Thin layer chromatographic analysis (solvent, ethyl acetate/hexane [2:8, v/v]) of the methyl ester of 12-oxophytodienoic acid obtained in this way showed the presence of a major (94%; R_f = 0.42) and a minor (6%; R_f = 0.47) isomer. The major isomer was due to *1*, in which the side chains attached to C-9 and C-13 had the *cis* relationship, whereas the latter isomer was the corresponding *trans* derivative *2*. These assignments follow from the work by Vick and Zimmerman, who showed that 12-oxophytodienoic acid biosynthesized from 13*(S)*-HPOT was the *cis* isomer (8) and from the fact that *1* prepared as described above was, as expected (8–11), rapidly isomerized into the more stable *trans* form *(2)* by base treatment (see below). Gas liquid chromatographic analysis of *1* showed a major peak at C 24.40 and a minor peak at C 24.00 corresponding to *1* and *2*, respectively. Such thermal isomerization of *cis* phytonoate derivatives during GLC has been reported (8).

Methyl 12-Oxo-10,15(Z)*-phytodienoate (*trans *isomer)* (2). *1* (1 mg) was treated with 0.1 M sodium hydroxide in 90% aqueous methanol at room temperature for one hr and subsequently extracted and treated with diazomethane. Following preparative TLC, about 0.8 mg of pure *2* was obtained. The ultraviolet spectrum of *2* showed an absorption band with λ_{max} at 222 nm (ε about 12,000). Gas liquid chromatographic analysis showed a single peak (C 24.00).

*Methyl 12-Oxophytonoate (*cis *and* trans *isomers) (4 and 9). 1* (1 mg) was subjected to catalytic hydrogenation, and the product was subjected to preparative TLC. In this way, about 0.7 mg of *4* was obtained. GLC showed a major peak at C-23.60 *(4)* and a minor peak at C-23.25 (due to *9* formed by thermal isomerization) (Fig. 2a). Treatment of *4* (0.5 mg) with 5 ml of 0.5 M NaOH in 50% aqueous methanol at 37 C for 18 hr followed by esterification resulted in the formation of a mixture of *9* (C 23.25) and *4* (C 23.60) in a ratio of about 92:8 (Fig. 2b). Alternatively, pure *9* could be prepared by catalytic hydrogenation

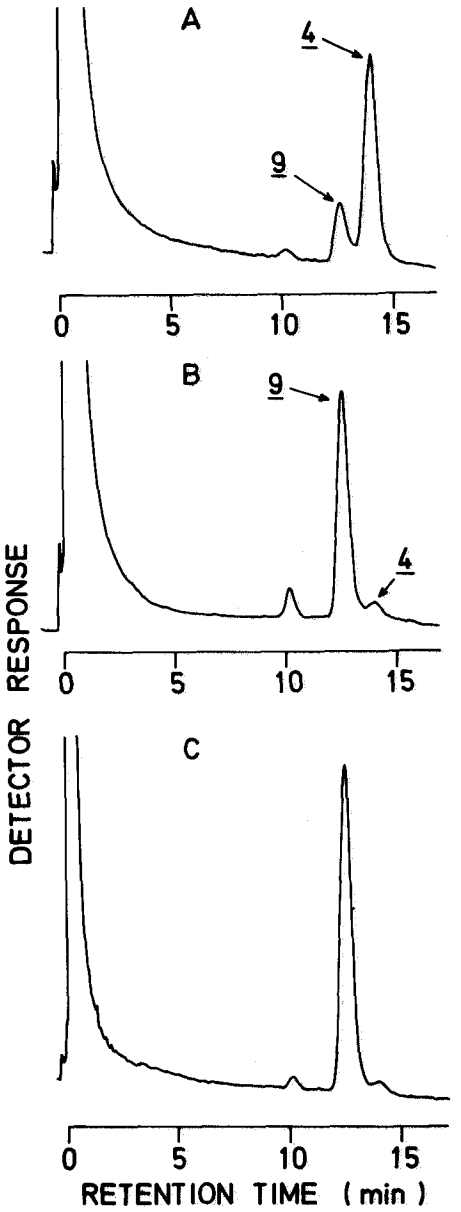

FIG. 2. GLC analysis of methyl 12-oxophytonoates. Column, 5% QF-1 on Supelcoport; column temperature, 190 C; injection port temperature, 220 C. (A) Injection of *4*. Thermal isomerization into *9* is apparent. (B) Injection of *9* (containing ca. 8% of *4*). (C) Injection of methyl 12-oxophytonoate obtained by catalytic hydrogenation of Compound B.

of *2*. No separation of *4* and *9* was observed on TLC analysis (solvent system, ethyl acetate/hexane (2:8, v/v); R_f = 0.68).

The mass spectrum of *9* showed prominent ions at m/e 279 (M-31, 4%), 240 (M-70 [β-cleavage with loss of CH_2=CH-C_3H_7], 14), 153 (M-157 [loss of ·$(CH_2)_7$-$COOCH_3$], 22), 83 (100) and 82 (50).

Methyl 12-hydroxy-15(Z)*-phytoenoates (*trans *isomers, two epimers) (6 and* 11*). 2* (1 mg) was treated with sodium borohydride, and the product was subjected to TLC (solvent, ethyl acetate/hexane (25:75, v/v)). Two compounds appeared, i.e. *6* (39%; R_f = 0.59) and *11* (61%; R_f = 0.48). The mass spectrum of the Me_3Si derivative of *11* showed

prominent ions at m/e 382 (M, 1%), 367 (M-15, 1), 351 (M-31, 1), 311 (M-71 [loss of $\cdot C_5H_{11}$], 2), 292 (M-90 [loss of Me_3SiOH], 5), 249 (3), 225 (M-157 [loss of $\cdot(CH_2)_7$-$COOCH_3$], 100) and 135 (225-90, 22). The mass spectrum of the trimethylsilyl (Me_3Si) derivative of *6* was similar to that of *11* although, in this case, the ion m/e 135 (225-90) was the base peak.

To examine the relative configuration of the alcohol group at C-12 and the pentyl side chain at C-13 of *6* and *11*, the following experiment was carried out (Fig. 1). *6* and *11* (0.5 mg) were separately acetylated and subjected to oxidative ozonolysis. The products were treated with 1 M NaOH in 80% aqueous methanol at room temperature for 18 hr. The hydrolysis mixtures were acidified to pH 1 and extracted with two portions of ethyl acetate. Analysis of the esterified products by TLC (solvent, ethyl acetate/hexane [25:75, v/v]) demonstrated the formation of diester *12* (R_f = 0.20) from *11*, whereas the product obtained from *6* contained lactone *7* (R_f = 0.34) and diester *8* (R_f = 0.22) in a ratio of about 2:1. The structures of diesters *8* and *12* were confirmed by mass spectrometry (Me_3Si derivatives; prominent ions at m/e 371 (M-15, 23%), 355 (M-31, 1), 339 (M-[15+32], 3), 313 (M-73 [loss of $\cdot CH_2$-$COOCH_3$], 8), 312 (M-74 [loss of CH_2=C(OH)OCH_3], 13), 155 (M-[74+157] [loss of CH_2=C(OH)OCH_3 plus $\cdot(CH_2)_7$-$COOCH_3$], 100), and 129 (CH_2=CH-CH=O^+SiMe_3, 26). The structure of lactone *7* was established by its mass spectrum, which showed a molecular ion at m/e 282, its conversion into *8* by alkaline hydrolysis followed by esterification, and its conversion into triol *3* by $LiAlH_4$ reduction.

It followed from the above conversions that *6* had the *cis* relationship between the C-12 alcohol group and the C-13 side chain, while in *11* the relationship between the corresponding substituents was *trans*.

*Methyl 12-hydroxyphytonoates (*trans *isomers, two epimers) (*5 *and* 10*). 5* and *10* were prepared by catalytic hydrogenation of *6* and *11*, respectively. The R_f-values found on TLC analysis were 0.58 *(5)* and 0.51 *(10)* (solvent, ethyl acetate/hexane [25:75, v/v]), and the C-values found on GLC analysis of the Me_3Si derivatives were 20.00 *(5)* and 19.85 *(10)*. The mass spectra of the two derivatives were virtually identical and showed prominent ions at m/e 384 (M, 1%), 369 (M-15, 15), 337 (M-[15+32], 9), 294 (M-90, 10), 137 (M-[157+90] [loss of $\cdot(CH_2)_7$-$COOCH_3$ plus Me_3SiOH], 7) and 129 (CH_2=CH-CH=O^+SiMe_3, 100).

Methods for isolation and structure determination. TLC was carried out with precoated plates (Kieselgel 60, 0.25 mm) from E. Merck (Darmstadt, FRG). Material was located by spraying with 2′,7′-dichlorofluorescein and viewing under UV light. HPLC was performed using a column (300 × 8 mm) of Polygosil C_{18} 5 μ and acetonitrile/water (85:15, v/v) at a flow rate of 1.5 ml/min. The absorbancy of the effluent at 222 nm was measured. GLC was performed with a F&M Biomedical gas chromatograph model 402 using a column of 5% QF-1 on Supelcoport. Gas chromatography-mass spectrometry (GC-MS) was carried out with an LKB 9000S instrument. The electron energy was set at 22.5 eV, and the trap current was 60 μA. Ultraviolet spectra were recorded with a Hewlett-Packard model 8450A UV/VIS spectrophotometer. Radioactivity was determined with a Packard Tri-Carb series 4000 liquid scintillation counter. A Berthold Dünnschichtscanner II was used for determination of radioactivity on TLC plates.

Sodium borohydride reduction of carbonyl compounds (0.1–2 mg) was carried out at room temperature for 30 min with 20 mg of $NaBH_4$ in 2 ml of methanol. $LiAlH_4$ reduction was performed by refluxing the sample (0.1–1 mg) for two hr with 70 mg of $LiAlH_4$ in 15 ml of diethyl ether. Methods for catalytic hydrogenation (12), oxidative ozonolysis (13), and preparation of Me_3Si (12) and *O*-methyloxime derivatives (1) were as described.

*Method for measurement of aqueous half-life of 12,13(*S*)-epoxy-9(*Z*),11-octadecadienoic acid in the presence of albumins.* 13*(S)*-[1-^{14}C]HPOD (90 nmol, 3.3 kBq) in 50 μl of acetonitrile was stirred with 7 ml of enzyme preparation for 20 sec at 0 C. One ml of serum albumin solution in potassium phosphate buffer was added (final concentration of albumin, 15 mg/ml), and stirring at 0 C continued. Aliquots of 1 ml were removed 2, 4, 8, 15, 25 and 40 min after addition of serum albumin. In the case of egg albumin, the times used were 20, 40, 60, 80 sec and 2, 5, 10 and 15 min. Samples were treated with 20 ml of methanol and kept for one hr at room temperature. [1-^{14}C]Oleic acid (152 Bq) was added as an internal standard, and the mixtures were extracted with diethyl ether. The esterified materials were subjected to radio-TLC (solvent, ethyl acetate/hexane [2:8, v/v]). The peaks corresponding to radioactive methyl 12-oxo-13-methoxy-9*(Z)*-octadecenoate (R_f = 0.69; formed from allene oxide in the presence of methanol) and methyl oleate (R_f = 0.84) were cut out and weighed. The ratios determined for the different time points were plotted on a logarithmic scale vs time, and the half-life times were calculated.

RESULTS AND DISCUSSION

Stabilization of allene oxide by serum albumins. As seen in Figure 3, degradation of 12,13*(S)*-epoxy-9*(Z)*,11-octadecadienoic acid in aqueous medium followed first-order kinetics. The half-life time in the absence of albumin was ca. 33 sec (1). In the presence of different serum albumins, the half-life was increased by a factor of 9–26. On the other hand, egg albumin, which is unrelated to vertebrate serum albumins, did not stabilize the allene oxide. As seen in Table 1, the efficacy of stabilizing allene oxide by the different serum albumins tested was bovine > human > equine. Interestingly, the same ranking order was found for these albumins in stabilizing leukotriene A_4 (5). It seems likely that stabilization occurs by binding of the unstable compound to hydrophobic binding sites of the albumin molecule. Studies are in progress to examine the possible role of specific binding sites I and II (14) in stabilizing allene oxide.

Isolation and structure of Compound B. During studies of the half-life of allene oxide in the presence of bovine serum albumin described above, an unknown compound was observed with an R_f-value intermediate to those of methyl 12-oxo-13-hydroxy-9*(Z)*-octadecenoate and the methyl ester of 13*(S)*-HPOD. As seen in Figure 4A, the yield of the new compound (B) was maximal (24% of the recovered product) when allene oxide generated from 13*(S)*-HPOD was treated for one hr at 0 C with 15 mg/ml of bovine serum albumin before quenching with methanol. When the time of treatment with albumin was reduced to 15 min, the yield of Compound B dropped to 8%. Also, formation of 12-oxo-13-hydroxyoctadecenoate was some-

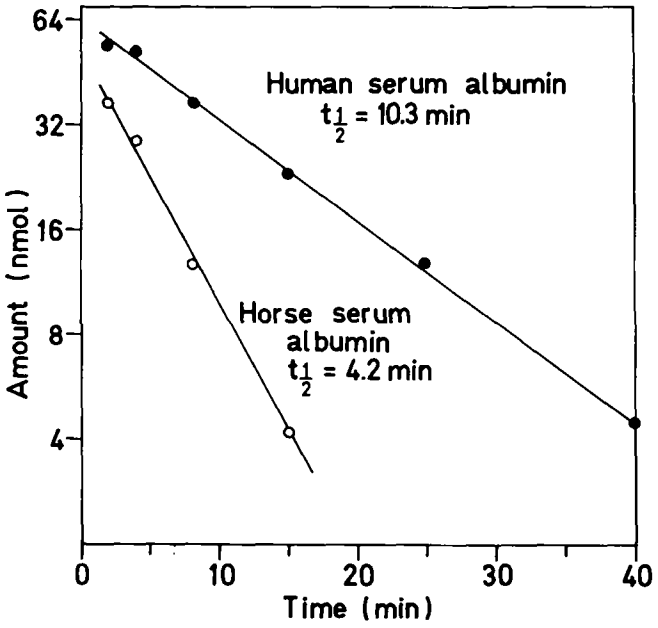

FIG. 3. Degradation of 12,13(*S*)-epoxy-9(*Z*),11-octadecadienoic acid in the presence of human serum albumin (15 mg/ml; – ● – ● – ● –) and horse serum albumin (15 mg/ml; —O—O—O—).

TABLE 1

Stabilization of 12,13(*S*)-Epoxy-9(*Z*),11-octadecadienoic Acid by Albumins (15 mg/ml)

Albumin	Half-life of allene oxide, mean ± S.D. (min)
—	0.55[a]
Bovine	14.1 ± 1.8 (n = 3)
Human	11.6 ± 1.2 (n = 3)
Equine	4.8 ± 0.5 (n = 3)
Chicken egg	0.59 ± 0.02[b] (n = 3)

[a]Ref. 1.

[b]Initial phase, during which 80% of allene oxide was hydrolyzed into α-ketol.

what reduced. Instead, an increased yield of methyl 12-oxo-13-methoxy-9(*Z*)-octadecenoate was noticed (Fig. 4B). If the albumin treatment was omitted, i.e. the allene oxide generated was directly treated with methanol, Compound B was not detectable, and the yield of methyl 12-oxo-13-methoxyoctadecenoate was further increased (Fig. 4C). Additionally, when allene oxide was allowed to hydrolyze into 12-oxo-13-hydroxy-9(*Z*)-octadecenoic acid before addition of albumin, only methyl 12-oxo-13-hydroxyoctadecenoate was observed (Fig. 4D). These experiments thus demonstrated an albumin- and time-dependent formation of Compound B from 12,13(*S*)-epoxy-9(*Z*),11-octadecadienoic acid.

Larger amounts of Compound B were prepared in the following way: 13(*S*)-[1-^{14}C]HPOD, 3.3 mg, was stirred with 42 ml of enzyme preparation at 0 C for 30 sec. A solution of 675 mg of fatty acid-free bovine serum albumin in 3 ml of potassium phosphate buffer was added, and

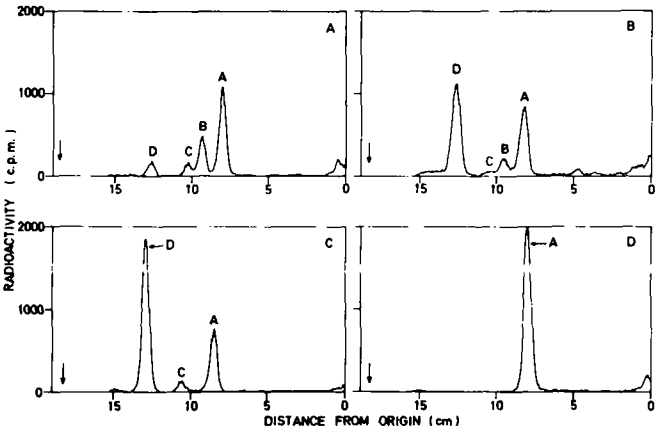

FIG. 4. Thin layer radiochromatographic analysis of products formed upon incubation of 13(*S*)-[1-^{14}C]HPOD. (A) Consecutive treatments were as follows: 1) stirring of 90 nmol of 13(*S*)-HPOD with 5 ml of enzyme preparation for 10 sec at 0 C; 2) addition of 1 ml of solution of bovine serum albumin (final concentration, 15 mg/ml) and stirring for 60 min at 0 C; 3) addition of 60 ml of methanol. (B) As in A, but time of treatment with albumin was 15 min. (C) Consecutive treatments as follows: 1) stirring of 90 nmol of 13(*S*)-HPOD with 5 ml of enzyme preparation for 10 sec at 0 C; 2) addition of 50 ml of methanol. (D) As in A, but time of treatment with enzyme preparation was five min.

Peak A, methyl 12-oxo-13-hydroxy-9(*Z*)-octadecenoate; peak B, Compound B; peak C, methyl 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoate; peak D, methyl 12-oxo-13-methoxy-9(*Z*)-octadecenoate. Solvent system, ethyl acetate/hexane (2:8, v/v). Solvent front is indicated by arrow.

the mixture was stirred at 0 C for 60 min. The incubation mixture was added to 135 ml of methanol and kept at room temperature for 30 min. The product obtained by diethyl ether extraction (recovery of radioactivity, about 85%) was treated with diazomethane and subjected to TLC (Fig. 4). Compound B obtained in this way was radiochemically pure. Traces of unlabeled impurities were removed by reversed-phase HPLC (Compound B eluted with an effluent volume of 28.2–30.1 ml).

The mass spectrum of Compound B is given in Figure 5. As seen, prominent ions appeared at m/e 308 (M, 3%), 277 (M-31, 13), 238 (M-70 [β-cleavage with loss of CH_2=CH-C_3H_7], 38), 206 (238-32, 22), 178 (25), 165 (M-143 [loss of ·$(CH_2)_6$-$COOCH_3$], 12), 151 (M-157 [loss of ·$(CH_2)_7$-$COOCH_3$], 30), 109 (46), 96 (100), and 82 (49). The similarity of this spectrum with that of *1* suggested that Compound B was a phytonoate derivative. The molecular ion at m/e 308 indicated the presence of one double bond. This double bond had to be located in the five-membered ring because the ions at m/e 238 and 151 showed that the side chains attached to C-13 and C-9, respectively, were both saturated.

