipid classes after cell isolation varied between 44% (for triglycerides and esters of retinol and cholesterol) and 58% (for free cholesterol). The recovery of retinoids determined by HPLC was calculated to be 74%. All these calculated recoveries are in agreement with the recoveries reported on other substances using the same isolation procedure. The one exception was the recovery of free fatty acids, which was 7% only. This discrepancy is possibly caused by the metabolism of free fatty acids during the isolation procedure or the generation of free fatty acids during liver homogenization. Similar calculations showed that parenchymal cells contained 80% of the free fatty acids, 85% of the free cholesterol, 95% of the triglycerides and 58% of the esters of retinol and cholesterol present in the liver (Table 4). While Kupffer and endothelial cells contributed very little to the total neutral lipids in the liver, fat-storing cells accounted for 15% of the free fatty acids and 37% of the cholesteryl and retinyl esters. On the basis of the HPLC data, the distribution of retinoids over the different liver cell types was calculated to be the following: parenchymal cells, 14%; fat-storing cells, 83%; endothelial cells, 2%; Kupffer cells, 1% (Table 4).

Phospholipid composition of isolated cell preparations. A pilot experiment showed that parenchymal cells contained 10 times more phospholipid (160 μg/10^6 cells, n = 2) than did sinusoidal cells (13-17 μg/10^6 cells, n = 5). A similar ratio was observed for the protein contents of the two cell type populations (Table 1). The phospholipid composition of the different liver cell types was very similar, i.e., phosphatidylcholine, 48-59%; phosphatidylethanolamine, 27-33%; sphingomyelin, 9-16%; and lysophosphatidylcholine, 2-7% (Fig. 4).

The recoveries of phospholipids calculated on the basis of the cellular composition of the liver were on the same order of magnitude as the recovery of neutral lipids, namely, 38, 44, 35 and 26% for phosphatidylcholine, phosphatidylethanolamine, sphingomyelin and lysophosphatidylcholine, respectively.

Neutral lipid composition of lipid droplets. The neutral lipid composition of both lipid droplet fractions and pellet

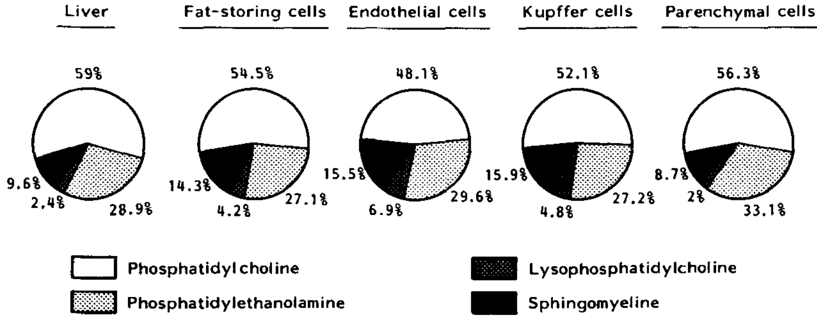

FIG. 4. Diagrams showing the phospholipid composition of fat-storing, endothelial, Kupffer and parenchymal cells and liver homogenates, expressed as percentage of the total amount of phospholipid determined. Phospholipid classes identified and included are phosphatidylcholine, phosphatidylethanolamine, sphingomyelin and lysophosphatidylcholine.

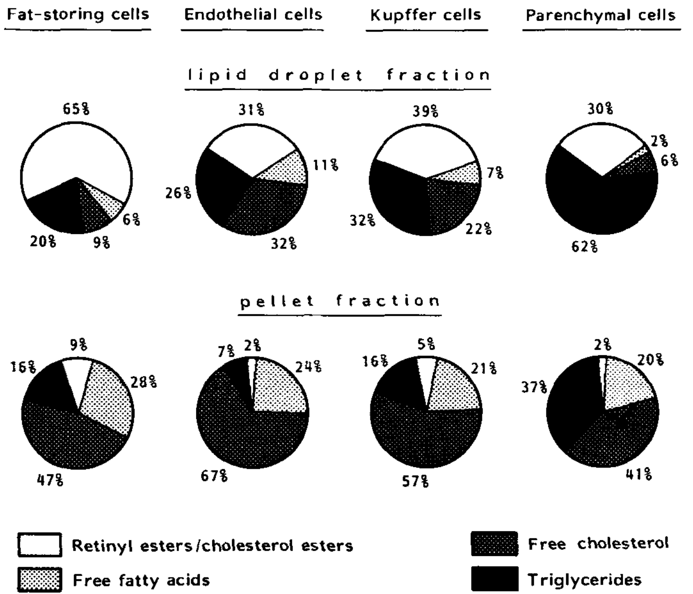

FIG. 5. Diagrams showing the neutral lipid composition of lipid droplet and pellet fractions obtained from fat-storing, endothelial, Kupffer and parenchymal cells, expressed as percentage of the total amount of neutral lipid determined. Neutral lipid classes identified and included are free fatty acids, cholesterol, triglycerides and esters of cholesterol and retinol.

fractions derived from the various purified cell types is given in Figure 5. The total neutral lipids recovered in both fractions represent 74% of the neutral lipids present in endothelial, Kupffer and parenchymal cells and 54% in fat-storing cells. The 54% recovery from fat-storing cell preparations is mainly due to a low recovery of esters (36%).

The pellet fractions of the four cell types were enriched in free fatty acids and free cholesterol but not in triglycerides and esters of retinol and cholesterol. Since the pellets consisted of the remaining cell organelles, it implies that these organelles contain mainly free fatty acids and cholesterol, while lipid droplets comprise triglycerides and esters of retinol and cholesterol (Fig. 5).

Lipid droplet fractions from both isolated endothelial cells and Kupffer cells contained hardly any lipid droplets. Most of the lipid present in these cells was recovered in their pellet fractions. Lipid droplets from parenchymal cells comprised triglycerides for 62%, contrary to fat-storing cell lipid droplets, which contained mainly retinyl and cholesteryl esters (65%). These results strengthen the data obtained in total cell fractions, showing that parenchymal cells mainly store triglycerides and some cholesteryl esters.

DISCUSSION

This report deals with the lipid composition of total liver, all major liver cell types and their lipid droplets.

The contents of free and esterified cholesterol in the serum of the rats used are in the same range as reported previously for age-matched rats (16,21). In the literature, considerable variation has been reported in serum triglyceride levels, and this relates to differences in the time of sampling and the rat strain used (16–19). Compared to these data, triglyceride levels of serum determined in

the rat strain used in this study were on the same order of magnitude.

The contents of total cholesterol, triglycerides and phospholipids in total liver homogenates were also comparable to those reported for age-matched rats (18–20). The retinyl ester content of the 12-mo-old rat livers used in this study is in the same range as values reported in the literature using modern HPLC techniques (4,22,23). Plasma retinol and retinyl ester levels were normal (24).

Lipid droplets were isolated from cell homogenates in a single centrifugation step. The sizes of isolated parenchymal cell lipid droplets were similar to those reported for isolated hepatic (25) and parenchymal cell lipid droplets (26). Isolated parenchymal cell lipid droplets showed an electron dense rim, which could be indicative of the presence of a unilamellar membrane (26). Fat-storing cell lipid droplets were more translucent. A thin electron-dense layer was often observed on the periphery, which was sometimes associated with residual cytoplasm. These droplets were larger than those observed in vivo (27,28), in cultured cells (29) and in freshly isolated fat-storing cells (30). Large droplets might have been generated by fusion of smaller droplets during the isolation procedure, since no limiting membrane was observed. Wake (5,27) reported the presence of membrane-bound (type I) and nonmembrane-bound (type II) lipid droplets in rat fat-storing cells. Type I lipid droplets correspond to lipid droplets surrounded by lysosomes (31,32). The type I lipid droplets are thought to play a role in the generation (30) or digestion (31) of fat-storing cell lipid droplets. The digestion of lipid droplets was mainly observed in hypervitaminosis A (31). Since no limiting membrane was observed to surround the lipid droplets in our studies, it seems most likely that the neutral lipid composition of these lipid droplet fractions represents the storage conditions for retinoids in normal rats.

The data presented here showed a similar distribution of the major phospholipids for all cell types tested. These data are in good agreement with those reported by Gabellec et al. (7) on the phospholipid composition of parenchymal, Kupffer and endothelial cells.

Fat-storing cells are comparable to endothelial and Kupffer cells in both size and protein content. Fat-storing cells, however, contain significantly more free cholesterol than do endothelial cells. These data indicate either that fat-storing cells also contain cholesterol as a lipid droplet constituent or that these cells contain considerably more cell membranes. A significant but small portion of this free cholesterol is indeed still present in the lipid droplet fractions obtained from these cells (8). Electron microscopic observations in humans (33) and rats (34) show that fat-storing cells possess numerous large extensions that allow extensive contacts with all liver cell types and the space of Disse. Blouin et al. (1) showed that both fat-storing cells and endothelial cells indeed contained (as a percentage) more plasma membranes than did Kupffer cells.

The results presented in this paper provide additional data on some aspects of the functions of different cell types in the liver. As shown in this and previous papers (4,6), fat-storing cells are the main retinoid storage sites in the liver. The two cell types most important in handling the vitamin are parenchymal and fat-storing cells (4,6). Parenchymal cells take up chylomicron remnant particles, which transport dietary retinoids mainly as retinyl esters (35). The parenchymal cells are also able to hydrolyze these esters by retinyl palmitate hydrolase activity and to transport retinol within the cell by the cellular retinol binding protein (6,36). Moreover, parenchymal cells synthesize and secrete the retinol binding protein that transports retinol in the blood (37,38). Fat-storing cells store the vitamin as retinyl esters and are also able to hydrolyze retinol from these stores by retinyl palmitate hydrolase activity and to transport retinol within the cell by the cellular retinol binding protein (6). Blomhoff et al. (36) showed that the fat-storing cells and parenchymal cells of rat liver also contain the acyl CoA:retinol acyltransferase activity, which is necessary to esterify retinol with a free fatty acid. These data indicate that both cell types are able to generate and utilize free fatty acids for handling the vitamin. It is shown in this paper that the majority of the neutral lipids present in fat-storing cells consists of retinyl esters (8), but substantial amounts of triglycerides are also present. It is tempting to speculate that these triglycerides serve as a storage site for the free fatty acids needed for the esterification of retinol.

The majority of neutral lipids in parenchymal cells consisted of triglycerides; this is related to the liver's important function in formation and secretion of very low density lipoproteins (39–41). Cholesteryl esters are also present in the parenchymal cell lipid droplet fractions as a consequence of the parenchymal cell's role in cholesterol synthesis and lipoprotein uptake.

Lipid droplet fractions isolated from endothelial and Kupffer cells contained minor amounts of neutral lipids. Most neutral lipids were recovered in the pellet fraction mainly as cholesterol and free fatty acids. Sinusoidal endothelial and Kupffer cells were reported to play a significant role in the uptake and metabolism of several lipoproteins (42,43). Lipids probably are not stored but degraded by means of lysosomal enzymes present in these cells (43–45).

Data presented in this study show that the cell types present in liver differ considerably in their neutral lipid composition. These differences are more apparent in the specific lipid storage organelle, the lipid droplet. It is concluded that the differences in neutral lipid composition described in this paper correlate well with the functions of the various cell types in liver lipid metabolism.

METHODS

Two Procedures to Remove Polar Contaminants from a Crude Brain Lipid Extract by Using Prepacked Reversed-phase Columns

Titus Kyrklund
Institute of Neurobiology, University of Goteborg, POB 33031, S-400 33 Goteborg, Sweden

Two procedures were developed using prepacked, reversed-phase columns (Bond Elut) for the separation of lipids from water-soluble contaminants. A crude lipid extract from brain tissue was diluted stepwise with a methanol/water (method 1) or a methanol/saline (method 2) mixture and, with each step, was passed through the column. As the polarity of the solvent was increased, all lipids became bound to the column, while the water-soluble compounds remained in the eluate. After three subsequent dilutions and column elutions, the eluate containing the more polar contaminants was discarded. The bound lipids were then eluted with a small volume of chloroform/methanol (1:2, v/v). Alternatively two fractions were eluted, the first fraction eluted with methanol/water (12:1, v/v), contained gangliosides, phosphatidylserine, phosphatidylinositol, phosphatidic acid and sulfatides. The second fraction, eluted with chloroform/methanol (1:2, v/v), contained all remaining phospholipids, cerebrosides and cholesterol. For both methods a quantitative recovery of cholesterol and phospholipids was obtained. In method 2, when water was replaced by saline in the dilution solvent mixture, gangliosides were also bound and quantitatively recovered.
Lipids 22, 274–277 (1987).

For the extraction of lipids from various tissues, chloroform/methanol solvent mixtures are most commonly used (1,2). The crude extracts obtained contain small amounts of nonlipid substances that can interfere with the subsequent quantitative determination of the various lipids. Removal of the nonlipid contaminants is often done either by partitioning against a salt solution (1) or by using chromatography on a dextran gel column (3). These methods become quite elaborate when numerous samples are to be run with several solvent evaporations.

Recently, reversed-phase columns have been shown useful for isolation and purification of gangliosides from the upper phase obtained after partitioning (4). They have also been used for separation of radioactive lipid precursors from product complex lipids in a microsomal preparation, where the entire reaction mixture was poured onto the column without a previous extraction of the lipids (5). In both methods, the solvent composition was that of a theoretical upper phase (TUP) (chloroform/methanol/aqueous salt solution, 3:48:47, v/v/v). Such a polar solvent dissolves gangliosides readily, but not other lipids.

The present report starts with a standard chloroform/methanol total lipid extract. Two methods were developed according to the same general principle. By a stepwise dilution of the crude extract with a methanol/water (method 1) or methanol/saline (method 2) mixture followed by elution through a C-18 reversed-phase column, the complete lipid sample can be bound to the column while polar contaminants remain in the eluate. The lipid sample can then be easily eluted with a less polar solvent. The simplified procedure (method 1) results in a purified lipid sample, similar to the lower phase of Folch et al. (1). In the second method (method 2), where water was substituted with saline (4), gangliosides also were completely bound to the column. Two fractions were eluted in method 2, similar to those obtained after ion-exchange chromatography (13).

MATERIALS AND METHODS

Chemicals. All chemicals and solvents were of reagent grade. C-18 Bond Elut columns (2.8 ml, 500 mg sorbent) were from Analytichem International (Harbor City, California) and 0.25-mm thin layer chromatography (TLC) plates, Silica Gel 60, were from Merck (Darmstadt, Federal Republic of Germany). [^{3}H]Glucose and [^{14}C]-dipalmitoyl phosphatidylcholine were purchased from Amersham (Buckinghamshire, England). The elution apparatus was similar to that previously described (6). Standard luer-lock stopcocks were attached to the lid of the apparatus.

Tissue preparation. Lipids were extracted from the tissue with chloroform/methanol. Approximately 2 g frozen brain was homogenized in 20 ml methanol, to which 10 ml chloroform was added. The homogenate was centrifuged at 1000 × g for 10 min, and the pellet was then reextracted by the same procedure. All steps were carried out at 0–4 C.

Method 1. To 6 ml of the crude extract, corresponding to about 200 mg fresh brain, 8 ml of methanol/water (1:1, v/v) was added and mixed to homogeneity. If the lipid content of the samples was high, the mixture became slightly turbid at the first dilution. This did not affect the recovery. The whole mixture was poured onto a C-18 Bond Elut column equipped with a 50-ml reservoir. The column was preequilibrated with 2 ml methanol. New columns were washed with 6 ml chloroform/methanol (1:2, v/v) before use. Column elution was carried out under a constant gentle vacuum with an elution speed of 1–2 ml/min. Another 8 ml of methanol/water (1:1, v/v) was added to the eluate, mixed and passed through the same column. The resulting eluate was once again mixed with 8 ml of methanol/water and passed through the column as before. As soon as all liquid had passed the columns, the stopcocks were closed, to keep elution volumes reasonably constant and to avoid changing the column properties by allowing the columns to dry. The last eluate was normally discarded before elution of the bound lipids. A 5-ml container was mounted on top of the column, and the lipids were eluted at a moderate rate with two portions of 4.0 ml chloroform/methanol (1:2, v/v). This final eluate was used for quantitative analyses of lipid classes. The final elution from the column was also done with 4 × 2-ml

portions to verify the completeness of the elution. The columns could be reused 3-5 times without any appreciable decrease in column flow. The elution speed was drastically decreased if the columns were overloaded; thus sample breakthrough hardly occurred.

Bidirectional qualitative TLC was done on the purified extract (9). In the first direction, chloroform/methanol/water was used in the proportions 65:25:4 and in the second direction chloroform/methanol/acetone/acetic acid/water (10:2:4:2:1, v/v/v/v/v) was used. The plates were exposed to hydrochloric acid vapors for 2 min between the first and second directions. Lipid spots were visualized by charring with a cupric sulfate reagent (10). Identification of the various lipid spots was done by comparing with appropriate standard mixtures and by their characteristic fatty acid patterns upon gas-chromatographic analysis. In addition, ninhydrin spray reagent (Merck) was used to detect nonlipid material.

A reference method was compared to method 1. From the same crude extract as used for method 1, 6-ml samples were purified by partitioning in principle according to Folch et al. (1). These samples were first taken to dryness by rotary evaporation and then redissolved in chloroform/methanol (2:1, v/v). To the resulting extracts, 0.2 volumes of 0.9% NaCl in water were added, and the tubes were vortexed and centrifuged at 2000 × g for 10 min. The upper phase was removed by aspiration, and the lower phase was taken to dryness and then redissolved in 8 ml chloroform/methanol (1:2, v/v).

Cholesterol was determined on the extracts from method 1 and from the reference methods according to Franley and Amador (7). Their phosphorus contents were also determined (8).

An experiment to study the recovery of a labeled lipid and a water-soluble residue was carried out by adding [^{3}H]labeled glucose (50 μCi) and [^{14}C]labeled dipalmitoyl phosphatidylcholine (5 μCi) to a 60-ml sample of crude brain-lipid extract. Six-ml aliquots of the extract were diluted and passed through the Bond Elut columns according to the procedure described above. Radioactivity was determined in both the crude lipid extract and in the lipid fraction eluted from the column using double label liquid scintillation counting.

Method 2. Method 2 was a slight modification of method 1. After a first dilution of the crude extract with methanol/water (1:1, v/v) and a column elution step identical to method 1, the second and third dilutions and column elution steps were carried out with methanol/0.9% saline (1:1, v/v). The column was then washed with 2 ml water to remove salt before elution of the lipids. The lipids were then eluted in two fractions, the first (I) with two 4-ml portions of methanol/water (12:1, v/v) and the second (II) with two 4-ml portions of chloroform/methanol (1:2, v/v).

The reference partitioning method was performed as described above for method 1, except that after aspiration of the upper phase the surface was rinsed with two 1-ml portions of TUP. The combined upper phases were diluted with methanol to 8 ml.

Unidirectional TLC was done on all fractions in method 2 and reference methods. The plate was developed in chloroform/methanol/water (65:25:4, v/v/v) and visualized by charring (10). The ganglioside-containing fractions were also developed in chloroform/methanol/0.25% $CaCl_2$ (60:35:8, v/v/v). Identification of the individual lipid bands was done as for method 1. To separate phosphatidylserine and phosphatidylinositol, the same bidirectional TLC was performed as described for method 1. Gangliosides were identified by development of blue color after charring with a modified reagent, which also contained 1 ml 3% resorcinol solution added to 100 ml of the original reagent (10) used in method 1. Individual gangliosides were identified tentatively.

Phospholipids and cholesterol were determined on fractions I and II of method 2 and on the lower phase of the reference method as described above. Sialic acid was analyzed, without a prior dialysis, by the method of Svennerholm (11), modified by Miettinen and Takki-Luukkainen (12). A slight modification was made in adding 1-butanol to the samples prior to color development. Thus, samples that also contained lipids other than gangliosides were completely dissolved in the reaction mixture. Aliquots of the lipid extracts were sampled into narrow 10-ml screw cap tubes and evaporated to dryness in a stream of nitrogen. To the dried samples, 0.38 ml 1-butanol was added, and the tubes were vortexed. Then 1.2 ml water or sialic acid standard solution in water, containing 7.5, 15.0 and 22.5 μg sialic acid, followed by 1.2 ml resorcinol reagent was added, and the tubes were vortexed again. The butanol was completely dissolved in the reaction mixture. The tubes were heated in a boiling water bath for 30 min. To the tubes, when they had cooled, 2.13 ml butyl acetate was added. The tubes were vortexed and then centrifuged at 2000 × g for 5 min. The clear upper layer was read on a spectrophotometer at 580 nm. Since a slight discoloring was observed in the crude extract samples, sample blanks of the corresponding amount of ganglioside-free brain lipids were run throughout the procedure. The sample blank readings were subtracted from the sample readings.

RESULTS

The simplified reversed-phase column procedure (method 1) presented in this report and the reference partitioning method resulted in almost the same quantitative recovery of cholesterol and phospholipids. (Total phospholipids [mg ± S.D.]: method 1, 12.4 ± 0.28; reference method, 12.0 ± 0.13. Cholesterol: method 1, 4.83 ± 0.14; reference method, 4.76 ± 0.06.) The recovery of radioactive phosphatidylcholine was high and the added [^{3}H]labeled glucose was effectively washed away from the column (Table 1). Almost all the bound lipid (>99%) was eluted

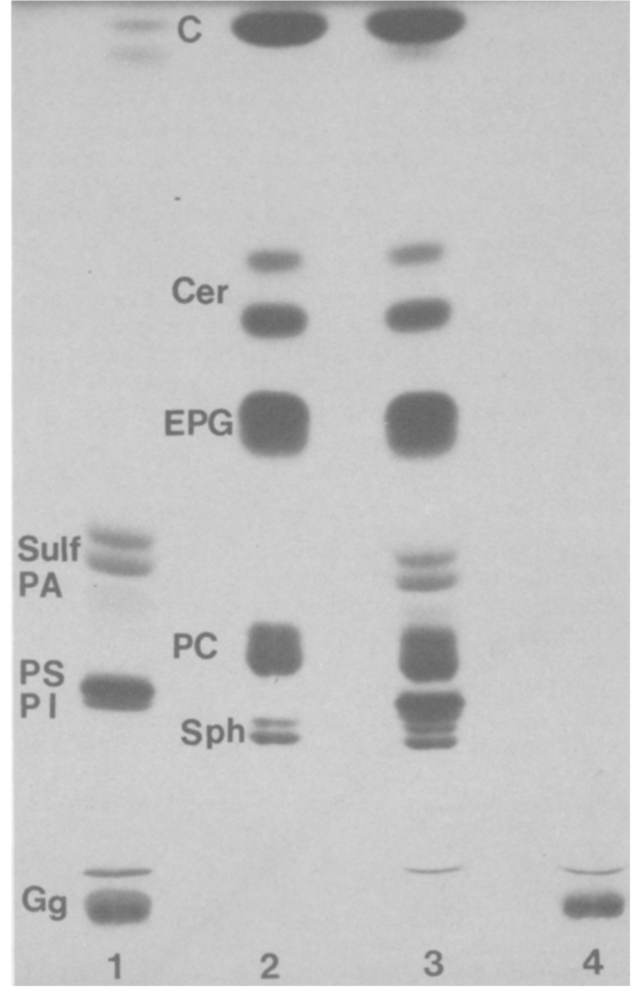

FIG. 1. A unidirectional thin layer chromatograph of a brain lipid extract purified with method 2 on C-18 Bond Elut reversed-phase columns and of a reference method. The plate was developed in chloroform/methanol/water (65:25:4, v/v/v) and visualized by charring. Lane 1, fraction I; lane 2, fraction II; lane 3, lower phase of reference method; lane 4, upper phase of reference method; C, cholesterol and neutral lipids; Cer, cerebrosides; Sulf, sulfatides; EPG, ethanolamine phosphoglycerides; PC, choline phosphoglycerides; PA, phosphatidic acid; PI, phosphatidylinositol; PS, phosphatidylserine; Sph, sphingomyelin; Gg, gangliosides.

with the first two portions of chloroform/methanol (1:2, v/v), and the final portion eluted contained no detectable lipid. However, the eluate of method 1 was more contaminated by gangliosides than the lower phase of the partitioning method (about 20% of the total sialic acid content). Ninhydrin positive spots were not observed after TLC other than for serine and ethanolamine phosphoglycerides (data not shown).

Besides a high recovery of cholesterol and phospholipids in method 2, a high recovery and a low variation between samples was obtained for the gangliosides in this method (Table 2). As indicated in Figures 1 and 2, two well-characterized fractions were eluted in method 2. Fraction I contained gangliosides, acidic phospholipids (phosphatidylserine, phosphatidylinositol, phosphatidic acid) and sulfatides, and fraction II neutral phospholipids (ethanolamine and choline phospholipids, sphingomyelin and cerebrosides). In fraction II, 97% of the cholesterol was eluted; 3% of the cholesterol or cholesterol derivatives was eluted with fraction I. No contamination of gangliosides could be observed in fraction II (Table 2 and Fig. 2). However, in the reference method there was a lower recovery of the bands corresponding to G_{M1} and G_{M3} gangliosides compared to method 2 (Figs. 1 and 2).

DISCUSSION

Using the common partitioning method according to Folch et al. (1), the lipids and the contaminants exist in two liquid phases of about equal volume. Therefore, after aspiration of the upper layer, the surface of the lower layer has to be washed repeatedly to ensure dilution of residual contaminants. In so doing, there is always the possibility of removing some of the lower phase or interfacial fluff. However, with the reversed-phase column methods, the lipids become bound to the column and occupy a very

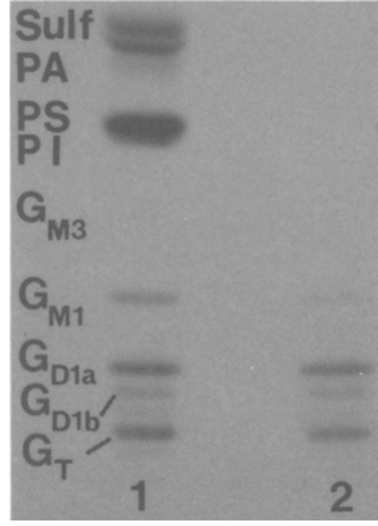

FIG. 2. A unidirectional thin layer chromatograph of a brain lipid extract purified with method 2 on C-18 Bond Elut reversed-phase columns and of a reference method. The plate was developed in chloroform/methanol/0.25% $CaCl_2$ (60:35:8, v/v/v) and visualized by charring. Lane 1, fraction I; lane 2, upper phase of reference method; Sulf, sulfatides; PA, phosphatidic acid; PI, phosphatidylinositol; PS, phosphatidylserine; gangliosides G_{M3}, G_{M1}, G_{D1a}, G_{D1b} and G_T (nomenclature by Svennerholm).

small volume. The polar contaminants remain in solution in the very diluted aqueous phase. The bound lipids can then be directly eluted with a known volume of a less polar solvent and quantitatively determined.

The principle for the presented methods was to start with a lipid extract in a less polar solvent and, by stepwise dilution, to obtain a successively more polar solvent without phase separation. However, phase separation will occur if the water content or the salt concentration is further increased. As a consequence, the first dilution of the extract cannot be done with saline or with a higher water content.

A successful purification of the lipid extract by the reversed-phase column methods was evident from the complete removal of added labeled glucose and the absence of ninhydrin positive spots other than lipids after TLC. The presented methods were also as accurate as the reference method for quantitative lipid determinations. For gangliosides, method 2 had an even better recovery than the reference method. An advantage of the presented methods was that they take less time, since several samples can be run in parallel and no solvent evaporations are necessary (max. 90 min from crude to purified and/or fractionated extract). Furthermore, there is an obvious advantage in the direct separation of the components in the two fractions I and II. Thus a separate ion-exchange step to separate acidic from neutral phospholipids (13) is unnecessary. We feel that the methods presented here for the purification and partial fractionation of crude lipid extracts have several applications for routine lipid analytical work and that they are very suitable for automation.

Fate of 7,12-Dimethylbenz(*a*)anthracene Absorbed from the Rat Intestine and Transported in Chylomicrons

Mats B. Lindstrom*, **James A. Barrowman**[1] and **Bengt Borgstrom**
Department of Physiological Chemistry, University of Lund, PO Box 94, S-221 00 Lund, Sweden

Chylomicrons obtained from the thoracic duct of rats fed [^{3}H]7,12-dimethylbenz(*a*)anthracene (DMBA), a polycyclic aromatic hydrocarbon, were infused intravenously into rats with bile fistulas. Over 17 hr, 55.9 ± 3.2% (mean ± SEM) of the radioactivity was recovered in bile and 6.7 ± 0.5% in urine. Minor amounts were deposited in liver, kidneys and epididymal fat pads. Injection of DMBA in ethanolic solution gave a similar pattern, while biliary DMBA metabolites resulted in higher recovery in urine and lower recovery in fat. In conclusion, the major part of chylomicron DMBA is rapidly excreted via the biliary route, while a fraction is probably retained in adipose tissue.
Lipids 22, 278–281 (1987).

Polycyclic aromatic hydrocarbons (PAH), which constitute a major class of lipophilic xenobiotics of environmental and toxicological importance, are formed during incomplete combustion of fossil fuels and as a result of food processing (1). This group of nonpolar compounds contains several well-recognized carcinogens, such as benzo(*a*)pyrene, 3-methylcholanthrene and 7,12-dimethylbenz(*a*)anthracene (DMBA). DMBA is a potent mammary carcinogen, extensively used in experimental studies in rodents (2). It is readily absorbed from the gastrointestinal tract when presented as a solute in dietary lipid (3). The major proportion of DMBA taken up by the enterocyte is metabolized and transported to the liver via the portal venous blood (4), which is followed by biliary excretion and enterohepatic circulation of the metabolites. However, some of the absorbed DMBA passes through the enterocyte unmetabolized and is transported by the lymph as a solute of the triglyceride core of chylomicrons (5). The fate of DMBA that escapes metabolism in the enterocyte is of interest, since the compound has the opportunity to reach peripheral tissues. The aim of this investigation was to examine the fate of DMBA reaching the systemic circulation as a chylomicron solute.

MATERIALS AND METHODS

Chemicals. [G-^{3}H]7,12-dimethylbenz(*a*)anthracene (Amersham, Little Chalfont, United Kingdom) was 97.8% pure according to the manufacturer. Unlabeled DMBA was obtained from Sigma (St. Louis, Missouri).

Preparation of chylomicrons containing [^{3}H]DMBA from "donor" rats. Male Sprague-Dawley rats (ALAB, Stockholm, Sweden) weighing 250–350 g and fed a standard pellet diet were used for the study. On the day before surgery, solid food was withdrawn, and rats were allowed to drink ad libitum a glucose-saline solution containing 2.5% glucose, 0.5% NaCl and 0.05% KCl (w/v). Under ether anesthesia, the infradiaphragmatic portion of the thoracic duct was cannulated with clear vinyl tubing (SV 31, id 0.50 mm, od 0.80 mm; Dural Plastics and Engineering, Dural, N.S.W., Australia). A duodenal catheter of the same tubing was introduced through the antrum of the stomach. It was secured with a purse-string suture in the stomach wall, and the tip was located about 2 cm distal to the pyloric sphincter. Both catheters were led out through stab wounds in the flank. Postoperatively, the animals were kept in restraining cages at 30 C and infused intraduodenally with the glucose-saline solution at 1.8 ml/hr. Approximately 24 hr after surgery, the rats received over one hour an intraduodenal infusion of 1 ml corn oil containing 5 nmol [^{3}H]DMBA (sp act 50 μCi/nmol). Lymph was collected in 30-min samples, and the samples containing the highest amounts of radioactivity (about 2–4 hr after start of the [^{3}H]DMBA-corn oil infusion) were pooled. The lymph was diluted with a solution containing 1.1% NaCl and was centrifuged in a 6 × 14 ml swing-out rotor for 2 hr at 10 C in polycarbonate tubes at 25,000 rpm (g_{av} = 75,000) in an MSE prepspin 50 centrifuge. The supernatant layer containing the chylomicrons was harvested after tube slicing. Thin layer chromatography (TLC) of chylomicrons was carried out on silicic acid plates (Kieselgel 60 on alumina; Merck, Darmstadt, Federal Republic of Germany) to determine the identity of the ^{3}H activity. Aliquots of the chylomicron fraction were put directly on the plates, which were developed with ether/hexane (5:95, v/v). Unlabeled DMBA used as reference was visualized with iodine vapor, and the corresponding area containing [^{3}H]DMBA was cut out and radioactivity was measured after addition of 10 ml of Emulsifier Scintillator 299 (Packard Instruments Co., Downers Grove, Illinois).

Intravenous infusion of chylomicrons containing [^{3}H]DMBA into "recipient" rats. Recipient rats were treated in the same way as donor rats before surgery. Under ether anesthesia, the bile duct was cannulated near the hilum of the liver with a 5-mm-long polyethylene tubing (PP 10; 0.28 mm id, 0.61 mm od; Portex, Hithe, United Kingdom) connected to an SV 31 clear vinyl tubing, which was led out through a stab wound in the flank. An intravenous infusion was set up through a tail vein by passing a PP 10 catheter through an 18-gauge hypodermic needle (Yale no. 5196; Becton Dickinson, Mississauga, Ontario, Canada) and securing the catheter with a drop of cyanoacrylate glue. After surgery, the rats were kept in restraining cages at 30 C, and during the whole experiment (except when radiolabeled infusates were administered) were given an intravenous infusion of 145 mM NaCl and 5 mM KCl at 0.6 ml/hr. The day after surgery the recipient rats received a tail vein infusion at a rate of 0.6 ml/hr over 1.5 hr of radiolabeled chylomicrons (containing ca. 10 pmol DMBA; chylomicrons

were prepared from lymph of 1–3 donor rats) resuspended in a solution containing 145 mM NaCl and 5 mM KCl (this infusate is denoted as DMBA-CM in the following). Bile samples were continuously collected before, during and after this infusion. Urine was also continuously collected from the start of the chylomicron infusion. For comparison, a group of rats with biliary fistulas and intravenous tail vein catheters received over 1.5 hr an infusion of rat serum to which had been added an ethanolic solution of [^{3}H]DMBA (ca. 5 nmol [^{3}H]DMBA in 50 μl ethanol + rat serum to a total volume of 1 ml [DMBA-ES infusate]). Bile, urine and tissue samples were collected as described above. An additional group of rats received over 1.5 hr an intravenous infusion of bile (DMBA-BM infusate; containing ca. 200 pmol of DMBA metabolites) collected from the DMBA-ES rats. Consequently this bile (collected during the first 7 hr after start of the DMBA-ES infusion) contained biliary metabolites of [^{3}H]DMBA. After 22 hr, the DMBA-ES and DMBA-BM rats were killed. The liver, kidneys and epididymal fat pads were excised and weighed, and samples were taken for radioactivity counting. For practical reasons, due to the time needed for preparation of fresh chylomicrons, the DMBA-CM rats were killed after 17 hr instead of 22 hr.

Radioactivity measurements. Aliquots of lymph, bile and urine were brought to a total volume of 1 ml by addition of distilled water and were mixed with 10 ml Emulsifier Scintillator 299 (Packard) for liquid scintillation counting in a Packard Tri-Carb 4530. Aliquots of tissue (ca. 100 mg) were dissolved at 55 C overnight in 1 ml of Soluene 350 (Packard) before addition of 10 ml Dimilume-30 (Packard).

Statistics. Data are expressed as mean ± standard error of the mean (SEM). Statistical analyses were performed using Student's t-test.

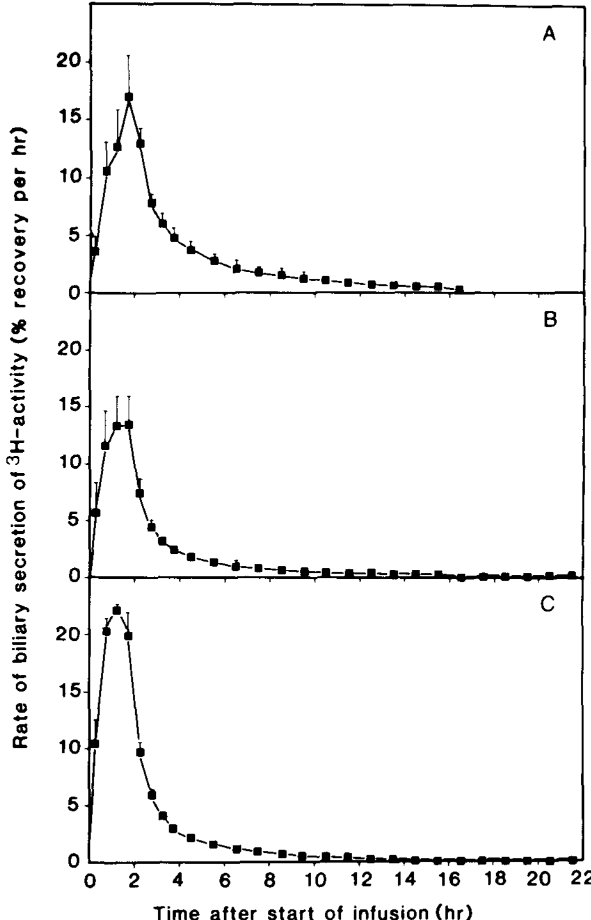

FIG. 1. Rate of biliary secretion of ^{3}H activity as a function of time after start of a 1.5-hr intravenous infusion of [^{3}H]DMBA-labeled chylomicrons (A), of [^{3}H]DMBA in ethanol solution mixed with rat serum (B) or of biliary [^{3}H]DMBA metabolites in bile (C) to rats with bile fistulas. Secretion rate is expressed as % recovery/hr of the total dose infused. Points represent mean ± SEM of values obtained from 6 (A and C) or 7 (B) rats.

RESULTS

TLC showed that practically all the radiolabel (>99%) was present as the native compound in the chylomicrons obtained from rats with lymph fistulas that were fed [^{3}H]DMBA.

When DMBA-CM (chylomicrons containing DMBA) were infused intravenously, the radiolabel rapidly appeared in bile, as is shown in Figure 1A. The major part of the total amount recovered in bile was secreted within 4 hr after start of the infusion. During the following period of the experiment, the biliary secretion rate was constantly low.

A similar pattern of biliary radiolabel secretion was obtained when DMBA-ES (DMBA dispersed in ethanol and serum) (Fig. 1B) and DMBA-BM (biliary metabolites of DMBA) were infused (Fig. 1C). Figure 2 shows the cumulative recovery of radiolabel during the first 3 hr, which was higher for DMBA-BM than for DMBA-CM 3 hr after the start of infusion ($p < 0.05$). The difference in recovery after 3 hr between DMBA-CM and DMBA-ES was not significant.

Table 1 shows the recovery of ^{3}H activity in bile, urine and some tissues after intravenous infusion of DMBA-CM, DMBA-ES or DMBA-BM. In the case of DMBA-CM, the major amount was recovered in the bile (55.9 ± 3.2%), whereas a minor portion was found in the urine (6.7 ± 0.5%). Similar results were obtained when DMBA-ES was infused, whereas the urinary recovery of radiolabel in rats receiving DMBA-BM was considerably greater than in animals receiving DMBA-CM. However, the major excretory route was bile in all three groups.

DISCUSSION

The present study shows that a proportion of DMBA absorbed from the small intestine is transported unmetabolized as a chylomicron solute. The major proportion of DMBA injected intravenously as chylomicron solutes in this study was recovered in bile, and the pattern of recovery was close to that obtained when the compound was given by intravenous injection as an ethanolic solution in serum. The necessity of metabolic transformation of DMBA by the liver prior to biliary excretion could account for the fact that ^{3}H activity appeared at a slower rate after infusion of DMBA-CM or DMBA-ES compared to DMBA-BM. Relatively little radioactivity appeared in the urine when DMBA-CM or DMBA-ES was infused; this is presumably derived from polar metabolites of DMBA that have entered the systemic circulation. Tissue

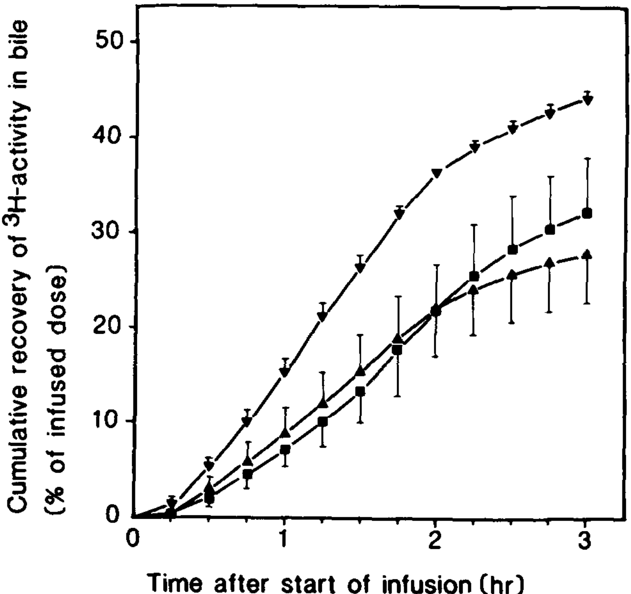

FIG. 2. Cumulative recovery of ^{3}H activity in bile as a function of time after start of a 1.5-hr intravenous infusion of [^{3}H]DMBA-labeled chylomicrons (■), of [^{3}H]DMBA in ethanol solution mixed with rat serum (▲), or of biliary [^{3}H]DMBA metabolites in bile (▼) to rats with bile fistulas. Points represent mean ± SEM of values obtained from 6 (■ and ▼) or 7 (▲) rats.

TABLE 1

Recovery of ^{3}H Activity 17 Hr (DMBA-CM) or 22 Hr (DMBA-ES and DMBA-BM) After Start of a 1.5-Hr Intravenous Infusion of [^{3}H]DMBA or Biliary [^{3}H]DMBA Metabolites to Rats with Bile Fistulas[a]

	DMBA-CM (n = 6)	DMBA-ES (n = 7)	DMBA-BM (n = 6)
Bile	55.86 ± 3.21	40.85 ± 4.85	58.40 ± 1.03
Urine	6.73 ± 0.52	3.42 ± 0.59	22.87 ± 1.06
Liver	3.73 ± 0.45	1.04 ± 0.04	2.39 ± 0.05
Kidneys	1.04 ± 0.17	0.20 ± 0.04	2.94 ± 0.11
Epididymal fat pads	0.55 ± 0.05	0.13 ± 0.04	0.03 ± 0.01
Total recovery	67.91 ± 4.03	45.64 ± 4.94	86.63 ± 1.85

[a]Data are expressed as mean ± SEM. DMBA-CM, [^{3}H]DMBA-labeled chylomicrons obtained from thoracic duct lymph from rats given an intraduodenal infusion of [^{3}H]DMBA as a solute in corn oil; DMBA-ES, [^{3}H]DMBA in ethanol solution mixed with rat serum before the intravenous infusion; DMBA-BM, biliary metabolites of [^{3}H]DMBA obtained from rats with bile fistulas that were given an intravenous infusion of [^{3}H]DMBA in ethanol solution mixed with rat serum.

levels at 17 hr were low; there was, however, a small deposition of DMBA in epididymal adipose tissue, which was greater than that observed when the compound was given in ethanolic solution. Only trace amounts of radiolabel were recovered in fat tissue when the biliary metabolites of DMBA were given. From Figure 1 it is evident that after ca. 12 hr the difference in biliary secretion rate of ^{3}H activity between the three experimental groups is negligible. Consequently, the fact that the rats were killed after 17 or 22 hr does not affect the results of the experiment, since no significant changes in tissue distribution occur between 17 and 22 hr.

There is a substantial proportion of administered radiolabel that was not accounted for. This was presumably distributed among other tissues. With the assumption that DMBA is handled similarly by all forms of adipose tissue, which constitutes 7.08% of body weight (6), the total recovery of ^{3}H activity in adipose tissue has been estimated to be 15.7 ± 4.4% 17 hr after infusion of DMBA-CM. One tissue not examined that might have contained appreciable amounts of the compound is lung, since a study of benzo(*a*)pyrene disposition after intravenous injection of chylomicrons mixed with the radiolabeled hydrocarbon showed that lung contained higher amounts of radioactivity per unit weight of tissue than liver, kidneys, brain, muscle, fat or ovaries (7). Another possibility not examined was fecal excretion as a result of transintestinal secretion.

Many nutrient and non-nutrient lipid-soluble compounds in the diet travel in lymph as core solutes in chylomicrons. These include fat-soluble vitamins, cholesteryl esters, DDT (8) and PAH (9). The major part of chylomicron triglyceride is taken up in extrahepatic tissue as a result of lipoprotein lipase activity; >80% of the cholesteryl esters of chylomicrons are taken up by the liver via chylomicron remnants (10). Vitamin A esters are a relatively nonexchangeable component of chylomicrons and their remnants and are taken up quantitatively by the liver with the remnants (11). By contrast, significant amounts of vitamin D_3 are transferred from chylomicrons to other plasma fractions (12). Whether DMBA remains with chylomicron remnants like vitamin A esters or exchanges with other plasma lipoprotein fractions is not known. Benzo(*a*)pyrene has been reported to transfer from chylomicrons to the low density lipoprotein (LDL) and the high density lipoprotein (HDL) fractions (7,13).

The present results suggest that DMBA in chylomicron triglyceride is largely available for liver metabolism followed by biliary excretion, but that deposition of the compound in adipose and other tissues also has to be considered. However, several aspects of transfer of DMBA between lipoprotein classes as well as uptake into and elimination from different organs remain to be investigated before the principles determining the fate of this PAH can be established.

[Received October 17, 1986]

Effect of Environmental Temperature Changes on Liver Δ6 and Δ5 Fatty Acid Desaturases Depressed by Hyperglycidic Diet on Male Rats

Ana Ves Losada and **Raúl O. Peluffo***
Instituto de Investigaciones Bioquimicas de La Plata (INIBIOLP), CONICET-UNLP, Facultad de Ciencias Médicas, calles 60 y 120, (1900) La Plata, Argentina

Male rats maintained on a control diet at 24 C and shifted to 12 C for five days showed no modification in Δ6 or Δ5 desaturase activity. When Δ6 and Δ5 desaturase activities were diminished by a hyperglycidic diet, shifting to cold increased both enzymatic activities. In general, modifications observed in liver microsomal fatty acid composition are consistent with those associated with the enzymatic desaturation activity.
Lipids 22, 282-284 (1987).

A response of poikilotherms to environmental temperature changes is the alteration of membrane lipid composition associated with the degree of unsaturation of fatty acids (1,2).

While the metabolic basis for increasing unsaturation is not entirely clear, there is evidence that cold-adapted organisms show higher rates of production of unsaturated acids than do warm-adapted organisms (3-5). Thus, enhanced rates of desaturation may account for some of the fatty acid composition changes that accompany cold adaptation. In eucaryotic organisms, the endoplasmic reticulum could constitute a kind of self-regulated system for maintaining an optimal physical state by means of activation or deactivation of desaturation reactions.

The effect of temperature on membrane fluidity is not as obvious in homeothermic animals as in poikilotherms. In previous studies done in this laboratory (6) in which female rats were adapted to warm temperature (30-32 C) for 20-25 days and then shifted to colder temperature (13-15 C) for different periods of time, Δ6 and Δ5 desaturase activities increased 24 hr after cold exposure. Male rats adapted under the same conditions did not show significant changes in Δ6 desaturase activity.

Since a hyperglycidic diet (HD) depressed Δ6 desaturase activity, it was thought that, starting from decreased enzymatic activity levels, it would be possible to observe in male rats an increase of this enzyme due to cold temperature.

For this purpose, male rats were fed on HD and shifted to different temperatures. Activities of Δ6 and Δ5 desaturase and hepatic microsomal fatty acid composition were determined.

MATERIALS AND METHODS

[1-^{14}C]Linoleic acid (54.7 mCi/mmol, 98.5% radiochemically pure, 1% *trans* isomer) and [1-^{14}C]eicosa-8,11,14-trienoic acid (54.9 mCi/mmol, 99% radiochemically pure, <3% *trans* isomer) were purchased from New England Nuclear (Boston, Massachusetts). Cofactors used for the enzymatic reactions were provided by Sigma Chemical Co. (St. Louis, Missouri) and all unlabeled fatty acids were from Nu-Chek Prep (Elysian, Minnesota). All chemicals and solvents were of analytical grade.

Animals and their treatment. White male Wistar rats, 60-75 days old and weighing 190-220 g, were maintained on Cargill rat chow and housed individually in temperature-controlled rooms at 24 ± 1 C. All animals were subjected daily to 12 hr light and 12 hr darkness, with midnight being the midpoint of the dark period.

The animals were divided into two groups of 15 animals, fed different isocaloric diets (4.4 cal/g food) and maintained for two days at 24 ± 1 C. Food and tap water were given ad libitum. One group received a control diet (CD) and the other HD. After this period, each group was subdivided into three groups of five animals, each with the same dietary conditions. One group from each diet was shifted to a cold room at 12 ± 1 C (group I [CD] and group II [HD]); two other groups were maintained at the same temperature (group III [CD] and group IV [HD]) and the last two groups transferred to a warmed room at 31 ± 1 C (group V [CD] and group VI [HD]). After five days under these conditions, the animals were killed at 8 a.m. to avoid circadian effects (7), and liver microsomes were isolated as described previously (6).

The diets contained equal amounts of salts and vitamins (8), casein, maize oil, glucose and starch, which were used as sources of protein, fat and carbohydrate, respectively. In the CD, 55, 20 and 25% of the calories were supplied as carbohydrate (100% starch), protein and fat. The distribution of calories in the HD was as follows: 69% carbohydrate (62% starch and 38% glucose), 6% protein and 25% fat.

Enzymatic assays. Reactions were initiated by the addition of microsomal protein to preincubated flasks containing 0.25 M sucrose, 0.15 M KCl, 0.04 M potassium phosphate buffer (pH 7.2), 1.41 mM N-acetyl cysteine, 0.04 M KF, 1.3 mM ATP, 0.06 mM CoA, 0.87 mM NADH, 5 mM $MgCl_2$, 5 nmol [1-^{14}C]labeled acid and 45 nmol unlabeled acid in a final volume of 1.6 ml. For Δ6 desaturase assays, linoleic acid was used as substrate and 3 mg of protein; for Δ5 desaturase assays, the substrate was eicosa-8,11,14-trienoic acid and 2 mg of microsomal protein. Reaction mixtures were incubated with constant shaking at 36 C for 15 min.

The protein was determined by the Lowry procedure using crystalline bovine serum albumin as standard (9). The desaturation reaction was stopped by addition of 2 ml of 10% KOH in ethanol. The fatty acids were recovered by saponification of the incubation mixture (45 min at 82 C), acidification and extraction with petroleum ether (bp 30-40 C). The fatty acids were esterified with methanolic 3 M HCl (1 hr at 64 C).

The analyses were carried out by gas liquid radiochromatography in a Model 893 Packard apparatus equipped with a proportional counter using GP 10% SP 2330 on Chromosorb WAW (100-120 mesh) (10).

The relative radioactivity in [1-^{14}C]substrate and [1-^{14}C]product was determined by measuring the area of

*To whom correspondence should be addressed. Member of the Carrera del Investigador Científico, Consejo Nacional de Investigaciones Científicas y Técnicas.

the counter output peaks by triangulation in the radiochromatograms.

Fatty acid analysis. Total microsomal lipids were extracted using the method of Folch et al. (11), and methyl esters were prepared and analyzed by gas liquid chromatography in a Hewlett-Packard model 5840-A chromatograph equipped with the 5840-A 6C terminal and using a 6-ft column filled with 10% SP 2330 on 100/200 mesh Chromosorb WAW.

Statistical analysis. Data were analyzed by the two-way analysis of variance and Duncan's Multiple Range test.

RESULTS AND DISCUSSION

The effect of environmental temperature observed in rats feeding on CD and HD on Δ6 and Δ5 desaturase activities is shown in Figure 1.

The enzymatic activity of Δ6 desaturase was not modified in those rats on a CD adapted to temperatures of 31 and 12 C when compared to those at 24 C (Fig. 1). These results agree with those of González et al. (6), which showed no significant differences in Δ6 desaturase activity in male rats previously warm-adapted (20–25 days at 31 C) and then shifted to 14 C for 5 days. However, in female rats, an increase in the activity of Δ6 desaturase was observed, and this change was related to estradiol levels (12).

On the contrary, a decrease of the environmental temperature to 12 C evoked an increase of the Δ6 desaturase activity in those rats fed a diet rich in carbohydrates compared to animals maintained at 24 and 31 C.

Peluffo and Brenner (13) found that Δ6 desaturase enzymatic activity in rats kept at 24 C is not modified when isocaloric diets are given in which 5, 15 or 25% of the calories is supplied by proteins. On the other hand, diets with a high carbohydrate content (15,19) decrease Δ6 desaturase enzymatic activity. We may suppose, therefore, that the decrease observed in Δ6 desaturase enzymatic activity at 24 and 31 C as a consequence of the hyperglycidic diet (Fig. 1) is due to its high carbohydrate and not its low protein content. However, the decrease evoked at 12 C was not significant, suggesting that some factors counterbalanced the depressing effect of the hypercarbohydrate diet.

An increase in Δ5 desaturase activity was observed both in rats on a CD and those on a HD kept at 12 C compared to those at 31 C (Fig. 1). There was an increase in Δ5

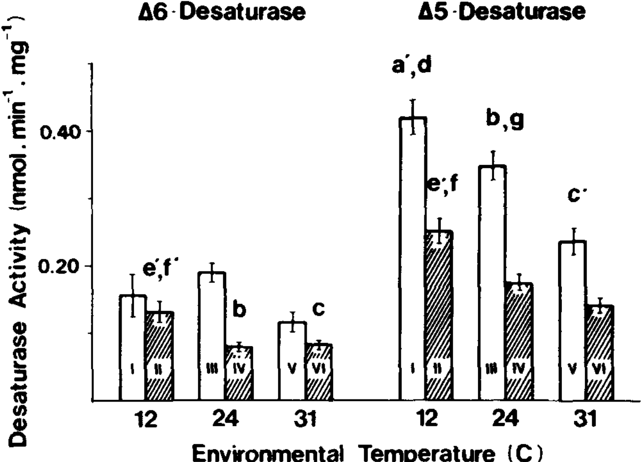

FIG. 1. Effect of environmental temperature on liver microsomal Δ6 and Δ5 desaturase activities in male rats fed control (open bars) and hyperglycidic (shaded bars) diets. Desaturase enzyme assays were carried out as described in Materials and Methods for the six groups of animals described in the text. Results are shown as the mean of 5 rats ± S.E. The type of group is shown within the columns. Letters above the bars indicate significant differences at 1%: a, group I vs group II; b, III vs IV; c, V vs VI; d, I vs V; e, II vs IV; f, II vs VI; and g, III vs V; a', c', e' and f' indicate significant differences at 5%.

Fatty acid composition was determined by gas liquid chromatography as described in Materials and Methods for the 6 groups of animals described in the text. Only main fatty acids were considered. Results are shown as mean of 5 rats ± S.E. Letters indicate significant differences at 1%: *a*, group I vs group II; *b*, III vs IV; *c*, V vs VI; *d*, I vs III; *e*, I vs V; *f*, III vs V; *g*, II vs IV; *h*, II vs VI; *i*, IV vs VI; *a'*, *b'*, *c'*, *f'*, *g'*, *h'* and *i'* indicate significant differences at 5%.

desaturase activity only in HD rats kept at 12 C compared to those at 24 C. The highest activity was observed in the animals kept at the lowest temperatures.

The Δ5 desaturase enzymatic activity decreased in animals on a HD compared to rats on a CD, irrespective of environmental temperature.

Although we do not know the mechanism of the HD effect, we do know that epinephrine (16,17) and cAMP (17) evoke a decrease of fatty acid desaturase activity. Moreover, glucocorticoids also induce a decrease of desaturase activity (18). However, Jeffcoat and James (19) were unable to detect a decrease of Δ5 desaturase activity when feeding rats a diet rich in sucrose.

Fatty acid composition of lipids was also studied, since changes in microsomal desaturation can be detected in microsomal lipids (20). In this respect, animals fed a HD and kept at 12 C show a higher unsaturation index than animals kept at 24 and 31 C. This could be related to an increase of Δ6 and Δ5 desaturation. The effect of the HD is shown in Table 1. In all animals, the decrease in the 20:4n-6/18:2n-6 ratio is in accord with a decrease of Δ6 and Δ5 desaturase activities (Fig. 1). However, in those rats kept at 12 C, no modification in Δ6 desaturase activity was observed.

Rats kept on CD and HD at 12 C showed a decrease in 20:3n-6 and an increase in 20:4n-6 compared to those groups at higher temperatures; these changes could be attributed to the increase of Δ5 desaturase activity caused by low temperature.

In conclusion, results suggest that cold evokes an increase of Δ6 and Δ5 desaturase activities when these enzymes are suppressed by dietary factors, such as a hyperglycidic diet.

[Received August 20, 1986]

1-Acyl-2-acetyl-*sn*-glycero-3-phosphocholine from Stimulated Human Polymorphonuclear Leukocytes

Kiyoshi Satouchi[a], Makoto Oda[b] and Kunihiko Saito[a]
[a]Department of Medical Chemistry and [b]The First Department of Internal Medicine, Kansai Medical School, Moriguchi Osaka 570, Japan

1-Acyl-2-acetyl-*sn*-glycero-3-phosphocholine (1-acyl-2-acetyl GPC) was found in the fraction of platelet-activating factor obtained from stimulated human polymorphonuclear leukocytes (PMN). The amount of 1-acyl-2-acetyl GPC obtained from 1 × 10^7 PMN stimulated with ionophore A23187 at 37 C for 15 min ranged from 8 to 56 pmol (32 ± 10 pmol, mean ± standard error; n = 4). The main species was 16:0 palmitoyl (17 ± 5 pmol), followed by 18:0 stearoyl (8 ± 3 pmol) and 18:1 oleoyl (7 ± 3 pmol).

Although the physiological significance is unknown, 1-acyl-2-acetyl GPC was always detected when 1-alkyl-2-acetyl GPC was detected.
Lipids 22, 285–287 (1987).

The platelet-activating factor (PAF) generated by human polymorphonuclear leukocytes (PMN) was identified by selected ion monitoring (SIM) and fast atom bombardment mass spectrometry (FAB-MS) as 1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (1-alkyl-2-acetyl GPC), composed mainly of 16:0 1-hexadecyl-2-acetyl species (1–3). [The abbreviation PAF refers to biological activity. To avoid confusion, each molecular species of 1-alkyl-2-acetyl GPC is termed by its systematic name and each species of 1-acyl-2-acetyl GPC by its trivial name.] At the same time, it was shown by mass spectrometry that 1-acyl-2-acetyl-*sn*-glycero-3-phosphocholine (1-acyl-2-acetyl GPC), in which a fatty acyl group is substituted for a long chain alcohol at the *sn*-1 position, is generated by stimulated rabbit PMN and that its predominant species was 16:0 palmitoyl, followed by 18:1 oleoyl and 18:0 stearoyl (4).

A well-known potential of 1-acyl-2-acetyl GPC is its ability to compete with 1-alkyl-2-acetyl GPC for acetylhydrolase (5,6). Recently, cell-associated PAF generated by PMN stimulated with formyl-methionyl-leucyl-phenylalanine (FMLP) was shown to act as a feedback inhibitor of PAF biosynthesis (7).

In this work, we extended our previous studies (4) by SIM examination to the PAF fraction from stimulated human PMN, and we also examined the potential role of 1-acyl-2-acetyl GPC.

MATERIALS AND METHODS

Chemicals. The chemotactic peptide FMLP was purchased from the Protein Research Foundation (Osaka, Japan). Calcium ionophore A23187 was obtained from Calbiochem-Behring (San Diego, California). 1-Acyl-2-acetyl GPC, a mixture of the palmitoyl and stearoyl species (2:1, w/w), was synthesized by mixing acetic anhydride and the respective lysocholine phosphoglycerides (4). Sources of other chemicals were as described in our recent publications (4,8,9).

Isolation of PMN and platelets. The procedure for isolation of human PMN, involving dextran sedimentation, Ficoll-paque gradient centrifugation and hypotonic treatment to lyse erythrocytes, was described previously (8). Preparation of washed rabbit platelets essentially following the method of Pinckard et al. (10) has been described previously in further detail (9). Human platelet-rich plasma (PRP) was prepared by centrifuging citrated blood at 225 × g for 15 min at 25 C.

SIM analysis of molecular species. Human PMN from 100 ml of citrated blood were resuspended at a concentration of 6 × 10^6 cells/ml in Tyrode's solution containing 0.25% bovine serum albumin (BSA) and 1.3 mM $CaCl_2$. The procedures used to activate PMN and to extract, isolate and derivatize 1-alkyl-2-acetyl GPC and 1-acyl-2-acetyl GPC were as described previously (4). In the extraction step, 200 ng of 1-hexadecyl-2-acetyl-d_3 GPC and 100 ng of 1-heptadecanoyl-2-acetyl-d_3 GPC were added as internal standards. Lipids of interest were located from their positions relative to the standards, which were located by the rhodamine method (4). Three types of ions, $(CH_3CO+74)^+$, $(alkyl+130)^+$ and $(M-57)^+$, were monitored. Other conditions for SIM were as described previously (1).

Effect of 1-acyl-2-acetyl GPC on the production of PAF by PMN. Samples of 5 ml of human PMN (5 × 10^6 PMN/ml Tyrode's gelatin solution, pH 7.2, containing 1.3 mM $CaCl_2$) were preincubated with 1 × 10^{-10} M 1-acyl-2-acetyl GPC for 1 min at 37 C and then were stimulated with 1 × 10^{-6} M FMLP for 2.5 min. The reaction mixtures were transferred to other glass tubes, and total lipids were extracted by the systems of Bligh and Dyer (11). The lipid extract was suspended in 2.5 mg BSA/ml saline. The amount of PAF equivalents generated by PMN was measured as described (12) by aggregation of washed rabbit platelets, except for no addition of cycloxygenase inhibitor and ADP scavenger. 1-Hexadecyl-2-acetyl GPC was used as a standard, because human PMN produce this species predominantly (1–3).

RESULTS AND DISCUSSION

Simultaneous presence of 1-alkyl-2-acetyl GPC and 1-acyl-2-acetyl GPC. The presence of both 1-alkyl-2-acetyl GPC and 1-acyl-2-acetyl GPC in stimulated human PMN was demonstrated by SIM analysis of PAF samples before separation of the two types by thin layer chromatography (TLC). Upon monitoring at m/z 117, six peaks were recorded with retention times of 0′53″, 1′05″, 1′20″, 1′38″, 2′06″ and 2′36″ (Fig. 1). From comparison of their retention times with those of standards, as well as monitoring at m/z $(M-57)^+$, six molecular species were identified in the four main peaks: 1-hexadecyl-2-acetyl GPC (m/z 415, 1′05″), 1-palmitoyl-2-acetyl GPC (m/z 429, 1′20″), 1-octadecenyl-2-acetyl GPC (m/z 441, 1′36″), 1-octadecyl-2-acetyl GPC (m/z 443, 1′43″), 1-oleoyl-2-acetyl GPC (m/z 455, 2′00″) and 1-stearoyl-2-acetyl GPC (m/z 457, 2′05″), in order of their elutions. However, as stressed previously (4), it is necessary to consider the presence of odd-numbered 1-alkyl-2-acetyl GPC on the analysis of even-numbered 1-acyl-2-acetyl GPC. To this end, the spot

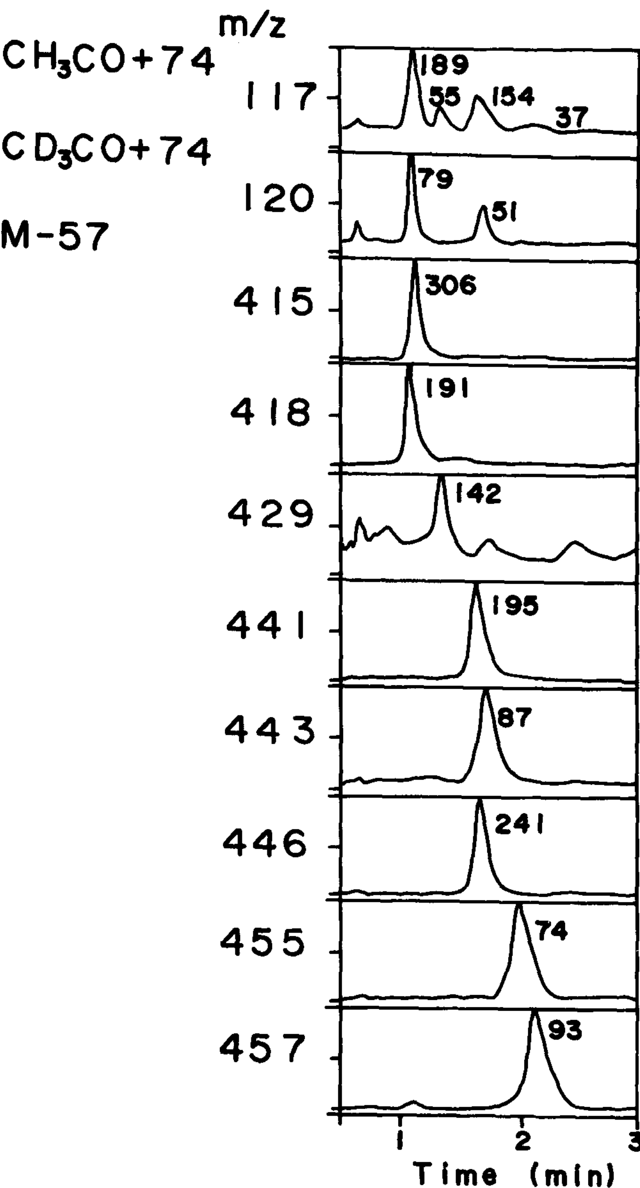

FIG. 1. Selected ion monitoring (SIM) trace of platelet-activating factor (PAF) sample from stimulated human polymorphonuclear leukocytes (PMN). Human PMN (1.2×10^8 cells) were challenged with 2.5×10^{-6} M ionophore A23187. The PAF fraction was purified from the cells plus medium and derivatized. SIM analyses were performed separately for the acetyl group and groups with molecular weights of the 1-alkyl-2-acetyl and 1-acyl-2-acetyl GPCs. The signals at m/z 418 and m/z 446 were those of ions of internal standards. Peak areas are shown on the right of each peak.

corresponding to 1-alkyl-2-acetyl-3-*tert*-butyldimethylsilyl (*t*-BDMS) glycerol was purified by TLC in hexane/diethylether (9:1, v/v) (1). By monitoring at m/z 117, the peaks at 1′20″ and 2′06″ almost disappeared, leading to the conclusion that the quantities of odd-numbered 1-alkyl-2-acetyl GPC are minute. Accordingly, simultaneous quantitations were performed using calibration curves of the $(M\text{-}57)^+$ ion of 1-alkyl-2-acetyl GPC (1,9) and 1-acyl-2-acetyl GPC (4). The amounts of 1-alkyl-2-acetyl GPC in 1×10^7 PMN (n = 4) were 94 ± 36 pmol (mean ± standard error) of 1-hexadecyl-2-acetyl GPC, 37 ± 13 pmol of 1-octadecenyl-2-acetyl GPC and 29 ± 12 pmol of 1-octadecyl-2-acetyl GPC. In contrast, one-fifth of this amount of 1-acyl-2-acetyl GPC was detected. The main species was 1-palmitoyl-2-acetyl GPC (17 ± 5 pmol), followed by 1-stearoyl-2-acetyl GPC (8 ± 3 pmol) and 1-oleoyl-2-acetyl GPC (7 ± 3 pmol). A close correlation was found between the amounts of 1-alkyl-2-acetyl GPC and 1-acyl-2-acetyl GPC. In many experiments, including the present one, PAF was detected with iodine vapor. This procedure was found to affect the quantitation of unsaturated species of both types (4), so saturated species were represented. The amounts of 1-hexadecyl- (71 ± 19 pmol) plus 1-octadecyl-2-acetyl GPC (21 ± 7 pmol) per 1×10^7 PMN were plotted on the x-axis and those of 1-palmitoyl- (15 ± 3 pmol) plus 1-stearoyl-2-acetyl GPC (5 ± 2 pmol) on the y-axis. PAF fractions 4 to 8 were detected by the iodine method and quantitated with 1-palmitoyl-2-acetyl-d_3-GPC as an internal standard. The regression equation was $Y = 0.17\ X + 4.91$ with a correlation coefficient of $r = 0.989$ (n = 8). This is quite in contrast to the regression equation of rabbit PMN, $Y = 0.66\ X + 11.61$, $r = 0.940$ (4).

There is no direct method available for measurements of 1-acyl-2-acetyl GPC and 1-alkyl-2-acetyl GPC in mixtures of the two. The peak of intact 1-palmitoyl-2-acetyl GPC overlapped that of 1-pentadecyl-2-acetyl GPC on high performance liquid chromatography (HPLC) (13), and peaks of derivatives of 1-palmitoyl-2-acetyl species overlapped those of 1-heptadecyl-2-acetyl species on GC with packed column (4). In fact, Weintraub detected 1-palmitoyl-2-acetyl GPC by FAB-MS as one component in the peak separated by reversed-phase HPLC, in which 1-pentadecyl, 1-hexadecenyl and 1-octadidecenyl-2-acetyl GPC were also detected (14). So, it is necessary to separate these types of PAF before analyses of molecular species. Ramesha and Pickett analyzed the molecular species of PAF from ionophore A23187-stimulated rat peritoneal PMN without their separation (15). They used capillary GC/negative ion chemical ionization mass spectrometry of the molecular ion, $(M)^-$, for PAF determination (16), and detected three isometric peaks of 1-heptadecyl-2-acetyl GPC and also 1-nonadecyl-2-acetyl GPC. Judging from the retention times and mass numbers of these fractions, they could have contained 1-acyl-2-acetyl GPC in addition to odd-numbered 1-alkyl-2-acetyl GPC. Assuming that these fractions consisted entirely of 1-acyl-2-acetyl GPC, the percentage of this type was at most 2.2%, as calculated simply as the sum of the peak areas. Thus the contribution of 1-acyl-2-acetyl GPC seems to be minute in rat PMN.

Biological effect of 1-acyl-2-acetyl GPC. The biological activity of 1-acyl-2-acetyl GPC was assessed by measuring its ability to elicit platelet aggregation or to inhibit aggregation of human PRP induced by 1-alkyl-2-acetyl GPC in an aggregometer (Nikko Hematracer, PAT-4A). The platelets were stirred at 1000 rpm, and changes in light transmission were recorded with time. Experiments were completed within 1 hr after PRP preparation (17). 1-Acyl-2-acetyl GPC is a weak agonist to human PRP, as it is to washed rabbit platelets (18). Even at 2×10^{-6} M, it induced a very weak primary aggregating response. In contrast, 1-alkyl-2-acetyl GPC elicited an immediate and irreversible aggregating response of human PRP at a concentration of 1×10^{-7} M. At a concentration of 6×10^{-8} M, it caused biphasic aggregation, and at a lower

concentration, it caused no secondary aggregation, reversible aggregation only being noted. Preincubation of 1-acyl-2-acetyl GPC with PRP or simultaneous addition of 1-acyl-2-acetyl GPC at a final concentration of 2×10^{-6} M with 6×10^{-8} M 1-alkyl-2-acetyl GPC had no inhibitory or stimulatory effect on biphasic aggregation elicited by the latter.

We have demonstrated that most of the 1-alkyl-2-acetyl GPC generated by ionophore A23187-stimulated PMN remained cell-associated (1,8), and this was also observed when opsonized zymosan or FMLP was employed as a stimulus (19). We found that 1-acyl-2-acetyl GPC was also mainly cell-associated. When PMN treated with ionophore A23187 were separated by rapid centrifugation, 31 ± 8 pmol ($n = 2$) saturated 1-acyl-2-acetyl GPC per 1×10^7 PMN remained in a cell-associated form, while 4 ± 2 pmol ($n = 3$) was detected in the supernatant. At the same time, 77 ± 40 pmol ($n = 2$) of saturated 1-alkyl-2-acetyl GPC was recovered in the cell pellet and 10 ± 4 pmol ($n = 3$) in the supernatant fraction. Ludwig et al. demonstrated recently that this cell-associated PAF acts as a feedback inhibitor of PAF biosynthesis (7). Accordingly, we examined the possible role of 1-acyl-2-acetyl GPC as an inhibitor of the PAF synthesis by PMN.

PAF production, measured 2.5 min after stimulation, was greatest on stimulation with 1×10^{-6} M FMLP. The amount of PAF produced by 5×10^6 PMN was 356 ± 121 fmol with a range of 140 to 700 fmol ($n = 5$). The high degree of variability of PAF production by human PMN was also observed by Ludwig et al. (20). Assuming that one-fifth of this amount is acyl type and 90% of this is cell-associated, it is calculated to be 60 fmol per 5×10^6 PMN. Next, about 10–20% of exogenously added PAF associated with PMN (21). Accordingly, we preincubated PMN with 1×10^{-10} M 1-acyl-2-acetyl GPC for 1 min. Roughly, 10–20 fmol is expected to be associated with 5×10^6 PMN. They were stimulated with 1×10^{-6} M FMLP for 2.5 min. The amount of PAF produced by 5×10^6 PMN was 324 ± 105 fmol with a range of 80 to 620 fmol ($n = 5$). So preincubation of PMN with 1-acyl-2-acetyl GPC was inhibitory, but a special role of acyl-type PAF as feedback inhibitor would be ruled out at the initial phase of PAF biosynthesis.

Finally, the physiological significance of 1-acyl-2-acetyl GPC is still obscure. However, as stressed by Hanahan in a recent review (22), it does not mean that this type of PAF is not metabolically important.

ACKNOWLEDGMENT

This study was supported in part by a Grant-in-Aid for Special Project Research (59122001) from the Ministry of Education, Science, and Culture of Japan and a Grant-in-Aid from the Mochida Memorial Foundation for Medical Pharmaceutical Research for 1985. H. Konoshi prepared the manuscript.

Acyltransferases in Subcellular Fractions of Developing Seeds of Rape (*Brassica napus* L.)

Denis J. Murphy[a] **and Kumar D. Mukherjee**[b,*]
[a]University of Durham, Department of Botany, Durham, DH1 3LE, England, U.K., and [b]Federal Center for Lipid Research, Institute for Biochemistry and Technology, H.P. Kaufmann Institute, Piusallee 68, D-4400 Muenster, Federal Republic of Germany

Acyltransferase activities responsible for the transfer of oleoyl moieties from oleoyl-CoA to various lipids have been examined in subcellular fractions of developing seeds of rape, *Brassica napus* L. In the absence of exogenous acyl acceptors, the microsomal and oil body fractions transferred oleoyl moieties mostly to phosphatidylcholines and phosphatidic acids, although there was substantial incorporation of the oleoyl moieties into monoacylglycerols, diacylglycerols and triacylglycerols. The soluble (150,000-g supernatant) fraction incorporated oleoyl moieties mainly into the neutral lipids (monoacylglycerols and diacylglycerols) and also exhibited a relatively high acyl-CoA hydrolase activity. In the presence of the exogenous acyl acceptors, lysophosphatidylcholine and lysophosphatidic acid, both microsomal and oil body fractions transferred most of the oleoyl moieties to phosphatidylcholines and phosphatidic acids, respectively. Other lysophospholipids, such as lysophosphatidylethanolamine and lysophosphatidylinositol, were not very effective as acyl acceptors, nor were glycerol-3-phosphate, monoacylglycerols or diacylglycerols. In contrast, the soluble fraction showed little or no stimulation of acyltransfer in the presence of exogenous lysophospholipids but was able to utilize, to some extent, exogenous monoacylglycerols and diacylglycerols as acyl acceptors.
***Lipids 22,* 293–298 (1987).**

Triacylglycerol biosynthesis is believed to occur in oilseeds via the Kennedy pathway (1), as in animal tissues. In many oilseeds, however, acyl groups are also channeled toward a phosphatidylcholine pool, which is probably the substrate for the desaturase(s) involved in the formation of polyunsaturated acyl moieties (2,3). The polyunsaturated acyl moieties then return to the Kennedy pathway as diacylglycerols (4–6) and/or acyl-CoA derivatives (6–8). The relative rates of the following reactions in oilseeds remain to be determined, and the involvement of these pathways in the formation of triacylglycerols is the subject of some controversy (3–6,9,10):

$$\text{Acyl-CoA} + \text{Lysophosphatidylcholine} \rightleftharpoons \text{Phosphatidylcholine} + \text{CoASH}$$
$$\text{1,2-Diacylglycerol} + \text{CDP-choline} \rightleftharpoons \text{Phosphatidylcholine} + \text{CMP}$$

Equally unclear is the subcellular localization of the various enzymes involved in triacylglycerol biosynthesis. Most studies have previously been concentrated on the so-called "microsomal" fraction, i.e., the membrane fraction sedimenting between 10,000 and 100,000 g. This membrane fraction contains most of the enzymes involved in triacylglycerol biosynthesis, but it may not be the only, or even the major, site of each of the constituent enzymes involved. The oil body fraction has been reported as a major site of triacylglycerol formation in seeds of crambé (11), mustard (12) and castor (13) and of wax ester formation in jojoba seeds (14). The high (19%, w/w) protein content reported for crambé oil bodies (11) contrasts with that for oil bodies from peanut (0.2%, w/w) and from linseed and safflower (2.5%, w/w) (15). The finding that linseed and safflower oil bodies contain only four major polypeptides of 14–18 kDa casts some doubt on the biosynthetic capacity of these organelles (3). The biosynthetic capacity of the soluble fraction from developing oilseeds has hitherto been neglected. Recently, however, a soluble glycerol-3-phosphate acyltransferase has been purified from cocoa seeds (16), and developing mustard seeds have been shown to exhibit soluble acyltransferase activities (12).

In the present study, the acyltransferase activities leading to triacylglycerol biosynthesis were examined in developing seeds of oilseed rape, which is a major oilseed crop in northern Europe, Asia and Canada. The subcellular distribution of acyltransferases has been examined in microsomal, oil body and soluble fractions obtained from the seed homogenate.

MATERIALS AND METHODS

Materials. Developing seeds of rape, var. Jet Neuf, were harvested at a period of high triacylglycerol formation, i.e., 4–5 weeks after flowering, and immediately frozen to −80 C. The seeds used in the present study were a gift of A. R. Slabas (Unilever Research, Sharnbrook, Welwyn, Bedfordshire, United Kingdom). [1-^{14}C]Oleoyl-CoA (2.068 KBq.nmol^{-1}) was purchased from Amersham-Buchler (Braunschweig, Federal Republic of Germany). Oleoyl-CoA, glycerol-3-phosphate, 1-oleoylglycerol, dioleoylglycerols (85% *sn*-1,3 and 15% *sn*-1,2[2,3] isomers), 1-acyllysophospholipids (oleoyllysophosphatidylcholine, oleoyllysophosphatidic acid, palmitoyllysophosphatidylethanolamine and lysophosphatidylinositol [from soybean]), and CoASH were obtained from Sigma-Chemie (Muenchen, Federal Republic of Germany). All other reagents and adsorbents were from E. Merck (Darmstadt, Federal Republic of Germany). Lipid standards for thin layer chromatography (TLC) were either from Sigma-Chemie or Applied Science Laboratories (State College, Pennsylvania).

Isolation of subcellular fractions. All operations were carried out at 4 C. Frozen seeds (10 g) were ground in a mortar in a total of 40 ml isolation buffer consisting of 50 mM HEPES-KOH, pH 7.4, 1 mM EDTA, 1 mM DTT and 0.5 M sucrose. The brei was filtered through one layer of Miracloth to yield the homogenate fraction, which was centrifuged at 12,000 × g for 20 min to yield floating oil body (O_1), supernatant (S_1) and pellet (P_1) fractions. $MgCl_2$ was added to the supernatant to a final concentration of 50 mM to precipitate the microsomal membranes. The microsomal fraction was then sedimented at 20,000 × g for 15 min. The resulting supernatant (S_2) was subjected to further centrifugation at 150,000 × g for 2 hr to obtain a soluble protein fraction. O_1 was dispersed in isolation

*To whom correspondence should be addressed.

buffer by gentle passage through a ground-glass homogenizer and centrifuged at 20,000 × g for 15 min to yield a washed oil body fraction. This procedure was repeated three times until no further membranous material sedimented and a thick creamy washed oil body fraction was obtained. The washed oil body and the microsomal fractions were resuspended in a medium consisting of 50 mM HEPES-KOH, pH 7.4, 1 mM DTT and 10 mM $MgCl_2$.

Incubations. Aliquots of subcellular fractions corresponding to 0.2–0.4 mg protein were incubated in a total volume of 500 µl of a medium consisting of 50 mM HEPES-KOH, pH 7.4, 1 mM ATP, 0.3 mM CoASH, 5 mM $MgCl_2$ and 1 mM 2-mercaptoethanol. Incubations were started by adding 3.7 KBq [1-^{14}C]oleoyl-CoA at a final concentration of 20 nmol oleoyl-CoA per assay. When lysophospholipids or mixtures of mono- and diacylglycerols were used as exogenous acyl acceptors, 100 nmol of these lipids were added as sonicated dispersions as described elsewhere (17). Incubations were carried out at 23 C in open glass tubes with shaking and were terminated by the addition of 10 ml chloroform/methanol (2:1, v/v) to produce a monophasic extract. To this extract was added 2 ml of an aqueous solution of 0.1% acetic acid containing 0.7% NaCl, which resulted in partitioning of all water-soluble constituents, including acyl-CoA derivatives, into the upper aqueous phase. The lower phase containing the chloroform-soluble lipids was recovered and analyzed.

Lipid and protein analysis. Methods for analysis of chloroform-soluble lipids and detection of acyl-CoA in the aqueous phase after partitioning of the lipids were identical to those described previously (17,18). In addition, the following systems for TLC were employed.

To detect monoacylglycerols, the total lipids were applied to layers of Silica Gel H, and the chromatoplates were developed twice with diethyl ether to a height of 2 cm from the origin. Upon subsequent development of the chromatoplates up to the top with hexane/diethyl ether/acetic acid (70:30:1, v/v/v), the monoacylglycerols, diacylglycerols, unesterified fatty acids and triacylglycerols were separated from each other and from the mixture of phospholipids and glycolipids that remained at the origin.

The identity of individual classes of phospholipids and glycolipids was established by TLC on Silica Gel H using two different solvent systems, i.e., chloroform/acetone/methanol/acetic acid/water (10:4:2:2:1, v/v/v/v/v) and chloroform/methanol/concentrated ammonium hydroxide (65:35:5, v/v/v). Monoacylglycerols were also separated on boric acid-impregnated Silica Gel H chromatoplates for the purpose of positional analysis of acyl groups (19).

Protein content of the subcellular fractions was determined according to an established method (20).

RESULTS AND DISCUSSION

The time course of metabolism of [1-^{14}C]oleoyl-CoA by microsomal, oil body and soluble fractions from developing rapeseed are shown in Figure 1. All of these incubations were performed in the absence of exogenous acyl acceptors. As previously shown for safflower (21–23), sunflower (7,24), crambé (11) and other oilseeds (8,25) the microsomal fraction rapidly incorporated oleoyl moieties into phosphatidylcholines (Fig. 1). The oil body fraction

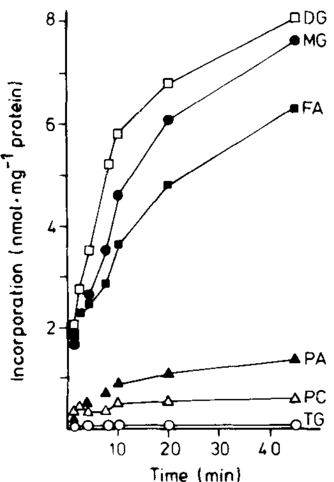

FIG. 1. Time course of incorporation of oleoyl moieties into lipids upon incubation of subcellular fractions of developing rapeseed with [1-^{14}C]oleoyl-CoA. Microsomes, oil body and a soluble fraction from developing rapeseed were incubated for different periods with 3.7 KBq [1-^{14}C]oleoyl-CoA (20 nmol) and the incorporation of oleoyl moieties (nmol.mg^{-1} protein) into various lipids was determined as described in the text: ●, monoacylglycerols; □, diacylglycerols; ○, triacylglycerols; ■, unesterified fatty acids; ▲, phosphatidic acids; △, phosphatidylcholines. All values are means of at least two independent experiments.

also incorporated most of the oleoyl moieties into phosphatidylcholines, although there was a rapid incorporation of oleoyl moieties into phosphatidic acids as well (Fig. 1). This contrasts with mustard oil bodies, which incorporated three times as much of the oleoyl moieties from oleoyl-CoA into phosphatidic acids than into phosphatidylcholines in one hour (12). The soluble fraction incorporated relatively little of the oleoyl moieties into any of the polar lipids (Fig. 1). None of the subcellular fractions of developing rapeseed incorporated significant amounts of oleoyl moieties into the glycolipids.