Conclusive evidence for the presence of a cyclopentenone structure in Compound B was provided by ultraviolet spectrometry, which showed an absorption band with λ_{max} at 222 nm (ε about 12,000).

The mass spectrum of the *O*-methyloxime derivative of Compound B showed prominent ions at m/e 337 (M, 51%), 306 (M-31, 100), 274 (M-[31+32], 46), 267 (M-70 [β-cleavage with loss of CH_2=CH-C_3H_7], 77), 236 (267-31, 95), 194 (M-143 [probably loss of ·$(CH_2)_6$-$COOCH_3$], 43), and 124 (194-70, 53).

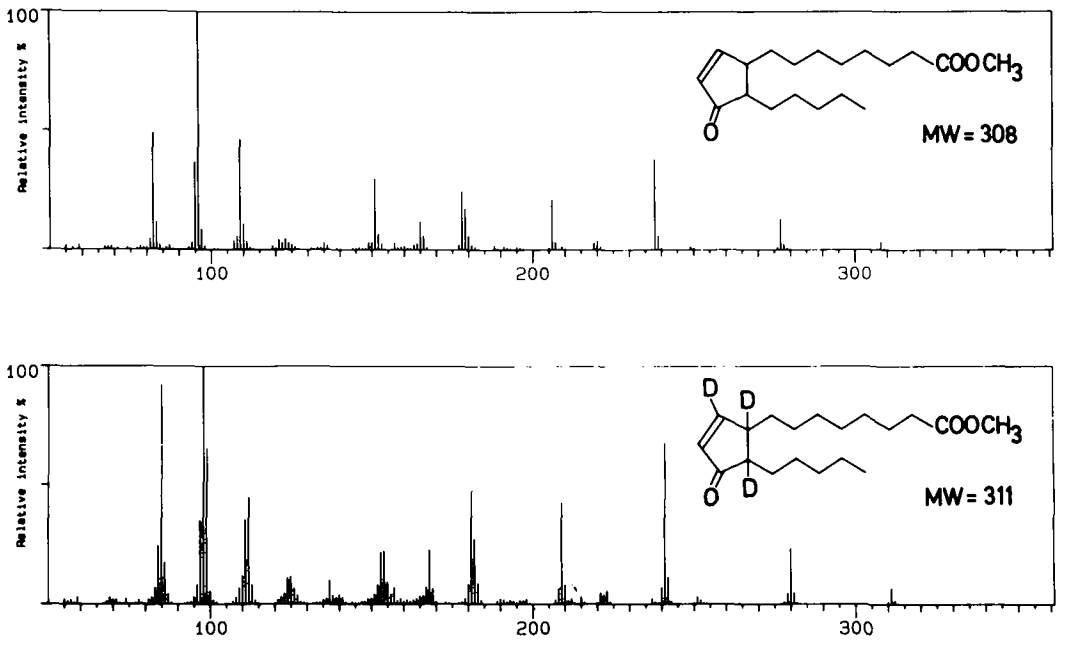

FIG. 5. Mass spectra of Compound B (upper) and of Compound B obtained following incubation of 13*(S)*-[9,10,12,13-$^2H_4$]-HPOD (lower).

Treatment of Compound B with 0.5 M NaOH in 50% aqueous methanol at 70 C for one hr resulted in smooth conversion into an isomeric derivative having λ_{max} at 238 nm (ε about 16,000). The mass spectrum of the methyl ester of this compound (C-value, 24.80) showed prominent ions at m/e 308 (M, 14%), 277 (M-31, 10), 179 (M-129 [elimination of $\cdot(CH_2)_5$-$COOCH_3$ by cleavage between C-6 and C-7], 92), 166 (M-142 [elimination of CH_2=CH-$(CH_2)_4$-$COOCH_3$ by cleavage between C-7 and C-8 and transfer of 1 H], 8), 151 (M-157 [elimination of $\cdot(CH_2)_7$-$COOCH_3$], 100), 123 (14) and 110 (21). This fragmentation pattern was similar to those reported for methyl 12-oxo-9(13),15*(Z)*-phytodienoate (8) and 2-heptyl-3-(7-carbomethoxyheptyl)-cyclopent-2-enone (15). On the basis of the data mentioned, the derivative obtained by treatment of Compound B with sodium hydroxide was assigned the structure 12-oxo-9-13)-phytoenoic acid (free acid of *13*, see Fig. 6).

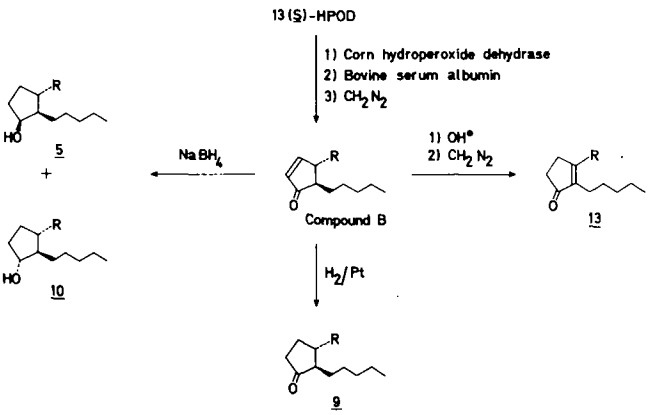

FIG. 6. Chemical conversions carried out on Compound B (shown as the 9*(S)*,13*(R)* enantiomer). R, $(CH_2)_7$-$COOCH_3$.

Catalytic hydrogenation of Compound B afforded a dihydro derivative that was identical to a methyl 12-oxophytonoate as judged by TLC and mass spectrometry (reference compounds: *4* and *9*). The retention time of the major peak of hydrogenated Compound B was identical with that of *9* although a minor peak (less than 5%) appeared at the position of *4* (Fig. 2). Thus, the two side chains attached to the ring structure of Compound B had mainly (>95%) the *trans* relationship. Phytonoic and jasmonic acid derivatives in which the relative configuration of the two side chains is *cis* are readily isomerized into the more stable *trans* derivatives by acid, base, or heat (8–11). Thus, it was conceivable that Compound B initially formed from the allene oxide had the *cis* relationship between the side chains but underwent isomerization into the *trans* compound during the isolation procedures. Also, interaction of Compound B with a hydrophobic alkaline microenvironment of albumin (5) possibly would promote such an isomerization. Incubations of 13*(S)*-[9,10,12,13-$^2H_4$]-HPOD were carried out to determine whether Compound B was initially formed as the *cis* or *trans* derivative. Analysis of Compound B by mass spectrometry revealed the presence of 91% trideuterated and 9% dideuterated molecules (Fig. 5). Because the deuterated hydroperoxide incubated consisted of 93% tetradeuterated and 7% trideuterated molecules, it was apparent that Compound B almost completely retained 3 deuteriums (at C-9, C-10, and C-13) and, as expected, lost the C-12 deuterium. Retention of the C-13 deuterium atom meant that no appreciable exchange of hydrogen/deuterium occurred at this carbon, neither during the incubation period with albumin nor during the isolation procedures. Consequently, Compound B formed from 12,13*(S)*-epoxy-9*(Z)*,11-octadecadienoic acid in the presence of albumin had the *trans* relationship between its two side chains.

Sodium borohydride reduction of Compound B afforded two epimeric methyl 12-hydroxyphytonoates. The two epimers were formed in a ratio of 4:6 and were found to be identical with *5* and *10,* respectively, as judged by analysis by TLC, GLC and mass spectrometry (Fig. 6).

On the basis of these data, Compound B was assigned the structure methyl 3-oxo-2-pentyl-cyclopent-4-en-1-octanoate, i.e. the methyl ester of 12-oxo-10-phytoenoic acid (*trans* isomer) (Fig. 8).

Enantiomeric composition of Compound B. 5 and *10,* prepared from Compound B (above and Fig. 6), were separately treated with (−)-menthylchloroformate (13), and the resulting (−)-menthoxycarbonyl (MC) derivatives were purified by TLC (solvent system, ethyl acetate/hexane [7:93, v/v]). Each of the MC derivatives gave two peaks of diastereomers when analyzed by GLC. The two diastereomers of *5*-MC appeared in a ratio of 58:42 (faster to slower eluting diastereomer, respectively; separation factor, 1.08) (Fig. 7A). As expected, the two diastereomers of *10*-MC appeared in similar proportions (59:41, slower to faster eluting derivative, respectively; separation factor, 1.05). Thus, Compound B formed from 12,13*(S)*-epoxy-9*(Z)*,11-octadecadienoic acid essentially was racemic, which is in agreement with its formation by a nonenzymatic, albumin-promoted reaction.

Enantiomeric composition of 1. The methyl ester of 12-oxo-10,15*(Z)*-phytodienoic acid *(1)* was converted into *5* and *10* by successive treatments with sodium hydroxide, sodium borohydride, and hydrogen gas (Fig. 1). The MC derivatives of *5* and *10* were prepared and analyzed by GLC as described above for Compound B. The MC derivative of *5* separated into two diastereomers in a ratio of 82:18 (slower to faster eluting diastereomer, respectively; separation factor, 1.08) (Fig. 7B). Two diastereomers were observed upon GLC analysis of *10*-MC. The ratio found was 78:22 (faster to slower eluting isomer). However, due to the small separation factor (1.05), the percentage of the minor, slower eluting diastereomer probably was overestimated.

Vick and Zimmerman have provided evidence that 12-oxo-10,15*(Z)*-phytodienoic acid serves as the precursor of (+)-7-iso-jasmonic acid in plant tissue (16). In that context, it was notable that 12-oxo-10,15*(Z)*-phytodienoic acid biosynthesized from 13*(S)*-HPOT in the presence of corn hydroperoxide dehydrase was found not to be optically pure but a mixture of enantiomers in a 82:18 ratio. The absolute configurations of the major and minor enantiomers of *1* and of Compound B recently have been determined (Hamberg, M., Miersch, O., and Sembdner, G., unpublished data).

This study demonstrates that 12,13*(S)*-epoxy-9*(Z)*,11-octadecadienoic acid, a fatty acid allene oxide derived from 13*(S)*-HPOD, is strongly stabilized by serum albumins. Stabilization was greatest with bovine serum albumin and probably was due to binding of allene oxide to hydrophobic binding sites of the albumin molecule.

Degradation of allene oxide in the presence of bovine serum albumin led to the formation of a cyclopentenone derivative, i.e. essentially racemic 12-oxo-10-phytoenoic acid (*trans* isomer) (Fig. 8). In this context, previous studies in which cyclopentenones have been isolated following peracid epoxidation of vinylallene derivatives should be mentioned (17,18). Allene oxides and/or cyclopropanones were suggested as intermediates in those conversions.

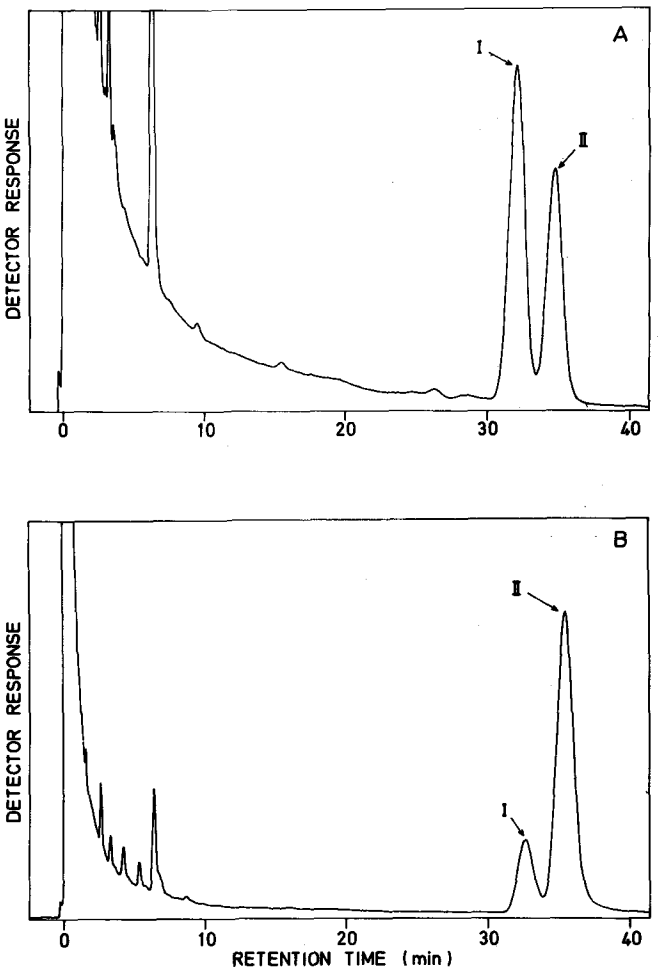

FIG. 7. Steric analysis of MC derivative of *5* derived from Compound B (A) and from methyl 12-oxo-10,15*(Z)*-phytodienoate (B). Column, 5% QF-1; column temperature, 220 C.

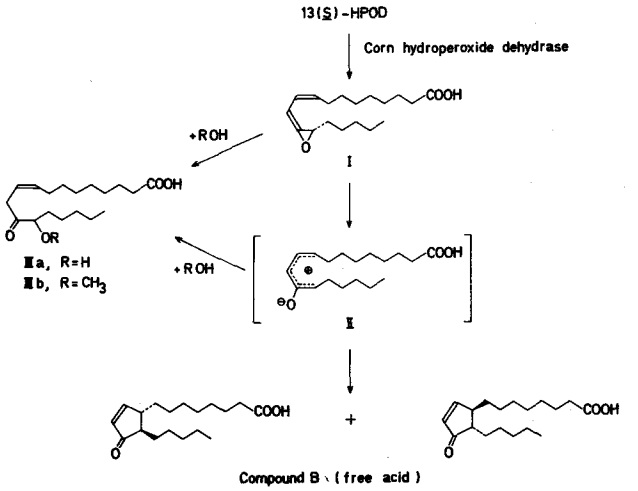

FIG. 8. Cyclization of allene oxide generated from 13*(S)*-HPOD. I, 12,13*(S)*-epoxy-9*(Z)*,11-octadecadienoic acid; II, dipolar ion formed from I by heterolysis of the bond between the epoxide oxygen and C-13; IIIa, 12-oxo-13-hydroxy-9*(Z)*-octadecenoic acid; IIIb, 12-oxo-13-methoxy-9*(Z)*-octadecenoic acid.

Our finding that an enzymatically generated fatty acid allene oxide can cyclize into a cyclopentenone derivative under suitable conditions suggests that an allene oxide is similarly involved as the precursor of 12-oxo-10,15*(Z)*-phytodienoic acid in different plant tissues. This proposal is supported by recent experiments that have shown that using conditions under which 12-oxophytodienoic acid is biosynthesized from 13*(S)*-HPOT, transient formation of 12,13*(S)*-epoxy-9*(Z)*,11,15*(Z)*-octadecatrienoic acid can be detected by chemical and physical methods (Hamberg, M., unpublished data).

Compensatory Mechanisms in Erythrocyte Lipids in Patients with Atherosclerosis

Jerzy Michalak[a,*], Adam Kadziolka[b], Romualda Pruszkowska[b], Andrzej Ledwozyw[b] and Andrzej Madejczyk[a]

[a]Clinic of Vascular Surgery, Institute of Surgery, Medical Academy, 16 Staszica St., 20-081 Lublin, Poland, and [b]Department of Pathophysiology, The Veterinary Faculty, Agricultural Academy, 12 Akademicka St., 20-033 Lublin, Poland

The quantitative composition of phospholipids and fatty acids of erythrocytes was investigated in patients with atherosclerosis. It was stated that the erythrocyte lipids of atherosclerotic patients contained smaller quantities of phosphatidylcholine and phosphatidylinositol, a significantly larger quantity of sphingomyelin, and higher sphingomyelin/phosphatidylcholine and cholesterol/phospholipid ratios. The existence of compensatory changes was stated, which was evident in the reduction of palmitic and stearic acids and the increase of linoleic and eicosatrienoic acids in erythrocyte phospholipids. These changes in fatty acid composition probably cause minimal changes in the membrane fluidity induced by an increased cholesterol/phospholipid and sphingomyelin/phosphatidylcholine ratios. This paper was the first evidence of occurrence of those changes in erythrocytes during spontaneous atherosclerosis in human.

Lipids 23, 476–480 (1988).

The maintenance of membrane fluidity in precisely determined limits is one of indispensable conditions of proper functioning of cells. The principal influence of the membrane fluidity is exerted by the composition of lipid fatty acids, the nature and quantitative composition of individual phospholipid classes, and the value of cholesterol/phospholipid and sphingomyelin/phosphatidylcholine ratios.

The increase of the unsaturation degree of fatty acids intensifies the membrane fluidity, while the increase of cholesterol/phospholipid and sphingomyelin/phosphatidylcholine ratios reduces it. In physiological conditions, the lipids of erythrocyte cell membrane are "fluid," i.e. the lateral mobility of lipids is relatively quick (1).

Cholesterol, an integral component of cell membranes, maintains a lipid bilayer in an "intermediate fluid" state, ensuring greater mobility of the acyl chains in the gel state and limiting it in the liquid-crystalline state (2–4). This so-called condensing effect plays an essential role in functioning of the membrane enzymes (5,6), in processes of a substance transport across the cell membrane (7–9), and in maintaining of adequate rheologic properties of erythrocytes (10,11). Erythrocytes do not possess an enzymatic apparatus necessary for the synthesis of phospholipids and cholesterol (12), and, due to this, the changes in the lipid composition of the plasma lipoproteins (13). An increase of the cholesterol/phospholipid ratio in the plasma lipoproteins and the erythrocyte cell membranes, the blood platelets, the liver cells and the endothelium cell membranes is one of the typical metabolic disorders in the course of atherosclerosis (12). Such changes, impairing the normal structure of cell membranes, may give rise to significant disorders in their functions.

In a previous paper (14), we examined the cytoprotective effect of prostaglandins on the erythrocytes of patients with atherosclerosis, stating slight differences in the osmotic resistance of erythrocytes and the lack of differences in the strength of this prostaglandin effect on healthy red blood cells and those in atherosclerotic patients.

The aim of this paper is to state whether there are any compensatory mechanisms in the erythrocytes of atherosclerotic patients, which would allow the integrity of the cell membrane in spite of the changes in the lipid composition induced by a disease.

MATERIALS AND METHODS

Blood taken from 24 male patients with atherosclerosis was used for estimations. The patients were divided into two groups: 15 patients on whom reconstruction of iliac and femoral arteries had been performed, and nine patients who had their limbs amputated at the thigh because of the extent of lesions. The control group (C) comprised of 11 males of the same age in whom detailed clinical examinations failed to demonstrate any disease and routine laboratory investigations gave normal results falling into the range accepted as not pathological.

In the fasting, serum of all patients and controls, the levels of triglycerides (TG), total cholesterol (Chol) and phospholipids (PL) were routinely determined using diagnostic test kits supplied by Boehringer (Mannheim, West Germany). High density lipoprotein (HDL) fraction of each serum also was obtained by the precipitation method using Boehringer kits, and the levels of the same components in this fraction were determined by the same methods as in whole serum as well. The type of dyslipidaemia in atherosclerotic patients was determined by electrophoretic separation of serum lipoprotines in agarose gel (15) and was found to be type IV according to Fredrickson (16) in all cases. Plasma and HDL lipid values of all patients are shown in Table 1.

All patients and controls fed a common nationwide Polish diet with an energetic value of 14693 kJ/person/daily. Animal fat consumption was 97 g/person/day, and the consumption of vegetable fat was only 25 g/person/day. Polyunsaturated fat intake did not exceeded 10% of the total (17). This diet remain unchanged within three months before experiment.

Lipids were extracted according to Bouhours and Bouhours (18). The lipid extract was dissolved in a small quantity of the chloroform/methanol (2:1, v/v) and phospholipid classes were separated by thin layer chromatography on the Silica Gel G plates (E. Merck, Darmstadt, West Germany). The neutral lipids were separated in solvent system: light petroleum/diethyl ether/acetic acid (90:10:1, v/v/v). Phospholipids were separated according

to Stein and Smith (19). Chromatograms were visualized in iodine vapors, and compounds were identified by comparing their R_f values with those of standards (Sigma Chemical Co., St. Louis, MO). Individual spots were scraped off, and the gel was successively extracted with 5 ml each of chloroform, chloroform/methanol (2:1, v/v), chloroform/methanol (1:2, v/v) and methanol.

The pooled extracts were evaporated in vacuum, and cholesterol was determined in appropriate fractions according to Zlatkis et al. (20) and phosphorus as described by Bartlett (21).

In the parallel experiment, the zones containing phospholipid fractions were scraped off, extracted with 2 × 5 ml of the chloroform/methanol (1:1, v/v); the pooled extracts were evaporated in vacuum; the fatty acids were saponified with methanolic KOH (22). After acidification (1 M HCl) to pH = 2.0, the acids were extracted with light petroleum and turned into methyl esters with BF_3-methanol complex (Theodor Schuchardt, Hohenbrunn, West Germany) (23).

The composition and the quantity of fatty acids were determined by the gas chromatography with a Perkin Elmer F-30 gas chromatograph (Perkin Elmer Ltd., Beaconsfield, Bucks., England) as described (24). Identification of the components was carried out by comparing their retention times with those of standards (Applied Science Labs., State College, PA). Margaric acid was used as the internal standard. The peak fields and the retention times were measured by a computerized integrator System I (Spectra Physics, Santa Clara, CA). To resolute the components of very close retention times, the capillary column 50 m × 0.2 mm i.d., coated with CP Sil 88 also was used (Chrompack, Middelburg, Netherlands). The carrier gas was nitrogen, flow rate 0.5 mi/min, oven temperature from 220–270 C programmed with a rate of 1 C/min with flame ionization detector.

Student's unpaired t-test was used for comparing normally distributed data, and Wilcoxon's signed rank test for comparing data that normally were not distributed (25).

RESULTS

Table 2 shows the composition of phospholipids and sphingomyelin/phosphatidylcholine and cholesterol/phospholipid ratios in erythrocytes of healthy persons and those with atherosclerosis. It should be noted that there

was a significant reduction of the phosphatidylcholine quantity and increase of the phosphatidylserine and sphingomyelin quantities in erythrocytes of patients with atherosclerosis. The increase of cholesterol/phospholipid and sphingomyelin/phosphatidylcholine ratios in both groups also was significant. The differences in content of phospholipid fractions between both groups of atherosclerotic patients appeared not to be significant with exception of phosphatidylinositol.

Table 3 shows the fatty acid composition of the phosphatidylcholine fraction of erythrocytes. It can be observed that there is a considerable decrease of 16:0, 18:0 and 20:4ω6 acids, and a highly significant increase of 18:1ω9, 18:2ω6 and 20:3ω6 acids in the erythrocytes of patients with atherosclerosis.

Similar changes can be seen in fatty acid composition of phosphatidylethanolamine (Table 4) and phosphatidylinositol (Table 5). In the phosphatidylserine fraction (Table 6), the reduction of 16:0 and 18:0 is accompanied by the lowering of 20:4ω6 in group I, and its increase in group II to the level observed in the control. The sphingomyelin fraction of erythrocytes does not contain

fatty acids of the ω3 series (Table 7). Changes in acids of this fraction were found to be statistically not significant.

DISCUSSION

In this paper, we stated that the sphingomyelin and cholesterol quantities increase, and the phosphatidylcholine quantities in decrease in erythrocytes of atherosclerotic patients. These changes produce the increase of the sphingomyelin/phosphatidylcholine ratio similar to the phenomenon observed in abetalipoproteinaemia (26); the increase of the cholesterol/phospholipid ratio is similar to the increase in spur cell anemia (27). This leads to the reduction of cell membrane fluidity and reduces the

changes in contour of red blood cells (28). The increase of sphingomyelin and the decrease of phosphatidylcholine quantities in the course of atherosclerosis also were observed in the cells of aortal intima and media (29,30). Sphingomyelin stabilizes the bilayer structure of cell membranes (31), while too high cholesterol content destabilizes it (32); the increase of sphingomyelin quantity can be treated as the compensatory change in response to the increase of cholesterol.

The fluidity of cell membranes also depends on the fatty acid composition and their degree of unsaturation (33,34). It generally is accepted that unsaturated fatty acids intensify the membrane fluidity while saturated ones reduce it (12). The composition of acids of the plasma phospholipids in the course of atherosclerosis undergoes changes characterized by the increase in 16:0, 18:0 and 18:1ω9 (35); similar changes in the phosphatidylcholine fraction of the atherosclerotic aorta were noted by Böttcher and Van Gent (30).

Dietary manipulation also produces the changes in the composition of cell membrane fatty acids. Brasitus et al. (36) asserted that feeding a diet containing large amounts of 18:2ω6 increases the lipid fluidity and the unsaturation degree of acyl chains of erythrocyte membranes, thus producing the increase in 18:2ω6 and 20:4ω6 levels in the phospholipids of cell membranes. The diet supplemented with cholesterol causes an increase of 18:1ω9 and 20:3ω6 and decreases the amounts of 18:0 and 18:2ω6 in the erythrocyte phosphatidylcholine fraction in rats (37). In dogs, feeding an atherogenic diet produces an increase of 18:1ω9, 20:3ω9 and 20:3ω6 and a reduction of 18:2ω6 and 20:4ω6 in the lipids of mitochondria and microsomes of liver cells (38). In guinea pigs, the cholesterol supply causes a reduction of 16:0 and 18:0 and an increase of 18:1ω9, 20:3ω6 and 20:4ω6 in the lipids of erythrocytes (39). In rabbits, feeding cholesterol produces an increase of the cholesterol/phospholipid ratio (40).

The changes in lipid composition decrease above are accompanied by compensatory mechanisms tending to maintain the cell homeostasis. Brasitus et al. (36) showed that the increase in the amount of unsaturated fatty acids is compensated by the increase of cholesterol/phospholipid ratio. Schouten et al. (41) proved that an increase of 20:5ω3 is compensated by the decrease of 18:2ω6 in the phosphatidylcholine fraction of erythrocytes. Schouten et al. (41) stated that increase of the cholesterol/phospholipid ratio goes along with the compensatory decrease of 18:0 decrease of 18:0 and the increase of 18:2ω6. The increase of 20:3ω6 observed by the same team in other experiments (37,41) is an adaptive change in response to the increase of the cholesterol/phospholipid ratio. The increased cholesterol/phospholipid ratio in erythrocytes of the guinea pig fed an atherogenic diet produces the compensatory decrease of 16:0 and 18:0 and an increase of 20:3ω6 and 20:4ω6 (39). Similar changes were observed by Gibson et al. in lipids of subcellular fractions of liver, kidney, brain and heart in rats (42).

The stated decrease of 16:0 and 18:0 and the increase of 18:2ω6 and 20:3ω6 in the erythrocyte phospholipid fraction in atherosclerotic patients also can be regarded as compensatory changes aimed at the maintenance of adequate physico-chemical properties of the cell membrane in response to the increased cholesterol/phospholipid and sphingomyelin/phospholipidcholine ratios. Popp-Snijders et al. recently showed that the compensatory changes described above are sufficient for maintaining adequate fluidity of erythrocyte membrane (43).

The compensatory mechanisms that we have observed may explain previously stated (14) lack of differences in the strength of the cytoprotective effect of prostaglandins on erythrocytes of healthy persons and patients with atherosclerosis. The investigations of Borochov and Shinitzky (44) suggest that the availability of surface receptors of red blood cell membrane depends on its fluidity. The compensatory changes of the kind described above can be the reason for identical availability of receptors for prostaglandins in both cases.

[Received January 12, 1987; Revision accepted December 11, 1987]

METHODS

Composition of Mixed Octadecadienoates via Ozonolysis, Chromatography and Computer Solution of Linear Equations[1]

H.J. Dutton[a], S.B. Johnson[a], F.J. Pusch[a], M.S.F. Lie Ken Jie[b], F.D. Gunstone[c] and R.T. Holman[a,*]

An approach to the analysis of 55 possible nonconjugated positional isomers of octadecadienoic acid is described and tested with mixtures of individual synthetic methyl esters. In the first example, by ozonolysis a seven-component mixture consisting of *cis,cis* 5,12-, 6,10-, 6,11-, 6,12-, 7,12-, 8,12-, and 9,12-octadecadienoates was converted to aldehydes, aldehyde-esters and dialdehydes. These fragments were separated on a 50 m × 0.2 mm free fatty acid phase (FFAP) vitreous silica capillary column. Equations for an arbitrarily restricted 12 × 15 matrix of linear simultaneous equations and a computer solution of the matrix provided the composition of the initial methyl octadecadienoate mixture. The power and significance of this method became apparent with the observation that only two of the seven isomers in the known mixture were resolved as single peaks by state-of-the-art capillary gas chromatography, but all seven were identified and estimated with acceptable error by the ozonolysis-capillary gas chromatography-computer procedure. In a generalized approach to the analysis of the 55 possible nonconjugated isomers, a computer program selects the appropriate matrix of linear simultaneous equations based on the aldehyde data supplied by the analyst. Twenty of 21 combinations of seven isomeric esters taken five at a time have been analyzed to assess the efficiency of the method. To illustrate applicability at this stage of development, the method has been used to analyze the diene products of the hydrazine reduction of γ-linolenic acid and the diene products from the biological desaturation of isomeric monoenes. The possibility of distinguishing geometric and positional isomers of 18:2 has been opened by the observed separation of *cis*- and *trans*-unsaturated aldehydes and aldehyde-esters.

***Lipids 23,* 481–489 (1988).**

Methods for the analysis of positional isomers of octadecadienoates as they occur in mixtures of chemical or biological origin generally are lacking (1). A procedure for the analysis of 18:2 isomers from partially hydrogenated fats has been described (2) but was not applicable to samples of biological origin because the range of double-bond positions permitted was too limited. It involved ozonization and reduction to form alcohols, gas chromatographic separation of the alcohols, alcohol-esters, dialcohol fragments and, finally, mathematically identifying the component 18:2 isomers in the original mixture and estimating their proportions from the proportions of the fragments produced.

In this report, an improved procedure is proposed for the analysis of a wider range of isomers such as may be expected in biological studies (3). Based on the capillary gas chromatographic (CGC) separation and measurement of the aldehydes, which are more quantitatively formed from the ozonides than are alcohols, the method permits analysis of mixtures of isomeric nonconjugated dienoic acids with double bonds ranging from the Δ3 to Δ15 positions, limits that are reasonable for biological samples. The method has been tested previously (4) with seven known mixtures of synthetic isomeric dienoic fatty acid methyl esters (5) and upon the diene products of the hydrazine reduction of γ-linolenic acid for which the products are predictable, and those preliminary results appeared in the Congress' Proceedings (4). This final report is based mainly upon new data in which alkaline isomerization was used for measurement of 1,4-dienes rather than malondialdehyde and on tests of the method with 21 known model mixtures of 18:2 acids.

EXPERIMENTAL

Synthetic mixtures. Synthetic isomers of *cis,cis*-18:2 (5) were used to prepare mixtures of known composition for analysis and development of procedure. The initial mixture consisted of equal amounts by weight of *cis,cis*-5,12-, 6,10-, 6,11-, 6,12-, 7,12-, 8,12- and 9,12-octadecadienoic acid methyl esters. The major test of the approach was by a series of 21 synthetic equimixtures of the same seven isomeric esters taken five at a time.

Ozonizations. Ozonizations were performed by bubbling a stream of 10% O_3 in oxygen (50 ml/min) through petroleum ether solutions (ca. 20–100 μg of esters in 20–100 μl) cooled by a CO_2-acetone bath. Ozone was produced in a small glow discharge generator powered by a Tesla coil (6) or in a Bonner-type generator (7). After partial evaporation of the petroleum ether with a stream of N_2 at room temperature, an amount of triphenylphosphine in diethyl ether (8) twice the sample weight was added to reduce the ozonides to aldehydic products.

CGC separations. CGC separations of individual aldehyde (A), aldehyde-ester (AE) and dialdehyde (AA) fragments were performed using a 50 m × 0.2 mm free fatty acid phase (FFAP) (Carbowax) column (Supelco, Inc., Bellefonte, PA) and a 50 m × 0.2 mm SP 2330 vitreous silica column (Scientific Glass Engineering, Inc., Austin, TX). The FFAP capillary column was used isothermally at 185 C and 190 C to partially separate the

initial mixtures of methyl octadecadienoates (Table 1). To separate aldehydic products, both the SP 2330 and FFAP columns were programmed from 40 C to 220 C at a rate of 6 C/min in a Packard Model 428 gas chromatograph equipped with a flame ionization detector. Peak areas and retention times were measured by an IMSAI 8080 microprocessor.

Conjugatable double bonds. The percentage of methylene-interrupted dienes was determined as a preferred alternative to or in addition to the CGC measurement of malondialdehyde (AA3), which is poorly detected because it has only one ionizable carbon atom. The alkaline conjugation was performed in the injection port with tetramethylammonium hydroxide, and the nonconjugated dienes were separated and measured by CGC (9). The malondialdehyde equivalent to the conjugatable dienes was calculated and used in the matrix solution.

Mathematical procedures for the seven-component initial equimixture. The analytical problem involves a matrix of linear simultaneous equations relating the occurrence and proportions of the several possible A, AA and AE fragments arising from a broad range of isomeric 18:2 structures (2). This matrix is shown in Figure 1. Because conjugated isomers rarely are found in animal lipids,

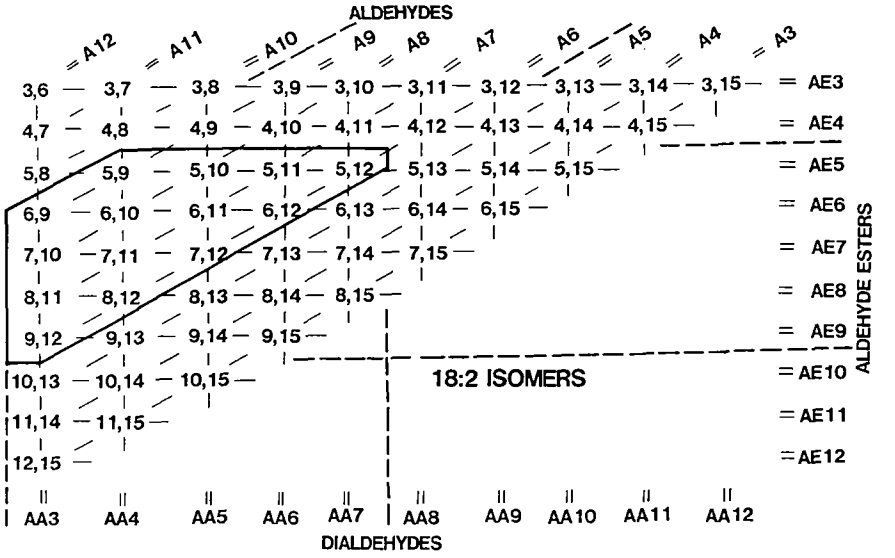

FIG. 1. Triangular representation of 30 linear simultaneous equations relating 55 nonconjugated 18:2 isomers to A, AA and AE fragments. AE homologs are summations horizontally; AA homologs are vertical summations; A homologs are diagonal summations, as shown. Enclosed area includes the equations limited by the range of analytical data supplied.

these isomers were excluded from consideration. There are 55 positional, nonconjugated isomers of 18:2 possible, with double bonds ranging from positions Δ3 to Δ15. Isomers of 18:2 outside this range also are very unlikely in natural samples, and even those 18:1 isomers from which they might be derived occur in hydrogenated fats in vanishingly small proportions. For these 55 isomers, there are at a maximum only 30 aldehydic products possible by ozonolysis and reduction. Obviously, such a matrix cannot be solved nor need it be in most practical samples because relatively few isomers occur in any given system. In the earlier application to the diene structures expected in partially hydrogenated oils (2), the "single skip principle" was applied, in which only one of the two double bonds of a methylene-interrupted diene is expected to shift in a given molecule during hydrogenation. Application of the single skip principle here reduced the matrix to 15 equations, relating 12 unknowns that should permit mathematical solutions. Applying a narrower matrix for the range Δ5 to Δ12, covering the range of double bond positions occurring in the model esters, the aldehydic products of an equimixture of the seven synthetic dienes were analyzed (Fig. 2), the products identified and the matrix equations solved as shown in Figure 3.

The restriction of the single skip that applies to hydrogenation may not be valid for unknown biological systems, and a more generalized procedure for limiting the numbers of equations was needed. Accordingly, an initial subroutine, BRAIN, to the computer program was devised to select the appropriate equations involving only those isomers that could yield the aldehydic products observed. This same elimination of unneeded equations can also be performed graphically, as shown in Figure 1 by the broken lines that intersect to include an area (solid lines) of 14 unknowns and 14 equations required by AE5 to AE9, AA3 to AA7 and A6 to A9. This reduction in matrix size is followed by a routine, DIENES, which makes further deletions of isomers to be considered by deletion of the minor aldehydic components, if necessary, to achieve a solution. It also employs the subroutine, ORTHO (2), which solves the remaining matrix iteratively. This composite program is available from the first author. A first test of this generalized approach was made with the same equimixture of seven available synthetic isomers of 18:2 whose double bonds occurred at carbons 5 through 12. Despite the 13 equations relating 12 unknowns, this matrix was not solved directly for the seven-component mixture because of redundancies (2). Therefore, a strategy successively considering only 10 of the 12 isomers at a time and evaluating the results for minimum error was undertaken. The average for six minimum error solutions is given in the last column of Table 1. This strategy, while acceptable for knowns, is not justifiable for unknowns.

Mathematical procedure for the 21 five-component mixtures of seven esters. To evaluate accuracy and precision of the general analytical method and matrix system, a series of 21 mixtures of the seven esters taken five at a time was made as indicated in Table 2. Computer

solutions of 20 of these 21 mixtures were successful using analytical input data from the model mixtures. The combination omitting esters F (8,12-) and G (9,12-), designated in Table 2 as -FG, was not solved by manual algebra or by our direct computer methods. The combination -BC is of particular interest because the solution was obvious by direct inspection of either the AA or the AE data, uniquely identifying esters present.