The relatively high level of incorporation of oleoyl moieties into mono- and diacylglycerols by all subcellular fractions (Fig. 1) was somewhat surprising. It has been reported that monoacylglycerols were labeled from [U-^{14}C]glycerol in crambé oil bodies (11) and from [1-^{14}C]-glycerol-3-phosphate in microsomes from safflower (26) and avocado (27) and in cucumber cotyledon homogenates (28), but in most cases the extent of labeling was relatively low. In a recent study, however, relatively high proportions of labeled monoacylglycerols were formed from [1-^{14}C]oleoyl-CoA in homogenate, oil body and soluble fractions from developing mustard seeds (12). Monoacylglycerols migrate only a short distance from the origin of the chromatograms in most commonly used solvent systems for TLC of neutral lipids, and are therefore poorly resolved from the polar lipid band remaining at the origin. In the present study, the monoacylglycerols were allowed to migrate 2 cm from the origin together with the other neutral lipids by double development with diethyl ether, which was followed by fractionation of the neutral lipids with hexane/diethyl ether/acetic acid (70:30:1, v/v/v). The monoacylglycerols were further analyzed by chromatography on boric acid-impregnated thin layer plates. This showed that essentially all of the oleoyl moieties were incorporated into the *sn*-1(3) position of monoacylglycerols.

The nature of the diacylglycerols labeled with [1-^{14}C]-oleoyl moieties that were formed in the various fractions was determined by TLC on Silica Gel H. The ratio of labeled 1,2-(2,3) diacylglycerols to 1,3-diacylglycerols ranged from 1:2 to 2:1 in microsomes, 1:1 to 3:1 in oil bodies and 2:1 to 3:1 in the soluble fraction.

In addition to actively incorporating oleoyl moieties into mono- and diacylglycerols, the soluble fraction contained a considerable thioesterase activity, as evidenced by the large proportion of radioactive oleic acid formed (Fig. 1). Similar observations have been reported for soluble fractions from developing seeds of safflower (21) and mustard (12). Thioesterase activities were also found in the microsomal and oil body fractions in the present study, but these were at much lower levels than that of the soluble fraction (data not shown).

Since all three subcellular fractions of developing rapeseed were able to efficiently transfer oleoyl moieties onto endogenous complex lipids, it was of interest to investigate their capacity to utilize exogenous acyl acceptors in the presence of oleoyl-CoA. In Table 1, the effect of a wide range of acyl acceptors on the incorporation of oleoyl moieties from oleoyl-CoA is shown for each subcellular fraction. In the case of the microsomal and oil body fractions, the most dramatic results were obtained with lysophosphatidylcholine and lysophosphatidic acid, both of which caused a greatly increased uptake of oleoyl moieties from oleoyl-CoA and also the specific channelling of these moieties into the corresponding diacylphospholipids. This was not the case with the other two exogenous lysophospholipids used here, i.e., lysophosphatidylethanolamine and lysophosphatidylinositol. Therefore,

the acyltransferase(s) responsible for transfer of oleoyl moieties to phosphatidylcholines and phosphatidic acids in microsomes and oil bodies of rapeseed appear to have a far greater degree of specificity for acyl acceptors than those present in microsomes from safflower seeds (29).

The addition of either glycerol-3-phosphate or a mixture of mono- and diacylglycerols was expected to result in an increase in the flow of intermediates through the Kennedy pathway (1) and therefore to increase [1-^{14}C]-oleoyl-CoA incorporation, as has been observed in other oilseeds (7,10,12,30). In the case of microsomes and oil bodies from rapeseed, however, these exogenous acyl acceptors caused a slight but definite decrease in incorporation of oleoyl moieties (Table 1). Despite the overall decrease in incorporation, the microsomes from rapeseed incorporated more oleoyl moieties into phosphatidic acids in the presence of glycerol-3-phosphate, while the incorporation into phosphatidylcholines was halved (Table 1). This is consistent with an increased flux through the earlier part of the Kennedy pathway and an associated decrease in acyl transfer to phosphatidylcholines, but there was no evidence of increased synthesis of di- or triacylglycerols in the presence of exogenous glycerol-3-phosphate. This implies that there was no increase in the flow of acyl groups through the later part of the Kennedy pathway.

As compared to microsomes, the oil bodies from rapeseed incorporated higher proportions of oleoyl moieties into neutral lipids in the presence of exogenous glycerol-3-phosphate (Table 1). There was also a sizeable increase in the incorporation of oleoyl moieties into phosphatidic acids. Therefore, the oil body fraction from developing rapeseed represents a better source (on a mg^{-1} protein basis) of Kennedy pathway activities as a whole than does the microsomal fraction.

The soluble fraction was deficient in lysophospholipid acyltransferase(s) and in diacylglycerol acyltransferase (Table 1). Thus, even when diacylglycerol formation was stimulated by exogenous acyl acceptors, such as lysophosphatidic acid and mono- plus diacylglycerols, no more than trace amounts of triacylglycerols were detected. Concomitant with the stimulation of incorporation of oleoyl moieties into diacylglycerols, an increase in monoacylglycerol labeling was observed (Table 1). The latter could have been formed by two possible reactions, i.e., acyl hydrolysis of diacylglycerols or cleavage of the phosphate group by a lysophosphatidic acid phosphatase. Germinating rapeseed is a good source of acylhydrolase activity (31), which has been localized in both the microsomal (32) and oil body (33) fractions, but it is not known whether developing seeds, such as those used in the present study, contain any of this activity. Acyl hydrolysis by nonspecific hydrolase(s) is another possibility, and the soluble fraction from rapeseed did contain an acyl-CoA hydrolase activity (Fig. 1), which may be due to such a nonspecific hydrolase. If the monoacylglycerols were generated instead by a lysophosphatidic acid phosphatase, this could have been due to overlapping specificity of phosphatidic acid phosphatase, which is a Kennedy pathway enzyme responsible for the formation of diacylglycerols. This latter activity has been detected in both microsomal and soluble fractions from castor bean endosperm (34). A monoacylglycerol kinase, which catalyzes the reaction

$$\text{monoacylglycerol} + \text{ATP} \rightarrow \text{lysophosphatidic acid} + \text{ADP}$$

has been found in soluble fractions from pig brain (35,36) and rat liver (37). In all these cases, the activity was closely associated with a diacylglycerol kinase activity. A lysophosphatidic acid phosphatase activity has been found in microsomes from avocado mesocarp, where monoacylglycerols were a major product of incubation with ^{14}C-glycerol or ^{14}C-glycerol-3-phosphate (27). It may, therefore, be a reversible monoacylglycerol/diacylglycerol kinase/phosphatase activity that is responsible for the accumulation of mono- and diacylglycerols in soluble fractions of developing rapeseed.

While microsomes and oil bodies from developing rapeseed rapidly incorporated oleoyl moieties from oleoyl-CoA into phosphatidic acids and phosphatidylcholines, relatively little triacylglycerol was formed as compared to microsomes from sunflower (7) or safflower (38). In other cases, however, the extent of incorporation of oleoyl moieties into triacylglycerols was close to that found in the present study, e.g., in safflower (21), sunflower (24), linseed (8) and mustard (12). It has been reported that, in the absence of glycerol-3-phosphate, phosphatidylcholine is mainly labeled by direct transfer of oleoyl moieties from oleoyl-CoA to lysophosphatidylcholine (10,22,24,29). In the presence of unlabeled glycerol-3-phosphate and a working Kennedy pathway, the equilibrium between phosphatidylcholines and diacylglycerols will result in the efflux of label from phosphatidylcholines and toward triacylglycerols (7,10).

In an attempt to stimulate the flow of oleoyl moieties from phosphatidylcholines toward triacylglycerols, a pulse-chase experiment was performed. Microsomal and oil body fractions of rapeseed were preincubated for 30 min with 20 nmol [1-^{14}C]oleoyl-CoA in the presence of 100 nmol lysophosphatidylcholine (Table 2). This ensured that the vast majority of oleoyl moieties incorporated were transferred to phosphatidylcholines. A large excess of unlabeled oleoyl-CoA (100 nmol) plus 100 nmol each of lysophosphatidic acid and glycerol-3-phosphate was then added to each incubation mixture, which were incubated for up to another two hours. Despite the large dilution of [1-^{14}C]oleoyl-CoA at 30 min, there was a further substantial incorporation of ^{14}C-oleoyl moieties upon the addition of lysophosphatidic acid and glycerol-3-phosphate, as shown in Table 2. No evidence of an efflux of ^{14}C-oleoyl moieties from phosphatidylcholines was observed, even after a further 2-hr incubation under conditions of active phosphatidic acid synthesis. The results from microsomal and oil body fractions were essentially similar. Oil bodies incorporated much more of the oleoyl moieties into phosphatidic acids in the absence of lysophosphatidic acid and responded to its presence with a 50% increase in this incorporation. Microsomes incorporated negligible proportions of oleoyl moieties into phosphatidic acids in the absence of lysophosphatidic acid (and the presence of lysophosphatidylcholine), but increased this incorporation 60-fold in the presence of lysophosphatidic acid. In both subcellular fractions, however, there was no increase in the labeling of any of the neutral lipids and no decrease in the labeling of phosphatidylcholines.

These results imply that the major activities present in both oil body and microsomal fractions of rapeseed

PC, phosphatidylcholines; PA, phosphatidic acids; PL, phospholipids; TG, triacylglycerols.
[a]Microsomes and oil bodies from developing rapeseed were incubated for 30 min with 3.7 KBq [1-^{14}C]oleoyl-CoA (20 nmol) in the presence of 100 nmol lysophosphatidylcholine. Thereafter, 100 nmol each of unlabeled oleoyl-CoA, glycerol-3-phosphate and lysophosphatidic acid were added and the incubations were continued for various periods. Incorporation of oleoyl moieties into various lipids was determined. Values are the means of at least two independent experiments.

were the lysophospholipid acyltransferases leading to the formation of phosphatidic acids and phosphatidylcholines. These activities were almost entirely absent from the soluble fraction. In the presence of appropriate acyl acceptors, these activities dwarfed the other acyltransferases and channeled as much as 95% of the oleoyl moieties from the added oleoyl-CoA onto a particular phospholipid. Although both fractions, and particularly the oil bodies, were capable of modest rates of triacylglycerol synthesis, the huge increase in the labeling of phosphatidic acids in the presence of exogenous lysophosphatidic acid did not lead to correspondingly large increases in triacylglycerol (or even diacylglycerol) formation (Table 2). This could possibly be explained by the relatively large endogenous diacylglycerol pool in the developing rapeseed fractions used in the present study. If the two reactions that are believed to channel acyl moieties into the diacylglycerol pool are truly equilibrium reactions, i.e.,

$$\text{phosphatidylcholine} \underset{\text{CMP}\ \ \text{CDP-choline}}{\overset{\text{CMP}\ \ \text{CDP-choline}}{\rightleftharpoons}} \text{diacylglycerol}$$

$$\text{phosphatidic acid} + \text{ADP} \longleftrightarrow \text{diacylglycerol} + \text{ATP}$$

then the presence of a large diacylglycerol pool would effectively prevent any large-scale flow of labeled oleoyl moieties toward triacylglycerols. The soluble fraction, which contained no detectable endogenous diacylglycerols, actively incorporated oleoyl moieties into diacylglycerols, but apparently lacked the further acyltransferase responsible for triacylglycerol formation. Such a diacylglycerol acyltransferase from a particulate fraction from safflower seeds has recently been described (38).

The effect on metabolism of oleoyl-CoA of incubating mixtures of the various subcellular fractions is shown in Table 3. It is clear that in each case the various fractions exhibited their characteristic patterns of metabolism of oleoyl-CoA with the result that an average labeling pattern was obtained. For example, when the microsomal and soluble fractions were incubated together, the labeling pattern was approximately the same as if an average had been taken of each fraction's individual labeling pattern. The total incorporation of ^{14}C-oleoyl moieties was greatly reduced in the combined fractions compared to the sum of the individual fractions.

In one experiment, the oil bodies from rapeseed were delipidated by three gentle extractions with pentane. This led to removal of most of the storage oil without denaturing the proteins associated with the oil bodies, since the oleate incorporation activities were similar both before and after the delipidation (Table 3). Therefore, the lipid-synthesizing enzymes present in the oil body fraction of rapeseed can function in the absence of most of the oil.

To summarize, it was found that microsomal, oil body and soluble fractions of developing rapeseed were all capable of high rates of metabolism of oleoyl-CoA. The microsomal and oil body fractions possessed all the activities of the Kennedy pathway for triacylglycerol biosynthesis. The major activities in these fractions were the lysophospholipid acyltransferases responsible for the formation of phosphatidic acids and phosphatidylcholines. At present it is not clear whether these are separate enzymes, but the lack of acyltransferase in the presence of lysophosphatidylethanolamine and lysophosphatidylinositol rules out a single, completely nonspecific lysophospholipid acyltransferase able to utilize any lysophospholipid substrate. The flow of acyl groups further along the Kennedy pathway toward triacylglycerols may have been inhibited by the presence of a large endogenous

TABLE 3

Incorporation of Oleoyl Moieties into Lipids of Subcellular Fractions of Developing Rapeseed and Their Mixtures upon Incubation with [1-^{14}C]Oleoyl-CoA

Fraction	Incorporation of oleoyl moieties into lipids (nmol·mg^{-1} protein)[a]

MG, monoacylglycerols; DG, diacylglycerols; TG, triacylglycerols; PA, phosphatidic acids; PC, phosphatidylcholines; PL, phospholipids; tr, traces.

[a]Microsomes, oil bodies, delipidated oil bodies and soluble fraction from developing rapeseed and their mixtures were incubated with 3.7 KBq [1-^{14}C]oleoyl-CoA (20 nmol), and the incorporation of oleoyl moieties into various lipids was determined. Values are the means of at least two independent experiments.

diacylglycerol pool in these fractions, i.e., by keeping the equilibrium between phosphatidic acids and diacylglycerols very much toward the former. In contrast, the soluble fraction, which had no endogenous diacylglycerols, mainly formed mono- and diacylglycerols. This fraction was, however, unable to form triacylglycerols or phosphatidylcholines in any significant quantity, but was capable of some phosphatidic acid synthesis—although, unlike the other fractions, the latter activity was not stimulated in the presence of lysophosphatidic acid. The apparent presence of glycerol-3-phosphate acyltransferase activity in all three subcellular fractions of rapeseed is of interest considering recent reports on the properties of this enzyme in both microsomes of safflower seed (26) and a soluble fraction from cocoa seed (16).

It is also clear from the present study that the enzymes responsible for the biosynthesis of triacylglycerols are by no means exclusively or even mostly localized in the microsomal fraction, as has been often assumed hitherto.

[Received October 21, 1986]

The Kinetics of the Autoxidation of Polyunsaturated Fatty Acids

John P. Cosgrove, Daniel F. Church and William A. Pryor*
Departments of Chemistry and Biochemistry and The Biodynamics Institute, Louisiana State University, Baton Rouge, LA 70803

The kinetics of the autoxidation of a series of polyunsaturated fatty acids (PUFA) with increasing degrees of unsaturation and the mono-, di- and triglycerides of linoleate have been studied in homogeneous chlorobenzene solution at 37 C under 760 torr of oxygen. The autoxidations were initiated by thermal decomposition of azo initiators and followed by measuring the rate of oxygen uptake. The rate of chain initiation was determined by the induction period method using α-tocopherol as the chain-breaking antioxidant. The measured oxidizabilities of the PUFA are linearly dependent on the number of doubly allylic positions present in the molecule. Thus, the oxidizability of linoleate is 2.03×10^{-2} $M^{-1/2}$ $sec^{-1/2}$, and the value for docosahexaenoate is five times greater, 10.15×10^{-2} $M^{-1/2}$ $sec^{-1/2}$. The rate of autoxidation for all PUFA studied and for the mono- and diglyceride is proportional to the substrate concentration and to the square root of the rate of chain initiation, implying that the autoxidation of these compounds follows the usual kinetic rate law. The autoxidation of the triglyceride is more complex and does not appear to follow the same rate law at all substrate concentrations. This deviation from the usual kinetic rate expression may be due to lipid aggregation at low concentrations of the triglyceride.
***Lipids 22,* 299–304 (1987).**

The autoxidation of polyunsaturated fatty acids (PUFA) has received much attention due to its involvement in food spoilage and the relevance of lipid peroxidation in vivo to membrane damage, aging, heart disease and cancer (1-3). Many workers have studied the quantitative aspects of autoxidation to better understand the kinetics and mechanisms of these important reactions (4-6). However, these workers have concentrated on linoleate (18:2) and linolenate (18:3). The previous very early work (7) on the relative rate of oxygen uptake by the more highly unsaturated PUFA did not control the rates of radical initiation. Therefore, we have reinvestigated this important area of current interest.

This paper presents the first quantitative kinetics study of the more highly unsaturated PUFA, arachidonate (20:4) and docosahexaenoate (22:6) as well as comparative data on 18:2 and 18:3 and the mono-, di- and triglycerides of 18:2. These results should be useful in the quantitative evaluation of the autoxidation of mixtures of PUFA in biological systems.

The autoxidation of many organic materials is known to be a free radical chain process which, in homogeneous solution at sufficient oxygen pressures, proceeds by the mechanism shown (Scheme 1) (8,9). RH represents the organic substrate, in this case a PUFA molecule, and R· is the carbon-centered radical formed by abstraction of a doubly allylic hydrogen atom. The carbon-centered radical, R·, rapidly reacts with molecular oxygen to give the chain-carrying peroxyl radical, ROO· [2] (10). In the steady-state analysis of this reaction scheme, the rate of oxygen consumption is given by equation 5, where k_p and

INITIATION:

$$RH \rightarrow R\cdot \qquad \text{RATE} = R_i \qquad [1]$$

PROPAGATION:

$$R\cdot + O_2 \xrightarrow{k_o} ROO\cdot \qquad [2]$$

$$ROO\cdot + RH \xrightarrow{k_p} ROOH + R\cdot \qquad [3]$$

TERMINATION:

$$2ROO\cdot \xrightarrow{2k_t} \text{NONRADICAL PRODUCTS} + O_2 \qquad [4]$$

SCHEME 1

k_t are the rate constants for the rate-controlling propagation step [3] and chain termination step [4], respectively. The ratio of these rate constants, $k_p/(2k_t)^{1/2}$, is referred to as oxidizability and is a measure of the ease with which the substrate will undergo autoxidation.

$$-d[O_2]/dt = \{k_p/(2k_t)^{1/2}\}[RH]R_i^{1/2} \qquad [5]$$

To allow quantitative studies on the kinetics of autoxidation, the rate of chain initiation, R_i, must be controlled and measurable. This is generally achieved by using thermally labile azo initiators, which decompose to give two radicals at a known and constant rate, as shown in equation 6, where I· is any organic molecular fragment.

$$I-N=N-I \xrightarrow{k_d} 2I\cdot + N_2 \qquad [6]$$

$$I\cdot + O_2 \xrightarrow{RH} IOOH + R\cdot \qquad [7]$$

The rate of initiation, R_i, is governed by the rate constant for the rate of decomposition of the initiator, k_d, as well as by the efficiency of the primordial radicals, I·, initiating equation 7 rather than recombining in the solvent cage in which they are formed. The value of R_i is generally measured by the induction period method (11), using equation 8, where ArOH is a phenolic antioxidant.

$$R_i = n[ArOH]/\tau \qquad [8]$$

Determination of the time, τ, that the rate of oxygen uptake is inhibited allows the calculation of R_i if n, the stoichiometric factor, is known. (The factor n is defined as the number of radicals trapped by each molecule of antioxidant.) α-Tocopherol is known to have an n value of 2 and is also one of the best phenolic antioxidants known (12). Once R_i is known, the initiator efficiency, e—the number of initiator radicals that initiate—can be calculated using equation 9. The kinetic chain length, KCL, is the number of substrate molecules oxidized per initiating radical, and can be obtained from equation 10.

$$e = R_i/2k_d[In] \qquad [9]$$

$$KCL = \{-d[O_2]/dt\}/R_i \qquad [10]$$

Values of $k_p/(2k_t)^{1/2}$ and the KCL for the autoxidation of PUFA can readily be obtained using the above kinetic expressions.

MATERIALS AND METHODS

Materials. Methyl linoleate (18:2) and ethyl linolenate (18:3), 99%, were obtained from Sigma Chemical Co. (St. Louis, Missouri). Methyl arachidonate (20:4), methyl docosahexaenoate (22:6) and the mono-, di- and triglycerides of 18:2, all greater than 99% pure, were obtained from Nu-Chek-Prep (Elysian, Minnesota). The diglyceride was a mixture of the 1,2- and 1,3-isomers. 2,2′-Azobis(2-methylpropionitrile) (AIBN) was obtained from Kodak Chemical (Rochester, New York). 2,2′-Azobis(2,4-dimethylvaleronitrile) (DMVN) was obtained from Polysciences (Warrington, Pennsylvania). Di-tert-butyl hyponitrite (DBHN) was prepared by published procedure (13). Chlorobenzene, HPLC grade, was obtained from Aldrich Chemical Co. (Milwaukee, Wisconsin) and stored over molecular sieves. D-α-Tocopherol (α-T) was obtained from Henkel Corp. (Minneapolis, Minnesota). All chemicals were used as received.

Autoxidation procedures. All oxidations were carried out at 37 C under 760 torr of O_2 in an automatic recording gas absorption apparatus similar to those described elsewhere (14,15). The apparatus consists of a calibrated Validyne DP 15-30 pressure transducer (±1.25 psi) and CD-12 transducer indicator connected to a strip chart recorder. Both the transducer and reaction vessel were thermostatted at 37 C (±0.05 C).

In a typical experiment, a known volume of a chlorobenzene solution of the appropriate PUFA was put in the reaction vessel. The vessel and solution were saturated with oxygen by passing a stream of the gas over the rapidly stirred solution for 15 to 20 min. After sufficient time was allowed for the solution to come to thermal equilibrium (10–15 min), a known volume of initiator in chlorobenzene was added using a long-needle microliter syringe. Oxygen uptake by the autoxidizing PUFA began immediately upon addition of the initiator. Rates of oxygen uptake by the solution were calculated from the slope of the linear recorder trace after correcting for nitrogen evolution and oxygen uptake by the initiator radicals and oxygen evolved by the termination reaction (4).

The rate of chain initiation, R_i, was determined by the induction period method (11). Known amounts of a chlorobenzene solution of α-tocopherol were added to the autoxidizing PUFA. Using n = 2 for α-T (12) and the length of time, τ, that the oxygen uptake is inhibited, R_i was calculated from equation 8, by plotting 2[α-T] against τ and calculating the slope. The oxidizability, $k_p/(2k_t)^{1/2}$, of the PUFA was determined by measuring the rate of oxygen uptake in several runs where the rate of initiation and the PUFA concentration had both been varied. From equation 5, the oxidizability is equal to the slope of a line obtained by plotting the rate of oxygen uptake against $[PUFA]R_i^{1/2}$. The reproducibility of this method is quite good, 1 or 2% based on the errors in the slopes, and the absolute oxidizability values reported here are estimated to be accurate to ±10%.

The rate constants for the decomposition of the initiators, k_d, were determined by measuring the rate of nitrogen evolution from a chlorobenzene solution of the initiator in the same apparatus used for the autoxidations (16). The initiator solutions were deoxygenated by bubbling with nitrogen in the apparatus for 15 to 20 min prior to the start of the experiment.

RESULTS

A typical trace representing the oxygen uptake of an autoxidizing solution of PUFA is shown in Figure 1 for 20:4, and includes both the uninhibited and the α-tocopherol–inhibited reactions. It should be noted that the rate of oxygen uptake is the same before and after the inhibition period. The length of the induction period, τ, together with the concentration of α-T, can be used to calculate the rate of chain initiation, R_i, from equation 8. A number of injections of α-T were made, with care taken that the rate returned to the uninhibited value before the next injection of α-T was made. By measuring τ for various concentrations of α-T, a plot was constructed based on equation 8. The slope of the resulting straight line is equal to R_i for that particular kinetic run, as shown in Figure 2.

The data shown in Table 1 for the various PUFA were obtained by varying the concentrations of both the PUFA and the initiator and determining R_i as described above. Then, if equation 5 is obeyed, a plot of the rate of oxygen uptake vs $[PUFA]R_i^{1/2}$ should give a straight line with the slope equal to the oxidizability for that particular PUFA. Figure 3 shows the data in Table 1 plotted for all PUFA studied. The oxidizabilities (in units of $M^{-1/2}$ $sec^{-1/2}$) obtained from these lines are 18:2, 2.03×10^{-2}; 18:3, 4.07×10^{-2}; 20:4, 5.75×10^{-2}; and 22:6, 10.15×10^{-2}.

The average e for AIBN in all the runs in Table 1 was 66 ± 7%. This is in good agreement with data on this initiator in other systems (17,18). The efficiency of DMVN was higher but also more variable, with an average of 78 ± 15%. It should be noted, however, that the oxidizability of the PUFA is independent of the initiator employed.

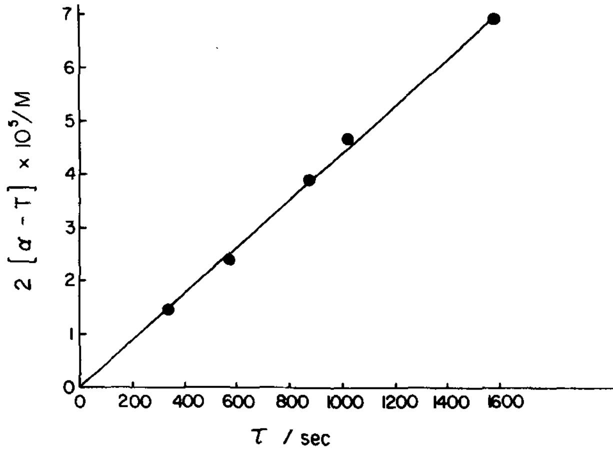

FIG. 2. Plot of $2[\alpha\text{-}T]$ vs τ for the autoxidation of 0.332 M 20:4 in chlorobenzene initiated with .1072 M 2,2-azobis(2-methylpropionitrile). Slope of the line equals R_i.

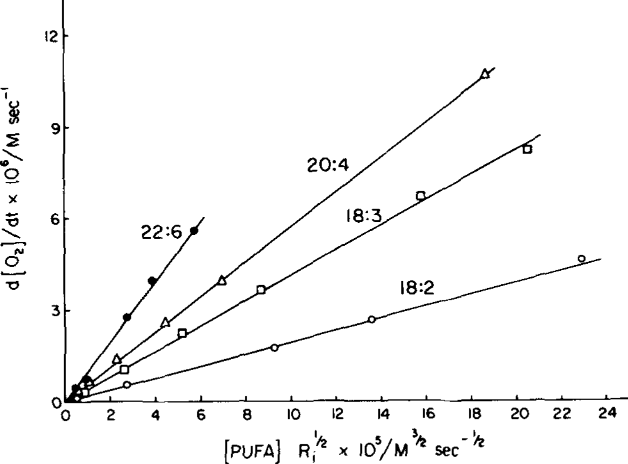

FIG. 3. Plots of $d[O_2]/dt$ vs $[PUFA]R_i^{1/2}$ for the four polyunsaturated fatty acids (PUFA) studied. Data taken from Table 1. ○, 18:2; □, 18:3; △, 20:4; ●, 22:6. The slope of the line equals the oxidizability of that PUFA.

The kinetic chain lengths (KCL) in these reactions were long, ranging from 10 to about 300. The long chain lengths together with the high efficiencies cause the correction due to nitrogen evolution and oxygen uptake by the initiators to be quite small, generally less than 5% of the measured rate of oxygen uptake.

To investigate the effects of more than one unsaturated fatty acid chain in the same lipid molecule, the oxidizabilities of the mono-, di- and triglycerides of 18:2 were measured. These determinations were done in the same manner as described for the individual PUFA; the results

PUFA, polyunsaturated fatty acid; KCL, kinetic chain length.

[a]Rate corrected for N_2 given off and O_2 taken up by initiator and O_2 given off by termination reaction.

[b]Di-tert-butyl hyponitrile; $k_d = 8.57 \times 10^{-6}$ sec^{-1}, forms butoxyl radical upon decomposition, which does not react with oxygen.

[c]2,2′-Azobis(2,4-dimethylvaleronitrile); $k_d = 2.43 \times 10^{-6}$ sec^{-1}.

[d]2,2′-Azobis(2-methylpropionitrile); $k_d = 3.05 \times 10^{-7}$ sec^{-1}.

are shown in Table 2. The data for the monoglyceride of 18:2 give an oxidizability of 2.68×10^{-2} $M^{-1/2}$ $sec^{-1/2}$. This value is somewhat higher than that obtained for the methyl ester of 18:2. The average efficiencies for DMVN and DBHN in this system were 73 ± 13% and 66 ± 3%, respectively. The value for DMVN is similar to the efficiency reported for the individual PUFA, while the efficiency for DBHN was the same as that reported for other systems (4).

The diglyceride of 18:2 had a greater oxidizability than the monoglyceride, the value being 5.89×10^{-2} $M^{-1/2}$ $sec^{-1/2}$. While the efficiency with which DBHN initiated radical chains was about the expected value, 63% (4), the efficiency of DMVN was 88 ± 9%. This value is greater than the efficiency found with the other substrates studied.

The data on the triglyceride of 18:2, shown in Table 2, appear somewhat more complex. The least squares line of the plot of $d[O_2]/dt$ vs $[PUFA]R_i^{1/2}$ gives the oxidizability for the triglyceride as 7.98×10^{-2} $M^{-1/2}$ $sec^{-1/2}$. This value is three times that determined for the monoglyceride of 18:2. However, the oxidizability is not constant as the concentration of the ester is increased, as it is with the other substrates studied. Both AIBN and DBHN had about the expected efficiency when used with the triglyceride: 68 ± 2% and 72 ± 10%, respectively. However, the DMVN gave an average efficiency of 100 ± 2% with this substrate.

DISCUSSION

The autoxidation of many organic substances is a free radical chain process that obeys the kinetic expression in equation 5 (8,9). By control of the variables in that expression, it is possible to obtain a quantitative measure of the susceptibility of a substrate to undergo autoxidation, $k_p/(2k_t)^{1/2}$. Previous work on the rates of oxidation of PUFA reported that the relative maximum rates of autoxidation at 37 C were in the ratios 1:2:4:—:8 as the number of doubly allylic positions increased from 1 to 5 (7,19). However, that work was done by measuring the rate of oxygen uptake by spontaneously autoxidizing samples of pure PUFA, and no attempt was made to control or even measure the R_i. Using thermally labile azo initiators to control R_i and the induction period

method to accurately measure R_i, we have determined the oxidizabilities of a number of PUFA.

The linear correlations, shown in Figure 3, and the constancy of the data given in Table 1 imply that all PUFA obey the kinetic expression given by equation 5. We determined the values of $k_p/(2k_t)^{1/2}$ for 18:2 and 18:3 to be 2.03×10^{-2} $M^{-1/2}$ $sec^{-1/2}$ and 4.07×10^{-2} $M^{-1/2}$ $sec^{-1/2}$ at 37 C; these values compare quite well with the values of 2.1×10^{-2} $M^{-1/2}$ $sec^{-1/2}$ and 3.9×10^{-2} $M^{-1/2}$ $sec^{-1/2}$ at 30 C measured by Howard and Ingold (20). Our results on the more highly unsaturated PUFA, 20:4 and 22:6, are 5.75×10^{-2} and 10.15×10^{-2} $M^{-1/2}$ $sec^{-1/2}$, respectively, and are among the highest substrate oxidizabilities reported at 37 C, demonstrating the susceptibility of highly unsaturated compounds to autoxidation.

Our data for the oxidizability of PUFA indicate that these values are linearly related to the number of doubly allylic positions present in the molecule. As the number of doubly allylic positions increases in the series from 1:2:3:—:5, the ratio of the oxidizabilities increases to 1:2:3:—:5. At equal concentrations of PUFA and equal rates of initiation, the rate of oxygen uptake follows this same ratio. The previously reported ratio of oxidizabilities for the PUFA series from 18:2 to 22:6 of 1:2:4:—:8, therefore, is not correct.

The linear relationship between ease of autoxidation and the number of doubly allylic positions predicts an oxidizability of about 2.0×10^{-2} $M^{-1/2}$ $sec^{-1/2}$ per activated methylene group at 37 C. This relationship allows us to speculate on the oxidizability of docosapentaenoate (22:5), which we did not study. (This compound is not readily available commercially in sufficient quantity and purity to allow accurate kinetic studies.) Based on an oxidizability of 2.0×10^{-2} $M^{-1/2}$ $sec^{-1/2}$ per doubly allylic position, 22:5 with four active methylene groups, should have an oxidizability of about 8.0×10^{-2} $M^{-1/2}$ $sec^{-1/2}$. The large oxidizability values for the highly unsaturated PUFA, 22:5 and 22:6, can quantitatively explain why tissues rich in these substances, such as the retina, are so susceptible to free radical damage (21,22).

The use of the mono-, di- and triglycerides of 18:2 allows us to investigate the effect of more than one unsaturated chain contained in the same molecule. The oxidizability for the monoglyceride of 18:2 was determined to be 2.68×10^{-2} $M^{-1/2}$ $sec^{-1/2}$. As with the other PUFA esters, the measured oxidizability for the monoglyceride was linearly dependent on the substrate concentration and on the square root of the rate of initiation and also independent of the type of initiator used. With the PUFA and the monoglyceride, DMVN was the most efficient initiator, with an average of about 75 ± 14%, similar to that reported in previous work in homogeneous solution (23). The DBHN and AIBN behaved as expected with all the PUFA and the monoglyceride. The average efficiencies are in agreement with those reported in the literature for other systems: 66 ± 7% for AIBN (17,18) and 66 ± 3% for DBHN (4).

The difference in oxidizability between the monoglyceride and the methyl ester of 18:2, although small, is of interest. The oxidizability should be dependent on the number of activated methylene groups in the fatty acid carbon chain and should be independent of the ester functionality, and the methyl ester and the monoglyceride would be expected to have the same oxidizability. The small difference between the oxidizability of 18:2 and the monoglyceride is possibly due to the more polar nature of the latter. The chain-carrying peroxyl radicals have some polar character in the ground state that is lost in the termination reaction (24,25). The polar nature of the ester functionality in the monoglyceride may serve to inhibit the termination reaction slightly, decreasing $2k_t$ and resulting in a larger value of $k_p/(2k_t)^{1/2}$ for the monoglyceride.

On the basis of doubly allylic positions per molecule, the oxidizability of the diglyceride should be twice that of the monoglyceride. However, for a molecule with two separate oxidizable side chains held close to one another in space, k_p could be increased relative to two individual molecules. This would imply that the diglyceride would have a larger oxidizability than predicted on the basis of the number of doubly allylic positions present in the molecule. We determined the oxidizability of the diglyceride to be 5.89×10^{-2} $M^{-1/2}$ $sec^{-1/2}$ and found that this compound also obeyed the kinetics represented by equation 5 in the concentration ranges studied. This value is more than twice the value found for the monoglyceride, but when one considers the errors involved in these measurements, the significance of the difference is questionable. However, the diglyceride was a mixture of the 1,2- and 1,3-isomers of dilinoleoyl glycerol. To fully investigate the effect of the relative positions of the two linoleate chains in a diglyceride, it would be interesting to determine the oxidizability of the pure 1,2- and 1,3-isomers.

The determination of the oxidizability of the triglyceride of 18:2 was of interest because this compound has three linoleate chains held in close proximity to one another. However, the kinetics of the autoxidation of the triglyceride seem more complex than for the other substrates studied. The plot of $d[O_2]/dt$ vs $[PUFA]R_i^{1/2}$ gives a slope of 7.98×10^{-2} $M^{-1/2}$ $sec^{-1/2}$, exactly three times the value found for the monoglyceride. However, based on the present data, the triglyceride does not appear to follow classical autoxidation kinetics. The oxidizability decreases by about a factor of 2 as the concentration of triglyceride is increased at constant R_i (i.e., see lines 3 and 7 for triglyceride in Table 2). For a compound that obeys equation 5, the overall order of the reaction with respect to $[PUFA]R_i^{1/2}$ should be 1.0. In fact, for all substrates studied, except the triglyceride, the average overall order is 1.002 ± .014, in excellent agreement with the theoretical value. However, for the triglyceride, the overall order is about 0.84. While the absolute value of this number is not significant, the fact that it is not 1.0 indicates that the triglyceride does not obey the kinetic expression given in equation 5. This deviation from the standard kinetics appears greatest at low triglyceride concentrations. The data show that as the concentration of triglyceride increases, the overall order of the reaction with respect to $[PUFA]R_i^{1/2}$ approaches 1.0. This change in reaction order may be due to lipid aggregation at low concentrations of the triglyceride. It has been shown that phospholipids in homogeneous organic solution do not follow the classical autoxidation kinetics, reportedly due to lipid aggregation (26). While aggregation may be occurring with the triglyceride, it seems likely that the mono- and diglyceride would also form aggregates. However, aggregate formation may occur at different concentrations for the three glycerides and a wider range of

substrate concentrations needs to be studied to probe this point. Since equation 5 is not followed for the triglyceride of 18:2, the reported oxidizability is of little significance, and this substance will require a more thorough investigation.

The triglyceride also appears to give anomalous e values for one of the initiators. Using PUFA and the monoglyceride as substrates, AIBN and DBHN gave e equal to about 66% and DMVN about 75%, values expected from previous work. Both DBHN and AIBN were well behaved with the di- and triglyceride, giving the same e value as reported above. For DMVN, however, e increased to 88 ± 9% for the diglyceride and to 100 ± 2% for the triglyceride. We are not able to explain these increases in e, but they are not due to an increase in k_d for DMVN in the presence of the di- or triglyceride. This implies that these two glycerides somehow alter the solvent cage around the initiator molecules, allowing more radicals to escape the cage. Why this would occur only for DMVN and not DBHN or AIBN is not clear.

In conclusion, we have shown that the oxidizability of simple PUFA esters is directly related to the number of doubly allylic positions present in the molecule. This relationship does not appear to apply to the mono-, di- and triglycerides of 18:2, however. In fact, the triglyceride does not follow the classical autoxidation kinetics, and more work is required to elucidate the kinetics and mechanisms of its autoxidation.

ACKNOWLEDGMENTS

This work was supported in part by a grant from the National Institutes of Health. We are grateful to Graham Burton and Keith Ingold for aid with the transducer apparatus, to Laura Efferson for technical assistance and to the Henkel Corp. for gifts of α-tocopherol.

Net Lipid Transfer Between Lipoproteins in Fish-Eye Disease Plasma Supplemented with Normal High Density Lipoproteins

Leif Holmquist* and **Lars A. Carlson**
King Gustaf V Research Institute and the Department of Internal Medicine, Karolinska Institute and Karolinska Hospital, Stockholm, Sweden

Native fish-eye disease plasma, which is deficient of both high density lipoproteins (HDL) and lecithin–cholesterol acyltransferase activity (α-LCAT), processing the free cholesterol of these lipoproteins, has been supplemented with normal isolated HDL_2 or HDL_3 and incubated in vitro at 37 C. After incubation for 0, 7.5 and 24 hr the very low density (VLDL) and low density (LDL) lipoproteins as well as HDL were isolated, and their contents of triglycerides, phospholipids and free, esterified and total cholesterol were quantified. The resulting net mass transfer of the different lipids revealed a functioning transfer of cholesteryl esters and all other analyzed lipids between the lipoproteins, although no de novo esterification of the HDL cholesterol by LCAT in this plasma occurred. In accordance with previous findings there was a functioning esterification process of the free cholesterol of the combined VLDL and LDL of fish-eye disease plasma. The present results make it reasonable to conclude that the lack of HDL cholesterol esterification in this disease is not a result of a deficiency of cholesteryl ester transfer or lipid transfer activities.
Lipids 22, **305–311 (1987).**

Fish-eye disease (FED) is a familial dyslipoproteinemia (1,2), characterized by hypoalphalipoproteinemia associated with a specific deficiency of high density lipoprotein lecithin–cholesterol acyltransferase activity (α-LCAT) in plasma (3), but having a normally functioning cholesterol esterification activity acting on the combined very low density (VLDL) and low density (LDL) lipoproteins (β-LCAT) (3,4). Of several possible defects that might cause deficiency of α-LCAT, one would be a defective or deficient lipid transfer protein acting together with a postulated complex composed of LCAT and apolipoproteins forming a "cholesteryl ester transfer complex" (5) that could both synthesize and distribute cholesteryl esters to acceptor lipoproteins.

It has previously been demonstrated (6) that gross lipid transfer protein activities were normal when estimated in lipoprotein-depleted FED plasma. However, in light of the recently formulated hypothesis of α- and β-LCAT activities in plasma (3), the deficiency of α-LCAT activity in FED might be associated with or caused by a malfunctioning lipid transfer protein specific for high density lipoprotein (HDL) cholesteryl esters.

Determination of the flux of the cholesteryl esters of FED HDL in whole plasma is, however, hampered by the fact that the plasma cholesterol concentration level and the cholesteryl ester percentage of this lipoprotein are reduced by 90% and 75%, respectively, compared to normal plasma (7).

In the present investigation we have studied the in vitro incubation-induced changes of the lipid compositions of VLDL, LDL and HDL of FED plasma supplemented with normal HDL subfractions, with and without LCAT inhibitor, in order to evaluate the quality of the cholesteryl ester transfer activity in such plasma. The results are reported herein.

EXPERIMENTAL PROCEDURES

The FED patient no. 1 (S.R.) has been described in detail previously (1,2). Venous blood was taken from the patient in the mornings after overnight fast into vacutainer plastic tubes containing disodium EDTA. The tubes were immediately placed into crushed ice. Plasma was recovered within 30 min by low speed centrifugation at 2 C and was stored in crushed ice. Merthiolate® normally added to plasma in our work with lipoproteins was omitted. Free cholesterol and cholesteryl esters were quantified enzymatically in duplicate, directly on aliquots of plasma and on the lipoprotein fractions obtained after ultracentrifugation, by means of Merck kits 14106, 14107 and 14108 (Darmstadt, Federal Republic of Germany). The lipids of the plasma lipoproteins VLDL, LDL and HDL were extracted with chloroform/methanol (v/v) (8). Phospholipids and triglyceride concentrations were estimated in triplicate and duplicate, respectively, on aliquots of the chloroform phase as previously described (9,10). The coefficients of variation (number of estimates in parentheses) were 2.7% (75), 3.5% (57), 3.1% (57) and 1.1% (36) for between-run reproducibility of determinations of triglycerides, free cholesterol, esterified cholesterol and phospholipids, respectively. Concentrated normal HDL_2 and HDL_3 were defined as HDL subfractions (11) with density regions between 1.070 and 1.125 kg/l and 1.125 and 1.210 kg/l, respectively, and were isolated by preparative ultracentrifugation and dialyzed against 0.15 mol/l sodium chloride as described previously (Holmquist, L., and Carlson, L.A., submitted for publication). As a test for possible contamination of isolated normal HDL preparations by LCAT activity, preparations were mixed with a solution of essentially fatty acid-free bovine serum albumin, 5% final concentration, and incubated for 24 hr at 0 and 37 C. Estimations of free cholesterol and cholesteryl ester contents of the incubation mixtures showed that less than 14% of the free cholesterol was converted to cholesteryl esters after 24 hr of incubation (96% was obtained on incubations with autologous lipoprotein-depleted plasma), and no change of particle size could be detected. This indicates that HDL-associated LCAT activity is negligible in the HDL preparations obtained by the present method of preparation (11). Polyacrylamide gradient gel electrophoresis was performed as previously reported (2). Isolations of plasma lipoproteins (VLDL [d < 1.006 kg/l], LDL [d = 1.006–1.063 kg/l] and HDL [d = 1.063–1.21 kg/l]) after the incubation experiments were made by preparative ultracentrifugation at 1 C on a routine basis (12) using a Beckman L8-55 ultracentrifuge equipped with a type 50.3 Ti rotor and Quick-Seal Ultra-Clear tubes (6 ml) (Beckman Instruments, Palo Alto, California).

Incubation experiments. Ice-cold FED plasma (11.0 and 9.50 ml for HDL_2 and HDL_3 experiments, respectively) obtained as described above was mixed with concentrated HDL_2 (0.70 ml) or HDL_3 (1.90 ml) preparations (11). In experiments with LCAT inhibitor, 0.12–0.14 ml of phosphate-buffered 100 mmol/l disodium 5,5′-dithiobis-(2-nitrobenzoate) (DTNB), pH 7.4, was added to the plasma mixtures to 1 mmol/l final concentration. By addition of 0.15 mol/l sodium chloride solution, the final volumes of the incubation mixtures were adjusted to 13.3 and 11.5 ml for experiments with HDL_2 and HDL_3, respectively, resulting in 17% dilution of the original plasma. In experiments with native FED plasma, 0.15 mol/l sodium chloride solution was added to give the same final dilution as above, thus maintaining the LCAT and transfer protein concentrations equal in all incubation experiments.

The final concentrations of free cholesterol originating from HDL_2 or HDL_3 in the incubation mixtures were equimolar and adjusted to yield values representative of their average abundance in normal plasma.

Table 1 shows the compositions and cholesterol concentrations for the different incubation mixtures. Incubations were performed at 37 C in the dark under N_2 atmosphere.

RESULTS

Table 2 shows the concentration values for triglycerides, total, free and esterified cholesterol, cholesteryl ester percentage and phospholipids in VLDL, LDL and HDL fractions, estimated at 0, 7.5 and 24 hr of incubation of mixtures of FED plasma, alone or supplemented with normal isolated HDL_2 or HDL_3. The corresponding values obtained at incubation experiments of the same designs as above but performed in the presence of the LCAT inhibitor DTNB, run in parallel, are shown in Table 3.

Triglycerides. The triglycerides of the VLDL fraction of the different incubation mixtures decreased by 0.4–0.5 mmol/l, independently if β-LCAT was active or inhibited by DTNB. There was a concomitant increase in LDL triglycerides corresponding to about 0.4 mmol/l in native FED plasma and in such plasma supplemented with HDL_2. The increase in LDL triglycerides in plasma supplemented with HDL_3 was somewhat lower, about 0.3 mmol/l; however, this was associated with a correspondingly higher increase in triglycerides, 0.1 mmol/l, of the HDL fraction of the HDL_3-supplemented plasma compared to the 0.06 mmol/l triglyceride increase in the HDL fraction in experiments with HDL_2. The triglyceride concentrations of HDL in native FED plasma were too low to estimate accurately. The observed increase in triglycerides of LDL and HDL_2 or HDL_3 were of the same order whether LCAT was active or inhibited. Thus the decrease in VLDL triglyceride concentrations in all incubation experiments was completely balanced by the sum of the increase in triglycerides of the matching LDL and HDL fractions.

Cholesteryl esters. In the presence of the LCAT inhibitor DTNB, the cholesteryl ester concentration of VLDL of all three incubation mixtures increased by about 0.4 mmol/l on incubation. This increase in VLDL cholesteryl esters of the native FED plasma reflected a decrease in cholesteryl ester content by about 0.3 mmol/l of the LDL fraction of this plasma. The decrease in cholesteryl ester concentration of FED HDL was not possible to estimate accurately as its concentration was too low.

The decrease in cholesteryl ester content of LDL in plasma supplemented with HDL_2 or HDL_3 was 0.06 and 0.08 mmol/l lower, respectively, than that for LDL in native FED plasma. This reduced decrease in cholesteryl esters of such LDL compared to native plasma LDL was matched, however, by a decrease in cholesteryl ester concentration of 0.12 and 0.23 mmol/l in HDL_2 and HDL_3, respectively, in corresponding incubation experiments with these lipoproteins. Thus the molar increase in cholesteryl esters of the VLDL fractions corresponded in all experiments to the sum of the decrease in these lipids of LDL and HDL lipoproteins. In none of these experiments with LCAT inhibitor was there any de novo synthesis of whole plasma cholesteryl esters in 24 hr of incubation.

In the corresponding incubation experiments without LCAT inhibitor, the cholesteryl ester content of VLDL increased by 0.3–0.4 mmol/l. In LDL of incubated native FED plasma, a rise (0.06 mmol/l) of cholesteryl esters could also be observed. In the HDL fraction of this plasma, which had an extremely low cholesteryl ester content, no change of this lipid could be observed. In the LDL fractions of the HDL_2- and HDL_3-supplemented plasmas there were 0.34 and 0.33 mmol/l increases of the cholesteryl ester content, respectively, while the cholesteryl ester content of the HDL_2 and HDL_3 fractions decreased by about 0.1 and 0.2 mmol/l, respectively.

In the LCAT-active incubation mixtures of native FED

TC, Total cholesterol as sum of free and esterified cholesterol; DTNB, disodium 5,5′-dithiobis-(2-nitrobenzoate).

plasma and of such plasma supplemented with HDL_2 or HDL_3, there was de novo synthesis of 0.4, 0.6 and 0.5 mmol/l, respectively, of cholesteryl esters after 24 hr of incubation.

Free cholesterol. In LCAT-inhibited incubation experiments there was a slight increase in the free cholesterol content of VLDL by about 0.1 mmol/l, corresponding to a decrease in free cholesterol of LDL and HDL. The most predominant decrease of free cholesterol was found in the HDL of native FED plasma, which was reduced by 60% of its total free cholesterol. The decreases in free cholesterol content of the HDL_2 and HDL_3 lipoprotein fractions in corresponding incubations were only about 20%, but the absolute decrease was similar to the decrease in free cholesterol of the HDL originating from FED plasma. Within the error of estimation, the increases in the free cholesterol content of VLDL roughly corresponded to the total decrease in this lipid of the LDL and HDL fractions.

The recovery of free cholesterol in total isolated lipoproteins after 24 hr of incubation in the presence of LCAT inhibitor ranged from 96% to 103% for all three incubation mixtures, related to the free cholesterol concentrations estimated at start of the different incubations.

In LCAT-active incubations there was a slight increase (0.08 mmol/l) in free cholesterol of the VLDL of native

FED plasma. Such plasma, however, demonstrated a large decrease (0.50 mmol/l) in free cholesterol content of its LDL fraction.

In incubation experiments with active LCAT and HDL_2 or HDL_3, no change in free cholesterol of VLDL was found. The decrease in this lipid of the corresponding LDL fractions was about 0.3 mmol/l.

In all experiments, there was a decrease in the free cholesterol concentration of the HDL fractions. The relative reductions of free cholesterol of the HDL fractions of native, HDL_2- and HDL_3-supplemented FED plasma were about 100%, 50% and 50%, respectively.

Altogether, free cholesterol decreased in native FED plasma and the plasma supplemented with HDL_2 or HDL_3 by 0.6, 0.4 and 0.4 mmol/l, respectively, after 24 hr incubation when LCAT was active. The decrease in free cholesterol of these plasmas was mainly associated with a decrease in this lipid of LDL and HDL.

Total cholesterol. In experiments with LCAT inhibitor, the total cholesterol content of VLDL of all different incubations increased by 0.4–0.5 mmol/l. There was a concomitant 0.2–0.4 mmol/l decrease in total LDL cholesterol. Also, total cholesterol decreased in HDL of the different mixtures. The total cholesterol of the FED HDL decreased by 0.06 mmol/l, corresponding to a reduction of about 50% of total cholesterol initially present. In incubations with HDL_2 this fraction lost 0.17 mmol/l of total cholesterol, whereas in experiments with HDL_3 the loss increased to 0.23 mmol/l, both values representing total HDL cholesterol reduction by 40%. In all LCAT-inhibited experiments, the increases in total cholesterol of VLDL were balanced by the sum of the decreases in this lipid of LDL and HDL.

In LCAT-active incubations there was also an increase in VLDL total cholesterol of about 0.3–0.4 mmol/l; that value is somewhat smaller than that obtained when the enzyme was inhibited. In LDL of native FED plasma there was a corresponding decrease (0.4 mmol/l) in total LDL cholesterol, but a higher reduction (0.09 mmol/l) of its total HDL cholesterol than was seen with LCAT inhibitor. This figure, however, which has a large error of estimation due to the low cholesterol concentration, corresponds to an 87% reduction of total HDL cholesterol.

In the incubations with HDL_2 and HDL_3 the decreases in total cholesterol of these fractions were 0.20 and 0.28 mmol/l, respectively, yielding almost the same values as obtained for these lipoprotein fractions in the presence of the LCAT inhibitor DTNB. The decrease in total cholesterol content of HDL_2 and HDL_3 balanced the increase in total VLDL cholesterol in LCAT-active incubations, whereas the total cholesterol contents of the corresponding LDL fractions were essentially unchanged. The recovery of total cholesterol after 24 hr of incubation, estimated in total lipoproteins, as compared to concentrations at start of incubation ranged from 95% to 106% in all experiments with and without LCAT inhibitor.

Cholesteryl ester percentage. The cholesteryl ester percentage increased from 50% to 60% in VLDL of all incubation mixtures when LCAT inhibitor was present. However, in the corresponding LDL fractions there were virtually no changes of the relative amounts of cholesteryl ester showing a value of ca. 56%.

The cholesteryl ester percentages of FED HDL, normal HDL_2 and HDL_3 are close to 20%, 70% and 80%, respectively. It was not possible to accurately estimate changes of the cholesteryl ester percentage of HDL in incubation experiments with native FED plasmas. However, there was a tendency toward increase in relative cholesteryl ester content (to about 50%) due to a decrease in free cholesterol of the FED HDL, which was not associated with an increase in cholesteryl ester content. In the HDL fractions of the plasmas supplemented with HDL_2 or HDL_3, the cholesteryl ester percentage decreased from 56% to 46% and 69% to 58%, respectively, upon incubation with LCAT inhibitor.

When LCAT was active the cholesteryl ester percentage of VLDL also increased in all experiments from about 50% to 65%, which is a little greater increase than that obtained in the corresponding incubation with LCAT inhibitor.

In incubation mixtures with active LCAT, there was also an increase in the cholesteryl ester percentage of the LDL lipoproteins from about 55% to 65%.

At the start of incubation of FED plasma supplemented with normal HDL_2, the mean cholesteryl ester percentage of the combined HDL_2 and FED HDL originally present in such plasma was 57%. After a 24-hr reaction this percentage increased to 68%, which is the normal value for native HDL_2.

In incubation experiments with active LCAT and HDL_3, there was no change of the cholesteryl ester percentage, showing a starting value of 68%, representing a mean of the added HDL_3 and of autologous FED HDL.

Phospholipids. When whole native FED plasma and such plasma supplemented with normal isolated HDL_2 or HDL_3 was incubated with the LCAT inhibitor DTNB, followed by isolation of VLDL, LDL and HDL and estimation of their phospholipid contents, these lipids were recovered in 96% to 104% yields, calculated from the phospholipid concentrations at start of the incubations.

In these three LCAT-inhibited plasma mixtures, the phospholipid contents of their VLDL fractions virtually did not change on incubation for 24 hr. In experiments with native plasma the phospholipid content of LDL increased by 0.17 mmol/l, which corresponded to a 0.12 mmol/l decrease in the plasma HDL phospholipid content, the latter decrease representing a reduction by 52% of the initial HDL phospholipid concentration.

HDL_2-supplemented FED plasma demonstrated a slight increase in phospholipid content of LDL corresponding to a possible slight decrease in this lipid of the HDL fraction, in the presence of LCAT inhibitor. In HDL_3-supplemented plasma, similar slight changes of phospholipids of LDL and HDL occurred on incubation with LCAT inhibitor.

The concentration of phospholipids decreased by approximately 0.15 mmol/l in each of the VLDL, LDL and HDL fractions of all three incubation mixtures after a 24-hr incubation under conditions where LCAT was active. The total loss of phospholipids estimated in total lipoproteins isolated from each incubation mixture after 24 hr of incubation with active LCAT was about 0.45 mmol/l.

Particle size pattern of HDL. The HDL fractions of all incubation mixtures were isolated at 0 hr and after 7.5 and 24 hr of incubation, and their particle size patterns were analyzed by polyacrylamide gradient gel electrophoresis and staining for proteins. The results are

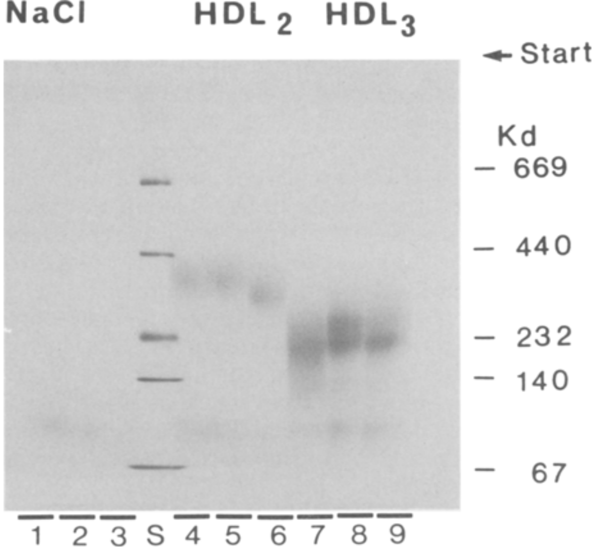

FIG. 1. Electrophoretogram of polyacrylamide gradient gel electrophoresis of the high density lipoprotein (HDL) fraction (d = 1.063–1.21 kg/l) isolated after 0, 7.5 and 24 hr of incubation at 37 C of native fish-eye disease (FED) plasma and such plasma supplemented with isolated normal HDL_2 or HDL_3. Zones are stained by Coomassie Brilliant Blue. 1–3, Native FED plasma incubated for 0, 7.5 and 24 hr, respectively; 4–6, FED plasma supplemented with HDL_2 incubated for 0, 7.5 and 24 hr, respectively; 7–9, FED plasma supplemented with HDL_3 incubated for 0, 7.5 and 24 hr, respectively; s, molecular mass markers same as in ref. 7; Kd, kilodalton.

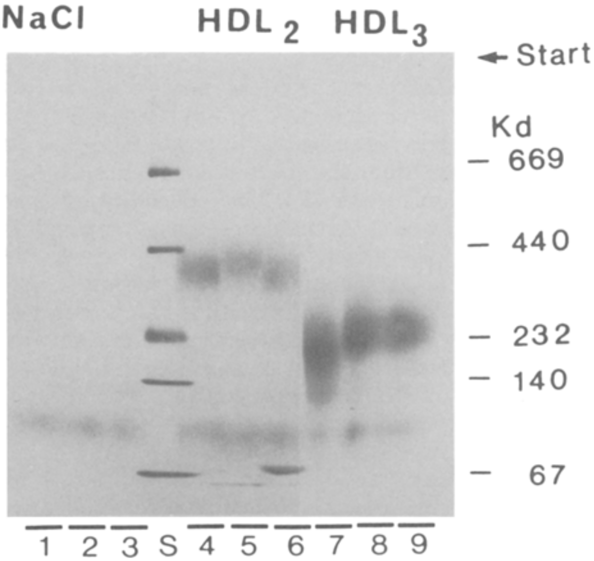

FIG. 2. This figure represents the same incubation experiments as in Fig. 1, but performed in the presence of the LCAT inhibitor disodium 5,5′-dithiobis-(2-nitrobenzoate).

shown in Figures 1 and 2. These figures demonstrate that the native FED plasma HDL and this HDL in plasma supplemented with HDL_2 almost disappeared after 24 hr of incubation with active LCAT. At supplementation of plasma with HDL_3, however, FED HDL seemed less affected by incubation or its position on the electrophoretogram might be superimposed by small HDL particles produced from the added isolated HDL_3 particles as a result of the incubation process.

In the corresponding incubations with LCAT inhibitor, FED HDL did not seem to be affected by the incubation process. The small FED HDL particles did not seem to fuse with the added normal HDL_2 or HDL_3, but remained as homogenous particle populations. In all experiments with and without LCAT inhibitor there was an incubation-induced increase of the size of the HDL_3 particles related to the added HDL_3 preparation. By contrast, after 24 hr of incubation the HDL_2 fraction was unaffected or slightly reduced in particle size.

DISCUSSION

It has been postulated that plasma cholesteryl esters are primarily formed in HDL_3 or in a subfraction of these lipoproteins by the action of LCAT on the free cholesterol at the HDL particle surface. Formed esters are subsequently distributed to acceptor lipoproteins of lower densities (13) by active lipid transfer proteins exchanging lipids between VLDL, LDL and HDL (for review see 14–16).

However, evidence has been presented that in FED plasma almost all cholesteryl esters are synthesized within the β-lipoproteins (VLDL and LDL) by the direct action of LCAT activity (β-LCAT) (3,4). This plasma virtually lacks the property to esterify the free cholesterol of isolated normal HDL_3 as well as that of the very small, but spherical, free cholesterol-rich HDL particles present in both FED and LCAT-deficient plasma (2,7,17). These latter lipoproteins have been demonstrated to be excellent substrates for normal LCAT (3,17,18). As β-LCAT also could be demonstrated in HDL-depleted normal plasma to esterify the free cholesterol of both autologous and homologous combined VLDL and LDL (4), we introduced the hypothesis that there normally exist two LCAT activities denoted α- and β-LCAT in normal plasma, specific for HDL and combined VLDL and LDL, respectively (3). According to this concept fish-eye disease is an α-LCAT deficiency syndrome. The apparent deficiency of the HDL cholesterol esterifying activity (α-LCAT) might be explained in several ways. One obvious possibility is that one of two isoenzymes of LCAT, which according to our hypothesis is present in normal plasma, is lacking in FED plasma. A second possibility would be that FED β-LCAT is a mutant of a normal LCAT, resulting in an enzyme lacking activity for HDL cholesterol but with a functioning β-lipoprotein esterifying activity. In the present study a possible role of a lacking or impaired cholesteryl ester transfer or lipid transfer activity has been considered as yet another cause for the apparent lack of α-LCAT.

It has been suggested that LCAT exists in plasma in a complex with apolipoprotein A-I, which is qualitatively normal in fish-eye disease (19), and apolipoprotein D, which has been ascribed the role of a cholesteryl ester transfer protein residing in HDL (5). The observed preference of normal LCAT for HDL_3 in incubations in vitro with isolated lipoproteins was suggested to be an artifact induced by the ultracentrifugation isolation technique (5). It was proposed that instead of acting directly on lipoprotein particles, LCAT esterifies free cholesterol present in

an LCAT-apo A-I-apo D complex and that all major lipoprotein fractions of plasma could act as recipients of the enzymatically synthesized cholesteryl esters (5).

Evidently combined VLDL and LDL functions as substrate for an active LCAT (β-LCAT) in FED plasma. It has also previously been demonstrated that cholesteryl ester transfer activity in lipoprotein-depleted FED plasma is normal (6) and that this plasma contains normal apolipoproteins A-I and D, although in strongly reduced concentrations compared to normal plasma (2,19). Thus the basic qualitative requirements for a functioning cholesterol-esterifying complex (5) as described above seem fulfilled in fish-eye disease.

However, as FED HDL total cholesterol and relative amount of cholesteryl esters are reduced by 90% and 75%, respectively, in plasma, relative to what is normal, it has not been possible to confirm in vitro with autologous lipoproteins a normal cholesteryl ester transfer from HDL to VLDL or LDL.

Thus this transfer activity together with triglyceride and phospholipid transfer activities were measured in the present study as net mass lipid transfer between VLDL, LDL and HDL in whole FED plasma supplemented with normal isolated HDL_2 or HDL_3. The addition of normal HDL fractions to such plasma would favor the formation of a postulated LCAT-cholesteryl ester transfer protein complex, normalizing the plasma concentrations of both apolipoprotein A-I and D and other unknown potentially important apolipoprotein cofactors. Also subfractions of normal HDL_3 would have a favorable structure for initiation of cholesterol esterification (14,15) by the LCAT present in FED plasma, possibly induced by isolation of HDL_3 by preparative ultracentrifugation (5,16) as discussed above. In addition the increase in the cholesteryl ester content of the plasma HDL_2 or HDL_3 fraction to a normal level made it possible to study its change with time of incubation. The results from the present experiments with FED plasma supplemented with isolated normal HDL_2 or HDL_3 and incubated in the presence of the LCAT inhibitor DTNB clearly demonstrate a net mass reduction of the cholesteryl ester contents of both HDL_2 and HDL_3 and of LDL accompanied by an increase in these lipids in VLDL. There was a concomitant decrease in the triglyceride content of VLDL associated with an increase in this lipid in HDL_2 or HDL_3 and in LDL. This indicates a functioning cholesteryl ester transfer from HDL to lipoproteins of lower densities, in agreement with what has been observed to occur in normal plasma (13–16,20). From the values for cholesteryl ester content of the HDL fraction of FED plasma supplemented with HDL_2 or HDL_3 at 0 hr and after incubation for 7.5 hr in the presence of DTNB, which inhibits LCAT (Table 3), a cholesteryl ester transfer rate of 16 μmol cholesteryl ester $\times$ hour^{-1} $\times$ liter plasma^{-1} may be calculated for the direction HDL to lipoproteins of lower densities. This figure is well within the range of the corresponding cholesteryl ester transfer rates obtained with whole plasma of normolipidemic subjects, which ranged from 12 to 40 (mean of 24) μmol cholesteryl ester $\times$ hour^{-1} $\times$ liter plasma^{-1}, and higher than those of hypertriglyceridemic subjects with documented vascular disease, whose rates varied within 0 to 15 (mean of 9) μmol $\times$ hour^{-1} $\times$ liter plasma^{-1}, as reported by Fielding et al. (21).

The concentrations of free cholesterol and phospholipids of the FED HDL decreased in incubations with LCAT inhibitor and native FED plasma. The quantitative yields of the lipids of whole plasma after incubation, however, indicate that this lipoprotein partly fuses or is taken up by the other lipoproteins in the plasma.

Also in LCAT-active incubations there was an evident cholesteryl ester transfer between added HDL_2 or HDL_3, and the other lipoproteins in the incubation mixtures balanced by triglyceride transferred in an expected counterflow direction as described above. An increase in total cholesteryl ester content was observed in such plasma mixtures that were of the same order of magnitude as previously reported for native FED plasma (2). Concomitantly the total phospholipid content of the plasma mixture decreased stoichometrically with the synthesis of new cholesteryl esters. The decrease of free cholesterol was most apparent in the LDL fraction, whereas it remained practically unchanged in VLDL. Phospholipids decreased in both VLDL and LDL and in added HDL_2 or HDL_3 by approximately the same molar amount when LCAT was active. In native FED plasma the degradation of its small HDL particles was pronounced, as estimated by a decrease in major lipid components. In addition polyacrylamide gradient gel electrophoresis showed a fading of the stain of the zone corresponding to the FED HDL particle population in LCAT-active incubations with native FED plasma and in such plasma supplemented with HDL_2. There was no degradation of FED HDL detectable by gradient gel electrophoresis in experiments with HDL_3 or when incubations were performed with LCAT inhibitor. However, both HDL_2 and HDL_3 have been demonstrated to have an inhibitory effect on β-LCAT, with the latter HDL subfraction being the strongest inhibitor of the fish-eye disease enzyme (Holmquist, L., and Carlson, L.A., submitted for publication).

The added HDL_3 particles were enlarged on incubation when LCAT was either active or inhibited, whereas the HDL_2 fraction was less affected; this is in agreement with previous findings from the effect of incubation on normal plasma HDL particle size (22). There also seemed to be an increase in the amount of small particles accompanying the enlargement of the added HDL_3 particles on incubation (Fig. 1), which is consonant with the results reported by Nichols et al. (23) for incubation experiments with HDL studied by polyacrylamide gradient gel electrophoresis.

De novo synthesis of cholesteryl esters in the HDL fractions could not be detected in any incubation experiment, although both β-LCAT and cholesteryl ester transfer activities of FED plasma were active, resulting in an increase in the plasma cholesteryl ester content of about 0.5 mmol/l. On incubation, the cholesteryl ester content of added normal HDL_2 or HDL_3 decreased with the same value whether LCAT was active or inhibited. The polyacrylamide gradient gel electrophoresis experiments indicate that the small-sized FED HDL particles in the incubation mixture did not increase in particle size, in contrast to what they do when acted upon by normal LCAT, which concomitantly increased their relative cholesteryl ester content from about 20% to 100% (3).

The zone on the polyacrylamide gradient gel electrophoretogram corresponding to FED HDL almost disappeared after 24 hr of incubation in experiments with native FED plasma and such plasma supplemented with

normal HDL_2. This phenomenon was observed earlier but was less pronounced in undiluted FED plasma (3), which had a somewhat higher amount of HDL than plasma in the present experiments. The fading of HDL-stainable material thus does not seem to be an artifact of the electrophoresis, but might be a result of reduction of HDL particle size or increase in density following particle lipid degradation (Table 2). This should give rise to loss of HDL in the 1.063-1.21 kg/l fraction on ultracentrifugation.

All the results of this study indicate that esterification of cholesterol in FED plasma occurs in combined VLDL and LDL, as previously suggested by an active β-LCAT (3), even during conditions that would favor primary esterification of the free cholesterol in normal HDL subfractions.

These results also favor the hypothesis that there might exist α- and β-LCAT activities with different substrate specificities, the α-LCAT being deficient in fish-eye disease.

Recent experiments have further demonstrated that FED HDL particles are normalized in respect to both particle size and cholesteryl ester content by total lipoprotein-depleted pig plasma (24) which is deficient of cholesteryl ester transfer activity (16). This further supports the view that the abnormally small-sized and cholesteryl ester-poor FED HDL are the result of a specific lack of an LCAT enzyme activity rather than impaired lipid transfer activities or lipid acceptor properties of the plasma lipoproteins.

Periodate-Induced Lipid Oxidation of Erythrocyte Membranes

Masatoshi Beppu and **Kiyomi Kikugawa***
Tokyo College of Pharmacy, 1432-1 Horinouchi, Hachioji, Tokyo 192-03, Japan

Exposure of human erythrocyte ghosts to 0.2-5 mM periodate at 0 C for 15 min resulted in an increase of thiobarbituric acid-reactive substances and fluorescent materials in the membrane. This increase was suppressed by radical scavengers, butylated hydroxytoluene and thiourea, indicating that periodate caused lipid oxidation of ghosts. A role of hemoglobin in the periodate-induced lipid oxidation of ghosts was suggested by the fact that the oxidation was augmented by hemoglobin and inhibited by an iron chelator, desferrioxamine. Treatment of ghosts with periodate caused membrane protein cross-linking with and without disulfide bridge. Erythrocytes were also susceptible to lipid oxidation by periodate, but only disulfide-mediated protein cross-linking was observed. Erythrocytes treated with neuraminidase or trypsin were less susceptible, but those treated with neuraminidase along with galactose oxidase were nearly as susceptible as untreated cells. The effect of galactose oxidase was diminished by reduction of the enzyme-treated cells with borohydride. These results indicate that the aldehyde moieties generated by periodate at the sialyl residues or those generated by galactose oxidase at the terminal galactosyl or *N*-acetyl galactosaminyl residues of the membrane glycoconjugates play a stimulating role in the periodate-induced membrane lipid oxidation.
***Lipids 22,* 312-317 (1987).**

It has been demonstrated that periodate treatment of lymphocytes (1-4), macrophages (2) and erythrocytes (4-6) induces a variety of functional changes in these cells. For example, periodate treatment of erythrocytes renders them susceptible to macrophage recognition (5) and cytolysis by lymphocytes (4). It has been known that the sialyl residues of glycoproteins of the cell membranes are readily oxidized to the aldehyde-bearing derivatives by periodate (7,8), and most of the functional alterations of the cell membranes have been ascribed to the oxidation of the sialyl residues. Protein is also susceptible to periodate and affords cross-linked proteins with disulfide bridge (6,9). Reversible formation of aqueous channels or pores in the erythrocyte membrane by periodate is regarded as a consequence of the disulfide bridge formation (6).

In view of a possible involvement of lipid oxidation in the periodate-induced damage and functional changes of the cell membranes, it is important to clarify the characteristic nature of lipid oxidation of the cell membranes by periodate. We have investigated the reaction of human erythrocytes and ghosts with periodate. We will demonstrate here that extensive lipid oxidation takes place both in erythrocytes and in ghosts and will show that sialyl residues of the membrane glycoconjugates affect the periodate-induced lipid oxidation of the membrane.

MATERIALS AND METHODS

Materials. Sodium metaperiodate, thiobarbituric acid (TBA) and thiourea were obtained from Wako Pure Chemical Industries. Butylated hydroxytoluene (BHT) and desferrioxamine (Desferal) were from Nikki Universal Company and Ciba-Geigy, respectively. Linoleic acid and methyl linoleate were from Nippon Oil and Fats Company. Oleic acid and methyl linolenate were from Nakarai Chemicals. γ-Linolenic acid was from Sigma Chemical Co. Neurminidase (E.C.3.2.1.18, *Vibrio cholerae*) was from Behringerke AG. *N*-Acetylneuraminic acid (NANA, type VI) and soybean trypsin inhibitor were from Sigma. Trypsin (bovine pancreas) and galactose oxidase (E.C.1.1.3.9, *Dactylium dendroides*) were from Worthington Diagnostic Systems. Hemoglobin was purified from the human erythrocyte lysate by CM Sephadex C-50 ion exchange column chromatography as described elsewhere (10).

Erythrocytes and ghosts. Human venous blood was collected from a healthy donor using citrate-phosphate-dextrose as an anticoagulant and was stored at 4 C for use within a few days. The blood was centrifuged to remove plasma and buffy coats. Erythrocytes were washed 4 times with isotonic saline and resuspended in Dulbecco's phosphate-buffered saline (DPBS, pH 7.2). Erythrocyte ghosts were isolated according to the method of Dodge et al. (11) and were stored at −20 C in aliquots for use. Hemoglobin content in the ghosts was usually 1-3% of the total proteins as determined by the method reported (11). Protein concentrations were determined by the method of Lowry et al. (12).

Measurement of sialic acid. Free sialic acids were determined by the method of Warren (13). To a sample solution (0.2 ml) was added 0.1 ml of 0.2 M sodium metaperiodate in 9 M phosphoric acid, and the solution was kept at 22 C for 20 min. After destroying an excess amount of periodate by addition of 1.0 ml of 10% sodium arsenite solution in 0.05 M sulfuric acid-0.5 M sodium sulfate, the mixture was heated with 3.0 ml of 0.6% TBA in 0.5 M sodium sulfate at 100 C for 15 min. After cooling, the mixture was extracted with 4.3 ml of cyclohexanone, and the absorbance at 549 nm of the extract was recorded. The standard NANA solution was similarly treated as a control. For the determination of the total sialic acid contents of intact erythrocytes and ghosts, the cells were heated in 0.05 M sulfuric acid at 80 C for 1 hr, and the released sialic acid was purified by successive passing through Dowex 50 (H^+) and Dowex 1 (formate) columns (13).

To estimate the amounts of the unoxidized sialic acid residues in the periodate-treated ghosts, the control and the oxidized ghosts (1-3 mg protein/ml) were treated with neuraminidase (25 mU/ml) at 37 C for 30 min, and the released sialic acid in the supernatant was determined.

For measurement of the amounts of sialic acid residues released from the neuraminidase-treated erythrocytes, the supernatant was directly subjected to sialic acid determination. The supernatant of the trypsin-treated erythrocytes was successively incubated with neuraminidase (25 mU/ml) at 37 C for 3 hr to release free sialic acid for assay.

Measurement of lipid oxidation. (a) Formation of TBA-reactive substances. Lipid oxidation of the membranes was assessed by measuring TBA-reactive substances (TBA-RS) according to the method of Buege and Aust

*To whom correspondence should be addressed.

(14). Briefly, 1.0 ml of a membrane suspension (2–3 mg protein/ml) was mixed with 2.0 ml of a solution of 0.375% TBA-trichloroacetic acid (TCA)-0.25 N HCl containing 0.01% BHT, and the mixture was heated at 100 C for 15 min. After cooling, the mixture was centrifuged, and the absorbance at 532 nm of the supernatant was measured. The amount of TBA-RS was expressed as the absorbance at 532 nm for the membrane specimen containing 2 mg protein.

Measurement of TBA-RS of fatty acids and their methyl esters was carried out as follows. The sample was heated in a mixture of 1.0 ml of 0.5% TBA and 2.9 ml of 0.5% TCA at 60 C for 90 min under anaerobic conditions. After cooling, the mixture was extracted with 3.0 ml of chloroform to give a clear aqueous phase. The absorbance at 532 nm of the aqueous phase was recorded.

(b) Formation of fluorescence. Formation of fluorescent substances in the membranes was assessed as an index of lipid oxidation (15). For this purpose, the membranes were solubilized in 5% sodium dodecyl sulfate (SDS)–10 mM sodium phosphate buffer (pH 7.0). Fluorescence intensities were measured at an excitation maximum of 354 nm and an emission maximum of 437 nm. Relative fluorescence intensity of the solubilized membrane against 0.1 μM quinine sulfate was expressed for the protein concentration of 10 mg/ml.

SDS polyacrylamide gel electrophoresis. SDS gel electrophoresis was performed by the method of Laemmli (16) in a 7.5% gel. Ghosts were solubilized in the Laemmli sample buffer. For preparation of nonreduced samples, 2-mercaptoethanol was omitted from the sample buffer. Sample containing 40 μg protein was loaded for each lane. Protein bands were visualized by staining with Coomassie Brilliant Blue R-250. Major protein bands of erythrocyte membrane are numbered according to Steck (17).

Treatment of erythrocytes and ghosts with periodate. A suspension of intact or enzyme-treated erythrocytes (hematocrit value 20%) was mixed with an equal volume of freshly prepared 0.4–10 mM sodium metaperiodate solution in DPBS. The reaction was performed at 0 C for 15 min in the dark with occasional mixing. The cells were recovered by washing four times with DPBS at 0–4 C. The ghosts were prepared by hypotonic hemolysis using standard procedures (11) and were resuspended in 10 mM phosphate buffer (pH 7.0) for subsequent analysis.

Reaction of ghosts, intact or from the enzyme-treated erythrocytes, with periodate was carried out by mixing the ghost suspension (5 mg protein/ml) in 10 mM phosphate buffer (pH 7.0) with an equal volume of the periodate solution. After incubation at 0 C for 15 min in the dark, the ghosts were recovered by centrifugation (15,000 × g, 20 min) and washed four times with 10 mM phosphate buffer (pH 7.0) at 0–4 C. The recovered ghosts were resuspended in the same buffer for subsequent analysis.

Treatment of erythrocytes with enzymes. An erythrocyte suspension (hematocrit value 50%) in DPBS was incubated with neuraminidase (25 mU/ml), trypsin (0.1 mg/ml) or neuraminidase (25 mU/ml) plus galactose oxidase (10 U/ml) at 37 C for 30 min. The trypsinized cell suspension was incubated for a further 3 min with trypsin inhibitor (0.2 mg/ml). The cells and the supernatant were separated by centrifugation. The supernatant was subjected to sialic acid determination. The cell pellet was washed three times with DPBS to give the enzyme-treated erythrocytes. The ghosts were prepared by using standard procedures (11).

RESULTS

Human erythrocyte ghosts were treated with 5 mM periodate at 0 C for 15 min. Loss of the sialic acid residues was assessed by TBA reagent according to the method of Warren (13) (Fig. 1A). Sialic acid that can be released from untreated ghosts by neuraminidase (90% of the total sialic acid) formed the color with a maximum absorption at 549 nm, which was identical with that of the standard NANA. The supernatant of the enzyme digest of the periodate-treated ghosts exhibited an absorbance at 549 nm, as low as 5% of that of the untreated ghosts. Thus, most of the sialic acid residues on the ghosts were lost by the periodate treatment. They were oxidized probably to 8- or 7-carbon analogues bearing aldehyde moieties (7,8).

TBA-RS of the ghosts were measured as an index of lipid oxidation (14) (Fig. 1B). Untreated ghosts produced a color with a maximum absorption at 532 nm, which was identical with that of the standard malonaldehyde. The periodate-treated ghosts revealed much higher absorbance at 532 nm, indicating that formation of TBA-RS was accelerated by the treatment. This substantial increase in TBA-RS may be due to lipid oxidation of the ghosts.

To examine the ability of periodate to oxidize unsaturated fatty acids and their methyl esters, emulsified fatty acids were incubated with periodate. While incubation of methyl linoleate with 5 mM periodate at 0 C for 15 min under aerobic conditions showed no significant increase in TBA-RS, incubation of linoleic acid, methyl linoleate, γ-linolenic acid and methyl linolenate with 50 mM periodate at 37 C for 48 hr resulted in a substantial increase in TBA-RS (Table 1). Periodate at the relatively high concentration can accelerate oxidation of the unsaturated fatty acids.

Ghosts were treated with various concentrations of periodate at 0 C for 15 min. TBA-RS accumulated in the

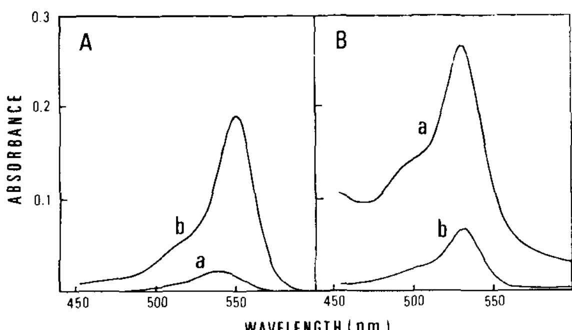

FIG. 1. Absorption spectra of thiobarbituric acid (TBA) color in sialic acid measurement (A) and TBA-reactive substances (RS) (B) of the periodate-treated ghosts. A: Spectra of TBA color from the sialic acid residues released from the ghosts by neuraminidase. B: Spectra of TBA-RS due to lipid oxidation in the ghosts. Absorbance obtained for the ghosts containing 2 mg protein was presented. a) Ghosts (2.5 mg protein/ml) treated with 5 mM periodate at 0 C for 15 min. b) Untreated ghosts, which contained 30 μg total sialic acid/mg protein and released 27 μg sialic acid by neuraminidase digestion.

TABLE 1

Oxidation of Unsaturated Fatty Acids by Periodate[a]

Unsaturated fatty acid	Thiobarbituric acid–reactive substances ($A_{532\ nm}$)[b]		
	No incubation	Incubated without periodate	Incubated with periodate
Oleic acid	0.000	0.000	0.000
Linoleic acid	0.009	0.053	0.088
Methyl linoleate	0.019	0.044	0.279
γ-Linolenic acid	0.491	0.579	0.665
Methyl linolenate	1.93	14.0	33.3

[a]An emulsified mixture (10 ml) of an unsaturated fatty acid or its methyl ester (20 mM) and periodate (50 mM) was incubated at 37 C for 48 hr in the dark in a loosely capped tube. At the end of the incubation, 1.7 ml of a solution of 10% sodium arsenite–0.05 M sulfuric acid–0.5 M sodium sulfate was added to destroy the residual periodate, and the mixture was extracted with 1.5 vol chloroform. Each 2 ml of the chloroform layer was evaporated to dryness to determine thiobarbituric acid–reactive substances.

[b]Values derived from 20 μmol of each unsaturated fatty acid are shown.