In the first test of the entire procedure, nine dispersed combinations of five isomers listed in Table 2 were chosen for analysis. CGC analyses of the methyl esters were made first to see if any of the combinations could be analyzed without the ozonization-computer matrix procedure. None of the mixtures was separable into its five components. After ozonization, reduction and CGC of the aldehydic products, computer solutions of the matrices were calculated, and the standard deviations of the values for each isomer occurring in the many combinations were calculated. In these calculations, percentage of conjugatable isomers by alkali isomerization-CGC (9) was used in lieu of measurement of percent malondialdehyde by ozonolysis-CGC.

Following the discovery that the -FG combination could not be solved directly, the remaining 11 combinations of the 21 were analyzed by the ozonization-computer procedure. Spreadsheets were exploited for the laborious calculation of corrected mole percentage and integrated graphics for stacked-bar histograms were used as helps in development. The data from this extended series of model mixtures also are in Table 2.

Solutions of linear simultaneous equations were performed using the improved FORTRAN program, which eliminated from consideration those isomers for which no experimental data existed and deleted the related equations from the matrix. The program minimized the sum-squared error of all possible solutions by an iterative process, and printed out the observed input data, the values for the data used, and the absolute error and the percentage error between the latter two. When a negative value was found, the program set that isomer at zero, and the calculation was repeated. This program, the spreadsheets and the graphics were run on an Apple IIe computer (10). The program is available from the Hormel Institute[2] (10).

Standard dienes. The synthetic isomeric 18:2 fatty acid methyl esters (5) had *cis-cis* double bonds at the 5,12-, 6,10-, 6,11-, 6,12-, 7,12- and 8,12- positions. In addition, methyl linoleate (9,12-18:2) and methyl linoelaidate (t9,t12-) were obtained from NuChek Prep., Inc. (Elysian, MN). These isomers covered the range of double bond positions from Δ5 to Δ12.

Hydrazine-reduced γ-linolenic acid. Dienes from hydrazine-reduced γ-linolenic acid were prepared in the following way: to 10 μl of 6,9,12-octadecatrienoic acid (γ-linolenic acid, 18:3ω6) dissolved in 1.6 ml of methyl alcohol, 0.3 ml of hydrazine hydrate (64%) was added; and oxygen gas (50 ml/min) then was bubbled for 10 min into the reaction mixture in a 20 C water bath. The reaction mixture was then acidified with 3 N methanolic HCl, extracted with petroleum ether, washed with water, dried, esterified with BF_3-methanol (14% w/v), extracted with petroleum ether and washed. The resultant methyl esters were separated by thin layer chromatography (TLC) on 2% silver nitrate-treated Silica Gel H plates using petroleum ether-diethyl ether (100:10, v/v) as solvent to obtain the diene fraction, which theoretically should be equal parts of 6,9-, 9,12- and 6,12-18:2.

Liver phospholipids (PL). Liver PL from a rat fed 18% partially hydrogenated soybean oil (PHSO) were isolated and used to test the analytical method on a biological sample likely to contain 18:2 isomers (11). After conversion to methyl esters, the diene fraction was isolated by $AgNO_3$-TLC, and the C_{18} dienes were separated from C_{20} dienes by high performance liquid chromatography (HPLC) on an ALTEX C-18 column using 95% methanol.

RESULTS

Analysis of the seven-component known mixture. CGC of an equimixture of the seven isomeric methyl octadecadienoates listed above showed three major unresolved peaks and a fourth peak that was more completely resolved and integrated (Fig. 4). From the retention times for the individual components (4), the identifications of components within each peak could be made.

The equimixture of the seven isomeric methyl octadecadienoates also was ozonized, reduced, and the resultant AE, AA and A fragments were separated by temperature-programmed CGC (Fig. 2). Identifications of aldehydic fragments were made by ozonizing the individual isomers and CGC separation of the resulting aldehydic fragments. Plots of elutin temperature vs chain length of A, AE and AA fragments each gave a linear relationship (4,12). This

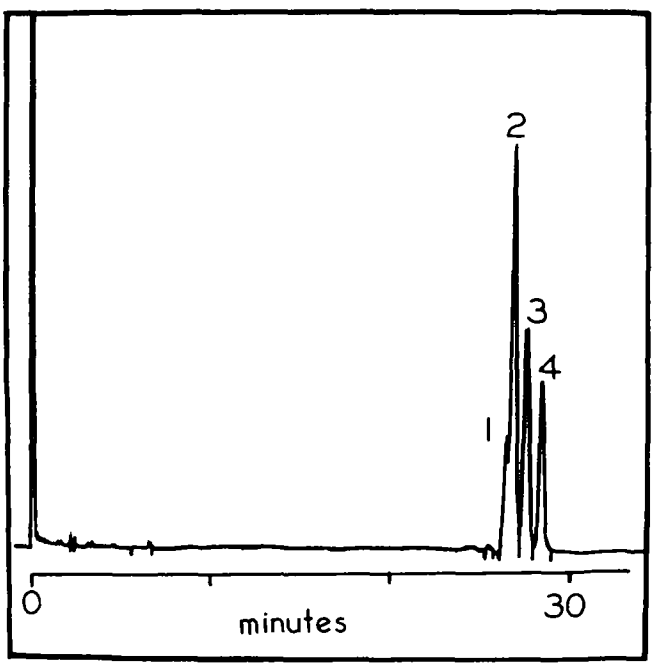

FIG. 4. CGC separation of the seven-component synthetic mixture of methyl octadecadienoates. Peak 1: 6,11-isomer. Peak 2: 6,10-, 5,12- and 7,12-isomers. Peak 3: 6,12- and 8,12-isomers. Peak 4: 9,12-isomer. (50 M FFAP column at 190 C.)

[2]All necessary FORTRAN programming and instructions for use on Apple II computers and a demonstration routine on disk will be supplied by the first author upon request. (Include a blank 5¼" diskette and a self-addressed, stamped mailing carton.)

includes the peak corresponding to malondialdehyde, which is small because of its one ionizable carbon atom, and which therefore is less reliable for quantitative purposes. It has been used previously to qualitatively establish the structure of methylene-interrupted double bonds in individual trienes and tetraenes (13). Only those peaks that fell where expected were considered in the calculations, and spurious peaks were ignored. Of particular concern was the large unidentified peak that sometimes followed AE7. Our study of the kinetics of ozonization indicated that it forms in proportion to the AE fragments. In packed 1/8″ columns, this peak is not resolved from AE7 and it gives such large and erroneous values for AE7 to make the data arising from packed columns invalid, and to make CGC the tool of necessity.

Table 3 gives the uncorrected areas from Figure 2, the areas corrected for ionizable carbon atoms (14), the molar percentages adding up to 100% for each type of fragment and, finally, the identities of the isomers contributing to each peak. These molar percentage values were the input data used in the computer program. The percentage of conjugatable diene obtained by injection port alkali isomerization-CGC was 13.7% corresponding to 13.6% in Table 3 for AA3 (9).

A computer printout showing these input data (first column) and the matrix of 18:2 isomers derived from them are shown in Figure 3A. The first solution (Fig. 3B) gave two negative values that were eliminated in the next iteration. Figure 3C shows the final solution.

In the equimixture analyzed, each isomer has as its unique expression, one AE or one AA or both (Table 1). Therefore, a qualitative analysis should be feasible from the AE and A produced, and a quantitative analysis is feasible from the proportions of the products (Table 1). However, in those instances in which an isomer could be measured independently by two different aldehydic fragments, discrepancies between the two calculations were apparent (Table 3). For example, measurement of 5,12-18:2 by the AE5 alone gave 23.2%, but using the AA7 alone gave 13.2%, an example of the experimental error of analysis by direct calculation. Table 1 compares the composition of the known mixture of standard 18:2 isomers by gravimetry with its analysis by the methods of CGC, by direct calculation, by computer matrix solution with a restricted matrix, and in the last column, by an unrestricted matrix that examined all 66 possible combinations of 12 esters taken 10 at a time, and selected six solutions of minimum error for averaging.

CGC analysis of the 21 five-component known mixtures of the seven esters. Direct CGC of the 10 experimental mixtures -AC, -AE, -AG, -BD, -BE, -CE, -CG, -DF, -EF and -FG resolved only two peaks in four of the mixtures, three peaks in five, and four peaks in one. Four peaks also were found in the first seven-component mixture described above, but only the 9,12 isomer was clearly separated in all mixtures. These measurements showed the inadequacy of current CGC for separation of 18:2 isomers.

Ozonolysis, reduction, CGC of aldehydes and computer matrix solutions of the data gave for the first nine equimixtures an average value of 19.3% ± 5.1% (S.D., n = 9). The difference between this average and the expected 20% for each is accounted for by small percentages of isomers that were required by the computer solution for minimizing the error of the input data. In these calculations, the percentage of conjugatable dienes was used in lieu of the percentage of malondialdehyde by CGC measurement. The alkali conjugation-CGC analyses on eight mixtures that contained linoleate (20%) had an average percentage value of 17.6% ± 2.4 (S.D.) conjugatable

TABLE 3

Aldehyde Fragments Obtained from Ozonolysis and Reduction of the Seven-component 18:2 Mixture

Fragments	Temp.	Time	Peak area	Ionized carbons	Corrected area	Mol %	Contributing diene(s)

A8	107.1	9.52	6,099	7	871	15.9	6,10-
					5,476	99.9	

isomers. It should be noted that with the highly efficient inlet splitters of modern CGCs and their inherently low residence time, the conversion of linoleate to conjugated diene was only 64% compared with 95–96% for direct injection in the old-style packed column GCs and/or the micro reactor apparatus as originally published (9). The 64% correction factor found for the conjugation of methyl linoleate brought conjugated diene values for these known mixtures near theory. In the analyses of the remaining 11 combinations, theoretical values of 20% for malondialdehyde were used.

As noted above, it was found that neither the computer nor manual algebraic attempts could solve one of the combinations (-FG); therefore, it became mandatory to run the remaining 11 combinations (-AB, -AD, -AF, -BC, -BE, -BG, -CD, -CF, -DE, -DG and -EG) through the matrix procedure. Spreadsheets were used for routine calculations and conversions of CGC areas to percentage mole fractions.

Much of the assignable error of the final calculation arose from error in input data. This became clear when stacked-bar histograms were constructed (directly from the spreadsheet). The heights of bars representing amounts of individual AE, AA and A analyses should be 0%, 20% or multiples of 20% up to 100%. Variability in input data from the 20% multiples was apparent and inevitably contributed to the error of computer output data.

Partial ozonization of a methyl linoleate-methyl linolelaidate mixture. Partial ozonization of *cis*- and *trans*-isomers of 18:2 yields mixtures of *cis*- and *trans*-unsaturated aldehydes and aldehyde esters that are distinguishable by CGC. An equimixture of these isomers was ozonized, leaving 3.1 and 3.9 mol % of unreacted methyl linolelaidate and methyl linoleate, respectively (12). CGC (SP 2330 temperature-programmed from 40–240 C at a rate of 2 C/min) gave two peaks in the temperature/time window expected for unsaturated aldehydes of 12 carbon atom length—the first, 6.2 mol % *trans*-3-dodecenal, the second 2.5 mol % of *cis*-3-dodecenal. Peaks of 1.4 and 1.1 mol % were present in the region expected for 3-*trans* C_{12} aldester and 3-*cis* C_{12} aldester just preceding the elution of the two parent ester peaks. From this and other partial ozonizations of the linoleate-linolelaidate mixture, it is apparent that *cis* and *trans* aldehydes and *cis* and *trans* aldehyde esters can be separated as well as the parent linoleate and linolelaidate on a CGC SP 2330 column.

Analysis of dienes from hydrazine-reduced γ-linolenic acid. The capillary chromatogram of the hydrazine reduction mixture is shown in Figure 5. All three expected isomers were detected, 6,9-, 6,12- and 9,12-18:2. Table 4 gives the compositions of the hydrazine reaction mixture before and after isolation of the dienes by $AgNO_3$-TLC. It compares the theoretical composition with analyses by direct CGC of the 18:2 isomers and by the ozonolysis-matrix procedure. CGC and ozonolysis matrix solution gave values that deviate similarly from theory.

Analysis of dienes from rat liver phospholipid. The capillary gas chromatogram for the 18:2 isomers isolated from liver PL of one rat fed PHSO showed three major peaks whose shapes indicated multiple unseparated isomers, which accounted for 25.3, 23.4 and 51.3% in order of their elution. After ozonization of the mixture, the following aldehydes were found: AE5, AE6, AE7, AE8, AE9, AA3, AA4, AA5, AA6, AA7, A6, A7, A8 and A9. The analysis of the 18:2 isomers by ozonolysis and matrix solution revealed at least five components, with values for 9,12-18:2 varying from 38.8 to 51.5% on replicates, to be compared with analysis by CGC (51.3%) and by total conjugatable dienes (53.4%). Application of the ozonolysis-matrix solution procedure to relevant biological problems will be the subject of a later report.

DISCUSSION

The thesis that "Every Advance in Scientific Knowledge is First an Advance in Technique" has as its converse the reality that advances in scientific knowledge frequently must await developments in technique. Thus, study of the metabolism of isomers of linoleic acid is impeded by the absence of an adequate methodology for the analysis

of 18:2 isomers (1). It is this vacuum that the present preliminary studies attempt to fill so that future advances in scientific knowledge may be facilitated.

The only previous attempt at analysis of naturally occurring 18:2 isomers known to us attempted to match AE and A fragments formed from the mixtures, assuming methylene interruption (15). Without measurements of the AA fragments, such data can lead to ambiguous compositions of mixtures. The present method measures the dialdehyde fragments as well, and the malondialdehyde can be estimated from measurement of methylene-interrupted dienes by alkaline isomerization. The computer-assisted assembly of diene structures matches all three types of aldehyde fragments (A, AA, AE) derived from a dienoic acid. Our analysis of the known seven-component mixture showed an average error of ±1.2% on true gravimentric values of 14.3% or a relative error of 8.4% (Table 1). For 28 analyses of the 20 combinations of five pure esters (Table 2), an average percentage content of the individual components (present in all samples at 20% each) was estimated to be 19.0% ± 0.43 (S.D., n = 140), or a maximum relative error of about 25%. The average of components detected and reported but not actually present in the samples was 0.57% ± 0.14 (S.E.M., n = 140). Thus, the chance of missing a major component or of reporting an absent component is very small. The computer deletion of components less than 2% of the total to achieve convergence prevented gross errors of this kind. In the analysis of the products of hydrazine reduction of γ-linolenic acid, the matrix solution gave an average error of ±1.57% on an average theoretical value of 33.3%, or a relative error of 4.7% (Table 4). This degree of precision, far from ideal, may be useful in biological experiments in which the analysis of the positional dienoic isomers of biological interest is required, and in which the range of isomers is more restricted than in this study. It should be useful, especially in detecting major unexpected isomers.

On one hand, the present investigation was made feasible by the availability of pure synthetic isomeric octadecadienoates over a decade ago (4), permitting studies on known structures in mixture. On the other hand, progress was limited by the need for the development of techniques such as high-resolution CGC for the separation of aldehydes and the advent of computers in biological research. The development of CGC and computer procedures for matrix solution made the present project possible.

Using all, even redundant, information is an advantage of the matrix solution procedure. It provides for the least-squares minimization of all values entered. One disadvantage is the reporting of small proportions of isomers that may not be present. For example, the 5,10- and 7,10-isomers of Table 1 can be justified because A8, AE5, AE7, AA5 and AA3 were observed among the products of ozonolysis in Table 3. Another disadvantage is the need for eliminating minor aldehydic components from the input data to cause a matrix solution to converge. Thus, the solutions reached are approximations, presence or absence of minor components cannot be ascertained, and the quantification is less precise.

Comparison of results from the CGC of the initial methyl octadecadienoate mixtures with the results of the ozonization procedures shows that even with state-of-the-art CGC, only one of the seven synthetic isomer mixtures could be sufficiently resolved to be measured. Even two of the three isomers of 18:2 in the products of hydrazine reduction overlapped, giving an inflection point not always detectable as a binary peak. It is hardly likely that others of the potential 55 isomers to be encountered would be more separable. The ozonolysis-computer procedure is capable of estimating components in mixtures that cannot be resolved by present state-of-the-art CGC.

In the first use of our method on a biological sample (summarized only briefly here), unusual diene structures have been detected in liver PL. More comprehensive subsequent experiments confirmed and extended this observation (18). The unexpected dienes may be substrates for elongation and/or desaturation reactions in vivo to produce longer chain polyunsaturated fatty acids of unusual structure. In turn, these may be substrates for synthesis of eicosanoids of unusual structures and biological activities (3,16). This proposed method now will permit a more detailed study of the first step in the cascade of biological reactions that may have unpredictable and subtle effects upon metabolism.

The need for improving the precision of our preliminary analytical ozonolysis procedure is obvious. The yield of aldehydes by reductive-ozonolysis is not quantitative; it appears to vary with structure of dienoic fatty acid, whether mono- or dialdehyde is formed and, according to our unpublished kinetic studies, with degree of ozonization. These indications point the way for future improvements in our current methodology.

A measurement of the malondialdehyde peak has in the past been improved by a second injection 7- to 10-fold greater in size to amplify the minor peaks (2). Equivalent analyses for alpha methylene groups by nuclear magnetic resonance (NMR) and conjugatable dienes by alkaline isomerization (17), by lipoxygenase (17), or by injector port alkaline isomerization-gas chromatography (9) also are available. The latter procedure was employed in this study because it is easily performed and requires only a small sample, but it also needs improvement in precision.

In the future, the method needs to be extended to distinguish the *cis*- and *trans*-isomers. Hope that this can be achieved is found in the observation of the formation and CGC separation of *cis*- and *trans*-unsaturated aldehydes and aldehyde esters after partial ozonization. Information on the geometric configuration of the double bonds closest to the methyl group of the dienoic fatty acids would come from the configurations of the unsaturated aldehyde fragments, and on the double bonds closest to the ester end from the unsaturated aldehyde ester fragments.

The ozonization, CGC and computer matrix procedure at its present stage of development should be adaptable by minor modifications of program and procedure to the isomers of 20:2 that are known to occur in liver. The projected method should have broad applications to current analytical, biochemical and nutritional problems. These are the directions for our current biological studies.

ACKNOWLEDGMENTS

This investigation was supported in part by USPHS Grant HL 08214 from the Program Projects Branch, Extramural Programs, National Heart, Lung and Blood Institute, by USPHS Grant HL 21513 from

the National Heart, Lung and Blood Institute, Liver Research Center Grant PO-AM 34931 from the NIH, and by The Hormel Foundation. Joanne Gellerman and Don Sand assisted with the HPLC of the dienes.

[Received March 9, 1987; Revision accepted December 18, 1987]

Determination of Individual Long-chain Fatty Acyl-CoA Esters in Heart and Skeletal Muscle

F. Molaparast-Saless, E. Shrago*, T.L. Spennetta, S. Donatello, L.M. Kneeland, S.H. Nellis and A.J. Liedtke
Departments of Medicine and Nutritional Sciences, University of Wisconsin, Madison WI 53706

A method has been developed for determination of individual long-chain fatty acyl-CoA esters from heart and skeletal muscle using high performance liquid chromatography (HPLC). The esters were extracted from freeze-clamped tissue of pig and rat hearts and rat skeletal muscle for analysis on a radially compressed C_{18} 5μ reverse-phase column. Nine peaks in the extract with carbon chain lengths from C_{12} to C_{20} that subsequently disappeared on alkaline hydrolysis were identified. The major acyl-CoA peaks were 14:1, 18:2, 16:0 and 18:1 and additionally in rat heart 18:0. Total long-chain acyl-CoA esters obtained by summation of the individual molecular species was 11.34 ± 1.48 nmol/g wet wt. pig heart; 14.51 ± 2.11 nmol/g wet wt. in rat heart, and 4.35 ± 0.71 nmol/g wet wt. in rat skeletal muscle. These values were approximately 132% of those obtained using a separate procedure that measured total CoA by HPLC after alkaline hydrolysis of the esters. The described method demonstrates the quantitation of individual acyl-CoA species in muscle tissue. Therefore, it has a number of advantages in that it permits information to be obtained on the individual molecular species under various nutritional and metabolic conditions.
Lipids 23, 490–492 (1988).