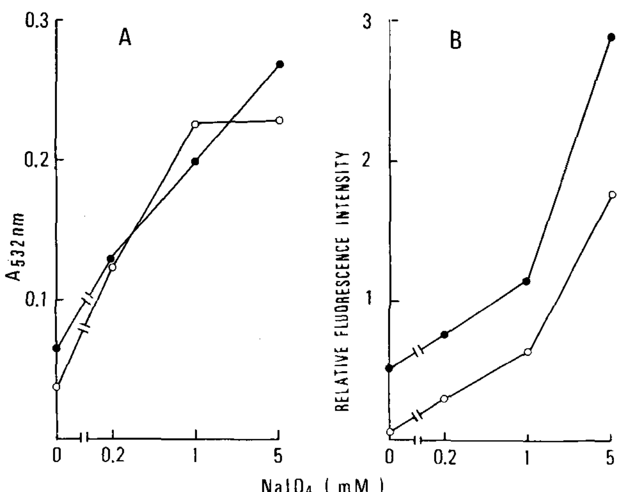

FIG. 2. Formation of thiobarbituric acid–reactive substances (A) and fluorescence (B) in the periodate-treated ghosts and erythrocytes. ●, Suspension of ghosts (2.5 mg protein/ml) in periodate solution at the indicated concentration was incubated at 0 C for 15 min. ○, Erythrocyte suspension (10%) in periodate solution at the indicated concentration was incubated at 0 C for 15 min. The ghosts were prepared by hypotonic hemolysis for the assay. $A_{532\ nm}$ is expressed for the amount of ghosts containing 2 mg protein.

membranes at the periodate concentrations above 0.2 mM (Fig. 2A). Formation of fluorescence was examined as another index of lipid oxidation (15). The maximum wavelengths of the fluorescence spectra of the membranes were 354 (excitation) and 437 nm (emission), similar to those of the erythrocyte membranes oxidized by organic hydroperoxides (18) and 13-linoleic acid hydroperoxide (19). The fluorescent substances accumulated in the membranes at the periodate concentrations above 0.2 mM (Fig. 2B). The fluorescent substances distributed in both

TABLE 2

Inhibition of Periodate-Induced Thiobarbituric Acid-Reactive Substances (TBA-RS) and Fluorescence Formation in Ghosts[a]

Treatment of ghosts	TBA-RS[b] ($A_{532\ nm}$/ 2 mg protein)	Relative fluorescence intensity[b]
Control (no treatment)	0.029 (10)	0.88 (23)
Periodate	0.286 (100)	3.83 (100)
Periodate in the presence of		
Butylated hydroxytoluene (0.1 mM)	0.142 (50)	1.11 (29)
Thiourea (30 mM)	0.032 (11)	0.90 (23)
Desferrioxamine (0.5 mM)	0.042 (15)	0.92 (24)

[a]Ghosts (2.5 mg protein/ml) were treated with 1 mM periodate at 0 C for 15 min in the presence or absence of the indicated compounds.

[b]Numbers in parentheses are TBA values or fluorescence intensities expressed as percentage of the values of the ghosts treated with periodate alone.

lipid and protein fractions (data not shown). The periodate-induced TBA-RS formation in ghosts was inhibited partially by BHT and completely by thiourea and desferrioxamine (Table 2). Formation of fluorescence was inhibited completely by these reagents (Table 2). These inhibitory effects are probably due to specific properties of the compounds—i.e., BHT is an antioxidant of lipid oxidation, thiourea a hydroxyl radical scavenger and desferrioxamine a potent iron chelator (18,20)—and not to a nonspecific reaction between these compounds with periodate. This is supported by the fact that the periodate concentration is 10-fold that of BHT (Table 2), whereas in the case of thiourea and desferrioxamine, it was observed that urea, an analogous compound of thiourea, and desferrioxamine saturated with Fe^{3+} were ineffective under the same conditions. These results indicate that the radical reactions are involved in the periodate-induced TBA-RS and fluorescence formation and substantiate that lipid oxidation is induced in ghosts by periodate. Inhibition of the periodate-induced lipid oxidation of ghosts by desferrioxamine suggests an essential role for hemoglobin in the reactions (21,22). The periodate-induced TBA-RS and fluorescence formation in ghosts increased with the concentrations of exogenously added hemoglobin (Fig. 3). In this case, hemoglobin alone did not induce lipid oxidation. It is evident that the periodate-induced lipid oxidation of ghosts was catalytically accelerated by hemoglobin.

Cross-linking of the membrane proteins was analyzed by SDS gel electrophoresis in the presence or absence of 2-mercaptoethanol (Fig. 4). Under nonreducing conditions (Fig. 4A), bands 1, 2, 3, 4.1, 4.2 and 5 diminished as the periodate concentration increased (lanes 2–4). At 5 mM periodate, these bands totally disappeared (lane 4). As these bands diminished, higher molecular weight proteins appeared near the top of the gel (lanes 2–4). There were no remarkable differences in the protein band patterns before (Fig. 4A) and after (Fig. 4B) reduction with 2-mercaptoethanol. Hence, extensive protein cross-links other than disulfide bridges were formed by the periodate treatment. Effects of BHT, thiourea and desferrioxamine on the protein cross-linking were analyzed under reducing

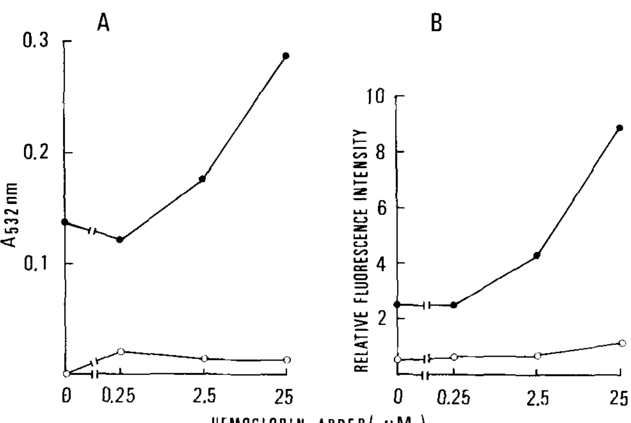

FIG. 3. Effect of hemoglobin on periodate-induced thiobarbituric acid-reactive substances (A) and fluorescence (B) formation in the ghosts. Ghosts (2.5 mg protein/ml) were treated with (●) or without (○) 1 mM periodate in the presence of increasing amounts of hemoglobin at 0 C for 15 min. The ghost preparation originally contained hemoglobin (2.7% of the total protein), which corresponded to 1 μM under the reaction condition. $A_{532\ nm}$ is expressed for the amount of ghosts containing 2 mg protein.

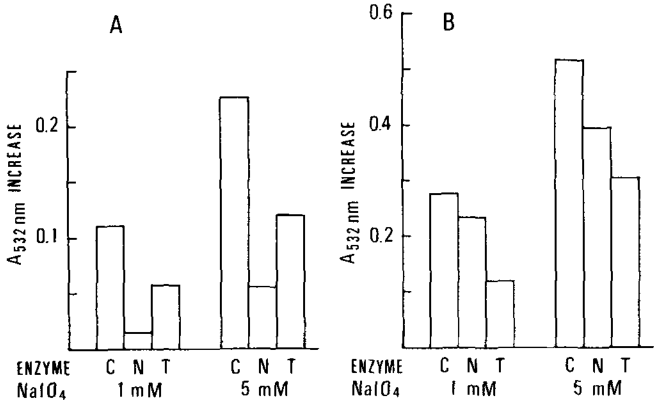

FIG. 5. Effects of neuraminidase and trypsin treatment of erythrocytes on the periodate-induced thiobarbituric acid-reactive substances formation in erythrocytes (A) and ghosts (B). An erythrocyte suspension (50%) was preincubated with neuraminidase (N), trypsin (T) or without the enzymes (C), as described in Materials and Methods. The neuraminidase (N)- and trypsin (T)-treated cells contained 40% and 64% of the original sialic acid contents, respectively. The enzyme-treated cell suspensions (10%) in periodate solution at the indicated concentrations were incubated at 0 C for 15 min. The ghosts (2.5 mg protein/ml) prepared from the preincubated erythrocytes were similarly treated with periodate. $A_{532\ nm}$ is expressed for the amount of ghosts containing 2 mg protein.

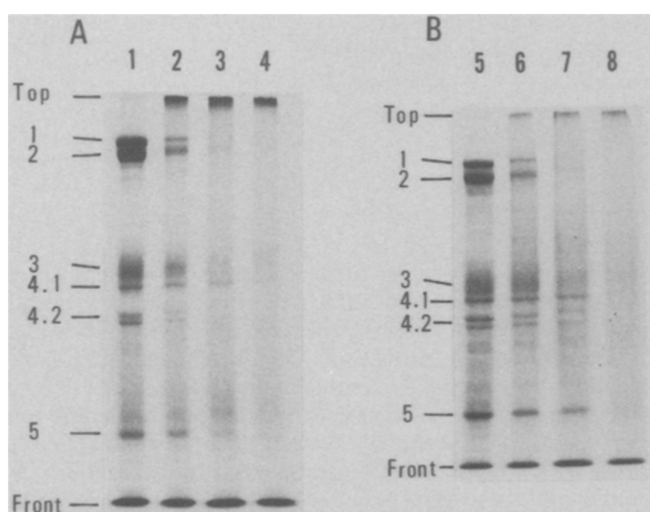

FIG. 4. SDS polyacrylamide gel electrophoresis of the periodate-treated ghosts. Electrophoresis was performed under nonreducing (A) and reducing (B) conditions. Control ghosts, lanes 1 and 5; ghosts treated with 0.2 mM periodate, lanes 2 and 6; 1 mM periodate, lanes 3 and 7; and 5 mM periodate, lanes 4 and 8. Treatment of ghosts with periodate was performed as described in the legend to Fig. 2.

conditions. All of these agents inhibited the periodate-induced loss of the protein bands and the appearance of the high molecular weight proteins, suggesting that the nonreducible cross-linking of the ghost proteins was due to lipid oxidation.

Erythrocytes were treated with periodate at 0 C for 15 min, and the modified ghosts isolated were analyzed for TBA-RS and fluorescence formation. Accumulation of TBA-RS and fluorescence increased at the periodate concentrations above 0.2 mM (Fig. 2). On an SDS electrophoresis gel under nonreducing conditions, the membrane specimen from the cells treated with 5 mM periodate indicated partial disappearance of bands 1 and 2 and concomitant appearance of the higher molecular weight proteins. Under reducing conditions, however, all the bands remained intact. The results indicate that the periodate-induced membrane protein cross-linking in erythrocytes was due to only disulfide bridge formation.

To assess the effect of oxidation of the cell surface sialyl residues, the sialyl residues were removed by neuraminidase and trypsin before exposure to periodate. Treatment with neuraminidase and trypsin removed 60% and 36% of the total sialic acid of the erythrocyte surface, respectively. The enzyme-treated erythrocytes were exposed to periodate. As shown in Figure 5A, the periodate (1 mM)-induced increase of TBA-RS of the neuraminidase-treated cells was much less than that of the untreated control cells. The periodate-induced increase of TBA-RS of the trypsin-treated cells was also lower than that of the control cells. Similar effect of the enzyme treatment was observed when these cells were exposed to 5 mM periodate. Suppression of TBA-RS formation by the enzyme treatment was also observed when the ghosts isolated from the enzyme-treated erythrocytes were exposed to periodate (Fig. 5B). These results indicate that the removal of the sialyl residues from the membranes reduced the susceptibility of erythrocytes to the periodate-induced lipid oxidation.

The aldehyde moieties produced by periodate in the sialyl residues may be responsible for the stimulatory effect in the periodate-induced lipid oxidation. The effect of aldehyde moieties produced enzymatically at the galactosyl and *N*-acetyl galactosaminyl residues of the desialylated cell surface was examined. Erythrocytes were treated with neuraminidase along with galactose oxidase, an enzyme that generates aldehyde moieties at the terminal galactosyl and *N*-acetyl galactosaminyl residues of the carbohydrate chains (23,24). The enzyme-treated cells were then exposed to periodate. As shown in Table 3, the periodate-induced TBA-RS formation of the neuraminidase-treated

TABLE 3

Effect of Galactose Oxidase Treatment of Desialylated Erythrocytes on the Periodate-Induced Thiobarbituric Acid–Reactive Substances (TBA-RS) Formation

Pretreatment[a]	TBA-RS ($A_{532\ nm}$/2 mg protein) Without periodate[b]	TBA-RS ($A_{532\ nm}$/2 mg protein) With 5 mM periodate[b]	Increase in TBA-RS (% of control)
Control	0.039 ± 0.001[c] 0.058 ± 0.002[d]	0.184 ± 0.023[c] 0.177 ± 0.010[d]	100[c] 100[d]
Neuraminidase	0.035 ± 0.001[c]	0.086 ± 0.013[c]	35[c]
Neuraminidase + galactose oxidase	0.042 ± 0.002[c] 0.047 ± 0.010[d]	0.141 ± 0.004[c] 0.142 ± 0.018[d]	68[c] 80[d]
Neuraminidase + galactose oxidase, then $NaBH_4$	0.044 ± 0.010[d]	0.089 ± 0.013[d]	38[d]
$NaBH_4$	0.046 ± 0.002[d]	0.156 ± 0.007[d]	92[d]

[a]An erythrocyte suspension (50%) was preincubated with neuraminidase or neuraminidase plus galactose oxidase or without the enzymes, as described in Materials and Methods. The residual sialic acid on the cells treated with neuraminidase and neuraminidase plus galactose oxidase were 28% and 34% of the original sialic acid contents, respectively. In experiment 2, the enzyme-treated or untreated erythrocyte suspensions (20%) were incubated with or without 5 mM $NaBH_4$ in 50 mM phosphate buffer containing 0.11 M NaCl (pH 7.5) followed by washing three times with Dulbecco's phosphate-buffered saline.

[b]The pretreated cell suspensions (10%) were incubated at 0 C for 15 min with or without 5 mM periodate. Values shown are mean ± SD of triplicate incubations.

[c]Experiment 1.

[d]Experiment 2.

cells was as low as 35% of that of untreated cells, whereas that of the cells treated with neuraminidase along with galactose oxidase was 68% and 80%. Although galactose oxidase generates hydrogen peroxide during the oxidation of the substrates (23), the peroxide generated under these conditions did not cause lipid oxidation because the enzyme treatment alone did not result in the increase in TBA-RS formation. Thus, galactose oxidase substantially compensated the loss of susceptibility of the desialylated cells to periodate. Reduction of the neuraminidase and galactose oxidase–treated cells with borohydride substantially suppressed the recovered susceptibility of the cells to periodate, while reduction of the untreated cells affected their susceptibility only slightly, indicating involvement of the aldehyde moieties generated by galactose oxidase in its effect. These results suggest that generation of aldehyde moieties at the terminal carbohydrate residues of the erythrocyte surface glycoconjugates renders the cells susceptible to periodate-induced lipid oxidation.

DISCUSSION

Periodate-treated erythrocytes are susceptible to macrophage recognition (5) and cytolysis by lymphocytes (4). To elucidate the mechanism of periodate-induced changes in biological responses, it is important to clarify the chemical changes of the membrane constituents. Periodate cleaves vicinal α-glycols (25), and sialic acid residues of the cell surface carbohydrate chains are preferentially oxidized at the low concentrations (8). The oxidized form of the sialyl residues, 8- and 7-carbon analogues, contains an aldehyde moiety at the 8 and 7 positions of the residues, respectively (7,8). Periodate also oxidizes proteins. Oxidation of tyrosine and cysteine residues of isolated spectrin by periodate at 22 C was reported (9). Heller et al. (6) reported that methionine was oxidized by the periodate treatment of erythrocytes at 0 C and that thiol groups of the membrane proteins were oxidized to disulfides, which caused an increase in membrane permeability.

In this report, we have verified the lipid oxidation of erythrocyte membranes by periodate and showed the characteristic nature of the reaction. The conversion of sialyl residues to the oxidized forms was confirmed by measurement of intact sialyl residues on the periodate-treated ghosts. Involvement of radical reactions was shown by the inhibition of TBA-RS and fluorescence formation by BHT and thiourea. Inhibition by desferrioxamine suggested that a certain iron species was essential for the periodate-induced lipid oxidation of ghosts. The iron species in ghosts is likely to be originated from hemoglobin. We have previously demonstrated that hemoglobin stimulated the 13-linoleic acid hydroperoxide-induced lipid oxidation of ghosts and that this was inhibited by desferrioxamine (21). Gutteridge (22) also has reported that desferrioxamine inhibited the methemoglobin-stimulated lipid oxidation of liposomes. The catalytic action of hemoglobin appeared to be mediated by some iron complexes released from the protein upon interaction with lipid hydroperoxide. Oxidation of unsaturated fatty acids by periodate required higher concentrations

of periodate, higher temperature and longer exposure than that of the erythrocyte membranes. The presence of hemoglobin in ghosts may be one of the factors for the higher susceptibility of ghosts to periodate-induced lipid oxidation.

SDS gel electrophoresis analysis of the periodate-treated ghosts suggested that there were two types of membrane protein cross-linking, with and without disulfide bridge. The protein cross-linking without disulfide bridge may be formed as a consequence of lipid oxidation. The protein cross-linking with disulfide bridge may be formed by a direct action of periodate to the proteins or by an indirect action via lipid oxidation. SDS gel electrophoresis of the ghosts from the periodate-treated erythrocytes suggested that most membrane protein cross-links were due to disulfide bridges, which was consistent with the observation of Heller et al. (6). This may indicate that erythrocytes are less susceptible to lipid oxidation than ghosts. Cytoplasmic enzymes protective against oxidation may be involved (26). A high content of cytoplasmic hemoglobin may also protect the membrane since the high concentration of hemoglobin appears to behave as a lipid radical scavenger (21,27).

It is interesting to note that the aldehyde groups formed in the sialyl residues by periodate oxidation seem to play a stimulating role in the periodate-induced lipid oxidation. Susceptibility of erythrocytes to the periodate-induced lipid oxidation decreased when cell surface sialyl residues were removed. The removed sialyl residues may be mostly those of glycophorin, considering its high sialic acid content (28) and susceptibility to trypsin (29). The aldehyde moieties generated by galactose oxidase at the terminal galactose or *N*-acetyl galactosamine of the desialylated cell surface carbohydrate chains were also effective in stimulating the lipid oxidation. It is not known at present how the aldehyde moieties of the cell surface carbohydrate chains render the membrane susceptible to lipod oxidation by periodate. Conversion of the hydroxyl groups at the termini of the carbohydrate chains of membrane glycoproteins to aldehydes might cause conformational changes of the glycoproteins or membrane perturbations, resulting in an increased accessibility of or a decreased cellular protective function against periodate.

[Received June 18, 1986]

Comparison of the Clearances of Serum Chylomicron Triglycerides Enriched with Eicosapentaenoic Acid or Oleic Acid

Isabel S. Chen[a,*], Truc Le[b], Satchithanandam Subramanian[c], Marie M. Cassidy[b], Alan J. Sheppard[a] and George V. Vahouny[c,1]

[a]Division of Nutrition, Food and Drug Administration, Washington, DC 20204, and the Departments of [b]Physiology and [c]Biochemistry, George Washington University School of Medicine, Washington, DC 20037

Rat mesenteric lymph chylomicrons containing triglycerides enriched with either [^{14}C]oleic acid (OA) or [^{14}C]-eicosapentaenoic acid (EPA) were prepared by ultracentrifugation of lymph samples collected for 6 hr after a single duodenal infusion of an emulsion containing either fatty acid. These chylomicrons were injected into the jugular vein of recipient rats and, at various time intervals, blood was drawn and serum was assayed for radioactivity. In separate animals, serum lipoprotein fractions were separated by ultracentrifugation, and the redistribution of labeled fatty acid among circulating lipoproteins was determined by liquid scintillation spectrometry. When the early disappearance rates (10 min) of either total serum radioactivity or specifically the chylomicron fraction were compared, there were no differences between the groups receiving OA- or EPA-enriched chylomicrons. However, disappearance rates of EPA-enriched chylomicrons were slower than those of OA-enriched chylomicrons from 25 to 90 min. The small but significant differences in the disappearance rates for the longer time periods cannot be ascertained without further studies. At 5 min after injection of either type of chylomicron, the d < 1.006 g/ml lipoprotein fraction of serum chylomicrons and very low density lipoproteins contained almost 90% of the original radioactivity. By 240 min, when less than 2% of the radioactivity remained, this radioactivity in the d < 1.006 g/ml fraction was 43-46%, with concomitant increases in the low and high density lipoprotein fractions and in the lipoprotein-free serum. ***Lipids 22,*** **318-321 (1987).**

Relatively large amounts of dietary fish oil containing the ω-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid may reduce plasma triglyceride and cholesterol levels in humans and experimental animals (1-7), may alter hepatic lipoprotein production (8-10) and may modify prostaglandin metabolism (11-13). These responses may explain, at least in part, the lower incidence of ischemic heart disease and thrombosis in Greenland Eskimos (14), Japanese who live in fishing villages (15) and coastal-dwelling Turks (16).

Harris and Connor (17) observed that the plasma triglyceride elevation was smaller after a single dose of salmon oil than after a control (corn oil) fat dose; they suggested that this was due to a more rapid serum clearance of the ω-3 fatty acid-containing chylomicrons. However, Brockerhoff et al. (18) and Bottino et al. (19) suggested that fish oils may not be digested as efficiently as triglycerides containing more conventional fatty acids (e.g., ω-6 and ω-9 types), which could also explain the lower plasma triglyceride responses to dietary fish oils. We have found that cardiac lipoprotein lipase activity on chylomicron triglycerides enriched with EPA is comparable to that on chylomicron triglycerides enriched with oleate during recirculating rat heart perfusion (20).

The purposes of the present study were a) to compare the serum clearance of chylomicron triglycerides enriched with either [^{14}C]EPA or [^{14}C]oleic acid (OA) and b) to compare the rates and degrees of redistribution of [^{14}C]EPA and [^{14}C]OA from chylomicrons among serum lipoproteins.

MATERIALS AND METHODS

Bovine serum albumin fraction V (fatty acid-poor), sodium taurocholate and nonradioactive OA and EPA were obtained from Sigma Chemical Co. (St. Louis, Missouri). Isotopic fatty acids, labeled in the carboxyl position, were obtained from New England Nuclear (Boston, Massachusetts). Other chemicals and solvents were of the highest purity.

The test emulsions used for intraduodenal administration were prepared as described earlier (21) and included (per 1.5 ml physiological saline) 25 mg bovine serum albumin, 86 mg sodium taurocholate and 0.3 mmol OA or EPA. In addition, each emulsion contained 10 μCi of the respective [1-^{14}C]labeled fatty acid. The emulsions were prepared immediately before use and rehomogenized before each administration.

Adult male albino rats of the Wistar strain (Charles River Laboratories, Wilmington, Massachusetts), ca. 250 g, were allowed food (Purina Rat Chow, Ralston Purina Co., St. Louis, Missouri) and water ad libitum before use. Each group had four rats. The animals, under sodium pentobarbital anesthesia, were subjected to cannulation of the mesenteric lymphatic duct, and an indwelling catheter was placed in the duodenum for continuous administration of physiological saline-5% glucose (3 ml/hr). After the rats were fasted overnight, the saline-glucose infusion was interrupted, 1.5 ml of the appropriate test emulsion was infused via the duodenal catheter, and the saline-glucose infusion was reestablished. Lymph was collected on ice for 6 hr and was subjected to ultracentrifugation at d < 1.006 g/ml (3×10^6 g min) to obtain chylomicrons (21), which were purified by flotation under the same conditions. Then the distribution of chylomicron lipid fractions was determined as described previously (22).

After recipient rats were anesthetized by intraperitoneal injection with sodium pentobarbital, an indwelling catheter was inserted in the jugular vein. The chylomicron suspension (1.0-1.2 ml containing 0.012 mmol fatty acid equivalents; ca. 1×10^6 dpm) was injected and the catheter was rinsed with 1 ml saline. At 0, 2, 5, 10, 25, 60 and 90 min, 0.3 ml of blood was drawn and allowed to clot. Serum was separated by centrifugation ($100 \times$ g) and counted by liquid scintillation spectrometry. The weights of the recipient animals for all studies were not

*To whom correspondence should be addressed.
[1]Deceased.

statistically different. For the serum clearance study, rats given OA-enriched chylomicrons weighed 283 ± 8.4 g, and those given EPA-enriched chylomicrons weighed 287 ± 5.5 g. Each group comprised eight or nine rats.

Clearance of chylomicrons and redistribution of the labeled EPA or OA among the serum lipoproteins were performed by using similar bolus injections of chylomicrons, prepared as above, into the anesthetized recipient rats. Four rats were used for each time period and each group. Their body weights varied from 262 ± 7.5 g to 276 ± 10.0 g. At either 0, 5, 30, 90 or 240 min, animals were killed by cardiac puncture. Serum was separated by centrifugation (100 × g), and aliquots were subjected to ultracentrifugation to separate major lymph lipoproteins as described by Havel et al. (23). These included chylomicrons (d < 1.006 g/ml, 3 × 10^6 g min), very low density lipoproteins (VLDL, d < 1.006 g/ml, 1 × 10^8 g min), intermediate density lipoproteins (IDL, d = 1.006–1.019 g/ml, 1 × 10^8 g min), low density lipoproteins (LDL, d = 1.1019–1.063 g/ml, 1.3 × 10^8 g min) high density lipoproteins (HDL, d = 1.063–1.21 g/ml, 1.7 × 10^8 g min) and infranatant fraction (d > 1.21 g/ml, 1.7 × 10^8 g min). Aliquots (100–250 µl) of each lipoprotein fraction were taken for liquid scintillation spectrometry. Student's t-test was used to analyze the data.

RESULTS

As reported earlier (22), about three-quarters of the absorbed OA or EPA was recovered as lymph chylomicrons (62.5% for OA and 75.8% for EPA), and the majority of the remainder was recovered with the d < 1.006 g/ml VLDL fraction. Analyses of these chylomicron lipids from donor rat lymph (Table 1) showed that almost 90% of the OA and nearly 87% of the EPA were associated with the chylomicron triglycerides. These distributions are also comparable to those reported earlier (22).

Figure 1 shows the clearance of total radioactivity from serum over 90 min after a single bolus of either OA- or EPA-enriched chylomicrons. During the first 2 min after infusion, the disappearance rates of radioactivity for OA and EPA were similar and represented 44–50% clearance of these lipids from the circulation. At periods of 25 min up to 90 min, there were small but significant differences ($P < 0.05$) between the residual radioactivities in the serum for the EPA and OA groups.

The specific clearance curves for chylomicron radioactivity are summarized in Figure 2. For these studies, four rats were killed at each of the four time periods for each bolus infusion, and chylomicrons were assayed in each serum sample. Again the disappearance rate of chylomicron radioactivity was comparable for the two recipient groups, and except for the 90-min analysis, showed no statistical differences. Thus, approximately 60% of chylomicron radioactivity was cleared from serum by 5 min, 92–95% by 30 min and 96–98% by 90 min, and less than 2% chylomicron radioactivity remained by 240 min.

TABLE 1

Distribution of Radiolabeled Oleic Acid or Eicosapentaenoic Acid among the Lymph Chylomicron Lipids

Administered fatty acid	Chylomicron lipids (% distribution)				
	TG	MG-DG	PL	UFA	CE
Oleic	90.5	1.3	2.0	2.8	3.4
Eicosapentaenoic	86.8	3.0	3.9	2.1	4.2

Treatment of animals, collection of lymph and separation of lymph lipoproteins and lipids are described in Materials and Methods. TG, triglycerides; MG-DG, mono- and diglycerides; PL, phospholipids; UFA, unesterified fatty acids; CE, cholesteryl esters.

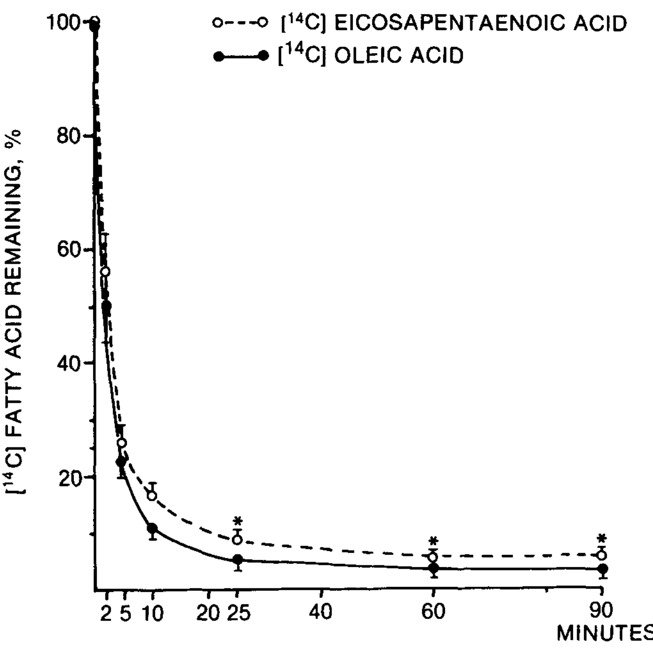

FIG. 1. Clearance of ^{14}C-labeled fatty acids in serum after a single bolus injection of oleic acid- or eicosapentaenoic acid-enriched chylomicrons. Each point is the mean ± S.E. of values from eight or nine rats. *, $p < 0.05$.

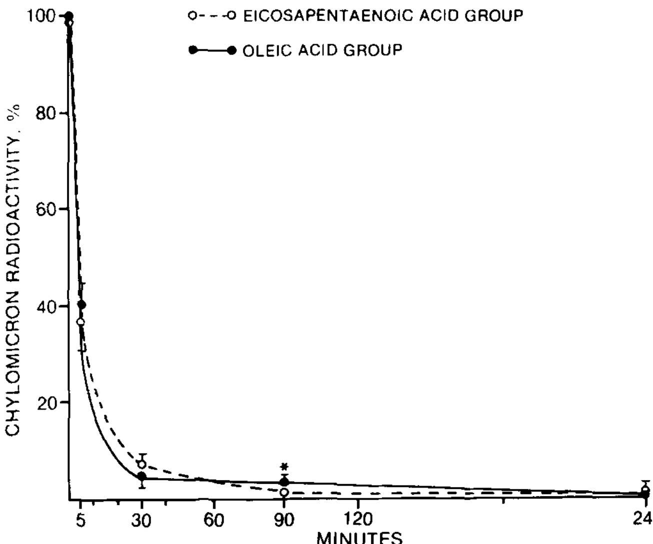

FIG. 2. Chylomicron clearance (% chylomicron remaining) after a single bolus injection of oleic acid- or eicosapentaenoic acid-enriched chylomicrons. Each point is the mean ± S.E. of values from four rats. *, $p < 0.05$.

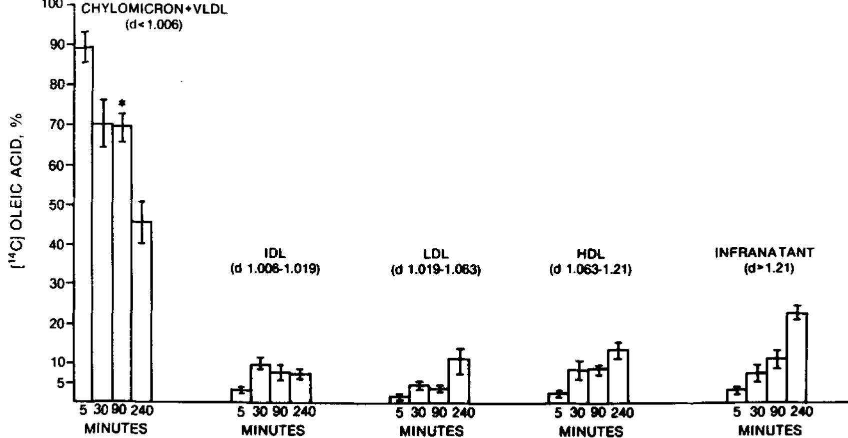

FIG. 3. Redistribution of [14C]oleic acid in serum lipoproteins (%) after a single bolus injection of oleic acid-enriched chylomicrons. Each point is the mean ± S.E. of values from four rats. *, $p < 0.05$.

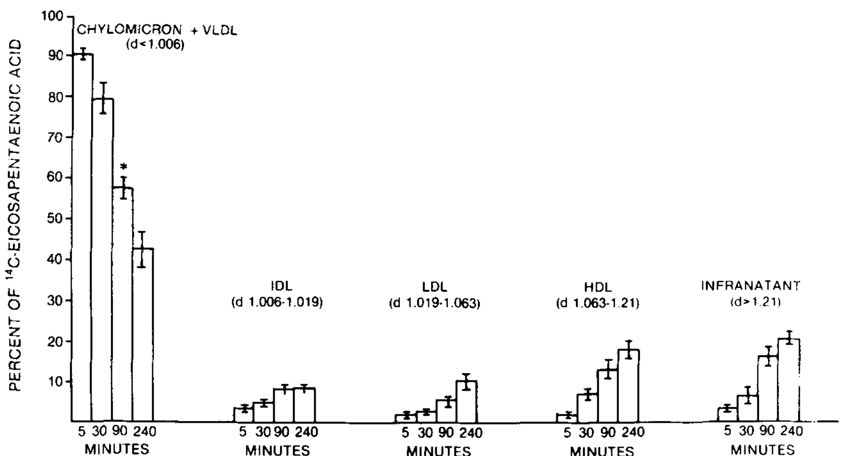

FIG. 4. Redistribution of [14C]eicosapentaenoic acid in serum lipoproteins (%) after a single bolus injection of eicosapentaenoic acid-enriched chylomicrons. Each point is the mean ± S.E. of values from four rats. *, $p < 0.05$.

The distributions of the serum radioactivity among various lipoprotein fractions at periods up to 240 min after infusion are shown in Figures 3 and 4. With OA-enriched chylomicrons (Fig. 3), after 5 min, when total serum radioactivity had decreased to about 60% of that infused, almost 90% was recovered as d < 1.006 g/ml lipoproteins, with almost equal amounts in the remaining lipoprotein and lipoprotein-free serum fractions. By 30 min, there were increases in the percentage of remaining radioactivity in d > 1.006 g/ml lipoproteins. By 240 min, when serum radioactivity represented less than 2% of the injected dose, d > 1.006 g/ml fraction radioactivity had increased to over half (55%) of the total, with the largest increases in the higher density lipoproteins (d > 1.019 g/ml LDL and HDL) and the lipoprotein-free fraction.

Similar temporal redistributions of radioactivity were evident when rats were given EPA-enriched chylomicrons (Fig. 4).

DISCUSSION

The present study was designed to assess whether chylomicron triglycerides enriched in EPA were lipolyzed efficiently by membrane-supported lipoprotein lipase of the capillary vessels and subsequently cleared efficiently from the circulation. This experimental design was based on a variety of earlier reports concerning the poor digestibility of triglycerides containing eicosapentaenoate (18,19) due to steric hindrance by EPA and the suggestion that absorbed salmon oil was cleared more rapidly from plasma after absorption from the intestine (17). We have demonstrated that the unesterified EPA is absorbed as efficiently as oleic or arachidonic acids into the thoracic duct and that the subsequent lymphatic transport and lipoprotein distribution of the absorbed EPA is comparable to that of other fatty acids (22). We also found that the initial peripheral degradation of EPA-enriched chylomicron triglycerides by membrane-supported lipoprotein

lipase in the heart muscle is similar to that with chylomicrons enriched with oleate (20). Our present study demonstrates that the overall clearances of the EPA-enriched and oleate-enriched chylomicrons from the circulation are essentially the same. The small differences observed between the residual radioactivities of the injected fatty acids in the serum at the later time periods (Fig. 1) cannot be ascertained. Further studies are needed to clarify this point.

Unlike intestinal pancreatic lipase, the membrane-supported lipoprotein lipase apparently shows little discrimination in the hydrolysis of triglycerides enriched with either EPA or OA. This was also observed during recirculating heart perfusion in vitro (20). Thus, there is no evidence of steric hindrance, as appears to be the case for pancreatic lipase in hydrolysis of fish oil triglycerides containing EPA (18,19).

The redistribution of labeled fatty acid among serum lipoproteins during chylomicron metabolism was comparable for the two fatty acids. However, the distribution of each fatty acid among the major esterified lipid fractions in each ultracentrifugal fraction was not determined. Based on other studies (24), it is likely that the subsequent metabolism of EPA-enriched chylomicrons results in incorporation of EPA largely into the phospholipid fraction of tissue membranes and lipoproteins, in contrast to the distribution of oleate.

Thermal and Metal-Catalyzed Decomposition of Methyl Linolenate Hydroperoxides

E.N. Frankel*, W.E. Neff, E. Selke and D.D. Brooks
Northern Regional Research Center, Agricultural Research Service, U.S. Department of Agriculture, Peoria, IL 61604

Much work has been reported on the volatile oxidative products of fats and their impact on flavor deterioration, cellular damage and the decrease in safety of fat-containing foods. However, relatively little information is available on the mechanism of hydroperoxide decomposition. Pure methyl linolenate hydroperoxides were decomposed thermally at 150 C and catalytically with ferric chloride-ascorbic acid at room temperature. The volatile decomposition products were collected on porous polymer (Tenax) traps and concentrated by gel permeation chromatography. The total volatile products showed significant differences in composition by capillary gas chromatography-mass spectrometry (GC-MS). Thermal decomposition produced much more methyl octanoate (60.1%) and less 2,4-heptadienal (0.5%) than catalytic decomposition (13.2 and 60.8%, respectively). The volatiles from the ferric chloride-ascorbic acid system also contained unique products tentatively identified by GC-MS as isomers of chloromethyl butene. These results may have important implications in evaluating precursors of flavor deterioration in vegetable oils containing linolenate and in understanding better the biological significance of lipid peroxidation.
***Lipids 22,* 322-327 (1987).**

Foods containing polyunsaturated fats and vegetable oils develop flavor problems when subjected to prolonged storage (1), when heated at the elevated temperatures of cooking and frying (2,3) and when exposed to light (4). Despite the considerable information now available on the oxidative deterioration of fats (5-8), the mechanism of this oxidatively derived flavor deterioration is still not well understood. The association of volatile oxidation products with cellular damage (9,10) and with a decrease in safety of fat-containing foods (5) is also not well supported by direct evidence.

The 9- and 13-isomers of linoleic and linolenic acid hydroperoxides prepared by lipoxygenase were previously decomposed in the presence of metals and reducing agents, and the aldehydes formed were identified as the 2,4-dinitrophenyl hydrazone (DNPH) derivatives (11,12). In other studies the isomeric mixtures of hydroperoxides formed by autoxidation and photosensitized oxidation were decomposed thermally, and the volatile products were investigated by gas chromatography-mass spectrometry (GC-MS) (13). This technique permits identification of a wide variety of hydrocarbons, aldehydes, alcohols, esters, aldehyde esters, furans, ketones and lactones. The mechanisms of decomposition of different fatty ester hydroperoxides (13,14) and secondary lipid oxidation products (15,16) were clarified by GC-MS analyses of volatile decomposition products.

Primary and secondary products of lipid oxidation were shown to react with DNA by determining the fluorescence formed in the presence of metals and ascorbic acid (17). The same oxidation products were tested by the Ames reversion assay and found to be weakly mutagenic in *Salmonella typhimurium* strains TA 97 and/or TA 100 (18). In previous work (19), we used GC-MS to study the thermal and acid decomposition products of linoleate and linolenate hydroperoxides and secondary products. In this paper we compare the volatile products obtained from pure methyl linolenate hydroperoxides decomposed thermally at 150 C and catalytically in the presence of ferric chloride and ascorbic acid at room temperature. The volatiles, trapped in a porous polymer (Tenax) column and concentrated by gel permeation chromatography (GPC), were analyzed by capillary GC and GC-MS.

EXPERIMENTAL PROCEDURES

Preparations. Pure hydroperoxides were prepared by silicic acid column chromatography from methyl linolenate autoxidized at 40 C (20). The purity of the hydroperoxides was checked by thin layer chromatography (TLC) and by peroxide value (6100 me/kg) determination. Analysis of isomers by high pressure liquid chromatography of the hydroxystearate derivatives (21) gave the following composition: 31% 9-, 12% 12-, 12% 13- and 45% 16-hydroperoxides. For the isolation of volatile decomposition products it was essential to remove the antioxidant BHT used as preservative in diethyl ether. Redistilled reagent-grade diethyl ether was chromatographed in 50-ml portions through a short column containing 10 g silicic acid previously activated at 120 C. The resulting ether was stored at 0 C and checked for peroxide iodometrically before use.

Tenax (Anspec Co., Ann Arbor, Michigan) used to trap volatiles was activated by washing 3-g portions placed in a chromatographic column with 50 ml distilled and chromatographed diethyl ether. The column was then purged with dry nitrogen for 30 min at room temperature until the ether was removed and at 150 C overnight.

Decomposition. Methyl linolenate hydroperoxides were decomposed either thermally at 150 C or catalytically with ferric chloride and ascorbic acid at room temperature in a reaction flask attached to a trap containing 500 mg activated Tenax porous polymer. Reactions were continued until the hydroperoxides were almost completely decomposed as indicated by TLC (20).

For thermal decomposition, 500 mg of methyl linolenate hydroperoxides was purged with air, which was purified through a drying tube (sodium sulfate) and a short Tenax trap, and heated at 150 C for 30 min. After cooling to room temperature, the Tenax trap was weighed and then washed with 5 ml chromatographed diethyl ether. The amount of volatiles trapped was determined by reweighing the Tenax after removing the solvent and drying. An aliquot of the Tenax ether eluate was analyzed directly by capillary GC. The decomposition mixture was dissolved in methylene chloride and separated by GPC. The low molecular weight fraction was made up to 5.0 ml with methylene chloride, and the weight of decomposition

products was determined from an aliquot by gently removing the solvent at 0 C.

Conditions for the catalytic decomposition with ferric chloride and ascorbic acid were similar to those used previously for fluorescence formation in the presence of DNA (17). Methyl linolenate hydroperoxides (500 mg) were stirred in 1.8 ml buffer solution at pH 6.1 (100 ml 0.1 M KH_2PO_4 and 14 ml 0.1 M NaOH) containing 0.06 ml Tween-20 and 1.2 ml ascorbic acid (2.76 g per 25 ml water). The reaction flask was attached to a Tenax trap. The iron catalyst (1.3 ml of a solution containing 3.83 g $FeCl_3$ in 25 ml water) was then added, and the reaction mixture was purged with purified air and stirred magnetically for 4 hr at room temperature. The Tenax trap was eluted with diethyl ether as above. The residual emulsion was transferred with water and extracted with chromatographed diethyl ether. The ether extract was concentrated by gently sweeping with nitrogen, and the product was separated by GPC.

GPC. A DuPont high performance liquid chromatograph (DuPont Instruments, Wilmington, Delaware) was used with two glass columns (9 × 1000 mm) connected in series and packed with Bio-Beads S-X2 (Bio-Rad Labs, Richmond, California). Methylene chloride was used as mobile phase at a flow rate of 0.5-1 ml/min and pressure of 16-19 bars. Samples of 30 mg dissolved in methylene chloride were injected, and the separation was followed with refractive index (Waters Assoc., Milford, Massachusetts) and ultraviolet detectors (DuPont at 274 nm). Molecular weights of recovered fractions were determined by vapor pressure osmometry using benzene as solvent.

GLC. Volatile decomposition products recovered from the Tenax and GPC eluates were analyzed by GLC with a Perkin-Elmer instrument (Model Sigma 300, Norwalk, Connecticut), equipped with a capillary column (DB 1701, J & W Scientific Co., Rancho Cordova, California) cooled to −20 C with liquid nitrogen. Column temperature was programmed to 260 C at 5 C per min with a final hold of 10 min. The integrated relative peak areas were calculated as weight percent. Methyl hexanoate was used as internal standard. Volatile decomposition products were identified like before (13,22) by matching mass spectra with those of our reference library and by confirming GC retention data with known reference compounds.

RESULTS

Previous studies on the aldehyde decomposition products of oxidized fats were based mainly on analyses of suitable DNPH derivatives (23), which are difficult to prepare and to regenerate from polyunsaturated carbonyl compounds. GC and GC-MS methodologies have provided a significant improvement by affording direct analyses of volatile aldehyde and nonaldehyde products formed by lipid oxidation. In the present study, improved techniques, such as Tenax trapping and GPC, were used together with capillary GC and GC-MS to investigate the volatile oxidation products generated from linolenate hydroperoxides at room temperature.

The porous polymer Tenax (poly[2,6-diphenyl-p-phenylene oxide]) is considered one of the best adsorbents for concentration of organic volatile compounds, with many applications in flavor, atmospheric pollution and headspace analyses of biochemical samples (24,25). In this work, volatile products formed during the decomposition of linolenate hydroperoxide were trapped in a Tenax column. While the recovery of hydrocarbons and simple alcohols and ethers was reported to be in the 75-90% range, some of the simple alcohols were retained poorly with Tenax (25).

GPC has been used to separate and analyze high molecular weight products in heated fats (26) and oxidized methyl linoleate (27) and linolenate (28). In this study, we used a similar GPC system to separate low molecular weight volatile compounds from decomposed methyl linolenate hydroperoxides. The GPC system used consisted of polystyrene divinyl benzene beads and methylene chloride as solvent. The separation was followed by refractive index and UV detection (Fig. 1). In the top chromatograms, obtained with the sample decomposed with ferric chloride-ascorbic acid, the refractive index curve shows a major peak due to oligomer with a molecular weight of 625, representing 73% (by weight) of the total. The UV curve shows greater absorption at 274 nm in the monomer than in the oligomer peak. The third peak is due to low molecular weight volatile decomposition products, which are not detected by refractive index. The

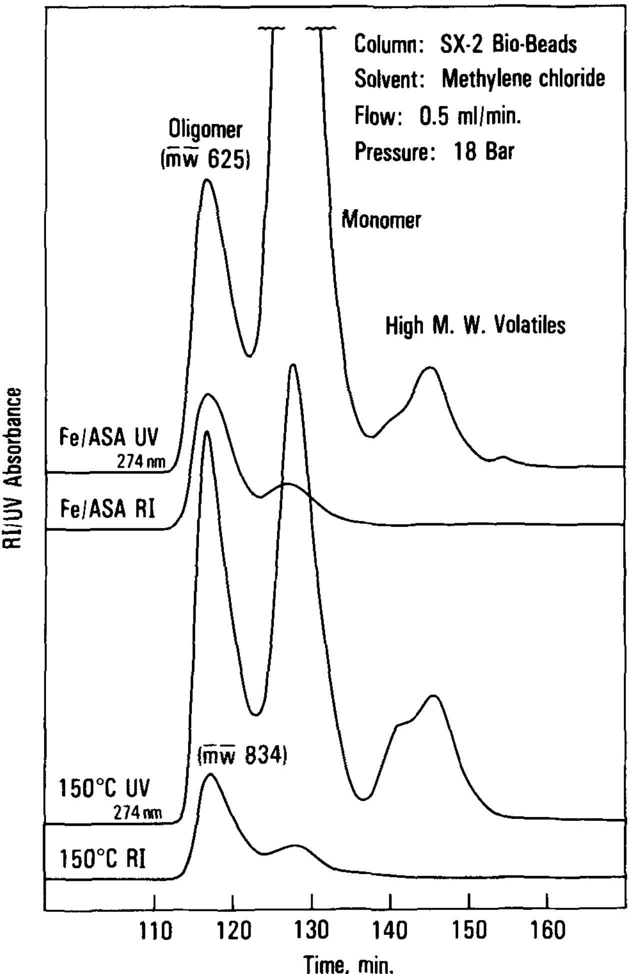

FIG. 1. Gel permeation chromatography of decomposition products of methyl linolenate hydroperoxides. Top curves: Fe/ASA, ferric chloride-ascorbic acid; bottom curves, thermal at 150 C. (UV, ultraviolet detection at 274 nm; RI, refractive index detection.)

bottom chromatograms, obtained with the hydroperoxides decomposed at 150 C, show the same relationship. The refractive index curve shows a major oligomer peak, representing 62% by weight, with a molecular weight of 834. The UV curve shows a significant peak after the monomer peak, due to the high molecular weight volatile decomposition products.

The monomeric GPC-2 fractions were examined by TLC and spectrophotometry. The absence of unreacted hydroperoxides was confirmed by TLC (20). The monomers from samples decomposed with ferric chloride–ascorbic acid gave more intense UV absorption at 275 nm, due to conjugated keto dienes (29), than the monomers from thermally decomposed hydroperoxides. Weak infrared bands, due to conjugated carbonyls, were also obtained at 1639 cm^{-1} with the thermally decomposed sample, and at 1633 and 1687 cm^{-1} with the catalytically decomposed sample. Although TLC indicated the absence of hydroperoxides, weak UV absorption obtained at 231 nm may indicate the presence of epoxy or epidioxy compounds with diene conjugation. Further structural studies on the oligomer and monomer GPC fractions (GPC-1 and GPC-2) are reported elsewhere (28).

The relative weight compositions of the volatiles recovered by Tenax trapping and GPC are summarized in Table 1. Total volatiles, including the Tenax eluate and GPC low molecular weight fraction, represented 7.43% in the linolenate hydroperoxides decomposed at 150 C and only 2.1% in the sample decomposed with ferric chloride and ascorbic acid. Although these volatile products represent a small portion of the total decomposition materials, they probably have an important impact on flavor and biological effects of lipid oxidation (14).

Capillary GC analyses showed that the aldehydes and other volatile compounds recovered on the Tenax trap were of lower molecular weight than the volatiles obtained by GPC. Tenax volatiles produced by thermal decomposition included significant amounts of propanal, 1-penten-3-ol, 2-pentenal, 2,4-heptadienal and methyl octanoate and small amounts of butanal, ethyl furan, 2-butenal, 1-penten-3-one and methyl heptanoate (Table 2). On the other hand, the Tenax volatiles produced by decomposition with ferric chloride and ascorbic acid included significantly higher relative concentrations of propanal, butanal and 2,4-heptadienal, much less methyl octanoate and no ethyl furan, 1-penten-3-one, 1-penten-3-ol or 2-pentenal.

In addition, GC-MS indicated major amounts of chloromethyl butenes in the Tenax volatiles from the sample decomposed with ferric chloride–ascorbic acid. The mass spectra obtained for these unusual components in the chromatograms were in good agreement with library spectra for 1-, 2- or 3-(chloromethyl)1-butene, with major masses at m/z 41, 53, 55, 69, 89 and 104, due to the molecular ion for the elemental formula C_5H_9Cl. Although the matches were good, this identification is only tentative because the authentic compounds were not available. The origin of these chlorinated compounds is unknown.

The volatiles separated from the reaction mixtures by GPC were of higher molecular weight than the Tenax volatiles. The GPC volatiles produced by thermal decomposition included a significant amount of methyl octanoate, smaller amounts of 2,4-heptadienal, 2,4,7-decatrienal and methyl 9-oxo-nonanoate and minor amounts of methyl heptanoate and methyl 8-oxo-octanoate (Table 2). In comparison, the GPC volatiles produced by decomposition with ferric chloride–ascorbic acid included much larger amounts of 2,4-heptadienal and smaller amounts of methyl octanoate and 2,4,7-decatrienal.

The weight percent compositions of both Tenax and GPC fractions were used to calculate the total volatile composition. The total volatiles recovered after thermal decomposition included major amounts of methyl octanoate and smaller amounts of 2,4-heptadienal, 2,4,7-decatrienal and methyl 9-oxo-nonanoate (Table 2). On the other hand, the total volatiles recovered after decomposition with ferric chloride–ascorbic acid included major amounts of 2,4-heptadienal and smaller amounts of methyl octanoate and 9-oxo-nonanoate.

DISCUSSION

Working with autoxidized methyl linolenate, Kimoto and Gaddis (30) found no difference in the distribution of monocarbonyls, identified as DNPH derivatives, after

TABLE 1

Relative Weight Composition of Volatile Fractions from the Decomposition of Methyl Linolenate Hydroperoxides

		Thermal (150 C)		Fe-ascorbate

decomposition by heat (165 C) and by ferrous chloride, cupric stearate and hematin. They observed major amounts of propanal and 2,4-heptadienal and smaller amounts of 2-pentenal and what was believed to be trienals. Later, Grosch (12) also identified the monocarbonyls (as DNPH derivatives) formed from pure linolenate hydroperoxides decomposed with trace metals in the presence of ascorbic acid. He reported major amounts of propanal and 2-hexenal from the 9-hydroperoxide isomer and 2-pentenal and 2-hexenal from the 13-hydroperoxide isomer.

When we analyzed by GC-MS the thermal decomposition products from the mixture of 9-, 12-, 13- and 16-hydroperoxides formed by autoxidation of linolenate (13), the major volatiles included ethane, 2,4-heptadienal, methyl octanoate, decatrienal and methyl 9-oxo-nonanoate. The mechanism advanced to explain the major volatile decomposition products (14) involves homolytic cleavage on either side of the hydroperoxide groups (Fig. 2). Significant differences were also observed between thermal and acid decomposition products from monohydroperoxides and secondary oxidation products (19). The differences in volatile decomposition patterns were explained by assuming that thermal decomposition proceeds by homolytic β-scission on both sides of the hydroperoxide group, whereas acid decomposition involves selective heterolytic splitting between the hydroperoxide group and the allylic double bond. On theoretical grounds, a "mixed" homolytic-heterolytic type mechanism was also invoked for the thermal decomposition of hydroperoxides (19).

In the present work, significant qualitative and quantitative differences were found in the volatiles products obtained by decomposing linolenate hydroperoxides by

FIG. 2. Main cleavage mechanism recognized for linolenate hydroperoxides. Percentages given on the right are the weight composition found for the hydroperoxides of methyl linolenate. R = $-(CH_2)_7-COOCH_3$.

TABLE 3

Origin of Major Volatile Products from Decomposition of Methyl Linolenate Hydroperoxides

Major volatiles	Thermal (150 C) (Rel %)	Fe-ascorbate (Rel %)	Origin (Ln-OOH[a])	Cleavage type[b]
2,4-Heptadienal	10.5	60.8	12-OOH	Homolytic

Propanal	1.0	2.3	16-OOH	Heterolytic

[a]Linolenate hydroperoxide isomers, based on scheme in Fig. 2.

[b]Based on scheme in ref. 19: homolytic cleavage occurs on both sides of the hydroperoxide group; heterolytic cleavage occurs selectively on one side between the hydroperoxide group and the allylic double bond.

heating at 150 C or by treating with ferric chloride-ascorbic acid at room temperature. Thermal decomposition produced more volatiles (7.4%), which were dominated by methyl octanoate. Decomposition with ferric chloride-ascorbic acid produced less volatiles (2.1%), which were dominated by 2,4-heptadienal. Table 3 summarizes the major volatiles, their probable hydroperoxide origin and the cleavage types, which account for their formation. Although 2,4-heptadienal is the major decomposition product observed with ferric chloride-ascorbic acid, it is derived from the 12-hydroperoxide isomer, which constitutes only 12% of the hydroperoxides in autoxidized methyl linolenate (Fig. 2) (6). On the other hand, the major thermal decomposition product, methyl octanoate, originates from the 9-hydroperoxide isomer, which constitutes 31% of the linolenate hydroperoxides. 2,4,7-Decatrienal and methyl 9-oxononanoate, formed in smaller amounts under both thermal and metal-catalyzed decomposition, also originate from the 9-hydroperoxide isomer.

The differences in volatile profiles obtained between decomposition by heat and by ferric chloride-ascorbic acid cannot be attributed to different cleavage mechanisms because the main volatile products obtained under both conditions can be formed by homolytic cleavage of either the 9- or 12-hydroperoxide isomers (Fig. 2). However, the minor volatile compounds including butanal, ethyl furan, penten-3-one, 1-penten-3-ol, 2-pentenal, methyl octanoate and 8-oxo-octanoate, cannot be explained by the homolytic cleavage mechanism in Figure 2. A more complex mixture of minor compounds was produced by heat than by decomposition with ferric chloride-ascorbic acid. Unique thermal decomposition products included ethyl furan, penten-3-one, 1-penten-3-ol and 2-pentenal (Table 2). 1-Penten-3-ol can be explained by the same mechanism suggested previously for 1-octen-3-ol (14), involving the reaction of a hydroxyl radical with the 2-pentene radical formed by homolytic cleavage of the 13-linolenate hydroperoxide. However, the origin of the other volatiles is unclear. The differences in the volatile profiles observed in this study suggest that heat treatments of oils and metal contamination may have different effects on the flavor deterioration of oils containing linolenate.

Other significant decomposition products of linolenate hydroperoxides include oligomers and monomeric secondary oxidation products. The oligomer fraction isolated by GPC (Fig. 1) was found to be a rich source of volatiles (28). Like monohydroperoxides and secondary oxidation products, these high molecular weight volatile precursors may have an important impact on flavor deterioration in unsaturated fats.

[Received October 27, 1986]

Efficacy of Linoleic Acid Administered Rectally as Monoglyceride

Armand Christophe[1], **Eldon G. Hill** and **Ralph T. Holman***
The Hormel Institute, University of Minnesota, 801 16th Ave. NE, Austin, MN 55912

The potential of the rectal route for administration of essential fatty acids (EFA) as monoglyceride (MG) was investigated. EFA-deficient rats were supplemented with 14 mg linoleic acid/day for 3 days. Supplementation was either by oral administration as corn oil, orally as corn oil-derived MG or rectally as MG. The patterns of polyunsaturated fatty acids (PUFA) in liver and serum lipids, characteristic of EFA deficiency, were altered in the direction of normalcy in similar magnitude by all modes of supplementation, indicating that the rectal route may be useful for administration of EFA. The amounts of phospholipids (PL) and free fatty acids (FFA) in liver changed by all modes of administration. The magnitude of change of total PL and of FFA in liver depended upon the chemical form in which linoleic acid was administered and the route of administration, indicating that these factors affect lipid metabolism.
Lipids 22, 328–332 (1987).

Patients with partial loss of the small intestine cannot absorb orally fed fats, and eventually develop EFA deficiency (1). Intravenous fat alimentation may provoke signs of intolerance (2), thus limiting this treatment for EFA deficiency (1,3), and alternative routes for providing EFA may be of value. Dermal application of oils (4–6) or of fatty acid mixtures (7) rich in EFA have been tried, with variable results. In humans (8), rabbits (9) and dogs (10), medium chain triglycerides (TG) are taken up when administered rectally. In rabbits, saturated long chain TG administered rectally are absorbed, but unsaturated long chain TG are not (10). In man, small doses of linoleic acid administered in suppositories as sodium linoleate (11) are absorbed. MG have physico-chemical properties considered favorable for rectal uptake (12) and have been useful in introducing fat orally in instances of impaired digestion and transport (13,14). The purpose of this study was to explore the potential of the rectal route for the administration of linoleic acid MG to relieve the biochemical indicators of EFA deficiency, and changes in lipid levels were measured quantitatively. The short-term effects of rectal administration of a suboptimal dose of linoleic acid MG, equal to one-third of the estimated minimum daily requirement, were measured. The results were compared with those obtained after oral administration of the same amount of linoleic acid either as MG or TG.

MATERIALS AND METHODS

Experimental animals. EFA deficiency was induced by feeding male Sprague-Dawley weanling rats a fat-free semipurified diet for 4 weeks (15). The diet consisted of 25.5% vitamin-free casein, 65% sucrose, 4% cellulose (alphacel, NBCo Biochemicals, Division of ICN Biochemicals, Cleveland, Ohio), 3.5% Williams-Briggs salt mix (ICN) and vitamins (3). The diet was provided ad libitum, and the animals had free access to water. Male Sprague-Dawley rats fed from weaning the same diet with corn oil added (2.7:100) served as normal controls on an adequate intake of EFA. Rats were kept individually in an environmentally controlled laboratory animal facility (50–60% relative humidity, 22–24 C, 12-hr light/dark cycle, laminar flow ventilation) in cages with wire floors to minimize coprophagy. The average weight of the EFA-deficient rats was 185 g at age 7 wk. An isomeric equilibrium mixture of MG prepared from corn oil was obtained from Eastman Kodak (Myverol® type 18-92; Rochester, New York). Diet containing MG and diet containing corn oil were prepared by mixing 2.7 g MG or 2.5 g corn oil, respectively, dissolved in 300 ml acetone and 100 g fat-free diet and evaporating the acetone under vacuum at a temperature not exceeding 35 C. These diets, which contained 14 mg linoleic acid/g, were stored under N_2 at 4 C and given daily for 3 days. The fatty acid compositions of corn oil and corn oil-derived MG were, respectively, 16:0, 6.2 and 6.6%; 18:0, 4.6 and 4.2%; 18:1ω9, 16.4 and 16.4%; 18:2ω6, 63.4 and 65.6%; 18:3ω3, 0.1 and 0.1%; 20:3ω3, 0.4 and 0.3%.

Experimental protocol. The EFA-deficient rats were divided into four groups of five animals each. The first group continued to receive the fat-free diet ad libitum. The second group received the fat-free diet ad libitum, but each evening for three days, 27 mg of the linoleic acid-rich MG containing 14 mg linoleic acid was given rectally. The MG was molten (melting point 41 C) and was delivered with a Gilson pipet with a prewarmed plastic disposable tip from which the point was cut. The plastic tip was inserted about 1.5 cm into the rectum. Usually, the rats' being handled provoked defecation, after which the MG was delivered. No leakage of MG was observed, and the treatment did not result in diarrhea. The third and fourth groups received the fat-free diet ad libitum only during the day. Each day for three days this food was removed in the evening and replaced by 1 g of diet containing MG or corn oil for the oral MG and oral TG groups, respectively. In this way, all the rats ate the predetermined amount of linoleic acid (14 mg/day). After three days' administration of linoleic acid to the second, third and fourth groups, all rats were killed by decapitation and their blood and livers were collected.

Liver and serum lipids were extracted with chloroform/methanol (2:1, v/v) as described previously (16,17). The extract was dried under vacuum, the amount of total lipid was determined gravimetrically and the residue was redissolved in chloroform (1 ml/10 mg of lipid). One ml of chloroform solution containing 1 mg of diheptadecanoyl *sn*-3 phosphatidylcholine (Sigma Chemical, St. Louis, Missouri), 80 μg pentadecanoic acid, 750 μg triheptadecanoate and 300 μg cholesteryl heptadecanoate (all from Nu-Chek Prep, Elysian, Minnesota) was added to 1 ml of the liver lipid extract. Liver PL, FFA, TG and cholesteryl esters (CE), with their respective internal standards, were isolated by thin layer chromatography (15) and converted into methyl esters by treatment with 14% BF_3 in methanol for 90 min at 75 C. The same lipid classes from serum were separated by silicic acid-impregnated

paper (ITLC paper, Gelman Instruments Co., Ann Arbor, Michigan) (16) and converted into methyl esters by the same method. The methyl esters were analyzed by gas chromatography using a 50 m × 0.2 mm i.d. wall-coated open tubular capillary column loaded with FFAP (Scientific Glass Engineering, Austin, Texas) with an He column flow of 0.45 ml/min and a split ratio of 1:70, temperature-programmed from 190-220 C at 2 C/min and held for 18 min at 220 C. Peak identification was made by comparison with known methyl ester standards (Nu-Chek-Prep). The internal standards enabled quantification of the fatty acids of liver PL, FFA, TG and CE. The analytical data were entered into a PDP-12 computer (Digital Equipment Corp., Maynard, Massachusetts) and appropriate FOCAL programs were used (16) to calculate the parameters, which have proven useful to evaluate changes in the pattern of fatty acids (3). Significances between different groups were calculated using Student's t-test for comparison of the means. For the rats on the fat-free diet that were or were not given MG rectally, 50 μl of the total liver extract was fractionated to estimate the amount of total PL and their subfractions by phosphorus content (18).

RESULTS

The fatty acid compositions of the liver PL of rats of the four groups were measured, and the percentages and standard errors of the means of fatty acids in liver PL are included in Table 1. The rats on the fat-free diet had a much higher level of 20:3ω9 and much lower levels of 18:2ω6 and 20:4ω6 in their liver PL than did the rats on the EFA-adequate diet (results not shown), indicating EFA deficiency in the former group. Similar analyses of liver CE, TG and FFA and of serum PL, CE, TG and FFA confirmed EFA deficiency in the fat-free group (data not shown).

Table 1 shows that each mode of linoleic acid administration significantly affected the fatty acid composition of liver PL, partially correcting the EFA deficiency. The data show that rectal linoleic acid administration as MG was equivalent to supplementation by mouth either as MG or TG, as judged by its effect on the fatty acid composition of liver PL. Comparisons of the fatty acid compositions of liver FFA, TG and CE led to the same conclusion. For almost all parameters measured (Tables 1 and 2), the effect of linoleic acid administration, either rectally as MG or orally as MG or TG, was qualitatively the same on liver lipid fatty acid compositions. Quantitatively, differences between oral or rectal administration were minor. In liver, the rectal administration of linoleic acid-rich MG for three days decreased the percentage of 20:3ω9 in all lipid classes (Tables 1 and 2). This decrease was significant in all lipid classes except CE, in which 20:3ω9 was a minor component (1.8% in the fat-free group). Linoleic acid-rich MG administered rectally significantly increased the percentage of 18:2ω6 in all lipids (Tables 1 and 2) except the TG, in which 18:2ω6 was low even in the EFA-adequate group (2.6%).

In the rectally supplemented group, the amount of PL in the liver measured by its fatty acid content (Table 3) or by its phosphorus content (190 ± 96 vs 310 ± 93 μmol/liver; $p < 0.025$) was significantly lower than in the nonsupplemented group. The amount of FFA was significantly higher in the rectally supplemented group than in the nonsupplemented group (Table 3). Liver weights themselves were not significantly different. Effects of oral supplementation on the amount of PL and FFA in liver were in the same direction but were less pronounced than the effects of rectal supplementation (Table 3). Because the amount of phospholipid in EFA-deficient rat liver was lowered by supplementation with linoleate, the amount of arachidonate decreased in the PL

EFA, essential fatty acids; MG, monoglycerides; TG, triglycerides; PL, phospholipids; FFA, free fatty acids.

[a]Values are μmol/liver ± standard error of the mean.

[b]Significance of difference from fat-free groups is indicated by ***, $p < 0.001$; **, $p < 0.01$; *, $p < 0.05$.

[c]Significance of difference from rectal MG group is indicated by †, $p < 0.001$.

fraction, although its proportion did not change. There was also a decrease in the amount of 20:3ω9, but an increase in the amount of 18:2ω6. The decrease in the amount of PL was accompanied by an increase in the amount of FFA, which was most pronounced in the rectally supplemented group. As a consequence of the elevated FFA, the reduced percentage of 20:3ω9 was an increased amount.

The reduction in the amount of PL induced by rectal administration of linoleic acid-rich MG was due to decreases in cardiolipin (50% of pretreatment concentration), phosphatidylcholine (55%), phosphatidylethanolamine (69%), phosphatidylserine (67%), sphingomyelin (73%) and phosphatidylinositol (77%) as measured by their phosphorus contents. Lysophospholipid content (104%) was unchanged.

The three modes of administering linoleate each affected the fatty acid compositions of the serum lipid classes. Within each lipid class, the changes induced by linoleate supplementation were generally in the same direction, but differed somewhat in magnitude (results not shown).

DISCUSSION

The MG derivative was chosen for rectal administration of linoleic acid because it is nonionic, fat-soluble yet quite polar, and its physical properties are considered favorable for rectal uptake (12). MG form very viscous nonoily phases in contact with water (19), which mediates against leakage and rapid expulsion from the rectum. The important issue was to measure whether rectal absorption of linoleic acid occurred when administered as MG; this effect was measurable after a very short term of supplementation. A logical control is administration of linoleic acid as TG by mouth, because it is the natural route for EFA supplementation and is thoroughly documented in the EFA-deficient rat. Most of the voluminous literature on nutritional effects of EFA describes studies in which EFA were provided in the form of TG; this literature has been reviewed (3,20,21,22). Because unsaturated TG were reported not to be absorbed from the rectum (10), this control was not included in the study. A control group given oral MG was included to confirm the efficiency of the MG utilization when administered orally. The rats used for this study were fed the fat-free diet for four weeks. They were clearly EFA deficient, as judged from the low 18:2ω6 and 20:4ω6 and high 20:3ω9 acid contents of their liver PL, compared to the rats on the EFA-adequate diet.

A three-day administration of EFA was chosen to test whether short-term rectal administration of linoleic acid-rich MG is feasible and effective, and because changes in the fatty acid composition of liver lipids of EFA-deficient rats were already apparent within 24 hr after linoleic acid administration (23). Full recovery including restoration of 20:4ω6 to normal values would have taken much longer (24). The amount of linoleic acid administered represents about 0.32% of the calories, and the 7-wk-old EFA-deficient rats consumed about 11 g of fat-free diet per day. This dose is 32% of the minimum daily requirement, is high enough to induce significant increases in PUFA in liver lipids and is in the linear portion of the dose-response curve, (25) where its effect is most easily detected and measured. Differences due to modes of administration should be maximally measurable in this range.

Oral administration of linoleic acid as corn oil induced changes in the fatty acid composition of liver and serum lipids that are characteristic of early recovery of EFA deficiency (26). Rectal administration of linoleic acid-rich MG induced several significant changes in fatty acid parameters, which in most instances were very similar in magnitude to the effects induced by the same amount of linoleic acid given orally as corn oil or as corn oil-derived MG. This indicates that linoleic acid was efficiently absorbed when administered rectally as linoleic acid-rich MG.

Some of the linoleic acid administered rectally as MG may have been taken in orally due to the rat's habits of coprophagy and rectal preening. Coprophagy was minimized by housing rats individually in cages with wire bottoms (½″ mesh). Defecation was induced by the rat's being handled prior to dosing, and the small dose (27 mg) of viscous MG was introduced 1.5 cm into the empty rectum, minimizing the possibility of leakage to the exterior. The significant differences in the amounts of PL and FFA in liver after administration of MG either orally or rectally indicates oral uptake of rectally administered MG must be small, if there is any.

Rectal administration of linoleic acid-rich MG was more efficient in reducing the amount of PL fatty acids and in increasing the amount of FFA in liver than was oral administration of linoleate (Table 3). This finding demonstrates that the route of administration of linoleate may have an effect on lipid metabolism.

Almost all changes in fatty acid composition that assess early recovery from EFA deficiency (26) were found to be significantly and equally restored by rectal linoleic acid-rich MG and by oral administration of linoleic acid either as TG or MG. These results indicate that the rectal route may have potential for administration of EFA. Differences in physiology of absorption from the lower gastrointestinal tract are known to exist between rats and man. Studies in primates may be advisable before attempting rectal administration of EFA as MG to supplement stressed humans unable to take food by mouth.

Platelet-Activating Factor Modulates Phospholipid Acylation in Human Neutrophils

Jen-sie Tou
Department of Biochemistry, Tulane University School of Medicine, New Orleans, LA 70112

The present study showed that platelet-activating factor (1-O-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine, PAF), but not lysoPAF (1-O-hexadecyl-*sn*-glycero-3-phosphocholine) rapidly (within 15 sec) stimulated the incorporation of both [1-^{14}C]arachidonate and [1-^{14}C]docosahexaenoate into phosphatidylinositol (PI) and phosphatidylcholine (PC) in human neutrophils. Concomitantly, it inhibited the formation of labeled phosphatidic acid from both fatty acids. The magnitude of stimulation (percentage of control) was greater in PI than in PC for the incorporation of arachidonate and vice versa for the incorporation of docosahexaenoate. It reached a maximum at 10^{-7} M and started to decline at 10^{-6} M. Extracellular Ca^{2+} was not essential for the action of PAF on phospholipid acylation. The distribution of labeled arachidonate in the molecular species of PC was not altered by PAF after 1 min incubation, suggesting that the increased formation of arachidonyl-PC during the early stage of neutrophil-PAF interaction was not originated from the added PAF. No measurable changes in the mass of each phospholipid were detected in neutrophils challenged by PAF from 15 sec to 2 min. The data suggest that the increased incorporation of extracellular fatty acids into PI and PC elicited by PAF may be secondary to increased deacylation of these phospholipids, and the magnitude of stimulation reflects the specificity of acyltransferase catalyzing the acylation of lysoPI and lysoPC by fatty acyl-CoA.
Lipids 22, 333–337 (1987).

Platelet-activating factor (1-O-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, PAF) is a bioactive phospholipid with multiple biological effects (1–4). At nanomolar concentrations PAF stimulates human neutrophil chemotactic migration, superoxide production, aggregation, cytochalasin B-dependent exocytosis of azurophilic and specific lysosomal granules (5,6). It enhances human neutrophil superoxide generation in response to chemotactic peptide N-formyl-methionyl-leucyl-phenylalanine (fMet-Leu-Phe) (7). This bioactive phospholipid also modulates the metabolism of other phospholipids in neutrophils. It enhances the activity of polyphosphoinositide-specific phospholipase C in rabbit peritoneal neutrophils (8), the release of arachidonate from phosphatidylinositol (PI) and phosphatidylcholine (PC) by the action of phospholipase A_2 and the production of 5-hydroxyeicosatetraenoate (5-HETE) and 5,12-dihydroxyeicosatetraenoate or leukotriene B_4 (LTB_4) in cytochalasin B-treated rabbit peritoneal neutrophils (9). It also promotes arachidonate incorporation into PI and PC in neutrophils from guinea pig peritoneal exudates (10). Since neutrophils from human blood differ from elicited neutrophils in a number of respects (11–13), it is important to examine whether the increased incorporation of arachidonate into PI and PC occurs in human neutrophils in response to PAF.

Recently docosahexaenoate was found to be incorporated into PC and phosphatidylethanolamine (PE) by human neutrophils (14). This n-3 fatty acid was a relatively poor substrate for incorporation into PI compared to arachidonate and eicosapentaenoate (14). It is thus important to examine whether the incorporation of docosahexaenoate into phospholipids in these cells is responsive to PAF. The present study has demonstrated that PAF rapidly increases (within 15 sec) the incorporation of both arachidonate and docosahexaenoate into PI and PC by human neutrophils.

MATERIALS AND METHODS

Preparation of human neutrophils. Human blood was obtained from healthy donors who had received no medication in the previous two weeks. Neutrophils were isolated according to the method of Lee et al. (15). Thirty-ml portions of venous blood were each mixed with 4 ml of 0.15 M sodium citrate, pH 5.2, and 5 ml of 5% dextran T500 (Pharmacia Fine Chemicals, Piscataway, New Jersey) in 0.15 M NaCl and were allowed to sediment at room temperature for 30 min. The supernatants containing leukocyte-rich plasma were removed and centrifuged at 250 × g for 10 min at 20 C. After hypotonic lysis of contaminating erythrocytes, leukocytes were washed once and resuspended in a modified Krebs-Ringer HEPES (N-2-hydroxyethylpiperazine-N′-2-ethanesulfonic acid) buffer (118 mM NaCl, 4.74 mM KCl, 1.19 mM $MgSO_4$, 5 mM glucose, 16.3 mM HEPES, pH 7.4) at 20 × 10^6 cells/ml. Six-ml cell suspensions were layered on 6-ml Ficoll-Hypaque (Pharmacia) cushions and centrifuged at 400 × g for 20 min at 20 C to yield a neutrophil pellet, which was washed twice and suspended at a concentration of 20 × 10^6 cells/ml in the same buffer. Cell counts were made in a hemocytometer, and cell viability was measured by trypan blue exclusion and by lactate dehydrogenase release into the incubation medium as described previously (16). Cell preparations contained more than 95% neutrophils.

Incubation of cells. [1-^{14}C]Arachidonic acid (54.5 Ci/mol, New England Nuclear Corp., Boston, Massachusetts) or [1-^{14}C]docosahexaenoate (55.0 Ci/mol, New England Nuclear) was dissolved in 0.9% NaCl containing fatty acid–free bovine serum albumin (Miles Laboratories, Elkhart, Indiana; 4 mg/ml). PAF (1-O-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine, Novabiochem, Läufelfingen, Switzerland), lysoPAF (1-O-hexadecyl-*sn*-glycero-3-phosphocholine, Novabiochem) or lysoPC (1-acyl-*sn*-glycero-3-phosphocholine, Applied Science Laboratories, State College, Pennsylvania) was dissolved in 0.9% NaCl containing fatty acid–free bovine serum albumin (2.5 mg/ml). In a final volume of 2 ml, each tube contained 3.4 × 10^5 dpm (1.4 μM) [1-^{14}C]arachidonic acid or 3.6 × 10^5 dpm (1.5 μM) [1-^{14}C]docosahexaenoic acid, 1 mM $CaCl_2$, 0–10^{-6} M PAF (or 10^{-7} M lysoPAF or lysoPC) and 20 × 10^6 cells in 1.92 ml Krebs-Ringer HEPES buffer. In control tubes, an equivalent volume of 0.9% NaCl containing bovine serum albumin (2.5 mg/ml) was included. Incubations were initiated by the addition of 20 × 10^6 cells to each tube and were performed at 37 C.

Lipid extraction and analysis. Incubations were terminated by the addition of 5 ml methanol to each tube. Lipids were extracted according to the method of Bligh and Dyer (17) and dissolved in chloroform/methanol (2:1, v/v) containing 0.01% butylated hydroxytoluene. Individual phospholipids were resolved and analyzed as described previously (13). Since the phosphorus content of phosphatidic acid (PA) cannot be accurately measured, the radioactivity of individual phospholipids is expressed as dpm/6 × 10^6 cells.

The distribution of [^{14}C]arachidonate in the molecular species of PC was analyzed as described previously (14).

RESULTS

Figure 1 shows the time course of the effect of PAF on the incorporation of [1-^{14}C]arachidonate into phospholipids in human neutrophils. PAF stimulated the incorporation of [1-^{14}C]arachidonate into PI and PC at all time intervals (15 sec to 2 min). Concomitantly, it inhibited the formation of [1-^{14}C]arachidonoyl-PA. The magnitude of stimulation (percentage of control) varied widely with cells from individual donors, but an increased acylation of labeled arachidonate into PI and PC was consistently demonstrated after 15 sec incubation of cells with PAF. In two separate experiments, PAF at 10^{-7} M caused an increase in the radioactivity of PI and PC to 1278% and 287% of control, respectively, at 15 sec; and the radioactivity of PI and PC became 1888% and 1283% of control, respectively, at 1 min. The magnitude of stimulation on the formation of labeled PI and PC induced by PAF started to decline at 2 min incubation. The incorporation of arachidonate into PE was less responsive to the presence of PAF. An increased radioactivity of PE was observed only after 2 min incubation of neutrophils with PAF. Analysis of phospholipid classes by phosphorus determination showed no measurable changes in phospholipid composition during the neutrophil-PAF interaction. At all time intervals (15 sec to 2 min), the lipid phosphorus (μg) from 6 × 10^6 cells in the presence or absence of PAF (10^{-7} M) was 0.803 for PC; 0.580 for PE; 0.197 for phosphatidylserine (PS); 0.125 for PI; and 0.295 for sphingomyelin.

Figure 2 demonstrates the time course of the effect of PAF on the incorporation of [1-^{14}C]docosahexaenoate into phospholipids. PAF inhibited the incorporation of [1-^{14}C]-docosahexaenoate into PA, but it enhanced the incorporation of this n-3 fatty acid into PI and PC. In two separate experiments, the average radioactivities of PI and PC were increased to 403% and 880% of control, respectively, after 15 sec incubation and to 432% and 2118% of control, respectively, after 1 min incubation. The magnitude of stimulation by PAF on the formation of labeled PC but not PI started to decline after 2 min incubation.

PAF in a range of 10^{-10}–10^{-6} M elicited significant changes in the incorporation of [1-^{14}C]arachidonate into phospholipids after 1 min incubation (Fig. 3). Maximal incorporation of [1-^{14}C]arachidonate into PI and PC was observed at 10^{-7} M, and a decline in the stimulation of the acylation of both phospholipids occurred at 10^{-6} M. At the concentrations tested (10^{-9}–10^{-6} M), PAF decreased the formation of [^{14}C]arachidonoyl-PA.

PAF has been shown to promote Ca^{2+} uptake from extracellular medium by rabbit platelets (18) and rabbit peritoneal neutrophils (8). A requirement for extracellular Ca^{2+} has been demonstrated for the stimulatory effect of PAF on degranulation (8), but not on polyphosphoinositides-specific phospholipase C (8) or superoxide generation (19). To test if extracellular Ca^{2+} is required for the action of PAF on phospholipid acylation by polyunsaturated fatty acids, the incorporation of [1-^{14}C]arachidonate into phospholipids in cells incubated in the presence of 1 mM Ca^{2+} was compared with that in cells incubated in the presence of 1 mM EGTA [ethyleneglycol-bis-(β-aminoethylether)N,N′-tetracetic acid]. Table 1 shows

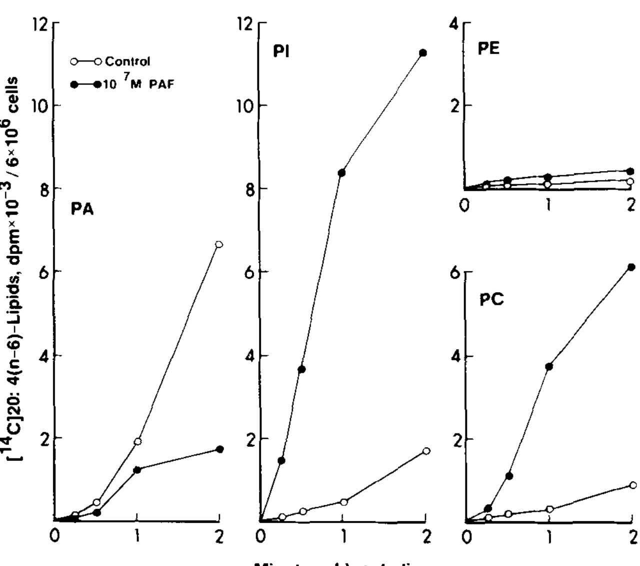

FIG. 1. Time course of the effect of PAF on the acylation of [1-^{14}C]arachidonate [20:4(n-6)] into phospholipids in human neutrophils. Neutrophils (20 × 10^6) were incubated at the indicated period of time (15 sec–2 min) with 3.4 × 10^5 dpm [1-^{14}C]arachidonate in the presence (●) or absence (○) of 10^{-7} M PAF. Each point represents the average value of duplicate incubations from two separate neutrophil preparations.

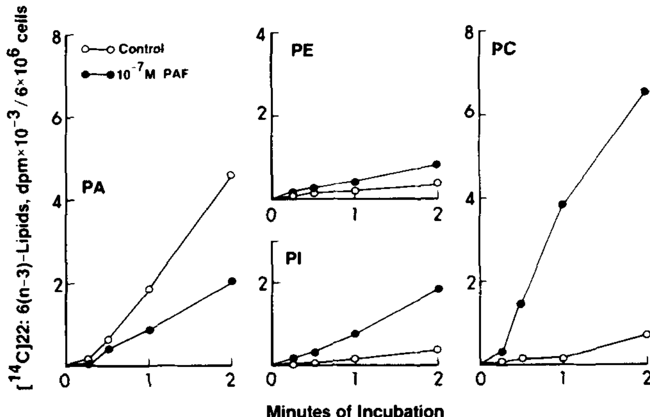

FIG. 2. Time course of the effect of PAF on the acylation of [1-^{14}C]docosahexaenote [22:6(n-3)] into phospholipids in human neutrophils. Neutrophils (20 × 10^6) were incubated at the indicated period of time (15 sec–2 min) with 3.6 × 10^5 dpm [1-^{14}C]docosahexaenote in the presence (●) or absence (○) of 10^{-7} M PAF. Each point represents the average value of duplicate incubations from two separate neutrophil preparations.