Under normal physiological conditions, fatty acids are the preferred substrate for myocardial metabolism (1–3) and during long-term exercise are a major source of energy for skeletal muscle (4,5). As a result of myocardial hypoxia or ischemia, the mitochondrial oxidation of fatty acids in heart is impaired, and there is a consequent intracellular accumulation of long-chain fatty acyl-CoA and acylcarnitine esters (1,3,6). There have been few, if any, studies on acyl-CoA levels in skeletal muscle, and relatively little information is available on the metabolism of the individual esters in any intact tissue. A method for extraction of long-chain acyl-CoAs from rat liver and separation of the individual esters by high performance liquid chromatography (HPLC) has been developed (7). More recently, the technique has been used for the determination of long-chain acyl-CoAs in brown adipose tissue (8). This communication describes the adaptation of the procedure to heart and skeletal muscle, which contain considerably less long-chain acyl-CoA than liver (7). For control purposes, the sum of the individual long-chain acyl-CoAs was compared with their total concentration determined directly by alkaline hydrolysis and measurement of CoASH (9).

MATERIALS AND METHODS

Materials. Long-chain acyl-CoA esters for use as HPLC standards were obtained from Sigma Chemical Co. (St. Louis, MO). All other chemicals and solvents were of the highest commercial grade possible.

Procurement and preparation of tissue samples. Eight adolescent swine weighing 45–70 kg were anesthetized with IV pentobarbitol (35 mg/kg), intubated with positive pressure ventilation using oxygen enriched room air (60–70% O_2) and the coronary arteries perfused via an arterial shunt connected extracorporally (10). Tissue samples of approximately 0.5 g were obtained at the completion of the two-hr aerobic procedure from the left anterior descending and left circumflex regions of the hearts. Rat hearts and total muscle from the hind limbs were removed as quickly as possible following the killing of 200–300 g animals maintained on Purina lab chow. Three to four hearts or muscles from both legs were pooled for single samples. All tissues were immediately frozen in liquid nitrogen and kept at −70 C until analyzed for long-chain fatty acyl-CoA esters.

Tissue long-chain acyl-CoA extraction. The procedure was based on that described previously for extraction of rat liver (7) with slight modification. Approximately 1–2 g of frozen tissue were powdered and suspended in 2 ml isopropanol and 2 ml 50 mM KH_2PO_4, pH 7.2, to extract the lipids as described by Mancha et al. (11) for a complex mixture of plant lipids. Free fatty acids and less polar lipids were removed by acidifying the suspension with 50 μl concentrated acetic acid and then extracted with petroleum ether saturated with 50% aqueous isopropanol. The long-chain acyl-CoA esters next were extracted with chloroform/methanol (1:2, v/v) after addition of 100 μl saturated $(NH_4)_2SO_4$ to the washed aqueous phase. The chloroform/methanol extract was roto-evaporated to dryness at 30–35 C.

To concentrate and purify the sample, a Waters C_{18} Sep-Pak was equilibrated with 2 ml methanol, 2 ml water and 2 ml 10 mM KH_2PO_4, pH 5.3. The sample was dissolved in 10 mM KH_2PO_4, pH 5.3 and applied to the Sep-pak. The Sep-pak was washed with 3 ml of 80% 10 mM KH_2PO_4 (pH 5.3)/20% acetonitrile. The sample was then eluted with 2 ml of buffer containing 30% 10 mM KH_2PO_4 (pH 5.3)/70% acetonitrile, followed by 2 ml of 75% methanol/% 10 mM KH_2PO_4, pH 5.3. The sample was evaporated to dryness with N_2, dissolved in 0.2 ml 10 mM KH_2PO_4/1 mM 2-Mercaptoethanol, pH 5.3, and injected into the HPLC system.

HPLC analysis of long-chain acyl-CoA. The analysis was carried out with a Waters Guard Column (2.3 cm length, 3.7 mm diameter) filled with a 37-50 Bondapak C-18 Corasil and a Waters Nova-Pak C_{18} reverse-phase (radial-pak cartridge, 10 cm length, 8 mm diameter). The two mobile phase solvents were A, 20% acetonitrile, 80% 10 mM KH_2PO_4, pH 5.3; and B, 70% acetonitrile, 30% 10 mM KH_2PO_4, pH 5.3. A slight modification of the linear gradient for elution of the long-chain acyl-CoA from that published (7) was divided into five steps. Step one was 92% solvent A reduced linearly to 72%, and 8% Solvent B increased linearly to 28% over a four-min period. Step two was 72% solvent A reduced linearly to 50%, and

*To whom correspondence should be addressed at 430 Nutritional Science Bldg., University of Wisconsin, Madison, WI 53706.
Abbreviation: HPLC, high performance liquid chromatography.

28% Solvent B increased linearly to 50% over a 10-min period. Step three was 50% solvent A reduced linearly to 25%, and 50% Solvent B increased linearly to 75% over a seven-min period. Step four was solvent A held at 25% and solvent B held at 75% for 10 min. Step five was 25% solvent A increased by curve 0.5 to 92%, and 75% Solvent B decreased by curve 0.5 to 8% over a 10-min period.

The volume of the sample injected was 200 μl, the flow rate 2 ml/min, total running time 41 min, and the equilibration time between runs was 10 min. The long-chain acyl-CoAs were detected at 254 nm at 0.016 absorbance units full-scale. Quantitation was based on peak areas, and excellent proportionality was obtained between the different volumes of the standard or extract injected and the concentrations of the individual esters. The equipment consisted of a Perkin Elmer Series 3B pump module, a variable wavelength detector with an autocontroller, a Sigma 15 data processor, and a Waters WISP 710 B automatic sample injector.

As a check to this method, total long-chain acyl-CoA also was determined by an independent HPLC method of Ingebretsen et al. (9) and modified in this laboratory for heart tissue. The CoA esters were extracted from pulverized frozen tissue by perchloric acid precipitation and assayed for free CoASH released by alkaline hydrolysis. To prevent oxidation, 20 mM 2-mercaptoethanol was added to the extracts throughout the base hydrolysis. Tissue samples were compared with acyl-CoA standards by co-chromatography using a Waters Partisil SAX (strong anion exchange) Radial-PAK cartridge (8 mm × 10 cm). Elution was isocratic using a solvent composition of thiodiglycol/2-propanol/196 mM phosphate buffer, pH 3.9 (0.05:2.0:97.95). The flow rate was 2 ml/min, and detection was at 260 nm. Sample recoveries of 95% were estimated by the addition of known amounts of palmitoyl-CoA to aliquots of tissue samples. Total tissue acyl-CoA content was compared with the sum of the individual esters separated above.

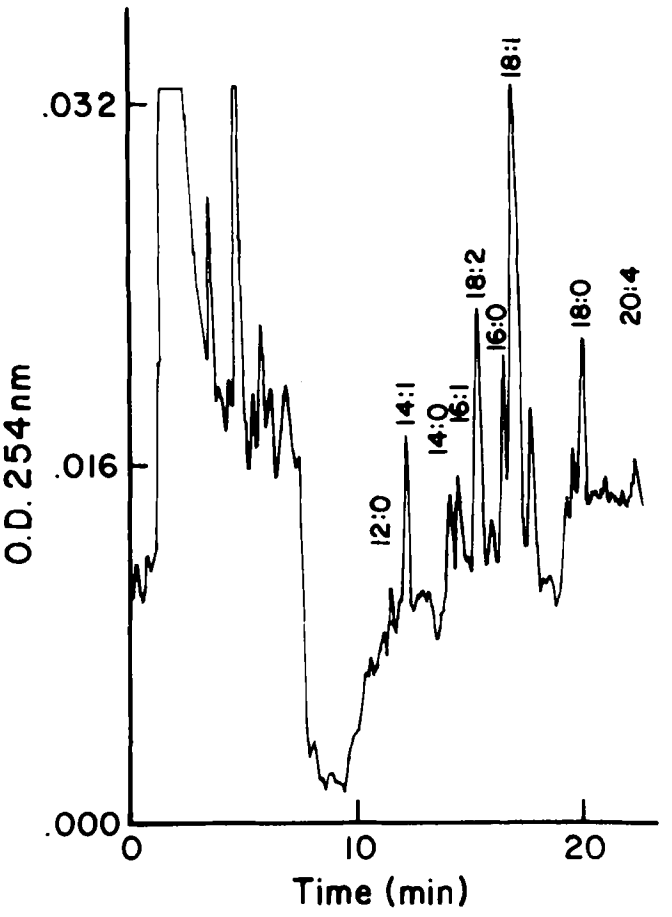

FIG. 1. HPLC separation of long-chain acyl-CoA esters from extracts of frozen powdered pig hearts. The procedure was carried out as described in Materials and Methods.

RESULTS

In a previous report (7), the chromatographic separation of a mixture of eight standard long-chain fatty acyl-CoA esters was demonstrated and verified by their disappearance following alkaline hydrolysis. More recently, the elution of added arachidonyl-CoA has extended the number to nine. This is a noteworthy addition to the procedure because in many tissues, arachidonic acid and its CoA thioester are substrates for a number of important enzymatic reactions, particularly in phospholipid and prostaglandin synthesis.

A typical separation pattern of long-chain acyl-CoA esters obtained from an extract of frozen pig heart tissue is shown in Figure 1. Although the baseline is somewhat skewed, possibly due to concentration of the extract, nine peaks in the order of increasing retention times easily were identified and quantified. These corresponded to the acyl CoAs 12:0, 14:1, 14:0, 16:1, 18:2, 16:0, 18:1, 18:0 and 20:4. The peak eluting just after 18:1 cannot be identified yet because it does not correspond to any of the available standards. Over 85% of radioactive palmitoyl and oleoyl CoA added before the chloroform/methanol extraction could be recovered.

Table 1 shows the concentrations of the individual long-chain acyl-CoA esters obtained from samples of pig heart, rat heart and rat skeletal muscle. Myristoleoyl-CoA (14:1), linoleoyl-CoA (18:2), palmitoyl-CoA (16:0) and oleoyl-CoA (18:1) were in the highest concentrations. In most samples, the amounts of lauryl (12:0) and arachidonyl (20:4) CoA were barely detectable. There essentially was no difference in the values from the pig heart tissue sites perfused by the left anterior descending and left circumflex arteries. The sum of the individual fatty acyl-CoA ester values was equivalent to approximately 132% of their concentration obtained from the separate HPLC analysis of total CoASH following alkaline hydrolysis of the esters (9). The two methods thus compare quite favorably. This latter method (9), which frequently has been frequently used and referred to in the literature, was specifically adapted for use in heart tissue for these respective experiments.

Rat and pig heart total and individual acyl-CoA esters are quite similar except for the relatively higher level of stearoyl-CoA in rat heart. Other than oleoyl-CoA, rat skeletal muscle contains considerably less acyl-CoA than heart. The quantity of long-chain acyl-CoA in heart and skeletal muscle is considerably less than that in liver requiring modifications in preparation of the tissue for

TABLE 1

Long-chain Acyl-CoA Levels in Pig Heart, Rat Heart and Rat Skeletal Muscle

HPLC analysis. In particular, the extract must be concentrated before separation and detection of the esters, which can result in some background noise. Use of the C_{18} Sep-Pak column for this purpose also removes a considerable amount of contaminants and facilitates concentrating the samples. This results in an increase in the peak heights relative to the baseline, thereby enhancing the reproducibility. Washing the column with buffer at the end of the run and running steps 4 and 5 for 15 rather than 10 min, if the baseline begins to rise at the end of the run, leads to a more stable baseline that is consistent from run-to-run. The minimal standard deviations of the values shown in Table 1 indicate that reproducibility is not a significant problem except for quantitation of the minor peaks.

DISCUSSION

The importance of fatty acid metabolism in overall cardiac and skeletal muscle performance is well-appreciated, although its potential role in pathophysiological states such as myocardial ischemia is not fully agreed upon and, in fact, is somewhat controversial (1,3,6,12-16). There is a considerable amount of detailed information on alterations of total free fatty acids as well as their acyl-CoA and acylcarnitine esters in the myocardium under different physiological and pathological conditions (6,10,12, 15,16). However, virtually no information is available for skeletal muscle. This study demonstrates that it now is feasible to obtain by direct analysis, a quantitative measurement of individual long-chain fatty acyl-CoA esters. Thus, it should be possible to determine their individual metabolic fluxes for different experimental conditions. Moreover, the method has been modified slightly to include separation and measurement of arachindonyl-CoA whose concentration might reflect the metabolism of arachidonic acid into various pathways including phospholipid and prostaglandin synthesis, which are very important in myocardial and skeletal muscle function.

The method described in this communication, which is relatively simple, should be of particular value for metabolic studies.

Nanogram Quantification of Nonpolar Lipid Classes in Environmental Samples by High Performance Thin Layer Chromatography

Maureen H. Conte* and **James K.B. Bishop**
Lamont-Doherty Geological Observatory of Columbia University, Palisades, NY 10964

A sensitive, simple, and rapid high performance thin layer chromatography (HPTLC) method that quantifies nanogram amounts of complex nonpolar lipid classes in environmental samples with a minimum of sample preparation is presented. The derivatization method is lipid-specific and insensitive to carbon number or the degree of unsaturation of the fatty acids composing the lipid class compounds. Nonpolar lipid classes ranging from 10 to over 500 ng easily may be quantified in the same sample run. The coefficient of variation for sample replicates on different plates ranged from 2.3% to 5.9%. Accuracy of the method is better than 15%. The nonpolar lipid class composition of <53 μm oceanic particles in a vertical depth profile of the upper 600 meters of the Slope Water was determined to illustrate the HPTLC method. The observed changes in particulate lipid class composition indicate that secondary production by deep-living organisms significantly alters suspended particle composition with depth in the water column.
***Lipids 23,* 493-500 (1988).**

Lipid classes are useful tracers of the sources and transformations of organic carbon in particulate material in the water column (1-4), sediments (5-7) and other environmental materials. However, complete characterization of the lipid classes in these samples has been limited by the lack of simple methods to resolve complex mixtures of plant, animal and microbial lipids, the time required for analyses by existing methodologies, and the small amount of material often available. In our studies of oceanic particulate material, we required an analytical technique that could adequately resolve and quantify sub-μg amounts of complex lipid classes yet was simple enough for routine analyses. No existing method satisfied these requirements.

Ideally, a method used to resolve and quantify complex lipid class composition in such small environmental samples should be very sensitive yet require a minimum amount of sample manipulation. Previous studies have used either column (1-4) or thin layer chromatography (5,7-9) to separate lipid classes, followed by gravimetric, spectrophotometric or gas chromatographic analyses to quantify the lipid fractions. These methods are tedious and time-consuming and allow only a few samples to be processed per day. The multiple steps involved can result in sample loss, fractionation or degradation. Moreover, complex lipid classes often overlap in the fractions so additional steps are required to purify each lipid class. Tens to hundreds of μg of total lipids may be needed to accurately quantify minor lipid classes in a complex sample by these methods. High performance liquid chromatography (HPLC) has been used to separate lipid classes (10,11), but quantitative measurement of the nonpolar lipid classes has not been achieved. Alternatively, lipid classes have been separated on thin-layer plates and derivatized in situ to form compounds that can be quantified by scanning densitometry (6,8,12-14). This method is more expedient than the above methods but requires μg amounts of lipid classes and has limited precision due to incomplete separation of complex lipid classes and high background noise. More recently, the Iatroscan/Chromarod system has been used to determine the lipid class composition in a variety of materials (15-21). While the Iatroscan/Chromarod has found widespread use in routine lipid analysis, the system has limitations in sub-μg analyses of complex lipids due to problems with nonreproducibility, poor precision, lack of sensitivity and nonlinearity of response (21-23). None of these techniques were sufficiently sensitive and expedient for routine analyses of lipid class composition in our samples.

However, recent advances in quantitative high performance thin layer chromatography (HPTLC) suggested that this method might be ideally suited for sub-μg quantification of complex lipid classes. Quantitative HPTLC combines the many inherent advantages of TLC with high resolution and subnanogram detection limits for a wide variety of compounds (24,25). The newly developed preadsorbent sample application zone on HPTLC plates eliminates the sample application difficulties previously encountered in HPTLC and serves to cleanup and narrowly focus the sample at the preadsorbent zone/silica gel interface, thus enhancing the separation of complex lipids (26). The development of fluorescent-inducing reagents (27-33) has enabled nanogram quantities of the major lipid classes to be detected easily in samples of uniform biological origin such as blood serum, amniotic fluid and tissue extracts (33-36). This study investigated whether HPTLC methods also were suitable for quantitative analyses of complex lipid classes of unknown composition in environmental samples.

In this paper, we show that HPTLC is a rapid, sensitive, quantitative and reproducible technique for sub-μg analyses of complex lipid classes in oceanic particulate material. The HPTLC method presented here generally is applicable to most materials. The resolution of complex lipid classes is more complete, and the optimal concentrations for quantitative work are nearly two orders of magnitude less with HPTLC than with currently employed methods, including the Iatroscan/Chromarod system. In addition, the method is very rapid and allows up to 50 analyses of crude lipid extracts to be easily completed per day.

METHODS

Materials and reagents. HPTLC silica gel plates (10 × 10 cm) with preadsorbent sample application zones were

obtained from Merck (Darmstadt, FRG). Lipid class standards were obtained from Nu-Chek Prep, Inc. (Elysian, MN). Free fatty acids were obtained from Sigma Chemical Co. (St. Louis, MO). Aminopropyl Bond-Elut disposable chromatography columns with stainless steel frits were used for preparative separation of lipid classes and were obtained from Analytichem International (Harbor City, CA). Prechanneled thin layer chromatography (TLC) plates with preadsorbent zones were used for purification of the lipid class fractions and were obtained from Whatman (Clifton, NJ). All solvents were chromatography grade.

Sample collection and preparation. Oceanic particulate material was collected from the upper 1000 meters using large-volume in situ fitration (37). Samples described in this paper are from the Slope Water 200 km off the coast of Virginia and were collected in June 1982. Further details of the collection method and the sample site can be found in Bishop et al. (38).

The filter samples were subsampled within two hr of retrieval. Each subsample represented about 10% of the total material collected by filtration and contained approximately 2 to 5 mg of organic carbon. Subsamples were placed in 20-ml test tubes and filled to the top with chloroform/methanol (2:1, v/v). The antioxidant BHT (0.05%, w/v) was added to the sample tubes approximately six months later. Samples were stored at −20 C until analyzed. There was no evidence of compound oxidation or hydrolysis, or fatty acid methyl ester formation in the samples during prolonged storage.

Lipids were extracted using a modification of the procedure described by Folch et al. (39). Cholesteryl formate was added as an internal TLC standard before extraction to correct for sample losses and spotting variability. The chloroform/methanol solvent in the sample tubes was vacuum-filtered through a fritted funnel into a separatory funnel, and the sample tube was refilled with fresh chloroform/methanol (2:1, v/v). The sample tube then was ultrasonicated in a cup horn at 12 C at 100 watts for 45 sec using a Sonifier cell disruptor (Heat Systems-Ultrasonics, Plainview, NY). This solvent then was filtered through the fritted funnel into the separatory funnel and the filters rinsed with solvent. Aqueous KCl (0.88%, w/v) (1/4 the volume of the total solvent) then was added to the separatory funnel and the lipids extracted into the lower organic phase. The lower phase then was rotary evaporated at 30 C to the point of dryness, redissolved in chloroform and passed through a mini-cleanup column containing sodium sulfate to remove any residual water. The final volume of the crude lipid extract then was adjusted to 2 ml with chloroform.

Standard lipid classes. Simple lipid class mixtures comprised of monoolein (MG), diolein (DG), triolein (TG), oleic acid (FFA), methyl oleate (FAME), stearyl oleate (WE), cholesterol (ST) and cholesteryl oleate (STE) were prepared in concentrations ranging from 1 to 160 ng/μl. The internal standard cholesteryl formate also was added to these standard mixtures to correct for spotting variability and evaporation. The amount of cholesteryl formate added to each standard was adjusted to produce an average final concentration of 50 ng per 10 μl spot.

Complex lipid classes purified from a larger sample of oceanic particulate material were used to calibrate the response of simple lipid class standards with the complex lipid classes found in samples. The lipid classes in the oceanic particulate material were separated using disposable aminopropyl Bond-Elut chromatography columns (40). The lipid class fractions then were purified by TLC using hexane/ether/acetic acid (80:20:1, v/v/v) as the developing solvent.

These sample lipid classes were independently quantified by capillary gas chromatography. The free fatty acid and triacylglycerol fractions were transesterified with 5% methanolic HCl (41) at 50 C for 12 hr to form fatty acid methyl esters. Nonadecanoic acid was added as an internal standard before transesterification. The fatty acid methyl esters were analyzed using a Carlo Erba 5160 gas chromatograph equipped with on-column injection. Chromatography was performed on a 50 m × 0.25 mm CP Sil 88 column (Chrompack, Bridgewater, NJ) programmed from 110 to 220 C at 5 C/min. The GC was interfaced to an Apple IIe computer using a SOFT 510 system (Data Acquisition Systems, Boston, MA) and peaks were quantified using DYSC chromatography software (Dynamic Solutions Corp., Pasadena, CA). The TG concentration was corrected to include the additional weight of the glycerol moiety.

Thin layer chromatography. HPTLC plates were predeveloped to remove impurities and binder material that impart a high background fluorescence. Plates first were predeveloped in methanol and then in the same polar solvent later used for development (methyl acetate/n-propanol/chloroform/methanol/43 mmol/l aqueous potassium chloride, 25:25:25:10:9, v/v/v/v/v) (35). A thin line was then scraped across the top of the plate about 3 mm from the top to prevent these impurities from back-diffusing into the upper part of the plate during later developments. The plates were then dried at room temperature and activated in a 110 C oven for one hr before chromatography. Plates were handled carefully to maintain a dust-free, unmarred surface.

Seven samples and two standard mixtures were applied to each 10 × 10 cm plate. The lipid class concentrations of the two standard mixtures bracketed the expected lipid class concentrations in the samples. Either 5 or 10 μl of lipid extract or standards were applied quantitatively to the preadsorbent zone about 5 mm from the end of the plate using an Oxford 5 μl fixed volume micropipette with a Teflon tip (Sherwood Medical, St. Louis, MO). This volume can be rapidly yet quantitatively applied to the preadsorbent zone of HPTLC plates and eliminated the need for a sample concentration step. Each sample was applied as a line of overlapping spots perpendicular to the preadsorbent interface and parallel to the direction of development. Spot diameter was maintained at <4 mm. This application method enables the sample lipids to be focused in a narrow band at the preadsorbent interface at the beginning of development. A gentle stream of nitrogen was used to evaporate the excess solvent during application. Although this application method results in slightly higher sample concentrations at the edges of the sample band than in the center, the uneven distribution has negligible effect on quantitation provided the width of the sample band is less than the slit height used for densitometry so that the entire sample band is scanned.

Plates were developed in saturated TLC tanks by one of two methods. Method I: the plate was developed in

hexane/heptane/ether/acetic acid (63:18.5:1, v/v/v/v) (35) for 10 min (6 cm), dried with a stream of unheated air using a hairdryer for two min, then developed twice in hexane/benzene (3:1, v/v) for 15 min.

While this developing method gave good resolution, the silica gel surface near the preadsorbent zone interface frequently was uneven, which caused problems with quantification by scanning densitometry. In addition, development by Method I did not completely separate the internal standard from the FAME region and wax esters from the steryl ester region. Therefore, later experiments used a different developing scheme (Method II) that moved the nonpolar lipids farther away from the preadsorbent zone interface and increased the resolution between the lipid classes. We also found Method II gave slightly lower backgrounds.

Method II: this method used a series of three developing solvents. The plate was first developed in carbon tetrachloride for eight min (5 cm) to narrowly band the sample lipids at the preadsorbent/silica gel interface and to remove the antioxidant BHT, which migrates with the solvent front, away from the sample zone. Next the plate was developed in methyl acetate/1-propanol/chloroform/methanol/43 mmol/1 KCl (25:25:25:10:9, v/v/v/v/v) for two min (0.4 cm) to separate the neutral lipids from the polar lipids and to remove the neutral lipids from the interface zone. The neutral lipids then were separated using double development in hexane/heptane/ether/acetic acid (63:18.5:18.5:1, v/v/v/v) (35) for eight min (6.5 cm). This double development increased the resolution of the lipid classes. Finally, the plate was developed in carbon tetrachloride for 30 min to more completely separate the internal standard cholesterol formate from fatty acid methyl esters, and steryl esters from wax esters. The plate was dried under a stream of unheated air using a hairdryer for two min between developments.

Derivatization. The lipid classes were derivatized using the method of Schmitz et al. (35). The developed plate was thoroughly air-dried and then dipped in the manganese chloride-sulfuric acid derivatizing reagent (3.2 g $MnCl_2$, 32 ml conc. H_2SO_4, 480 ml H_2O, 480 ml methanol) (27) for 20 sec. The back of the plate then was blotted to remove excess reagent and the plate dried with a cold hairdryer for five min to evaporate the solvents. The plate was placed in a 110 C oven for exactly 40 min to form fluorescent derivatives of the lipid classes. Following derivatization, plates were stored in a dessicator until scanned.

Densitometry. Plates were scanned using a Camag II scanning densitometer (Camag, Inc., Wrightsville Beach, NC) in the reflectance mode. The monochromator on the mercury light source was set for an excitation wavelength of 366 nm and 10 nm bandwidth. A 400 nm emission filter was used. Slit dimensions were 0.2 mm width by 6 mm height, so that the slit height completely covered the width of the sample lane. A scanning speed of 0.5 mm/sec was used. Sensitivity was adjusted so that the maximum peak on the plate was near 100% full-scale response of the densitometer.

Peaks were integrated using a SP 4270 integrator (Spectra-Physics, San Jose, CA). Baseline irregularity, incomplete peak resolution and the irregular peak shapes of some complex lipid classes, such as the triacylglycerols and wax esters, often limited the ability of this integrator to accurately detect and quantify compound peaks. More sophisticated peak detection and integration systems (such as the DAS/DYSC system used for GC analyses) should be used to improve the accuracy of baseline detection and peak quantification.

RESULTS AND DISCUSSION

A developed HPTLC plate illustrating the separation of nonpolar lipid classes in simple lipid class standard mixtures and samples of oceanic particles is shown in Figure 1. The major nonplar lipids are well separated above the preadsorbent zone/silica gel interface. The internal standard cholesteryl formate (CF) is well separated from the sample lipid classes. Monoacylglycerols, glycolipids and polar lipids remain at the interface. Note that while the standard lipid classes that are comprised of a single compound migrate in a tight band, the complex sample

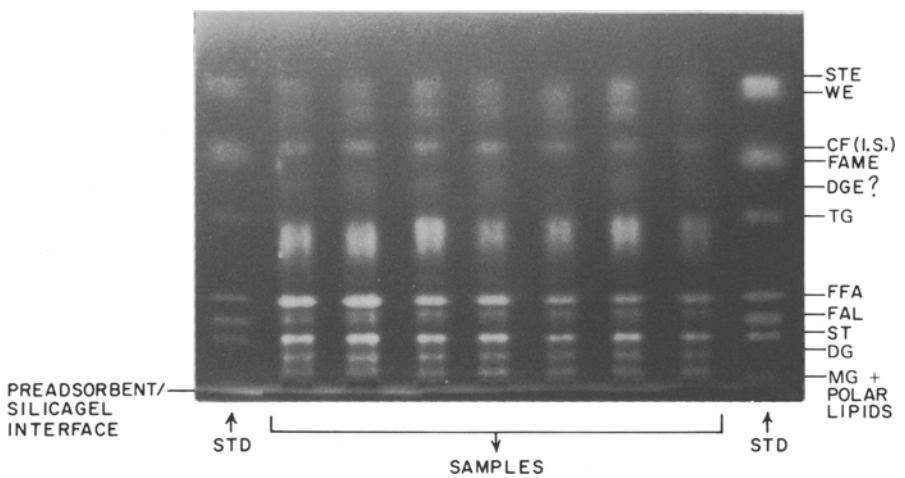

FIG. 1. Developed HPTLC plate showing the separation of nonpolar lipid classes in simple lipid standard mixtures and in samples of oceanic particles from a Slope Water profile taken in June 1982. Development was by Method I, as described in the text. The plate is viewed under UV light and has been overloaded for photographic purposes.

lipid classes migrate in a wide band due to the differences in relative mobilities of the fatty acids composing the lipid class compounds. This effect is especially pronounced for triacylglycerols and wax esters. The fluorescent response is lipid-specific; pigments do not react. In addition, the fluorescence of the different lipid classes show slight variations in color that aid in preliminary identification of sample unknowns.

Although much effort was made to standardize all aspects of the chromatography, variability in compound and background fluorescence often was significant, especially between plates run on separate days. Part of the background fluorescence could be attributed to impurities left in the plate or adsorbed following predevelopment. Lower backgrounds were obtained if the plate was predeveloped just before oven activation and use. Compound response and background fluorescence also is affected by the amount of residual solvent left on the plate. Some residual solvent is necessary for the derivatization reaction (a completely dried plate showed lower compound fluorescence) but too much solvent resulted in a high background. In addition, Schmitz et al. (35) found the development of fluorescence to be strongly time- and temperature-dependent. Therefore, slight differences in heating also may have been an additional source of variation. It is important to note that this interplate variability does not pose a problem in quantification because standards are run on the same plate as samples.

Much of the nonspecific background fluorescence diminished within the first few days, while compound fluorescence remained stable. Better results may be obtained if plates are allowed to sit dessicated for several days before scanning. No loss of sensitivity was detected when plates were rescanned after two months of dessicated storage. Therefore, plates can be stored for extended periods and easily rescanned or reintegrated to optimize quantification without rerunning the sample.

Standard curves. Standard curves demonstrate that nonpolar lipid classes varying by two orders of magnitude may be quantified on the same run. Response vs amount for simple lipid classes were constructed over a range of 5 to 300–700 ng. Two plates with standard lipid mixtures were run.

The first plate covered the range of standard lipid classes from 20–30 to 500–700 ng and was developed by Method I (Fig. 2). Response was proportional to the log of amount throughout the entire range for all classes except for cholesteryl oleate and methyl oleate, which showed linear relationships at concentrations below 100 ng. Standard curves for these compounds thus were split into two segments; a linear fit was used at low levels and a log linear fit at higher levels. Correlation coefficients better than 0.998 for all regression equations except the linear fit of cholesteryl oleate at concentrations <75 ng ($r^2 = 0.982$).

The second plate covered lower concentrations ranging from 5 to 200 ng. This plate was developed by Method II. Background fluorescence was significantly lower than on the first plate. The absolute limit of detection was 5 ng or less for all classes except for triacylglycerol, in which the limit of detection was 10 ng. Plate surface irregularity was the major factor limiting the ability to identify the sample peaks at the lowest levels. Response was a linear function of amount in the range of 5–120 ng

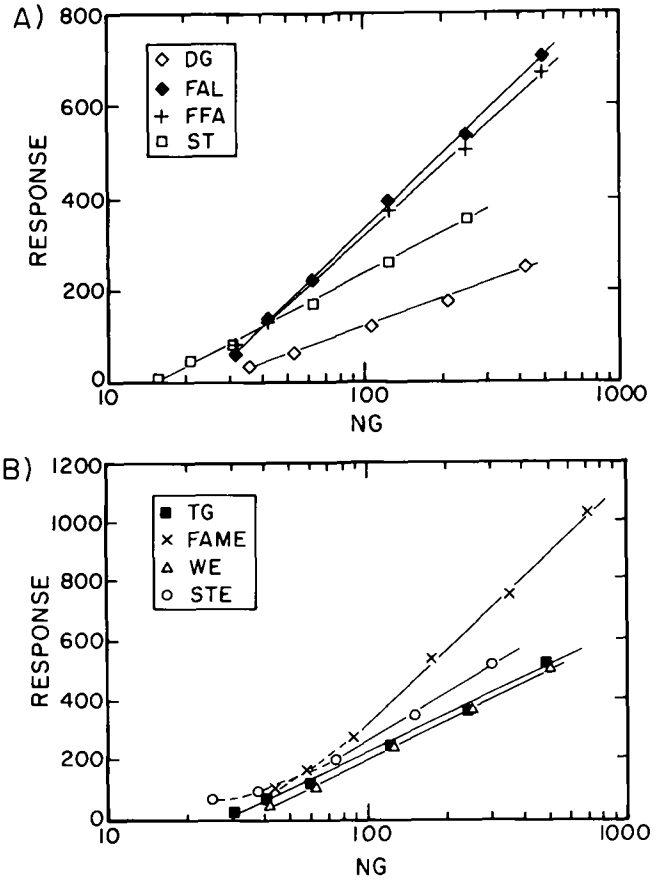

FIG. 2. Standard curves of fluorescent response vs log concentration for simple lipid classes on plate #1. Development was by Method I. Response is in arbitrary units. A) Standard curves for 1,3 diolein, cholesterol, oleyl alcohol and oleic acid; B) standard curves for triolein, methyl oleate, stearyl oleate and cholesteryl oleate.

(Fig. 3). However, response at 200 ng was significantly below that predicted from the linear standard curve, indicating the development of fluorescent quenching. Correlation coefficients of linear regression equations for 5–120 ng were over 0.996 for each standard.

In addition to the shapes of the standard curves, the relative responses of the various lipid classes also differed significantly between the two plates. Cholesterol and oleic acid, in particular, had much lower relative responses on the first plate. Schmitz et al. (35) found that fluorescence of the lipid derivatives increases with time to a maximum and then falls to zero as the derivatives ash. This decrease was found to be more rapid with cholesterol than with triacylglycerol. It is likely that the lower relative response of cholesterol and oleic acid on the first plate may have been due to partial ashing of their derivatives, which suggests that the timecourse of derivatization reactions also is influenced by conditions on the plate itself. As acidic conditions are necessary for fluorescence development, it is possible that slightly higher residual acid on the first plate due to differences in development may have influenced the reaction rates as well as the maximum fluorescence developed. Standardized conditions would reduce the interplate variability observed here. The highly significant standard curves demonstrate that excellent

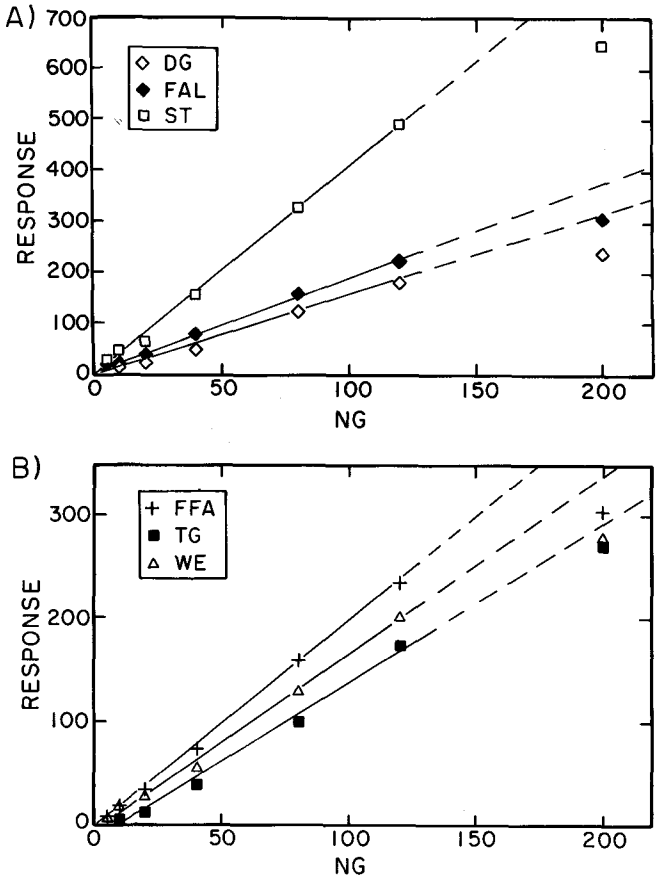

FIG. 3. Standard curves of fluorescent response vs concentration for simple lipid classes on plate #2. Development was by Method II, as described in the text. Response is in arbitrary units. quantitative results can be obtained throughout a wide range of reaction conditions.

The transition from a linear fit at tens of nanograms concentration to log linear fit at higher concentrations indicates that there is a threshold fluorescent density on the plate above which quenching of the response occurs. This transition from a linear to nonlinear relationship was also observed for lecithin and sphingomyelin derivatives formed by the reaction with HNO_3 vapors (36). Thus, the quenching response may be similar in all fluorescent derivatives, independent of the exact fluorescent inducing reagent.

Differences between the standard curves on the two plates indicate that the exact compound density at which this fluorescence threshold is first observed can vary significantly among plates. The first plate, which had a much higher background, exhibited nonlinearity at a much lower compound density. This suggests that quenching is a function of the overall background fluorescence of the plate as well as the total development of compound fluorescence during the derivatization reaction. These factors may explain the differences in the response vs concentration curves found in this study from that found by Schmitz et al. (35). Thus, external standards must be run on the same plate and in the same concentration range as sample compounds for accurate quantification. Because the concentration range at which nonlinearity first is observed differs from plate to plate, it is advisable to run several external standards if a wide range of sample concentrations is expected. For this purpose, a 10 × 20 cm HPTLC plate would allow both a complete standard curve and multiple samples to be developed simultaneously.

Calibration of sample lipid classes with standards. If standard lipid classes, which are comprised of only one compound, are to be used to quantify sample lipid classes, which are comprised of many different compounds, fluorescent response must depend solely on the concentration of lipid class present and not on the exact fatty acid composition of the lipid class. Two experiments were run to test for differences in response between simple liipid class standards and the real complex lipid classes encountered in samples.