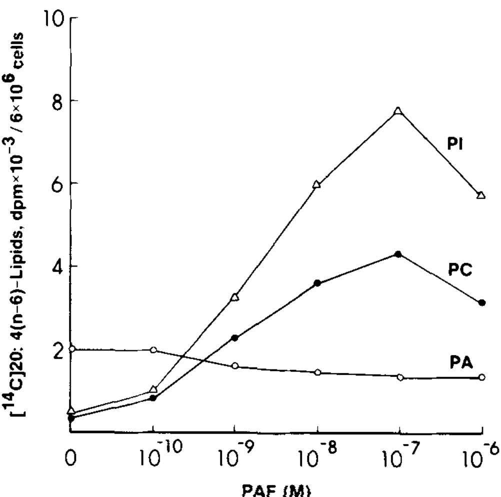

FIG. 3. Dose response to PAF for acylation of [1-^{14}C]arachidonate [20:4(n-6)] into phospholipids in human neutrophils. Neutrophils (20 × 10^6) were incubated for 1 min at 37 C with 3.4 × 10^5 dpm [1-^{14}C]-arachidonate and 0–10^{-6} M PAF. Each point represents the average value of duplicate incubations from two separate neutrophil preparations.

TABLE 1

Effect of External Ca^{2+} on [1-^{14}C]Arachidonate Incorporation into Phospholipids in Human Neutrophils in Response to PAF[a]

	Lipid	Radioactivity[b] (^{14}C dpm) Control	PAF	Mean % of control in the presence of PAF[c]
With Ca^{2+}	PA	2357	1146	57 ± 11
	PI	496	4558	1188 ± 377
	PC	383	2038	574 ± 122
Without Ca^{2+}	PA	1626	1184	66 ± 10
	PI	274	2676	1207 ± 350
	PC	296	1283	533 ± 152

PAF, platelet-activating factor; PA, phosphatidic acid; PI, phosphatidylinositol; PC, phosphatidylcholine.

[a]Human neutrophils (20 × 10^6 cells) were incubated for 1 min at 37 C with [1-^{14}C]arachidonic acid (3.4 × 10^5 dpm, 1.4 μM), Ca^{2+} (1.0 mM) or EGTA (1 mM), and PAF (10^{-7} M). In control incubations, PAF was replaced by an equivalent volume of bovine serum albumin (2.5 mg/ml in 0.9% NaCl).

[b]The results from a typical experiment. The radioactivity is expressed as dpm from 6 × 10^6 cells.

[c]Mean values ± S.D. from three experiments.

that extracellular Ca^{2+} was not essential for the increased incorporation of [1-^{14}C]arachidonate into PI or PC induced by 10^{-7} M PAF after 1 min incubation. Although the basal radioactivity of phospholipids was less in the presence of 1 mM EGTA than that in the presence of 1 mM Ca^{2+}, PAF evoked a similar magnitude of stimulation in both systems.

The possibility that the increased radioactivity of PC was originated from the added PAF was examined. [^{14}C]Arachidonoyl-PC was treated with phospholipase C,

TABLE 2

Effect of Platelet-Activating Factor (PAF) on the Distribution of [1-^{14}C]Arachidonate in Diacyl-, Alkylacyl- and Alkenylacyl-phosphatidylcholine[a]

	% of Total [1-^{14}]arachidonate in phosphatidylcholine Diacyl	Alkylacyl	Alkenylacyl
Control	84.7	14.1	1.20
PAF (10^{-7} M)	82.9	15.7	1.40

[a]Human neutrophils (20 × 10^6 cells) were incubated for 1 min at 37 C with [1-^{14}C]arachidonic acid (3.4 × 10^5 dpm, 1.4 μM), Ca^{2+} (1.0 mM) and PAF (10^{-7} M). In control incubations, PAF was replaced by an equivalent volume of bovine serum albumin (2.5 mg/ml in 0.9% NaCl). Each phosphatidylcholine preparation was purified from 40 × 10^6 neutrophils and was treated with phospholipase C as described in Materials and Methods. The amount of radioactivity in each class of resulting diglyceride acetates is the average value from two separate experiments and is expressed as a percentage of the total radioactivity recovered from the thin layer plate.

TABLE 3

Effect of LysoPAF and LysoPC on the Incorporation of [1-^{14}C]Arachidonate into PI and PC by Human Neutrophils[a]

	^{14}C dpm (% of control) PA	PI	PC
Control	100	100	100
PAF (10^{-7} M)	50 ± 12	1200 ± 391	650 ± 182
LysoPAF (10^{-7} M)	100 ± 2.7	100 ± 0.7	101 ± 2.2
LysoPC (10^{-7} M)	78 ± 6.5	99 ± 3.2	140 ± 14

[a]PAF, platelet-activating factor; PC, phosphatidylcholine; PI, phosphatidylinositol; PA, phosphatidic acid. Human neutrophils (20 × 10^6) suspended in Krebs-Ringer HEPES buffer were incubated for 1 min at 37 C with [1-^{14}C]arachidonic acid (3.4 × 10^5 dpm, 1.4 μM); Ca^{2+} (1.0 mM); and PAF (10^{-7} M) or lysoPAF (10^{-7} M) or lysoPC (10^{-7} M). In control incubations, PAF was replaced by an equivalent volume of bovine serum albumin (2.5 mg/ml in 0.9% NaCl). Data represent the average value ± S.D. from four separate neutrophil preparations.

and the resulting 1-radyl-2-acylglycerols were acetylated. The 1-radyl-2-acyl-3-acetylglycerols formed were then resolved into 1-alkenyl-2-acyl-3-acetylglycerol, 1-alkyl-2-acyl-3-acetylglycerol and 1,2-diacyl-3-acetylglycerol, and the radioactivity in each fraction was measured as described previously (14). After 1 min incubation, more than 80% of the total radioactivity appeared in the 1,2-diacyl-3-acetylglycerol fraction from both control cells and cells exposed to PAF (Table 2), suggesting that the increased [^{14}C]arachidonoyl-PC was not derived from the added PAF under the experimental conditions. Exogenous lysoPAF (10^{-7} M) had no effect on the formation of [^{14}C]arachidonoyl-PC after a 1-min incubation, whereas exogenous lysoPC (10^{-7} M) increased the formation of [^{14}C]arachidonoyl-PC and concomitantly decreased the formation of labeled PA (Table 3). On the other hand, the

presence of lysoPC in the incubation medium exhibited no influence on the incorporation of [1-^{14}C]arachidonate into PI.

DISCUSSION

Increased incorporation of arachidonate into PI has been shown to occur in neutrophils in response to fMet-Leu-Phe in the presence of cytochalasin B (20), calcium ionophore A23187 (20), phorbol myristate acetate (21) and phagocytosis of inert particles (21). However, the present study demonstrated a rapid onset (within 15 sec) of increased incorporation of both [1-^{14}C]arachidonate and [1-^{14}C]docosahexaenoate into PI and PC during human neutrophil-PAF interaction. It also demonstrated that PAF inhibited the formation of labeled PA from both fatty acids. These findings suggest that the increased formation of labeled PI and PC was not brought about by de novo synthesis but by increased acylation of lysoPI and lysoPC. They also suggest that in the presence of PAF, cellular arachidonate and docosahexaenoate were shunted to the acylation of lysoPI and lysoPC from the acylation of lysoPA. It remains to be determined whether the labeled PA participates in the formation of PI and PC in control neutrophils, as an arachidonate- or docosahexaenoate-labeled cytidine diphosphodiacylglycerol has not been identified, and previous studies have shown only a low level of [^{14}C]docosahexaenoyl-1,2-diacylglycerol in intact human neutrophils (14). The formation of docosahexaenoyl-PA does not seem to be unique in intact neutrophils; it has been demonstrated in bovine retinal microsomes (22).

The magnitude of stimulation by PAF on the formation of labeled PI and PC appears to be a reflection of the specificity of the acyltransferase catalyzing the acylation of lysoPI and lysoPC by fatty acyl-CoA. It was greater in PI than in PC for the incorporation of arachidonate and vice versa for the incorporation of docosahexaenoate. In human neutrophils, arachidonate was a better substrate for incorporation into PI than into PC (9,13,23, 24), whereas docosahexaenoate was a relatively poor substrate for incorporation into PI as compared to arachidonate (14).

A concentration-dependent stimulation by PAF of the incorporation of arachidonate into PI and PC demonstrated in the present study was also observed in guinea pig peritoneal neutrophils (10) and in lysosomal enzyme secretion by human neutrophils (5). The decreased responsiveness at PAF concentrations above 10^{-6} M does not appear to be caused by damage of cell membranes, as no increase in the release of lactate dehydrogenase was detected in the incubation medium. It could be caused by a rapid neutrophil desensitization for limiting the overall cellular response.

Extracellular Ca^{2+} was not found to be essential for the increased incorporation of [1-^{14}C]arachidonate into PI and PC induced by PAF in human neutrophils under the experimental conditions. It was required, however, for the stimulation by PAF of the formation of arachidonoyl-PC but not arachidonoyl-PI in neutrophils from guinea pig peritoneal exudates (10). The discrepancy in the sensitivity toward external Ca^{2+} for the increased formation of arachidonoyl-PC induced by PAF in cells from different species is not clear. It may reflect different Ca^{2+} sensitivity of acyltransferase and/or phospholipase A_2 from different cells, as the combined activities of these enzymes control the levels of lysoPC. Human neutrophils have a higher content of alkylacyl-PC than guinea pig peritoneal neutrophils (13,25), and a Ca^{2+}-independent phospholipase A_2 specific for alkylacyl-PC is present in human amniotic fluid (26). It remains to be studied whether a similar Ca^{2+}-independent phospholipase A_2 is present in human neutrophils besides the Ca^{2+}-dependent phospholipase A_2 (27).

PAF in human neutrophils (28), rabbit peritoneal neutrophils (29) and rabbit platelets (30,31) is metabolized to 1-O-alkyl-2-acyl-*sn*-glycero-3-phosphocholine after a deacetylation-reacylation cycle. Although added PAF caused no measurable changes in the distribution of labeled arachidonate in the diacyl-, alkylacyl- and alkenylacyl-PC after 1 min incubation, the acylation of lysoPAF derived from added PAF would contribute to the increased radioactivity of PC after a longer period of incubation. LysoPC but not lysoPAF was shown to be rapidly acylated by [1-^{14}C]arachidonate to form labeled PC. This finding is in accord with the study demonstrating that extracellular arachidonate was incorporated into diacyl-linked PC more rapidly than into the ether-linked class (13,24,32). An undetectable acylation of exogenous lysoPAF after 1 min incubation could also be due to a slower rate of lysoPAF uptake by neutrophils, as demonstrated in rabbit platelets (31). An acylation of exogenous lysoPC into cellular PC was also demonstrated in rabbit peritoneal neutrophils (33) and in human mixed leukocytes from patients with chronic myelogenous leukemia (34).

The increased incorporation of fatty acids into PI and PC during the neutrophil-PAF interaction may be secondary to increased deacylation of these phospholipids by the action of phospholipase A_2, because no measurable changes in the mass of each phospholipid were detected under the experimental conditions. It remains to be determined whether the activity of the acyltransferase(s) was increased during the neutrophil-PAF interaction in view of the rapid onset of increased formation of labeled PI and PC. An increased acylation of lysoPI and lysoPC by exogenous fatty acids in neutrophils in response to PAF may serve to replenish these phospholipids following deacylation. This may also divert exogenous arachidonate from the 5-lipoxygenase pathway, thereby attenuating the formation of LTB_4 and 5-HETE, both of which are mediators of inflammation (35,36).

[Received October 3, 1986]

The Influence of Dietary Fat on the Lipogenic Activity and Fatty Acid Composition of Rat White Adipose Tissue

Gary J. Nelson*, Darshan S. Kelley, Perla C. Schmidt and **Claire M. Serrato**
Biochemistry Research Unit, Western Human Nutrition Research Center, Agricultural Research Service, U.S. Department of Agriculture, P.O. Box 29997, Presidio of San Francisco, CA 94129

The in vivo fatty acid synthesis rate, selected enzyme activities and fatty acid composition of rat white adipose tissue from animals fed semisynthetic diets of differing fat type and content were studied. All animals were starved for 48 hr and then refed a fat-free (FF) diet for 48 hr. They were then divided into three groups. One group was continued on the FF diet for 48 hr. Another group was fed a diet containing 44% of calories from corn oil (CO). The final group was fed a diet containing 44% of calories from completely hydrogenated soybean oil (HSO). The animals on the FF diet had a marked increase in adipose tissue fatty acid synthesis during the 96-hr feeding period (as measured by ^{3}H incorporation into adipose fatty acids). Addition of either CO or HSO to the diets did not significantly inhibit fatty acid synthesis in dorsal or epididymal adipose tissue. The activities of the enzymes' fatty acid synthetase, ATP-citrate lyase and glucose-6-phosphate dehydrogenase increased on the FF diet and generally were not inhibited significantly by the addition of either fat to the diets. Linoleic acid was the major polyunsaturated fatty acid (ca. 22%) in adipose tissue. Monounsaturated fatty acids (palmitoleic, oleic, *cis*-vaccenic) made up ca. 38% of the total adipose fatty acids, while saturated fatty acids accounted for about 32% (myristic, palmitic and stearic). White adipose tissue in mature male rats was a major depot for n-3 fatty acids. There were differences in the fatty acid composition of epididymal and dorsal adipose tissue, particularly in their content of long chain, polyunsaturated fatty acids with epididymal tissue containing more of these compounds than dorsal fat. The fatty acid composition of the white adipose tissue did not change significantly during fasting or 96 hr of refeeding the FF diets. The addition of HSO to the diet for 48 hr had little influence on the adipose tissue fatty acid composition, but the addition of CO to the diet caused a 7% increase in the dorsal adipose tissue linoleate content (as percentage of total dorsal adipose tissue fatty acids) within 48 hr compared to animals fed the stock diet and those starved for 48 hr. The fatty acid synthesis data indicated that adipose tissue in the rat can continue to be a source of de novo fatty acid synthesis in animals consuming high-fat diets.
***Lipids 22,* 338–344 (1987).**

Adipose tissue is a major site of fatty acid synthesis in rats (1–4) as well as other mammalian species (5–8). However, the regulation of fatty acid synthesis in adipose tissue is extremely complex as it is influenced by many intrinsic and extrinsic factors, such as diet (3,4,5,9–12), age (13,14), hormones (15–17) and heredity (18). There is uncertainty about the role of dietary fat on the suppression of fatty acid synthesis in adipose tissue (19–21).

The fatty acid synthetic rates in white adipose tissue have been measured using various fatty acid precursors such as ^{14}C-glucose (22,23), ^{14}C-acetate (24) and tritiated water (25,26). This latter substance has become the label of choice to measure fatty acid synthesis because it avoids the confounding influence of the various metabolic pools and the recycling phenomenon of the carbon precursors (27,28). Nevertheless, when studying fatty acid synthesis in the whole animal, one encounters the problem that adipose tissue, while actively synthesizing fatty acids, is a repository for fatty acids synthesized de novo in the liver (29) as well as for fatty acids of exogeneous origin. Some investigators have attempted to resolve this matter by suppressing liver fatty acid synthesis by diet (24) or drugs (29), or by using short incubation periods (25).

In rats fed stock diets ad libitum, six major fatty acids (30)—palmitic, palmitoleic, stearic, oleic, *cis*-vaccenic and linoleic—constitute about 90% of the total fatty acids present in white adipose tissue. Linoleic acid is the major polyunsaturated fatty acid of rat white adipose tissue (31). Under appropriate conditions dietary fatty acids can influence the fatty acid composition of adipose tissue (32–34).

We have previously reported the effect of feeding fat-free (FF) and fat-containing diets on liver and plasma fatty acid composition (35), as well as the activity of liver lipogenic enzymes in rats fed these diets (36). The objective of this research was to investigate some of the parameters affecting the regulation of white adipose tissue fatty acid metabolism by dietary fat in mature rats fed a semisynthetic diet. Here we present data on the synthetic rate, some enzymes of the fatty acid synthetic pathway and the fatty acid composition of epididymal and dorsal adipose tissue as a function of time on the FF and high-fat diets. Under the conditions used in this study it was found that high-fat diets, both saturated and polyunsaturated, did not suppress fatty acid synthesis in adipose tissue.

MATERIALS AND METHODS

Materials, animals and diets. Male, Sprague-Dawley rats, 100 to 150 g, were purchased from Bantin and Kingman (Fremont, California). They were fed a stock diet from Ralston-Purina (Richmond, Indiana) until they had grown to 400 to 500 g in weight and were 120 to 140 days old. The animals were then segregated into three groups of 12 to 22 rats each, starved for 48 hr and then refed a FF diet (75% of calories from carbohydrates) for 48 hr. After that, one group was continued on the FF diet for another 48 hr. A second group was placed on a synthetic diet in which 44% of the calories was supplied by corn oil (CO). The remaining group was fed a diet in which 44% of the calories was supplied by completely hydrogenated soybean oil (HSO), a gift of Durkee Foods (Cleveland, Ohio) for 48 hr. The composition of the three diets has been reported previously (35). The fatty acid composition of the diet is listed in Table 1. Animals had access to the diets ad libitum, except that initially the animals were

[a]Fatty acids are designated by carbon chain length, number of double bonds and position of the first double bond from the methylene end of the molecule.

given approximately 3 ml of each diet by stomach tube. All animals consumed approximately the same number of calories regardless of diet group and appeared to find the diets palatable.

The animals were killed at 0, 24, 48, 72 and 96 hr after refeeding was begun. All animals received intraperitoneally tritiated H_2O (0.5 mCi/100 g body weight) one hr before they were killed. The tissues were removed and handled as previously described (37).

All organic solvents were obtained from Burdick and Jackson (Muskegon, Michigan). Purified fatty acid methyl ester reference standards were purchased from Nu-Chek Prep (Elysian, Minnesota).

Lipid extraction. Hydroquinone was added to all samples during processing. Three adipose tissue samples from each dietary group were extracted using $CHCl_3$-MeOH (2:1, v/v) by the procedures described previously (37) after being lyophilized to remove all traces of free tritiated water. This procedure was used to determine the percentage of fat present in the tissue based on the wet weight of the tissue. The total lipid extracts (TLE) were either prepared for transmethylation immediately or stored under nitrogen at −20 C until further processing. The remaining samples, which were the bulk, were lyophilized and transmethylated directly as dried tissue samples as described below.

Transmethylation. The transmethylations of the TLE to obtain the fatty acid methyl esters (FAME) were carried out using methanolic HCl (7%, w/w) (37) as previously described. For the direct transmethylation of the freeze-dried adipose tissue sample, the following procedure was used: Ca. 25 to 50 mg of dry tissue was placed directly in a 30-ml screw-capped culture tube to which a reflux condenser and drying tube were attached. Methanolic HCl (5 ml) was then added to the vial, and it was heated under reflux at 85 C for 2 hr. It was cooled to room temperature and processed similarly to the transmethylation of an aliquot of the TLE (37).

After transmethylation the FAME were extracted into hexane, purified and diluted in hexane to an appropriate concentration as described previously (37). They were then stored under N_2 at −20 C until analyzed by gas liquid chromatography (GLC) or by liquid scintillation count of the ^3H in the fatty acid moiety.

GLC of FAME. The FAME samples were analyzed as described previously (37) on fused-silica capillary columns coated with SP-2340 (Supelco, Bellefonte, Pennsylvania). Samples were chromatographed on a Perkin-Elmer Sigma 2000 coupled to a P-E 7500 computer loaded with a Chrom 3 data analysis program.

The quantitative accuracy of the GLC procedures was evaluated by using either purified single FAME or reference mixtures selected to cover the range of FAME present in the experimental samples. Accuracy of the analysis was estimated to be within 5% for the major components (greater than 10% of the total FAME in the sample) and within 10% for the minor components in the samples.

The cholesterol extracted into the hexane washes of the transmethylation procedure was not separated from FAME prior to injection of the samples in the chromatograph. However, cholesterol is largely decomposed during acidic transmethylation (38), and free cholesterol does not elute as a discrete peak from an SP-2340 column under the conditions used in this work (37).

The compositions (wt %) of the FAME in the rat samples were derived from the area percentages of the chromatograms as described previously (37). A chromatogram had between 30 and 50 discrete FAME peaks. Most minor peaks individually contributed less than 0.1% to the total area and were not identified with confidence. The major identified components usually comprised 97% to 99% of the total FAME present in the sample. For convenience, only selected major fatty acids are listed in the tables. The minor fatty acids are collectively presented as "sum of trace components," which varies from 4–6% of the total fatty acids present in the samples. Both identified and unidentified components are grouped together in this category.

Enzyme analysis. Adipose tissue samples were homogenized at 0 C in 4 volumes of HEPES (0.2 M)/EDTA (0.1 mM)/2-mercaptoethanol (10 mM) buffer, pH 7.4. The homogenates were centrifuged at 20,000 × g for 1 hr at 4 C. Supernatants recovered after this centrifugation were used for enzyme and protein determinations. Activities of fatty acid synthetase (FAS) were determined as previously reported (39). A unit of FAS is taken as the activity of enzyme required to synthesize 1 nmol of palmitic acid (equivalent to the oxidation of 14 nmol of NADPH)/min at 30 C. The activity of ATP-acid citrate lyase (ACL) was determined by the method of Linn et al. (40). One unit is defined as the activity necessary to catalyze the oxidation of 1 μmol NADH/min. Glucose 6-phosphate dehydrogenase (G6PDH) activity was determined by the procedures described previously (39). One unit of G6PDH represents the activity of enzyme necessary for the production of 1 μmol NADPH/min at 30 C. Activities of all enzymes are expressed as mU/mg protein.

Protein contents of tissue homogenates were determined by the method of Lowry et al. (41). All statistical

analysis of the data were done using the two-tailed student's t-test.

RESULTS

Starving the animals for 48 hr suppressed fatty acid synthesis and lipogenic enzyme activities in white adipose tissue compared to the animals fed the stock diet ad libitum, but had no influence on the fatty acid composition of the adipose tissue. Refeeding a FF diet stimulated adipose tissue lipogenic activity markedly by 48 hr to levels above that found in rats fed the stock diet and again without influencing the fatty acid composition of this tissue. Figure 1 presents the time course of fatty acid synthesis in rat dorsal adipose tissue. The animals on the FF diet exhibited an almost linear increase in fatty acid synthesis during the course of the study. No significant change in the rate of synthesis in the dorsal fat was detected when either corn oil or hydrogenated soybean oil was added to the diet at 48 hr. However, the variance in the experimental values was much larger in the groups receiving the high-fat diets. Nevertheless, there were no significant differences between the means of the fatty acid synthesis rates among any of the three diet groups at 72 or 96 hr.

Figures 2, 3 and 4 show the level of activity of the three enzymes measured in dorsal adipose tissue for the same time points as in Figure 1. Again, while individual variations were large, generally no significant differences were detected between the three dietary groups at 72 and 96 hr with the exception that animals on the HSO diet had suppressed FAS activity at 96 hr compared to animals on the FF and CO diets. All three enzymes showed increased activity after refeeding a FF diet compared to animals on the stock diet or those starved for 48 hr.

Epididymal adipose tissue enzymes were also investigated and showed approximately the same pattern as found in the dorsal tissue except that the activity levels were somewhat lower than those observed in the dorsal fat. The incorporation of ^{3}H into the fatty acids of epididymal fat was also about 50% lower than that observed

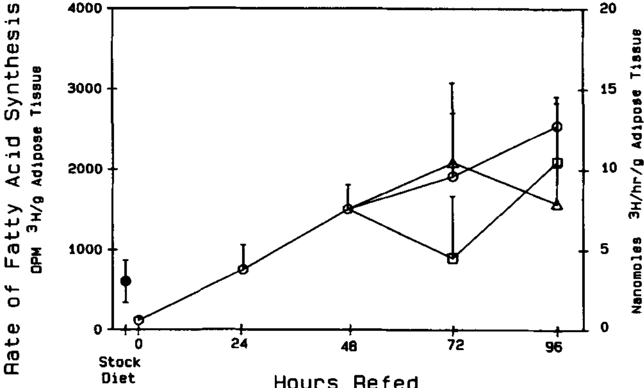

FIG. 1. Time course of fatty acid synthesis rate in dorsal adipose tissue from rats fed the three experimental diets. Symbols used are ●, stock diet; ○, fat-free diet; □, corn oil diet; △, hydrogenated soybean oil. Points are the means ± S.E.M. for groups of four to six animals. No statistically significant differences were detected between synthetic activities in animals on the fat-free diet and those on either the corn oil or hydrogenated soybean oil diets.

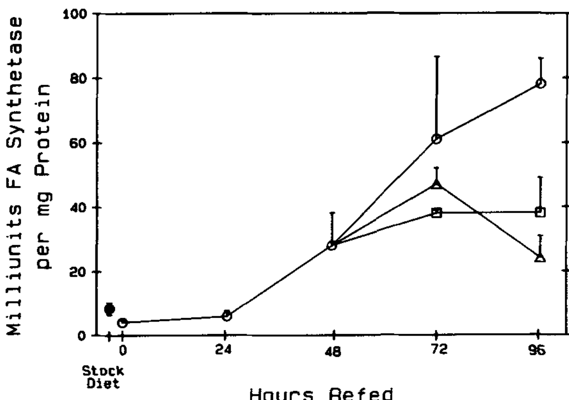

FIG. 2. Effect of different diets on the fatty acid synthetase activity in rat dorsal adipose tissue as a function of time on the diets. Symbols are the same as those in Fig. 1. The only difference that was statistically significant from the fat-free diet group was the 96-hr point for the hydrogenated soybean oil fed group, where $p < 0.01$.

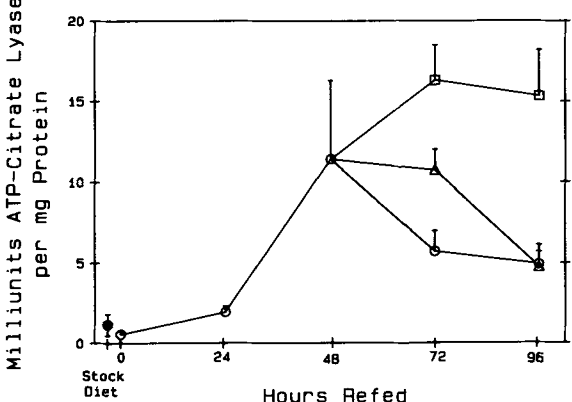

FIG. 3. Effect of different diets on ATP-citrate lyase activity in rat dorsal adipose tissue as a function of time on the diets. Symbols are as given in Fig. 1. Trends did not reach statistical significance during the 96-hr feeding period.

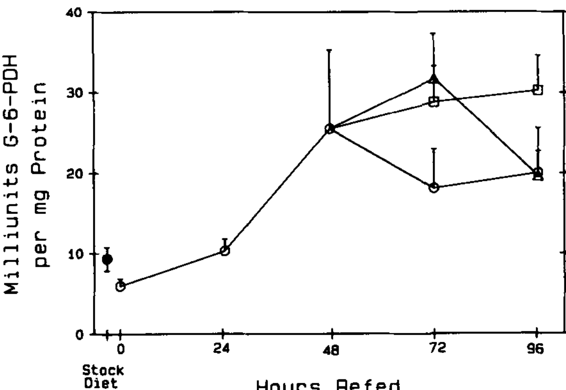

FIG. 4. Effect of different diets on the glucose-6-phosphate dehydrogenase activities in rat dorsal adipose tissue as a function of time on the diets. Symbols are the same as given in Fig. 1. No significant differences in the levels of enzyme activity were found among the tissues from animals in the three dietary groups.

in dorsal fat at equivalent time points. Actual data for the epididymal fat are not shown.

Table 2 gives the fatty acid composition of rat dorsal fat as a function of time and type of diet. There is relatively little change in the fatty acid composition between the animals starved for 48 hr and those refed a FF diet for 96 hr. There is a trend toward a reduction in the proportion of linoleate in adipose tissue after 96 hr on the FF diet, but this trend did not reach statistical significance. The only statistically significant change in any of the fatty acids in dorsal fat between the control animals and those on the FF diet was the 0.7% increase in *cis*-vaccenic acid at 96 hr.

When corn oil was added to the animals' diet after 48 hr on the FF diet, there was a statistically significant increase in the proportion of linoleate in dorsal fat. After 96 hr (48 hr on the CO diet) the linoleate level was 9% above that observed in the dorsal fat of the animals on the FF diet and 7% above the level in the dorsal fat of the animals starved for 48 hr. Other fatty acids showed statistically significant changes at 48 hr on the CO diet as well (see Table 2). Conversely, when saturated fat was added to the diet, there was little or no change in the fatty acid composition of the dorsal fat. Slight increases in the mean values for stearate, oleate and *cis*-vaccenic acids were noted in the dorsal fat of the animals fed saturated fat compared to animals on the stock diet or those starved for 48 hr. However, except for *cis*-vaccenic acid, the values were not significantly different at 96 hr.

It can also be observed from Table 2 that adipose tissue in the rat contains less than 1% arachidonic acid. Indeed, there is generally less arachidonic acid in adipose tissue than 22:6(n-3).

Table 3 lists the fatty acid composition of epididymal fat as a function of time and type of diet. Epididymal adipose tissue contains significantly larger proportion of polyunsaturated fatty acids than dorsal fat. In animals fed stock diets, the ratio of archidonic acid to the sum of n-3 20 and 22-carbon fatty acids is 0.34, while in epididymal fat this ratio is 0.25. Thus, there is almost 30% more n-3 fatty acids in epididymal fat proportionally to arachidonic acid than in dorsal fat.

DISCUSSION

It is generally agreed that dietary linoleic acid suppresses liver fatty acid synthesis (1,4,9,42–45), but several previous reports suggest that saturated fat does not suppress liver fatty acid synthesis (9,10,21,43,45–47). We recently reported (36) that in starved refed rats, high saturated-fat diets suppressed liver fatty acid synthesis equivalent to linoleate-containing diets. Some investigators, using various feeding periods (9,48), have suggested that fatty acid synthesis in adipose tissue is not inhibited by dietary fat. Reports on the enzymes of fatty acid synthesis indicate that rat adipose tissue fatty acid synthetic enzymes (usually measured in the epididymal fat pad) are not suppressed by dietary fat (5,10,17,21,49), although these studies used feeding periods and animals of ages different from those in this work. No consistent suppression of fatty acid synthesis was noted here in either dorsal or epididymal adipose tissue, even though linoleic acid was found to be rapidly incorporated into adipose fat. This suggests that other modulators of fatty acid synthesis, such as blood glucose levels, may play an important role in triggering fatty acid synthesis in adipose tissue.

Recently Gandemer et al. (25), using tritiated water and short incubation times to minimize the contribution from fatty acids synthesized de novo by the liver, indicated that in rats on a low-fat diet (0.3%) only 27% of the total fatty acids was synthesized in total body adipose tissue, whereas 42% of the fatty acid synthesis took place in the liver. Earlier work by Clarke and coworkers (4,9) and Romsos and Leveille (19) in meal-fed rats suggested that as much as 70% of the de novo fatty acid synthesis in the rat took place in the adipose tissue. High levels of dietary fat almost totally suppress liver fatty acid synthesis (9,21,36,46,50), and there is little if any transport of de novo synthesized fatty acids in the circulation by this time (35). Thus, the contribution of fatty acids synthesized in the liver to adipose tissue fatty acid stores should be minimal in rats on a high-fat diet.

It may be that a fat-fed animal synthesizes fatty acids primarily in the adipose tissue while those on a very low or fat-free diet synthesize fatty acids primarily in the liver with, perhaps, a substantial synthetic contribution from the adipose tissue. Factors including diet, age, sex, strain and caloric intake probably all affect the site of fatty acid synthesis, so considerable caution must be exercised in assigning the relative contribution of the liver or adipose tissue to de novo fatty acid synthesis in the rat. Meal feeding vs ad libitum feeding will also affect this ratio (48).

The fatty acid compositional data shown in Tables 2 and 3 were obtained by direct transmethylation of the lyophilized tissue. No compositional differences in the adipose fatty acid data could be detected between portions of the same adipose tissue sample processed by direct transesterification of the lyophilized tissue or by transesterification of the TLE from that tissue. The direct method was simple and quantitative, and saved considerable time and effort by avoiding the initial extraction step using $CHCl_3$/MeOH. This method works well for adipose tissue probably because adipose tissue is about 90% triglyceride and, hence, there are few proteins, carbohydrates or other nonlipoidal substances present to interfere with the reaction. Other investigators have also recently proposed one-step transesterification procedures (51,52) applicable to a variety of tissues. However, no attempt was made in this work to determine if this method was applicable to other tissues.

Palmitic, palmitoleic, stearic, oleic, *cis*-vaccenic and linoleic acids constitute almost 90% of total fatty acids (30,32,53) in adipose tissue. This may be true regardless of diet (30,31,54), which suggests that there are regulatory mechanisms controlling the fatty acid composition of this tissue other than the fatty acid composition of the diet. By comparing Tables 2 and 3 one can find subtle differences between the fatty acid compositions of the dorsal and epididymal fat. They may be due to differences in the amounts of phospholipids present in the two tissues, but any physiological significance of these differences remains obscure.

While dietary linoleic acid causes a rapid increase in the linoleic acid content of white adipose tissue, a high level of stearic acid in the diet has little influence on the content of this fatty acid in adipose tissue. The stearic acid level in adipose tissue is low, presumably due to the active Δ-9 dehydrogenase present in adipose tissue (33,54).

TABLE 2

Fatty Acid Composition of Rat Dorsal Adipose Tissue (Wt % of Total Fatty Acids)

It is possible that poor intestinal absorption of stearic acid is the reason that the hydrogenated fat diet had little influence on the fatty acid composition of the adipose tissue. However, all the animals in this study consumed approximately the same number of calories and gained about the same amount of weight. Additionally, 40% of the calories consumed in the hydrogenated fat diet were in the form of stearic acid, so that even a relatively poor absorption rate for this compound would still provide a significant amount of stearic acid for metabolic use as reported by Clarke et al. (9).

Most previous reports on the fatty acid composition of adipose tissue have not included data on the 20- and 22-carbon polyunsaturated fatty acids present in this tissue (30,34,55). In this work we observed significant amounts of 20:4(n-6), 22:5(n-3) and 22:6(n-3), and small, but measurable, amounts of 20:5(n-3) in both dorsal and epididymal fat. Indeed, the 22-carbon, n-3 polyunsaturated fatty acids constitute more of the adipose tissue fatty acids than arachidonic acid, an unusual circumstance in the rat, whose tissues usually contain relatively large amounts of arachidonic acid (35,56,57).

Adipose tissue is a major reservoir of fatty acids in the mature rat (22,57); indeed, the adipose tissue pool of fatty acids may be larger than all other carcass fatty acid pools combined (14,22,58). If all the individual long chain n-3 fatty acids in rat adipose tissue are summed, they represent between 3% and 4% of the total adipose fatty acids. This is in contrast to the arachidonic acid pool which, although much larger than the n-3 pool in rats, is concentrated in more physiologically active tissue, such as heart muscle (57,59), liver (35,37,60), nerve (61) and various others (53,57,61,62). The accumulation of n-3 fatty acids by adipose tissue may be an aging phenomenon as the 22-carbon, n-3 fatty acids are not precursors of physiologically active eicosanoids (63) and may accumulate in the adipose tissue with age.

There was no inhibition of the lipogenic enzymes, measured in white adipose tissue during the refeeding period of this study. When we fed corn oil to the animals, linoleic acid levels rose markedly in the adipose tissue within 48 hr, whereas feeding saturated fat had no influence on the fatty acid composition of the adipose tissue in the same time period. Feeding these two types of fat for longer periods could clarify whether these differences were due to slower absorption and/or transport of saturated fat or to different pathways for the metabolism of saturated versus polyunsaturated fatty acids in the rat.

Effect of Age and Dietary Fat (Fish, Corn and Coconut Oils) on Tocopherol Status of C57BL/6Nia Mice

Simin Nikbin Meydani*, Alice C. Shapiro, Mohsen Meydani, John B. Macauley and Jeffrey B. Blumberg
USDA Human Nutrition Research Center on Aging at Tufts University, 711 Washington St., Boston, MA 02111

The effect of age and dietary fat type on tocopherol status was investigated using young and old C57BL/6Nia mice fed semipurified diets containing 5% (by weight) fish, corn or coconut oils and supplemented with 30, 100 or 500 ppm dl-α-tocopheryl acetate for 6 wk. Tocopherol levels in the diets, plasma, liver, kidney and lung were measured by high performance liquid chromatography following appropriate extractions. The results indicate that mice fed fish oil maintain lower plasma and tissue tocopherol concentrations than those fed corn and coconut oils (fish < corn oil < coconut oil). The difference was not due to a loss of tocopherol prior to consumption, but rather appeared to occur during the absorption process. Old mice had lower plasma and liver tocopherol concentrations than young mice. Old mice fed fish oil, however, maintained plasma tocopherol levels better than young mice fed fish oil, presumably due to their larger tocopherol pool. No age effect was detected on kidney and lung tocopherol levels. It is concluded that tocopherol status is affected by age and dietary fat type, especially fish oil. *Lipids 22,* 345–350 (1987).

The dependency of tocopherol requirements on the level of polyunsaturated fats in the diet has been established (1–5). Most previous work, however, has concentrated on unsaturated oils of plant origin. Interaction of tocopherol with the polyunsaturated fatty acids of marine oils having higher degrees of unsaturation than those in plant oils has not been well studied. Data is especially lacking for aged animals, which possess more lipid peroxides (6,7) and might therefore be more susceptible to changes in antioxidant defense mechanisms such as tocopherol status.

The lower incidence of coronary heart disease in Greenland Eskimos (8) has been attributed to their high consumption of marine oils and their fatty acid components, especially eicosapentaenoic acid. Eicosapentaenoic acid is a precursor for the 3-series of prostaglandins and the 5-series of leukotrienes, which have been shown to have less potent aggregatory and inflammatory properties than the corresponding arachidonic acid metabolites (9, 10). These findings have renewed interest in fish oil and its potential use in the prevention and/or therapy of certain chronic cardiovascular and inflammatory diseases. However, over 50 years ago, Goettsch and Pappenheimer (11) reported extensive muscle lesions produced in rabbits fed diets supplemented with cod liver oil. Subsequently, Madsen et al. (12) showed that addition of cod liver oil to synthetic and natural food diets produced muscle lesions in rabbits, guinea pigs, goats and sheep. McKenzie et al. (13) later showed that this toxic effect of cod liver oil could be prevented by the administration of vitamin E.

The effect of fish oils on tocopherol status, which could influence some of the observed beneficial and toxic effects, has been mostly overlooked. In studies comparing the biological effects of fish oil with those of other dietary oils in mice, we noticed that serum tocopherol levels were different among different dietary groups, making interpretation of the data difficult. Therefore, the present study was conducted to compare the effect of fish oil on tocopherol status with that of corn and coconut oils in young and old mice.

MATERIALS AND METHODS

Animals and diets. Three-month (young) or 24-month (old) specific pathogen-free male C57BL/6Nia mice were purchased from the National Institute of Aging colonies at the Charles River Breeding Laboratories (Wilmington, Massachusetts) and were fed semipurified diets containing 5% (by weight) fat as either tocopherol-stripped corn oil, nonhydrogenated coconut oil (Tekland, Madison, Wisconsin) or fish oil (MAXEPA; a gift from R.P. Scherer Co., Troy, Michigan) and supplemented with 30, 100 or 500 ppm dl-α-tocopheryl acetate (Tekland) for 4 wk. The overall design of the study is shown in Figure 1; composition of the basal diet is shown in Table 1. Fresh diets were given daily just before the dark cycle (so that food did not sit in the jars for a long time before being consumed). Leftover food was discarded. The bulk of the diets, without oil, in powder form was prepared and stored at 4 C. Oils were mixed in smaller batches. Following addition of the oils, the diets were flushed with nitrogen and kept frozen. Samples of each diet were kept for tocopherol analysis.

Mice were housed individually in plastic cages with water and diets provided ad libitum. Weekly weights were obtained, and animals were checked daily for general health status.

Mice were anesthetized with nembutal (60 mg/kg BW) (Anthony Products Co., Arcadia, California). Blood was collected by heart puncture and plasma separated by cold centrifugation. Livers and kidneys were snap-frozen with

dl-α-Tocopheryl Acetate Concentration in Corn Oil, Coconut Oil and Fish Oil Diets

Dietary fat	dl-α-Tocopheryl acetate added to diet (ppm)	dl-α-Tocopheryl acetate[a] measured in diet (ppm)		
		0 hr	6 hr	24 hr
Coconut oil	30	27 ± 3	36 ± 9	26 ± 4
Coconut oil	500	538 ± 17	(476)[b]	562 ± 18
Corn oil	30	34 ± 3	28 ± 8	26 ± 5
Corn oil	500	529 ± 5	521 ± 45	547 ± 69
Fish oil	30	69 ± 5	(58)[b]	70 ± 1
Fish oil	500	538 ± 17	524 ± 20	512 ± 39

Mean ± SE; n = 3 for 0 hr, n = 2 for 6 and 24 hr.

[a]Values have been calculated from α-tocopherol values obtained in extracted samples (after saponification of dl-α-tocopheryl acetate in the diet) multiplied by a correction factor calculated by dividing α-tocopherol MW/dl-α-tocopheryl acetate MW.

[b]Single measurement.

liquid nitrogen. All samples were kept at −70 C for α-tocopherol analysis.

α-Tocopherol analysis. α-Tocopherol content of diets, plasma and tissues was measured by the modified high performance liquid chromatography (HPLC) method of Bieri et al. (14). Plasma samples were deproteinized with ethanol containing 0.01% BHT. α-Tocopheryl acetate was used as an internal standard. After centrifugation, supernatant was extracted with 5 vol hexane. The hexane layer was removed, dried and redissolved in ethanol. Tissue samples (ca. 50 mg) were homogenized twice with 5 ml acetone. The acetone layers were pooled, evaporated under nitrogen and redissolved in ethanol. Tocopherol in food samples exposed to air for 0, 6 and 24 hr was analyzed following saponification in the presence of excessive amounts of ascorbic acid followed by hexane extraction as described by Taylor (15). α-Tocopherol in the extracts was separated using a 15-cm HPLC column packed with 5 μ C18 particles developed with 100% methanol. Elution spectra were detected at 292 nm excitation and 340 emission with spectrofluorometer.

Statistical analysis. Results were analyzed by three-way analysis of variance and were compared using statistical analysis system (SAS), least square mean comparison for the effects of age, fat type and vitamin E level on plasma and tissue α-tocopherol levels. They are recorded as mean ± standard error (SE).

RESULTS

Table 2 shows the body weights of young and old mice fed different diets. There was no significant effect of fat type or vitamin E level on body weight.

Table 3 shows the tocopherol concentration measured in different diets, fresh and following 6 or 24 hr exposure to air at room temperature, to account for losses that might occur prior to consumption. Each sample was a mixture of top, middle and bottom sections of the food container. Two or three samples were extracted from each container. There was no statistically significant loss of dl-α-tocopheryl acetate in the diet due to type of fat or time of exposure to room temperature. The higher tocopherol content in the fish oil diet containing 30 ppm vitamin E is due to tocopherol added by the manufacturer. Analysis of MAXEPA fish oil revealed 600 mg tocopherol/kg fish oil, which contributes ca. 30 ppm to the diet.

Tables 4 and 5 show the plasma tocopherol concentration in young and old mice fed different diets. Young mice fed fish oil had a lower plasma tocopherol level compared to mice fed corn and coconut oils at all three levels of tocopherol ($P < 0.0001$ for overall fat effect). Increasing the tocopherol level to 100 and 500 ppm in coconut oil and corn oil diets increased plasma tocopherol level over 100%, while only a 39% increase in plasma α-tocopherol was observed after increasing tocopherol levels to 500 ppm in the fish oil diet. A similar trend was observed in old mice (Table 5), except the differences were not as marked, especially in mice fed 30 ppm vitamin E. In

general, old mice fed corn and coconut oils had lower plasma tocopherol levels than young mice fed similar diets ($P < 0.05$ for overall age effect). This was not true for old mice fed fish oil. Plasma tocopherol levels in old mice fed fish oil, however, were lower than those in young mice fed corn or coconut oils. Correlation coefficients (r) between dietary and plasma tocopherol levels in young mice were 0.84, 0.73 and 0.39 and in old mice were 0.40, 0.80 and 0.27 for diets containing coconut oil, corn oil and fish oil, respectively.

Since the difference in plasma tocopherol levels in mice fed different dietary fats was not due to a loss of tocopherol in diet (see Table 3), tissue tocopherol concentration was examined as an indicator of differences in the absorption and/or utilization of tocopherol due to dietary fat type. Young and old mice fed fish or corn oils had lower liver tocopherol concentrations than those fed coconut oil ($P < 0.0001$ for overall fat effect). The fat effect was more pronounced in mice fed 100 and 500 ppm tocopherol (Tables 6 and 7).

In young mice fed coconut and corn oils, increasing the tocopherol level from 30 to 500 ppm in the diet increased liver tocopherol concentration almost 10-fold ($P < 0.0001$ and 0.0002, respectively), whereas mice fed fish oil showed only a threefold increase ($P > 0.8$). Livers from old mice, like plasma, had a lower tocopherol concentration than those of young mice, except for old mice fed fish oil ($P < 0.0001$ for overall age effect). Similar to young mice,

old mice fed coconut or corn oils showed a significant increase in liver tocopherol concentration when dietary tocopherol was increased. No significant rise in liver tocopherol concentration was observed in mice fed fish oil. There was a significant overall effect of fat on liver tocopherol concentration, which was more pronounced at the higher tocopherol concentrations. In young mice, there was a significant correlation between plasma and liver tocopherol concentrations (r = 0.82, 0.76 and 0.41 for mice fed coconut oil, corn oil and fish oil, respectively). Plasma and liver tocopherol in the old mice were not significantly correlated.

Tables 8 and 9 show the tocopherol concentration of kidneys in young and old mice, respectively. Old mice had similar or slightly higher tocopherol concentrations than young mice. A significant fat effect was observed in young and old mice only at 500 ppm dietary vitamin E. There was a significant increase of kidney vitamin E concentration in young and old mice fed corn and coconut oils with increased dietary tocopherol. No significant rise of kidney tocopherol concentration in young mice fed fish oil was observed (Table 8). In old mice, a significant increase in kidney vitamin E concentration was observed regardless of the type of fat; however, the increase was less in mice fed fish oil. The fat effect on tocopherol concentration in kidney was significant only when dietary tocopherol was 500 ppm, at which level mice fed fish and corn oils had lower kidney tocopherol concentrations than mice fed coconut oil (Tables 8 and 9). Plasma tocopherol level was correlated with kidney tocopherol in mice fed coconut oil (r = 0.79 in young mice; r = 0.72 in old mice). A weaker correlation was observed in mice fed corn oil (r = 0.46 for young mice; r = 0.44 for old mice). In mice fed fish oil, plasma tocopherol did not correlate with kidney levels (r = 0.13), although a weak correlation was observed in old mice (r = 0.51). The same situation held for correlations between plasma and lung tocopherol levels (r = 0.17 in young mice; r = 0.58 in old mice).

Tables 10 and 11 show the concentration of tocopherol in lungs of young and old mice, respectively. Tocopherol concentrations in lung were very close to those of kidney; the values for young and old mice were also similar, with the old mice having slightly lower concentrations. Similarly, a significant increase in lung tocopherol concentration was observed only in young mice fed coconut and corn oils supplemented with 100 or 500 ppm tocopherol. Mice fed fish oil had a significantly lower lung tocopherol concentration than mice fed coconut oil (Tables 10 and 11).

DISCUSSION

Even before the role of vitamin E in preventing nutritional muscular dystrophy was fully recognized, the ability of cod liver oil to precipitate this lesion, particularly in herbivores, was well established (12). Later, it was demonstrated that vitamin E can antagonize the tendency of cod liver oil to induce muscular dystrophy. MacKenzie et al. (13), however, showed that vitamin E could not prevent muscular dystrophy if administered orally in cod liver oil. This effect of cod liver oil was attributed to its content of highly unsaturated fatty acids. Furthermore, since aging is associated with increased lipid peroxidation, and senescent rodents may have a higher requirement for tocopherol (16,17), we studied the effect of a low level (5%), short-term (6-wk) diet of fish oil, corn oil or coconut oil on the vitamin E status of young and old mice fed adequate or high levels of tocopherol.

The results indicate that young mice fed fish oil have significantly lower plasma tocopherol levels than those fed corn and coconut oils at all three levels of dietary tocopherol tested (30, 100 and 500 ppm). Mice fed corn oil tended to have lower tocopherol levels than mice fed coconut oil, but differences were significant only at 500 ppm dietary tocopherol. Mice fed coconut and corn oils showed significant increases in plasma tocopherol as dietary tocopherol increased. No significant increase in plasma tocopherol concentration was observed in mice fed fish oil. The lower plasma tocopherol level and lack of response to an increase in dietary tocopherol in mice fed fish oil was not due to oxidative loss of tocopherol in the

diet (Table 3). The lower plasma tocopherol level in mice fed fish oil can be due either to an interaction of fish oil and tocopherol at the gut level, as suggested by others (13,18,19), or to enhanced postabsorptive utilization of tocopherol compared to mice fed coconut and corn oils. Further studies are needed to clarify the mechanism of action.

In mice fed corn oil, the liver tocopherol concentration was lower than that of mice fed coconut oil and higher than that of those fed fish oil, which correlates well with the differences in degree of unsaturation between corn and fish oils. It is worth noting that only mice fed fish oil supplemented with 500 ppm vitamin E had plasma and liver tocopherol levels comparable to those fed coconut oil with 30 ppm vitamin E. This agrees with previous reports (13) that concurrent administration of fish oil and tocopherol did not alleviate signs of tocopherol deficiency. Old mice had lower plasma tocopherol levels than young mice, except those fed fish oil (see also 16). The higher plasma tocopherol level of old mice compared to that of young mice fed fish oil may be due to the larger pool of available tocopherol in old mice.

The effect of fat type and tocopherol supplementation on liver tocopherol concentration was similar in young and old mice. Mice fed fish and corn oils had lower tocopherol concentrations than those fed coconut oil. Increasing tocopherol concentration in mice fed fish oil did not increase liver tocopherol concentration. No age effect was apparent when old mice were compared to young mice fed fish oil; when plasma and liver tocopherol concentrations in old mice fed fish oil were compared to those of young mice fed other fats, a significant age effect was observed. The lower plasma tocopherol concentration in the aged mice may be due to decreased absorption and/or increased uptake and utilization of vitamin E by other tissues. This mechanism could be determined by measuring the postabsorption level of α-tocopherol in the lymphatic duct and unabsorbed tocopherol in the feces. Since kidney and lung tocopherol concentrations in old mice were equal to or slightly higher than those in young mice, the lower plasma concentration may be due to decreased absorption. If lower plasma and liver tocopherol content in old mice were due to increased catabolism, the age effect should have been exaggerated rather than abolished in mice fed fish oil.

The dietary fat effect on tocopherol concentrations of kidney and lung was significant only at the higher dietary vitamin E concentrations. This was in contrast to plasma and liver tocopherol concentrations, but in agreement with other reports (21,22). Studies in guinea pigs and rats (21,22) indicate that the depletion of tocopherol from plasma and liver is rapid relative to other organs. Therefore, a 6-wk dietary treatment might not have been long enough to reduce the tocopherol content of kidney and lung in mice fed fish oil. No significant rise in kidney and lung concentrations of tocopherol was observed in young mice fed fish oil, reflecting the observations in plasma and liver.

In conclusion, even after a short-term dietary regimen, animals fed fish oil maintain a lower tocopherol status than those fed corn or coconut oils. This effect should be taken into consideration when designing and interpreting experiments where the biological effects of fish oil are compared to those of other oils. Furthermore, plasma and liver levels of tocopherol are influenced by age in mice, whereas kidney and lung tocopherol do not appear to be altered by age when the diet contains 30 ppm or more vitamin E. The consequences of inadequate vitamin E intake by young and old individuals consuming different dietary fats should be examined.

[Received October 23, 1986]

Phosphatidylcholine as the Choline Donor in Sphingomyelin Synthesis[1]

C. Mark Eppler[2], Barbara Malewicz, Howard M. Jenkin and **Wolfgang J. Baumann***
The Hormel Institute, University of Minnesota, Austin, MN 55912

Sphingomyelin synthesis was studied in cultured Novikoff rat hepatoma cells by following transfer of [^{14}C]choline label into sphingomyelin (SPH). The study was facilitated by the fact that prelabeling of the cells with [*methyl*-^{14}C]choline resulted in rapid accumulation of essentially all the label (~95%) in phosphatidylcholine (PC). The redistribution of PC label during a 15-hr chase was dependent upon the extracellular choline concentration. Under conditions of free choline diffusion (500 μM choline), loss of label from PC was most pronounced, and the percentage of total radioactivity that became trapped in the extracellular water-soluble choline pool was an order of magnitude greater than in low choline medium (27 μM choline). Despite the significant loss of water-soluble label from the cells in high choline medium, SPH labeling proceeded at essentially the same rate at either choline concentration. During the label chase in 500 μM choline, the specific radioactivity of PC decreased, but the specific radioactivity of SPH continued to increase for 9–12 hr until it reached the specific radioactivity of PC. In the presence of 300 μM neophenoxine (NPO), transfer of label from PC into SPH was stimulated. NPO also decreased the specific radioactivity of PC to about the same extent as that of SPH was increased. Because transfer of choline label from PC to SPH was not affected by loss or dilution of water-soluble precursors, and because the specific radioactivity of PC and SPH, in the absence or presence of NPO, responded in a characteristic precursor product fashion, we conclude that sphingomyelin synthesis in Novikoff cells circumvents the water-soluble choline pool and that phosphatidylcholine serves as the immediate choline source. All our data support the phosphatidylcholine:ceramide cholinephosphotransferase pathway of sphingomyelin synthesis.
Lipids 22, 351–357 (1987).

Sphingomyelin (SPH) synthesis has been studied for almost three decades, with several pathways being established, and challenged thereafter. Early in vitro studies with particulate fractions from chicken liver hinted that SPH is synthesized by phosphocholine transfer from cytidine 5′-diphosphocholine (CDPcholine) to ceramide (2–4) quite in analogy to de novo phosphatidylcholine (PC) synthesis (5). In vivo experiments in rat brain showed that ceramide serves as SPH precursor (6). Evidence also emerged that sphingosylphosphocholine can be acylated with acyl-CoA by rat brain microsomes (7,8), yet the biosynthesis of sphingosylphosphocholine itself (9) remained uncertain (10,11).

Studies with SV-40 transformed mouse fibroblasts provided a first clue that the phosphocholine donor in SPH synthesis may be not CDPcholine but phosphatidylcholine (12–15), and ceramide was shown to serve as phosphocholine acceptor in this reaction (16). The PC:ceramide cholinephosphotransferase pathway was also demonstrated in lyophilized microsomes from mouse liver (17); however, in rat liver microsomes, CDPcholine and not PC appeared to be the phosphocholine donor (10). More recent studies on the cellular and subcellular level have provided additional evidence for the phosphatidylcholine:ceramide cholinephosphotransferase pathway in sphingomyelin synthesis (11, 18–22).

In the present study, we have examined the routes of SPH synthesis in cultured Novikoff rat hepatoma cells. Three characteristics of these cells proved particularly useful. First, we observed that when Novikoff cells are pulsed with [^{14}C]choline in spent medium, they rapidly incorporate essentially all the label into PC (~95%). This simplified following the flux of the label during the chase and facilitated interpretation of label chase kinetics. Second, Novikoff cells are known to take up choline by two different mechanisms (23). At low extracellular choline levels (<20 μM), active transport prevails, and the rate of choline transport is actually the rate-limiting step in choline phosphorylation. At higher choline concentrations, simple diffusion at a rate three times higher than active transport is the principal mode. These distinct modes of choline uptake permitted us to modulate the water-soluble choline pool and to evaluate its contribution to SPH synthesis. Third, we found that neophenoxine (NPO; 24) stimulates SPH synthesis in Novikoff cells at the expense of PC labeling. This made it possible to also modulate the flux of label through the lipid-associated choline pool and to assess the effect of such modulation on sphingomyelin synthesis.

EXPERIMENTAL PROCEDURES

Materials. S_{210} medium was obtained from Grand Island Biological Co. (Gibco, Grand Island, New York). S_{210} consists of Swim's 67G medium supplemented with succinic acid (75 mg/l) and sodium succinate (100 mg/l). Choline chloride was from Aldrich Chemical Co. (Milwaukee, Wisconsin) and [*methyl*-^{14}C]choline chloride from New England Nuclear (Boston, Massachusetts). Lysophosphatidylcholine (lysoPC) was prepared from egg yolk PC by phospholipase A_2 hydrolysis (25) using *Ophiophagus hannah* venom (Miami Serpentarium, Miami, Florida). NPO, *p*-chlorophenoxyethyl *N,N*-dimethylaminoethyl ether, was synthesized as we described previously (24).

Cell system. Novikoff rat hepatoma cells, subline N1S1-67 (26), were grown in shaker culture (110 rpm) at 37 C in S_{210} medium (pH 7.4) supplemented with meat peptone (2 g/l), penicillin (10^5 units/l), streptomycin (100 mg/l) and 5% newborn calf serum (K.C. Biologicals, Kansas City, Missouri). Cells were subcultured twice per week from a starting density of 3.5×10^5 cells/ml using fresh medium. Cell growth was monitored by cell counting and by following the rate of [^{3}H]thymidine incorporation. Thymidine incorporation was measured by incubating 2-ml samples of cell suspension with 0.5 μCi of

[^{3}H]thymidine (New England Nuclear; sp act 2 Ci/mmol) for 1 hr (27); the cells were washed three times with 2 ml of phosphate-buffered saline, and cell-associated and/or TCA precipitate-associated radioactivity (cpm/mg protein) was determined by scintillation counting. Protein was assayed according to Lowry et al. (28). Cell viability was routinely monitored by the trypan blue exclusion test. Cells used for experiments were taken from their logarithmic phase of growth (48 hr); in all experiments described, cell viability exceeded 95%.

Label chase in low and high choline media. Two-day-old Novikoff hepatoma cell cultures, averaging 2×10^6 cells/ml, were incubated, without changing the medium, with 1.5 μCi of [*methyl*-^{14}C]choline chloride (sp act 53.5 mCi/mmol) per 10^7 cells for 1.5 hr under standard growth conditions. After pulse labeling, the cells were washed twice with fresh growth medium and then were resuspended at a density of 1.5×10^6 cells/ml in one of three chase media: (a) the basal growth medium containing 27 μM choline (low choline medium); (b) the basal growth medium supplemented with choline chloride to a final concentration of 500 μM choline (high choline medium); and (c) the high choline medium (500 μM choline) supplemented with 300 μM NPO. Choline in the basal growth medium originated from choline bitartrate (15 μM) present in S_{210} medium and the choline in pluronic (7 μM), calf serum (5 μM), and meat peptone (<0.1 μM). Choline was assayed according to Gibson et al. (29). Chase incubations were carried out on triplicate cultures under standard growth conditions. At given intervals (3, 6, 9, 12 and 15 hr) in the 15-hr chase, 2.5-ml aliquots were removed from each culture and the samples were quickly chilled in ice. The cells were sedimented at 500 × g for 5 min, washed once with cold growth medium and analyzed. The supernatants were combined and kept frozen until analyzed.

Effect of choline concentration on [^{14}C]choline incorporation. Two-day-old cells were washed with fresh growth medium and then resuspended at 1.5×10^6 cells/ml in either low choline (27 μM) or high choline (500 μM) medium, each containing 54,000 cpm/ml of [*methyl*-^{14}C]-choline. The cells were incubated for 15 hr under standard growth conditions, and 2.5-ml aliquots were taken at given intervals. The cells were sedimented at 500 × g for 5 min and washed with cold growth medium, and phospholipid-associated label and water-soluble label in the cells were measured.

Analyses. Cells and culture media were extracted according to Bligh and Dyer (30). LysoPC was usually added to the extract to serve as carrier. Lipids were fractionated by thin-layer (0.5 mm) chromatography (TLC) on Silica Gel H (Merck, Darmstadt, West Germany) using chloroform/methanol/water (65:35:8, v/v/v) as developing solvent (solvent A). Fractions were made visible by brief exposure to iodine vapors. Individual fractions were assigned by comparing their migration rates with those of standards. In analytical TLC, choline phospholipids were also identified by spraying with a choline-specific molybdenum reagent (31). In preparative TLC (solvent A), bands corresponding to PC (Rf 0.43), SPH (Rf 0.33) and lysoPC (Rf 0.22) were scraped off, and the phospholipids were recovered by three successive elutions with chloroform/methanol/water (50:40:10, v/v/v, once; then 60:30:5, v/v/v, twice). Rechromatography of the PC and the SPH fractions on Silica Gel H layers, with chloroform/methanol/conc. aqueous ammonia (65:25:5, v/v/v; solvent B) as developing solvent (32) showed that in each case more than 90% of the radioactivity was associated with PC (Rf 0.27) and SPH (Rf 0.13). The SPH fraction proved resistant to hydrolysis in 1 N sodium hydroxide (33).

The water-soluble components of the upper Bligh-Dyer phase from cells and media were fractionated by TLC on Silica Gel H in the presence of carriers using 1-propanol/conc. aqueous ammonia (1:1, v/v) as developing solvent (15). Fractions were made visible by exposure to iodine vapors. The fractions comigrating with choline (Rf 0.04), phosphocholine (Rf 0.17), glycerophosphocholine (Rf 0.31) and CDPcholine (Rf 0.38) were isolated, and their radioactivities were measured after elution with methanol/water (1:2, v/v).

Radioactivity was counted on aliquots of the samples (400–20,000 cpm) using 10 ml of scintillation fluid. Scintillation fluid was prepared from 12 g of Omnifluor (New England Nuclear), Triton X-100 (1 l) and toluene (2 l). Phospholipid radioactivities given are those determined after TLC fractionation using solvent A. The specific radioactivity of PC and SPH was determined after repurification of the samples using solvent B. Phospholipid phosphorus was measured according to Bartlett (34).

RESULTS

The study was designed to compare the participation of the water-soluble and the lipid-associated choline pools in the transfer of [^{14}C]choline to SPH. Short-term exposure (90 min) of two-day-old Novikoff cells to [^{14}C]choline in spent medium resulted in the rapid accumulation of 92 to 98% of the total cell label in PC (Fig. 1). Only small amounts of label were initially associated with SPH (<3%) or water-soluble choline components.

Label chase in low and high choline media. Label was chased over 15-hr periods in either normal growth medium containing 27 μM choline or high choline medium containing 500 μM choline. Cells chased in either medium remained morphologically identical; showed identical growth rates as judged by cell count, protein content and rate of [^{3}H]thymidine incorporation (27); and maintained identical rates of phospholipid synthesis. During the entire chase, cell numbers typically increased 1.8-fold, and phospholipid content increased 2.5-fold in either culture.

Figure 1 compares the redistribution of label originally concentrated in PC within the 15-hr chase at low and high choline levels. It is apparent that in 27 μM choline there was less loss of label from PC (from 95 to 80% of total label) than in 500 μM choline (from 95 to 55%). Under conditions of free choline diffusion, loss of PC label was quite pronounced.

Figure 1 furthermore shows that at the low choline concentration, the proportion of water-soluble label in the medium remained rather constant (2–3%). At the high choline concentration, by contrast, the substantial loss of label from cell PC was reflected in an increased release of water-soluble label into the medium. The percentage of total radioactivity that finally appeared in the water-soluble choline pool of the high choline medium was about 10 times greater (23% of total) than that released into

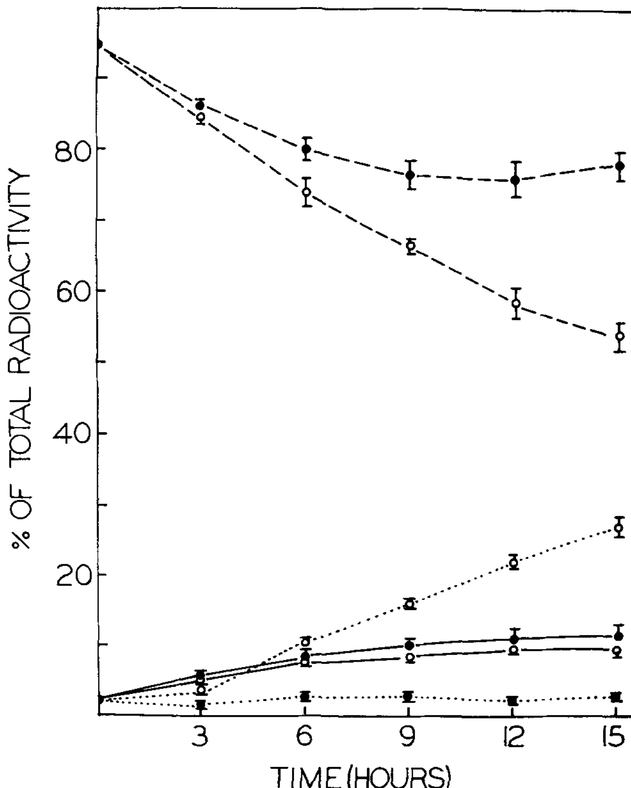

FIG. 1. Redistribution of [^{14}C]choline label in cultured Novikoff hepatoma cells during label chase in low and high choline media. Cells (2.25 × 10^{7} cells/15 ml) were prelabeled with [*methyl*-^{14}C]choline for 1.5 hr, and the label was chased for 15 hr in media containing either 27 μM (●) or 500 μM (○) choline. Redistribution of label between cell PC (— —), cell SPH(——) and the water-soluble components released into the medium (.....) is shown as percentage of total label recovered at various intervals from 2.5-ml aliquots of culture (1.3–1.7 × 10^{5} cpm). The data represent means of three triplicate experiments ± standard errors (n = 9).

the low choline medium (Fig. 1). TLC showed that about 90% of the label in high choline medium was actually associated with free choline. Progressive accumulation of [^{14}C]choline in the high choline medium suggests that label entering the medium was trapped there. Obviously, labeled choline could not effectively re-enter the cells and participate in phospholipid synthesis because of dilution with the very large excess of unlabeled choline in the medium.

The most significant finding that emerged from these experiments was that even though cells chased for 15 hr in high choline medium irretrievably lost most of the water-soluble label released from PC into the medium, they transferred label to SPH with essentially the same efficiency as did low choline cells. The radioactivity associated with cell SPH increased essentially at the same rate and reached about the same level (14% of total label) at either choline concentration (Fig. 1). Because transfer of choline label to SPH was not affected by loss or dilution of water-soluble precursors, these data strongly suggested that SPH synthesis in Novikoff cells circumvents the water-soluble choline pool and instead utilizes lipid-associated choline as precursor.

To assess the contribution of lipid-associated and water-soluble choline precursors to SPH synthesis in a more quantitative fashion, we compare in Table 1 label chase data of a representative experiment similar to the one described above (Fig. 1). Table 1 shows that initial PC labeling was high (153,000 cpm) and that only small amounts of radioactivity were initially associated with lysoPC (2,500 cpm), SPH (4,500 cpm) and the water-soluble choline components (7,500 cpm) of the cells. Throughout the chase, lysoPC labeling remained constant in low choline medium, but decreased in high choline medium (Table 1; NPO data are discussed below). Lipid-associated radioactivity released into the medium (largely as lysoPC) was quite independent of the extracellular choline concentration. The amount of water-soluble label in the cells grown in either medium was substantial (7,500–13,000 cpm) and was shown to be associated with phosphocholine (58–63%), glycerophosphocholine (28–33%), CDPcholine (5–9%) and free choline (1–3%). There was little change in this percentage distribution in the course of the chase. Total water-soluble label increased significantly during the chase in high choline cells (from 7,500 to 13,000 cpm). The relatively low level of water-soluble label (8,500 cpm) that remained in the cells after 15 hr in low choline medium is likely to reflect recycling of water-soluble label into choline phospholipids because of a general depletion of water-soluble precursors. This explanation is consistent with the fact that after 15 hr the amount of water-soluble label in the medium was also quite low (4,000 cpm). After 15 hr in high choline medium, by contrast, water-soluble label released into the medium reached a level about 10 times higher (41,000 cpm) than in low choline medium. The latter vividly illustrates the susceptibility of the Novikoff cell system to choline modulation.

Table 1 also shows that during the 15-hr chase in low choline medum, PC suffered only a relatively moderate loss of label (from 153,000 to 127,500 cpm); however, in high choline medium, loss of label from PC was substantial (from 153,000 to 91,000 cpm). The cells chased in 500 μM choline lost almost 2.5 times as much label (62,000 cpm) from PC as those chased in 27 μM choline (25,500 cpm); most of the difference (36,500 cpm) was accounted for by the increase of label in the water-soluble choline pool of the medium (41,000 cpm). During the same time, also, SPH labeling increased from 4,500 to 18,500 cpm in high choline cells and to 23,500 cpm in low choline cells. If one would presuppose that PC is the precursor of SPH, the somewhat lower level of SPH labeling in high choline cells could simply reflect the lower levels of PC label available in these cells. This is also consistent with the observation that the ratios of label associated with cell SPH vs cell PC (SPH/PC ratios) at 9 hr were essentially identical for cells grown in low (0.16) or high (0.15) choline medium, and the same held true at 15 hr (0.18 and 0.20, respectively). We therefore can conclude that SPH labeling is closely linked to PC labeling and is independent of the size of the water-soluble choline pool.

To further scrutinize the apparent metabolic relationship between PC and SPH, we followed their specific radioactivities during the label chase in high choline medium (Fig. 2; NPO data are discussed below). The plot illustrates that the specific radioactivity of PC declined throughout the entire 15-hr chase. By contrast, the specific radioactivity of SPH increased and then peaked at 9–12 hr when the specific radioactivity of SPH equaled the specific radioactivity of PC. This specific radioactivity pattern corresponds to the mathematical description of

TABLE 1

Redistribution of [^{14}C]Choline Label in Novikoff Hepatoma Cells During Label Chase in Low and High Choline Media and the Effect of Neophenoxine Supplementation[a]

	Distribution of radioactivity, cpm (% of total)

Total radioactivity	167,535 (100)	171,596 (100)	168,835 (100)	164,261 (100)	171,922 (100)	169,600 (100)	169,828 (100)

[a]Novikoff cells (2.25 × 10^7 cells/15 ml) were prelabeled with [^{14}C]choline for 1.5 hr and the label was chased for up to 15 hr in media containing 27 μM choline, or 500 μM choline in the absence or presence of 300 μM neophenoxine. The distribution of radioactivity (cpm) at various time points was determined on 2.5-ml aliquots of culture. Typical counting efficiency was >90%. Values given are averages of three incubations; average differences from the mean were less than ±5%.

[b]Water-soluble choline label in the cells was associated with phosphocholine (58–63%), glycerophosphocholine (28–33%), CDPcholine (5–9%) and free choline (1–3%).

a direct precursor-product relationship (35) and serves as additional, strong evidence that PC is the direct precursor of SPH.

Effect of choline concentration on [^{14}C]choline incorporation. The label chase experiments described above demonstrated that the redistribution of PC label was very dependent on the extracellular choline concentration. To ascertain that cells chased in high choline medium indeed took up enough unlabeled choline to account for the apparent dilution and subsequent depletion of intracellular, water-soluble choline label released from PC, choline uptake and intracellular redistribution of phospholipid and water-soluble label was followed at both choline concentrations. The experimental protocol was essentially that of the pulse label studies, except that the cells were carried through the "prelabeling" phase in the absence of radiolabel and through the "15-hr chase" phase in the presence of identical amounts (dpm) of radiolabel in 27 μM or in 500 μM choline (for details, see Experimental Procedures).

A comparison of [^{14}C]choline incorporation into the phospholipids of Novikoff cells grown in low (Fig. 3A) or high (Fig. 3B) choline medium shows that final incorporation of label into total choline phospholipids of low choline cells (118,000 cpm) was about 18.2-fold greater than incorporation of label into choline phospholipids of high choline cells (6,500 cpm). This ratio of choline phospholipid label in low vs high choline cells is essentially the same as the ratio (18.5:1) of the respective specific radioactivities of the extracellular choline provided in the two media. This is what one would expect of cells having equal rates of phospholipid synthesis but precursor pools of different specific radioactivities. These data furthermore imply that complete equilibration between intracellular and extracellular water-soluble choline label must have been attained within the time frame of the present experiment.

During the 15-hr experiment, choline labeling of the intracellular water-soluble pool followed a pattern quite different from that of choline phospholipids. Whereas cells grown in 500 μM choline kept accumulating water-soluble label at an essentially constant rate over the entire 15 hr growth period (Fig. 3B), the water-soluble label in cells grown in 27 μM choline (Fig. 3A) peaked at about 9 hr and then showed a rapid decline, reflecting choline depletion of the cultures.

Figure 3C depicts changes in the ratios of water-soluble vs phospholipid-associated cell label during the 15-hr growth phase in the two media. The data demonstrate that at the end of the experiment, the ratio of water-soluble vs phospholipid-associated label was about 14 times greater in high choline cells than it was in low choline cells. As we had shown that the rates of phospholipid synthesis were identical in both cells, the increased ratios of water-soluble vs phospholipid-associated label in high choline cells do directly reflect increased choline uptake.

Stimulation of SPH synthesis by NPO. We had previously shown (24,36) that hypolipidemic drugs of the clofibrate type, as well as their structural analogs

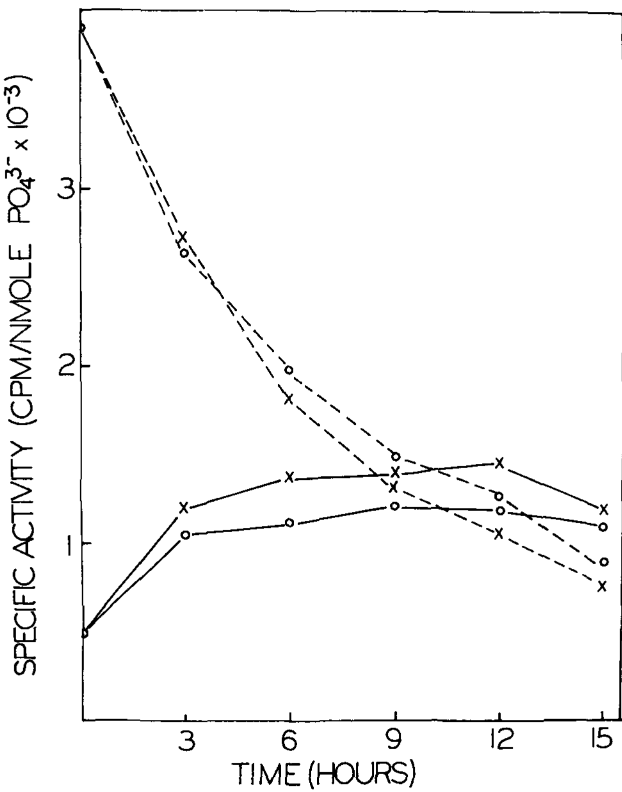

FIG. 2. Specific radioactivity of phosphatidylcholine and sphingomyelin in Novikoff cells during label chase in high choline medium. Cells were prelabeled with [*methyl*-^{14}C]choline, and the label was chased for up to 15 hr in media containing 500 μM choline (O) or 500 μM choline plus 300 μM neophenoxine (X). The specific radioactivity of PC (– – –) and SPH (——) was determined on pooled triplicate samples (experiments Table 1) that had been repurified by TLC (developing solvent B).

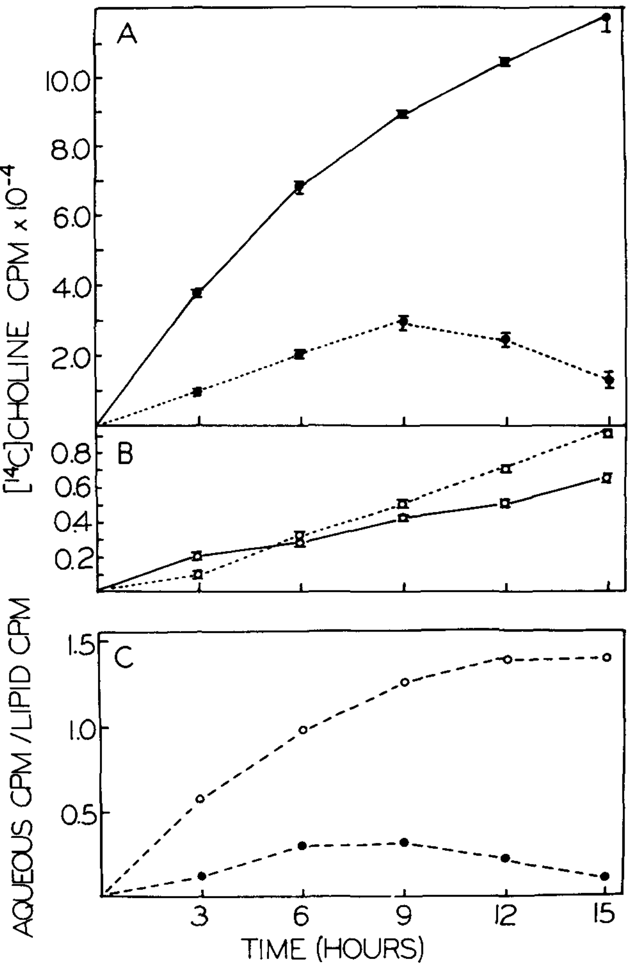

FIG. 3. Effect of choline concentration on [*methyl*-^{14}C]choline incorporation into the phospholipid and water-soluble cholines of Novikoff cells. Cells (2.25 × 10^7 cells/15 ml) were incubated for up to 15 hr with [^{14}C]choline (54,000 cpm/ml) in media containing either 27 μM (●) or 500 μM (O) choline. The distribution of label between the phospholipid (——) and water-soluble (.....) fractions of the cells from 2.5-ml aliquots of culture was followed in low (A) and high (B) choline medium. Changes in the ratios of water-soluble vs lipid-associated cell label (— —) at the two choline concentrations are shown in C. The data represent means ± deviations (n = 3).

centrophenoxine and neophenoxine, inhibit both enzymes of microsomal PC synthesis, namely CDPcholine:diacylglycerol cholinephosphotransferase and particularly acyl-CoA:lysolecithin acyltransferase (LLAT). In the present study, NPO was used to modulate the flux of label through the lipid-associated choline pool and to follow the effect of such modulation on SPH synthesis.

Table 1 shows the effect of 300 μM NPO during the 15-hr label chase in high choline (500 μM) medium. At this concentration, NPO did not affect cell growth. However, NPO led to a substantial loss in PC labeling (15,500 cpm). NPO, a potent inhibitor of lysoPC reacylation (24), also caused, as expected, an increase in cell lysoPC labeling (from 1,000 to 2,500 cpm). Moreover, there was a substantial increase (7,500 cpm) in the amount of phospholipid label found in the medium, and we could show that essentially all additional phospholipid label secreted by the cells was associated with lysoPC. The water-soluble pools, by contrast, were only little affected by NPO. However, NPO caused a significant stimulation of SPH synthesis (by 5,000 to 7,000 cpm) at the expense of PC labeling (Table 1).

Stimulated flux of label from PC to SPH due to NPO also became apparent when the specific radioactivities of PC and SPH were followed throughout the 15-hr chase. Figure 2 illustrates that the decrease in the specific radioactivity of PC due to NPO was mirrored in a concomitant increase of similar magnitude in the specific radioactivity of SPH. In the presence of NPO, the specific radioactivity of PC and SPH again showed the familiar precursor-product pattern.

Inhibition of SPH synthesis by p-chloromercuribenzoate (p-CMB). As a sulfhydryl reagent that is not readily internalized by cells, *p*-CMB has been used to inhibit enzymes located near the cell surface (37). Our inhibition studies with *p*-CMB were carried out following the protocol of the label chase experiments in low choline medium, except that *p*-CMB was added at time 0 and the chase was continued for only 5 hr to minimize the toxic effects of the agent. We observed that 0.025 mM *p*-CMB did not affect SPH labeling, but that 0.5 mM *p*-CMB proved highly toxic to the cells. At 0.10–0.15 mM, *p*-CMB did not cause cell death (viability > 90%). However, at these *p*-CMB concentrations transfer of label from PC to SPH was completely inhibited.

DISCUSSION

The discovery of the pathway of de novo phosphatidylcholine synthesis from diacylglycerol and CDPcholine 30 years ago (5) ranks as one of the milestones in lipid biochemistry. In the wake of this breakthrough, a route of SPH synthesis from ceramide and CDPcholine appeared equally attractive. Early in vitro studies with short chain (*N*-acetyl), isomeric ceramides and with CDPcholine as water-soluble phosphocholine donor were indeed encouraging (2,3). Yet questions remained, because the CDPcholine:ceramide cholinephosphotransferase required ceramides with an *N*-acetyl function instead of the natural, long chain *N*-acyl group, and it also showed a pronounced preference for *threo* ceramides, although natural sphingolipids possess the *erythro* configuration (38–40). Numerous attempts were made over the years to correct or rationalize these inconsistencies (4,41–43), and it was only a few years ago that reasonable evidence emerged that rat liver microsomes may be able to transfer phosphocholine from CDPcholine to *N*-palmitoyl-*erythro*-sphingenine (10).

For some time, the possibility was also considered that SPH may be synthesized by acylation of sphingosylphosphocholine. Studies with rat brain microsomes suggested that the acyl-CoA transacylase preferred *erythro*-sphingosylphosphocholine over its *threo* isomer (7,8); however, this pathway could not be confirmed in rat liver microsomes (10). Also, the synthesis of sphingosylphosphocholine from sphingenine, which was first observed in a particulate fraction from chicken liver (9), could not be reproduced in other systems (10,11).

In vivo experiments in rat brain had early shown that ceramide is readily converted to SPH (6). Also, the synthesis of ceramide from sphingenine and acyl-CoA became firmly established (10,44,45). A first indication that SPH synthesis from ceramide may utilize not water-soluble CDPcholine but the phospholipid pool as phosphocholine source emerged from studies with cultured SV-40 transformed mouse fibroblasts. By following the label chase kinetics of phosphate incorporation into individual phospholipid classes of these cells, it became apparent that phospholipid labeling generally reached constant rates within one hr, but that in the case of SPH a 6-hr lag phase did occur (12,14). Pulse labeling studies with [^{32}P]phosphate and [^{3}H]choline demonstrated that the ^{3}H/^{32}P ratio of PC and SPH remained quite constant throughout the chase and that PC labeling peaked at 3 hr, whereas SPH labeling increased for 20 hr (13), suggesting that PC and SPH use different precursor pools. Results of experiments with cell-free systems from SV-40 transformed mouse fibroblasts furthermore indicated that SPH labeling is not directly affected by choline, phosphocholine or CDPcholine, and that ceramide serves as phosphocholine acceptor in SPH synthesis (15,16). At about the same time, Ullman and Radin (17) demonstrated that lyophilized mouse liver microsomes can catalyze SPH synthesis from *erythro*-ceramide and that PC, but not CDPcholine, can serve as phosphocholine donor (18). However, rat liver microsomes were not able to utilize PC as phosphocholine donor, but CDPcholine was effective (10).

Evidence for a PC-dependent but CDPcholine-independent mode of SPH synthesis has also emerged from studies on a temperature-sensitive mutant of Chinese hamster ovary cells with a primary defect in CDPcholine synthetase activity (46). This mutant, when shifted to the restrictive temperature (40 C), showed an immediate decline in CDPcholine and PC labeling, where SPH synthesis remained stimulated for another 20 hr (47).

Labeling studies with cultured baby hamster kidney (BHK)-21 cells also provided rather strong evidence that CDPcholine could be excluded as the immediate source of the phosphocholine moiety of SPH and that PC was likely the in vivo phosphocholine donor (21). These conclusions were drawn by comparing the kinetics of [*methyl*-^{3}H]choline incorporation into CDPcholine and SPH and by following the transfer of [*methyl*-^{3}H]methionine-derived PC label to SPH. In the former experiment the primary evidence was that labeling of phosphocholine and CDPcholine rapidly declined during the chase while PC synthesis increased at a somewhat reduced rate during the first 2 hr and then declined; however, SPH synthesis proceeded at a nearly linear rate for at least 6 hr into the chase. The methionine labeling studies suggested a flux of label from PC to SPH without substantial CDPcholine labeling. However, the label chase experiments in the BHK system were somewhat hampered by the fact that at the onset of the [^{3}H]choline chase, nearly twice as much label was associated with phosphocholine as with phosphatidylcholine. It is also well known that the PC produced by the methylation pathway usually constitutes only a very small portion of total PC synthesis (48,49). This would still leave the possibility that parallel mechanisms of SPH synthesis do exist, with one pathway being dependent on the PC formed by the methylation route.