The first experiment demonstrated that fluorescence of derivatives is relatively insensitive to both the carbon number and the degree of unsaturation of the fatty acid constituents (Fig. 4). Six fatty acids, ranging from 18 to 22 carbons and from one to six double bonds, were developed on the same plate, and the total responses of 100 ng of each acid derivative determined. No systematic trend of absolute response with either carbon number or number of double bonds was found at this compound density. However, the coefficient of variation among the different acids on the plate was 13.5%, nearly three times that found for the coefficient of variation of sample replicates on different plates. If this variation, in fact, was due to different fatty acid responses, it implies about a 15% accuracy in quantification at this compound density when simple lipid class standards are used. We did not investigate whether this insensitivity to degree of unsaturation varied with compound density on the plate. However, results of this experiment indicate that the $MnCl_2$ derivatives are less sensitive to lipid class composition than other fluorescent derivatives that show a dependence of fluorescence on component fatty acid unsaturation (34,42,43).

Sample lipid classes also differ from standards in peak geometry on the developed plate. As seen in Figure 1, lipid standards comprised of only one compound migrate in a narrow concentrated zone during development and have well-defined peak shapes. In contrast, complex lipid classes migrate in a wide sample band due to the different relative mobilities of the saturated and highly unsaturated fatty acid constituents of the lipid class compounds. Band broadening alters the compound density of the sample lipid classes on the plate from that of standards; this may significantly affect the amount of fluorescent quenching for a given concentration.

A second experiment demonstrated that these differences in peak shape do not significantly affect the quantification of sample lipid classes (Fig. 5). Fatty acids and triacylglycerols were purified from a large sample of coeanic particulate material. Subsamples from each lipid class were transesterified and then quantified as FAME by capillary gas chromatography to independently determine the concentrations of the sample lipid classes. Three amounts of each sample class, spanning the amounts usually found in samples, were applied to a plate. The

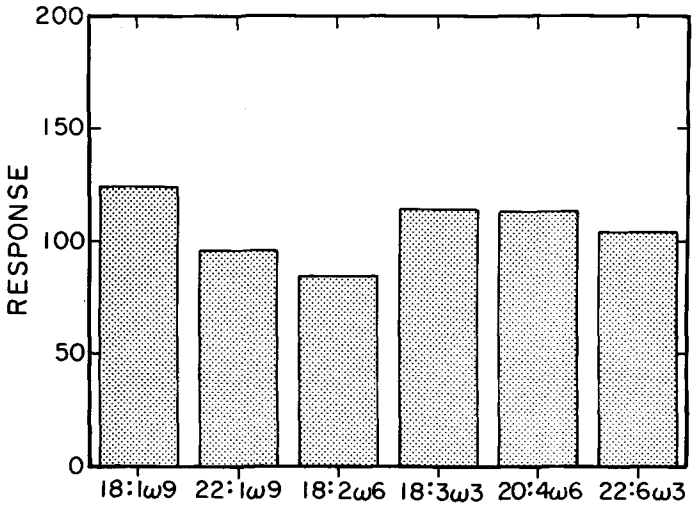

FIG. 4. Relative fluorescent response of 100 ng each of six fatty acids differing in both carbon number and number of double bonds. Development was by Method II. The coefficient of variation was 13.5%. There is no systematic trend of response with either chain length or degree of unsaturation.

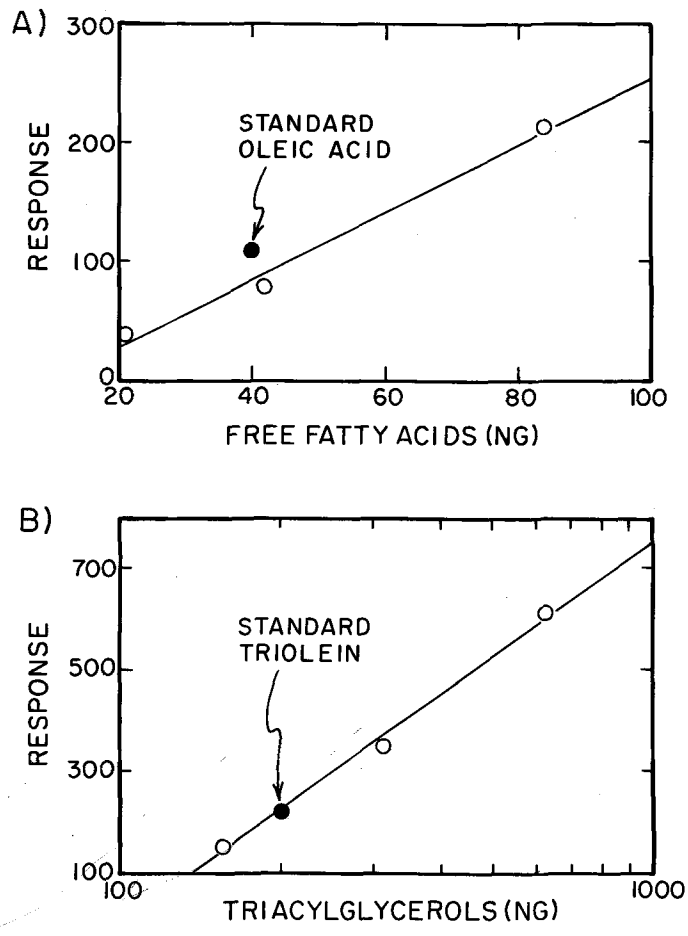

FIG. 5. Calibration of simple lipid standards with complex lipid classes purified from oceanic particulate material. Development was by Method II. The response of simple lipid standards is plotted for comparison against the regression curves calculated for the sample complex lipid classes. A) Fatty acids; B) triacylglycerols.

simple lipid standards oleic acid (FFA) and triolein (TG) were spotted in separate lanes. Regression curves were calculated for the sample lipids using a linear fit for free fatty acids (20–90 ng range) and a log linear fit for TG (150–600 ng range). Estimated amounts of the simple standards oleic acid and triolein calculated using the sample lipid class regression equations were compared with the actual amounts spotted. The standard oleic acid amount was estimated at 46 ng, within 15% of the actual amount of 40 ng spotted. The standard triolein amount was estimated at 198 ng, in excellent agreement with the actual amount of 200 ng. These results demonstrate that although slight differences in fluorescence may exist between simple lipid classes and the complex lipid classes found in samples, standards comprised of a single fatty acid constituent can be used to quantify complex lipid classes if standard and sample concentrations are in the same range. Alternatively, complex lipid mixtures approximating sample lipid class compositions could be used for more accurate quantification.

Application to samples of oceanic particulate material. Oceanic particulate material is an extremely complex environmental sample with plant, animal and microbial sources. There is a wide range of highly unsaturated fatty acids present in the acyl lipid classes. The demands of resolving this complex mixture and the large differences in class concentrations make the determination of lipid class composition in oceanic particles among the most difficult of lipid class analyses.

The HPTLC method was used to resolve and quantify the nonpolar lipid classes in a verical depth profile of <53 μm sized oceanic particulate material from the upper 600 meters of the Slope Water in June 1982. A representative chromatogram from a sample at 450 meters is shown in Figure 6. Major lipid classes were sterol, fatty alcohol, free fatty acid, TG, wax ester and a compound tentatively identified as DG. Another minor unidentified lipid, with a R_f similar to that of diacylglycerol ether (DGE) (44), was found just above the TG on the plate. FAME and STE were present only in trace amounts in these samples.

Lipid classes had a wide range of concentration in the same sample. Amounts spotted ranged from a minimum of about 20 ng for free fatty acids to a maximum of 600–700 ng for TG. Replicate sample analyses on separate plates yielded coefficients of variation of 5.9% and 2.3% for sterols (200 ng mean) and TG (300 ng mean), respectively.

The vertical depth profiles of sterol, TG, fatty alcohol and free fatty acid concentration are typical of many bulk property profiles in the upper 1000 meters of the ocean (Fig. 7A,B). These profiles reflect the primary production of particulate organic carbon (POC) in the photosynthetic zone in surface waters and a rapid net loss of POC with depth due to zooplankton grazing and oxidation. However, the wax ester profile (Fig. 7B) does not follow this trend and indicates that a secondary process controls the production and destruction of this compound class in the water column.

A large change is seen in the percent contribution of the individual lipid classes with depth (Fig. 8A,B). Fatty alcohols and free fatty acids both compose less than 5% of the total nonpolar lipids at all depths while sterols, TG, wax esters show large variations. TG (Fig. 8B) decrease

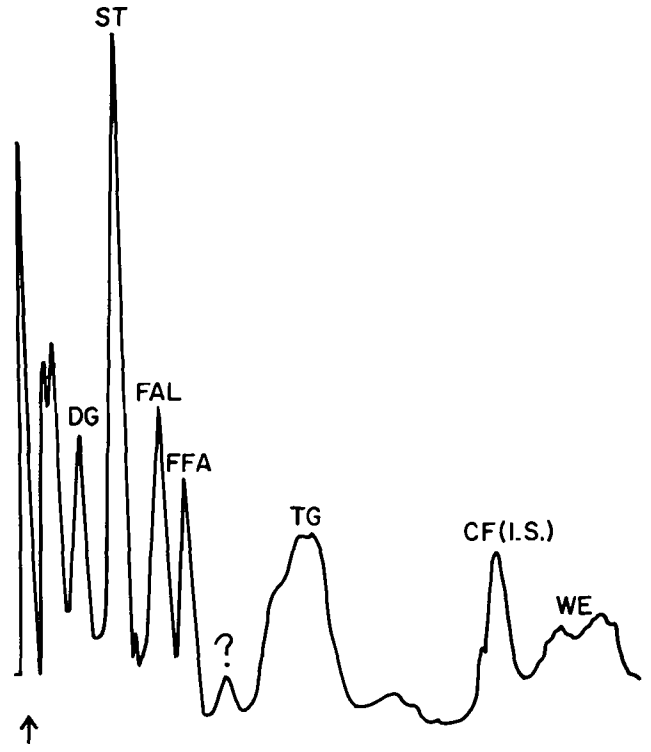

FIG. 6. Chromatogram of nonpolar lipid classes in a sample of oceanic particulate material from 450 m in the Slope Water in June 1982. Development was by Method I. The arrow indicates the preadsorbent zone/silica gel interface.

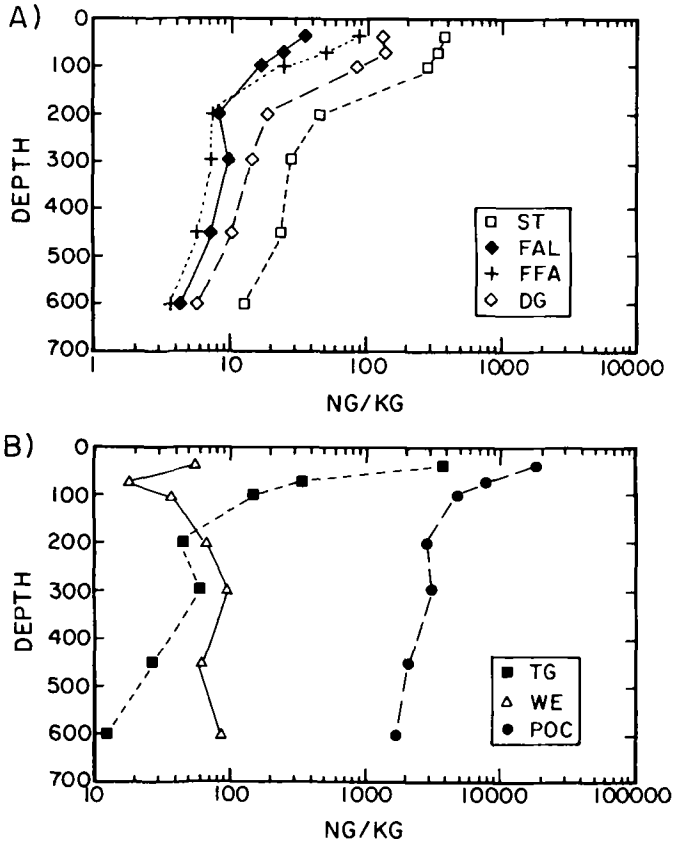

FIG. 7. Nonpolar lipid class concentrations in <53 μm particulate material in the Slope Water in June 1982. Concentration of total particulate organic carbon (POC) is given for comparison.

from over 80% of the total nonpolar lipids at the surface to only 10% in deep water. In contrast, wax esters show the reverse trend and increase from only a few percent of the total nonpolar lipid at the surface to 70% at 600 meters. This change in the dominant particulate lipid class with depth mirrors the general change with depth in the distributions of TG- and wax ester-producing organisms (9,45). Phytoplankton, which dominate the surface waters, synthesize almost exclusively TG. Zooplankton species may synthesize either TG or wax esters, but the major wax ester-synthesizing zooplankton in this temperate region are predominately meso- and bathypelagic. Thus, the increase with depth in the wax ester/TG ratio of the small particle pool most likely reflects changes in relative production of these two compounds by deep-living zooplankton. These results indicate that secondary production of POC by deep water zooplankton significantly alters the suspended particle pool in the water column.

Comparison of HPTLC with other methods. Quantitative HPTLC has several advantages over other methods used in lipid class analyses. The method presented here enables resolution and quantification of all the complex lipid classes in a crude lipid extract when the appropriate standards are run simultaneously on the same plate. Optimal amounts of lipid classes for highest resolution and accuracy in quantification range from 10 to 500 ng, which enables both major and trace lipid class concentrations to be determined from a single run. In addition, the lipid

specificity of the derivatization reaction in HPTLC minimizes interferences from pigments and other nonlipid compounds present in crude extract. In contrast, the Iatroscan/Chromarod method requires multiple developments and scans for resolution and quantification of all nonpolar lipid classes and requires extensive calibration of the flame ionization detector (FID) response to accurately quantify less than 1 μg of lipid classes.

The chromatographic methods used in this study are very simple and require no specialized equipment. The preadsorbent HPTLC plate eliminates many problems in HPTLC associated with applying very small volumes of crude extracts directly onto the silica gel surface. We have found that a simple, one-step application of dilute crude extracts with a Teflon-tipped pipette and development in standard chambers adequately resolves complex lipid classes. More sophisticated equipment and techniques will increase resolution but also increase cost and effort. Sensitivity in this study primarily was limited not by compound resolution but by the HPTLC plate. Further advances in HPTLC plate technology should continue to improve resolution and reduce the baseline problems associated with the plate surface.

The HPTLC method is rapid and requires no extensive calibration, so over 50 analyses easily can be made in one day. Run-to-run variability is less of a problem with HPTLC than with other methods because standards and samples are run simultaneously. In addition, the static nondestructive detection method allows samples to be scanned many times and in different modes to optimize quantification. In contrast, chromatographic conditions for Iatroscan/Chromarod analyses must be rigidly controlled for accurate results and detection by FID is destructive. Although the scanning densitometer for HPTLC is not inexpensive, it is not dedicated to a single analytical procedure. Therefore, HPTLC may be very cost effective because many diverse HPTLC methodologies may share the same instrument for detection.

We found quantitative HPTLC to be a rapid, simple and very sensitive technique for the analysis of complex lipid class composition in our samples of oceanic particulate material. The method shows much promise for other environmental sample analyses. In addition, the resolution and high sensitivity of the method makes it ideally suited for quantification of lipid classes before preparative scale separations by column chromatography, HPLC or TLC, and for purity checks of lipid fractions.

Influence of Diet on (n-3) and (n-6) Fatty Acids in Monkey Erythrocytes

Martha A. Carman and **Joyce L. Beare-Rogers***
Bureau of Nutritional Sciences, Food Directorate, Department of National Health and Welfare, Ottawa, K1A 0L2, Canada

Cynomolgus monkeys were fed oils high in linoleic acid or with half of the linoleic acid replaced by either (n-3) linolenic acid or marine fatty acids. When the diet contained similar quantities of linoleic and (n-3) linolenic acid, erythrocyte fatty acids maintained a ratio of (n-6) to (n-3) fatty acids of approximately 2:4. Fatty acids from menhaden oil enhanced the incorporation of eicosapentaenoic and docosahexaenoic acids into the monkey erythrocytes, the composition of which was not altered by additional α-tocopherol.
Lipids 23, 501-503 (1988).

Erythrocytes are suitable cells for detecting the prolonged intake of (n-3) fatty acids in rats (1) and the best available retrospective index of the types of fat ingested by humans (2). When both linoleic acid and (n-3) linolenic acid are provided, desaturases favor (n-3) metabolism (3), but transacylases preferably catalyze the incorporation of arachidonic acid (4).

This investigation on erythrocytes of the cynomolgus monkey was undertaken to determine the effect of equal dietary levels of linoleic acid and different (n-3) fatty acids. These were provided by either α-linolenic acid from linseed oil or C_{20} and C_{22} polyunsaturated fatty acids from menhaden oil. The fish oil also was fed with additional tocopherol to protect the polyunsaturated fatty acids.

MATERIAL AND METHODS

Twenty male and 20 female cynomolgus monkeys *(Macaca fascicularis)* of five to nine years of age previously had been used for testing poliomyelitis vaccine at Connaught Laboratories, Toronto, Ontario, and then for testing zinc supplements in the Department of National Health and Welfare, Ottawa. They were given a four-month rest period, taught to eat dough balls containing purified diet ingredients and orange flavoring, and distributed among four test groups on the basis of body weight and sex.

The basal diet contained in % by weight: sucrose, 26.45; corn starch, 21.07; casein, 21.43; alphacel, 10.00; Ausman-Hayes mineral mix, 4.75; Newberne-Hayes vitamin mix (5), 0.50; D,L-methionine 0.50; fat, 15.00. The Ausman-Hayes mineral mix contained, in g/kg, potassium phosphate, dibasic, K_2HPO_4, 327.908; calcium carbonate, $CaCO_3$, 290.485; sodium chloride, NaCl, 162.366; magnesium sulfate, $MgSO_4$-$7H_2O$, 98.732; calcium phosphate, dibasic, $CaHPO_4$-$2H_2O$, 72.597; magnesium oxide, MgO, 32.040; ferric citrate, (16.7 % Fe), 13.297; manganese sulphate, $MnSO_4$-H_2O, 1.221; zinc chloride, $ZnCl_2$, 0.915; cupric sulphate, $CuSO_4$-$5H_2O$, 0.290; potassium iodide, KI, 0.077; chromium acetate, $Cr(C_2H_3O_2)_3$, 0.044; sodium fluoride, NaF, 0.023; sodium selenite, Na_2SeO_3, 0.004. A 2.5% agar solution was mixed with the basal diet in a 2:5 ratio to produce dough and reduce surface exposed to air. The diet was made each week, divided into daily portions and stored at 4 C until fed.

The fat in diet 1 was 63.75% lard and 36.25% corn oil; diet 2, 66.0% lard and 34.0% linseed oil; diets 3 and 4, 15.6% lard, 16.1% corn oil and 68.3% menhaden oil. The fatty acid composition of each diet is given in Table 1. Diet 4 was supplemented to contain 213 μg α-tocopherol/g diet, whereas diet 3 contained 49 μg/g.