The experimental model we had on hand for the present study has clear advantages over those previously used. Prelabeling of cultured Novikoff rat hepatoma cells with [*methyl*-^{14}C]choline in spent medium resulted in the rapid accumulation of essentially all the label ($\sim$95%) in PC. This greatly facilitated following the flux of label during the chase. At 500 μM choline under conditions of free choline diffusion, loss of label from PC was much more pronounced than at 27 μM choline. In fact, the amount of water-soluble choline label trapped in high choline medium was an order of magnitude greater than in low choline medium. Yet despite the 10-fold dilution of water-soluble choline precursors in cells grown in high choline medium, SPH synthesis proceeded at essentially the same rate at both choline concentrations (Fig. 1 and Table 1). Because transfer of choline label from PC to SPH was not affected by loss or dilution of water-soluble precursors, we concluded that SPH synthesis in Novikoff hepatoma cells circumvents the water-soluble choline pool and that PC is the likely choline source for SPH synthesis.

Direct transfer of choline label from PC to SPH is also consistent with the changes in specific radioactivities that we observed for PC and SPH during the 15-hr chase. In a typical precursor-product fashion, the specific radioactivity of PC decreased while the specific radioactivity of SPH increased until SPH activity equaled PC activity (Fig. 2).

We furthermore found that NPO stimulated the transfer of label from PC to SPH. This made it possible to also modulate the flux of label through the lipid-associated choline pool and to follow specific radioactivity and precursor-product patterns under NPO-modulated conditions. The

mechanism by which NPO stimulates SPH synthesis from PC is presently not known; however, it is intriguing to note that certain glucocorticoids, such as dexamethasone, have also been shown to stimulate lysoPC and SPH synthesis in HeLa S3G cells (50) and to enhance SPH synthesis in 3T3-L1 fibroblasts (51). In the present context, the effect of NPO on PC and SPH labeling in Novikoff cells reemphasizes the close metabolic relationship between these two choline phospholipids.

It is well established that little SPH is present in the endoplasmic reticulum, but that SPH occurs at substantial levels in Golgi (12%) and particularly in plasma membrane (19%, ref. 52). Convincing evidence has emerged in recent years that SPH synthesis is localized in the plasma membrane (11,19-22,51), and our data are consistent with this observation.

In summary, it appears that SPH synthesis from ceramide and CDPcholine can be brought about in certain instances, particularly under in vitro conditions. On the cellular level, however, SPH synthesis is clearly independent of the cytosolic choline pool. Considering that the site of sphingomyelin synthesis is near the cell surface, use of a membrane-bound phosphocholine donor, such as phosphatidylcholine, may indeed be a necessity.

ACKNOWLEDGMENTS

This study was supported in part by U.S. Public Health Service Research Grant HL 08214 from the Program Projects Branch, Extramural Programs, and PHS Training Grant HL 07311, both from The National Heart, Lung and Blood Institute; by Research Grant CA 12150 from the National Cancer Institute; by Institutional Research Grant IN-13 from the American Cancer Society (to C.M.E.); and by The Hormel Foundation. We also wish to thank Drs. S. Parthasarathy and K. Hayase for their interest in the project and Mrs. Karan S. Crilly for technical assistance.

METHODS

Rapid Analysis of Jojoba Wax Fatty Acids and Alcohols After Derivatization Using Grignard Reagents

M. Pina, D. Pioch and J. Graille*
Division Chimie des Corps Gras, Departement Oleagineux (IRHO), Centre de Cooperation Internationale en Recherche Agronomique pour le Developpement (CIRAD), Montpellier, France

This method, based on the action of Grignard reagents, is an original approach to wax derivatization and differs from the methods previously described, which were essentially based on wax alcoholysis. Grignard reagents, especially magnesium ethyl bromide, react on ester functions to turn the wax constituents into primary and tertiary alcohols, the latter being the fatty acid derivatives. The mixture of these alcohols is analyzed by a single gas chromatographic injection. The overall time, about 1.5 hr, makes this method suitable for routine analysis. It could be also considered for analyzing low carbon condensation organic acid esters.
***Lipids 22,* 358-361 (1987).**

The development of jojoba farming *(Simmondsia chinensis)* throughout the world and the many applications of its wax led us to seek rapid methods of analyzing its principal constituents that would be suitable for a large number of samples. First, we developed a method involving the rapid derivatization of fatty acids and alcohols into ethyl esters and acetates, respectively, followed by a single gas chromatographic (GC) analysis (1). A simplified method, which is a variation of the one above, has recently been proposed, i.e., reduction in the time taken for fatty acid ethanolysis, elimination of the fatty alcohol esterification step, injection of the fatty acid ethyl esters and free fatty alcohols mixture (2). These two methods avoid the major inconveniences of methods previously proposed by Miwa (3-6) and others (7,8), namely, prohibitive length of derivatization procedure and/or the need for two GC analyses.

This work, which further reduces analysis time, involves an original derivatization method using the reaction of organo-magnesium compounds on ester functions, to turn the constituents of the wax into primary and tertiary alcohols, the latter being the fatty acid derivatives. The mixture containing these alcohols undergoes a single GC analysis, as before.

MATERIALS AND METHODS

Reagents. Anhydrous ethanol, benzene and diethyl ether were analytical grade solvents (Prolabo, Paris, France). The ethyl ether was dried over $CaCl_2$, then distilled over sodium, stored on $CaCl_2$ and filtered before use. The organo-magnesium compounds used (Aldrich Chimie, Strasbourg, France) are supplied in 3 M solution in ethyl ether. The jojoba wax was supplied by the CEA (Marcoule, France); its acidity was 0.3%.

Thin layer chromatography (TLC). These analytical or preparative techniques have been described previously (1). In the present method, the solvent is a hexane/ethyl ether mixture (90:10, v/v), and the Rf of the wax is then 0.65.

Derivatization with magnesium ethyl bromide. Each sample is treated in three perfectly dry 30-ml test tubes. Wax derivatization is carried out in tube no. 1 with a ground neck fitted with a $CaCl_2$ trap.

Four drops of jojoba wax are introduced from a Pasteur pipette, along with 4 ml of anhydrous ethyl ether and 1.5 ml of the 3 M ethereal magnesium ethyl bromide solution. The mixture is placed on a vibrating stirrer for 10 min at room temperature; the excess reagent and the magnesium complexes are destroyed by adding 1 ml of N aqueous HCl and shaking for 1 min; 10 ml of distilled water is added and stirring is continued for a further 10 min; the upper ethereal phase is transferred to tube no. 2 containing 10 ml of a 2% aqueous $NaHCO_3$ solution and stirred for 10 sec on a vortex; the upper ethereal phase is filtered over anhydrous sodium sulfate into tube no. 3; the ethereal phase is evaporated till dry in a stream of nitrogen and the ethyl ether is replaced by 4 ml of hexane; one μl of the hexane solution containing the tertiary and primary alcohols is analyzed by GC.

Reference derivatization. This method involves two steps: ethanolysis of the wax (derivatization of fatty acids into ethyl esters) and extraction of the ethyl esters and free fatty alcohols. Each sample is treated in two 30-ml test tubes.

Ethanolysis takes place in tube no. 1 equipped with an air condenser fitted with a $CaCl_2$ trap. Four drops of jojoba wax are introduced from a Pasteur pipette, along with 0.1 ml of benzene and 1 ml of 5 N ethanolic HCl solution obtained by bubbling gaseous HCl through anhydrous ethanol; the mixture is refluxed for 25 min in an oil bath at 95 C.

The derivatives are extracted as follows: the solvents and HCl are evaporated in a stream of nitrogen for 10 min at room temperature; 6 ml of demineralized water and 4 ml of hexane are added, and this is stirred on a vortex for 10 sec; the supernatant is transferred by syringe into tube no. 2 containing anhydrous sodium sulfate. One μl of the hexane solution containing the mixture of fatty acid ethyl esters and free fatty alcohols is injected directly into the chromatograph.

GC analysis of wax derivatives. The solutions containing the wax derivatives (either ethyl esters and free fatty alcohols in the reference method or primary and tertiary fatty alcohols where derivatization uses organo-magnesium compounds) are analyzed on a Carlo Erba 4160 chromatograph equipped with a flame ionization detector, connected to a Delsi Enica 10 integrator. The constituents

are separated on a DB Wax 30 W (J-W) fused silica capillary column with the following characteristics: length 30 m; internal diameter 0.317 mm; phase, Carbowax 20 M; film thickness 0.25 μm; injector-splitter at 250 C, detector at 275 C and oven 200 C except for mixture containing aromatic tertiary alcohols (220 C); carrier gas, helium; flow rate, 3 ml/min; splitting ratio 1/50.

RESULTS AND DISCUSSION

Derivatization reaction. The reactivity of Grignard reagents with respect to ester functions and their application in organic synthesis has been known for a long time; however, their use in organic analysis is very rare. Brockerhoff (9) astutely used magnesium methyl bromide to study the stereospecific distribution of triglyceride fatty acids in oils. This method consists in partly breaking down the triglycerides into partial glycerides, with the fatty acids being converted into tertiary fatty alcohols as shown on Scheme 1.

According to the reaction in Scheme 1, two organomagnesium molecules are required to transform one wax ester molecule. The reaction takes place in an anhydrous medium, hence particular care must be taken when drying the solvent. The complexes formed during the first step, along with the excess reagent, are instantaneously hydrolyzed in an acidic medium during the second step. The primary and tertiary alcohol series obtained constitute the wax derivatives. In practice, there must be a large amount of excess reagent in the reaction medium to ensure a complete reaction and trap any traces of water, which destroy this reagent; we established conditions leading to a quantitative reaction. In the case of ethyl magnesium bromide, when starting from a jojoba wax sample in the range of 1 g, we noted that the recovery of the products after the extraction step is quantitative. Moreover, the analysis of the extracted compounds by quantitative TLC (1) shows that the amount of products located in the three spots detected on the plate (residual wax, primary and tertiary alcohols) corresponds to the weight really deposited, using deposits of known amounts of standard (jojoba wax and pure derived alcohols).

Choice of the organo-magnesium reagent. It should be noted regarding the tertiary fatty alcohols that the nature of R″, the organo-magnesium compound radical, directly affects their molecular weights and, consequently, their chromatographic retention times. In effect, the carbon condensation of a derived tertiary alcohol is increased by twice the condensation of R″, compared with that of the corresponding fatty acid. Given this, particularly, the choice of R″ must be guided by the carbon condensation, but also the reactivity of the organo-magnesium compound and, possibly, by its commercial price and availability, although preparation of the reagent in the laboratory is no problem. Of the reagents tested, magnesium ethyl bromide was chosen because it gives the best results (no side products, fast reaction). With n-butyl and benzyl magnesium bromides, the reaction times are increased too much; by contrast, the reaction of methyl magnesium bromide is very fast, but gives side products.

Optimization of the reaction time was undertaken at room temperature with 1.5 equivalents of ethyl magnesium bromide. The time course study of reaction shows that wax conversion is complete after 10 min (Table 1).

GC analysis of derivatives. The GC analysis of jojoba wax derivatives obtained with magnesium ethyl bromide was carried out directly with a single injection on a commercially available fused silica capillary column (see Materials and Methods).

First, the study required the preparation of the 2 series of fatty alcohols by preparative TLC. The fact that the Rf values of the primary and tertiary alcohols are clearly distinct (0.10 and 0.40, respectively) makes it possible to apply large quantities while avoiding the reciprocal

SCHEME 1

contamination of fractions. Hence, the separation of the two families, followed by GC analysis, presents no problem whatsoever. Identification of the GC peaks obtained is simple; regarding the series of primary alcohols, reference should be made to the previous work (2) in which the wax was derivatized to yield fatty acid ethyl esters and free fatty alcohols. Chromatographic analysis of the primary alcohols is not, therefore, modified by the choice of organo-magnesium compound, although this is not the case, of course, with tertiary alcohols.

The chromatogram of the diethyl alkyl carbinols (tertiary alcohols) is similar to that of the ethyl esters derivatized from the same fatty acids, to within the retention times. Identification was completed by referring to the chromatograms of diethyl alkyl carbinols obtained through similar treatment with a mixture of known triglycerides (the standard mixture composed of coconut, palm, rapeseed and peanut oils contains the main fatty acids of jojoba wax). In this respect, it should be noted that derivatization using magnesium ethyl bromide could constitute a new analysis method for determining the fatty acid composition of oils.

A comparative study of the separate chromatograms for the two categories of alcohols with that obtained for

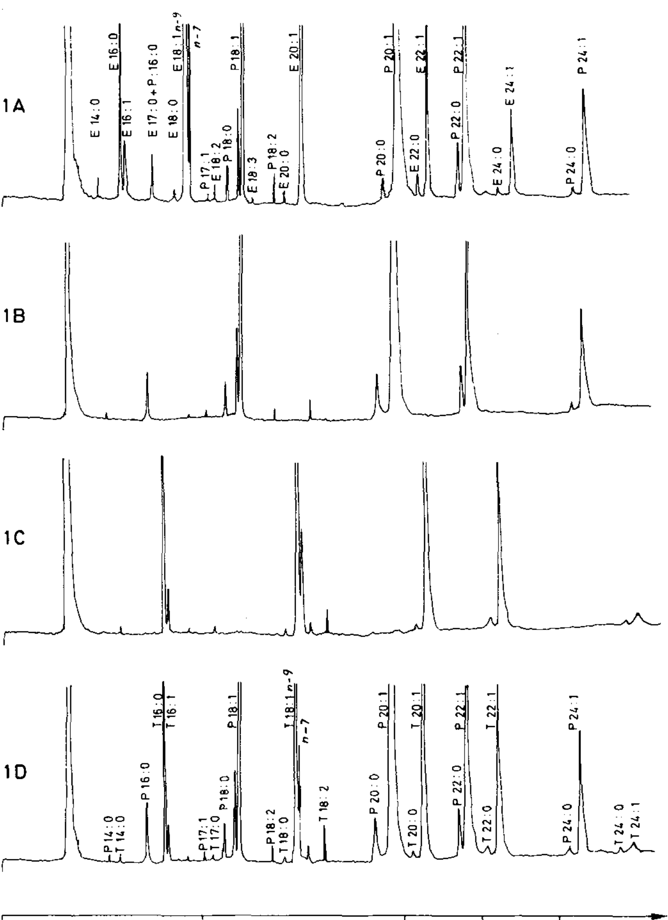

FIG. 1. Gas chromatograms of derived jojoba wax samples (DB Wax 30W). 1A, reference procedure (fatty acid ethyl esters + primary fatty alcohols); 1B, primary fatty alcohols; 1C, tertiary fatty alcohols; 1D, primary and tertiary fatty alcohols. Chart: 5 mm/min from 0 + 1000 sec and 1 mm/min after 1000 sec. Labeled peaks: E, fatty acid ethyl esters; P, primary fatty alcohols; T, tertiary fatty alcohols.

derivatized jojoba wax reveals that peak resolution is highly satisfactory (Fig. 1). For fatty acid derivatives, it should be noted that ethyl ester retention times are lower than those for the corresponding diethyl alkyl carbinols; they are delayed compared to primary alcohols, unlike in the reference method (Fig. 1). In effect, the difference in carbon condensation between a primary alcohol and the corresponding tertiary alcohol is equal to 2 n, where n is the number of carbon atoms of the magnesium alkyl or aryl compound. In the case of magnesium ethyl bromide, the difference equal to 4 carbon atoms explains why the chromatographic retention of the diethyl alkyl carbinol is greater than that of the corresponding primary fatty alcohol and, all the more so, than that of the ethyl ester.

It would have been more satisfactory to have obtained chromatograms in which the series of primary alcohols was completely eluted before that of the tertiary alcohols. The n-butyl and benzyl magnesium bromides were tested in light of this aim. The n-butyl radical, which adds 8 carbon atoms, brings to 24 the carbon condensation of the shortest tertiary alcohol derivatized from the C16 acid. Therefore, 24 is the carbon condensation of the heaviest primary alcohol. Although the branched structure lowers retention time compared to a linear homologue, we were unable to achieve this objective. In addition, the time taken for analysis would have been considerably longer. In aliphatic series, the R″ > n-butyl homologues were not tested because of the low reactivity of the corresponding bromo magnesium compounds.

The reactivity of the magnesium benzyl bromide is comparable to that of the n-butyl reagent (Table 1), but it adds 14 carbon atoms to the derivatized fatty acids; further, elution of this series of tertiary alcohols requires that the time taken for GC analysis be doubled, despite the high temperature, which is almost the limit for the stationary phase (oven temperature of 220 C, instead of the usual 200 C). In spite of the prohibitive length of the analysis time (more than 2 hr), the two groups of wax derivatives are still not totally separated. Consequently, derivatization using magnesium ethyl bromide is the quickest and most effective method from both a reactivity and chromatographic analysis point of view. Even if analysis time is slightly increased compared to the reference method (fatty acid ethyl esters), this method offers incomparable simplicity.

Jojoba wax composition was calculated from the average of five derivatizations and two GC analyses for each derivatization (Table 2). Derivatization of the wax constituents was also carried out according to the reference method (2). The compositions found from each of the methods are identical within the limits of unavoidable experimental error.

To conclude, the method proposed, based on the action of Grignard reagents, is an original approach to the derivatization of waxes and differs from the methods previously described, which were essentially based on wax alcoholysis. It also offers several advantages compared to the method we recently put forward: use of relatively cheap commercially available reagents, a single derivatization step and almost immediate reaction; operations carried out at room temperature, not even requiring a thermostatically controlled bath; very simple glassware adapted to the analysis of numerous samples. Complete sample analysis can be done in about 1.5 hr, enabling an

organized operator to treat several samples per day. Furthermore, this method could be considered for analyzing low carbon condensation organic acid esters, since the choice of a suitable magnesium compound would make it possible to obtain a heavier tertiary alcohol, thus avoiding losses; for those absorbing in UV, high pressure liquid chromatographic analysis should be easy.

High Performance Liquid Chromatographic Analysis of 1-Alkyl-2-acyl- and 1-Alkyl-3-acyl-*sn*-glycerols[1]

Thomas A. Foglia[a,*], P.D. Vail[a] and Takashi Iwama[b]
[a]Eastern Regional Research Center, Philadelphia, Pennsylvania, and [b]Nippon Oil and Fats Co., Amagasaki, Japan

A high performance liquid chromatographic (HPLC) method is described for separation and quantitation of 1-alkyl-3-acyl- and 1-alkyl-2-acyl-*sn*-glycerol, products of the detritylation reaction of 1-alkyl-2-acyl-3-trityl-*sn*-glycerol. The alkyl glycerides were separated on a 25 cm × 4.6 mm ID column packed with ∼5-6 μm silica and eluted isocratically with isooctane/isopropanol (98:2, v/v) as mobile phase. The good separation and linear refractive index (RI) detector responses using cholesterol as an internal standard indicated the applicability of the method not only for the quantitative determination of the alkylglycerols but also for their semipreparative isolation. This HPLC method shows excellent reproducibility and accuracy and is applicable to other types of glycerides such as mono- and diacylglycerols.
Lipids 22, 362-365 (1987).

Common precursors for the stereospecific synthesis of 1-alkyl- neutral and phospholipids are 1-alkyl-2-acyl-3-trityl-*sn*-glycerols in which the trityl group is used to protect the hydroxyl group at the 3-position of glycerol (1,2). The next step in the synthetic sequence is removal of the trityl protecting group, under general acid catalysis, to yield 1-alkyl-2-acyl-*sn*-glycerols as key intermediates (Scheme 1). Acylation or phosphorylation of the latter glycerides gives the desired 1-alkyl- neutral or phosphoglyceride, respectively. Quite often, however, removal of the trityl protecting group is complicated by the concomitant migration of the 2-acyl moiety to yield the isomeric 1-alkyl-3-acyl-*sn*-glycerol derivative (3-6). As a consequence of this acyl rearrangement, it is necessary to separate and quantify these isomeric alkyl glycerides prior to further modification. A number of analytical methods, including column chromatography (7), thin layer chromatography (TLC) (8,9), high performance liquid chromatography (HPLC) (10,11) and gas liquid chromatography (GLC) (12) have been reported for separation and quantitative determination of mixtures of mono-, di- and triacylglycerols. For the isolation of glycerides for subsequent chemical manipulation, however, HPLC methods are more advantageous than other analytical methods because of their nondestructive nature, greater range of sample capacity and ease or rapidity of operation. Moreover, HPLC has the potential not only for isolating partial glycerides from reaction mixtures but also for their subsequent purification. This paper describes the separation and quantitative determination of mixtures of various 1-alkyl-2-acyl- and 1-alkyl-3-acyl-*sn*-glycerols as well as their semipreparative isolation by normal phase HPLC with isocratic elution.

MATERIALS AND METHODS

Materials. 1-Alkyl-2-acyl-3-trityl-*sn*-glycerols were synthesized in our laboratory starting with D-mannitol (99%) obtained from Aldrich Chemical Co. (Milwaukee, Wisconsin). Oleic acid (>99.6%) used for the synthesis of oleoyl chloride (12) for acylation of the secondary hydroxyl group of glycerol was from Nippon Oil and Fats Co. (Amagasaki, Japan). Acetyl chloride (98.5%) was obtained from J.T. Baker Chemical Co. (Philipsburg, New Jersey); palmitoyl chloride (98%) and benzoyl chloride (99%) were obtained from Aldrich. Stearoyl chloride was synthesized in our laboratory. Triphenylmethanol used for the synthesis of triphenylchloromethane for tritylation of the primary hydroxyl group of glycerol was obtained from Eastman Organic Chemicals (Rochester, New York). The detritylation catalyst, boron trifluoride etherate, was obtained from Eastman Kodak Co. (Rochester, New York) and distilled prior to use. Isooctane and isopropanol used for HPLC separations were obtained from American Burdick & Jackson (Muskegon, Michigan). Cholesterol standard (>98%) was obtained from NuChek Prep (Elysian, Minnesota).

Analytical system. (a) Chromatograph: The solvent delivery system consisted of a Beckman Model 110A solvent delivery module equipped with a Waters Differential Refractometer Model R401 detector (Waters Associates, Milford, Massachusetts) and an Altex 210 injector. (b) Analytical HPLC column: Zorbax SIL, 4.6 mm ID × 25 cm (∼5-6 μm, DuPont Co., Wilmington, Delaware). Sepralyte Diol, 4.6 mm ID × 25 cm (5 μm, Analytichem International, Harbor City, California). Semipreparative HPLC column: Dynamax Prepacked Silica Column, 10 mm ID × 25 cm (8 μm, Rainin Instrument Co., Woburn, Massachusetts). (c) Integrator and recorder: Chromatopac C-R3A (Shimadzu Co., Columbia, Maryland). (d) HPLC conditions: The samples were eluted isocratically with 98% isooctane/2% isopropanol (v/v) at a flow rate of 1 ml/min (analytical HPLC) or 3 ml/min (semipreparative HPLC). Injection volumes were 20 μl (analytical HPLC) or 100 μl (preparative HPLC), and the samples were injected via loop injectors.

Syntheses. 1,2-Isopropylidene-*sn*-glycerol was prepared from D-mannitol via the lead tetraacetate cleavage of 1,2,5,6-diisopropylidene-D-mannitol to 1,2-isopropylidene-*sn*-glyceraldehdyde and subsequent reduction of the aldehyde with sodium borohydride according to the procedure established by Eibl (14). $[\alpha]_D^{25}$ + 14.5° (0.169 mg/ml, CH_3OH). Infrared spectrum: 3425 cm^{-1} (OH), 1378 and 1368 cm^{-1} (isopropyl).

[1]Presented in part at the AOCS annual meeting, Honolulu, Hawaii, May 1986.

3-Hexadecyl-*sn*-glycerol was prepared from 1,2-isopropylidene-*sn*-glycerol by reaction with sodium hydride in dimethylformamide followed by alkylation with hexadecylbromide, mp 64.9–67.0 C, lit. mp 65–67 C (13). Infrared spectrum 3405, 3326 and 3240 cm^{-1} (OH), 1127 cm^{-1} (C-O-C).

3-Hexadecyl-*sn*-glycerol was converted to its enantiomer, 1-hexadecyl-*sn*-glycerol, according to the method of Chacko and Hanahan (15). Reaction of 3-hexadecyl-*sn*-glycerol with p-toluene-sulfonyl chloride yielded the ditosylate derivative, which underwent SN_2 displacement with acetate anion to give 1-hexadecyl-2,3-diacetoxy-*sn*-glycerol. Alkaline hydrolysis of the diacetate gave the desired 1-hexadecyl-*sn*-glycerol, mp 64.4–66.0 C, lit. mp 65–67 C (15). Infrared spectrum: 3405, 3333 and 3240 cm^{-1} (OH), 1130 cm^{-1} (C-O-C).

1-Hexadecyl-2-oleoyl-3-trityl-*sn*-glycerol was synthesized by tritylation at the 3-position of 1-hexadecyl-*sn*-glycerol followed by acylation at the 2-position of the resultant 1-hexadecyl-3-trityl-*sn*-glycerol (16). Infrared spectrum: 3085, 3055 and 3020 cm^{-1} (triphenylmethyl), 3000 cm^{-1} (-CH=CH-), 1733 cm^{-1} (-C=O). Other 1-hexadecyl-2-acyl-3-trityl-*sn*-glycerols were prepared in a similar manner.

Detritylation reaction. The detritylation reaction was carried out using a modification of Hermetter and Pattauf's method (16). 1-Hexadecyl-2-oleoyl-3-trityl-*sn*-glycerol (40 μmol), BF_3-CH_3OH catalyst (40 μmol) and methylene chloride (2 ml) were placed into a 4-ml glass vial equipped with a magnetic stirrer. After the vial was sealed with a viton seal under nitrogen, the mixture was stirred for ~30–60 min at 22 C. Similar reactions were performed with other 1-hexadecyl-2-acyl-3-trityl-*sn*-glycerols having various acyl groups at the 2-position (Table 2). The corresponding detritylation products, 1-hexadecyl-2-acyl-*sn*-glycerol and 1-hexadecyl-3-acyl-*sn*-glycerol were isolated by semipreparative HPLC described above.

Internal standard calibration. Standards containing 10 to 40 μmol of 1-hexadecyl-2-oleoyl-3-trityl-*sn*-glycerol, 1-hexadecyl-2-oleoyl-*sn*-glycerol, 1-hexadecyl-3-oleoyl-*sn*-glycerol and cholesterol (internal standard) were prepared in 1 ml of isooctane/isopropanol (98:2, v/v). The diradyl glycerol solution and standard cholesterol solutions were mixed (~50–200 μl) and analyzed by analytical HPLC. The weight ratios (w/w) of the alkyl glycerol (W) to the internal standard (WS) were varied between 0.1 and 1.4. Similar analyses were performed for the other diradyl glycerols having different acyl groups at the 2-position (Table 2).

RESULTS AND DISCUSSION

1-Alkyl-2-acyl glycerols are one of the more important classes of intermediates for the syntheses of 1-alkyl phospholipids. Much effort has been given to the synthesis and characterization of this class of lipid since migration of the 2-acyl unit to more thermodynamically stable 1,3-isomer is very facile. It is well known that the isomerization of the 1,2-isomer to 1,3-isomer is subject to general acid or base catalysis (17). As a result of this rearrangement, rapid methods are needed for analysis and purification of these partial glycerides. In this study, we have established an excellent separation method for this class of alkyl glycerol by normal phase HPLC.

HPLC and internal standard. HPLC separations of a test mixture consisting of (a) 1-hexadecyl-2-oleoyl-3-trityl-*sn*-glycerol, (b) triphenylmethyl alcohol, (c) 1-hexadecyl-3-oleoyl-*sn*-glycerol, (d) 1-hexadecyl-2-oleoyl-*sn*-glycerol and (e) cholesterol (IS) are shown in Figure 1. As the chromatograms indicate, some differences can be seen in the separations between the silica column and the diol column used in this study. The difference in retention times between the 1,3- and 1,2-isomers found in the HPLC on silica was larger than on the diol column, and no peaks for detritylation reaction products were found after elution of the 1,2-isomer. The data suggested the possibility of using a silica HPLC separation for the quantitative analysis of detritylation reaction mixtures and for preparative HPLC. Cholesterol is a suitable internal standard for quantitation.

Figure 2 shows the effect of solvent strength on the separation of a test mixture. As the results indicate, a better resolution of the five components in the test mixture was obtained with an increase in the amount of isooctane in the solvent system. However, it should be noted that the decreased solubility of triphenylmethanol with this mobile phase composition caused deterioration of the HPLC column and interfered with the HPLC analysis. The efficiency of the column was restored after washing it with 90:10 isooctane/isopropanol. Accordingly, it seems that a solvent system of isooctane/isopropanol of 98:2 composition is the preferred solvent system.

Figure 3 gives the RI detector responses of (a) 1-hexadecyl-2-oleoyl-*sn*-glycerol, (b) 1-hexadecyl-3-oleoyl-*sn*-glycerol and (c) 1-hexadecyl-2-oleoyl-3-trityl-*sn*-glycerol. The

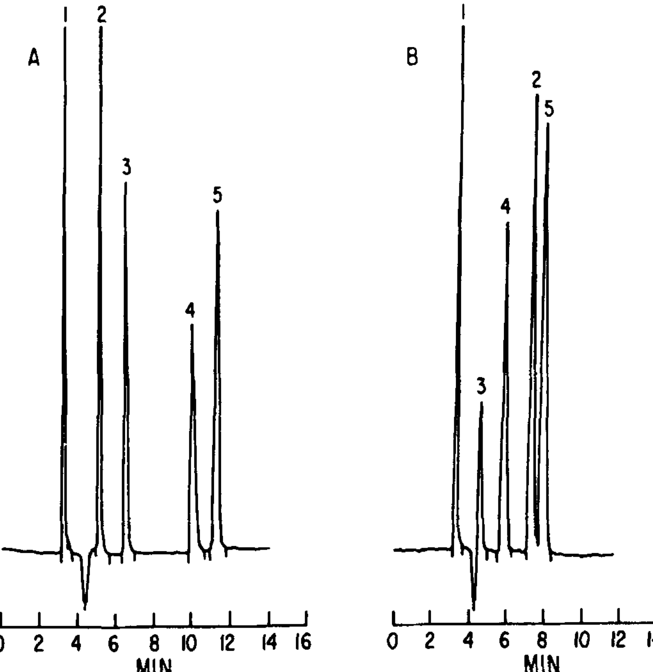

FIG. 1. HPLC chromatograms of a test mixture. Panel A, silica column; panel B, diol column. Compounds separated: 1) 1-hexadecyl-2-oleyl-3-trityl-*sn*-glycerol, 2) triphenylmethanol, 3) 1-hexadecyl-3-oleoyl-*sn*-glycerol, 4) 1-hexadecyl-2-oleoyl-*sn*-glycerol and 5) cholesterol.

data are plotted as weight ratio of the alkylglycerol to the internal standard (W/W_{IS}) along the ordinate and HPLC area ratios (A/A_{IS}) along the abscissa. In the case of the RI detector, good linear relation and sensitivity were obtained in the weight ratio range of 0 to 1.2 (alkylglycerol/standard). Detector response factors were calculated from the slope of each line, and the standard deviations obtained for the four different test mixtures (Table 1) (A, 1.7%; B, 1.3%; C, 1.4%, respectively) indicate that the method has good reproducibility and accuracy for the quantitative analysis of alkylglycerols.

In the quantitative analysis of the detritylation reaction, the mole fraction of each material was calculated from the following equation, where each weight ratio was obtained from each HPLC area ratio using the response factors given in Figure 3.

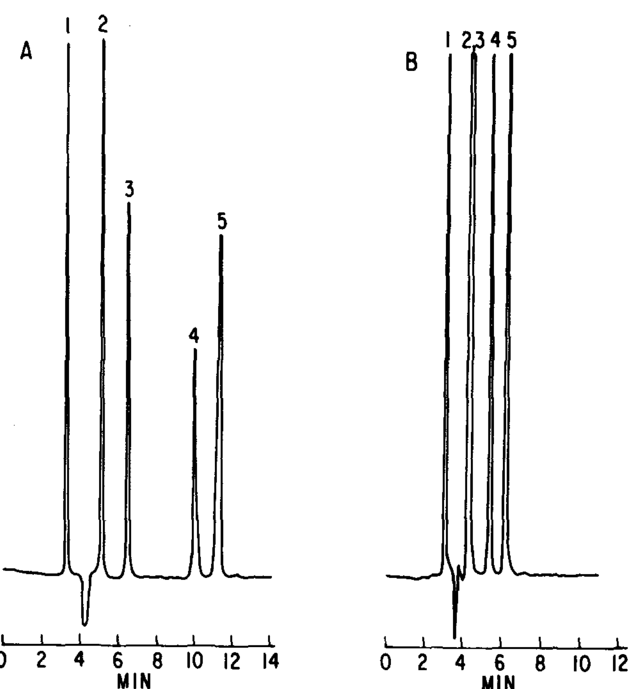

FIG. 2. Effect of solvent on the separation of a test mixture. A) Isooctane/isopropanol, 98:2 (v/v); B) isooctane/isopropanol, 95:5 (v/v). 1) 1-Hexadecyl-2-oleoyl-3-trityl-*sn*-glycerol, 2) triphenylmethanol, 3) 1-hexadecyl-3-oleoyl-*sn*-glycerol, (4) 1-hexadecyl-2-oleoyl-*sn*-glycerol and 5) cholesterol.

$$F_A = \frac{\frac{WA/WIS}{MA}}{\frac{WA/WIS}{MA} + \frac{WB/WIS}{MB} + \frac{WC/WIS}{MC}}$$

where F is the mole fraction of the alkylglycerol in the reaction mixture. WA/WIS, WB/WIS and WC/WIS are the weight ratios of materials A, B and C, respectively. MA, MB and MC are the molecular weights of materials A, B and C, respectively.

Retention time of alkylglycerols. The retention times obtained using the conditions given in Materials and Methods for 1-hexadecyl-2-acyl-3-trityl-, 1-hexadecyl-3- and 1-hexadecyl-2-acyl-*sn*-glycerols containing various fatty acyl chains are given in Table 2. As the data show, the retention times of the alkylglycerols increased with a decrease of the carbon chain length of the fatty acyl residue due to an increase of its polarity. Separation of mixtures of various molecular species for each lipid class

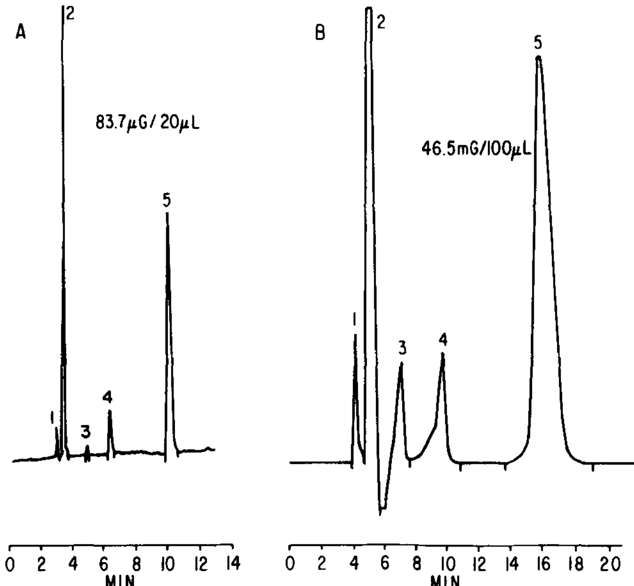

FIG. 4. HPLC chromatograms of detritylation reaction product. A) Analytical HPLC silica column—98.2 (v/v) isooctane/isopropanol, flow of 1.0 ml/min; B) semipreparative HPLC silica column—98:2 (v/v) isooctane/isopropanol, flow of 3 ml/min. 1) 1-Hexadecyl-2-oleoyl-3-trityl-*sn*-glycerol, 2) methyl triphenylmethyl ether, 3) triphenylmenthanol, 4) 1-hexadecyl-3-oleoyl-*sn*-glycerol and 5) 1-hexadecyl-2-oleoyl-*sn*-glycerol.

was not always possible with the HPLC conditions used. However, a complete separation of individual isomeric lipid species, 1,2,3-, 1,3- and 1,2-glycerols, was obtained under the conditions. The separation among these three derivatives increased with a decrease in the carbon chain of fatty acid acyl residue, with the largest separations obtained with the acetyl derivatives. The last entry in Table 2 shows that the method is also applicable to the separation of mono-, di- and triacylglycerols, giving the same order of elution as observed with the alkylacylglycerols. However, substitution of an acyl residue for alkyl increases retention times for all three acyl glycerides. This indicates the decreased polarity of an alkoxy group compared to an acyloxy substituent.

Preparative HPLC application. To obtain information on the utility of preparative column HPLC for the isolation of the 1,2- and 1,3-alkylacyl isomers, both the analytical and preparative HPLC columns were compared at different sample loadings (Fig. 4). The sample used for these chromatograms was obtained by the detritylation reaction of 1-hexadecyl-2-oleoyl-3-trityl-*sn*-glycerol at a reaction temperature of 22 C, in methylene chloride solvent, BF_3-CH_3OH to glyceride molar ratio of 1:1 and a reaction time of 5 min. As the data show, a comparable separation and sensitivity was obtained on the semipreparative silica column as with the analytical silica column. This result suggested the further possibility of using HPLC for the semipreparative isolation and purification of the isomeric 1-alkyl-2-acyl and 1-alkyl-3-acyl-*sn*-glycerols listed in Table 2.

At the present stage of the study, only the semipreparative column was used for this purpose. In the future, we are planning to use preparative columns with larger ID for isolation of larger amounts of synthetic mixed alkylacylglycerol isomers.

[Received September 29, 1986]

Quantitation of Baboon Lipoproteins by High Performance Gel Exclusion Chromatography

Mary C. Williams[a], **Rampratap S. Kushwaha**[a,*] and **Henry C. McGill Jr.**[a,b]
[a]Department of Physiology and Medicine, Southwest Foundation for Biomedical Research, San Antonio, and [b]Department of Pathology, University of Texas Health Science Center, San Antonio, Texas

High performance liquid chromatography with gel exclusion columns was used for quantitative measurement of plasma lipoproteins. A combination of columns TKS 4000 PW and 3000 PW gave good separation of very low (VLDL), low (LDL) and high (HDL) density lipoproteins. The area under each lipoprotein peak detected by absorbance at 280 nm was measured by digitizing and was expressed as cm^2. Purified lipoprotein standards isolated by ultracentrifugation were also chromatographed in increasing concentrations. The area under the lipoprotein standard peak was linearly related to the amount of total protein over a wide range. The areas of most of the measured plasma lipoproteins were within the linear range. The relationship between the area and the amount of protein for each standard was used to quantitate the amount of protein and was expressed as mg/dl plasma. This technique is simple and requires a small amount of plasma. The validated technique was applied to a large population of pedigreed baboons. An average plasma lipoprotein profile of feral baboons on the chow diet was characterized by a high level of HDL (90.9 ± 30.7 mg/dl) with a lesser amount of LDL (29.1 ± 13.2 mg/dl). VLDL was present in much lower concentration (8.6 ± 2.6 mg/dl). Feeding a high cholesterol and high saturated fat (HCHF) diet raised both LDL (1.5-fold) and HDL levels (1.3-fold) without changing VLDL levels. Progeny of sires with low response to dietary cholesterol increased their HDL protein when challenged with HCHF diet without any change in their LDL or VLDL. Progeny of high-responding sires, however, had increases in both their HDL and LDL levels when challenged with HCHF diet. The survey of lipoprotein profiles of the pedigreed baboon colony disclosed a number of animals with interesting and unusual lipoprotein patterns.
***Lipids 22,* 366–374 (1987).**

Plasma concentrations of lipoproteins are affected by both genetic and environmental factors. Because plasma lipoproteins are involved in the pathogenesis of atherosclerosis, many efforts have been devoted to determining the factors that control their concentration and composition, both in humans and in animal models. Nonhuman primates have been widely used because of their close phylogenetic relationship to man. We have used the baboon (*Papio* sp.) because its lipid and lipoprotein metabolism is similar in many ways to that of humans, and because it exhibits a wide variety of plasma lipoprotein profiles (phenotypes) that are presumed to be of genetic origin. Since 1973, we have developed, by selective breeding and positive assortative mating, families of baboons with distinctive lipoprotein phenotypes. Genetic analyses have shown that some phenotypes are heritable (1) and are due to the effects of major genes (2). Most of these phenotypes are modulated by diet as well as by breeding.

The systematic study of both genetic and dietary effects on these lipoprotein phenotypes required a rapid quantitative method to measure concentrations of major lipoprotein classes in plasma. We used high performance gel exclusion liquid chromatography (HPLC), which has been shown to separate lipoproteins (3–5). A previous report described the qualitative validation of the method (6). This report describes quantitative validation of the method and its application to the measurement of lipoproteins in several families of pedigreed baboons with normal and abnormal lipoprotein phenotypes.

METHODS

Subjects. About 500 pedigreed baboons, the result of 10 years of selective breeding, were available for the survey of plasma lipoprotein phenotypes. For this analysis of results obtained by HPLC, we selected 96 feral animals and 97 progeny of 21 sires and 86 dams. Sires were selected on the basis of the response of their plasma cholesterol concentrations to an atherogenic diet rich in cholesterol and saturated fat. One group of sires (n = 7) had low responses, and a second group (n = 8) had high responses to the challenge diet. The third group (n = 6), called the control group, was selected randomly. The feral animals ranged from nine to 20 years in age at the time of sampling. Progeny were between three and five years old at the time of analysis. Blood was drawn while animals were consuming monkey chow, and again after consuming a diet enriched in cholesterol and saturated fat for seven weeks. The compositions of these diets are given in Table 1.

Isolation of plasma lipoproteins for HPLC. Animals fasted for 16 to 20 hr were immobilized with ketamine (10 mg/kg) and bled to obtain 3 ml of blood in tubes containing EDTA (1 mg/ml). The plasma was obtained by

TABLE 1

Compositions of Chow and High-Cholesterol, High-Fat (HCHF) Diets

Nutrients	Chow diet	HCHF diet[a]
Carbohydrates (% cal)	62	40
Protein (% cal)	28	20
Fat (% cal)	10	40
Energy (kcal per 100 g diet)	329	377
Cholesterol (mg/kcal)	0.03	1.7

[a]HCHF diet was prepared by mixing 81.4% (dry weight basis) of Purina monkey meal 5-5045-6 (a special mix with no added fat, dehydrated alfalfa, sodium chloride, ascorbic acid or retinyl acetate) with lard (16.5%), sodium chloride (1.1%), retinyl acetate (0.005%), ascorbic acetate (0.2%) and cholesterol (0.74%).

centrifuging the blood in a low-speed centrifuge (TJ6B, Beckman Co., Palo Alto, California) at 3000 rpm (1900 × g) for 30 min at 6 C. Plasma (1.0 ml) was adjusted to a density of 1.21 g/ml by adding solid potassium bromide and was ultracentrifuged (Beckman L5-50 and L3-50) in a 50 Ti rotor at a speed of 45,000 rpm for 24 hr at 6 C. After ultracentrifugation, lipoproteins were harvested by pipetting the upper 3.0 ml. These lipoproteins were used for the characterization and quantitation of lipoprotein profiles by HPLC.

Separation of lipoproteins by HPLC. Plasma lipoproteins were separated by HPLC by using gel exclusion columns as reported previously (6). A Waters HPLC Model 204 with 6000A pump and UV detector (Model 440) (Waters Assoc., Milford, Massachusetts) was used. The lipoprotein peaks were detected by monitoring absorbance at 280 nm with a Perkin-Elmer Sigma 15 recorder-integrator (Perkin-Elmer Corp., Norwalk, Connecticut). Separation in Tris acetate buffer, 0.2 M, pH 7.0, was achieved by a combination of gel permeation columns, a guard column TSK GP WPC (100 × 7.5 mm), a TSK 4000 PW (600 × 7.5 mm) and a TSK 3000 PW (600 × 7.5 mm, Kratos, Westwood, New Jersey). A flow rate of 0.2 ml/min was used with a recorder speed of 0.1 cm/min. Each sample was injected in a volume of 300 μl (equal to 100 μl of plasma) by a Waters WISP maintained at 5 C in a refrigerated chromatography chamber (Powers, Hatboro, Pennsylvania). When fractions were collected, a Foxy fraction collector (ISCO, Lincoln, Nebraska) maintained at 5 C in a chromatography chamber was used.

Separation of lipoproteins by density gradient ultracentrifugation. Lipoproteins were separated by density gradient ultracentrifugation using a modified method of Redgrave et al. (7). Plasma samples (2.0 ml) were pipetted into polyallomer centrifuge tubes, and plasma was adjusted to d 1.30 g/ml by adding solid potassium bromide (0.430 g/ml). A discontinuous gradient was formed by layering 1.5 ml of d 1.21 g/ml KBr solution, followed by 1.5 ml of d 1.125 g/ml, 1.5 ml of d 1.070 g/ml, 2.0 ml of d 1.063 g/ml and 1.5 ml of d 1.019 g/ml KBr solutions. Finally, the contents were layered with 1.2 ml of saline solution (d 1.006 g/ml). The salt solutions were layered using a 22-gauge hypodermic needle attached to a syringe with the piston removed as described by Redgrave et al. (7). The samples were centrifuged for 24 hr at 39,000 rpm using an SW 41 Ti rotor at 6 C in a Beckman ultracentrifuge model L8-70 (Beckman).

After centrifugation, the tube was placed on a gradient tube fractionator (FS 101, Hoefer Scientific Instruments, San Francisco, California) and punctured in the side close to the bottom. Fluorinert FC-40 (Sigma Chemical Co., St. Louis, Missouri) was then pumped and the sample placed through an optical density monitor attached to a recorder (ISCO) using a peristaltic pump (Gibson Medical Electronics, Middleton, Michigan) and 0.4-ml fractions were collected. The fractions corresponding to different lipoprotein peaks, as monitored by absorbance, were pooled.

Isolation and chromatography of lipoprotein standards. Lipoprotein standards for identification and quantification of lipoprotein peaks separated by HPLC were separated by sequential ultracentrifugation as described previously (6). Very low density lipoproteins (VLDL), LDL and high density lipoprotein (HDL) were isolated at d 1.006 g/ml, d 1.019–1.063 g/ml and d 1.063–1.21 g/ml, respectively. An abnormal lipoprotein between LDL and HDL (HDL_1) was isolated from an animal positive for this lipoprotein at d 1.045–1.070 g/ml. Lipoproteins were floated at least two times at their respective densities by ultracentrifugation. The pure lipoprotein fractions used as standards gave single bands corresponding to their characteristic electrophoretic mobility on 1% agarose gel electrophoresis (8). Likewise, on HPLC, a single peak was obtained (6). The protein concentrations of lipoprotein standards were measured by the method of Lowry et al. (9). We then chromatographed standards by HPLC in varying concentrations and kept the conditions for HPLC similar to those used for plasma lipoprotein separation.

Quantitation of cholesterol in lipoproteins separated by density gradient ultracentrifugation and HPLC. To compare the recovery of cholesterol in lipoproteins separated by density gradient ultracentrifugation and HPLC, blood was obtained from seven animals (four on chow and three on HCHF diet) after an overnight fast. Plasma lipoproteins were fractionated by density gradient ultracentrifugation and HPLC as described earlier. Lipoproteins separated by both methods were assayed for cholesterol by an enzymatic method at a sensitivity of 1 μg cholesterol with a precision of ±4% using a cholesterol measurement kit (Sigma).

Quantitation of lipoprotein profiles. Lipoprotein profiles obtained after HPLC separation were digitized, and the area under each peak was expressed as cm^2. Initially the areas were measured by using a sonic digitizer (Science Accessories, Southport, Connecticut) attached to a minicomputer (Zobex, San Diego, California) with a video display unit (ADMS 3A+ Dumb terminal, Lear Siegler, Anaheim, California). The program was designed locally and integrated the area under the curve between any two arbitrary points plotted by digitizer. Later, the areas were measured by using the digital Paintbrush system (The Computer Colorworks, Sausalito, California) attached to an IBM PC computer (IBM, Boca Raton, Florida).

Standard lipoproteins separated by HPLC were digitized in a similar way, and the area under the peak was expressed as cm^2. This value of the peak was plotted against the Lowry protein values to determine the linear range of proteins in various lipoproteins. The relationship between the area and the amount of protein in each standard curve was used to quantitate the lipoprotein in corresponding peaks of the animal's lipoprotein profile separated by HPLC.

Statistical analysis. The data for densitometric areas and protein concentrations for each lipoprotein standard gave a straight line when fitted by the criterion of least squares. The correlation coefficients for these regression lines were highly significant ($P < 0.01$). These equations for straight lines were then used to calculate the lipoprotein concentrations in the plasma by using the densitometric areas. The data for lipoprotein cholesterol or protein measured by two methods were compared by using two-way analysis of variance (ANOVA) considering the two methods as two blocks and repeated measurements or animals as treatments. Similarly, the lipoprotein data for the chow and HCHF diet within each group were compared using two-way ANOVA considering lipoprotein protein concentration as two blocks and animals as treatments. Lipoprotein protein concentrations for groups were compared by one way ANOVA. After detection of

significant differences by ANOVA, individual means were compared using Duncan's New Multiple Range Test to see which pairs of means were different. The recovery of cholesterol in lipoproteins by two methods was compared using one-way ANOVA.

RESULTS

Identification of lipoproteins separated by HPLC. The lipoprotein peaks separated by HPLC were identified by comparing their retention times with those of purified lipoprotein standards and apoprotein composition as described previously (6). The lipoprotein patterns separated by HPLC and the cholesterol distribution among the fractions separated resembled those of density gradient ultracentrifugation (Fig. 1). As described previously (6), the first peak, which eluted at 82-90 min, corresponded to VLDL. It was followed by LDL with a retention time of 95-109 min and HDL with a retention time of 115-130 min. Albumin was eluted at 140 min; however, it was not present in any detectable amounts in these samples. In some cases a peak corresponding to intermediate density lipoproteins (IDL) was eluted at 91-93 min. Usually there was no detectable material between LDL and HDL peaks. However, if there was a peak or a shoulder to an HDL peak between 100-115 min, the area was digitized and expressed as HDL_1. In cases where the LDL peak was not symmetrical and had a shoulder peak between 90-95 min, the area was digitized as Lp(a).

The recovery of cholesterol in VLDL + LDL by HPLC method was 42 ± 13% as compared to 37 ± 14% by density gradient ultracentrifugation (Table 2). The recovery of VLDL + LDL cholesterol was significantly higher by HPLC than by density gradient ultracentrifugation. The total recovery of cholesterol (91 ± 8% by HPLC vs 90 ± 8% by density gradient ultracentrifugation) or the recovery of cholesterol in HDL (49 ± 10% by HPLC vs 53 ± 9% by density gradient ultracentrifugation) were not significantly different by the two methods. It is possible that the larger volume collected by density gradient ultracentrifugation for the VLDL + LDL fraction may have decreased the sensitivity of the cholesterol, resulting in lower recovery. The apoproteins separated by 3.5% and 10% polyacrylamide sodium dodecyl sulfate gels (10) from these peaks, as described previously (6), were characteristic of these lipoproteins.

Quantitation of plasma lipoprotein profiles. Most plasma lipoproteins were separated by HPLC into three peaks corresponding to VLDL, LDL and HDL as in the

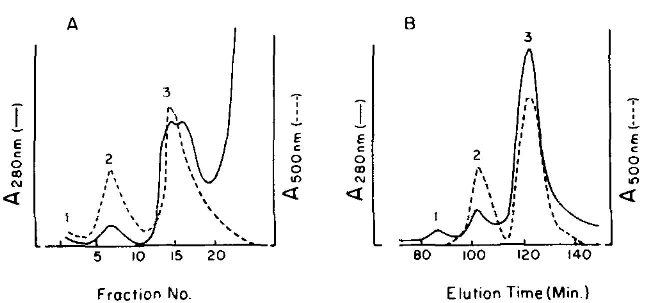

FIG. 1. Distribution of cholesterol (– – –) and protein (——) in lipoproteins separated by density gradient ultracentrifugation (A) and by high performance liquid chromatography using a combination of PW4000 and PW3000 columns (B). Lipoproteins were identified by using standards, density, and apolipoprotein composition. Peaks are labeled 1, very low density lipoproteins; 2, low density lipoproteins; 3, high density lipoproteins. Cholesterol in fractions was measured by the enzymatic method (A500 nm), and proteins were monitored at A280 nm.

VLDL, very low density lipoproteins; LDL, low density lipoproteins; HDL, high density lipoproteins.

[a]Animals 1-4 fed the chow diet and 5-7 were fed a high-cholesterol, high-saturated fat diet.

[b]Recoveries of cholesterol in fractions represent percent of plasma cholesterol.

[c]Recovery of cholesterol in VLDL + LDL separated by HPLC was significantly higher ($P < 0.01$) than that by density gradient ultracentrifugation.

[d]Recoveries of cholesterol were not significantly different by the two methods.

case of density gradient ultracentrifugation (Fig. 1). An albumin peak was sometimes seen after the HDL peak. As shown in Figure 2, the areas under the lipoprotein peaks were linearly related to the amount of total protein in lipoprotein standards over a wide range. Areas of most of the lipoprotein peaks in lipoprotein profiles were within the linear range for each lipoprotein. The relationship between the area and the amount of protein in each standard was used to quantitate the amount of protein and expressed as mg/dl plasma.

The protein values measured by this method in LDL and HDL were compared to those measured by the method of Lowry et al. (9). Plasma samples from four animals fed a chow diet and four animals fed the HCHF diet were separated by HPLC and the fractions corresponding to LDL and HDL were pooled. The protein

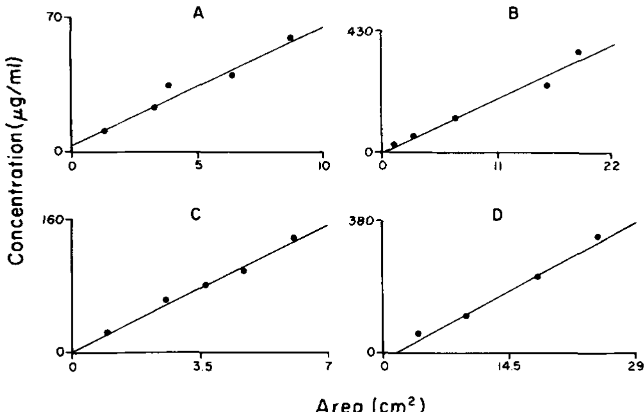

FIG. 2. Relationship between protein concentration and area for lipoprotein standards: A, very low density lipoprotein (VLDL); B, low density lipoprotein (LDL); C, HDL_1 (the unusual lipoprotein separated between LDL and high density lipoprotein [HDL]); and D, HDL. Lines for the standards were drawn by fitting the data by the method of least squares. Correlation coefficients for regression lines for VLDL, LDL, HDL_1 and HDL were 0.984 ($P < 0.01$), 0.968 ($P < 0.01$), 0.990 ($P < 0.01$) and 0.996 ($P < 0.01$), respectively.

contents were measured by the Lowry method (9) and compared with those measured by digitizing. As shown in Table 3, the protein values measured by the two methods were similar.

Lipoprotein profiles of feral baboons. The concentrations of protein in plasma lipoproteins of 96 feral baboons is shown in Table 4. An average plasma lipoprotein protein profile of baboons on the chow diet is characterized by a high concentration of HDL protein (90.9 ± 30.7 mg/dl) with a lesser amount of LDL protein (29.1 ± 13.2 mg/dl) (Table 4). VLDL protein was present in much lower concentrations (8.6 ± 2.6 mg/dl). Smaller concentrations of IDL occasionally seen were not quantitated. These columns did not resolve HDL_2 and HDL_3 completely; however, as reported earlier (6), the major peak of HDL corresponded to HDL_2. Feeding the HCHF diet increased both LDL protein (43.1 ± 21.4 mg/dl) and HDL protein (112.4 ± 34.7 mg/dl) significantly (Table 4). There was no increase in VLDL protein. The distribution of LDL and HDL protein levels in the plasma of the 96 feral baboons consuming chow and also consuming the HCHF diet is given in Figure 3. The LDL protein values varied from 9.2 to 80.1 mg/dl on the chow diet and 11.8 to 121.8 mg/dl on the HCHF diet (Fig. 3). The values for plasma HDL protein varied from 28.8 to 161.92 mg/dl on the chow diet and 29.7 to 194.5 mg/dl on the HCHF diet (Fig. 3).

Plasma lipoprotein profiles of progeny from selected sires. Ninety-seven progeny from three different sire groups were divided on the basis of the responses of the sires' serum cholesterol concentraton to an HCHF diet. The first group of sires had a low response to the HCHF diet (low responders). The second group of sires had a high response to the HCHF (high responders). The third group was a randomly selected group of control sires. Progeny from the control sire group had lipoprotein profiles similar to those in the feral group (Table 4). Progeny of low responders had low levels of HDL on the chow diet (Table 4); however, these values were not significantly different from other groups. There was an increase in their plasma HDL protein upon feeding the HCHF diet (78.4 ± 16.9 mg/dl on chow vs 114.3 ± 31.9 mg/dl on the HCHF diet).

[a]Values for LDL by HPLC and Lowry are not significantly different ($P > 0.05$).

[b]Values for HDL by HPLC and Lowry are not significantly different ($P > 0.05$).

TABLE 4

Lipoprotein Protein Values of Baboons on Chow and High-Cholesterol, High-Fat (HCHF) Diet[a]

Group (n)	Chow diet			HCHF diet		
	VLDL	LDL	HDL	VLDL	LDL	HDL
1. Feral (96)	8.6 ± 2.6[b]	29.1 ± 13.2	90.9 ± 30.7	8.7 ± 6.2	43.1 ± 21.4[e]	112.4 ± 34.7[e]
2. Progeny of low-responding sires (22)	7.9 ± 1.5	29.6 ± 9.0	78.4 ± 16.9	7.5 ± 1.0	31.5 ± 15.2[g]	114.3 ± 31.9[e]
3. Progeny of high-responding sires (55)	7.7 ± 1.5	30.3 ± 9.9	99.3 ± 31.6	8.3 ± 2.8	57.0 ± 28.3[e]	127.6 ± 39.5[e]
4. Progeny of control sires (21)	8.1 ± 0.8	36.0 ± 15.4	90.1 ± 26.3	7.6 ± 1.2	44.4 ± 18.7[e]	128.7 ± 35.2[e]
5. Animals with high HDL_1 (18)	5.2 ± 3.9	30.5 ± 13.4	96.3 ± 27.9 (6.8 ± 3.4)[d]	6.8 ± 3.4	61.4 ± 32.3[e]	113.3 ± 37.3 (44.1 ± 12.2)[d,e]
6. Animals with Lp(a) (17)	6.1 ± 2.5	31.1 ± 7.9 (4.8 ± 2.4)[c]	77.4 ± 26.8	5.4 ± 3.7	48.3 ± 27.7[e] (5.2 ± 2.5)[c]	127.9 ± 48.1[e]
7. Animals with high VLDL (15)	8.2 ± 1.5	33.4 ± 12.2	88.4 ± 18.9	17.1 ± 11.5[e,f]	48.7 ± 24.5[e]	102.3 ± 40.3[e]

VLDL, very low density lipoproteins; LDL, low density lipoproteins; HDL, high density lipoproteins.
[a]Lipoproteins were measured after separation by HPLC.
[b]Values have been expressed as mg/dl plasma, mean ± S.D.
[c]Values in parentheses are for Lp(a).
[d]Values in parentheses are for HDL_1.
[e]Values for lipoproteins are significantly greater ($P < 0.05$) than in those on the chow diet within the same group.
[f]Values for lipoproteins are significantly greater ($P < 0.05$) than those for other groups on the same diet.
[g]Values for LDL on HCHF diet in group 2 are significantly different from those of groups 3, 5, 6 and 7 on the same diet. LDL values on HCHF diet for groups 1 and 4 are significantly different from those of group 5 on the same diet.

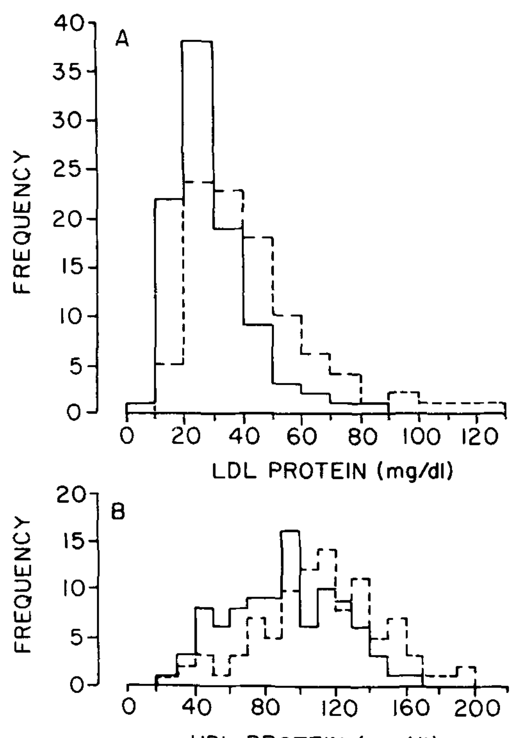

FIG. 3. The distribution of low density lipoprotein (LDL) protein (A) and high density lipoprotein (HDL) protein (B) levels in the plasma of feral baboons (n = 96) on the chow (——) and the high cholesterol high saturated fat diet (– – –).

However, there was very little change in their LDL levels (29.6 ± 9.0 mg/dl on chow vs 31.5 ± 15.2 mg/dl on HCHF diet). On the other hand, progeny of high responders had significant increases in both LDL and HDL levels (Table 4).

The distributions of LDL protein in progeny of low and high responders were similar when they were consuming the chow diet (Fig. 4). However, upon feeding the HCHF diet, LDL distribution changed considerably. The high responding group had a wider distribution of LDL protein (Fig. 4). HDL protein in these animals was also distributed over a wide range on both chow and HCHF diets (Fig. 5). LDL protein values for the high-responding group were significantly higher than for the low-responding group on HCHF diet. However, on the chow diet the values were not different. HDL protein values in the low-responding group were lower than in the high-responding group (78.4 ± 16.9 mg/dl in low responders group vs 99.3 ± 31.6 mg/dl in high responders); however, these values were not significantly different. Upon feeding the HCHF diet, HDL was raised in both groups, and the values between these groups were not significantly different. The control group had a distribution similar to that for the feral group.

A few animals with low LDL levels showed very little change in their LDL levels when challenged with HCHF diet. In contrast, some animals with high LDL protein levels on the chow diet, when challenged with the HCHF diet, raised their LDL protein level considerably, and those values stayed at the higher part of the distribution. The lipoprotein profiles of these animals are given in Figure 6.

Animals with high and low levels of HDL protein were also identified. Lipoprotein patterns of high and low HDL animals are shown in Figure 7.

Unusual lipoprotein patterns. Progeny of a few sires had unusual lipoprotein patterns, with a peak between LDL and HDL (Fig. 7). This lipoprotein was originally described as $F^{\circ}_{1.20}$ 9–28 lipoprotein based on its flotation characteristics by analytical ultracentrifugation (11). Because its physical characteristics and composition are similar to what has been called HDL_1, we have used that term for it (12). This lipoprotein was separated either as a distinct peak between LDL and HDL or as a shoulder to the HDL peak (6). It is seen principally in the plasma of animals consuming the HCHF diet (Fig. 7). The average protein concentration of HDL_1 in animals with this lipoprotein on the HCHF diet was 44.1 ± 12.2 mg/dl. Occasionally this lipoprotein was seen on the chow diet; however, the protein content was very low (Table 4).

Some animals had a lipoprotein pattern in which a small peak preceded the main regular peak of LDL (Fig. 8). Upon density gradient ultracentrifugation, a small peak followed the regular LDL peak (Fig. 8). It appears, therefore, that the small peak detected by HPLC had a higher density but a larger size than LDL. This peak seems to represent Lp(a) (13). The concentration of Lp(a) protein in animals with this lipoprotein peak was estimated to be 4.8 ± 2.4 mg/dl on the chow diet. Cholesterol and saturated fat feeding did not affect the concentration of this lipoprotein. This lipoprotein pattern occurred mainly in the progeny of two sires.

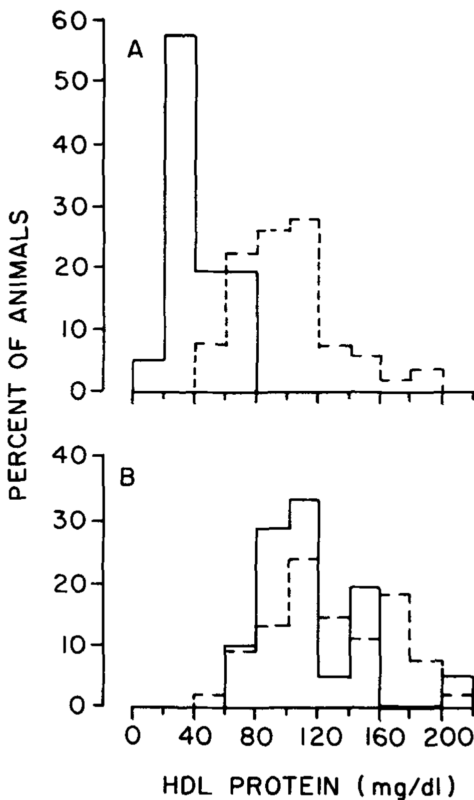

FIG. 5. The distribution of high density lipoprotein (HDL) protein levels in the plasma of pedigreed progeny from low-responding (——) and high-responding (– – –) sires on the chow (A) and the high cholesterol, high saturated fat diet (B).

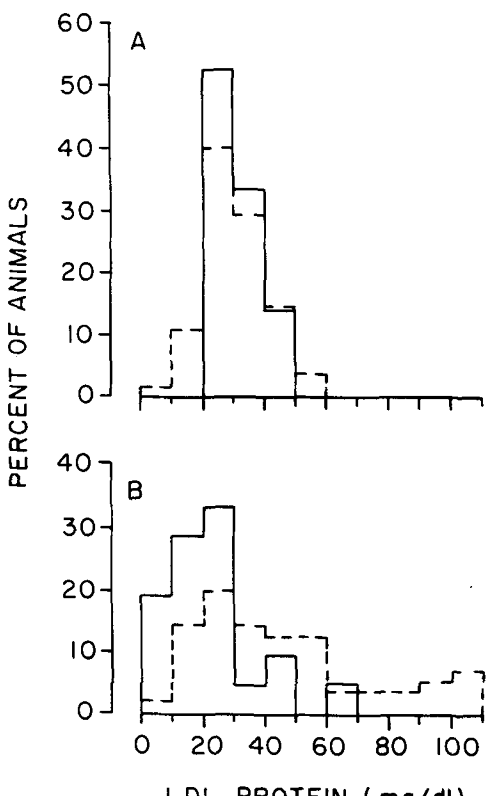

FIG. 4. The distribution of low density lipoprotein (LDL) protein levels in the plasma of pedigreed progeny from low-responding (——) and high-responding (– – –) sires on the chow (A) and the high cholesterol, high saturated fat diet (B).

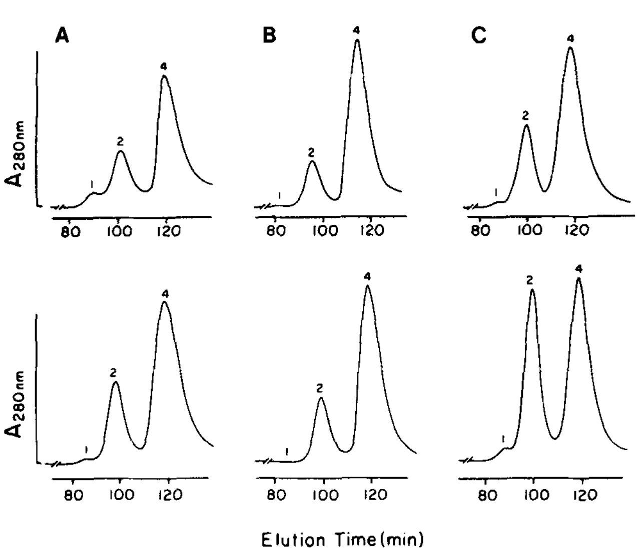

FIG. 6. Lipoprotein patterns separated by high performance liquid chromatography for representative animals showing different phenotypes. Numbers 1, 2 and 4 represent very low density, low density (LDL) and high density lipoproteins, respectively. Lipoprotein patterns A, B and C correspond to average profile, low LDL animals and high LDL animals, respectively. Lipoprotein patterns in the top row are from the chow diet and in the bottom row from the high cholesterol, high saturated fat diet.

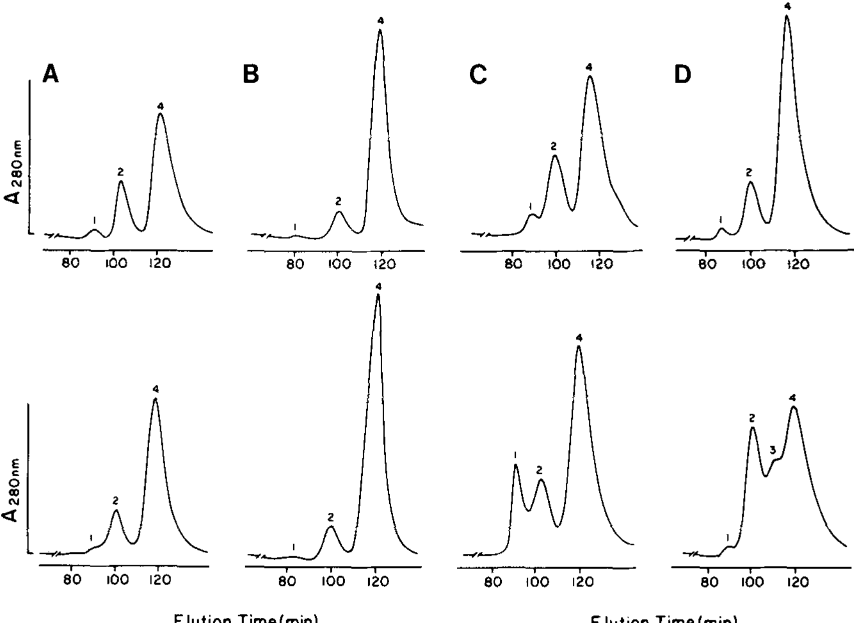

FIG. 7. Lipoprotein patterns separated by high performance liquid chromatography for representative animals showing different phenotypes on chow (top row) and high cholesterol, high saturated fat diet (bottom row). Numbers 1, 2, 3 and 4 correspond to very low density lipoprotein (VLDL), low density lipoprotein (LDL), HDL_1 and high density lipoprotein (HDL), respectively. Phenotypes A, B, C and D correspond to low HDL, high HDL, high VLDL and high LDL with high HDL_1, respectively.

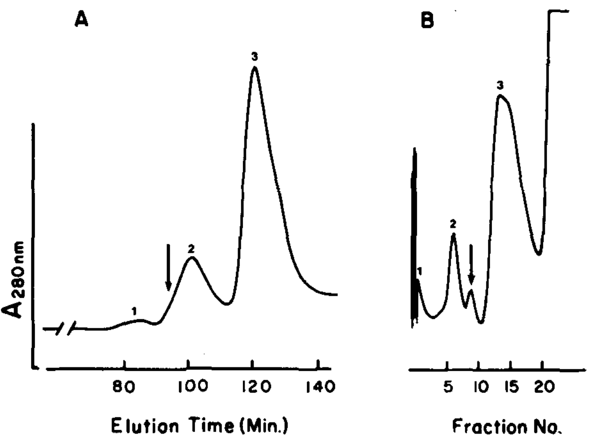

FIG. 8. Lipoproteins separated by high performance liquid chromatography (HPLC) (A) and density gradient ultracentrifugation (B). Numbers 1, 2 and 3 correspond to very low density, low density (LDL) and high density lipoproteins. On separation by HPLC, LDL has a shoulder peak (elution time 90–95 min, denoted with arrow) with larger particles than regular LDL. On separation by density gradient, the second peak of LDL (denoted with arrow) has higher density.

A few animals accumulated relatively high levels of VLDL (Fig. 7) in their plasma when challenged with the HCHF diet (Table 4). The VLDL protein values on the HCHF diet for this group were significantly higher than for other groups. Our studies were not able to determine whether the VLDL was rich in cholesterol or had β-mobility on agarose gel electrophoresis.

DISCUSSION

Comparison with other methods. A number of methods exist for measuring plasma lipoproteins. Most are laborious and time-consuming and require ultracentrifugation (7,13–17), column chromatography (18) or electrophoresis (19–21). The most extensively used technique is that standardized by the Lipid Research Clinics Program (15). According to this method, plasma lipoprotein cholesterol is measured following separation of lipoproteins by ultracentrifugation and precipitation with heparin-manganese chloride. Most of the other methods also measure lipoprotein cholesterol or lipids. Recent studies suggest that apolipoproteins may be better discriminators of atherogenesis than lipids (22–25). The HPLC technique for apolipoproteins is simple, measures total protein (although not individual apolipoproteins) and is convenient for screening a large population. Smaller plasma samples are required, and therefore the technique can be used for the quantification of infant plasma lipoproteins. The technique was validated and applied in a large population of pedigreed baboons. A number of abnormal lipoprotein phenotypes or dyslipoproteinemias were demonstrated.

The recovery of lipoproteins as indicated by total cholesterol in lipoproteins was greater than 90%. The area under the lipoprotein peak detected by absorbance at 280 nm was linearly related to the amount of total protein in each lipoprotein standard over a wide range. Areas under the lipoprotein peaks separated from 50–100 μl plasma were well within this range. Thus, the protein concentrations of lipoproteins were measured accurately, and the protein measured by this method gave values similar to those given by the Lowry method (9) after pooling the

fractions. Using a combination of these columns, the major lipoproteins were resolved; however, the HDL subfractions could not be resolved well.

Application to survey of lipoprotein phenotypes. The lipoprotein profiles of more than 500 pedigreed baboons on two diets (chow and HCHF) were characterized by this method. The lipoprotein phenotype of 96 feral, unselected baboons (the "average" baboon) was characterized by a high concentration of HDL with varying amounts of LDL. VLDL was present in detectable amounts but much less than that in normal human subjects (26). In most cases intermediate density lipoprotein was not detected in plasma lipoproteins. Feeding a diet enriched in cholesterol and saturated fat increased both LDL and HDL, but the increase varied among individuals. Thus, the response to cholesterol diet in baboons seems to be similar to that in humans (27), where both apo-B and apo-A-I were significantly increased by feeding a fat- and cholesterol-rich diet.

This technique was also applied to survey the lipoprotein profiles of pedigreed baboon progeny in three different sire groups. These progeny groups were selected on the basis of the response of sires to the HCHF diet. The groups were low-responding, high-responding and control (unselected). Lipoprotein levels were similar in all three groups on the chow diet. However, response to HCHF diet was different among these groups. Response to HCHF diet in control and high-responding progeny groups was similar to that in the feral group except that the high-responding group had high LDL levels. The low-responding group did not have any increase in LDL levels. All the groups, however, had significant increases in HDL levels. Thus the high- and low-responding groups differed in LDL levels on the HCHF diet, suggesting that there was a modulation of dietary response by the genetic make-up of these animals. Among these groups a few animals showed very little or no change in their LDL when challenged with the HCHF diet. These animals did have a significant increase in their HDL and were called low LDL animals. In contrast, some animals with high LDL on the chow diet had extreme response to HCHF diet in their LDL levels. These animals, like low LDL animals, had increases in their HDL and thus were called high LDL animals. Similarly, animals with high and low HDL without a difference in LDL levels in response to the HCHF diet were also recognized. These genetic animals can be used to study the metabolic differences responsible for differing levels of LDL and HDL.

Several interesting and unusual lipoprotein phenotypes were detected by this HPLC survey of lipoproteins in the pedigreed progeny of the colony. These dyslipoproteinemic patterns differed from the average lipoprotein pattern in several respects. One of the dyslipoproteinemias was characterized by the presence of lipoproteins intermediate to LDL and HDL. These were induced mainly by feeding a diet rich in cholesterol and saturated fat (12) and contained mostly apoproteins A-I and E. They are different from Lp(a) as they do not contain apo-B (11). These lipoproteins are similar to HDL_C (28), but since progeny of only two sires showed HDL_1 on a fat and cholesterol diet, and since in some cases they were present on the chow diet (6), it is unlikely that they are identical to HDL_C. Other dyslipoproteinemias were characterized by the presence of either high or low levels of LDL and HDL without affecting the levels of other lipoproteins. In some animals a distinct peak of Lp(a) was detected. Progeny and sires had similar lipoprotein phenotypes, a finding consistent with the sire effects on serum cholesterol observed by Mott et al. (29) and major gene effects on lipoprotein phenotypes observed by VandeBerg et al. (2).

Nocturnal intragastric feeding has been shown to be an effective means to improve clinical and biochemical features in glycogen storage disease type I (GSD-I). In this study, we investigated the fatty acid patterns in a whole plasma and in circulating lipoproteins in patients on this therapy. The results demonstrated massive concentration of total fatty acids coupled with higher levels of triglycerides, free cholesterol, cholesterol ester and phospholipids. This hyperlipidemia involved all fatty acids without distinction of carbon or bond numbers. However, the increase was more pronounced for saturated than polyunsaturated fatty acids, as was demonstrated by the ratios of both oleic acid to linoleic acid (1.91 ± 0.40 vs 0.80 ± 0.09 in controls) and of ω3 + ω6 to ω9 fatty acid families (0.92 ± 0.11 vs 1.66 ± 0.08 in controls). The fatty acid patterns in very low (VLDL), low (LDL) and high (HDL) density lipoprotein showed substantial differences in composition, reflecting an association between an abnormal lipoprotein pattern and essential fatty acid deficiency. Furthermore, GSD-I patients exhibited a significant increase in VLDL (17 ± 2 vs 47 ± 7 mg/dl) and LDL cholesterol (124 ± 7 vs 206 ± 24 mg/dl), coupled with a decrease in HDL cholesterol (49 ± 4 vs 28 ± 3 mg/dl). These data documenting high LDL cholesterol and low HDL cholesterol associated with an increased concentration and proportion of saturated fatty acids suggest that GSD-I patients on nocturnal intragastric feeding are at high risk for atherosclerosis and its complications.
Lipids 22, 381-385 (1987).

Von Gierke's disease (glycogen storage disease type I [GSD-I]) is caused by an inherited defect of glucose-6-phosphatase that leads to glycogen accumulation in liver, muscles and kidneys (1). In addition to hepatomegaly, hypoglycemia and failure to thrive, varying degrees of hyperlipidemia and hypercholesterolemia are present in patients with this disorder (2-5).

It has been shown that nocturnal and continuous infusion of glucose and amino acids is helpful and markedly improves metabolic complications and growth (6,7). Although beneficial, the treatment has a limited capacity to return plasma lipids and lipoproteins toward normal. In a previous study, increased very low (VLDL) and low (LDL) density lipoprotein cholesterol and low levels of high density lipoprotein (HDL) cholesterol have remained troublesome features in view of their correlation to cardiovascular disease (8).

On the other hand, this form of treatment could lead to essential fatty acid (EFA) deficiency, because requirements are calculated as a percentage of total energy (9). A similar situation has already been documented in patients with protein-calorie malnutrition treated with hypertonic glucose and amino acids (10-12). Because of elevated pyruvate concentration generated by glycolysis, the synthesis of saturated fatty acids is increased. The strong correlation between saturated fatty acids and the incidence of coronary heart disease calls for careful consideration, in view of our previously documented findings in the same patients (8) and because saturated fat appears to have an effect on cholesterol levels (13) and LDL (14).

The present study was designed to investigate the fatty acid composition in whole plasma and in the major lipoprotein classes. The results could be useful in understanding the metabolic and biochemical alterations in GSD-I patients. Furthermore, the findings could be useful for designing strategies for intervention adapted to both short- and long-term outcomes of GSD-I patients.

MATERIALS AND METHODS

Patients. Six patients (four females and two males, ages between 10 and 22 years) with biopsy-proven GSD-I comprised the subjects. All patients were hospitalized at the time of investigation and had been receiving nocturnal intragastric feeding for 5-6 years. The infusion consisted of one-third of estimated caloric requirements as Vivonex HN from Norwich Eaton (Cambridge, Ontario, Canada), which contains (per liter) 211 g carbohydrate, 43.3 g crystalline amino acids and 0.87 g fat in the form of safflower (75% of polyunsaturated fatty acids [PUFA]). The diurnal diet provided a caloric proportion of 60-70% carbohydrate, 15-20% protein and the rest fat. The follow-up showed an improvement in clinical growth and biochemical parameters (blood glucose levels, lactate, pyruvate, uric acid and SGOT). A substantial decrease was also found in the levels of triglyceride (TG, 45%) and total cholesterol (TC, 29%). Six healthy subjects, matched for age and sex and having ideal body weights, served as controls. Blood was collected on EDTA (1 mg/ml) and sodium azide (0.05%) 4 hr after cessation of nocturnal intragastric feeding.

Isolation of lipoproteins. Lipoprotein fractions were isolated by sequential ultracentrifugation according to Havel et al. (15) with a Ti-50 rotor in a Beckman Model L5-65 ultracentrifuge. VLDL and LDL were prepared at 1.006 g/ml and 1.063 g/ml, respectively, following centrifugation at 100,000 × g for 18 hr at 5 C. The HDL fraction was obtained by adjusting the LDL infranatant to 1.21 g/ml and by centrifuging for 48 hr. Lipoproteins were washed by one additional spin at their respective densities and dialyzed exhaustively against 0.15 M NaCl, 0.001 M EDTA, pH 7.0.

Lipid and lipoprotein determinations. The whole plasma was assayed for TG, TC and free cholesterol (FC) using commercial kits (Boehringer Mannheim, Montreal, Canada). Esterified cholesterol was calculated as the difference between TC and FC. Phospholipids were determined by the method of Bartlett (16). HDL cholesterol was measured after precipitation of VLDL and LDL with

phosphotungstic acid (17). The assay for LDL cholesterol was performed using polyvinylsulphate (Boehringer Mannheim) (18). VLDL cholesterol was calculated from the difference between cholesterol in the polyvinylsulphate supernatant and HDL cholesterol. Electron microscopy of VLDL particles was performed on a Zeiss EM-10 microscope, using negative staining with 1% phosphotungstic acid (pH 7.2), as described previously (19). The diameter of 500–800 particles was then determined.

Gas liquid chromatography analyses. Fatty acids in whole plasma and in the different lipoprotein fractions were assayed by an improved method recently described by this laboratory (20). Briefly, each sample to be analyzed underwent direct transesterification or specific methylation of free fatty acid (FFA), followed by injection into a HP 5880 gas chromatograph using a 30-m fused silica column wall coated with SP 2330.

Statistical analysis. All data were expressed as mean ± SEM. Statistical differences were assessed by the Student's two-tail t-test. Any statistical significance less than $P < 0.05$ was admissible.

RESULTS

Data in the six GSD-I patients compared to the six age-matched controls showed persistent hypertriglyceridemia (768 ± 190 vs 64 ± 3 mg/dl), hypercholesterolemia (282 ± 32 vs 183 ± 10 mg/dl) and hyperphospholipidemia (472 ± 40 vs 184 ± 5) despite 5–6 yr of nocturnal intragastric feeding (Table 1) and a general improvement of some of the clinical and metabolic manifestations of the disease. VLDL particles were larger (401 ± 17 vs 308 ± 11Å, $P < 0.05$) and contained a higher concentration of TG than controls (625 ± 196 vs 31 ± 4 mg/dl, $P < 0.01$). Cholesterol content of VLDL (47 ± 7 vs 17 ± 2 mg/dl) as well as that of LDL (206 ± 24 vs 124 ± 7 mg/dl) was increased, while that of HDL (28 ± 3 vs 49 ± 4 mg/dl) was decreased. When measured, the percentage of cholesterol ester (CE) was found to be lower in GSD-I (62 ± 3%) than in healthy controls (74 ± 1%).

Table 2 shows that total plasma fatty acids were greatly increased in patients compared to controls. The total increase was close to fourfold and affected all fatty acids. However, the proportion of saturated fatty acids was higher and that of essential unsaturates (linoleic, arachidonic and docosahexaenoic acids) was lower. The relative drop in unsaturates affected the ω3 and ω6 families and led to a decrease in the 18:1ω9/18:2ω6 ratio as well as an increase in the ω3 and ω6 over the ω9 fatty acid family. The 18:2ω6/20:4ω6 ratio also was significantly lower when compared to controls.

When the fatty acid composition of individual lipoprotein fractions was analyzed, it was different from that of controls (Table 3). VLDL and LDL showed a comparable increase of myristic, palmitic and palmitoleic acids along with a proportionate drop in linoleic and docosahexaenoic acids. The HDL fraction showed only a decline in the latter two fatty acids. The 18:1ω9/18:2ω6 ratio was significantly increased in the LDL and HDL fractions. However, only a trend in the same direction appeared in the case of the VLDL, which showed a decrease of oleic acid. The 18:2ω6/20:4ω6 ratios of all lipoprotein classes were decreased.

DISCUSSION

Increased levels of plasma lipids and VLDL and LDL cholesterol with a decline in percentages of both CE and HDL cholesterol have previously been reported in patients with GSD-I following nocturnal intragastric feeding (8). The present study confirms these findings but provides additional information on the profile of plasma and lipoprotein fatty acids. Plasma fatty acids were distinctly increased. However, the pattern of fatty acids was abnormal, in that relative to the saturates and monounsaturates the PUFA were decreased. It should be noted that in the GSD-I patients about 10% of total calories was derived from fat. It is therefore likely that their daily intake of PUFA was below the 5–6% total kcal generally considered desirable (21).

However, these changes could also be due to the well-known increase in lipogenesis from carbohydrates, which constitute the predominant source of calories in GSD-I patients on nocturnal intragastric feeding. This is consonant with the demonstration that liver homogenates from individuals with glucose-6-phosphatase deficiency convert citrate to fatty acids (22). A further argument comes from the observations by Sadeghi-Nijad et al. (23) suggesting that excess hepatic glycolysis causes an increase in hepatic content of NADH, NADPH and acetyl CoA, three compounds important in fatty acid and cholesterol synthesis (1). Therefore, it is likely that an

[c] $p < .005$.
[d] $p < 0.01$.

increase in glycerol and acetyl CoA generated from the glycolytic pathway, together with high levels of reduced cofactors, could sustain an increased rate of TG and lipoprotein synthesis. Thus de novo synthesis results in an increased concentration of saturates and monounsaturates relative to the polyunsaturates which cannot be produced endogenously. The biochemical criteria for EFA deficiency, i.e., increased 18:1/18:2 ratio coupled with an increase in the ω3 and ω6/ω9 families, are well established. The patients studied met these criteria for EFA deficiency, as the ratios observed were comparable to those previously reported (24-26).

Even though there was no clinical evidence of EFA deficiency, the relative decrease in PUFA could be responsible for some of the anomalies observed in lipid profiles of these patients: i) The imbalance reflected by the abnormal ratio of nonessential/essential fatty acids could affect the composition, interconversion and clearance of the major lipoprotein fractions. For instance, the lipoprotein lipase (LPL) substrate interaction could be prejudiced in view of observations showing a high affinity of LPL for TG made up of PUFA (27). In our previous investigation (8), we demonstrated that the catabolism of plasma TG is impaired in this disorder. LPL activity was also substantially reduced in patients. Whether the mechanism of hypertriglyceridemia in these patients is related to an inhibitory factor or to the excessive amount of saturated fatty acids remains to be investigated.

ii) The recovery of TG-derived fatty acids in peripheral tissues as mirrored by the FFA fraction shows a predominance of saturated fatty acids because tissues in GSD-I patients probably contain an inordinate proportion of saturates and monounsaturates. Had membrane composition been examined, it is possible that a relative deficiency of EFA could have been documented, since there is ample evidence that EFA deficiency may lead to alterations in PUFA profile of tissue lipids (28,29). More important is the fact that such changes are known to be associated with alterations of structure and function (30).

iii) Lecithin cholesterol acyltransferase (LCAT), the second lipoprotein-related enzyme, uses mainly HDL as a substrate, translocating linoleic acid at the 2-position of lecithin to FC. Regarding the normal main product of the LCAT reaction in plasma, cholesteryl linoleate is the most abundant (31). LCAT also necessitates apo A-I as a cofactor for its activity (31). Since the latter apoprotein was found to be normal in concentration (8), we therefore suggest that EFA may be a limiting factor for the cholesterol esterification in view of its low level (Table 1). Therefore, CE transfer from HDL to VLDL and to LDL might be also affected because of the reduced capacity of these patients to esterify (8).

It is well known that unsaturated fatty acids are desaturated and elongated in endoplasmic reticulum membranes of many tissues (32). The reactions ending in 20:4 from 18:2 are $9,12\text{-}18{:}2 \xrightarrow{\Delta 6} 6,9,12\text{-}18{:}3 \rightarrow 20{:}3 \xrightarrow{\Delta 5} 20{:}4$ and involve Δ6 and Δ5-desaturases. The first enzyme in the chain has a key position and a regulatory function. Brenner has demonstrated that its activity can be modified by dietary and hormonal changes (32). For instance, glucose refeeding, a hyperprotein diet and insulin administration reactivate the enzyme (32). Thus, in our patients, the possible relationship between nocturnal intragastric feeding combined with frequent daytime feeding and Δ6-desaturase activity could explain the lower ratio of 18:2ω6/20:4ω6, which provides an estimate for elongation and desaturation steps. Thus, the much lower values observed suggest that the elongation and desaturation processes are increased in GSD-I patients. A decreased growth rate is one of the clinical features associated with EFA deficiency (33) and, according to Holman, a decrease in growth could postpone the appearance of deficiency (34). Accordingly, this suggests that the impaired growth of GSD-I patients could be due in part to a relative degree of EFA deficiency. On the basis of our observations, it is suggested that the administration of PUFA to these subjects might lead to improved growth.

Hyperlipidemia, as seen in GSD-I patients, may be an important risk factor for heart disease. At this time, we have not detected any clinical indications of coronary artery disease in our young patients. Atherosclerotic changes have, however, been observed in arteries of young asymptomatic children growing up in industrialized countries (35). Therefore, particular attention should be given to all children with hyperlipidemia. Recently, the American Heart Association Committee recommended a "prudent modification of diet" even for healthy children and adolescents as a means of influencing the plasma lipids. Numerous reports have confirmed the effectiveness of PUFA diets in lowering hyperlipidemia (36-38). All studies were uniform in reporting a favorable trend toward decreased LDL cholesterol. Other studies described a fall in the plasma TG (39) and an increase of PUFA percentage associated with lipoproteins (40,41). Since there is a well-known association of saturated fatty acids (42), increased LDL (43), elevated plasma TG (44) and a low HDL level (43) with increased prevalence of coronary heart disease, it seems appropriate to treat our patients who also present these biochemical risk factors with a diet enriched in polyunsaturated fat.

Growth Support and Metabolism of Phytosterols in *Paramecium tetraurelia*

Bruce D. Whitaker[1] **and David L. Nelson***
Department of Biochemistry, University of Wisconsin-Madison, College of Agricultural and Life Sciences, Madison, WI 53706

The basis of the growth requirement of *Paramecium* for one of several structurally similar phytosterols is not known. Previous research has indicated that selective esterification of only growth-promoting sterols may be a key. In this study, it was found that under certain conditions sterols that fail to support growth (e.g., cholesterol) can be esterified in large amounts in *Paramecium*. We found no compelling evidence to support the hypothesis that steryl esters serve a specialized role in the fatty acid metabolism of the cell. Octadecenoic acid, essential for cell growth, was the major fatty acid in both steryl esters and triglycerides. It was also shown that *P. tetraurelia* can dehydrogenate Δ^0 and Δ^7, as well as Δ^5-3β-hydroxy sterols, to yield the conjugated 5,7-diene derivative. These results indicate the presence of a Δ^5, in addition to a Δ^7, desaturase of the sterol nucleus in this ciliate. Two C_{24} α-ethyl sterols, Δ^{22}-stigmastenol (Δ^{22}) and stigmastanol (Δ^0), were shown for the first time to promote growth. Finally, we found that non-growth-promoting sterols may compose a high percentage of the free sterols of the surface membrane without adversely affecting cell growth or viability. These data support the conclusion that the growth requirement for select phytosterols in *Paramecium* does not involve the structural or functional role of "bulk" sterols in cell membranes.
***Lipids 22,* 386–396 (1987).**

The growth requirement for a phytosterol in the ciliated protozoan *Paramecium aurelia* was determined 30 years ago by Conner et al. (1,2). This sterol requirement was subsequently shown to be highly specific. Only a small group of structurally similar phytosterols was found to support growth of this organism in an axenic medium (3). Alkyl substitution (usually ethylation) at C-24 of the sterol side chain was shown to be essential for nutritional activity, and desaturation at C-22,23 of the side chain was shown to enhance activity. Epimerization of the ethyl group at C-24 had no effect.

The basis of auxotrophy for select phytosterols in *Paramecium* is unknown. One hypothesis, forwarded by Conner et al. (4), is that sterol esterification is somehow requisite for cell growth. This proposal was based on a study comparing the metabolism of the growth-promoting sterol stigmasterol with that of the non-growth-promoting sterol cholesterol in *P. aurelia.* It was shown that although both of these Δ^5 sterols were dehydrogenated at the 7,8 position to yield their 5,7-diene derivatives, no cholesterol or 7-dehydrocholesterol was incorporated into the steryl ester (SE) pool. Thus, the data indicated that only growth-promoting 3β-hydroxy sterols are esterified to fatty acids.

In this study, we have expanded the scope of the investigation by Conner et al. (4) to encompass the promotion of growth by and metabolism of a variety of phytosterols in *P. tetraurelia* in both monoxenic and axenic culture. The monoxenic medium used in these experiments was devised to eliminate the problem of contaminant sterols in the crude axenic and monoxenic cerophyl media customarily used for culture of *Paramecium* (5). The axenic medium used in this study was essentially the same as that used by Conner et al. (4), with the exception that cholesterol present in the 1-α-cephalin component was removed in only select series of experiments. Several dramatic quantitative and qualitative differences were found in the growth support and metabolism of phytosterols in monoxenic vs axenic cultures of *P. tetraurelia,* which prompted us to report results with both types of media.

We have tested the hypothesis linking sterol esterification with growth support by comparing the sterol composition of SE from axenic cultures of *Paramecium* with or without cholesterol and supplemented with one of six growth-promoting phytosterols. In addition, the fatty acid composition of SE and triglycerides (TG) has been compared for *P. tetraurelia* cultures supplemented with different phytosterols. This segment of the study was carried out to pursue the possibility that SE perform some specialized function in the fatty acid metabolism of *Paramecium,* rather than serving merely as a nontoxic reserve of sterols and free fatty acids. Also, the question of why the 3-keto steroid $\Delta^{4,22}$-stigmastadienone supports growth of *Paramecium* (3), particularly in light of the sterol esterification hypothesis, has been addressed. Finally, several experiments were performed to determine the extent to which non-growth-promoting sterols can replace stigmasterol and 7-dehydrostigmasterol in the ciliary membrane of *Paramecium.*

MATERIALS AND METHODS

Monoxenic cultures. Initial studies of sterol growth support, uptake and metabolism in *Paramecium* were performed by adding the appropriate sterol(s), sterol derivative or keto-steroid in an ethanolic solution to 3-(N-morpholino)propanesulfonic acid (MOPS) basal medium, autoclaving for 40 min and subsequently adding a dense suspension of *Escherichia coli* B prior to inoculation with *Paramecium* (6). (The concentration of phytosterols added to monoxenic cultures in these experiments, ≅1–5 μg/ml, was well above their solubility in water. Sterols added in ethanolic solution to room temperature MOPS basal medium in this concentration range immediately precipitated, forming large particulate aggregates. Upon autoclaving, the sterols were dispersed as a suspension of fine particles.) MOPS medium consisted of the following: 15 mM MOPS, 3 mM KCl, 1 mM $CaCl_2$, KOH to pH 6.2 plus NaOH to pH 6.5. *E. coli* cultures were grown in 0.4% minimal glucose medium (6) (potassium phosphates plus salts and 20% glucose solutions autoclaved separately).

Abbreviations: FAME, fatty acyl methyl ester; GLC, gas liquid chromatography; MOPS, 3-(N-morpholino)propanesulfonic acid; SE, steryl ester; TG, triglyceride; TLC, thin layer chromatography.

Flask cultures (1 l total volume) were started with a 0.5% v/v inoculum and grown to early stationary phase (20–24 hr; $A_{650\ nm} \cong 1.8$) on a gyratory shaker at 28 C. Bacteria were harvested by centrifugation for 5 min at 6,500 × g in sterilized Corex bottles, washed once in cold sterile MOPS, recentrifuged and resuspended in a few milliliters of sterile MOPS medium. The dense *E. coli* suspension derived from 1 l of medium was evenly distributed in flasks containing sterile MOPS medium plus sterol (2 l total volume), which were then inoculated at 100–200 cells/ml with *P. tetraurelia* wild-type 51S from an early stationary phase MOPS plus *E. coli* culture (5 μg/ml stigmasterol) and incubated at 25 C.

Control experiments were carried out to determine if steroids added to MOPS basal medium were altered during autoclaving or metabolized by *E. coli.* Stigmasterol, stigmasteryl acetate, stigmastadienone, cholesterol or cholesteryl myristate was added to 5 μg/ml to two sets of 250-ml flasks containing 40 ml of MOPS medium. After autoclaving, one set of flasks was immediately extracted with hexane/ether (1:1, v/v). A dense suspension of *E. coli* was added to the second set of flasks and allowed to incubate at 28 C for 24 hr. Following incubation, the bacteria were harvested by centrifugation and extracted with $CHCl_3$-MeOH (2:1, v/v). The MOPS medium supernatant was also extracted with hexane/ether (1:1, v/v). The following briefly summarizes the results: There was no evidence of metabolism of any of the steroid supplements by *E. coli.* Neither stigmasteryl acetate nor cholesteryl myristate was hydrolyzed during autoclaving or during incubation with the bacteria. However, 20–50% of the recovered steroid was associated with the bacterial pellet, even after washing and recentrifugation. This suggests that a substantial fraction of the steroid supplemented to the medium was taken up by, or adsorbed to, *E. coli.* Also, impurities detected by gas liquid chromatography (GLC) indicated that for both cholesterol and stigmastadienone, ≅10–20% of the added steroid was degraded (perhaps oxygenated) during autoclaving.

Axenic cultures. In the second study of growth support and metabolism of phytosterols in *P. tetraurelia,* the wild-type strain 51S was cultured in Soldo's crude axenic medium (7). This is a proteose and trypticase peptone plus yeast nucleic acid–based medium, rich in added vitamins and high in free fatty acids (≅45 μg/ml), and includes phosphatidylethanolamine (1-α-cephalin) of high polyunsaturated fatty acid content. Sterol was added at 2–5 μg/ml in an ethanolic solution (final [ethanol] ≤ 0.1%) prior to autoclaving. This medium contained ≥2 μg/ml cholesterol, a contaminant of the 1-α-cephalin component (4) (Sigma Chemical Co., St. Louis, Missouri). In the final series of experiments, the 1-α-cephalin was purified (>90% of the cholesterol removed) by silicic acid column chromatography (8,9) prior to addition to the axenic medium. Axenic cultures were inoculated at ≅100 cells/ml from a mid-log phase culture supplemented with 5 μg/ml stigmasterol (inoculum ≤ 2% total culture volume) and incubated at 25 C.

Cell harvest, deciliation and lipid extraction. Monoxenic and axenic cultures of *P. tetraurelia* (51S) were harvested by centrifugation in pear-shaped oil-testing centrifuge tubes at 250 × g for 2 min. Monoxenic cultures were harvested at early stationary phase (70–80 hr growth; nearly cleared of *E. coli*; 0.9–1.2 × 10^4 cells/ml), while axenic cultures were harvested at mid-log phase (70–80 hr growth; 6–8 × 10^3 cells/ml). The cell pellet was washed twice with MOPS basal medium (25 C) prior to deciliation or lipid extraction of whole cells. Cells from monoxenic cultures were deciliated by the calcium shock procedure described by Adoutte et al. (10), except that MOPS basal medium was used in place of Dryl's salt solution. Total lipid was extracted from whole cells or cilia by the method of Folch et al. (11). The chloroform/methanol (2:1, v/v) extraction was carried out in screw cap centrifuge tubes under N_2, in dim light. Butylated hydroxytoluene was added to the solvent mixture at 15 μg/ml to limit oxidation of lipids. All organic solvents were redistilled in glass.

Lipid fractionation and analysis. Total lipids extracted from *Paramecium* grown in either monoxenic or axenic culture were fractionated by silicic acid column chromatography in two steps: (i) A 1.5-ml slurry of 100–200 mesh Bio-Sil A (Bio-Rad, Richmond, California) in $CHCl_3$ was loaded into a 5¾" Pasteur pipet column plugged with glass wool. The column was washed with 5 ml of $CHCl_3$, and the lipid extract was applied in 0.5 ml $CHCl_3$. Neutral lipids were eluted with 6 ml $CHCl_3$, dried under a stream of N_2 and redissolved in 0.5 ml hexane (8,9). (ii) A second Pasteur pipet column was loaded with a 1.5-ml slurry of silicic acid in hexane. Neutral lipids were applied to the column and fractionated with a step gradient of hexane/diethyl ether (8,9). Hydrocarbons and steryl esters were eluted with 100% hexane (3 ml), triglycerides with hexane/ether (99:1, v/v) (6 ml), and fatty acids and alcohols with hexane/ether (95:5, v/v) (4 ml). The column was then stripped with $CHCl_3$ (5 ml) to yield the free sterol fraction (plus small amounts of mono- and diglycerides). The lipid composition of the step-gradient column fractions was examined by thin layer chromatography (TLC) on 250 μ silica gel 60, 20 × 20 cm glass TLC plates (Merck, Rahway, New Jersey) developed in hexane/diethyl ether/formic acid (80:20:2, v/v/v) and visualized with $FeCl_3$ spray reagent (9,12). Lipid fractions were dissolved in $CHCl_3$ and stored at −20 C under N_2 for no more than one week prior to sterol and fatty acid analysis.

The free sterol content of *Paramecium* from both monoxenic and axenic cultures was generally in the range of 40–80 μg per 10^6 cells. Free sterols and other steroids from the neutral lipids of *Paramecium* were tentatively identified by their GLC retention times relative to known standards. The instruments used for this analysis were a Varian 3700 gas chromatograph in tandem with a CDS-111 integrator. Sterols were separated on a 3 ft, 2 mm id glass coil column packed with 3% OV 17 on 100/120 mesh Supelcoport (Supelco, Bellefonte, Pennsylvania). The N_2 flow rate was 20 cc/min, the oven temperature was 260 C (isothermal) and the injector and detector temperatures were 320 C and 350 C, respectively.

More rigorous identification of sterol metabolites from *Paramecium* entailed the following: conversion of 3β-hydroxy sterols to steryl acetates with acetic anhydride (13); GLC analysis of steryl acetates (GLC retention times increased relative to free sterols); separation of steryl acetates according to the number of double bonds in the ring system and alkyl side chain by elution from a column of silicic acid impregnated with 20% $AgNO_3$ (w/w) using a step gradient of hexane/benzene (14); GLC

analysis of steryl acetates in the column fractions; and UV absorbance and mass spectra of steryl acetates and/or free sterols using a Gilford UV-VIS microprocessor-controlled System 2600 spectrophotometer and an AEI Model MS9 mass spectrometer, respectively. UV spectra were indicative of the presence or absence of conjugated double bonds in the B ring at the 5,6 and 7,8 positions. The $\Delta^{5,7}$ sterols have characteristic absorbance maxima in the UV at 271, 281.5 and 293 nm (15). Identification of sterols and steryl acetates by mass spectrometry was based on the M^+ ion (or M^+-60 for steryl acetates), as well as a comparison of the mass numbers and proportions of the major mass fragments with values reported in the literature (16,17). A combination of these methods (argentation column chromatography, UV spectrophotometry and mass spectrometry) was used to help determine the sterol composition of a given free or esterified sterol fraction whenever GLC alone was inadequate. For example, spinasterol ($\Delta^{7,22}$) and 7-dehydrostigmasterol ($\Delta^{5,7,22}$) had very close GLC retention times, but UV absorbance and mass spectra clearly showed that most of the former was dehydrogenated to yield the latter in both axenic and monoxenic cultures.

Fatty acids of steryl esters and triglycerides were transesterified to fatty acyl methyl esters (FAME) for GLC analysis by reacting with 0.5 N sodium methoxide in dry methanol as described by Luddy et al. (18). This reaction also liberated free sterols from steryl esters, which could then be analyzed by GLC. Gas chromatography of FAME was carried out on a 6 ft, 2 mm id glass coil column packed with 10% SP2330 on 100/120 mesh Chromosorb (Supelco). The N_2 flow rate was 20 cc/min, the column oven temperature was 190 C (isothermal) and the injector and detector temperatures were 250 C and 300 C, respectively. Identification of FAME from SE and TG of *Paramecium* was based on comparison of GLC retention times with those of known standards purchased from Sigma and Supelco and generated from total lipids of *E. coli* B. Identification was substantiated or expanded using two methods. The first was separation of subclasses of FAME according to the number of double bonds on 10% (w/w) $AgNO_3$-impregnated TLC plates (250 μ silica gel 60, 5 × 20 cm) developed with hexane/diethyl ether (90:10, v/v) (to separate saturated, mono- and dienoic) or 40:60 (v/v) (to separate tri- and tetraenoic) (9). The FAME subclasses were then scraped from the TLC plates, eluted from the silica gel and analyzed by GLC. The second method was saturation of all double bonds by vortexing a hexane solution of FAME sealed under an atmosphere of H_2 in the presence of 5% paladium catalyst on charcoal (Amend Drug and Chemical, New York, New York), followed by GLC analysis (9). These two methods gave a good estimation of the ratio of 16, 18 and 20 carbon fatty acids, and resolved the FAME pairs 17:cyc/16:2 and 19:cyc/18:2, which otherwise were not separated by GLC. (The 17- and 19-carbon cyclopropane fatty acids were derived from *E. coli* [19], and thus were present only in monoxenic cultures of *Paramecium*.)

Commercial and natural sources of sterols, sterol derivatives and steroids. Table 1 lists the source and

TABLE 1

Sterols, Steryl Acetates, Steryl Esters and Steroids: Sources and Purity

	Source	Purity[a] (%)	Major contaminant
Sterols			
Campesterol [(24R)-ergost-5-en-3β-ol]	Sigma Chem. Co.	99	None
Cholesterol [cholest-5-en-3β-ol]	Sigma Chem. Co.	99	None
Lanosterol [lanosta-8,24-dien-3β-ol]	Sigma Chem. Co.	≅70	Unknown
Stigmastanol	Sigma Chem. Co.	70	Campestanol (30%)
Stigmasterol I [stigmasta-5,22E-dien-3β-ol]	Sigma Chem. Co.	92	Sitosterol (5%)
Stigmasterol II	Applied Science Labs	98	None
Sitosterol [stigmast-5-en-3β-ol]	Applied Science Labs	97	Campesterol (2%)
Fucosterol [(24E)-stigmasta-5,24(28)-dien-3β-ol]	Steraloids, Inc.	99	None
Ergosterol [ergosta-5,7,22E-trien-3β-ol]	Aldrich Chem. Co.	98	None
Δ^{22}-Stigmastenol [stigmast-22E-en-3β-ol]	*Dictyostelium discoideum*	92	Stigmastanol (8%)
Spinasterol [stigmasta-7,22E-dien-3β-ol]	Spinach leaves	70	Δ^{7}-Stigmastenol (20%)
Brassicasterol [ergosta-5,22E-dien-3β-ol]	*Brassica rapa* seed	94	Sitosterol (4%)
Steryl acetates

purity of the various sterols, steryl esters, steryl acetates and the 3-keto steroid used in this study. Commercially acquired sterols were recrystallized twice from 100% ethanol. Purity was determined by GLC. The 5-dihydro derivative of stigmasterol, Δ^{22}-stigmastenol, and the pentacyclic triterpenoid alcohol tetrahymanol were isolated from amoebae of *Dictyostelium discoideum* (20) and cells of *Tetrahymena pyriformis* (21), respectively. These two compounds were purified by the following series of procedures. (i) Total lipids were extracted from washed cell pellets with chloroform/methanol (2:1, v/v) (11). (ii) The neutral lipid fraction was eluted from a silicic acid column with five column volumes of $CHCl_3$. (iii) After drying on a rotary evaporator, neutral lipids were saponified in 1 N KOH (95% ethanol) in a sealed culture tube under N_2 at 80 C for 2 hr, and the nonsaponifiables were extracted twice with hexane (9). (iv) The hexane extract was dried on a rotary evaporator and the sterols or triterpenoids were recrystallized twice from hot ethanol.

The phytosterols spinasterol ($\Delta^{7,22}$-stigmastadienol) and brassicasterol were isolated from spinach leaves and seed of *Brassica rapa* (rapeseed), respectively. Neutral lipids from these two plant sources were fractionated and saponified as described above in procedures i-iii. The dried nonsaponifiables were dissolved in ethanol and the 3β-hydroxy sterols precipitated with digitonin (13) (Sigma). The washed digitonides were refluxed in acetic anhydride to form steryl acetates (13), which recrystallized upon cooling. A second recrystallization was then performed from hot acetone/ethanol (1:1, v/v).

Without further purification, the steryl acetates from spinach were dissolved in benzene and hydrolyzed with 0.5 N sodium methoxide in dry methanol (18) to yield free sterols (≅70% spinasterol). As brassicasterol composed only ≅10% of the phytosterols from rapeseed oil, further purification was required. This was accomplished through argentation column chromatography (14) (four repetitions) followed by argentation TLC (22). The brassicasteryl acetate obtained by these procedures was 94% pure as determined by GLC and was hydrolyzed to the free sterol as described above for the spinach steryl acetates.

RESULTS

Growth-promoting phytosterols. Eleven 3β-hydroxy sterols, two steryl esters, two steryl acetates, one keto steroid and one pentacyclic triterpenoid alcohol were tested for the ability to support growth of *P. tetraurelia* in monoxenic culture when supplied at 5 μg/ml (Table 2). Six C_{29} phytosterols (stigmasterol, sitosterol, spinasterol, stigmastanol, Δ^{22}-stigmastenol and fucosterol), one C_{28} phytosterol (brassicasterol) and the C_{29} 3-keto steroid $\Delta^{4,22}$-stigmastadienone were found to support growth, enabling ≥5 cell divisions with complete clearing of the *E. coli* suspension. All of these steroids, with the exception of fucosterol, which was not tested, were found to promote growth in axenic culture as well (Table 2). Stigmastanol and Δ^{22}-stigmastenol, both C_{29} with a saturated ring system, were shown for the first time to be growth-promoting sterols. As reported previously (3),

TABLE 2

Uptake and Growth Support of Steroids in Monoxenic (M) and Axenic (A) Cultures of *P. tetraurelia*

Steroid/triterpenoid	Carbon no.	Unsaturation	R at C-24	Uptake		Growth	
				M	A	M	A
Stigmasterol	C_{29}	$\Delta^{5,22}$	α-C_2H_5	+	+	+	+
Sitosterol	C_{29}	Δ^{5}	α-C_2H_5	+	+	+	+
Δ22-Stigmastenol	C_{29}	Δ^{22}	α-C_2H_5	+	+	+	+
Stigmastanol	C_{29}	Δ^{0}	α-C_2H_5	+	+	+	+
Spinasterol	C_{29}	Δ^{7}	α-C_2H_5	+	+	+	+

Tetrahymanol	C_{30}[d]	Δ^{0}	—	+	N.D.	0	N.D.

Uptake of the listed steroids in monoxenic and axenic cultures was determined by coretention with standards on gas liquid chromatography (GLC) following extraction and column fractionation of lipids from washed whole cells (see Materials and Methods). In the case of cholesteryl ester supplementation, the steryl ester column fraction was subjected to alkaline methanolysis followed by GLC analysis of the free sterols yielded by this procedure. The criterion set for growth support (+) by a given steroid in both monoxenic and axenic cultures was completion of ≥5 cell divisions 72-96 hr postinoculation. For monoxenic cultures, this also entailed complete clearing of the *E. coli* suspension. (Note the exception to the criterion set for growth support by campesterol and ergosterol in monoxenic cultures cited in Results.)

[a]N.D., No data.

[c]Free sterol C#.

[d]4,4′-Dimethylpentacyclic triterpenoid alcohol.

stigmasteryl acetate supported growth of *Paramecium* in axenic culture. However, in monoxenic culture this compound repeatedly failed to promote growth.

Uptake and metabolism of non-growth-promoting steroids and triterpenoids. P. tetraurelia in monoxenic cultures supplemented with 1 μg/ml stigmasterol was tested for the ability to take up and metabolize the sterols, sterol derivatives and the pentacyclic triterpenoid tetrahymanol (added at 5 μg/ml), which were found not to support growth (Table 2). These data were not tabulated, but are summarized in the following two paragraphs.

Each of the free sterols, the two steryl acetates and tetrahymanol were taken up readily; they comprised 50–90% of the total steroid/triterpenoid pool. Cholesteryl esters were taken up freely, and cholesterol plus 7-dehydrocholesterol comprised >50% of the free sterol fraction. Also, at the time of harvest ≅30% of the ester in the medium had been hydrolyzed. As cholesteryl esters were not hydrolyzed during autoclaving or during incubation with *E. coli* alone (see Materials and Methods), we assume that the deesterification was performed by *Paramecium*. Ergosteryl acetate was not deacylated, and stigmasteryl acetate was not dehydrogenated to the 7-dehydro derivative.

Non-growth-promoting sterols included cholesterol (C_{27}, Δ^5), lanosterol (C_{30}, $\Delta^{8,24}$, 4,4′,14-trimethyl), campesterol (C_{28}, Δ^5) and ergosterol (C_{28}, $\Delta^{5,7,22}$). The latter two C_{28} sterols initially appeared to support growth in monoxenic culture, but failed to do so in subsequent subcultures. Also, in axenic culture these two sterols clearly failed to promote growth. Campestanol (C_{28}, Δ^0), a 30% contaminant of the Sigma stigmastanol preparation, is presumed not to support growth, based on the data for related C_{28} sterols (Table 2 and ref. 3). Cholesterol, campesterol and campestanol were dehydrogenated to yield the $\Delta^{5,7}$-diene derivatives. Lanosterol and ergosterol were not further dehydrogenated.

Metabolism of growth-promoting phytosterols in monoxenic cultures. Monoxenic cultures of *P. tetraurelia* supplemented with the phytosterols listed in Table 3 were harvested at early stationary phase and analyzed for dehydrogenation and esterification of the supplemental sterols. The Δ^5 sterols stigmasterol, sitosterol, fucosterol and brassicasterol were dehydrogenated at the 7,8 position of the B ring, yielding 7-dehydrostigmasterol, 7-dehydrositosterol, 7-dehydrofucosterol and ergosterol, respectively. Spinasterol, the Δ^7 analog of stigmasterol, was dehydrogenated at the 5,6 position, yielding 7-dehydrostigmasterol.

TABLE 3

Metabolism of Growth-Promoting Phytosterols: Monoxenic Cultures

Monoxenic cultures were supplemented at the indicated concentrations with phytosterols shown to support growth in the previous series of experiments (Table 2). Cultures were harvested at early stationary phase (70–80 hr growth; nearly cleared of *E. coli*, 0.9–1.2 × 10^4 cells/ml). Lipids were extracted from washed whole cells and fractionated by silicic acid column chromatography prior to analysis of the FS and SE fractions. "Major metabolites" column presents the percentage of the total FS fraction represented by dehydrogenated and de-ethylated derivatives of the phytosterol(s) supplemented to the culture medium. "Esterified sterols" column presents the percentage of the total SE fraction represented by fatty acyl esters of both metabolized and unmetabolized phytosterols. Percentages of the various sterols included in the FS and SE fractions were determined by gas liquid chromatography (GLC) aided by mass spectrometry. SE were cleaved by alkaline methanolysis prior to GLC analysis of the sterol composition of this fraction. The total sterol mass in both the FS and SE fractions was quantified by integration of GLC peak areas followed by comparison of these with the peak area of a stigmasterol standard solution of known concentration (1.0 mg/ml in 2,2,4-trimethylpentane). The FS to SE mass ratio was then calculated from the values obtained by this method. (See Materials and Methods for details of culturing and lipid analysis.)

[a]Percentage of the total free sterol fraction (i.e., both metabolized and unmetabolized sterols).

[b]FS:SE, free sterol to steryl ester mass ratio.

The two C_{29} sterols with a saturated ring system, Δ^{22}-stigmastenol and stigmastanol, were dehydrogenated at both the 5,6 and 7,8 positions of the B ring, yielding 7-dehydrostigmasterol and 7-dehydrositosterol, respectively. The 3-keto steroid $\Delta^{4,22}$-stigmastadienone was reduced at the 3 position and hydrogenated at Δ^4 to yield Δ^{22}-stigmastenol. The identity of this metabolite was established by GLC retention time and by the very close match of its mass spectrum with that of Δ^{22}-stigmasten-3β-ol isolated from *Dictyostelium*. As indicated above, stigmastenol was further desaturated at both the 5,6 and 7,8 positions, yielding 7-dehydrostigmasterol.

In monoxenic cultures supplemented with either stigmasterol, Δ^{22}-stigmastenol, fucosterol, stigmastanol plus campestanol or sitosterol, 5,7-diene sterols composed $\cong$25% of the free sterol pool. The percentage of $\Delta^{5,7}$ sterols in the free sterol fraction was somewhat higher ($\cong$38%) in cultures supplemented with either brassicasterol or stigmastadienone. In the latter case, the ketone comprised $\cong$40% of the total steroids, excluding SE. Cultures supplemented with spinasterol had an exceptionally high percentage (>80%) of 5,7-diene sterols, principally 7-dehydrostigmasterol, in the free sterol pool.

In addition to the 5,7-diene sterols produced via dehydrogenation of the Δ^0, Δ^5 or Δ^7 phytosterols supplied in the medium, the free sterol pool of cultures supplemented with any of the C_{29} phytosterols included one of two unknowns (designated as unknowns A and B) in the range of 5–15% of the total. Results of argentation column chromatographic fractionation plus GLC and mass spectral analysis of these unknowns strongly suggest their identification as $\Delta^{5,7,22}$-cholestatrien-3β-ol (unknown A) and 7-dehydrocholesterol (unknown B). These sterols probably are formed via deethylation at C-24 of 7-dehydrostigmasterol and 7-dehydrositosterol, respectively.

The steryl ester fraction from stationary phase monoxenic cultures of *P. tetraurelia* in general comprised a small percentage (between 0.5 and 10%) of the total cellular sterols. The SE pool was largest in cultures supplemented with either stigmasterol or stigmastadienone, where 7-dehydrostigmasterol constituted 80–85% of the esterified sterol and stigmasterol or Δ^{22}-stigmastenol the remaining 15–20%. In cultures supplemented with Δ^{22}-stigmastenol, stigmastanol plus campestanol or sitosterol, the SE pool was 10–20 times smaller. The SE fractions from these cultures contained virtually no 5,7-diene sterols, in contrast to SE of cells grown on stigmasterol or stigmastadienone. In cells grown on brassicasterol (4 μg/ml) or spinasterol (2 μg/ml), SE were negligible. Monoxenic cultures supplemented with fucosterol were not analyzed for SE content. The apparent presence of cholesterol (based solely on GLC retention time) in the SE fraction of cultures supplemented with either Δ^{22}-stigmastenol or sitosterol is puzzling, but could be the result of contamination of the supplemental sterols.

Effect of exogenous sterol supplement on the free sterol composition of whole cells and cilia from monoxenic cultures. Table 4 presents the distribution of both growth-promoting and non-growth-promoting sterols (and their 7-dehydro derivatives) in whole cells and cilia from monoxenic cultures. When one of the three phytosterols stigmasterol, fucosterol or campesterol was added alone to the medium, the ratio of the added Δ^5-sterol to its 7-dehydro derivative was $\cong$3:1 in whole cells compared to $\cong$1:3 in cilia. Thus, as indicated in a previous study (5),

TABLE 4

Effect of Exogenous Sterol Supplement on the Free Sterol Composition of Whole Cells and Cilia: Monoxenic Cultures

Sterol supplement	Conc. (μg/ml)	Major free sterols of whole cells	%[a]	Major free sterols of cilia	%[a]

stigmasterol	0.5	7-Dehydrostigmasterol	4	7-Dehydrostigmasterol	52

Monoxenic cultures were supplemented with either a high concentration of a growth-promoting phytosterol alone, or a high concentration of a non-growth-promoting sterol plus a low concentration of stigmasterol. Cultures were harvested at early stationary phase, and the washed cells were deciliated by a calcium shock procedure modified from that of Adoutte et al. (9). Cell bodies and cilia were analyzed for their free sterol composition by gas liquid chromatography.

[a]Data are intended to show relative proportions of the major sterols. Minor sterols comprise remaining percentages.

[b]Campesterol alone does not promote growth (Table 2), but did support growth well on the first subculture with stigmasterol-grown cells.

$\Delta^{5,7}$-sterols appear to be preferentially introduced into the ciliary membrane.

In experiments in which a "high" concentration of a non-growth-promoting sterol/triterpenoid was included in the medium (cholesterol, ergosterol or tetrahymanol), a low concentration of stigmasterol was also included as the growth-promoting sterol. Under these conditions, the non-growth-promoting compound constituted ⩾70% of the free "sterol" pool of whole cells, and in the cases of ergosterol and cholesterol plus 7-dehydrocholesterol, ⩾75% of the ciliary sterols. In contrast, tetrahymanol replaced less than half of the ciliary sterols (43%), despite a 10-fold excess over stigmasterol in the medium. This result was not surprising in light of the structural differences of tetrahymanol from the C_{27}, C_{28} and C_{29} sterols and the apparent preferential incorporation of $\Delta^{5,7}$-sterols into the ciliary membrane.

As we have found previously (5), only free sterols, and not steryl esters, are found in cilia of both monoxenic cells (Table 4) and axenic cells (data not shown) of *P. tetraurelia* 51S.

Metabolism of growth-promoting phytosterols in axenic cultures. Axenic cultures of *P. tetraurelia* with or without cholesterol (see Materials and Methods) supplemented with the phytosterols listed in Table 5 were harvested at mid-log phase and analyzed for dehydrogenation and esterification of the supplemental sterols. As expected, the level of cholesterol and its 7-dehydro derivative was higher in the free sterol pool of cultures grown on axenic medium containing the higher concentration of cholesterol. Regardless of the cholesterol level or the phytosterol supplement, 5,7-dienes constituted ⩾70% of the free sterols in axenic cultures. This was generally 2–3 times higher than the percentage of $\Delta^{5,7}$-sterols in comparable monoxenic cultures. The level of $\Delta^{5,7}$-sterols was exceptionally high (⩾95%) in axenic cultures supplemented with spinasterol. This was also observed in monoxenic cultures. For each of the eight growth-promoting steroids, the major metabolites were the same in axenic and monoxenic cultures. Thus, Δ^{5}-sterols were 7-dehydrogenated, Δ^{7}-sterol was 5-dehydrogenated, Δ^{0}- or Δ^{22}-sterols were 5,7-dehydrogenated, $\Delta^{4,22}$-stigmastadien-3-one was converted to Δ^{22}-stigmastenol and in turn to 7-dehydrostigmasterol, and there was evidence of deethylation of 7-dehydrostigmasterol to yield $\Delta^{5,7,22}$-cholestatrien-3β-ol.

The SE pool of axenic cultures was far larger than that of equivalent monoxenic cultures, regardless of the phytosterol supplement or cholesterol level. The percentage of total sterols (free plus esterified) in the SE fraction varied with the growth-promoting sterol supplement and the cholesterol level. Cholesterol appeared to promote esterification with some supplements (brassicasterol and spinasterol), but had the opposite effect with others (Δ^{22}-stigmastenol, stigmastanol plus campestanol, and sitosterol). Only in cultures supplemented with stigmasterol was the sterol composition of the SE fraction unaffected by the presence of cholesterol in the axenic medium; 7-dehydrostigmasterol and stigmasterol in a ratio of ⩾2–3:1 comprised >90% of the esterified sterol. For all other phytosterol supplements, axenic cultures grown on high cholesterol medium included this sterol and its 7-dehydro derivative as major constituents of the SE pool, ranging from 44–95% of the esterified sterol. The sterol composition of SE from cultures grown on low cholesterol axenic medium generally resembled the composition of the free sterol pool when the supplements were stigmasterol, Δ^{22}-stigmastenol, sitosterol or stigmastadienone. With either stigmastanol plus campestanol or spinasterol supplementation, the SE fraction of low cholesterol axenic cultures was greatly enriched in unmetabolized (i.e., not dehydrogenated) sterols. This correlated with a high percentage (≅30%) of phytosterol contaminants (mainly campestanol or Δ^{7}-stigmastenol) in these two sterol supplements. In low cholesterol axenic cultures supplemented with 2 μg/ml brassicasterol, cholesterol was the major esterified sterol in the relatively small steryl ester pool.

Fatty acids of steryl esters vs triglycerides from monoxenic and axenic cultures. A comparison was made of the fatty acid profiles of SE vs TG from both monoxenic and axenic cultures with several different phytosterol supplements. In the case of monoxenic cultures (Table 6), the only supplements yielding sufficient SE for a reliable analysis of the fatty acid profile were stigmasterol and stigmastadienone. Analyses of TG fatty acids from monoxenic cultures supplied with Δ^{22}-stigmastenol, stigmastanol plus campestanol, or sitosterol were also performed. The SE and TG fatty acids were compared for axenic cultures supplemented with stigmasterol, sitosterol, spinasterol or brassicasterol. In the case of the latter two phytosterol supplements, analyses were performed for axenic cultures both with and without cholesterol, while for stigmasterol and sitosterol supplements only cultures including cholesterol were analyzed (Table 7).

The major differences in the FAME profiles of SE vs TG from monoxenic cultures (Table 6) were the ratio of the two cyclopropane fatty acids of *E. coli* (9,10-methylene-hexadecanoic acid and 11,12-methyleneoctadecanoic acid) (19), and the proportion of palmitate (16:0) and palmitoleate (16:1). The 17:cyc to 19:cyc ratio was ≅1:5 for SE FAME and ≅1.6:1 for TG FAME in monoxenic cultures supplemented with either stigmasterol or stigmastadienone. Also, the proportion of 16:0 plus 16:1 was twofold higher in triglycerides than in steryl esters. In both SE and TG, *cis*-vaccenate (*cis*-11-octadecenoic acid) was the major fatty acid, ranging from ≅35–48%. The percentage of 18:1(11) in SE vs TG was slightly higher in monoxenic cultures supplemented with stigmasterol and significantly higher in stigmastadienone-supplemented cultures.

As was the case for monoxenic cultures, the percentage of 16:0 was considerably higher (two- to threefold) in TG compared with SE from axenic cultures, regardless of the cholesterol concentration in the medium or the phytosterol supplement (Table 7). Comparable with the data for monoxenic cultures, *cis*-9-octadecenoic acid (oleic acid) was the major fatty acid in both SE and TG of all axenic cultures, ranging from 38 to 57%. For axenic cultures in which cholesterol constituted a large percentage of the esterified sterol, the amount of 18:1(9) was significantly greater in SE vs TG. In contrast, axenic cultures, which included a large percentage of 7-dehydrostigmasterol in the steryl ester pool, had equal levels of 18:1(9) in SE and TG, but also had a significantly greater proportion of polyunsaturated 20-carbon fatty acids in SE, particularly arachidonate (20:4). Thus, there appears to be some

TABLE 5

Metabolism of Growth-Promoting Phytosterols: Axenic Cultures With and Without Cholesterol (≅2 μg/ml)

Cells were grown in Soldo's crude axenic medium supplemented with growth-promoting phytosterols (see Table 2) at the indicated concentrations. One series of cultures contained ≥2 μg/ml cholesterol as a contaminant of the medium (with cholesterol), while in a second series ≥90% of the cholesterol was removed (without cholesterol). Axenic cultures were harvested at mid-log phase (70–80 hr growth; 6–8 × 10^3 cells/ml). Lipids were extracted from the washed cells and fractionated by silicic acid column chromatography. The sterol composition of the free sterol and steryl ester fractions was analyzed by gas liquid chromatography and mass spectrometry. "Major metabolites" presents the percentage of the total free sterol fraction represented by dehydrogenated and deethylated derivatives of the sterol(s) present in the culture medium, while "Esterified sterol" includes fatty acyl esters of both metabolized and unmetabolized sterols. The ratio of free sterols to steryl esters was derived as described in the legend to Table 3.

[a]Percentage of the total free sterol fraction (i.e., both metabolized and unmetabolized sterols).

[b]Free sterol to steryl ester mass ratio.

specificity in the chain length and degree of unsaturation of fatty acids esterified to different sterols in *Paramecium.*

DISCUSSION

Although a number of free-living ciliated protozoans show an enhancement of growth when supplementary sterols are available (23-27), the genus *Paramecium* appears to be unique in the absolute requirement of phytosterols for growth (1-3,28). Species of the related genus *Tetrahymena* are capable of synthesizing the pentacyclic triterpenoid tetrahymanol, which in the absence of supplements fulfills the structural/functional role of sterols in this organism (29,30). A wide variety of 3β-hydroxy sterols and their acetates or fatty acyl esters can be utilized by species of *Tetrahymena,* and their inclusion in the nutrient medium generally both enhances growth and suppresses synthesis of tetrahymanol (24-27,31-36). In contrast, the phytosterol requirement in *Paramecium* is highly specific with respect to molecular structure (3,4). It is the basis of this structural specificity of growth-promoting phytosterols in *Paramecium* that we seek to determine.

The results presented here and elsewhere (4,5) show clearly that selective uptake is not the explanation for growth support by certain phytosterols in *P. tetraurelia.* A second possible explanation for the sterol specificity is a vital interaction with other membrane components that is critically dependent on molecular structure. For the plasma membrane, at least, this does not appear to be the case. In appropriately supplemented cultures of *Paramecium,* ≥75% of the sterol in the ciliary (plasma) membrane can be replaced by cholesterol and its 7-dehydro derivative, or ergosterol (Table 4), with no obvious deleterious effects on cell growth or morphology (5; unpublished observation). The possibility remains that some other subcellular organelle membrane is restricted to include only growth-promoting phytosterols.

A third hypothetical explanation for the sterol requirement of *Paramecium* is that some metabolic product of growth-promoting phytosterols is essential for growth and/or cell division. Previously, the two well-established metabolic products of 3β-hydroxy sterols in *P. aurelia* were the 7-dehydro derivatives of Δ^5 sterols and fatty acyl esters. Data presented in this study indicate that *Paramecium* possesses a Δ^5 steroid ring desaturase in addition to the Δ^7 desaturase, thus enabling the double desaturation of saturated ring phytosterols (e.g., stigmastanol, campestanol and Δ^{22}-stigmastenol). The activity of these two desaturases results in the efficient production of $\Delta^{5,7}$-sterols via dehydrogenation of both growth-promoting and non-growth-promoting Δ^0, Δ^7 and Δ^5 precursors. Although $\Delta^{5,7}$-sterols are preferentially incorporated into the ciliary membrane of *P. tetraurelia* (32) (Table 4), and therefore are apparently optimal to fulfill the structural requirements of the cell membrane, their production may not be linked with the promotion of growth by phytosterols. A pivotal question in this regard is whether brassicasterol ($\Delta^{5,22}$; C-24 β-CH_3) can truly support growth, as its 7-dehydro derivative, ergosterol, clearly cannot. At present, it seems likely that the apparent promotion of growth by brassicasterol is due to low level contamination with sitosterol, and that only C-24 α-ethyl or ethylidene sterols are able to promote growth (4).

The second established metabolic pathway of 3β-hydroxy sterols in *Paramecium,* fatty acyl esterification, has been suggested by Conner et al. (4) to be linked with the promotion of growth by phytosterols. This conclusion

Data indicate the relative percentage of total fatty acids in SE or TG. The fatty acid composition of steryl esters and triglycerides was compared for early stationary phase cells from monoxenic cultures supplemented with either stigmasterol or stigmastadienone at 5.0 μg/ml. These were the only steroid supplements yielding sufficient steryl esters for an accurate analysis of fatty acid composition. For the sake of comparison, the fatty acid composition of triglycerides from monoxenic cultures supplemented with several other phytosterols was also analyzed. The SE and TG fractions were isolated from neutral lipids of whole cells by silicic acid column chromatography. Fatty acids acylated to either sterols or glycerol were transesterified with sodium methoxide to yield FAME for gas liquid chromatographic analysis. (See Materials and Methods for details of lipid analysis.)

Data indicate the relative percentage of total fatty acids in SE or TG. The fatty acid composition of SE and TG was compared for log phase cells from axenic cultures supplemented with different growth-promoting phytosterols at the indicated concentrations. In the first series of experiments the axenic medium contained ⩾2 μg/ml cholesterol as a contaminant (with cholesterol), while in the second series ⩾90% of the cholesterol was removed from one pair of cultures supplemented with either brassicasterol or spinasterol (without cholesterol). The SE and TG fractions were isolated from neutral lipids of whole cells by silicic acid column chromatography. Fatty acids acylated to either sterols or glycerol were transesterified with sodium methoxide to yield FAME for gas liquid chromatographic analysis. (See Materials and Methods for details of culturing and lipid analysis.)

was based on the results of a study comparing the metabolism of stigmasterol and cholesterol in *P. aurelia*. Growth-promoting stigmasterol and 7-dehydrostigmasterol were esterified, while non-growth-promoting cholesterol and 7-dehydrocholesterol were not. We have confirmed this result for axenic cultures of *P. tetraurelia*, but have also shown that in cultures supplied with cholesterol and a growth-promoting phytosterol other than stigmasterol, fatty acyl esters of cholesterol and 7-dehydrocholesterol can compose >90% of the SE pool. Thus, selective esterification of only growth-promoting phytosterols does not occur. Furthermore, the fatty acid profiles of cholesteryl and stigmasteryl esters from axenic cells were similar, both predominated by the essential fatty acid 18:1(9). Although it appears unlikely at present, it is still possible that fatty acyl esters of growth-promoting phytosterols perform some specialized, vital role in the fatty acid metabolism of *Paramecium*. It seems more probable, based on the data presented here, that steryl esters in *Paramecium* may serve the threefold purpose of storing growth-promoting sterols when they are abundant in the medium, storing essential or useful fatty acids in a nontoxic form and sequestering non-growth-promoting sterols when they are abundant relative to growth-promoting sterols. The last of these functions has been described in the yeast *Saccharomyces cerevisiae* (37,38). The detection of SE in the ciliary membrane of *P. tetraurelia* has recently been reported by Kaneshiro et al. (39). We were unable to confirm this, finding only free sterols as we reported previously (5).

In addition to fatty acyl esterification and 5,6 and/or 7,8 dehydrogenation of 3β-hydroxy sterols, two other facets of sterol metabolism in *Paramecium* were indicated in the course of this work. Data supporting the conclusion that 7-dehydrostigmasterol and 7-dehydrositosterol can be deethylated by *P. tetraurelia* to yield $\Delta^{5,7,22}$-cholestatriene and 7-dehydrocholesterol, respectively, were obtained by GLC, ultraviolet and mass spectrometric analyses (data not shown). Deethylation of phytosterols at C-24 has been demonstrated previously in *Tetrahymena* (40,41), which preferentially incorporates $\Delta^{5,7,22}$-cholestatriene into the ciliary membrane (42). However, the role of this metabolic pathway in *Paramecium* is uncertain, as it results in the conversion of growth-promoting precursors to non-growth-promoting products (4). The anomalous growth support of *P. tetraurelia* by $\Delta^{4,22}$-stigmastadien-3-one has been explained with the demonstrated conversion of this 3-keto steroid to Δ^{22}-stigmastenol, which necessarily entails the reduction of the 3-keto to 3β-hydroxy group and the saturation of the 4,5 double bond. Similar metabolism of a Δ^{4},3-keto steroid has been demonstrated in *Tetrahymena furgasoni* (43).

In summary, the basis of the growth requirement for specific phytosterols in *Paramecium* does not appear to be related to the structural/functional role of sterols in cell membranes. Nor is there any evidence to suggest a link between the major metabolites of sterols in *Paramecium* (i.e., fatty acyl esters and dehydrogenated or deethylated derivatives) and the ability of their precursors to support growth. Recent experiments in this laboratory have shown that cholesterol can spare the requirement for stigmasterol in *P. tetraurelia* if one supplies the latter at a subsupportive concentration (manuscript to be submitted) (Table 4). When cholesterol is provided

at 1.0 μg/ml, the required threshold level of stigmasterol is ≅0.015-0.020 μg/ml in both axenic and monoxenic cultures (manuscript to be submitted). In cells grown to stationary phase with this ratio of cholesterol to stigmasterol, there is virtually no stigmasterol or 7-dehydrostigmasterol in the ciliary membrane. Thus, the "bulk" sterol requirement for membrane biosynthesis in *Paramecium* can be satisfied by the non-growth-promoting sterol cholesterol and its 7-dehydro derivative. Similar results have recently been reported in *Saccharomyces cerevisiae* for both sterol-deficient mutants (44) and anaerobic wild-type cultures treated with an inhibitor of sterol biosynthesis (45,46). An absolute requirement for traces of a Δ^5; C-24, β-methyl; 3β-hydroxy sterol has been demonstrated for this yeast, although a wide variety of sterols can fulfill the "bulk" membrane requirement (44-46). Finally, Guyer and Bloch (27) have recently found that ergosterol can stimulate growth of *Tetrahymena setosa* at a concentration well below that required to inhibit synthesis of tetrahymanol. They conclude that the trace amounts of sterol needed by *T. setosa* do not serve to replace tetrahymanol in membranes, but function in some other manner, perhaps metabolic.

In light of these data, it appears that in *Saccharomyces*, *Paramecium* and *Tetrahymena setosa* there are at least two roles for cellular sterols. The first of these is the structural/functional role in cell membranes, which is quite nonspecific. The second, perhaps "hormonal," role is much more specific with regard to molecular structure and requires a relatively small amount. It remains to be determined exactly what function this minor sterol component serves and whether it is the growth-promoting sterol per se, or some minor metabolite as yet undetected, that carries out this function.

[Received June 9, 1986]

Electron Microscopic Cytochemistry of Cyclopropenoids in Cottonseed (*Gossypium hirsutum* L.) Tissues

L.Y. Yatsu[*,a] **and H.W. Kircher**[1,b]

[a]Southern Regional Research Center, New Orleans, Louisiana, and [b]Department of Agricultural Chemistry, University of Arizona, Tucson, Arizona

An electron microscopic cytochemical procedure for locating cyclopropenoids (CYP) in oilseeds is proposed. The procedure is based on the fact that metallic silver is produced when $AgNO_3$ reacts with CYP. Since so many other compounds react with $AgNO_3$, we treated specimens that do and do not contain CYP with $AgNO_3$ and looked for electron-dense stains that were unique to CYP(+) seeds. Virtually everything in all seed specimens, regardless of the presence or absence of CYP, was stained. However, cottonseeds contained two additional staining constituents not found in controls: (i) certain large, intracellular droplets, and (ii) the cuticles, both occurring exclusively in the axial organs. Extraction of the specimens with ether abolished the stainability of the droplets but did not affect cuticles. Arguments for the validity of the test are presented.
Lipids 22, 397-400 (1987).

Cottonseeds contain 30–35% oil, 0.6–1.1% of which is cyclopropenoid fatty acids (1). This small quantity of cyclopropenoid (CYP), however, can cause highly deleterious and undesirable results if ingested by animals. For instance, lard from pigs becomes hard (2), butter from cows becomes sticky and its melting point is raised higher than normal (3) and whites of chicken eggs turn pink in storage (4). CYP also causes elevated plasma and liver cholesterol levels in laboratory animals and a higher incidence of aortic atherosclerosis than normal (5). It causes growth to be stunted when fed in moderate amounts and death when fed in higher amounts (6). CYP acts as a synergist for the carcinogen aflatoxin (7) and has proved to be a carcinogen itself (8). Therefore, although the level of CYP in commercial cottonseed oil is not toxic to humans, and there are many methods of destroying or removing it (9), interest in all aspects of this compound continues. One of the things cottonseed processors have wanted to know is where in the seed CYP is stored.

Fisher and Cherry (10) conducted a histochemical study of cottonseed to find where CYP are stored. They excised various parts of the seeds, extracted the parts with ether and analyzed the ether extracts by gas liquid chromatography. They found the bulk of the ether-extractable cyclopropenoid fatty acids of cottonseed in the axial organs and very little in the cotyledons. More recently, Wood (11) stated that cyclopropenoid fatty acids of cottonseed are located almost exclusively, *if not* totally, in the hypocotyls.

Our task was to find the cytological location of CYP. The procedure that we devised was based on the fact that $AgNO_3$ reacts with CYP to produce metallic silver. Our strategy was to stain both CYP(+) and CYP(−) seeds with $AgNO_3$, then to search for electron dense deposits in CYP(+) seeds that were not in CYP(−) control seeds. Two $AgNO_3$-staining sites were found in cottonseed (both in the axial organs) that were absent from control seeds. They were (i) certain large intracellular droplets and (ii) the cuticle of the epidermal cells. The droplets did not stain after specimens were extracted with ether, but cuticle stainability persisted. We do not yet know the chemistry of the cuticular material but conclude that $AgNO_3$-reactive lipids are stored in the droplets.

MATERIALS AND METHODS

Cottonseeds were soaked in 2% glutaraldehyde/0.05 M cacodylate buffer, pH 7.0, until soft and pliable; axial organs and cotyledon tissues were excised. The excised specimens were fixed in fresh fixative overnight and serially dehydrated in aqueous ethanols to the 80% ethanol level. Two sets of controls were used: seeds that do not have CYP (e.g., peanut and squash) and cottonseed tissue that was extracted with ether.

Artificial "spherosomes" were prepared as before (12). Briefly, vegetable oils and phospholipids were emulsified in water with a Branson sonicator. A 2% solution of agar was boiled, cooled to 45–40 C and mixed with an equal volume of emulsion (warmed to 40–45 C), then centrifuged. The cream layers on the tops of the centrifuge tubes, immobilized in agar, were cut into specimen-sized pieces and dehydrated serially to 80% alcohol. *Sterculia foetida* oil (13) was used to make CYP-containing spherosomes and peanut and soy oils were used to make control spherosomes.

Spherosomes were harvested from cottonseed axial organs and cotyledon tissues. Cottonseeds were soaked in water briefly (until softened), and respective organs were excised. Each sample was ground in a mortar and pestle with water and fine sand. The homogenates were centrifuged, and the fatty layers were collected for study. (In later studies, the entire operation was conducted at ice temperatures to slow metabolism (14) and to thicken the triglycerides, in hopes of preserving the fat droplets.) Samples for light microscopy were placed on a slide and viewed as is. Specimens to be viewed in an electron microscope were treated in the same manner as with artificial spherosomes above.

CYP cytochemistry was conducted on specimens serially dehydrated to 80% ethanol. The samples were placed into a staining solution of 80% saturated $AgNO_3$ dissolved in 95% ethanol and incubated at 65 C for 4 hr. After incubation, specimens were rinsed thoroughly with 95% ethanol, transferred to acetone and embedded in Spurr's epoxy resin. Thin sections were cut on a Porter-Blum MT-2 ultramicrotome with a diamond knife and viewed in a Philips EM-200 electron microscope. We refrained from using metallic fixatives or stains to avoid confusion with stains imparted by $AgNO_3$. Control tissues were treated in the same manner.

RESULTS AND DISCUSSION

Almost a hundred years ago it was noted that cottonseed oil reacts with $AgNO_3$. This information was used as the

basis for a test to detect cottonseed oil adulteration of olive oil (15). More recently, Kircher (16) showed that brown spots that developed on his lipid chromatograms when sprayed with alcoholic $AgNO_3$ were due to the reaction between $AgNO_3$ and the CYP moiety of sterculic acid. Oxidation of CYP was coupled to the reduction of $AgNO_3$ to form metallic silver. We wondered if this reaction would take place in situ in biological tissues; if so, could $AgNO_3$ serve as an electron microscopic cytochemical stain for CYP?

Because neutral lipids extracted from cottonseed meals contain CYP (1,10,11,17) and the storage site of neutral lipids in cottonseed is in intracellular fat droplets, or spherosomes (18), our first guess was that the CYP fatty acids would be found in spherosomes. In a preliminary feasibility test, artificial spherosomes (emulsion droplets) were stained with alcoholic $AgNO_3$ and examined in an electron microscope. Triglyceride droplets maintained their integrity in a 95% ethanolic stain carrier. No electron-dense stains were observed within or upon peanut or soy oil droplets (which do not have CYP), but myriad of electron-dense particles were seen on the surfaces of *Sterculia foetida* oil droplets (which do have CYP). $AgNO_3$ is hydrophilic and CYP-triglyceride is hydrophobic, so the reaction took place where the two phases meet—at the surface of the droplets.

Cottonseed specimens, which were a light cream color, turned to various shades of brown, depending on the

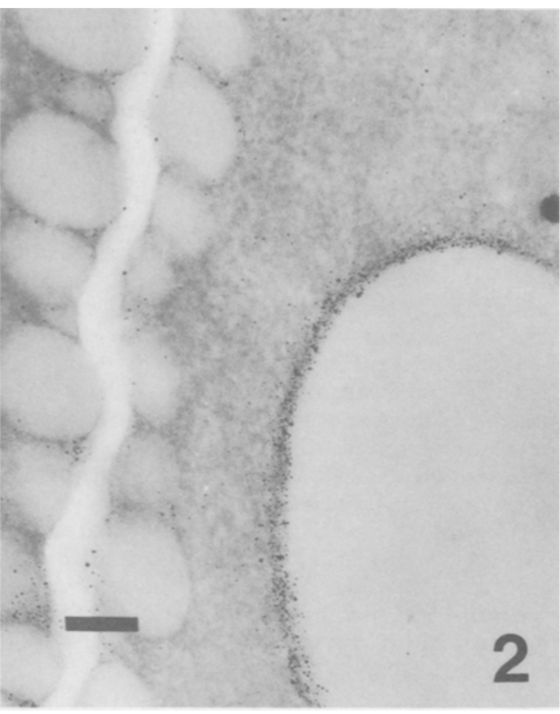

FIG. 2. A portion of Fig. 1 at higher magnification. Notice that the dark fringe around the droplet is actually a mass of fine, electron-dense specks. Although the diameter of the large droplet is only 3 to 10 times that of ordinary spherosomes, the volume is on the order of 27 to 1000 times. Bar indicates 0.5 μ.

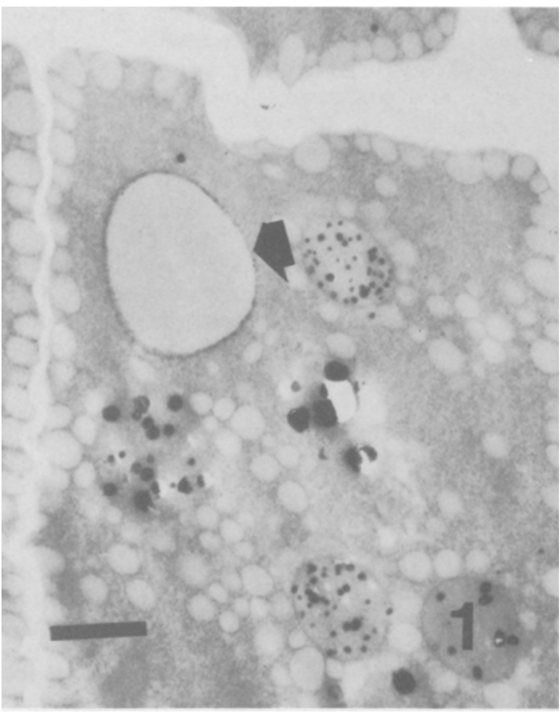

FIG. 1. Low magnification electron micrograph showing a portion of a cottonseed axial organ cell stained with $AgNO_3$. Note the large droplet in the upper left-hand corner of the cell with a dark fringe (large arrow); the large droplets are 3 to 10 times as large as ordinary spherosomes. This type of droplet and the cuticles stained in cottonseeds but not in controls. Another heavily staining site—the globoids in the protein bodies—is also visible. Globoids are not exclusive to cottonseeds. Bar indicates 2 μ.

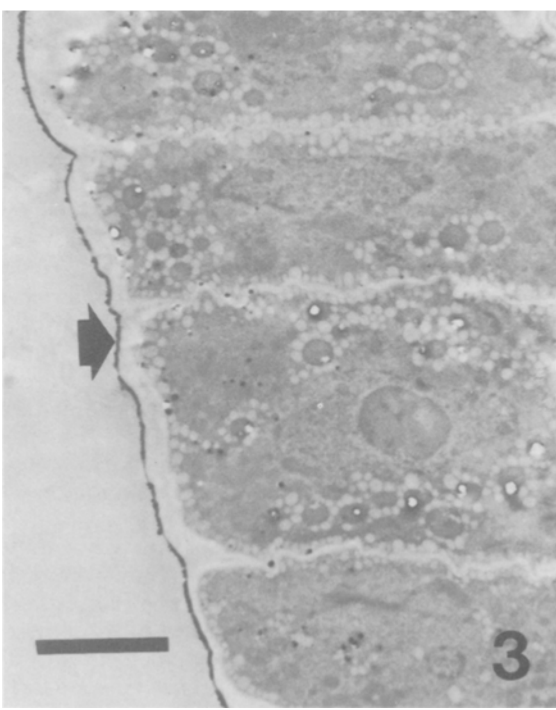

FIG. 3. Low magnification electron micrograph of some epidermal cells on a cottonseed axial organ. Note the dense deposition of silver on the cuticle (large arrow). Organelles are difficult to discern. The nucleolus and chromatin material of the nuclei and the aleurone grains tend to be slightly darker than the groundplasm of the cell. Some aleurone grains have holes at sites formerly occupied by globoids (see Fig. 1). Bar indicates 5 μ.

organ, when immersed in alcoholic $AgNO_3$. Axial organs turned brown quickly (within minutes), with colors ranging from light to very dark brown. The radicular region generally stained darkest; the tips (root caps) often remained much lighter. Interestingly, the outer surfaces of the axial organs often acquired a metallic sheen after $AgNO_3$ treatment. Cotyledons remained a light cream color for a long time, but eventually turned light tan.

Because silver nitrate reacts with most biologically important compounds (19–22), the strategy used in this study was to treat seeds that do and do not contain CYP with $AgNO_3$ and to look in CYP(+) seeds for electron-dense stains that were absent from CYP(−) seeds. Virtually all cytoplasmic elements were stained by alcoholic $AgNO_3$, regardless of the presence or absence of CYP. The cytoplasmic ground substance in all seeds examined was lightly stained with silver (Figs. 1–3); aleurone grains stained slightly darker. Nuclear ground plasma was weakly stained, with the nucleolus and chromatin material staining somewhat stronger. Ordinary spherosomes (in contrast to the large droplets discussed below) were *electron lucent with no* electron-dense stains within or upon the droplet surfaces. Cell walls were essentially unstained. Globoids, a notable exception, were stained very heavily (the chelation product of silver by phytic acid). Membranes were not stained by $AgNO_3$ (as they are with OsO_4 or permanganate); in fact, they often appeared in negative contrast. Consequently, organelles were difficult to discern (Figs. 1 and 3). We tried the $AgNO_3$ test on OsO_4-fixed cottonseed tissue but it did not work satisfactorily. OsO_4 not only caused the unsaturated lipids to turn black and smeary but, more importantly, caused numerous extraneous electron-dense deposits to appear when poststained with $AgNO_3$.

Three $AgNO_3$-staining sites were found in cottonseeds that were not present in control seeds. One site, the pigment gland, has already been eliminated as a site of CYP storage in cottonseeds (23). The stains in the glands were due to the reaction of silver ions with gossypol and/or related polyphenolic compounds (24). The other two sites, both in the axial organs, were (i) certain intracellular droplets and (ii) the cuticles of the epidermal cells. Droplets that stained with $AgNO_3$ had the same electron-density as ordinary spherosomes but were much larger, and tended to be embedded in or associated with cytoplasmic ground substance (Fig. 1). Silver particles that deposited on the surfaces of these large droplets were very small and fine compared to the large and coarse particles seen on the surfaces of *S. foetida* oil droplets. This may have been due to the fact that emulsion droplets have no membranes, whereas spherosomes are bounded by a "half unit membrane" (25), or perhaps because *S. foetida* oil has such a high concentration of CYP (13). Morphologically similar droplets in the axial organs of ether-extracted cottonseeds did not stain with $AgNO_3$, suggesting that a $AgNO_3$-reactive neutral lipid was extracted from the droplets.

Authentic spherosomes extracted from cottonseed axial organs turned yellow-brown when treated with $AgNO_3$, but spherosomes extracted from cottonseed cotyledons remained white. Light microscopic examination of $AgNO_3$-treated axial organ spherosomes showed patches of yellow-brown scattered about in the field, indicating that $AgNO_3$ reactivity was not uniformly distributed among all the fat droplets. We did not find the large droplets (seen in situ) in the isolated spherosome preparations. Instead, the size of the droplets varied widely and electron-dense grains, which were not on all droplets, were large and course (like those seen in the *Sterculia foetida* emulsions). We believe that the large droplets in the axial organs were broken during homogenization. The use of sand or cold temperatures did not seem to help preserve the integrity of the large droplets.

The outer surfaces of the epidermal cell walls (cuticles) were stained heavily with silver. Unlike with the droplets, ether extraction did not abolish the stainability of the cuticular material. We do not yet know the chemical composition of the $AgNO_3$-reactive substance, but because of its insolubility in hexane and apparent insolubility in $CHCl_3$/methanol, it cannot be a neutral lipid and is probably not a phospholipid (26,27). The copious deposits of metallic silver on the surfaces of the axial organs explain the metallic sheen we observed on the surfaces of $AgNO_3$-treated cottonseed axial organs.

Considerable evidence, albeit circumstantial, has been amassed in this study to indicate that CYP-neutral lipids of cottonseeds are located in certain large-sized droplets found in cells of the axial organs. Firstly, vegetable oils that react with $AgNO_3$ to produce a yellow-brown pigment and metallic silver are highly unusual (the only ones we are aware of are CYP lipids). These reactions took place in spherosome fractions extracted from cottonseed axial organs but not in those isolated from CYP(−) control seeds. Certain droplets that were most numerous in the radicular regions of the axial organs (in the same general area of the seeds where Fisher and Cherry [10] found the highest concentration of ether-extractable cyclopropenoid fatty acids) stained with alcoholic $AgNO_3$. Extraction of the tissues with ether abolished the stainability of the droplets. Therefore, we believe that the CYP lipids of cottonseeds are located in the large droplets in seed axial organs.

The results of this study also suggest that a heterogeneous population of lipid droplets exists in cottonseeds (one group that reacts with $AgNO_3$, the other that does not). However, if lipids are synthesized in a central location, e.g., plastids (28), and subsequently are dispersed to fat droplets, it seems reasonable to expect the lipid complement of the various droplets to be rather homogeneous. Because this does not seem to be the case in cottonseeds, CYP lipids must have special synthetic (not necessarily de novo) and storage processes. We wonder whether unusual lipids in other plants are also housed in special droplets. The sequestration of CYP lipids in special droplets answers how cottonseeds are able to synthesize unsaturated fatty acids in spite of the presence of CYP, a fatty acid synthetase inhibitor (29).

To recapitulate, we showed that a silver precipitate (not found in non-CYP seeds) occurred in certain large droplets and cuticles of cottonseed axial organs after alcoholic $AgNO_3$ treatment. The highest incidence of silver-reactive droplets was found in the same location where Fisher and Cherry (10) found the highest concentration of ether-soluble CYP. We found no evidence for such deposits in the cotyledons. Fisher and Cherry (10) found very little CYP in cotyledons, and Wood (11) suggested that there is no CYP in cotyledons. We show that $AgNO_3$ can be a useful tool in cytochemical studies of CYP; however, because reaction with $AgNO_3$ is not the exclusive domain of CYP, caution should be exercised in interpret-

ing such tests. We do not yet know the chemical nature of the $AgNO_3$-reactive substance in the cuticles, but as Halloin (30) suggested, one of the functions of CYP in cottonseeds may be protective, and we cannot rule out the possibility that the $AgNO_3$-reactive substance in the cuticles might be a cyclopropenoid. It will be recalled that high concentrations of CYP have also been reported in the axial organs of the durian seed (31) and in the seeds and roots (but not in the other parts, such as leaves, stems or trunk wood) of *Ceiba pentandra* and *S. foetida (32)*.

Lipid Peroxidation in Erythrocyte Membranes: Cholesterol Product Analysis in Photosensitized and Xanthine Oxidase–Catalyzed Reactions

Albert W. Girotti*, **Gary J. Bachowski** and **John E. Jordan**
Department of Biochemistry, Medical College of Wisconsin, Milwaukee, WI 53226

The effects of singlet oxygen- and oxygen radical–induced lipid peroxidation on cell membrane integrity were compared, using the human erythrocyte ghost as a model system. Resealed ghosts underwent lipid peroxidation and lysis (release of trapped glucose-6-P) when irradiated in the presence of uroporphyrin (UP) or when incubated with xanthine (X), xanthine oxidase (XO) and iron. The UP-sensitized process was inhibited by azide but not by phenolic antioxidants, consistent with singlet oxygen (nonradical) involvement. This was confirmed by showing that the predominant photoproduct of membrane cholesterol was the 5α-hydroperoxide. Total hydroperoxide (LOOH) content in UP-photooxidized ghosts increased linearly during the prelytic lag and throughout the period of rapid lysis. Unlike the photoreaction, X/XO/iron-dependent peroxidation and lysis was inhibited by catalase, superoxide dismutase and phenolic antioxidants, indicating O_2^-/H_2O_2 intermediacy and a free radical mechanism. Correspondingly, only radical reaction products of cholesterol were formed, notably the 7α-,7β-hydroperoxide pair. Membrane lysis had a distinct lag as in photooxidation; however, the LOOH profile was more complex, with an initial lag followed by a sharp increase and then slow decline. X/XO/iron-induced lysis commenced when LOOH levels were 2–3 times higher than in photosensitized lysis, suggesting that the pathways of membrane lesion formation are different in the two systems. In low concentrations, ascorbate exacerbated the damaging effects of photoperoxidation, switching the reaction from primarily singled oxygen- to oxygen radical–dependence, as indicated by cholesterol product analysis.
Lipids 22, 401–408 (1987).

Peroxidative degradation of unsaturated phospholipids and cholesterol in biological membranes is known to be deleterious to membrane structure and function. Lipid peroxidation can be triggered by partially reduced oxygen species (superoxide, O_2^-; hydrogen peroxide, H_2O_2; or hydroxyl radical, $OH^\cdot$) generated by oxidase-catalyzed reactions, autoxidation of electron donors (e.g., ascorbate and thiols), ionizing radiation and various other processes. Redox metals often play a role in initiating this type of peroxidation, which is then propagated by alkoxyl or peroxyl radical intermediates (1,2). Singlet molecular oxygen ($^1O_2$), typically generated by energy transfer from excited state dyes or pigments, also oxidizes unsaturated lipids. However, $^1O_2$ attacks directly via the "ene" mechanism, and free radical intermediates are not necessarily involved (3). Although both types of lipid peroxidation have been studied extensively in various model and natural systems, little is known about their relative damaging effects on any particular target membrane. Using resealed erythrocyte ghosts as a test system, we investigated this by tracking degree of lysis as a function of peroxide content in ghosts exposed to xanthine/xanthine oxidase as a source of oxygen radicals and to photoexcited uroporphyrin as a source of $^1O_2$. Definitive evidence for the involvement of these species was obtained by identifying specific oxidation products of cholesterol. Cholesterol product analysis was also used for probing mechanistic changes that occur during photooxidation of ghosts in the presence of ascorbate (4).

Abbreviations—PBS: phosphate-buffered saline (25 mM sodium phosphate, 125 mM NaCl, pH 7.4); LOOH: lipid hydroperoxide; BHT: butylated hydroxytoluene (2,6-di-t-butyl-4-methylphenol); DTP: 2,6-di-t-butylphenol; 5α-OOH: 3β-hydroxy-5α-cholest-6-ene-4-hydroperoxide; 5α-OH: 5α-cholest-6-ene-3β,5-diol; 7α-OOH: 3β-hydroxycholest-5-en-7α-hydroperoxide; 7β-OOH: 3β-hydroxycholest-5-en-7β-hydroperoxide; 7α-OH: cholest-5-en-3β,7α-diol; 7β-OH: cholest-5-en-3β,7β-diol; G6P: glucose-6-phosphate; TMPD: N,N,N′,N′-tetramethyl-p-phenylenediamine; AH⁻: ascorbate; UP: uroporphyrin I; PP: protoporphyrin IX.

MATERIALS AND METHODS

Materials. Freshly drawn human blood was obtained from the Blood Center of Southeastern Wisconsin (Milwaukee, WI) and used within two weeks. Uroporphyrin I (UP) and protoporphyrin IX (PP) were purchased from Porphyrin Products (Logan, UT); absorption spectral characteristics agreed with those previously reported for these porphyrins (5). Xanthine oxidase (grade III), glucose-6-phosphate (G6P) dehydrogenase (type VII), thymol-free catalase and Cu/Zn-superoxide dismutase were obtained from Sigma Chemical Co. (St. Louis, MO), as were xanthine, NADP, D-G6P, butylated hydroxytoluene (BHT), cholesterol, 3β-hydroxycholest-6-en-7-one (7-ketocholesterol) and egg yolk phosphatidylcholine. N,N,N′,N′-tetramethyl-p-phenylenediamine (TMPD), 2,6-di-t-butylphenol (DTP) and 2-thiobarbituric acid (TBA) were from Aldrich Chemical Co. (Milwaukee, WI), and sodium ascorbate (>98%) was from BDH Chemicals (Poole, England). All other chemicals were of highest purity available, and all aqueous solutions were prepared with deionized, glass-distilled water.

Resealed erythrocyte ghosts containing G6P as an encapsulated marker of membrane integrity were prepared as described previously (6). Unsealed ghosts were prepared by conventional hypotonic lysis, followed by washing and concentration in a Millipore-Pellicon tangential flow system (7). Stock membrane suspensions were blanketed with N_2 during storage at 4 C and typically were used within one week. Membrane protein was determined by the method of Lowry et al. (8).

Experimental conditions. Irraditions were carried out in matched, thermostated beakers (45-mm inner diameter) or in vials (20-mm diameter) inserted into 4-place Stirrer Baths (Yellow Springs Instruments, Yellow Springs, OH). Stirred suspensions of well-washed membranes, typically 1.8 × 10^9 ghosts (1 mg protein)/ml in

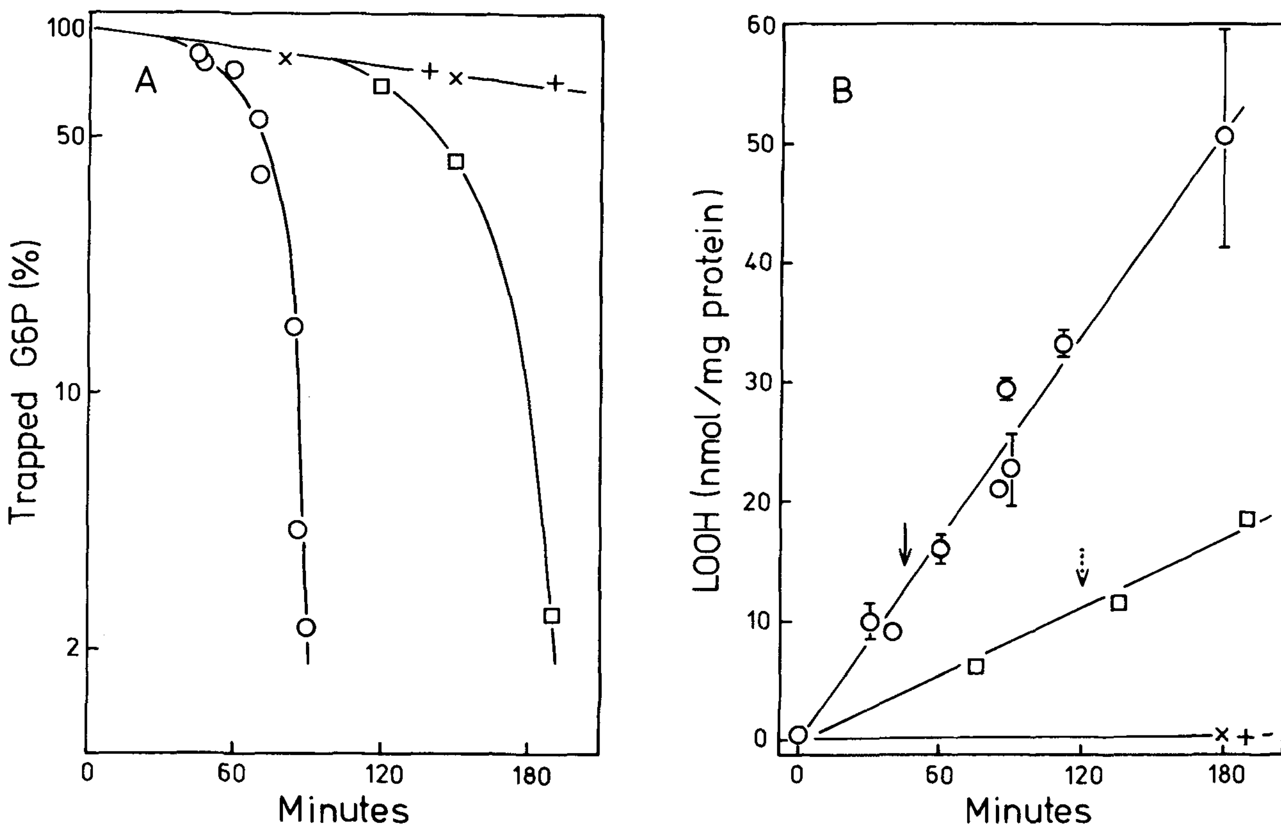

FIG. 1. Uroporphyrin (UP) photosensitized lipid peroxidation and lysis of resealed ghosts. Ghosts (1.0 mg protein/ml in PBS at 37 C) were irradiated continuously in the presence of 2μM UP (□) and 10 μM UP (○). The fluence rate at the suspension surfaces was 20 mW/cm^2. The dark controls contained 2 μM UP (+) and 10 μM UP (×). (A) Membrane lysis, as measured by release of trapped glucose-6-phosphate (G6P); (B) Lipid peroxidation, measured in terms of total hydroperoxide (LOOH) content. Error bars show means ± deviations of values from duplicate determinations. LOOH level at approximate time of incipient lysis is indicated by dotted arrow for 2 μM UP and solid arrow for 10 μM UP.

phosphate buffered saline (PBS; 25 mM sodium phosphate, 125 mM NaCl, pH 7.4), were sensitized with UP or PP and irradiated with broad band blue light as described previously (4). Fluence rate near the suspension surfaces was measured with a Yellow Springs radiometer. Unless indicated otherwise, reactions were run at 37 C. Enzymatic oxidations in the presence of xanthine, xanthine oxidase and iron were carried out as specified earlier (6). Azide was typically included to inactivate any residual catalase in the membranes; it was omitted when catalase was added diagnostically. Samples were removed periodically from reaction mixtures to assess lipid peroxidation (see below) and membrane lysis. Reactions were terminated by adding allopurinol to xanthine oxidase–containing samples and by keeping irradiated samples in the dark. Lysis of resealed ghosts was measured in terms of enhanced G6P efflux (6). Following rapid centrifugation (1–3 min after sampling), the marker was determined by coupling its G6P dehydrogenase–catalyzed oxidation to the reduction of NADP (A_{340}).

Quantitation of lipid peroxidation. Total lipid hydroperoxide content in oxidized membranes was determined iodometrically, using cumene hydroperoxide as the standard (9). Peroxidation of unsaturated lipids (except cholesterol) was also assessed by TBA assay in which malonaldehyde and other carbonyl by-products of peroxide decomposition react with TBA to produce colored adducts absorbing maximally at 532 nm. BHT was included to minimize autoxidation of unreacted lipids during the assay. Other details were as described earlier (6).

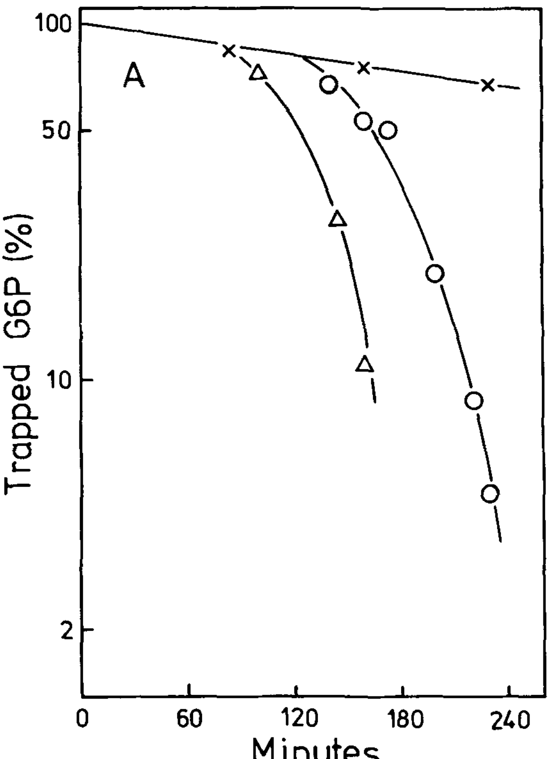
Chromatography of cholesterol oxidation products. Cholesterol products in photooxidized and xanthine/xanthine oxidase–treated membranes were analyzed by thin layer chromatography (TLC). The approach was adapted from previously published methods (10,11). Aliquots of 0.5 ml (0.45 mg total lipid) from reaction mixtures were mixed with 5 μl of 20 mM EDTA and extracted with 0.8 ml of chloroform/methanol (2:1, v/v) in polypropylene microfuge tubes. Retention of chelated iron in the aqueous phase minimized the possibility of hydroperoxide degradation during isolation. (Manipulations were done in subdued light when photosensitizers were present.) After centrifugation, 0.4 ml of the organic phase was transferred to a second microfuge tube. Reduction of the hydroperoxides to their relatively stable alcohols was accomplished by adding 25 μl of 40 mM $NaBH_4$ in methanol/10 mM NaOH. After 15 min incubation at room temperature, the solvent was evaporated by heating at 50 C under nitrogen. Up to three identical 0.4-ml samples (ca. 0.24 mg cholesterol) were combined during this step and stored at -20 C until analyzed. Borohydride reduction of 7-ketocholesterol yielded the epimeric 7α- and 7β-alcohols, which were used as standards. Each residue was dissolved in 10 μl of chloroform/methanol, applied to a Silica Gel-60 plate (EM Science, Cherry Hill, NJ) and chromatographed,

using heptane/ethyl acetate (1:1, v/v) as the solvent system. A single irrigation gave a satisfactory separation of the 5α-, 7α- and 7β-alcohols. Phospholipids remained at the origin in this system and therefore did not interfere with cholesterol product identification. After chromatography, plates were sprayed with 50% sulfuric acid and warmed briefly at 100 C to accelerate color development. In addition to cholesterol diols, partially separated hydroperoxide precursors (in nonreduced samples) could be detected; however, TMPD proved a more sensitive indicator for the latter. Immediately after color development, plates were photographed and in some instances scanned densitometrically, using a Hoefer instrument set in the reflectance mode.

RESULTS

Photosensitized vs oxidase-catalyzed lipid peroxidation and lysis. Resealed erythrocyte ghosts were studied as a model system for comparing the membrane-damaging effects of lipid peroxidation due to singlet oxygen and oxygen radical attack. Photoactivated UP was used as a source of $^1O_2$ (4), while xanthine oxidase acting on xanthine in the presence of iron was used as a source of O_2^-, H_2O_2 and other forms of partially reduced oxygen (6). Neither UP nor xanthine oxidase interact with the membrane, so that reactive species are initially generated in the medium rather than in the membrane per se. Time courses of lipid peroxidation (total lipid hydroperoxide [LOOH] formation) and lysis (accelerated release of G6P marker) were compared. Previous studies showed that increased G6P permeability under conditions of oxidative stress is correlated with lipid peroxidation damage (6,9,11). As shown in Figure 1A, continuous irradiation of UP-sensitized ghosts caused lysis after a lag period, the length of which depended on the porphyrin concentration. Dark or light controls containing or lacking porphyrin, respectively, released marker at the basal rate (5–10% per hr). LOOH content increased linearly throughout photooxidation, with no apparent lag (Fig. 1B). The threefold increase in rate upon going from 2 to 10 μM UP is approximately equal to the decrease in lag time to incipient lysis. At both concentrations of UP, lysis began when the LOOH level reached 11–13 nmol/mg protein (12–14 nmol/mg lipid).

The situation with xanthine/xanthine oxidase was more complex. Lysis commenced after a 2-hr lag, which could be shortened by adding H_2O_2 (0.1 mM) at the outset (Fig. 2A). Previous studies showed that lytic effects in this system are stimulated by iron and prevented by superoxide dismutase, catalase and chelators (e.g., EDTA, desferrioxamine), signifying O_2^- and H_2O_2 involvement via the iron-catalyzed Haber-Weiss cycle (6). On the other hand, photosensitized lysis by UP or PP showed no significant iron dependency and was not inhibited by catalase or superoxide dismutase (4,9). In contrast to photosensitized lipid peroxidation (Fig. 1B), xanthine/xanthine oxidase/iron-driven peroxidation showed a definite lag, which was shortened by supplementing with H_2O_2 (Fig. 2B). LOOH only began to accumulate after 30–60 min; a maximum level was



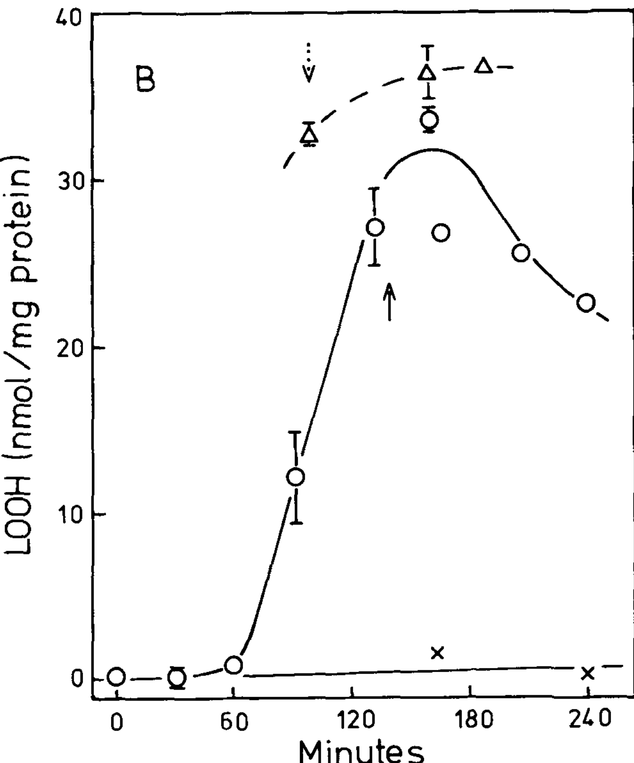


FIG. 2. Lipid peroxidation and lysis of resealed ghosts treated with xanthine, xanthine oxidase and iron. Membranes (1.0 mg protein/ml in PBS at 37 C) were incubated in the presence of xanthine oxidase (0.01 unit/ml), xanthine (1.0 mM), NaN_3 (0.1 mM) and $FeNH_4(SO_4)_2$ (0.1 mM) in the absence (○) and presence (Δ) of added H_2O_2 (0.1 mM). A control lacking oxidase and H_2O_2 was run alongside (×). (A) Membrane lysis (glucose-6-phosphate [G6P] release); (B) lipid hydroperoxide (LOOH) formation. Error bars show means ± deviations of values from duplicate determinations. Approximate time of incipient lysis is indicated by dotted arrow for H_2O_2 supplemented system and solid arrow for nonsupplemented system.

reached at about the time of lysis (150 min), followed by a decline. The LOOH content at incipient lysis (non-supplemented and H_2O_2-supplemented system) was 29–33 nmol/mg protein (32–36 nmol/mg lipid), i.e. 2–3 times higher than that observed in the photoreactions.

To gain additional insights into the mechanisms of photosensitized vs oxidase-catalyzed lipid peroxidation, we carried out these reactions in the presence of the phenolic antioxidants BHT and DTP. Both of these compounds are known to be excellent free radical traps. However, BHT may also react with or quench $^1O_2$ in competition with cholesterol and unsaturated fatty acyl groups (3). DTP on the other hand, is a relatively inefficient $^1O_2$ interceptor, making its use as a radical trap in the photodynamic system less problematic (3). As shown in Table 1, BHT at 10 μM (1–2 mol% of membrane phospholipid or cholesterol) strongly inhibited TBA-detectable lipid peroxidation in the xanthine/xanthine oxidase system and (not shown) prevented the formation of free radical oxidation products of cholesterol (see below). In contrast, 50 μM BHT failed to inhibit UP-sensitized peroxidation, but caused a small, albeit significant, decrease in the PP-sensitized reaction. DTP also inhibited the PP reaction (e.g., 35% at 2 hr), arguing in favor of radical (as opposed to $^1O_2$) trapping. Based on these results, a radical-mediated component (type I process) is apparent in the PP reaction, which may be favored by the ability of this relatively hydrophobic porphyrin to interact with the membrane (4). On the other hand, no free radical chemistry is apparent in the case of UP, which does not interact due to its high negative charge. Earlier studies (4) showed that azide inhibits UP- as well as PP-sensitized peroxidation, suggesting substantial $^1O_2$ intermediacy in each case.

Cholesterol oxidation products. Definitive evidence regarding oxidative mechanisms was sought by studying cholesterol oxidation. Cholesterol is converted to discrete products, the identification of which may allow $^1O_2$ and oxygen radical involvement in any given reaction to be distinguished (14). The obvious advantage is that this marker is an endogenous membrane lipid. As shown by the TLC results in Figure 3, xanthine/xanthine oxidase treatment of ghosts gave two cholesterol hydroperoxides whose borohydride reduction products comigrated with cholest-5-en-3β,7α-diol (7α-OH; R_f 0.15) and cholest-5-en-3β,7β-diol R_f 0.20), the epimeric pair associated with free radical oxidation (13,14). (Authentic 7β-OH; and 7β-OH were generated from 7-ketocholesterol and were distinguished from each other by the preponderance of the 7β-component.) No reaction occurred in the absence of xanthine oxidase or xanthine. The yield of 7α-OH and 7B-OH increased between 1 and 2 hr of incubation, slightly more of the latter being present at each time point. Densitometric comparison with known amounts of 7-OH indicated that <1% of the cholesterol was converted to these products. An additional component (R_f 0.37) has not yet been assigned. Catalase and superoxide dismutase prevented formation of these products when added individually to xanthine/xanthine oxidase reaction mixtures (Fig. 3). Thus, cholesterol oxidation is $O_2^{\cdot-}$- and H_2O_2-dependent, as previously reported for phospholipid peroxidation in this system (6).

The results of PP-sensitized photoxidation are also shown in Figure 3 for the sake of comparison. In this case a unique product of $^1O_2^-$- attack on cholesterol was

[a]Unsealed membranes were treated with xanthine (X)/xanthine oxidase (XO)/iron or irradiated in the presence of uroporphyrin (UP) or protoporphyrin (PP). Membrane protein concentration was 1 mg/ml, corresponding to ca. 0.7 mM phospholipid or 0.6 mM cholesterol in the bulk suspension. Other details are as indicated in Figures 1 and 2. Compensatory amounts of ethanol, the solvent used for BHT and DTP, were added to the reaction mixtures lacking these antioxidants. Lipid peroxidation was monitored in terms of TBA reactivity. Absorbance readings are corrected for zero-time values of controls not exposed to photooxidation or XO. (ΔA values for controls were 0.01 after 2 hr.) Experiments with PP (1 μM) were run at 10 C and with UP (10 μM) at 37 C. —, Not determined. Numbers with error limits are means ± deviation of values for duplicate determinations.

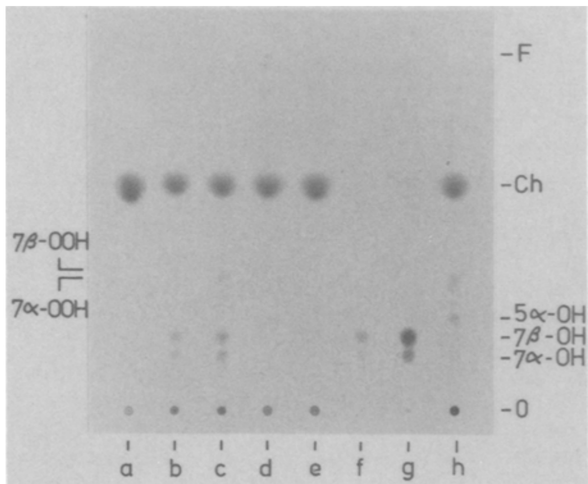

FIG. 3. Thin layer chromatography of cholesterol oxidation products from xanthine/xanthine oxidase/iron–treated ghosts. Extracted lipid hydroperoxides were reduced with $NaBH_4$. The standard reaction mixture (Std) was prepared as specified in Fig. 2. Lane a, Std − oxidase (120 min); b, Std (60 min); c, Std (120 min); d, Std + superoxide dismutase, 25 μg/ml (120 min); e, Std + catalase, 50 μg/ml (120 min); h, products of PP-sensitized photooxidation (cf Fig. 5). Sample loads (as starting cholesterol), 114 μg. Lanes f and g represent 7α-OH/7β-OH from 7-ketocholesterol, 0.8 μg and 8.0 μg respectively. Spots developed with 50% H_2SO_4 had the following colors: blue (5α-OH, 7α-OH, 7β-OH); magenta (Ch); gray (component between 5α-OH and Ch). Cholesterol 7α- and 7β-hydroperoxides in nonreduced samples were detected with N,N,N',N'-tetramethyl-p-phenylenediamine on a separate plate run alongside (positions shown with arrows). O, origin; F, solvent front.

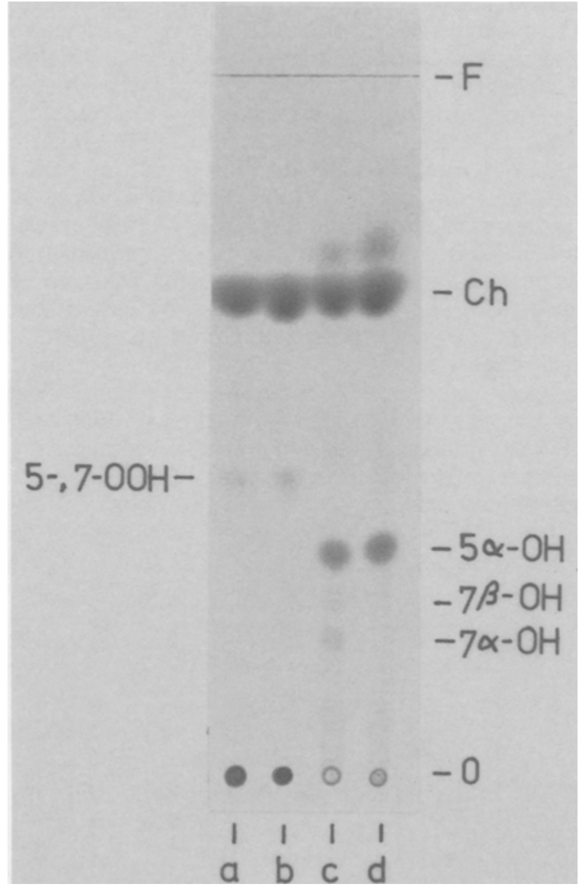

FIG. 4. Uroporphyrin- and protoporphyrin-sensitized photooxidation of membrane cholesterol. Thin layer chromatographic analysis was carried out after irradiating unsealed ghosts (1 mg protein/ml in phosphate-buffered saline at 37 C) for 1 hr in the presence of 5 μM PP (lane B) and 3 hr in the presence of 25 μM UP (lane C). Fluence rate, 20 mW/cm². Lane D shows a dark control (3 hr, no porphyrin) and lane A the 7-OH epimers from 7-ketocholesterol. Samples were reduced with borohydride before applying. The plate was scanned densitometrically immediately after developing. R_f values are as follows: 7α-OH, 0.13; 7β-OH, 0.19; 5α-OH, 0.23; Ch, 0.61. Ch peaks are deceptively small relative to diol peaks due to different color and lower absorptivity of Ch.

generated, namely, 3β-hydroxy-5α-cholest-6-ene-5-hydroperoxide (5α-OOH). A major component after borohydride reduction was more mobile (R_f 0.25) than the 7-OH epimers. It comigrated with material generated by rose bengal, a well-known $^1O_2$ sensitizer (data not shown), and on this basis was identified as 5α-OH. The absence of 5α-OH in xanthine oxidase–treated ghosts rules out any $^1O_2$ intermediacy in this reaction.

Additional evidence for the involvement of $^1O_2$ in photochemical peroxidation is provided in Figure 4, which shows densitometric scans of cholesterol products from PP- and UP-sensitized reactions. A significant 5α-OH peak was observed with each porphyrin, along with smaller amounts of the 7-OH epimers (7α-OH predominating). The latter might have arisen via the contributions of (i) type I (radical) photochemistry; (ii) general thermal decomposition of accumulating type II hydroperoxides; (iii) allylic decay of 5α-OOH to the more stable 7-OOH pair (15); or some combination of these pathways. The inability of BHT to protect against UP-sensitized phospholipid peroxidation (Table 1) argues against the first two possibilities in the case of this porphyrin. With PP, but not with UP, a component of similar color (gray) and mobility (R_f 0.35–0.37) to one seen with xanthine oxidase was observed (cf Fig. 3), and on this basis is ascribed to free radical reactions. (The component was shown not to be PP itself or oxidized PP.) This evidence, coupled with the partial inhibition of PP-driven lipid peroxidation by BHT or DTP (Table 1), supports our argument that PP photooxidizes partially via a type I mechanism.

To further clarify any type I contribution, we irradiated PP-sensitized ghosts at 10 C instead of 37 C in an effort to minimize thermally driven rearrangement of 5α-OOH (cf ref. 15). As shown in Figure 5 (lane c), 7α-OH and 7β-OH were still observed under these conditions after reduction of the hydroperoxides. Photooxidation in the presence of BHT strongly inhibited formation of the 7-OH epimers while not affecting 5α-cholest-6-ene-3β,5-diol (5α-OH) (lane d), as would be expected if the LOOH precursors are generated as described. The persistent spot of slightly greater mobility than cholesterol (lanes c and d) may represent dehydration product(s) of initially formed $^1O_2$ adduct (16).

Cholesterol photooxidation in the presence of ascorbate. As shown recently (4) and confirmed here (Table 2), peroxidation of polyunsaturated lipids in photosensitized ghosts is amplified markedly when irradiation is carried out in the presence of ascorbate (AH^-), a well-known electron donor. This is a new example of how AH^- (usually considered an antioxidant) can, under suitable conditions, act as a prooxidant. When

present at a low concentration (0.4 mM) at the start of a PP-sensitized reaction (Table 2), AH^- produced after 1 hr a nearly 10-fold increase in TBA reactivity over that observed without AH^-. Peroxidation was relatively insignificant in dark controls (minus or plus AH^-). EDTA abolished AH^--stimulated peroxidation, probably by removing membrane-bound iron that is required for redox cycling (4,9). BHT also inhibited the reaction, more so than it did basal photoperoxidation (Table 1); this is attributed mainly to quenching of alkoxyl radicals involved in propagation reactions (1,2). Stimulation was minimal at high concentrations of AH^- (e.g., 10 mM), presumably because antioxidant effects become more important.

To gain additional insights into the reaction mechanisms involved in these effects, we tracked cholesterol oxidation in the experiments described in Table 2. Samples were analyzed directly (Fig. 6A) or after borohydride reduction (Fig. 6B). As shown in Figure 6A, 0.4 mM AH^- caused striking changes, both qualitative and quantitative, in the cholesterol product profile of irradiated ghosts. Note that the major hydroperoxides appearing as a faint, poorly resolved doublet after 1 hr (lane d) are intensified with AH^- (lane f) and that the 7-OH epimers (undetectable in lane d) are now present in large amounts. Barely any 5α-OH is observed. In the presence of 10 mM AH^-, no hydroperoxides and much less of the 7-OH epimers are seen (lane h), which is consistent with the TBA results. Overall product yield was also less when BHT (lane i) or EDTA (lane j) was included along with 0.4 mM AH^-. In both cases peroxides were again apparent, and with EDTA no diols were seen. Borohydride reduction provided additional information (Fig. 6B). It is clear that $^1O_2$-driven peroxidation in the absence of AH^- shifted predominantly to free radical–mediated peroxidation in the presence of this reductant (compare lanes f and d). Moreover, inhibition of the AH^--stimulated reaction by BHT or EDTA was reflected in decreased amounts of 7α-OH/7β-OH and an increased amount of 5α-OH, the primary $^1O_2$-derived product (compare lanes f, i and j). Ascorbate may have diminished the yield of $^1O_2$ in this system, for example, by competing with ground state oxygen for PP triplet (17). Clearly, however, it could not have abolished $^1O_2$ formation, since considerable 5α-OH was detected when EDTA or BHT was present.

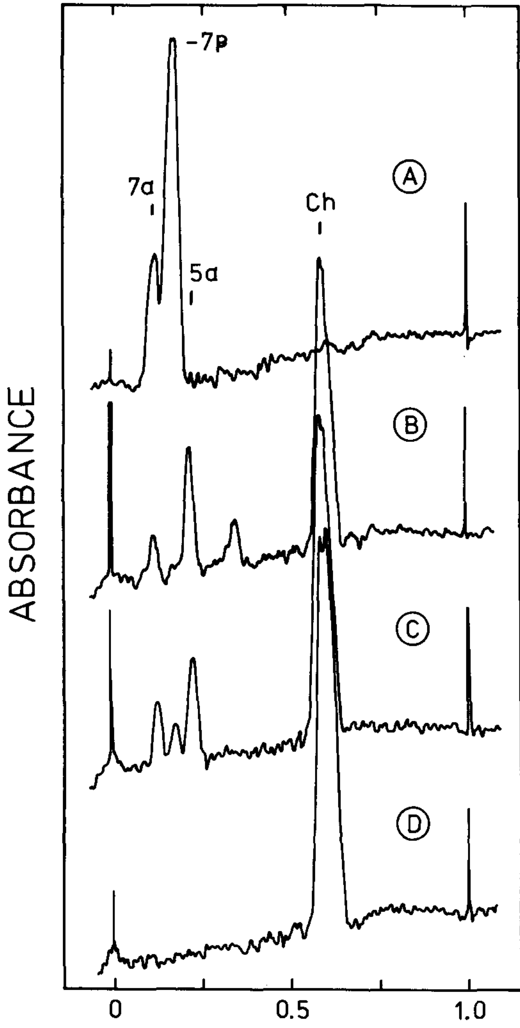

FIG. 5. Protoporphyrin (PP)-sensitized photooxidation of cholesterol: effect of butylated hydroxytoluene (BHT). Membranes were sensitized with 5 μM PP and irradiated for 2 hr at 10 C in the absence (lanes b and c) and presence (lanes a and d) of BHT (50 μM). The control mixture was adjusted to the same final concentration of ethanol (25 μM) that was introduced with BHT. Samples c and d were reduced with borohydride before chromatographing, while a and b were not reduced.

DISCUSSION

The cholesterol product analyses described in this work have provided important information about oxidative mechanisms in situ. Although cholesterol oxidation has been studied extensively in organic solvents and artificial membranes (14,18,19), very little has been done in natural membrane systems. The major obstacles encountered are limited material and low reaction rates. For example, $^1O_2$ reacts slowly with cholesterol ($k \sim 7 \times 10^4\ M^{-1}\ sec^{-1}$) compared with histidine ($k \sim 5 \times 10^7\ M^{-1}\ sec^{-1}$) (3,20). This makes product detection difficult and often requires

TABLE 2

Effects of Ascorbate on Protoporphyrin-Photosensitized Lipid Peroxidation[a]

	A_{532}		
Reaction system	10 min	30 min	60 min
Control (− AH^-)	—	—	0.055
Control (+ 0.4 AH^-)	—	0.050	0.058
Standard	0.048	0.068	0.114
+ 0.4 AH^-	0.075	0.293	0.615
+ 0.4 AH^-/EDTA	0.027	0.036	0.051
+ 0.4 AH^-/BHT	0.054	0.090	0.181
+ 10 AH^-	0.049	0.083	0.126

[a]The standard reaction mixture consisted of unsealed ghosts (1.0 mg protein/ml), $FeCl_3$ (25 μM) and PP (5 μM) is PBS at 37 C. Additional components in different experiments were as follows: AH (0.4 mM or 10 mM, as indicated); EDTA (0.1 mM); and BHT (0.03 mM). Suspensions were irradiated continuously (fluence rate 7.5 mW/cm^2), and samples were drawn for TBA assay at the indicated times. Nonirradiated controls (standard mixtures minus or plus AH^-) were run alongside. Zero-time A_{532} was 0.049 (0.025 for EDTA-containing system). —, Not determined.

the use of radiolabeled sterol (21). By analyzing large amounts of easily obtained material, we were able to determine cholesterol products directly, without having to resort to radiolabeling. Although the results are mainly qualitative, they demonstrate for the first time, for example, that a reductant like AH^- can switch $^1O_2$-dependent peroxidation to a free radical–dominated process, which greatly enhances the damaging effects of $^1O_2$ alone. In addition, the free radical nature of xanthine oxidase–catalyzed lipid peroxidation in cell membranes (6) has been verified by showing that 7α-OH and 7β-OH are formed. Recent evidence (22) that $^1O_2$ is not among the damaging oxidants produced by this enzyme was corroborated, ruling out earlier suggestions to the contrary.

By examining cholesterol products and the effects of phenolic antioxidants, we conclude that highly polar UP, which does not bind to the membrane, photosensitizes lipid peroxidation and lysis by a type II mechanism (reactions 1 and 2, where ^3UP is triplet excited state porphyrin and LH is unsaturated lipid).

$$^3UP + O_2 \rightarrow UP + {}^1O_2 \quad [1]$$

$$LH + {}^1O_2 \rightarrow LOOH \quad [2]$$

Although PP-sensitized photooxidation also involves $^1O_2$, a small part appears to be type I (radical) in nature. The reaction pathway in this case could be as follows:

$$^3PP + LH \rightarrow PP^{-\cdot} + H^+ + L^{\cdot} \quad [3]$$

$$L^{\cdot} + O_2 \rightarrow LOO^{\cdot} \quad [4]$$

$$LOO^{\cdot} + LH \rightarrow LOOH + L^{\cdot} \quad [5]$$

Reaction 3 depicts initiation of peroxidation via electron transfer, and reactions 4 and 5 show propagation. Autoxidation of $PP^{-\cdot}$ might also contribute to initiation by generating partially reduced oxygen species (17). Whether other relatively hydrophobic sensitizers will behave similarly in this membrane system remains to be established.

The results shown in Table 2 and Figure 2 suggest that in vivo phototoxic effects of lipid peroxidation might be influenced by AH^- or other cellular reductants. The following mechanism can be envisaged.

$$AH^- + Fe(III) \rightarrow A^{-\cdot} + H^+ + Fe(II) \quad [6]$$

$$LOOH + Fe(II) \rightarrow LO^{\cdot} + OH^- + Fe(III) \quad [7]$$

Cholesterol or phospholipid hydroperoxides generated by $^1O_2$ attack (reaction 2) undergo iron-catalyzed reduction to alkoxyl radicals (reactions 6 and 7), which then trigger rounds of free radical peroxidation (1,2,4). Thus, AH^- amplifies lipid peroxidation via 1-electron reduction of nascent photoperoxides. Molecular oxygen probably competes with LOOH for Fe(II) in reaction 7, in which case H_2O_2-dependent (Fenton) formation of strongly oxidizing $OH^{\cdot}$ might occur. We have found, however, that catalase not only fails to inhibit AH^--stimulated peroxidation (UP-sensitized), but consistently stimulates it (unpublished observation), indicating that the effect is not H_2O_2-dependent. Since $LO^{\cdot}$ is necessarily generated in the lipid matrix, it would not be surprising to find that this radical is a better initiator of peroxidation than hydroxyl.

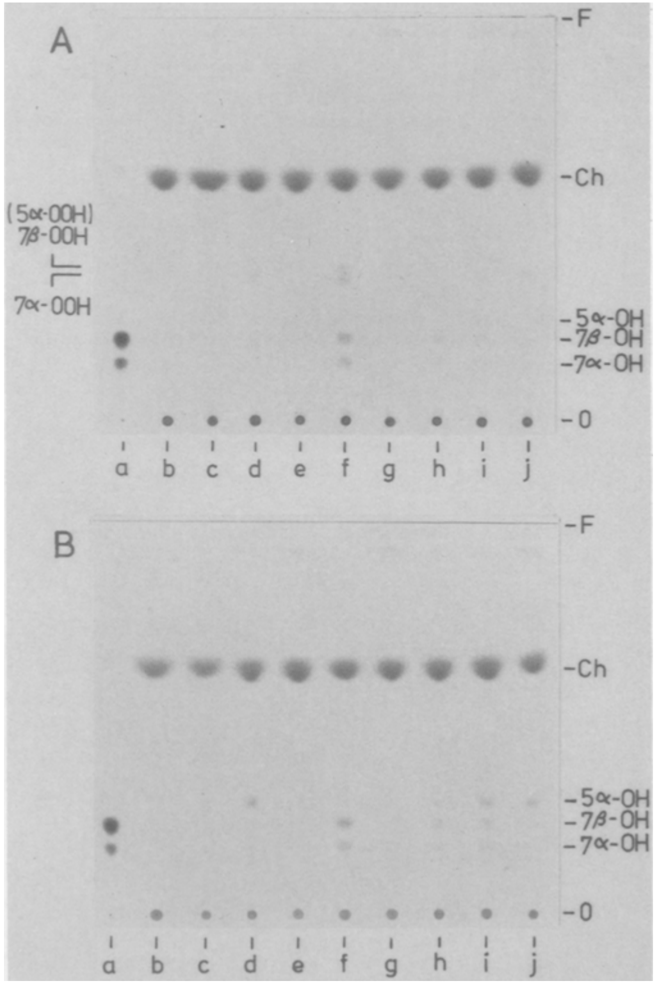

FIG. 6. Effects of ascorbate on protoporphyrin-sensitized photooxidation of cholesterol. Lipid extracts from the experiments described in Table 2 were analyzed by thin layer chromatography before (A) and after (B) borohydride reduction. Samples (0.16 mg in starting cholesterol) were analyzed after 10 min and 60 min of irradiation: standard reaction mixture (Std), 10 min (c) and 60 min (d); Std + 0.4 mM AH^-, 10 min (e) and 60 min (f); Std + 10 mM AH^-, 10 min (g) and 60 min (h); Std + 0.4 mM AH^-/0.03 mM BHT, 60 min (i); Std + 0.4 mM AH^-/0.1 mM EDTA, 60 min (j). A 60-min dark control is shown in lane b and authentic 7α-OH, 7β-OH from 7-ketocholesterol in lane a.

It is interesting that resealed ghosts treated with xanthine/xanthine oxidase/iron began to lyse (release G6P more rapidly) when their LOOH content was more than twice that of UP-photooxidized ghosts (Figs. 1 and 2). Therefore, the structural damage necessary to produce a marker-releasing pore appeared to be greater with the xanthine oxidase system. There is a qualitative difference in some of the hydroperoxides produced in systems of this type (Fig. 3; refs. 14,24,25), and it is possible that at any given LOOH level, enzymatically generated peroxides perturbed the bilayer less than photogenerated peroxides. Another possibility is suggested by our findings (unpublished) that xanthine oxidase treatment causes membrane aminolipids to be cross-linked, whereas photooxidation does not. Crosslinking could impede marker efflux, making it necessary for a greater fraction of lipid to be oxidized before net efflux occurs.

ACKNOWLEDGMENTS

We are grateful to Leland Smith for helpful discussions about cholesterol peroxide analysis. This work was supported by Grants PCM-8119286 and DCG-8501894 from the National Science Foundation.

METHODS

Loss of NADPH During Assays of HMG-CoA Reductase: Implications and Approaches to Minimize Errors

Gene C. Ness*, Laura C. Pendleton and A. Stacia Pendleton
Department of Biochemistry, College of Medicine, University of South Florida, Tampa, FL 33612

In assays of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase activity, preincubation of isolated washed microsomes with NADPH led to a time- and protein concentration–dependent loss of enzyme activity. This occurred despite the presence of an NADPH regenerating system. Addition of fresh NADP, glucose 6-phosphate and glucose 6-phosphate dehydrogenase restored activity. Of the individual components, only NADP was effective. Errors due to loss of NADPH are most pronounced in assays using high microsomal protein, low NADPH levels and preincubation with NADPH and when glutathione rather than dithiothreitol is present. To minimize the effects of NADPH depletion, it is recommended that (i) NADP and NADPH not be present during the preincubation period; (ii) incubation periods be relatively short; (iii) microsomal protein concentrations be less than 1 mg; and (iv) NADPH concentrations be 1 to 2 mM.
Lipids 22, 409–412 (1987).

With the recognition that purified preparations of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase represented a proteolytic fragment containing the active site rather than the intact enzyme (1), a shift back to studying the reductase within the microsomal membrane has occurred (2,3). Assay conditions, however, were developed to maximize the activity of the proteolytically modified form of the enzyme. For example, it has become standard practice to preincubate for 20 min with NADPH to reactivate this cold-sensitive enzyme (4). The native form of HMG-CoA reductase is not cold-liable (5). It also has been common to use 2–5 mM NADPH and 10 mM dithiothreitol in HMG-CoA reductase assays. However, it recently has been demonstrated that HMG-CoA reductase displays allosteric kinetics with respect to NADPH concentrations (3) and that the enzyme exists in both a disulfide-linked dimer and a free sulfhydryl monomer (2). Addition of 10 mM dithiothreitol can convert dimer to monomer (2). In view of these observations, reductase assays using lower NADPH concentrations and thiol conditions more closely approximating those found in vivo are desirable.

In an effort to identify a specific degradative system for HMG-CoA reductase, liver microsomes from rats fed colestipol were incubated with those from fasted rats. Although a marked decrease in mevalonate formation occurred, this did not result from inactivation of the reductase. Rather, as the data presented in this report show, a loss of NADPH occurred. The consequences of NADPH depletion and approaches to minimize its effects are addressed.

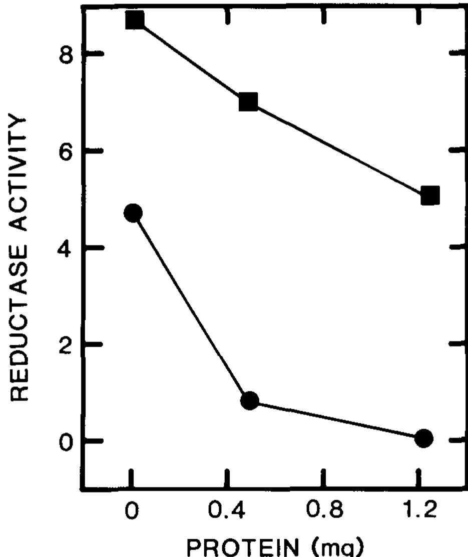

FIG. 1. Effect of adding hepatic microsomal protein from a fasted rat to HMG-CoA reductase reactions containing microsomes from a colestipol-fed rat. Reaction mixtures were either preincubated (●) or not (■) for 20 min at 37 C. All reactions contained 100 mM potassium phosphate buffer, pH 7.1; 200 mM potassium chloride; 5 mM reduced glutathione; 4 mM glucose 6-phosphate; 500 μM NADP$^+$; 0.5 units of glucose 6-phosphate dehydrogenase 70 μM RS[^{14}C]HMG-CoA (3,700 cpm/nmol) and 0.24 mg of liver microsomal protein from a colestipol-fed rat. Reaction mixture volumes were 300 μl. Reactions were started by the addition of HMG-CoA (●) or by adding microsomes that had been warmed to 37 C (■). Incubation was carried out at 37 C for 10 min. Reactions were stopped by the addition of 30 μl of 2.4 N HCl. Reductase activity is given as nmol of mevalonate formed for duplicate determinations.

MATERIALS AND METHODS

Male Sprague-Dawley rats weighing 125 to 150 g were purchased from Harland Industries (Madison, WI). Animals were maintained on 2% cholesterol or 2% colestipol and 0.04% mevinolin or were fasted 48 hr prior to being killed at the diurnal high point of the daily cycle (6). Lysosome-free microsomes were prepared in 0.25 M sucrose as previously described (6). HMG-CoA reductase activity was assayed by the radiochemical method using thin layer chromatography (TLC) for isolation of the lactonized product (7). Colestipol and mevinolin were gifts from Upjohn (Kalamazoo, MI) and Merck (Rahway, NJ), respectively.

RESULTS AND DISCUSSION

As shown in Figure 1, addition of increasing amounts of fasted microsomes decreased HMG-CoA reductase

*To whom correspondence should be addressed.
Abbreviations: HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; TLCK, Nα-p-tosyl L-lysine chloromethyl ketone; TLC, thin layer chromatography; EGTA, ethylene glycol bis (β-aminoethyl ether) N,N,N',N'-tetracetic acid; G6P, glucose 6-phosphate; G6PD, glucose 6-phosphate dehydrogenase.

activity in microsomes from colestipol-fed animals. This was most pronounced in the series where microsomes were preincubated. It is also apparent that preincubation of microsomes from colestipol-fed animals without adding microsomes from fasted rats significantly reduced reductase activity. Addition of various proteinase inhibitors, such as leupeptin, ethylene glycol bis (β-aminoethyl ether) (EGTA) and Nα-p-tosyl L-lysine chloromethyl ketone (TLCK) failed to prevent the decrease in reductase activity, suggesting that a proteinase might not be responsible for the loss of activity.

The possibility that the observed loss of reductase activity might not be unique to fasted microsomes was examined in the experiment depicted in Figure 2. Adding increasing amounts of liver microsomes from colestipol-fed rats also resulted in a decline in reductase activity that was dependent on preincubation time and amount of microsomal protein added.

Table 1 illustrates that the loss in reductase activity that occurs during preincubation results from a loss in the NADPH regenerating system. Adding fresh NADP, glucose 6-phosphate (G6P) and glucose 6-phosphate dehydrogenase (G6PD) (complete system) at the end of the preincubation period restored reductase activity. However, this activity is somewhat less than that seen in reactions started by adding both NADPH and HMG-CoA. Preincubation of microsomes for 20 min without NADPH does not inactivate, but rather stimulates reductase activity. Increasing the amount of NADPH in the preincubation mixture twofold does not offset the problem. As shown in Table 2, the complete NADPH regenerating system was more effective that any single component in restoring reductase activity. Of the individual components, only NADP was effective. The data indicate a nearly complete loss of NADP and a partial loss of G6P occurred during preincubation. These losses could not be prevented by addition of EDTA, liver cytosol or microsomal phosphatase inhibitors (8) fluoride or bovine serum albumin. Presumably, loss of NADPH would not occur in vivo. It is of interest that the loss of NADPH is not nearly as serious in reactions in which 10 mM dithiothreitol was used rather than 5 mM glutathione (Fig. 3).

Depletion of NADPH during preincubation and likely during the incubation period would be expected to have profound effects on studies of HMG-CoA reductase activity. As shown in Figure 4, preincubation with NADPH can result in serious errors in determination of the allosteric kinetics of HMG-CoA reductase. It is possible that the previously reported (3,7) allosteric

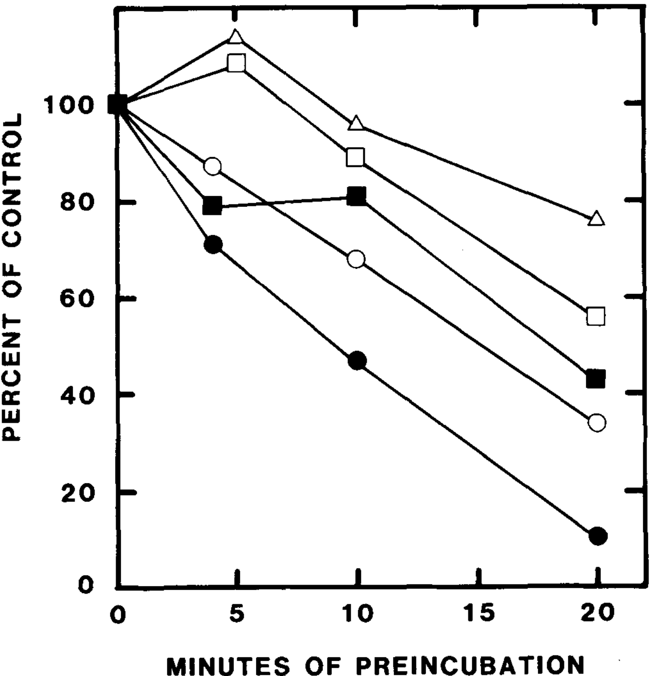

FIG. 2. Effect of microsomal protein concentration on loss of HMG-CoA reductase activity during preincubation with NADPH. Increasing amounts (0.15 mg [Δ], 0.30 [□], 0.50 [■], 0.70 [○] and 0.90 [●]) of microsomal protein from a colestipol-fed rat were preincubated for the indicated times in reaction mixtures as described in the legend to Fig. 1. Reactions were started by the addition of RS[^{14}C]HMG-CoA and incubated for 10 min at 37 C. Reductase activity is expressed as a percentage of that at zero min of preincubation for each series. Reductase activities in terms of nmol of mevalonate formed for the non-preincubated controls are 2.44 (Δ), 4.15 (□), 5.08 (■), 5.71 (○) and 6.12 (●).

TABLE 1

Decrease in HMG-CoA Reductase Activity During Preincubation, Apparently Resulting from Loss of the NADPH Regenerating System

Additions at 0 min	Additions at 20 min	Reductase activity (nmol/min/mg)
Microsomes, NADPH[a]	HMG-CoA	0.01
Microsomes, NADPH	NADPH, HMG-CoA	0.63
	Microsomes, NADPH, HMG-CoA	0.66
Microsomes	2× NADPH, HMG-CoA	1.52
Microsomes	NADPH, HMG-CoA	0.94
Microsomes, 2× NADPH	HMG-CoA	0.01

All reactions were preincubated for 20 min and incubated for 5 min at 37 C. Reaction mixtures contained 1 mg of microsomal protein from a colestipol-fed rat and components listed in the legend to Fig. 1. Values are the averages of duplicate determinations.

[a]NADPH refers to addition of NADP, glucose 6-phosphate and glucose 6-phosphate dehydrogenase.

TABLE 2

Effect of Individual Components of the NADPH Regenerating System on Restoration of HMG-CoA Reductase Activity Lost During Preincubation

Additions	Reductase activity (nmol/min/mg)
None	0.02
Complete	0.95
NADP	0.55
G6P	0.04
G6PD	0.07
NADP + G6P	0.73
NADP + G6PD	0.53

G6P, glucose 6-phosphate; G6PD, glucose 6-phosphate dehydrogenase. All reactions were preincubated for 18 min at 37 C and contained 0.9 mg of microsomal protein from a colestipol-fed rat and all the components listed in the legend to Fig. 1, including the NADPH regenerating system. Additions at 18 min were NADP, 0.5 mM; G6P, 4 mM and G6PD, 0.5 units (complete) or the indicated components. Two min later the reactions were started by addition of RS[^{14}C] HMG-CoA and incubated for 5 min. Values are the averages of duplicate determinations.

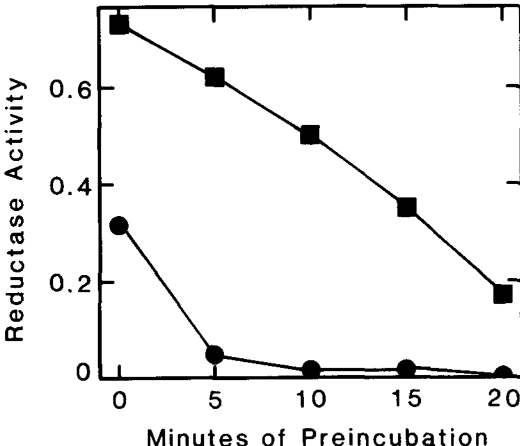

FIG. 3. Effect of thiol on loss of NADPH during preincubation. Microsomes (2.3 mg from a colestipol-fed rat) were preincubated for the indicated times with 5 mM glutathione (●) or 10 mM dithiothreitol (■) with the complete NADPH system described in the legend to Fig. 1 (500 μM NADPH). Reactions were started by the addition of [^{14}C]HMG-CoA. Reactions were stopped after 5 min. Reductase activity is given as nmol/min/mg.

NADPH-dependent kinetics (3,7) are either entirely due to NADPH depletion or are markedly affected by this problem. It is not possible to distinguish between these possibilities because of the need to use low NADPH concentrations and the lack of linearity with time at such levels.

One approach to the problem of NADPH depletion is simply to increase its concentration in reaction mixtures. However, substrate inhibition at high concentrations of NADPH has been reported for HMG-CoA reductase (9). We confirmed this. Generally, inhibition was observed at NADPH concentrations above 4 mM. In microsomes from rats fed mevinolin and colestipol, inhibition was apparent at 1 mM. The NADPH concentration at which inhibition occurred was decreased by incubation with higher concentrations of thiols, i.e., 10 mM dithiothreitol.

Recognition of the NADPH depletion problem allows formulation of more appropriate conditions for assaying native microsomal HMG-CoA reductase, as shown in Figure 5. Central to these conditions are deletion of a preincubation step, low microsomal protein concentrations, short incubation times and adequate NADPH concentration. Under these conditions, good linearity with time can be demonstrated even with 5 mM glutathione as the thiol present.

Over the years, numerous potential pitfalls in assaying HMG-CoA reductase activity have been identified. These include the nonspecificity of the anion exchange assay (10); presence of interfering activities, such as HMG-CoA lyase (11,12) and mevalonate kinase (13); proteolysis (1); and inhibition by R HMG-CoA (14). To this list, we now add microsomal depletion of NADPH.

It would appear that the NADPH-depleting activity is a constitutive microsomal activity. When high concentrations of microsomal protein are used to assay HMG-CoA reductase activity in conditions where the level of enzyme is low, an underestimation of activity can readily result. This could lead to erroneous conclusions concerning changes in enzyme levels caused by dietary and hormonal agents or in correlations with changes in rates of cholesterol synthesis.

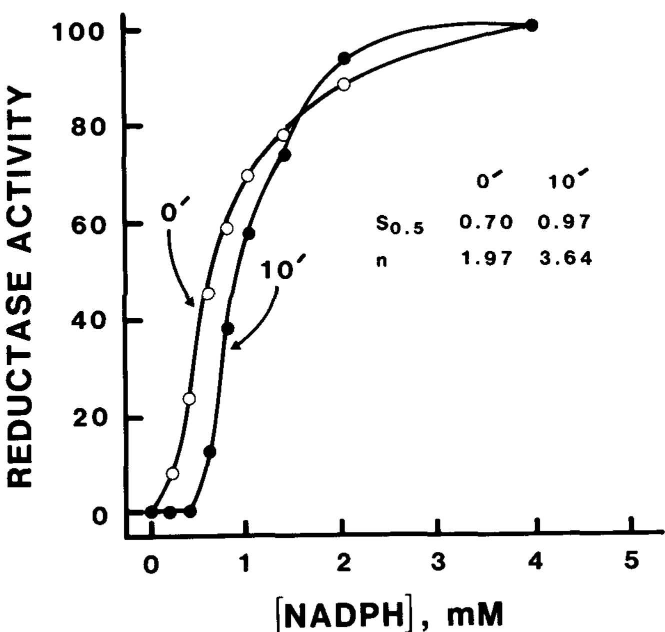

FIG. 4. Effect of preincubation on the allosteric kinetics of HMG-CoA reductase. Microsomes (0.22 mg) from a colestipol-fed rat were either preincubated for 10 min (●) or not (○) with the complete NADPH system. The reactions were started by the addition of [^{14}C]HMG-CoA. Reductase activity is given as a percentage of the maximal activity, 1.43 (●) and 0.92 (○) nmol/min/mg, respectively. The Hill coefficients (n) and $S_{0.5}$ values obtained from Hill plots are given. Reaction mixture components are as described in the legend to Fig. 1 except that the glucose 6-phosphate concentration was 20 mM.

More accurate determinations of microsomal HMG-

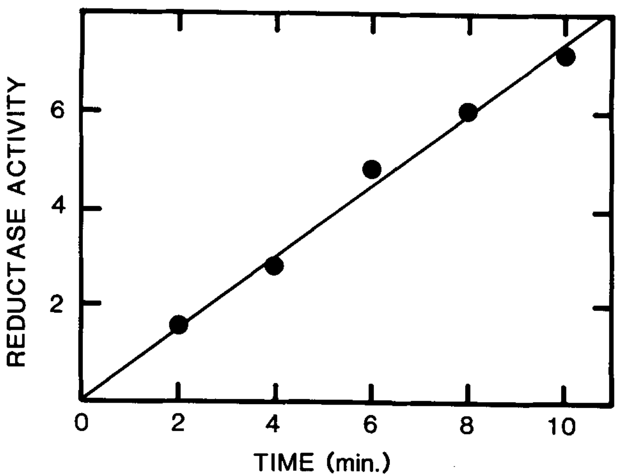

FIG. 5. Linearity of microsomal HMG-CoA reductase activity with incubation time. Reaction mixture components were as listed in the legend to Fig. 1 except that the concentration of NADP$^+$ was 1.5 mM, and 0.20 mg of microsomal protein from a rat fed colestipol was present in each reaction mixture. The microsomes were warmed at 37 C with glutathione, potassium phosphate buffer and potassium chloride for 10 min. The reactions were started by adding a mixture containing the NADP$^+$, glucose 6-phosphate, glucose 6-phosphate dehydrogenase, RS[^{14}C]HMG-CoA and 2 mM potassium phosphate buffer, which was warmed at 37 C for 5 min prior to addition. Reductase activity is given as nmol of mevalonate formed.

CoA reductase activity should aid in determining whether changes in rates of synthesis and degradation of HMG-CoA reductase mRNA and protein (15–18) or in the extent of posttranslation modifications such as phosphorylation (19) or sulfhydryl status (20) can totally account for a given change in enzyme activity.

Lipids containing hydroxy fatty acids or hydroxyacyl moieties are acetylated with [1-^{14}C]acetic anhydride or [^{3}H]acetic anhydride, and the content of hydroxy fatty acids or hydroxyacyl moieties is estimated from the specific radioactivity of the acetylated products with respect to that of radioactive standards, such as radioacetylated ricinoleic acid or triricinoleoylglycerol. Mixtures of triacylglycerols containing one, two and three hydroxyl groups per molecule are derivatized in a similar manner, and the resulting acetates are fractionated by thin layer chromatography according to the number of acetate groups per molecule. The relative proportion of each type of triacylglycerols in the mixture is estimated from the distribution of radioactivity in the various fractions. Applications of these techniques are demonstrated by the analysis of several seed lipids.
Lipids 22, 413-416 (1987).

Lipids containing hydroxy fatty acids occur widely in animals, plants and microorganisms (1,2). Several analytical techniques have been developed for the qualitative and quantitative analysis of hydroxy fatty acids and lipids containing hydroxyacyl moieties (3,4). Among these techniques, gas liquid chromatography (GLC) has been used most extensively. However, quantitative GLC of methyl esters of hydroxy fatty acids poses several problems, such as long retention times of these substances and relative instability at high temperatures (3). The quantitative analysis of lipids containing hydroxy fatty acids becomes especially difficult when highly reactive acids, such as dimorphecolic or kamlolenic acids, are present. Some of these problems can be partially solved by derivatization of the hydroxyl groups (3).

In the present communication, we describe procedures for the analysis of lipids containing hydroxy fatty acids or hydroxyacyl moieties. These procedures are based on isotopic derivative techniques, partly in conjunction with thin layer chromatography (TLC).

MATERIALS AND METHODS

Castor *(Ricinus communis)* beans were obtained from the Department of Botany, Aligarh Muslim University, Aligarh, India. *Wrightia tinctoria* seeds were supplied by the National Botanical Research Institute, Lucknow, India. *Grevillea decora* seeds were a gift from R. Kleiman, U.S. Department of Agriculture–Agricultural Research Service, Peoria, Illinois. Seeds of *Mallotus philippinensis, Onguekoa gore, Dimorphotheca aurantiaca, Artemisia absinthium* and *Strophanthus kombe* were provided by L. J. Morris, now at Unilever Research, Colworth House, Sharnbrook, Bedfordshire, England.

All reagents, solvents and adsorbents were products of E. Merck A.G. (Darmstadt, Federal Republic of Germany). Solvents were distilled before use. [1-^{14}C]Acetic anhydride (2 mCi/mmol) and [^{3}H]acetic anhydride (50 mCi/mmol) were purchased from NEN Chemicals GmbH (Dreieich, Federal Republic of Germany). TLC was carried out on glass plates (20 × 20 cm) coated with a 0.3-mm layer of Silica Gel H.

Thin layer chromatograms were assayed for radioactivity by means of a Berthold scanner LB 2760 (BF-Vertriebsgesellschaft, Wildbad, Federal Republic of Germany). The radioactivity of silica gel scrapings and lipid samples was determined using a Packard Tri-Carb C 2405 liquid scintillation spectrometer (Packard Instruments Co., Downers Grove, Illinois) using ^{14}C- or ^{3}H-labeled hexadecane as internal standard.

Lipids were extracted under nitrogen from finely ground seeds either with hexane at room temperature or with chloroform/methanol (2:1, v/v) as described elsewhere (5). Castor bean lipids were fractionated by TLC using hexane/diethyl ether/acetic acid (50:50:1, v/v/v) to isolate diricinoleoylacylglycerols and triricinoleoylglycerol. Saponification of lipids, removal of nonsaponifiable matter and liberation of fatty acids were carried out according to established procedures (6). Ricinoleic acid was isolated from the total fatty acids derived from castor bean lipids by TLC using hexane/diethyl ether/acetic acid (50:50:1, v/v/v) as developing solvent.

Radioactive acetic anhydride, diluted to desired specific radioactivity and dissolved in twice its volume of anhydrous pyridine, was used for acetylation. Lipid samples (50–100 mg) were reacted under nitrogen in screw-capped tubes with 1 ml of the acetylating mixture at room temperature overnight or at 50–60 C for 2 hr. After cooling to room temperature, the reaction mixture was diluted with 5 ml water, and the acetylated lipids were extracted three times with 3 ml each of hexane. The combined hexane extracts were washed three times each with 3 ml of 10% sulfuric acid, 3 ml of 10% aqueous sodium bicarbonate and finally with water. The solvent was evaporated, and residual traces of water were removed azeotropically with benzene/chloroform/methanol (1:1:1, v/v/v). The samples were weighed and dissolved in a known volume of hexane, and the radioactivity in aliquots was measured by liquid scintillation counting in Econofluor (NEN Chemicals).

An aliquot (10–20 mg) of the acetylated castor bean lipids was applied as a streak on a chromatoplate, which was then developed with hexane/diethyl ether/acetic acid (60:40:1, v/v/v). The lipid fractions were stained with iodine vapor and identified by cochromatography with unlabeled standards. The radioactively labeled fractions were located by scanning and scraped off. To the silica gel scraping, 100 µl water and 10 ml Aquasol-2 (NEN Chemicals) were added, and radioactivity was measured by liquid scintillation counting. All data reported are means of triplicate determinations.

RESULTS AND DISCUSSION

The methods reported here involve acetylation of lipids with radioactive reagents, such as [1-^{14}C]acetic anhydride or [^{3}H]acetic anhydride, followed by determination of the specific radioactivity of the acetylated products. The content of hydroxy fatty acids and/or hydroxyacyl moieties in the lipids is estimated by comparison of the specific radioactivity of the acetylated products with those of the corresponding isotopically labeled acetates of pure hydroxy fatty acids or their esters. Furthermore, radioactively labeled acetates derived from mixtures of lipids containing free hydroxyl groups are resolved by TLC into fractions differing by the number of acetate (corresponding to hydroxyl) groups per molecule. The distribution of radioactivity in the various fractions is determined to estimate the composition of such lipid mixtures.

Initially some standard samples containing known proportions of hydroxy fatty acids or hydroxyacyl moieties were acetylated with ^{14}C- or ^{3}H-labeled acetic anhydride. A blank of pure oleic acid was also treated with radioactive acetic anhydride to check whether traces of radioactivity remained in the samples after removal of excess reagent. The percentage of hydroxy fatty acid or hydroxyacyl moieties was estimated from the specific radioactivities of the corresponding acetates derived from ricinoleic acid and triricinoleoylglycerol, respectively. The data show a close agreement between the known values and those found experimentally (Table 1).

The hydroxy fatty acid content of a few selected seed lipids was determined by acetylation of the total lipids with [1-^{14}C]acetic anhydride/pyridine reagent of different specific activities. The content of hydroxy fatty acids plus hydroxyacyl moieties was calculated from the specific radioactivities of the acetylated products with reference to the specific radioactivity of the acetate derived from triricinoleoylglycerol as standard. It was found that essentially similar results are obtained with acetic anhydride reagents of various specific radioactivities. However, the sensitivity of the method increases with increasing specific radioactivity of the reagent (Table 2).

The percentage of hydroxy fatty acids plus hydroxyacyl moieties determined by radioacetylation of the total lipids of several seeds and the values reported in the literature are compared in Table 2. A good agreement is observed between these values in several cases.

In the lipids of *M. philippinensis* the value observed is much lower than that reported, most likely because large proportions of the hydroxyl groups of kamlolenic (18-hydroxyoctadeca-9,11,13-trienoic) acid present in these lipids are esterified as estolides (8). The lipids of *D. aurantiaca* contain a conjugated dienol, i.e., 9-hydroxy-octadeca-10,12-dienoic acid. Because of the reactive nature of the conjugated dienol structure, the percentage of this hydroxy fatty acid plus hydroxyacyl moieties in the total lipids has been determined by countercurrent distribution of the methyl esters of the total fatty acids (9). The percentage of hydroxy fatty acid obtained by

Dihydroxystearoylricinoleoylglycerols	19.1	6.39	5.0	4.9

[a]Calculations were made considering the number of hydroxyl groups per molecule.

radioacetylation (Table 2) is in close agreement with the literature value (9). In the seed lipids of *A. absinthium*, the value of hydroxy fatty acids plus hydroxyacyl moieties found is much higher than reported in the literature (11). This is obviously due to the presence of 23% epoxyacyl moieties (11), which react with acetic anhydride as well.

It is evident that the isotopic derivative technique described here is not a reliable method if part of the hydroxy fatty acids occur as estolides or if epoxides are present. Moreover, the presence of other hydroxy compounds, such as sterols, monoacylglycerols and diacylglycerols, which also react with acetic anhydride, can affect the results. Most of these problems were overcome by saponifying the seed lipids to cleave the estolide linkages and removing the unsaponifiable matter. The resulting mixed fatty acids were subjected to radioacetylation, and the hydroxy fatty acid content was determined from the specific radioactivity of the resulting acetates with reference to the specific radioactivity of the acetate derived from ricinoleic acid as standard. The results obtained with the lipids from three seed species show close agreement with values reported in the literature (Table 3).

The procedures described here also permit the analysis of mixtures of triacylglycerols containing different numbers of hydroxyl groups per molecule. The results of an analysis of the lipids of castor *(R. communis)* bean are presented to demonstrate the potential of the isotopic derivative technique in conjunction with TLC. Lipids of castor bean were reacted with [1-^{14}C]acetic anhydride/pyridine reagent, and the resulting acetylated lipids were fractionated by TLC. The relative proportions of the various lipid classes in the total mixture were determined from the ratio of radioactivities in these fractions, corrected in terms of the number of hydroxyl groups per molecule. The results shown in Table 4 agree well with those reported in the literature (7).

Isotopic derivative techniques have so far received limited attention for the analysis of lipid mixtures (15-20). High sensitivity and simplicity of these methods make them ideally suited for the analysis of lipids containing hydroxyl groups.

Specialty Lipids and Their Biofunctionality

Symposium held at the 76th AOCS Annual Meeting in Philadelphia, Pennsylvania, May 1985

Medium Chain Triglycerides and Structured Lipids

Vigen K. Babayan
New England Deaconess Hospital, Harvard Medical School, Boston, MA 02215

Lipids are an essential component of our body composition and necessary in our daily food intake. Conventional fats and oils are composed of glycerides of long chain fatty acids and are designated as long chain triglycerides (LCT). Body fat as well as the fats and oils in our daily intake fall into this category. In enteral and parenteral hyperalimentation, we can identify such LCT fats and oils. Soy, corn, safflower and sunflowerseed oils are typical of the LCT oils.

In the search for alternative noncarbohydrate fuels, medium chain triglycerides (MCT) are unique and have established themselves in the areas of malabsorption syndrome cases and infant care and as a high energy, rapidly available fuel. Structure lipids with a MCT backbone and linoleic acid built into the triglyceride molecule have been developed to optimize the triglyceride structure that is best for patients, particularly the critically ill. Structured lipids with built-in essential fatty acid components or other polyunsaturated fatty acids promise greater flexibility in patient care and nitrogen support.
Lipids 22, 417-420 (1987).

Recent years have brought a renewed interest in lipids and their role in the metabolic and dietetic applications in health care of hospitalized patients as well as the public at large (1-33; Shah, N.M., and Iber, F.L., private communication).

This symposium focuses on a specific, unique segment of the lipid picture: the medium chain triglycerides (MCT) and structure lipids prepared from them.

A review and summary is presented here to lay the groundwork for the papers that follow. Each presentation supplements the broad picture that is evolving from the animal and human research that is progressing at various universities and laboratories.

REVIEW AND DISCUSSION

Fats and oils of animal, vegetable and marine origin have a fatty acid spectrum that ranges from C_2-C_{24}, with variations in not only physical and chemical characteristics but also in isomers and positional structure in the triglyceride molecule. Most fats and oils are composed of long chain fatty acids and are termed long chain triglycerides (LCT). Dairy fat, meat fat and vegetable oils fall into this category (Table 1).

The lauric fats, however, are composed primarily of fatty acids of C_{14} chain length and shorter. Coconut and palm kernel oils are typical of this class of lauric fats. They represent the main source of the C_8-C_{10} acids required for synthesis of MCT (Table 2).

MCT are different from all of the fats and oils we conventionally use. Where conventional fats and oils are absorbed via the lymphatic system and are carnitine-dependent for chylomicron formation and transport, MCT are absorbed via the portal system, are not carnitine-dependent and do not require chylomicron formation. The metabolic pathways of the MCT and LCT distinguish the unique aspects of the MCT (Tables 3 and 4; Fig. 1).

Aside from the transport difference, MCT demonstrate certain additional characteristics of considerable advantage. Whereas lipids generally are slowly absorbed and metabolized and energy is expended to oxidize and utilize them as fuel or building blocks, MCT are absorbed and

metabolized as rapidly as glucose while having better than twice the caloric density of protein and carbohydrate. They are easily oxidized and utilized as fuel and energy, with little tendency to deposit as body fat. For a quick, high energy source, MCT are outstanding.

These unique features of MCT have been recognized and utilized over the years. Oral supplementations and enteral feeding formulas of MCT products are available for use in a variety of areas, including care of infants, epileptic children and cystic fibrosis patients and for intestinal resection (35-37). For such established areas of MCT use, the practice has been to physically mix 15-20% of a highly polyunsaturated vegetable oil (to insure essential fatty acid requirements) with the MCT oil (38).

In the area of parenteral nutrition, we have been limited for many years to lipid emulsions based on soybean oil and now safflower oil (Table 5). Both are LCT types of lipid and pose a number of problems.

The current practice of using lipid emulsion in a total parenteral nutrition (TPN) regimen has been based on the need for a noncarbohydrate source for fuel and energy and the need to satisfy essential fatty acid requirements and/or deficiencies. LCT supply caloric needs and alleviate essential fatty acid deficiency. They have, however, shown a tendency to deposit as fat (a large proportion of the infused lipid) rather than to satisfy immediate fuel requirements. LCT lipid emulsions also are too slow in clearing from the blood and oxidize too slowly to supply fuel and energy.

At present, there is controversy over the optimum feeding regimen for the critically ill patient. An all-carbohydrate TPN system may promote visceral protein attraction and obligatory hepatic lipogenesis. There is no consensus, however, that lipid emulsions composed of LCT are optimal. There is concern that these emulsions are less than ideal because of a relative carnitine deficiency that occurs in sepsis, which blocks their entry into the mitochondria for β-oxidation. Numerous additional studies have shown reduced clearance of these emulsions in the critically ill patient and increased potential for elongation, desaturation and deposition in the liver and other organs.

In contrast, MCT have been shown to have a carnitine-independent entry into the mitochondria, to have a more rapid β-oxidation and to be less likely to undergo elongation and deposition (39-42). Emulsions composed

TABLE 4

Rationale for Use of Medium Chain Triglycerides (MCT)

Physicochemical characteristics	Physiologic considerations	Potential therapeutic applications
MCT present more interfacial surface for enzyme action/unit time	Intraluminal enzymatic hydrolysis of AMCT is more rapid and complete than LCT	Decreased intraluminal concentrations of pancreatic lipase (pancreatic insufficiency, cystic fibrosis) Decreased small-bowel absorptive surface (intestinal resection)
Greater water solubility of MCT hydrolysis products	Bile salts are not required for dispersion in water	Decreased intraluminal concentrations of bile salts (intrahepatic and extrahepatic biliary-tract obstruction, chronic parenchymal liver disease)
Smaller molecular size of MCT vs LCT	Small amounts of MCT may enter intestinal cell without prior hydrolysis	Pancreatic insufficiency
Shorter chain length of fatty acids derived from MCT	More efficient penetration of diseased mucosal surface	Nontropical sprue, tropical sprue
Small molecular size and lower pK of fatty acids derived from MCT	Intramucosal metabolism of MCFA different from LCFA: Decreased affinity for esterifying enzymes Decreased affinity for activating enzymes Minimal reesterification of MCFA to MCT No chylomicron formation	Abeta-lipoproteinemia Hypobeta-lipoproteinemia
Greater water solubility of MCFA	Different routes of transport of MCT vs LCT: Portal transport of MCT (as MCFA) Lymphatic transport of LCT (as chylomicrons)	Lymphatic obstruction (lymphomas) Intestinal lymphangiectasia

principally of MCT may offer a unique and readily available fuel for the injured and stressed patient (43). Also, since MCT readily undergo β-oxidation, ketonemia is usually much more pronounced than with LCT emulsions. Skeletal muscle can readily burn ketone bodies for fuel and may spare the oxidation of branched chain amino acids and reduce skeletal protein catabolism (44–52).

In an effort to develop the optimum lipid structure for parenteral use, we considered structured lipids using MCT and LCT having linoleic and/or linolenic fatty acids. The resulting rearranged triglycerides have both medium chain fatty acids and a polyunsaturated fatty acid on the same glycerine molecule. Based upon the molar ratios of the MCT and the LCT with a high unsaturated fatty acid, one can obtain the structured lipid of the desired combinations (Fig. 2). We have considered further the structured lipids with an MCT backbone by adding the essential fatty acid (linoleic acid) into the triglyceride molecule at various levels (45,46).

If LCT emulsions are too slow in clearing and suffer from other drawbacks, and MCT emulsions may be too rapid in clearing and suffer from the absence of essential fatty acids, then the structured lipid with sufficient linoleic acid to satisfy essential fatty acid needs will also serve to slow down the clearance of the MCT backbone to a more acceptable level (Table 6). A structured lipid

TABLE 6

Approximate Composition of Glycerides

	Captex 810 series structured lipids (%)			
	A	B	C	D
I MCT (3 short)	62	39	15	3

III MCT (1 short, 2 long)	6	16	27	44
IV LCT (3 long)	<1	2	3	34

having about 25% linoleic acid (Captex 810B) appears to be suitable for such parenteral lipid emulsion use. Preclinical and clinical testing remains to supply the needed data to validate this concept. The animal studies to date are encouraging and show certain additional benefits for the use of such structured lipids in hyperalimentation. Further investigation is warranted.

The rationale for and concept of preparing structured lipids are gaining support of research laboratories. It appears feasible that triglycerides where at least one fatty acid is a polyunsaturated fatty acid and at least one is a medium chain fatty acid can be obtained in glyceride oils. The actual format and combination of the fatty acids on the glycerine molecule will have to be investigated. Whether we shall require specific structures of high purity or can take advantage of molecular rearrangement to yield a mixture of structures will be determined by the functionality of such compositions. It appears highly probable, however, that lipid compositions of medium and long chain glycerides will advance our application of such lipids, both for the treatment of patients and the general welfare of the public.

Medium Chain Triglycerides and Structured Lipids as Unique Nonglucose Energy Sources in Hyperalimentation

Edward A. Mascioli, Bruce R. Bistrian, Vigen K. Babayan and George L. Blackburn
New England Deaconess Hospital, Nutrition/Metabolism Laboratory, 194 Pilgrim Rd., Boston, MA 02215

This brief review will discuss recent work concerning new intravenous lipid emulsions for future use in clinical patients. Intravenous lipid emulsions currently available in the United States are derived from soybean or safflower oils and serve as sources of nonglucose, nitrogen-sparing calories and the essential fatty acid linoleic acid. Because of concerns that much of the infused long chain triglyceride is not oxidized readily and that there may be some immune system impairment, newer emulsions utilizing medium chain triglycerides have been developed.
Lipids 22, 421–423 (1987).

Long chain triglycerides. Intravenous feeding of hospitalized patients has evolved rapidly. Before the availability of lipid emulsions suitable for intravenous use, glucose was the only nonprotein source of calories. Meeting the full caloric needs of the patient with glucose often led to hepatic lipogenesis and increased respiratory work to expire the excessive carbon dioxide produced during lipogenesis (1). Because intravenous fat emulsions made from soy or safflower oils contain linoleic acid, an essential fatty acid, their use was implemented. These long chain triglycerides (LCT) serve as a nonglucose fuel that provides energy so that the body can use amino acids as protein and not as a caloric source (2). Since fat burns at a lower respiratory quotient than glucose—that is, it produces less carbon dioxide for the same amount of oxygen uptake—this is a benefit for patients with pulmonary compromise having problems expiring all the CO_2 they are producing. In addition, long chain fatty acids will inhibit lipogenesis from carbohydrate, thereby decreasing fatty livers. In the diabetic patient, lipid calories decrease insulin requirements if substituted for glucose calories.

Essential fatty acids. The requirement for linoleic acid is met by supplying 4% of calories as the essential fatty acid. Since soybean oil is slightly more than one-half linoleic acid, supplying 10% of total calories as a soybean oil lipid emulsion easily meets essential fatty acid requirements. The issue of α-linolenic acid being essential has recently been raised by anecdotal reports as well as work by Neuringer et al. (3). Based on this work, it seems that long chain ω3 fatty acids, found in high concentrations in the brain and retina, are essential fatty acids. The primate work emphasizes their essentiality for infants but not necessarily for adults. Unlike safflower oil, soybean oil contains 7 or 8% α-linolenic acid, and since the current commercial lipid emulsions are derived from soybean oil in whole or in part, supplying these emulsions would probably meet requirements for both linoleic and α-linolenic fatty acids.

Immune system effects. Fischer et al. gave mice intraperitoneal Intralipid® and then followed that with the administration of intraperitoneal Streptococcus (4). In the lipid-treated group, there were significantly increased mortality and bacteremia and decreased neutrophil chemotaxis. Shaw and Wolfe were developing an *Escherichia coli* sepsis dog model and reported 100% mortality in the animals when 10% lipid was infused for 1 or 2 hr prior to intravenous injection of bacteria (5). The dose in these studies was ca. 115 mg per kg body weight per hr, a clinically relevant dose. Fraser and colleagues showed decreased chemotaxis of monocytes in patients as well as in normal subjects after the intravenous administration of 100 g of fat over 8 hr (6). The reticuloendothelial system (RES) is that collection of cells in the body concerned with phagocytosis of particulate matter in the bloodstream. It consists primarily of macrophages in the liver, spleen and bone marrow. A fourth study highlighting the clinical significance of a well-functioning RES was done by Rimola et al. (7). They studied 41 cirrhotic patients with routine clinical and laboratory parameters as well as liver-spleen scans and technetium-99 sulfur colloid clearance from the blood. They found that the only parameters that predicted mortality or the development of bacteremia were the tests of RES function such as the liver-spleen scans and technetium-99 sulfur colloid clearance rates. All other clinical and laboratory parameters were insufficiently sensitive to detect clinically vital outcomes such as the incidences of bacteremia and mortality.

A problem with LCT emulsions is slow clearance of the infused triglyceride from the bloodstream. Also, clearance is not synonymous with oxidation of the fatty acids, a primary purpose for using the emulsion. For these reasons, as well as the fact that medium chain fatty acids are rapidly cleared from the blood and are rapidly oxidized independent of carnitine transport and poorly stored in adipose tissue, medium chain triglyceride (MCT) emulsions were looked to for clinical intravenous use (8–10).

Medium chain fatty acid preparations. MCT oil consists essentially of octanoic and decanoic acids (8 and 10 carbons long, respectively), whereas soybean and safflower oil consist almost exclusively of fatty acids of 16 and 18 carbon chain length (Table 1). The fatty acids exist as triglycerides. In soybean and safflower oils, the fatty acids on the triglyceride are long chain; in MCT, they are

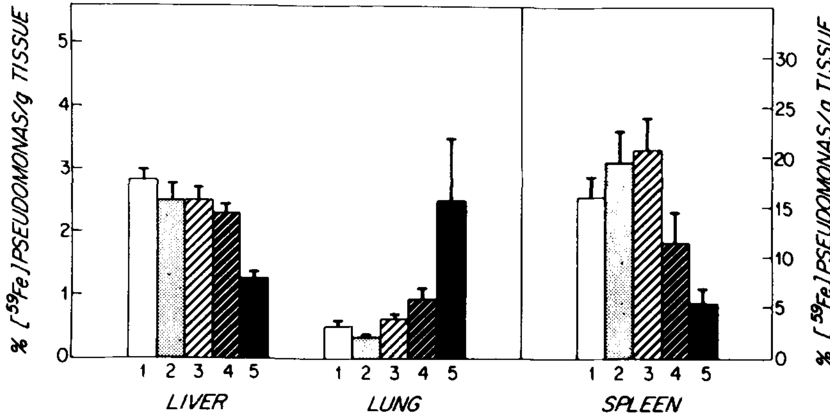

FIG. 1. Organ uptake of radiolabeled Pseudomonas following long chain triglyceride (LCT). Group 1, 100% glucose; group 2, 25% LCT/75% glucose; group 3, 50% LCT/50% glucose; group 4, 75% lipid/25% glucose; group 5, 100% LCT (ref. 11).

medium chain. A third group of triglycerides that has been investigated is that of structured lipids. These lipid molecules are triglycerides but are made from reesterified mixtures of MCT and LCT. The mixtures are hydrolyzed and allowed to reesterify randomly, thereby forming a triglyceride molecule of both medium and long chain fatty acids. As such, they are chemically distinct from physical mixtures of MCT and LCT.

Animal experiments. Our laboratory has recently published three experiments done on laboratory animals where these lipid emulsions were investigated. In the first experiment, rats were fed a total parenteral nutrition (TPN) regimen for three days (11). The rats had been given a 30% scald burn while anesthesized. At the end of three days, the animals were given a radiolabeled intravenous bacteremia; the clearance of this bacteremia into organs was measured. Rats were divided into groups that differed by the amount of fat (as LCT only) and glucose calories they received. It was shown that as the proportion of carbohydrate calories fell and that of lipid calories increased (the groups were equicaloric) there was a shift in the organ uptake of bacteria. Liver uptake decreased slowly with increasing lipid doses, whereas lung uptake of the radiolabeled bacteria increased markedly (Fig. 1). Next, different types of triglycerides at the same caloric proportions were given. The three lipids that were contrasted were LCT, MCT and structured lipid. LCT emulsions gave statistically increased lung uptake of the radiolabeled bacteria over that of the MCT and structured lipid groups (Fig. 2). Total caloric intake and proportion from fat calories were similar for these groups. This study emphasizes the fact that LCT blocks RES function whereas medium chain fatty acid-based lipid emulsions do not.

A second study was done by Hamawy et al. (12). Here, rats were given bilateral septic femoral fractures with the implantation of gauze containing *E. coli.* The animals were placed on TPN for four days and then studied. At the end of four days of TPN with septic fractures, blood was withdrawn and cultured to assess any bacteremia from the fractures. The group that received amino acids and dextrose but no lipid showed 10^3 bacteria/ml, as did

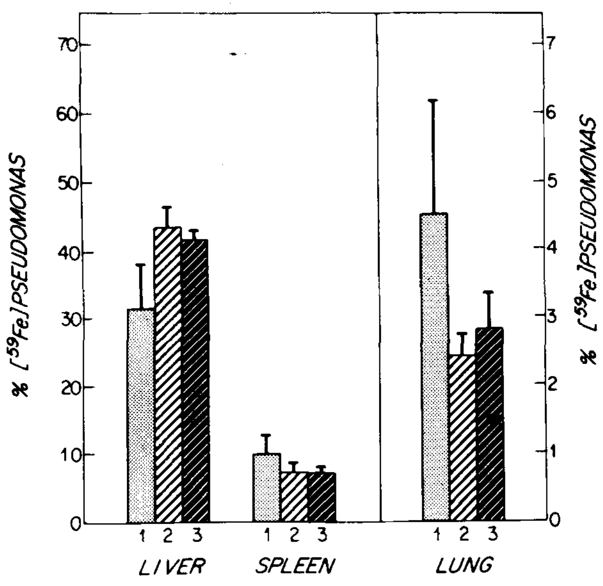

FIG. 2. Organ uptake of radiolabeled Pseudomonas following long chain (LCT), or medium chain triglyceride (MCT) or structured lipid. Group 1, LCT; group 2, MCT; group 3, structured triglyceride (ref. 11).

the group receiving one-third of its calories as LCT. The third group received a physical mixture of 75% MCT and 25% LCT as one-third of calories and showed no bacteremia (Fig. 3). Second, like in the experiment by Sobrado et al. described above, radiolabeled *E. coli* were injected into the blood. A statistically significant decrease in liver uptake of the *E. coli* bacteremia was seen in the LCT group compared with the 75% MCT and 25% LCT physical mixture group (Fig. 4). Inversely, in the lung, the MCT/LCT physical mixture group had a statistically significant lower uptake of bacteria compared with either the long chain or amino acid/dextrose TPN groups (Fig. 5). This study again highlights the significant difference in RES interference from intravenous lipid emulsions, with beneficial effects seen in the MCT/LCT physical mixture group.

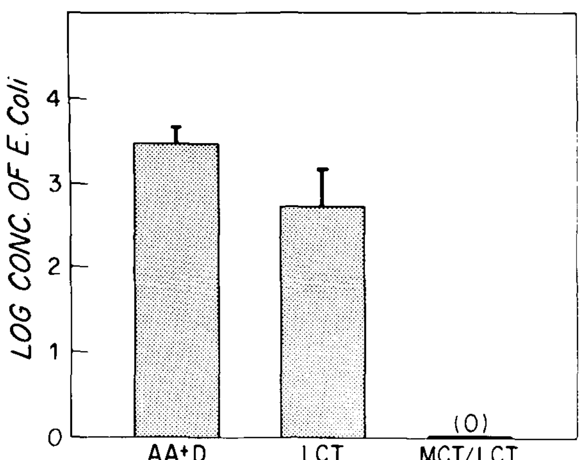

FIG. 3. Baseline bacteremia following septic fracture. AA + D, amino acids and dextrose; LCT, long chain triglyceride; MCT, medium chain triglyceride (ref. 12).

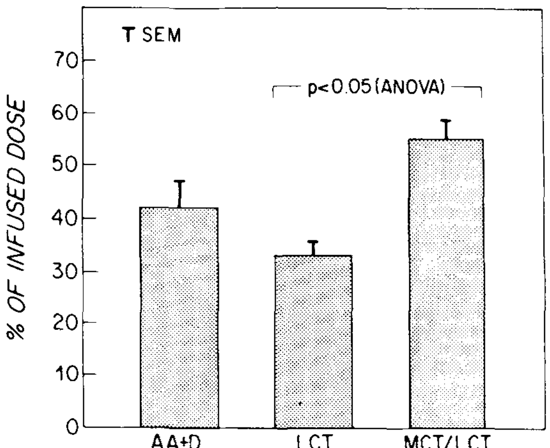

FIG. 4. Uptake of radiolabeled *E. coli* by the liver. AA + D, amino acids and dextrose; LCT, long chain triglyceride; MCT, medium chain triglyceride (ref. 12).

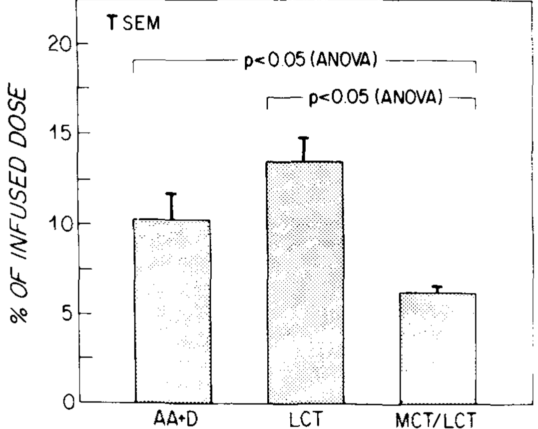

FIG. 5. Uptake of radiolabeled *E. coli* by the lung. AA + D, amino acids and dextrose; LCT, long chain triglyceride; MCT, medium chain triglyceride (ref. 12).

In the third study, by Mok et al. (13), rats also were given three days of TPN following a 25% scald burn done under anesthesia. The animals were divided into five groups according to TPN regimen. Group 1 was fed 200 calories per kg body weight per day as amino acids and dextrose and no lipid. Group 2 was fed ca. 300 calories/day, again consisting solely of amino acids and dextrose. Groups 3, 4 and 5 were fed ca. 300 calories/day with one-third of nonprotein calories as either LCT, MCT or structured lipid, respectively. The hypocaloric 200-kcal group and the MCT group lost weight during the experiment, whereas the other groups gained weight. This highlights the somewhat increased thermogenesis of MCT compared to other lipid fuels. Nitrogen balance did not differ significantly among the groups, but tended to show a higher balance in the structured lipid group. Albumin levels were measured and shown to be remarkably higher in the structured lipid group. This experiment shows the potential nitrogen-sparing benefits of structured lipid emulsions compared to other types of intravenous lipid.

Clinical data. We have begun to investigate intravenous MCT as a 75% MCT/25% LCT physical mixture in hospitalized patients. Preliminary analysis of the data shows that the fuels are safe and, as measured by serum triglyceride and free fatty acid analysis, are hydrolyzed and cleared rapidly. In addition, thermogenesis is noted in patients, but this was not accompanied by increased body temperature (14,15). European studies have shown similar results; they have had a 50/50 physical mixture of MCT and LCT available commercially for two years (16).

Studies to date support the notion that supplying all lipid calories in a TPN regimen as LCT is not the best nutritional care for patients. Giving a large proportion of these lipid calories as medium chain fatty acids, either as physical mixtures of MCT or as structured lipids, provides more readily oxidizable fuels with less interference of the reticuloendothelial component of the immune system.

[Received September 3, 1986]

Absorption of Safflower Oil and Structured Lipid Preparations in Patients with Cystic Fibrosis[1]

Van S. Hubbard[a,*] and **Mary C. McKenna**[b]
[a]Nutrient Metabolism and Obesity, Eating Disorders and Energy Regulation Programs, Nutritional Sciences Branch, Division of Digestive Diseases and Nutrition, National Institutes of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Westwood Building, Room 3A18, Bethesda, MD 20892 and [b]Division of Pediatric Research, Department of Pediatrics, University of Maryland School of Medicine, Baltimore, Maryland

Patients with cystic fibrosis (CF) and pancreatic insufficiency usually have decreased linoleic and increased oleic, palmitoleic and eicosatrienoic (20:3ω9) acids compared to normal values of blood and tissue lipids. These changes are consistent with early essential fatty acid deficiency and are observed despite the regular use of exogenous pancreatic enzyme supplementation. As part of a study to determine the relative role of malabsorption as the etiology for the altered fatty acid status, the change in total plasma fatty acids and in area percent of plasma linoleic acid was determined in CF patients and control subjects following the ingestion of various lipid supplements, including two safflower oil preparations and two structured lipid preparations. Fasting subjects consumed 36 g of lipid in a milkshake containing 15 g of protein and 45 g of carbohydrate. Plasma samples obtained 0, 2, 4, 6 and 8 hr after the meal showed that the CF patients absorbed all preparations when administered with their regular dose of pancreatic enzyme supplement. Comparison of the patterns of increase for total plasma fatty acids and area percent of plasma linoleic acid following the administration of the different lipid supplements in CF patients and control subjects suggests that (a) malabsorption alone is not the cause of the abnormal fatty acid composition in the lipids of CF patients and that increased caloric intake along with consumption of adequate amounts of linoleic acid should improve the linoleic acid status of CF patients; (b) there may be selectively increased metabolism of certain fatty acids from the ingested lipids in the relatively malnourished CF patient compared to control subjects; and (c) conditions favoring the persistence of nonpancreatic lipases seem also to favor absorption and utilization of the structured lipid preparation containing medium chain length fatty acids and linoleic acid in CF patients compared to control subjects.
Lipids 22, 424–428 (1987).

It has been recognized by many investigators that patients with cystic fibrosis (CF) and pancreatic insufficiency have changes in the fatty acid composition of their blood and tissue lipids consistent with early essential fatty acid deficiency, despite regular pancreatic enzyme supplementation (1–7). More recently, CF patients without clinical symptoms of exocrine pancreatic insufficiency have been reported to have altered fatty acid compositions (8–11). These patients usually have decreased linoleic (18:2ω6) and increased oleic, palmitoleic and eicosatrienoic (20:3ω9) acids relative to normal values.

The decrease in plasma and tissue linoleic acid levels generally has been attributed to the malabsorption associated with exocrine pancreatic insufficiency observed in 85–90% of CF patients. Altered hepatic fatty acid metabolism, including a decrease in desaturase activity, also has been suggested (1,7,12,13). In addition, decreased linoleic acid levels could be due, in part, to a restriction of dietary intake or an increased metabolic requirement for linoleic acid in CF patients with inadequate caloric intake. Decreased caloric intake in association with increased caloric needs in CF patients (14–17) could lead to metabolism of linoleic acid to meet immediate energy needs and consequently decrease the amount available as an essential fatty acid for elongation to arachidonic acid, prostaglandin biosynthesis, incorporation into membrane phospholipids and other functions (3,18–20).

Previous investigations of long-term supplementation of linoleic acid derived from a variety of sources have had inconsistent results (3,7,21–23). Studies in which major emphasis was placed on compliance and awareness of total caloric intake have demonstrated a possible benefit (24–26). As part of a study to understand and estimate the relative role of malabsorption as the cause of the fatty acid alterations in CF patients and to evaluate the efficacy of linoleic acid supplementation, the increase in plasma total fatty acids and percent linoleic acid content was determined after ingestion of test meals containing various lipid supplements. The test was somewhat analogous to a glucose tolerance test. The results of linoleic acid absorption from these test meals have been reported previously (13). This report presents new data regarding the absorption of total fatty acids from the preparations and compares this data with previously reported linoleic acid absorption patterns observed in CF patients and control subjects for each of the lipid preparations studied.

MATERIALS AND METHODS

Subjects. Nine CF patients with exocrine pancreatic insufficiency (four female, five male, aged 14–38 years) and seven control subjects (one female, six male, aged 19–37 years) were studied. The CF patients had a medical history and clinical evaluation indicative of CF diagnosis and a positive sweat test. Exocrine pancreatic insufficiency had been determined previously for each of the CF patients. CF patients were taking multivitamin supplements, exogenous pancreatic enzymes and oral antibiotics (dicloxacillin, tetracycline or trimethoprim-sulfamethoxazole). All CF subjects were clinically stable during the time of the study and had an NIH clinical score (27) between 50 and 90. Control subjects were volunteers without history or symptoms of malabsorption and no other known clinical illness. The studies were approved by the institute's clinical research subpanel, and informed consent was obtained from all subjects (and parents, where applicable).

Dietary lipid supplements. The supplements used for the linoleic acid absorption test were commercial

[1]Presented at the symposium on "Specialty Lipids and Their Biofunctionality" at the annual meeting of the American Oil Chemists' Society, Philadelphia, May 1985.
*To whom correspondence should be addressed.

safflower oil (Hain Pure Food Co., Los Angeles, California; with 74% of fatty acids as 18:2ω6), Microlipid, a 50% emulsion of safflower oil (Organon, West Orange, New Jersey; with 74% of fatty acids as 18:2ω6); and Captex 810B and Captex 810D (Capitol City Products Co., Columbus, Ohio; with 25% and 40% of fatty acids as 18:2ω6, respectively). Captex 810B and 810D are experimental oils made of synthetic triglyceride molecules that contain both medium chain and long chain fatty acids randomly esterified to glycerol. These products are made by mixing fractionated coconut oil (medium chain triglyceride [MCT]) with sunflower oil in specific proportions, hydrolyzing all of the triglycerides and allowing random reesterification of the fatty acids present into composite triglyceride molecules that contain fatty acids from both of the starting oils (28–30). The linoleic acid content of the final products was determined by varying the proportions of the starting MCT and sunflower oils. Some patients were not able to participate in the full study because of the length of the hospital stay involved. When patients were unable to participate in the full study, every effort was made to insure that the individuals were given safflower oil, Microlipid and Captex 810D in a random order as mentioned below. Captex 810B was omitted since it differed from the Captex 810D only in linoleic acid content.

Test procedure. The different lipid supplements were provided to the CF patients and normal subjects in a random order. Fasting subjects consumed 36 g of lipid mixed in 300 ml of a modified Lundh test meal (31) composed of an instant breakfast drink (Carnation Instant Breakfast) containing 15 g of protein, 45 g of carbohydrate, <0.5 g of fat and <0.1 g of linoleic acid, mixed with a fat-free skim milk. Since Microlipid was a 50% emulsion, it was necessary to add 72 g of this product to obtain the 36 g of lipid dose. CF patients took their usual dosage of oral pancreatic enzymes with the meal. Blood was obtained from all subjects at 0, 2, 4, 6 and 8 hr after receiving the meal and was placed on ice. Blood samples were centrifuged to obtain plasma, which was transferred to a Teflon-lined screw-top culture tube, and stored frozen at −20 C under nitrogen until analysis. Absorption tests with different lipid preparations on any individual patient or control subject were performed at least three days apart. Both CF and control subjects were given a fat-free meal after their blood had been withdrawn at the 6-hr time point.

Analytical methods. Duplicate samples of 1 ml plasma were added to an equal volume of ethanol containing 50 mg of ascorbic acid as an antioxidant and saponified with potassium hydroxide, under nitrogen at 65–70 C, neutralized with concentrated hydrochloric acid to release fatty acids, and extracted two times with hexane. Hexane extracts were transferred quantitatively to preweighed beakers, the hexane was evaporated, and the beakers were desiccated for 2 hr prior to reweighing to determine the total fatty acids gravimetrically. Samples were extracted, and fatty acid methyl esters were prepared with boron trifluoride as previously described (32). Fatty acid methyl esters were resuspended in a small volume (50 μl) of isooctane, stored under nitrogen at 4 C, and analyzed by gas chromatography within 24 hr of methylation. Fatty acid methyl esters were separated on an Ultrapak 15% silar 10C on gas chrom R column (Applied Science, Deerfield, Illinois), temperature programmed from 185 C at 6 C/min to a final temperature of 225 C on a Finnigan 9500 (Finnigan, San Jose, California) gas chromatograph (GC) or a Hewlett-Packard 3800 GC (Hewlett-Packard, Palo Alto, California) with an HP 3380A integrator. Individual fatty acids were identified by comparison of retention times to pure standards (Supelco, Bellefonte, Pennsylvania). Levels of linoleic acid were expressed as area percent of the total amount of fatty acids present. Results were expressed as increase in area percent of linoleic acid or increase in mg/dl of total plasma fatty acids, compared to zero time levels. Results were analyzed for significance using Student's t-test (33).

RESULTS

All subjects demonstrated the ability to absorb the fatty acids contained in the various lipid supplements. However, there was a tendency to have greater variability in absorption, both for linoleic acid and total fatty acids, among the CF patients.

The change in total plasma fatty acids in CF patients and control subjects following the administration of the liquid meal containing safflower oil is shown in Figure 1. The increase of total plasma fatty acids following the administration of safflower oil in both control subjects and CF patients was essentially identical, suggesting equal absorption rates for this oil. In control subjects, the increase in area percent of plasma linoleic acid shows a similar pattern to that of the increase in total plasma fatty acids (Fig. 2). However, there was an apparent delay in the increase in area percent of plasma linoleic acid compared to the increase in total plasma fatty acids in CF patients after ingestion of the safflower oil test meals (Fig. 3). The mean peak increase observed in area percent of plasma linoleic acid level in CF patients was not significantly different from that of controls (9.36% vs 10.95%, respectively). The absorption patterns for total plasma fatty acids and area percent of plasma linoleic acid levels following administration of Microlipid (data not shown) in both CF and control subjects were similar to that seen with unemulsified safflower oil.

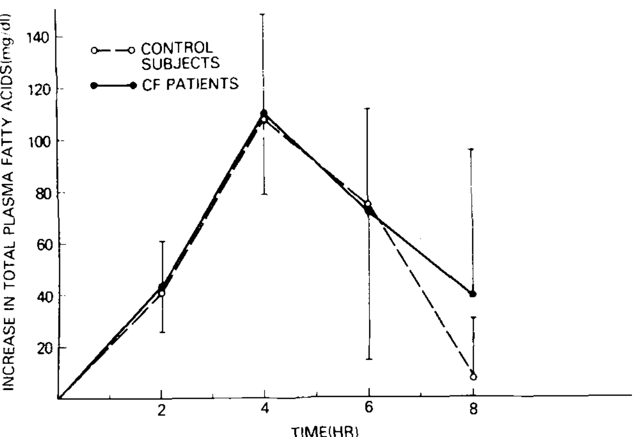

FIG. 1. Mean ± SEM increase in total plasma fatty acids over zero time values in control subjects (n = 7, ○) and cystic fibrosis patients (n = 9, ●) after ingestion of the 36-g dose of safflower oil in a test meal. Total plasma fatty acids were determined as described in Materials and Methods.

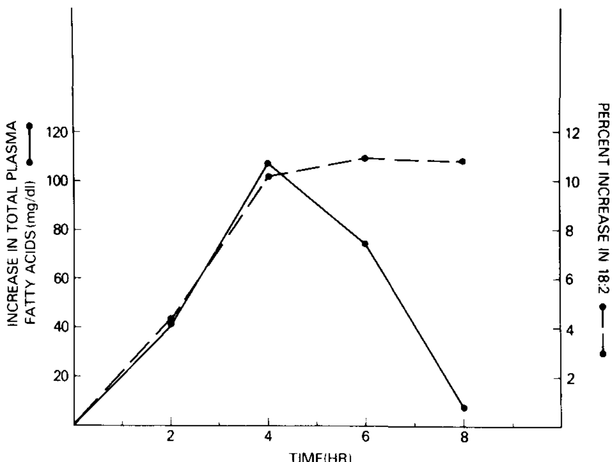

FIG. 2. Mean increase in total plasma fatty acids (solid line) and mean area percent increase of plasma linoleic acid (18:2) levels (dashed line) over zero time values in control subjects (n = 7) after ingestion of safflower oil. Plasma linoleic acid was determined as described in Materials and Methods.

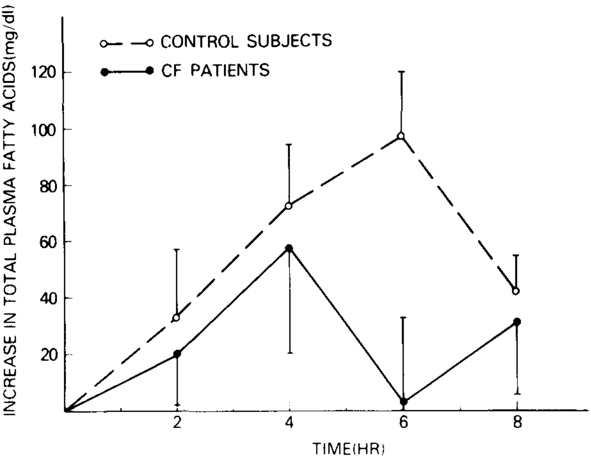

FIG. 4. Mean ± SEM increase in total plasma fatty acids over zero time values in control subjects (n = 7, ○) and cystic fibrosis patients (n = 6, ●) after ingestion of the 36-g dose of Captex 810D in a test meal.

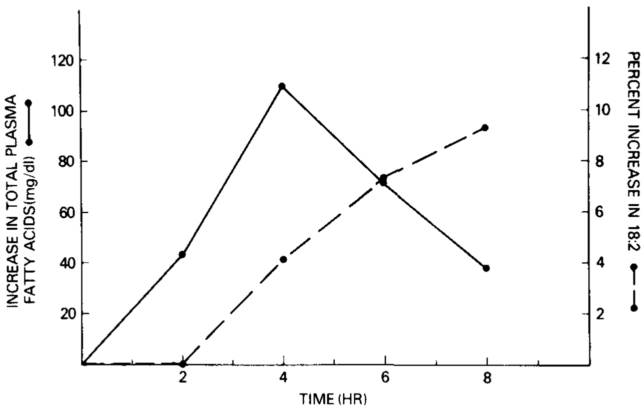

FIG. 3. Mean increase in total plasma fatty acids (solid line) and mean area percent increase of plasma linoleic acid (18:2) levels (dashed line) over zero time values in cystic fibrosis patients (n = 9) after ingestion of safflower oil. Note the delayed increase in percent linoleic acid relative to the increase of total plasma fatty acids.

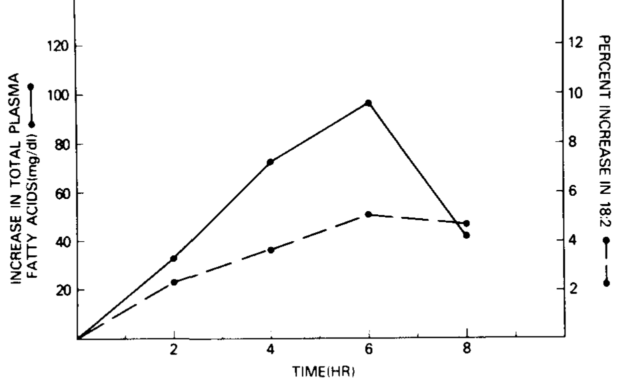

FIG. 5. Mean increase in total plasma fatty acids (solid line) and mean area percent increase of plasma linoleic acid (18:2) levels (dashed line) over zero time values in control subjects (n = 7) after ingestion of Captex 810D.

The pattern of increase in total plasma fatty acids following administration of Captex 810D also was similar for both CF and control subjects (Fig. 4). There appears to be a slight tendency for the CF patients to show a smaller increase in total plasma fatty acids relative to control subjects; however, no significant differences were found. In the control subjects, the increase in area percent of plasma linoleic acid occurred concurrently with the increase in total plasma fatty acids (Fig. 5), as it had with the safflower oil. However, the magnitude of change in area percent of plasma linoleic acid was less than that observed with the safflower oil preparation, since linoleic acid accounted for only 40% of the total fatty acids present in Captex 810D compared to 74% of the total fatty acids present in safflower oil. When Captex 810D was given to CF patients, the increase in area percent of linoleic acid occurred without a delay (Fig. 6), in contrast to the delayed increase following the ingestion of safflower oil (Fig. 3). In fact, with Captex 810D the peak

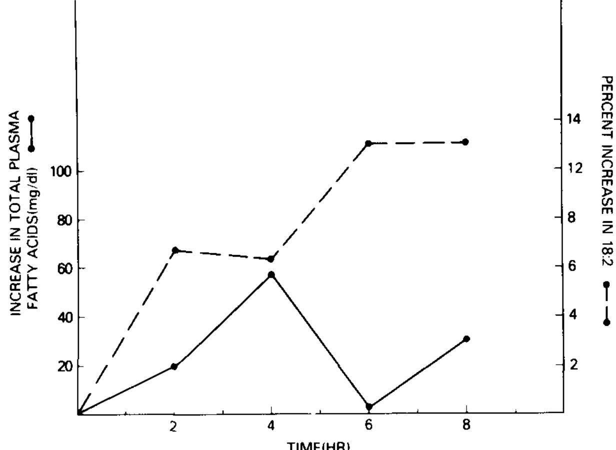

FIG. 6. Mean increase in total plasma fatty acids (solid line) and mean area percent increase of plasma linoleic acid (18:2) levels (dashed line) over zero time values in cystic fibrosis patients (n = 6) after ingestion of Captex 810D. Note the rapid rise in percent increase in 18:2 relative to the slower increase in total plasma fatty acids.

increase in area percent of plasma linoleic acid in CF patients was greater than the corresponding increase observed in control subjects ($p < 0.02$). When Captex 810B was given, the patterns of increase in total plasma fatty acids and area percent of plasma linoleic acid (data not shown) were similar to those observed with Captex 810D. However, the magnitude of the changes in area percent of plasma linoleic acid was smaller since linoleic acid accounted for only 25% of the total fatty acid content in Captex 810B.

DISCUSSION

The problem of marginal or inadequate linoleic acid status in CF patients has practical importance. Although altered fatty acid composition of blood and tissue lipids in the majority of CF patients may not be related to the basic defect, which is still unknown, there are data that suggest that altered lipid composition may potentiate some of the clinical manifestations of the disease (5,18,34).

Several types of lipid supplementation have been attempted in CF patients in an effort to correct the marginal essential fatty acid deficiency as well as to increase caloric intake (3,7,21–26). When MCT have been provided as the primary source of fat in the diet, alterations of fatty acid composition observed in lipids from CF patients became more abnormal (2). Long-term oral supplementation trials using corn oil or safflower oil have shown minimal or no improvement of linoleic acid status of CF patients (7,22,23). A problem with absorption of these oils has been proposed as one of the reasons for the failure to normalize linoleic acid status in these patients. However, it also has been suggested that underconsumption of calories related to their caloric needs (11,13) contributes to the marginal essential fatty acid status in CF patients. In this situation, the subject would utilize any ingested linoleic acid as a fuel for immediate energy needs rather than to meet essential fatty acid requirements.

Our data should help clarify the etiology of the abnormalities of fatty acid composition in CF patients. First, we have demonstrated that the magnitude of the increase in area percent of plasma linoleic acid and in total plasma fatty acids after ingestion of safflower oil is similar for both control subjects and CF patients as long as the CF patients are taking exogenous pancreatic enzymes at the time of the meal. Therefore, lack of absorption of the lipid supplement does not appear to be an adequate explanation of the altered fatty acid composition found in CF patients or of the lack of response to lipid supplementation trials. Second, the fact that the pattern of increase in total plasma fatty acids and corresponding increase in area percent of plasma linoleic acid after ingestion of the different lipid supplements investigated is different in the CF and control subjects supports the concept that the metabolism of the available dietary lipids is not the same in CF and control subjects.

In our previous work (13), it was not known whether the delay (relative to control subjects) in the increase in area percent of plasma linoleic acid observed in CF patients given the safflower oil test meal (Fig. 3) was due to differences in absorption of the ingested oil or a difference in metabolism of the absorbed products. However, the nearly identical pattern of change for total plasma fatty acids following the safflower oil test meal (Fig. 1) observed for both CF and control subjects suggests that a difference in absorption of the safflower oil in the two groups of subjects was unlikely. Thus, the delayed increase in area percent of plasma linoleic acid may be a consequence of increased metabolism of this unsaturated fatty acid in the relatively undernourished CF patients. CF patients with abnormal lipid fatty acid compositions also can be considered fat-deficient relative to control subjects. Consequently, our interpretation of the data is consistent with earlier studies in animals that demonstrated an increased rate of metabolism of orally fed linoleic acid to carbon dioxide in fat-deficient compared to normal mice (35).

The results observed following the administration of Captex 810D (Figs. 4–6) also support our hypothesis of selectively increased metabolism of certain fatty acids from the ingested lipids in the relatively malnourished CF patients compared to control subjects. Medium chain length fatty acids in the structured-lipid preparations provide a more preferable substrate for oxidative metabolism than long chain fatty acids (30,36,37). Thus, if these medium chain fatty acids are being more rapidly metabolized, the absorbed linoleic acid would appear as a larger proportion of the remaining plasma fatty acid pool.

The possibility of a more rapid absorption of Captex 810D compared to safflower oil in CF patients can be supported by the contribution of nonpancreatic lipases to the overall lipid digestion in these subjects (38). The preduodenal lipases are responsible for hydrolysis of dietary fat in the stomach. In earlier investigations with CF patients (38), this nonpancreatic lipolytic activity was attributed to lingual lipase, an enzyme secreted by the glands on the posterior aspects of the tongue. However, more recent studies have indicated that there is a gastric lipase that also contributes to intragastric lipolysis (39, 40). These preduodenal lipases have similar physical characteristics, including a low pH optimum and lack of dependence upon bile salts and co-lipase activity, that differ markedly from those characteristics of pancreatic lipase. The low duodenal pH (pH 4–5) and the relatively decreased levels of intraluminal bile salts in CF patients allow the persistence of lipolytic activity of these enzymes in the upper small intestine of CF subjects (38,40–42). Lingual lipase and presumably gastric lipase act preferentially on shorter chain triglycerides (43) such as those present in the Captex products, which would favor the utilization of these products compared to those containing long chain triglycerides such as safflower oil.

The data presented suggest that the structured-lipid preparations investigated provide efficient vehicles for the supplementation of linoleic acid to the CF patient. Our results indicate that malabsorption alone cannot account for the inadequate or marginal essential fatty acid status of CF patients, and that long-term consumption of supplemental linoleic acid in addition to adequate caloric intake should improve the linoleic acid status of most, if not all, CF patients. The interpretation of our data is consistent with observations reported by others (24–26). Randomly esterified synthetic triglycerides such as the structured lipids used in this study offer the advantage of providing shorter chain length fatty acids as a source of immediate energy through oxidative metabolism at the same time as providing essential fatty acids for repletion and maintenance of tissue stores. Such products would

seem especially well-suited to CF patients since the presence of shorter chain length fatty acids appears to enhance their utilization in this population of subjects.

ACKNOWLEDGMENTS

The Captex products were a gift from Cutter Laboratories (currently KabiVitrum Inc.), Berkeley, California. John Canham of Cutter Laboratories supported this study. The contributions of John G. Bieri, Loretta Liccini Duff, Dorothy Benton and the staff of the Nursing and Nutrition Departments, Clinical Center, National Institutes of Health, Bethesda, Maryland, are noted. This study was conducted in part within the Nutritional Biochemistry Section and Pediatric Metabolism Branch, NIDDK, NIH, Bethesda, Maryland.

Effects of feeding early in life a diet high in either long chain (LCT) or medium chain triglyceride (MCT) were studied on the development of adipose tissue in postweanling rats. The diets were similar in calorie distribution and identical in nutrients except for type of fat. The caloric distribution of the two diets by percent was LCT (corn oil)/protein/carbohydrate, 70/18/12 and MCT/corn oil/protein/carbohydrate, 66/4/18/12. Male littermates with less than 5% weight difference were pair-fed the two diets randomly at age 18–20 days. One-fourth of the rats were killed at 10, 16, 22 and 28 weeks of age and analyzed for adipose depots and adipose tissue cellularity. Results showed that the LCT-fed rats were significantly heavier, with larger epididymal, retroperitoneal, omental and subcutaneous fat pads than the respective pair-fed MCT rats. Also, LCT-fed rats had larger size and number of adipocytes than MCT-fed littermates. It is concluded that the type of fat in the diet, namely LCT or MCT, when fed early in life can influence the development of adipose tissue. MCT appears less lipogenic than LCT. The mechanism for the diminished adiposity of MCT-fed rats is related to extensive oxidation of MCT and its enhancement of thermogenesis leading to lessened energy efficiency.
Lipids 22, 429–434 (1987).

Tailormade medium chain triglycerides (MCT) for human consumption have been investigated and in use for over 25 years. Several reviews have dealt with their absorption, transport, metabolism and clinical uses (1–3). In the United States, the available MCT preparations are triglycerides whose constituent medium chain fatty acids (MCFA) are octanoic acid, 8:0 (65–70%); decanoic acid, 10:0 (20–35%); hexanoic acid, 6:0 (1–2%); and dodecanoic acid, 12:0 (1–2%). In Europe, MCT preparations tend to contain lower proportions of 8:0 and higher proportions of 10:0, at times in equal amounts, with trace quantities of 6:0 and 12:0. Although MCFA do appear in naturally occurring mixed triglycerides, pure edible MCT are derived semisynthetically from coconut oil or milk fat. For example, the fatty acids of coconut oil are hydrolyzed and molecularly distilled to yield three fractions: MCFA, relatively pure 12:0 and long chain fatty acids. MCFA are purified prior to reesterification with glycerol to form MCT (4). The final product (MCT) is a clear, light yellow oil with a melting point of −5 C, made up entirely of saturated MCFA ranging in length from 6:0 to 12:0.

Recently, studies of digestion, absorption and transport of MCT have been reviewed (3). It is clear that MCT is hydrolyzed efficiently in the lumen of the small intestine under conditions adverse to the hydrolysis of LCT (Fig. 1). Unlike LCT, in the absence of pancreatic lipase MCT is absorbed into the mucosa of the intestine, where it is hydrolyzed by a mucosal lipase into MCFA, which traverse the capillaries and are transported via the portal vein into the liver. In the liver, MCFA are extensively oxidized and, for this reason, are not incorporated into lipid ester moieties of lipoproteins. Also, less than 3% of ingested MCT are transported as chylomicrons. In view of the efficiency of their absorption and the uniqueness of their mode of transport, MCT have been used in the treatment of a variety of malabsorption syndromes, including long chain fat malabsorption in premature infants (5–7).

Infants and adults fed MCT as a major proportion of calories do not incorporate MCFA into adipose tissue. Feeding MCT to premature infants as 80% of dietary fat in formula diets deriving 50% of calories from fat has been shown to improve fat absorption and nitrogen retention (5,6). The growth curve of the MCT-fed infants did not differ significantly from that of the LCT-fed infants. However, the MCT-fed infants appeared more lean and

less fat clinically than the LCT-fed infants. Unfortunately, studies of body composition were not done on these infants. However, it was possible to study the effect of MCT on fat deposition in the rat (8). Three groups of rats were fed either a low fat diet, a diet containing 55% (by energy) MCT and 5% corn oil, or a diet containing 60% LCT in the form of corn oil. The results showed that, unlike LCT, MCT had a reductive effect on fat depots and, like LCT, had a depressive effect on lipogenesis. In contrast, the low fat, high carbohydrate diet had an enhancing effect on lipogenesis. In another study (9) in which food intake was precisely controlled by gastrostomy, body composition was measured in rats overfed with MCT- or LCT-containing diets that provided 50% calories in excess of normal consumption. The MCT-fed rats showed significantly smaller fat depots and adipocyte size than the LCT-fed controls. In a similar study, the mechanism of the reductive effect of MCT on fat depots was related in part to increased metabolic rate and enhanced thermogenesis (10).

The mass of adipose tissue in man and animals is dependent upon the number and size of its adipocytes. It is therefore conceivable to modify the ultimate dimension of the adipose depot in the body by factors that affect adipocyte replication and/or adipocyte size. In man and rat, the number of adipocytes has been reported as fixed at a certain age (11-13). During the postnatal period of growth, adipocyte proliferation continues until a maximum is attained, whereas further growth of adipose tissue occurs primarily as a result of adipocyte enlargement and not cell division (11). However, it has been reported that the adipocyte number can be increased in adult rats by feeding a diet high in long chain fat (14). Similarly, in the Osborne-Mendel rat, a high fat diet markedly increased the adipose tissue mass without significantly altering water, protein or ash content (15). The average human newborn infant has 500 g of fat in 4 billion adipocytes, each containing 0.12 μg of fat (16). In contrast, the normal nonobese adult has 30 billion adipocytes with 0.5 μg of fat per cell, while the obese adult may harbor 1 trillion adipocytes, each containing 0.6 to 1.2 μg of fat (17). Thus, a considerable increase in adipocyte number must occur from infancy to adulthood. Little is known about the regulatory mechanisms that control the growth of adipose tissue. Nutrition appears to be important. Preweaning undernutrition has been shown to result in an ultimate reduction in the cell number of the epididymal fat body of the rat (18). While undernutrition can result in a reduction of adipocyte number (and size), such a manipulation also can produce appreciable reduction in the cell number of the central nervous system (19). It is postulated that MCT feeding in early life will reduce adipose tissue mass with concurrent preservation of adequate nutrition. It is also postulated that chylomicrons resulting from the ingestion of LCT and not MCT are important stimuli for growth of adipose tissue. As LCT digestion and absorption improve postnatally, there is rapid accumulation of fat, associated with enhanced cellularity of the adipose tissue.

MATERIALS AND METHODS

Pregnant Sprague-Dawley rats fed a standard stock diet were allowed to deliver and nurse their pups in our laboratory. At weaning (18-20 days), male littermates from the same dam with weight difference of 5% or less were pair-fed and divided into two groups, to be fed an LCT or MCT diet. MCT was provided by Capital City Products Co. (Columbus, Ohio). The diets were identical in nutrients except for the type of fat and were similar in energy distribution. The LCT diet derived 70% of total energy from corn oil; the MCT derived 66% of total energy from MCT and 4% from corn oil (to supply essential fatty acid). Both diets contained 18% of total energy as protein and 12% as sucrose. Each diet yielded 3.9 kcal/g. The composition of the diets is shown in Table 1. Diet was placed in a cup anchored to the cage and covered with a screen mass and a broad funnel-like lid. In this way spillage was negligible. The animals were pair-fed their respective diets from weaning until they were killed. The animal that ate the least (usually the MCT rat) was allowed to eat ad libitum. The exact amount of food eaten by this rat was then given to the other rat of the pair at the next feeding. The amount of diet consumed was weighed and calculated three times per week. One-fourth of the rats were killed at 10, 12, 22 and 28 weeks of age. Various fat pads were removed as follows: A ventral midline vertical incision was cut toward the head. Two cuts were made laterally from the midline incision about 1 cm above the hip. Each epididymal pad was exposed and cut at the base of the epididymis toward the epididymal vessels. The cut then followed the vessels until the whole epididymal pad was freed. The left epididymal pad was used to determine number and size of the adipocytes. The retroperitoneal fat was removed by cutting its apex

at about the midinguinal point and at the medial border of the psoas muscle. The cut then followed the medial border of the psoas muscle until it reached just below the lower pole of the kidney and followed the lateral border of the kidney as far as possible toward the diaphragm. The retroperitoneal fat was freed from the underlying muscle and weighed. The left retroperitoneal fat was used to determine number and size of the adipocytes. The dorsal fat is a rectangular pad. The vertical lines ran through the shoulder from a point 1 cm above the hip to the neck. The caudal horizontal line ran from one vertical line to the other, 1 cm above the hip. The skin was carefully dissected out free of fat. Then this dorsal fat pad was carefully removed free of muscle and brown fat. It was weighed and used to determine cell number and size. The remaining subcutaneous fat was then dissected out and weighed; the omental fat was stripped off easily from the alimentary tract. Thus, the total fat was comprised of all the fat pads: right and left epididymal fat, right and left retroperitoneal fat, dorsal fat and remaining subcutaneous fat.

The cell count was determined by the method of Hirsch and Gallian (20) as follows: A certain amount of adipose tissue (one sample each from the left epididymal and retroperitoneal and two from the dorsal fat) weighing about 80 mg in several small pieces from different sites was weighed on a tared nylon mesh (200 μ) and placed in a polyethylene vial containing 15 ml of 2% osmium tetroxide in 0.05 M collidin buffer, pH 7.4. The tissue was incubated at 37 C for 48 hr. It was thoroughly washed, and the freed adipocytes were counted in a Coulter counter. The total adipocytes per piece of adipose tissue of known weight were thus calculated.

The cell size was determined as follows: One piece each of left epididymal, left retroperitoneal and dorsal fat (about 150 mg) were placed in separate 50-ml ground-glass stoppered tubes, followed by 20 ml of redistilled chloroform and 10 ml of redistilled methanol. The tube was allowed to stand in a cold room for 48 hr. Distilled water was added to the tube, which was shaken gently and allowed to stand for separation of the solution in the tube into two phases. The upper aqueous phase was removed. About 10-15 g of anhydrous sodium sulfate was added to the chloroform phase and shaken gently. Then 5 ml of the lipid phase was pipetted into a tared dish. The chloroform was allowed to evaporate completely, and the remaining lipid in the dish was weighed. Thus, the lipid content of the adipose tissue of known weight was divided by the number of cells, and in this way converted into cell size, expressed as μg of lipid (mainly triglyceride) per cell.

RESULTS

Body weight and weights of both epididymal, both retroperitoneal, total subcutaneous and omental fat pads of the two groups of rats at ages 10, 16, 22 and 28 wk are shown in Table 2. The LCT-fed rats were substantially heavier than their pair-fed MCT counterparts at all ages. The increment in body weight in the LCT over the MCT rats increases with age from 3.7% at age 10 wk to 8.5% at age 16 wk to 15% at ages 22 and 28 wk. All fat pads in the LCT group were significantly heavier than those of the pair-fed MCT rats at all ages. The increases in the weights of the epididymal, retroperitoneal and omental fat pads in the LCT group over those of the MCT group were 30-35% at age 10 wk and approximately 50% at ages 16, 22 and 28 wk. The subcutaneous fat, the largest dissectible fat pad in the rat, was 18-30% heavier in the LCT than in the MCT group at all ages. The total dissectible fat without the omental pad (so computed because the weights for the omental fat pads were not obtained at 22 and 28 wi) was 27-36% heavier in the LCT than in the MCT group at all ages.

The total lipid content of the left epididymal, left retroperitoneal and interscapular (dorsal) subcutaneous fat pads of the LCT and MCT groups at ages 10, 16, 22 and

28 wk is shown in Table 3. The LCT rats had significantly more lipid per unit weight of the three fat pads than their respective pair-fed MCT rats, except for the dorsal pad at 28 wk.

The fat cell size of the left epididymal, retroperitoneal and interscapular (dorsal) subcutaneous fat pads of the two groups at all ages is shown in Table 4. The LCT rats had significantly larger adipocytes in all depot fat pads than the MCT rats at all ages, except for the epididymal fat pad at age 10 wk and the dorsal fat pad at 28 wk.

The fat cell number of the left epididymal, retroperitoneal and interscapular (dorsal) subcutaneous fat pads of the two groups of rats at all ages is shown in Table 5. For the epididymal fat pad, the LCT rats tended to have a larger adipocyte number than the MCT rats at all ages, but the difference was significant only at 28 wk. For the retroperitoneal fat pad, the LCT rats had significantly more adipocytes at all ages. In contrast, the number of fat cells in the dorsal pad did not differ significantly between the LCT and the MCT groups.

DISCUSSION

The data show that the LCT-fed rats were significantly heavier than the respective pair-fed MCT rats at all ages. Also, the various adipose depots weighed on an average 30% to 50% more in the LCT- than in the MCT-fed rats. It is noteworthy that both groups of animals consumed the same amount of calories, and their diets, except for quality of fat content, were identical in caloric distribution and density. Under the conditions of pair-feeding, rats in the LCT group tended to finish their food, while those in the MCT group usually had food available throughout the 24 hr. Thus, the LCT-fed rats tended to be hungry and therefore more active than the MCT-fed rats. If the activity of both groups had been similar, the LCT-fed rats would have been heavier and their adipose depots larger, and the difference in the parameters between the two groups would have been more pronounced. A possible explanation for the diminished spontaneous food intake of rats fed MCT in comparison with animals

fed LCT ad libitum is the development of hyperketonemia during MCT feeding (2,21,22). For this reason, the present study used pair-feeding to ensure similarity in food intake in both groups of animals. Rats fed ad libitum a diet containing 20% lard were reported to be heavier than animals fed a diet containing 20% MCT and had larger epididymal fat pads. The energy requirement for weight maintenance was higher in rats fed MCT than in those fed lard (23). Pigs fed a 10% MCT diet exhibited weight gain and feed efficiency at a rate considerably lower than that of animals fed a 10% LCT diet (24). Premature infants fed a formula containing 40% of total calories from MCT gained less weight than infants fed an identical formula containing 50% of total energy from LCT (corn oil), despite the fact that the groups had the same calorie intake and that the MCT-fed infants absorbed more fat, protein, calcium and magnesium than the LCT-fed group (5,6).

This study supports the hypothesis that MCT feeding early in life results in diminished fat deposition and adipose tissue cellularity. The mechanism whereby MCT feeding results in diminished adiposity compared to LCT feeding may be related to vast differences in the modes of digestion, absorption and metabolism of the two triglycerides. In contrast to LCT, which appear in the systemic circulation as chylomicrons, the MCT-derived fatty acids are transported via the portal vein (25) to the liver, where they are extensively oxidized into CO_2 and other water-soluble metabolites, such as ketones, and are not incorporated into hepatic lipids to any appreciable extent (1,2). In the rat, the cumulative oxidation of labeled MCT over a period of 48 hr was about twice that of LCT (26). In both man and animals, the oxidation of MCT-derived fatty acids is not appreciably affected by the nutritional state. In contrast, feeding drastically reduces the oxidation of LCT-derived fatty acids (27). Thus, it appears that MCT must undergo obligatory oxidation in the liver after absorption and transport. The oxidative aqueous products other than CO_2 reach the systemic circulation and are utilized by various organs, including the adipose tissue. Theoretically the adipose tissue can synthesize long chain fatty acids from MCT-derived oxidative products. However, studies have shown that the adipose tissue in fact contains very little medium chain fatty acid (3). In contrast, the LCT moieties of chylomicrons are hydrolyzed, picked up and readily reesterified into triglycerides by the adipose tissue. Thus, the metabolic steps that lead to formation of triglycerides in adipose tissue are much simpler for LCT than for MCT. In the intact animal and in man, evidence suggests that MCT feeding is associated with enhanced thermogenesis, thus favoring diminished energy efficiency and reduced deposition of fat (10,28).

LCT-fed rats had not only larger fat depots but also higher lipid content per unit weight than MCT-fed rats. The weight increase of various fat depots in the LCT-fed rats was due to adipocytes being bigger and more numerous than in the MCT-fed rats. It is not known whether the increase in adipocyte number in the LCT group is due to actual proliferation or to fattening up of existing pre-adipocytes.

In virtually all mammalian species, the mammary gland synthesizes LCT and varying proportions of MCT (29). In rabbit milk, the predominant fat is MCT, reaching 80% of the milk fat. Smaller proportions of MCT in milk fat occur in the rat (30%), in the mouse (8%) and in man (12%). It appears that the mammary gland begins to synthesize MCT during pregnancy and maintains such synthesis during lactation through a remarkable mechanism involving an enzyme (thioesterase II) that segments long chain fatty acids (LCFA) into MCFA for incorporation into milk triglycerides (30). The fatty acid distribution on the triglyceride appears to favor digestion and absorption of the milk fat by the neonate in that the LCFA tend to occupy the 1 and 2 positions, while the 3 position is occupied by the MCFA (31,32). The net effect of this presentation of milk fat to the neonate is ease of hydrolysis and subsequent elaboration of MCFA, LCFA and long chain monoglycerides for enhanced intestinal absorption. Studies in man suggest a twofold increase in MCFA in breast milk of mothers at premature delivery and that the premature infant, when ingesting its own mother's milk for three months, receives 17% of total fat as MCFA, in contrast to 10% for the full-term infant (33). By increasing the proportion of dietary MCFA from MCT, it may be possible to circumvent the diminished

ability of the premature infant to digest and absorb LCT and concurrently to offer an easily oxidizable fat. The effect of starting MCT feeding in the neonatal period on the development of adipose tissue cellularity awaits further investigation. Our study demonstrates that the type of fat in the diet in the postweaning period can influence the development of adipose tissue cellularity. MCT feeding early in life may offer a potential measure for prevention and control of human obesity.

[Received September 3, 1986]

The Effect of Medium and Long Chain Triglyceride on Human Adipose Tissue Metabolism[1]

David P. Katz* and **Jerome L. Knittle**
Department of Pediatrics, Division of Nutrition and Metabolism, Mount Sinai School of Medicine, New York, NY 10029

Studies have been performed to assess the effects, in vivo and in vitro, of lipid emulsions on human adipose tissue prostaglandin production. Subcutaneous adipose tissue obtained either during elective surgery or by needle aspiration was studied in tissue culture or by using a perifusion apparatus. Physical mixtures of emulsions of long chain triglyceride (LCT) and/or medium chain triglyceride (MCT) were added to the tissue culture medium so that the final concentration was 400 mg/dl. After a 3-day incubation period the tissue was harvested, placed in buffer and used to determine in vitro production of prostaglandin E_2, prostacyclin I_2 (measured as its stable end product 6-keto $PGF_{1\alpha}$) and thromboxane A_2 (measured as TXB_2) by radioimmunoassay. The results demonstrated that samples incubated in 100% MCT had the most significant increase in prostaglandin production, while those incubated in 100% LCT had the most significant decrease in activity of the three prostaglandins assayed. The addition of LCT to MCT caused a stepwise decrease in adipose tissue prostaglandin production. The data suggest a pharmacological rather than a physiological effect of lipid emulsions containing MCT and/or LCT on adipose tissue prostaglandin production. In vivo effects of a 20% safflower oil emulsion, containing high levels of the essential fatty acid linoleate, were assessed in five pediatric patients. Adipose tissue was obtained before and after two and four weeks of treatment. Fatty acid profiles and prostaglandin production were determined. The results demonstrated that intravenous fat infusion increased the concentrations of linoleic and arachidonic acids found in adipose tissue within a short interval. The effect of intravenous fat infusion on human adipose tissue prostaglandin production was less predictable and may have been a function of the patients' disease and subsequent clinical course. These findings suggest that lipid emulsions should not be viewed solely as a source of intravenous energy, because they may have the potential to elicit changes in prostaglandin production as demonstrated by a human adipose tissue model.
Lipids 22, 435–441 (1987).

Adipose tissue is a dynamic organ central in maintaining caloric balance; it is capable of responding to a variety of metabolic, hormonal and nutritional influences. The structure and function of adipose tissue have generally been studied in the context of overnutrition as seen in the obese. The possible role of adipose tissue in the recovering, malnourished, hospitalized patient has largely been ignored.

The 10% and 20% lipid emulsions have been widely used as a source of intravenous energy or as a means for preventing or ameliorating essential fatty acid (EFA) deficiency in malnourished patients. The emulsions currently used contain 54% to 77% linoleic acid, an EFA. Linoleic acid is the biosynthetic precursor for another EFA, arachidonic acid. Further modification of this fatty acid yields a family of bioactive metabolites, commonly called the eicosanoids. These products include the prostaglandins, leukotrienes and hydroperoxy-arachidonate derivatives. It has been hypothesized that the high levels of linoleic acid delivered as part of a total parenteral nutrition (TPN) regimen may affect endogenous prostaglandin production. It has been demonstrated that fat emulsions are principally removed from the bloodstream by skeletal muscle and adipose tissue (1) and that adipose tissue produces prostaglandins (2–5); it thus was of interest to determine the effect of this nutriment on fat tissue metabolism.

MATERIALS AND METHODS

Experiments in our laboratory have been performed to assess the effect in vivo and in vitro of various lipids, triglycerides and fatty acids on the ability of human adipose tissue to make prostaglandins. To perform these experiments, we modified the perifusion apparatus (PA) of Allen et al. (6) to study the tissue under more physiological conditions. The PA is a glass water-jacketed column in which fat tissue is suspended and kept at a constant 37 C. Krebs-Ringer bicarbonate buffer (pH 7.4) is pumped through the top at a constant rate and automatically collected at the bottom using a fraction collector. At various intervals, any combination of substrates or drugs can be infused by a series of pumps. During the experiments described below, two PA were run simultaneously. One column functioned as a control, i.e., only buffer was pumped through, while the other was used for the experimental manipulation. The advantage of this system compared to the more traditional tissue culture is that, with the constant turnover of buffer through the PA, there are no metabolic end products in the chamber that may affect the response of the tissue under study. In the first series of experiments, adipose tissue was obtained from four obese subjects by needle aspiration using the method of Hirsch and Goldrick (7). The tissue was washed in cold 0.9% sterile saline and split into equal portions of 200–300 mg. The tissue was then suspended in the two PA and allowed to equilibrate for 5 min. The buffer used contained fatty acid–free albumin (5 mg/dl) and glucose (100 mg/dl) and was pumped at a rate sufficient to clear the volume of the column every 5 min. After a baseline period of 20 min, arachidonic acid that had been previously bound to albumin (8) at a concentration of 0.3–0.5 μmol/ml was infused into the experimental column for the duration of the experiment. Fractions were collected every 5 min and analyzed by radioimmunoassay (RIA) for prostaglandin E_2 (PGE_2), prostacyclin I_2 (measured as the stable metabolite 6-keto $PGF_{1\alpha}$) and thromboxane A_2 (measured as the stable metabolite TXB_2) (9–14).

In vitro effects of lipid emulsions on adipose tissue. In this investigation, physical mixtures of lipid emulsions containing 20% long chain triglyceride (LCT) from soybean oil and/or medium chain triglyceride (MCT) were made to assess the effect of concentrations of linoleic acid ranging from 0 to 54% (Katz, D.P., and Knittle, J.L., submitted for publication).

Subcutaneous human adipose tissue was obtained during elective abdominal surgery and resected from pieces that would otherwise have been discarded. All subsequent manipulations of the tissue were performed in a laminar flow hood. The tissue was washed in 0.9% sterile saline and then placed in tissue culture for 24 hr to equilibrate at 37 C in defined culture medium, RPMI 1640 with 20% fetal calf serum (Gibco Laboratories, Grand Island, New York). The defined culture medium with fetal calf serum contained less than 0.01% of the essential fatty acids, linoleic and arachidonic. At the end of the 24-hr period the tissue was harvested and washed in multiple volumes of 0.9% sterile saline. The tissue was then divided into portions of 200-300 mg each and placed into seven duplicate tissue culture flasks. To each flask 10 ml of the medium described above was added. At this time a physical mix of the different lipid emulsions to be tested was added to the duplicate flasks so that the final triglyceride concentration was 400 mg/dl. The flasks were then placed in a 37 C CO_2 incubator on a rocker platform (Bellco Glass, Vineland, New Jersey) to insure proper mixing. The tissue remained in culture for 3 days and was fed each day, as above, after the old medium was removed. At the end of the 3-day period the tissue was harvested and washed in 0.9% sterile saline. The samples were then used in experiments to measure in vitro prostaglandin production.

The tissue was separated into equal portions and placed in duplicate tissue culture flasks with Krebs-Ringer bicarbonate buffer (pH 7.4) containing fatty acid-free bovine serum albumin (5 mg/dl) (Sigma Chemical Co., St. Louis, Missouri) as prepared by the method of Chen (15) and glucose (1 mg/ml). It was then placed back into the CO_2 incubator on the rocker platform for 60 min. At the end of this incubation period the buffer was recovered and aliquoted for the determination of prostaglandins. The samples were analyzed in duplicate for prostacyclin I_2 (measured as the stable metabolite 6-keto $PGF_{1\alpha}$), thromboxane A_2 (measured as TXB_2) and PGE_2 by RIA (9-14). Determinations of fat cell size were made in each set of experiments so the data could be standardized (16).

In vivo effects of a lipid emulsion on human adipose tissue. Preliminary studies of the in vivo effect of an intravenous fat emulsion on adipose tissue prostaglandin metabolism have been performed in pediatric patients. A 20% safflower oil emulsion was administered to five subjects ranging in age from 4 to 12 years. These patients required TPN for a variety of reasons. After informed consent was obtained, adipose tissue samples were taken from the subjects before and two and four weeks after treatment. The subjects received the standard TPN regimen with a 20% intravenous fat emulsion for the duration of the study. The doses of lipid ranged from 0.5 to 2 g/kg body weight. Adipose tissue was used to determine fatty acid profiles and in in vitro experiments to measure prostaglandin production in a perifusion apparatus as described above. Samples were extracted overnight at 4 C in chloroform/methanol (2:1, v/v) (Fisher Scientific, Pittsburgh, Pennsylvania). Solvents had been previously redistilled. The resultant samples were methylated using a modification of Glass's method (17). Samples were then analyzed using a Hewlett Packard 5750 Gas Chromatograph equipped with a Hewlett Packard 3390A Reporting Integrator (Avondale, Pennsylvania). A modification of the temperature programming method of Mahadevan and Zieve was used (18).

RESULTS

The results depicted in Figure 1 demonstrate the production of PGE_2, 6-keto $PGF_{1\alpha}$ and TXB_2 by human adipose tissue. There was no significant difference in prostaglandin production between the two columns during the baseline period. The infusion of arachidonic acid bound to albumin caused an immediate, significant increase in the production of PGE_2, which remained elevated throughout the balance of the experiment (800-1950% change). The percent increases in production of both

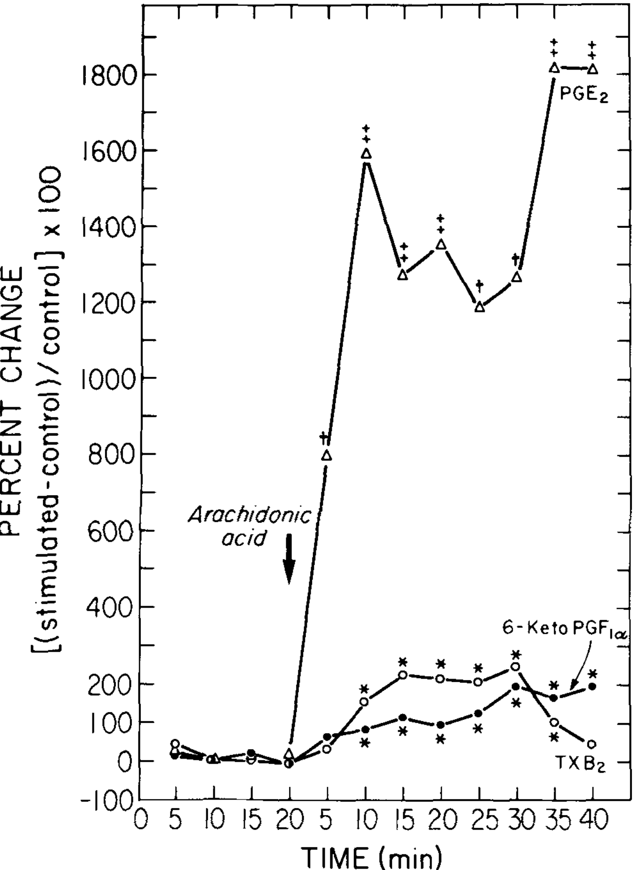

FIG. 1. Effect of arachidonic acid bound to albumin on human adipose tissue prostaglandin production. Adipose tissue was suspended in two identical perifusion apparatuses, and after a 20-min baseline period arachidonic acid bound to albumin was infused. The collected fractions were analyzed for PGE_2, 6-keto $PGF_{1\alpha}$ and TXB_2 by radioimmunoassay. Data was standardized and compared to zero by t-test. Results indicate that human adipose tissue obtained by needle aspiration can rapidly convert arachidonic acid to PGE_2, 6-keto $PGF_{1\alpha}$ and TXB_2. Each data point represents a mean level of the specific prostaglandin assayed. Standard error bars were omitted for clarity. *, $p < .05$; †, $p < .01$; and ††, $p < .001$.

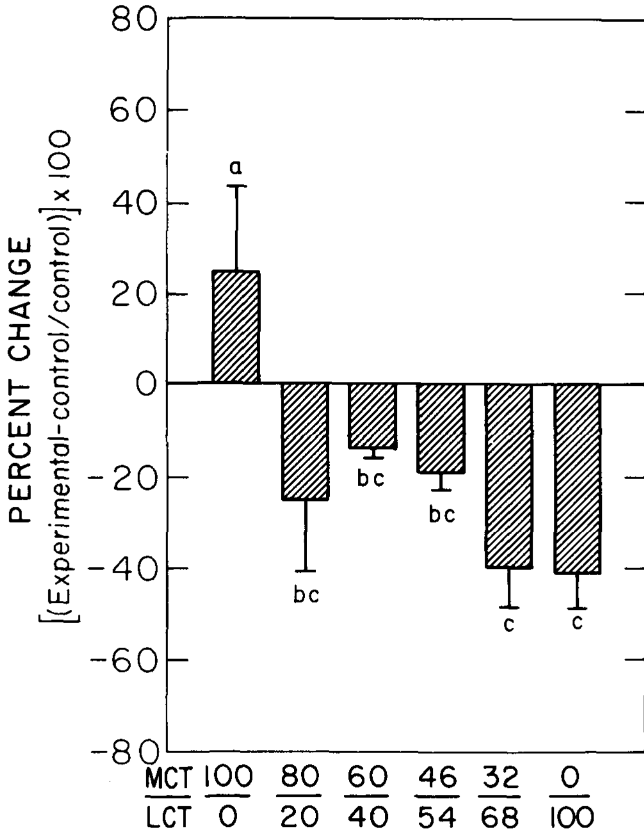

FIG. 2. Effect of physical mixtures of 20% lipid emulsions containing medium (MCT) and/or long chain (LCT) triglyceride on the production of thromboxane (TXB_2) by human adipose tissue. The percentage of MCT and/or LCT varied from 0% to 100%. This altered the concentration of linoleic acid in the incubation media from 0% to 54%. Data was standardized to percent change in activity compared to the control to account for individual variation within each experiment (n = 4). Data are expressed as means ± SEM and were compared by analysis of variance with post-hoc comparisons by Duncan's multiple range test. Means with different letters are statistically different from one another at p < .05.

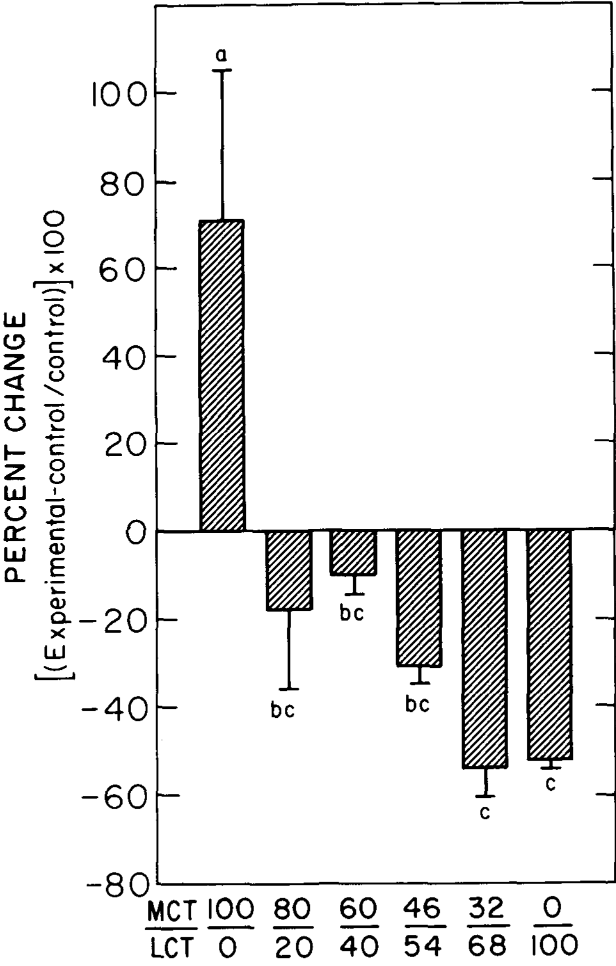

FIG. 3. Effect of physical mixtures of 20% lipid emulsions containing medium (MCT) and/or long chain (LCT) triglyceride on the production of prostacyclin (6-keto $PGF_{1\alpha}$) by human adipose tissue. The percentage of MCT and/or LCT varied from 0% to 100%. This altered the concentration of linoleic acid in the incubation media from 0% to 54%. Data was standardized to percent change in activity compared to the control to account for the individual variation within each experiment (n = 4). Data are expressed as means ± SEM and were compared by analysis of variance with post-hoc comparisons by Duncan's multiple range test. Means with different letters are statistically different from one another at p < .05.

6-keto $PGF_{1\alpha}$ and TXB_2, although not as immediate or dramatic, were also statistically significant (55–209% change). The results demonstrated that human adipose tissue produced the prostaglandins PGE_2, 6-keto $PGF_{1\alpha}$ and TXB_2 in vitro in significant quantities and could alter their production in response to the exogenous EFA arachidonate. This observation led us to investigate other possible uses of this model that would have direct implications on the nutrition of hospitalized patients.

In vitro effects of lipid emulsions on adipose tissue. To control for individual variation in basal production of prostaglandins in each experiment, the data was transformed to reflect the percent change in activity relative to the control flasks, which had no lipid added. The following formula was used: % change = (experimental-control)/control × 100. Comparisons of these data were made by analysis of variance using post-hoc comparisons by Duncan's multiple range test (19) and are summarized in Figures 2–4. The effect of MCT and/or LCT physical mixtures of lipid emulsions on the production of TXB_2 (Fig. 2), 6-keto $PGF_{1\alpha}$ (Fig. 3) and PGE_2 (Fig. 4) by human adipose tissue yielded similar results. Tissue incubated with MCT alone demonstrated a percent increase in the three prostaglandins assayed relative to the control. The addition of LCT, thereby increasing the percentage of linoleic acid, yielded a significant percent decrease in prostaglandin production compared to the control. Therefore, increasing the percentage of LCT (linoleic acid) in the incubation media caused stepwise percent decreases in the production of TXB_2, 6-keto $PGF_{1\alpha}$ and PGE_2.

In vivo effects of a lipid emulsion on human adipose tissue. Subjects 1, 4 and 5 had malnutrition secondary to a more serious disease process. Subjects 2 and 3 had existing inflammatory gastrointestinal disease that had progressed to the point that withholding enteral feedings was indicated. However, subject 2 was relatively well nourished compared to the other individuals studied. The effect of intravenous fat administration on fat cell size is illustrated in Figure 5. All five subjects demonstrated an increase in fat cell size after two and four weeks of

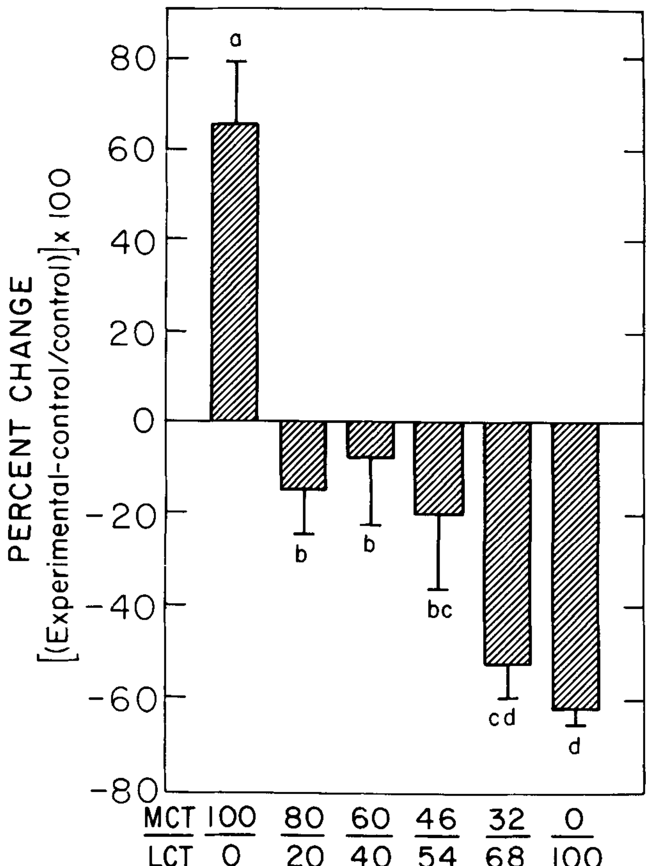

FIG. 4. Effect of physical mixtures of 20% lipid emulsions containing medium (MCT) and/or long chain (LCT) triglyceride on the production of prostaglandin E_2 by human adipose tissue. The percentage of MCT and/or LCT varied from 0% to 100%. This altered the concentration of linoleic acid in the incubation media from 0% to 54%. Data were standardized to percent change in activity compared to the control to account for the individual variation within each experiment (n = 4). Data are expressed as means ± SEM and were compared by analysis of variance with post-hoc comparisons by Duncan's multiple range test. Means with different letters are statistically different from one another at $p < .05$.

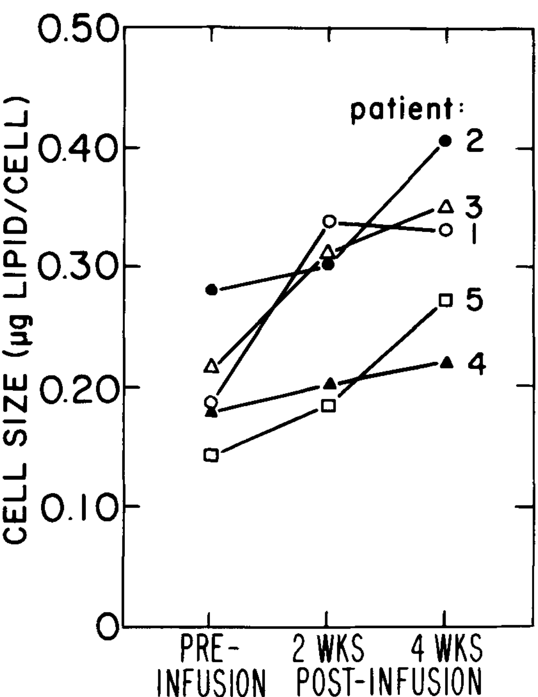

FIG. 5. Effect of intravenous fat administration on fat cell size in five pediatric subjects receiving total parenteral nutrition. Adipose tissue was obtained from the patients by needle aspiration before and after 2 and 4 weeks of treatment. Mean fat cell size (expressed as µg lipid/cell) increased as subjects gained weight over the course of treatment.

treatment. Although this observation must be linked with the fact that patients were gaining weight while receiving TPN, it is of interest that there was a significant increase in their fat cell size. The effect of intravenous fat administration can also be observed on the distribution of fatty acids found in the fat depot. The distribution of fatty acids is expressed as area percent. The upper half of Figure 6 illustrates the changes in linoleic acid levels during treatment. Pretreatment levels in the fat tissue ranged from 8% to 28%. These levels seemed to increase after two and four weeks of treatment. As illustrated in the lower half of Figure 6, the levels of arachidonic acid seemed to increase concomitant with the changes in linoleic acid levels. Therefore, intravenous fat administration with an emulsion high in linoleic acid increased the enrichment of EFA found in the adipose tissue depot in a relatively short time.

The effect of this fat emulsion on adipose tissue prostaglandin production is illustrated in Figure 7. Baseline production of 6-keto $PGF_{1\alpha}$ ranged from 4 to 272 pg/20 min/10^6 fat cell, whereas the levels of TXB_2 ranged from 323 to 4125 pg/20 min/10^6 fat cells. Effects of the infusion of lipid emulsion were variable depending on the subjects. Subjects 1 and 3 demonstrated significant increases in the production of both 6-keto $PGF_{1\alpha}$ and TXB_2 after two and four weeks of treatment. Subjects 2 and 4 demonstrated significant decreases in the production of both 6-keto $PGF_{1\alpha}$ and TXB_2 after two and four weeks of treatment. The production of 6-keto $PGF_{1\alpha}$ by subject 5 increased after two weeks, but significantly decreased after four weeks. The production of TXB_2 by subject 5 significantly decreased after 2 and 4 weeks of treatment. The results demonstrate that the production of the prostaglandins 6-keto $PGF_{1\alpha}$ and TXB_2 by adipose tissue in patients receiving intravenous fat emulsions can be variable and may be affected by the patients' disease and subsequent clinical course.

DISCUSSION

Adipose tissue once was considered an inert tissue reserve, where lipid droplets could cluster between connective tissue. Functionally, it was considered to be solely a means of body protection and thermal insulation. The pioneering studies of Wertheimer and Shapiro (20) demonstrated that the tissue had high levels of metabolic activity and played a central role in carbohydrate metabolism. Furthermore, they demonstrated that the tissue responded to a wide variety of humoral, hormonal, neural and nutritional factors (21).

The function of adipose tissue is the storage of metabolic fuel as triglyceride during times of caloric plenty,

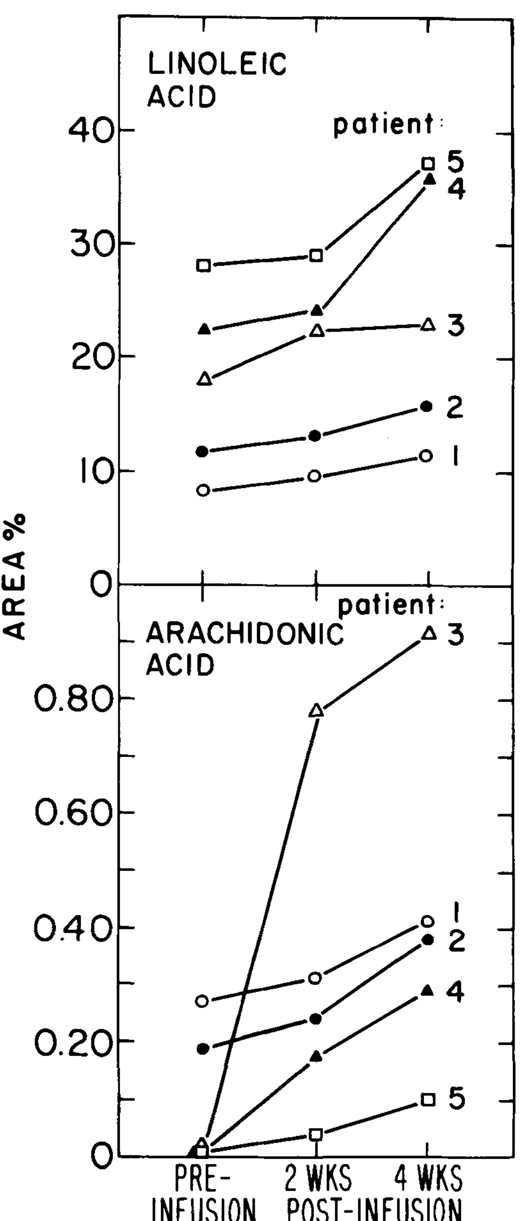

FIG. 6. Effect of infusion of an intravenous fat emulsion high in linoleic acid (77%) on the essential fatty acid profile found in adipose tissue. Five pediatric subjects received a 20% safflower oil lipid emulsion as part of a total parenteral nutrition regimen. Levels of linoleic and arachidonic acids found in adipose tissue are expressed as an area percent of all fatty acids analyzed. Adipose tissue samples were obtained before and after 2 and 4 weeks of treatment. Results demonstrate that intravenous fat infusions significantly increased the percentages of linoleic and arachidonic acids found in adipose tissue.

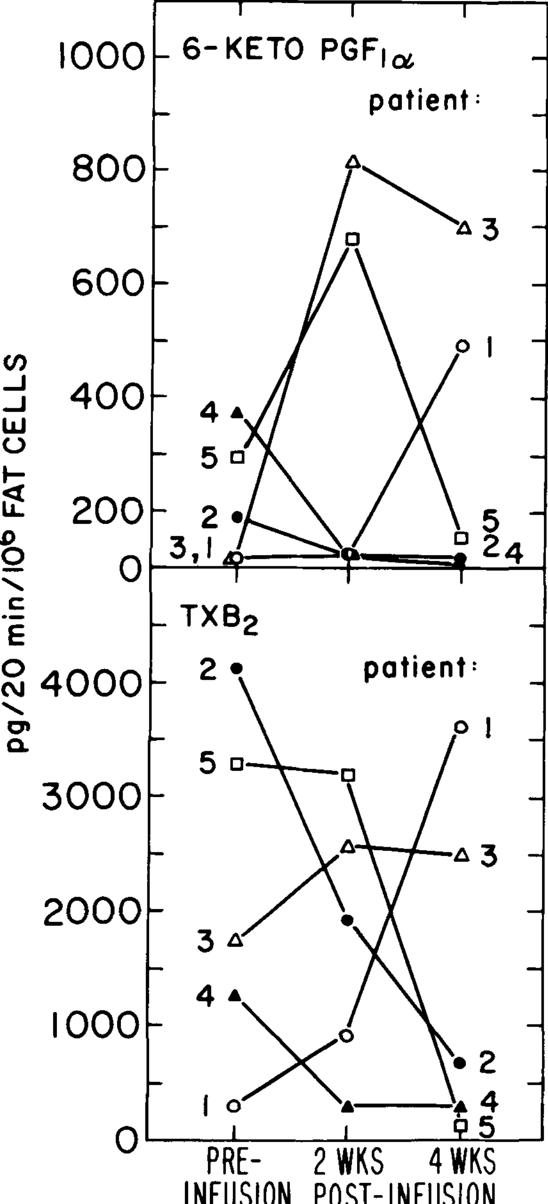

FIG. 7. Effect of infusion of an intravenous fat emulsion high in linoleic acid (77%) on adipose tissue prostaglandin production in five pediatric subjects who received a 20% safflower oil lipid emulsion as part of a total parenteral regimen for 4 weeks. Adipose tissue samples were obtained by needle aspiration before and after 2 and 4 weeks of treatment. The samples were suspended in a perifusion apparatus, and the resulting perfusate was analyzed for the prostaglandins prostacyclin I_2 (measured as 6-keto $PGF_{1\alpha}$) and thromboxane A_2 (measured as TXB_2). Results demonstrate that intravenous fat administration has an unpredictable effect on production of prostaglandins by adipose tissue. This may reflect the condition and clinical course of the patients studied.

and the release of that energy when required. In humans, triglycerides represent the major caloric reservoir of the body compared to the other potential body fuel components, i.e., glycogen and lean body mass. Cahill states in his classic review on starvation (22) in man, "Lipid synthesis and storage are prerequisites to survival in species in which mobility is critical." Therefore, the successful organism must be able to tightly regulate the uptake and release of lipid depending on exogenous and endogenous caloric requirements. The storage and mobilization of fat by adipose tissue is a process that is carefully regulated by several metabolic processes, including de novo fatty acid synthesis of lipids, esterification of long chain fatty acids to activated glycerol and hormone-stimulated lipolysis. Adipose tissue can synthesize long chain fatty acids from glucose and can esterify these fatty acids, as well as those derived from the diet in chylomicrons, to α-glycerophosphate to form triglyceride. This activity is

stimulated by availability of substrate and to a certain degree is regulated by circulating insulin levels. Insulin plays an anabolic role in relation to adipose tissue and can stimulate glucose oxidation, de novo fatty acid synthesis and triglyceride biosynthesis and can inhibit fatty acid breakdown (reviewed in ref. 23).

Lipolysis in adipose tissue consists of the breakdown of stored triglyceride by specific hormone-sensitive lipases and subsequent release of glycerol and free fatty acids (FFA) into the plasma. There is virtually no recycling of glycerol in adipose tissue because the enzyme glycerolkinase is absent. However, FFA may or may not be recycled (23). Virtually every hormone except insulin has been shown in in vitro models to stimulate lipolysis.

The balance between triglyceride storage and mobilization, and therefore the size of the adipose tissue depot, is a function of the overall supply of calories to the organism relative to its energy requirements. During periods of starvation, adipose tissue releases fat in the form of FFA. This is evident from the fact that plasma FFA levels are high in blood vessels draining areas rich in adipose tissue (24). Furthermore, plasma glycerol concentrations increase proportionally to changes in plasma FFA levels, suggesting complete hydrolysis of adipose tissue triglyceride prior to its mobilization (25–27). During feeding or refeeding in starved organisms, there is a rapid fall in plasma FFA levels due to a decrease in lipolysis. Therefore, during periods in which energy balance is positive, there is an increase in deposition of fatty acids as triglyceride in the depot.

The triacylglycerol stores in adipose tissue are continually undergoing lipolysis and reesterification. The net effect is that there is a continuous turnover of fatty acids in the neutral lipid pool. Therefore, the composition of the stored triglyceride is sensitive to changes in dietary fat intake. The intake of dietary fat leads to modification of the profile of fatty acids found in the adipose tissue depot. This modification begins the first time a newborn is fed (28) and continues throughout the life cycle. A number of investigators have demonstrated that adipose tissue fatty acid composition generally reflects an overall pattern of the long-term intake of dietary fatty acids (28–31). Adults fed diets high in linoleic acid double their proportion of this fatty acid found in their adipose tissue (from 11% to 22%) in at least three years (31). Similarly, if one feeds an odd chain fatty acid to animals, there is an increased enrichment of this fatty acid in adipose tissue over time (32–34). Therefore, one can modify the adipose tissue fatty acid profile by modifying enteral fat intake. This observation concerning the effect of the enteral fat intake led us to consider the possible effects of parenterally administered lipid.

The investigation of the effects of lipids, delivered in vivo or in vitro, on human adipose tissue, has demonstrated that fatty acid chain length and unsaturation have a direct effect on its metabolism. These effects include alterations in prostaglandin production, cell size and fatty acid profile. A number of investigators have previously demonstrated that dietary fats can mediate prostaglandin synthesis. Diets high in linoleic acid or with an increased polyunsaturated to saturated ratio generally yield an increase in prostaglandin production (35–40). This is in contrast to studies in which animals have been made EFA-deficient. In these experiments prostaglandin synthesis decreases overall because of decreased precursor availability and the competitive inhibition of the enzymes responsible for their synthesis (41,42). In addition, the abnormal fatty acid that accumulates during EFA deficiency, 5,8,11-eicosatrienoate (20:3ω9), cannot be used as a substrate for prostaglandin production (43,44) and has been shown to be an allosteric inhibitor (45).

Studies in which human volunteers received infusions of intravenous lipid preparations (safflower oil) demonstrated a significant increase in the production of urinary PGE_2 and PGI_2 compared to controls receiving saline (46). Therefore, in healthy volunteers, it is apparent that increased levels of linoleic acid generally increase the production of endogenous prostaglandins. The effect of intravenous fat on human adipose tissue prostaglandin production is less clear. Indeed, in our population there were obvious changes in cell size and fatty acid profile of the adipose tissue in the subjects studied. This is evidence that intravenous fat was indeed being taken up by the adipose tissue. This is supported by the findings of Rossner (1), who demonstrated that fat emulsions are principally removed from the bloodstream by adipose tissue and skeletal muscle. The reasons for the variability in adipose tissue prostaglandin production by these subjects, before and after treatment, are less clear and require further elucidation.

The inhibitory action of the high levels of linoleic acid found in the LCT emulsions is not unexpected. Jeremy et al. (47), using aortic rings from rats, tested whether the type and amount of fatty acids affected the conversion of arachidonic acid to prostacyclin I_2 (measured as 6-keto $PGF_{1\alpha}$). Generally, an increase in the fatty acid concentration caused a dose-dependent inhibition of prostacyclin synthesis. Linoleic and linolenic acids were the most inhibitory and palmitic the least. Although when linoleic acid is given orally or parenterally it appears to stimulate prostaglandin synthesis, its presence in incubation experiments at concentrations of 0.5 to 3.0 mmol/l is strikingly inhibitory. It can be postulated that its similar structure to arachidonic acid may cause a competitive inhibition of the cyclooxygenase, thereby causing a net decrease in prostaglandin production. Therefore, in this model system the triglyceride mixtures highest in linoleic acid may exert a pharmacological rather than a physiological effect.

The currently available fat emulsions provide linoleic acid (18:2ω6), an EFA, in concentrations that range from 54–77%. These levels far exceed the recommendation of the Food and Nutrition Board of the National Academy of Sciences that at least 3% of total energy be provided as polyunsaturated fat (48). Furthermore, in the intravenous fat routinely administered, the amount of linoleic acid is above the recognized average intake. This is approximately 6% of total energy intake (48). This observation prompted us to look at the in vitro and in vivo consequence of varying concentrations of linoleic acid on the production of prostaglandins by human adipose tissue.

Therapeutically, lipid emulsions have been viewed as a source of energy or a means of preventing or ameliorating EFA deficiency. However, the potential effect that this substrate, high in linoleic acid, has on endogenous prostaglandin metabolism has been ignored. Adipose tissue, which plays a key role in the regulation of whole

body lipid metabolism, may represent a useful model in elucidating this information. It is evident from the studies described that the type of fat calorie delivered, i.e., the chain length and degree of saturation, may have a distinct pharmacological activity elicited through the prostaglandin pathway. Theoretically, one could design lipid emulsions with a desired pharmacological activity to be given to patients with specific disease entities. Although it is arguable that a fat calorie is always a fat calorie, it is apparent that these substrates can cause changes in bioactivity when adipose tissue is used as a target organ. There is great potential for developing a new generation of lipid emulsions with desired pharmacological activity to treat hospitalized patients, and human adipose tissue may represent a useful model in determining their bioactivity.

[Received September 3, 1986]

Role of Brown Adipose Tissue in Thermogenesis Induced by Overfeeding a Diet Containing Medium Chain Triglyceride[1]

The role of brown adipose tissue in the mechanism of medium chain triglyceride (MCT)–induced thermogenesis was investigated. Under anesthesia, the interscapular brown adipose tissue (IBAT) was excised in male Sprague-Dawley rats, and the animals were fitted with gastrostomy tubes. After a 10-day recovery period, the animals were divided into two groups: one group received a diet containing MCT as 50% of calories, and the other group received an isocaloric diet containing long chain triglyceride (LCT). The diets were fed for 6 wk at a level of calorie intake that was 150% of the ad libitum intake of a parallel control group. During the last week of the study, resting and norepinephrine (NE)-stimulated O_2 consumption and CO_2 production were measured in a Noyons diaferometer. At the end of 6 wk, the animals were weighed and killed. The individual fat pads were dissected and weighed, and an aliquot of the right retroperitoneal fat pad was used to measure adipocyte size and number. The results showed that body weight and adipocyte size (but not adipocyte number) were significantly smaller in the MCT-fed compared to the LCT-fed animals. Resting as well as maximal NE-stimulated oxygen consumption values were significantly higher in the MCT-fed than the LCT-fed rats. It is concluded that the enhanced thermogenesis induced by MCT persists despite the absence of IBAT and that the phenomenon is likely related to more extensive oxidation of MCT- in contrast to LCT-derived fatty acids, thus leading to increased oxygen consumption, enhanced dissipation of energy as heat and diminished efficiency of weight gain and deposition of body fat.
Lipids 22, 442–444 (1987).

Brown adipose tissue (BAT) is currently implicated in the regulation of energy balance. In cold-adapted rats, hypertrophy and hyperplasia of BAT occur. Basal and norepinephrine (NE)-stimulated oxygen uptakes of cold-adapted rats increase to a great extent above the values for warm-acclimated control (1,2). This dramatic increase in nonshivering thermogenesis has been attributed to the activity of BAT and its unique capacity to uncouple oxidative phosphorylation leading to production of energy as heat rather than as ATP (3). The evidence for BAT as the site for nonshivering thermogenesis is very strong in rodents, although exceptions have been reported from studies on Djungarrian hamsters, where extensive excision of BAT had no significant effect on the respiratory response of the animal to infusion with NE (4). Recently, close similarities were reported to exist between the thermogenic response of cold-adapted and "cafeteria-fed" rats (5). Voluntary overfeeding of a highly palatable "cafeteria" diet was shown to be associated with an increase in the wet weight of interscapular BAT, enhanced oxygen consumption capacity and improved response to NE, leading to a lower efficiency of weight gain as compared to normal ad libitum feeding. The increase in oxygen consumption has been attributed to the increase in BAT content and activity (2,6,7). The role of BAT in this observed diet-induced thermogenesis is still a matter of controversy (8,9). Previous studies carried out in our laboratory have demonstrated that overfeeding adult rats 50% above maintenance with a diet containing medium chain triglyceride (MCT) leads to a higher basal as well as NE-stimulated oxygen consumption as compared to overfeeding an isocaloric diet containing long chain triglyceride (LCT). This increase in metabolic rate in MCT-fed rats was accompanied by less deposition of body fat in the MCT-fed than in the LCT-fed rats (10). The present study explores the possibility that interscapular brown adipose tissue (IBAT) may be involved as a mediator in curtailing fat deposition and in the thermogenic effect leading to diminished weight gain in rats in response to MCT feeding.

METHODS AND MATERIALS

Ten male Sprague Dawley rats were anesthesized with chloral hydrate. IBAT was excised, and the animals were then fitted with gastrostomy tubes. The rats were left to recover for a period of 10 days with ad libitum feeding and free access to water. After recovery, the rats were divided into two groups and fed via gastrostomy tube: one group received the MCT diet providing 4 kcal/ml, and the other group an isocaloric diet containing LCT. The composition of the two diets is shown in Table 1. The diets were fed twice daily for 6 wk at a level of calorie intake that was 150% of the intake of a parallel control group of six additional animals fed ad libitum. During the last

TABLE 1

Composition of the Diets

	MCT diet		LCT diet	
	% Wt	% Cal	% Wt	% Cal
MCT	25.0	45.0		
LCT (corn oil)	2.5	5.0	26.0	50.0
Casein	15.2	13.5	15.7	13.4
Sucrose	42.0	36.6	43.0	36.6
Cellulose	12.0		12.0	
Salt mixture	3.0		3.0	
Vitamin mixture	0.3		0.3	

MCT, medium chain triglyceride; LCT, long chain triglyceride.

week of the study, resting and NE (25 μg/100 g)-stimulated O_2 consumption and CO_2 production were measured using a Noyons diaferometer (Model MG4, 724E, Kipp and Zonen, Delft, Holland). The temperature within the metabolic chamber was 22.5 C. The resting metabolic rate (RMR) was measured over a 2-hr period starting 2 hr after the morning feeding. NE was injected subcutaneously immediately after RMR measurements were obtained. The metabolic rate was calculated from the O_2 consumption and CO_2 production data generated from the diaferometer. The caloric equivalent of the oxygen consumed in 24 hr was derived from standard tables, corrected for the respiratory quotient. At the end of 6 wk, the animals were weighed and killed by decapitation. Individual fat pads were dissected out and weighed from epididymal, retroperitoneal, omental and dorsal fat depots according to the method of Johnson and Hirsch (11). Total dissectible fat was computed by adding the weights of the individual fat pads. Fat cell size and number were measured from a sample of the right retroperitoneal fat pad using the photomicrographic method of Lavau et al. (12). The data were analyzed statistically by the independent t-test for two means.