Blood was drawn into a vacutainer tube containing sodium citrate from animals immobilized with 5 mg/kg

TABLE 1

Fatty Acid Composition of Diets[a]

Fatty acid	Diet 1	Diet 2	Diet 3	Diet 4

ketamine hydrochloride (Rogarsetic, Bristol Laboratories, Syracuse, NY). The hematological profile was obtained on a Coulter counter (Model S. Plus IV, Mississauga, Ontario). The blood was fractionated (1) and a weighed sample of purified erythrocytes extracted (6) and stored at 4 C. A portion of this was methylated (7) for gas chromatography on a fused silica column, Supelcowax 10, 30 m × 0.32 mm i.d., film of 0.25 μm, in a Varian Vista 6000 instrument with hydrogen as the carrier gas. The oven temperature was 130 C for 12 min, then increased 2 degrees per minute to 180 C for 18 min. The injector was at 250 C, and the detector was at 275 C. Calibration was achieved with the methyl ester of nonadecanoic acid as the internal standard. Results were expressed as μg fatty acid per 10^6 erythrocytes and subjected to statistical analysis of variance and Duncan's range test (8).

RESULTS AND DISCUSSION

The erythrocyte (n-6) and (n-3) fatty acids, determined on each monkey at intervals (Fig. 1), are given for the final period in Table 2. Group 1, fed a high level of linoleic acid and a low level of (n-3) linolenic acid, showed gradually increased concentrations of (n-6) fatty acid in erythrocytes with time, while group 2 fed approximately equal amounts of linoleic and (n-3) linolenic acid maintained a relatively constant proportion of total (n-6) to (n-3) fatty acids throughout the experimental feeding period. In contrast, the monkeys fed menhaden oil as a source of (n-3) fatty acids, groups 3 and 4, showed elevated 20:5 and 22:6 fatty acids as replacements for (n-6) fatty acids. Additional tocopherol had no effect on the composition of the erythrocyte fatty acids.

The diets had an equal distribution of saturated, monounsaturated and polyunsaturated fatty acids, the last contributing the essential fatty acids for the 2-position of glycerophosphatides, which with cholesterol compose most of the erythrocyte lipid (9). When the diet supplied similar amounts of linoleic acid and (n-3) linolenic acid, the ratio of the total (n-6) to (n-3) fatty acids remained at about 2:4. This indicated a close regulation for the conversion to long chain fatty acids and their incorporation into the cell. The long chain (n-3) fatty acid from fish oil, increased progressively in the erythrocyte. The elimination of the need for desaturation and elongation of substrates apparently resulted in less metabolic regulation of erythrocyte fatty acid composition.

The enhanced incorporation of the marine-type compared with the plant-type (n-3) fatty acids has been observed in human platelets (6,10,11) and rat tissues, notably the heart (1,12). Erythrocytes of the rabbit maintained a constant level of arachidonic acid when either (n-3) or (n-6) fatty acids was fed (13), but those of the marmoset monkey exhibited differences in arachidonic acid with dietary sheep perirenal fat or sunflowerseed oil, both low in (n-3) fatty acids (14). The respective n-6/n-3 ratios were 3.0 and 6.4, both of which were higher than those observed in the present experiment involving substantial

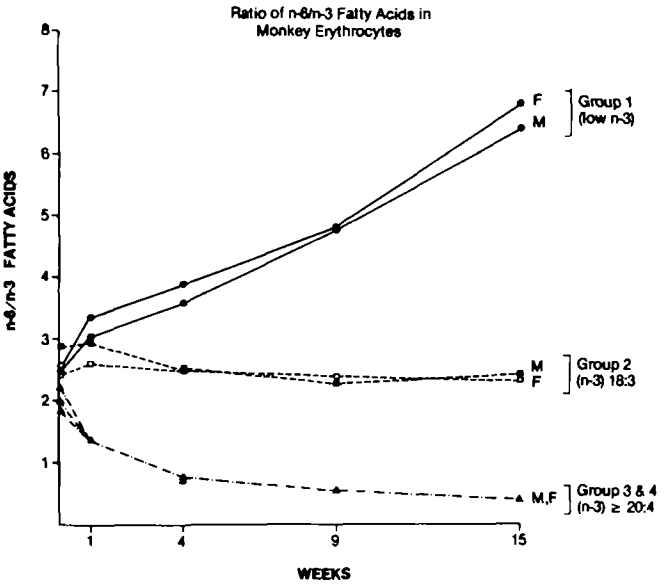

FIG. 1. The ratio of total (n-6) to (n-3) fatty acids of erythrocytes from monkeys fed different dietary fats during 15 wk.

quantities of dietary (n-3) fatty acids. A supply of preformed fatty acid substrates permitted an enhanced concentration of them in membrane lipids. This may be advantageous in some situations but may circumvent some metabolic control steps.

ACKNOWLEDGMENTS

The data are from a thesis by Martha A. Carman in partial fulfillment of requirements for a M.Sc., University of Ottawa. The menhaden oil was provided by the Zapata Haynie Corp., Reedville, VA. Nancy Versteeg and Rudy Hollywood rendered analytical assistance, and members of the Animal Resource Division cared for the animals. Svend Kaasgaard provided the tocopherol values for the diets.

[Received October 17, 1987; Revision accepted December 29, 1987]

Mammary Lipoprotein Lipase in Plasma of Cows After Parturition or Prolactin Infusion

James S. Liesman[a], Roy S. Emery*[,a], R. Michael Akers[b] and H. Allen Tucker[a]

[a]Department of Animal Sciences, Michigan State University, East Lansing, MI 48824, and [b]Department of Dairy Science, Virginia Polytechnic Institute and State University, Blacksburg, VA 24061

Plasma lipase activity from the mammary vein and a tail blood vessel was measured in periparturient Holstein cows treated in one of three ways: control, CB154 (2-Br-α-ergocryptin) or CB154 plus prolactin. CB154 administration decreased basal serum prolactin concentration by 80% and blocked the normal parturient increase of serum prolactin. In CB154 plus prolactin-treated cows, prolactin was infused continuously for six days starting five and eight days prepartum. Plasma lipase activity was not detectable up to 26 hr prepartum in control and CB154-treated cows or before the start of prolactin infusion in CB154 plus prolactin-treated cows. After two hr prepartum, plasma lipase activity was detected in all treatments. In CB154 plus prolactin-treated cows, plasma lipase activity was detected in the presence of high concentrations of serum progesterone four days after the start of prolactin infusion and at least two days before parturition. Plasma lipase activity was four times greater in the mammary vein than in the tail vessel at sampling times at which activity was detected in both vessels. We propose the difference between plasma lipase activity from the mammary vein and tail vessel is due to release of lipoprotein lipase from the mammary gland into blood, and this activity can be induced prepartum by prolactin or at parturition even if the parturient increase in prolactin is suppressed.

Lipids 23, 504–507 (1988).

Approximately 40% of bovine milk fat is derived from blood triglycerides (1) that have been hydrolyzed by lipoprotein lipase (LPL) at the luminal surface of the mammary gland capillary endothelium (2). LPL at the capillary endothelium usually is measured in plasma after heparin injection. However, lipase activity in plasma without prior injection of heparin has been measured in the lactating goat (3) and cow (4). This plasma lipase activity can be attributed in part to mammary LPL because the concentration of plasma lipase activity is greater in the mammary vein than in the mammary artery (3,4) and is inhibited by NaCl (3). This plasma lipase activity from the mammary vein of lactating cows has been reported by Shirley (4) to be 0.5% of that found after heparin injection.

LPL activity in mammary tissue increases markedly just before parturition and remains high throughout lactation in the guinea pig (5,6), rat (7) and cow (8). Prolactin increases mammary LPL activity in the pseudopregnant rabbit (9) and reestablishes mammary LPL activity after hypophysectomy in the lactating rat (10). But when prolactin secretion is inhibited by CB154 (2-Br-α-ergocryptin) in 20-day pregnant rats, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) increases mammary LPL activity while decreasing serum progesterone concentration (11). $PGF_{2\alpha}$ may be acting by reducing serum progesterone concentration because when progesterone and $PGF_{2\alpha}$ are administered together, mammary LPL activity does not increase.

The purpose of this study was to investigate plasma lipase activity in the periparturient cow and to show that most of this activity is due to mammary LPL released into the blood. The independent effects of prolactin and parturition on plasma lipase activity also are described. Other aspects of this study are reported (12,13).

MATERIALS AND METHODS

Treatments. Details of the experimental design and care of the animals are reported (12). The three treatment groups were control (n = 3), CB154 (n = 3) and CB154 plus prolactin (n = 2). For CB154 and CB154-plus-prolactin-treated cows, treatment with CB154 (Sandoz Inc., E. Hanover, NJ) commenced 12 days before expected parturition and continued through 10 days postpartum. CB154 (11 mg/100 kg BW) was injected subcutaneously either every four days, every two days or daily prepartum. All schedules of CB154 injection reduced concentration of prolactin in serum similarly (12). After parturition, CB154 and CB154 plus prolactin-treated cows were injected every two days.

Cows assigned to treatment with CB154 plus prolactin were infused with 6.0, 8.0, 9.8, 22.4 and 20.8 mg prolactin/hr (NIH-B4; NIH, Bethesda, MD) for 24 hr each, starting five days before the expected day of parturition. Infusions started at 2400 hr and rates were changed at 24-hr intervals (12).

Blood sampling and hormone assays. Blood for lipase assay was collected once every three days between 0900 and 1100 hr starting two wk before estimated calving date. Blood was obtained from the subcutaneous abdominal vein (Mammary vein) and the coccygeal vein or artery (tail vessel) in tubes containing potassium oxalate (2 mg/ml blood). Plasma was removed after centrifugation at 4 C and stored at −50 C until assayed 12 to 18 months after samples were taken. A standard stored with the samples showed no decrease in activity over the same period.

Blood samples for prolactin and progesterone determinations were taken twice daily (0700 and 1900 hr) from an indwelling jugular cannula one hr before feeding and milking. Hormones were quantified as described (12).

Lipase assay. Tri-[9,10(n)-^{3}H]oleoylglycerol, [9,10(n)-^{3}H]oleic acid and ACS scintillation fluid were obtained from Amersham (Arlington Heights, IL). Labeled triacylglycerol was purified by Florisil column chromatography (14) and was used within two months of chromatography. Unlabeled trioleoylglycerol, bovine serum albumin, Trizma base and Triton X-100 (acetyl phenoxy polyethoxyethanol) were obtained from Sigma Chemical Co. (St. Louis, MO). All other substances were reagent-grade, and all solvents were distilled before use.

Abbreviations: HTGL, hepatic triglyceride lipase; LPL, lipoprotein lipase.

The substrate mixture in a polyethylene 20 ml scintillation vial contained 150 μmol trioleoylglycerol; 70 μCi tri-[9,10(n)-^{3}H]oleoylglycerol; 2.5 ml heat-inactivated bovine serum; 8.1 ml 8% bovine serum albumin, 0.15 M NaCl, 0.24 M Tris-HCl (pH 8.6); and 0.9 ml 1% Triton X-100. The vial was placed in ice and the substrate mixture sonicated three times for one min with one-min pauses with a sonifier cell disruptor (Heat Systems-Ultrasonic, Plainview, NY, Model W185D) using a micro tip and a setting of 75 W.

Culture tubes (12 × 75 mm) for the lipase assay contained 0, 40 or 60 μl of sample plasma and 40 μl 3% bovine serum albumin with either 0.15 or 4.4 M NaCl. Enough heat-inactivated bovine serum was added to bring the volume to 100 μl. The incubation was started by adding 100 μl substrate mixture (final trioleoylglycerol concentration, 6.5 mM) and incubating in a shaking water bath at 37 C. After one hr, the assay was stopped and released [^{3}H]oleic acid separated from the acylglycerols with 1.65 ml methanol/chloroform/heptane (1.41:1.25:1, v/v/v) and 0.45 ml of alkaline buffer (58 mM sodium borate, 41 mM potassium carbonate titrated to pH 10.4 with 5 M potassium hydroxide) (15). After centrifugation at 20 C, 0.5 ml of the upper phase was transferred to scintillation vials with 10 ml of ACS scintillation fluid. Recovery of oleic acid in the 0.5 ml transferred was 25% as determined by replacing labeled trioleoglycerol with labeled oleic acid in the substrate mixture. Activity in the tubes containing 60 μl heat-inactivated bovine serum was subtracted from sample tubes to correct for background. Lipase activity for a sample was determined in duplicate at 40 and 60 μl of plasma and expressed as nmol fatty acid (FA)/hr/ml of plasma. Minimum detectable activity was 60 nmol FA/hr/ml plasma. Lipase activity was linear with time and plasma concentration.

Statistical methods. Plasma lipase activity for samples taken between two hr prepartum and 114 hr postpartum were analyzed by split plot analysis of variance (16). Cows were sampled once in period 1 from two hr prepartum to 52 hr postpartum and again in period 2 from 70 hr to 114 hr postpartum (Fig. 1). Samples taken in these two periods with plasma lipase activity below the detectable limit were set to zero and included in the analysis. Plasma lipase activity for samples from CB154 plus prolactin-treated cows taken after the start of prolactin infusion and before parturition were analyzed using Student's t-test.

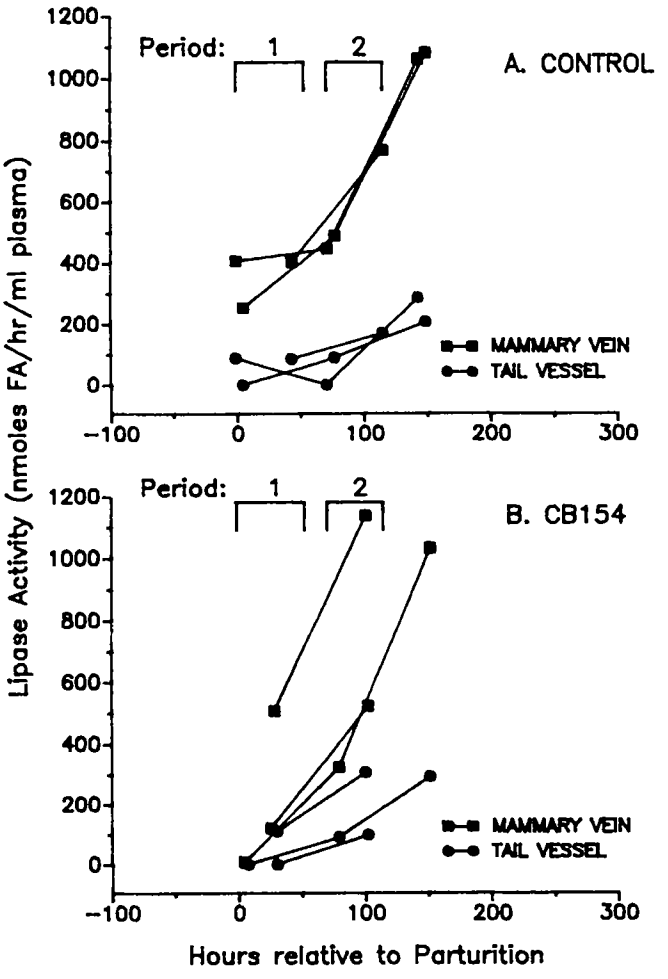

FIG. 1. Plasma lipase activity from the mammary vein and tail vessel for individual cows. (A) control cows; (B) CB154-treated cows. Cows were sampled once in each period.

RESULTS

Lipase activity. Lipase activity was not detectable in any plasma samples taken up to 26 hr prepartum in control and CB154 treated cows (sampling range is 1 to 14 days prepartum). Plasma lipase activity was detected in all but one of the mammary vein samples and most tail vessel samples after parturition in control, CB154 and CB154 plus prolactin-treated cows (Figs. 1 and 2). Between 2 hr prepartum and 120 hr postpartum, there were no significant differences among treatments or a significant treatment by period interaction. Mammary vein plasma lipase activity increased from period 1 to 2 ($P < 0.01$, Figs. 1 and 2).

In the two CB154 plus prolactin-treated cows, plasma lipase activity was detected in mammary vein plasma 82 and 106 hr after the start of prolactin infusion (Fig. 2). This was 92 and 43 hr before parturition, respectively. Plasma lipase activity was detected in all mammary vein and tail vessel samples 106 hr after the start of infusion.

In all treatments, lipase activity detected in mammary vein plasma was greater than tail vessel plasma lipase activity. Plasma lipase activity from the tail vessel was 23% that of the mammary vein plasma for observations in which activity was detected in both samples (range 18%-29%, n = 17).

Hormones. Results of hormone data have been reported (12). In control cows, serum prolactin averaged 29 ng/ml six to two days prepartum, reached an average peak of 194 ng/ml at parturition and declined to an average 28 ng/ml 2-10 days postpartum. Treatment with CB154 reduced serum prolactin concentration approximately 80% to 6 ng/ml. Serum prolactin concentration for CB154 plus prolactin-treated cows was similar to that for CB154 treated cows except during the time of prolactin infusion when serum prolactin concentration reached a peak of 350 ng/ml on day 5 of the infusion and then declined to its preinfusion level within six hr of the end of infusion. Treatment with CB154 and CB154 plus prolactin had no effect on the concentration of serum progesterone five

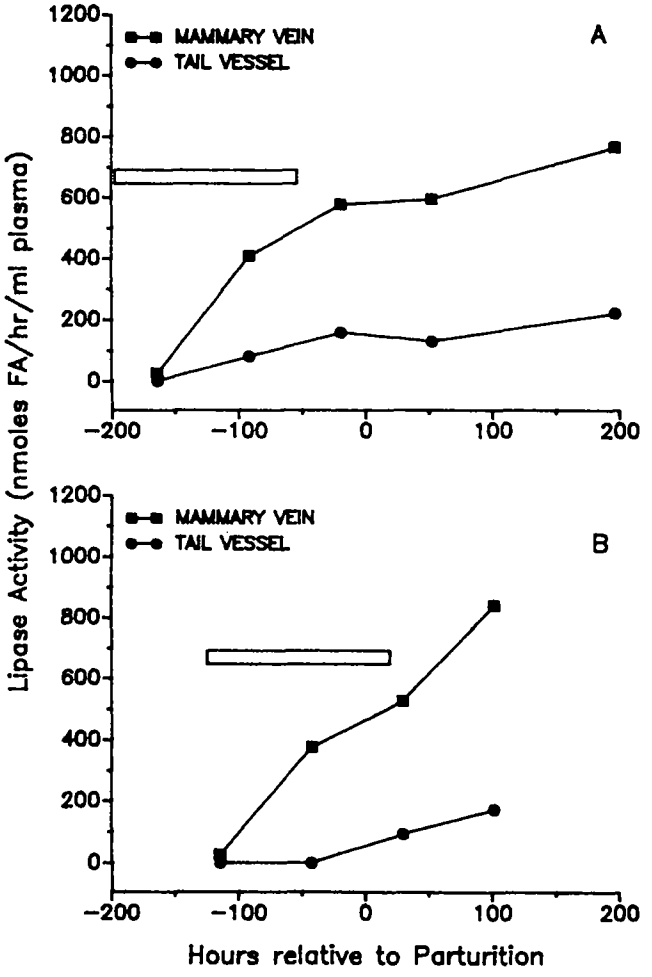

FIG. 2. Plasma lipase activity from the mammary vein and tail vessel during periparturient period for two cows treated with CB154 plus prolactin. (A) cow 1; (B) cow 2. Bars indicate time of prolactin infusion.

days prepartum to three days postpartum when compared with control. Between day 2 prepartum and day 2 postpartum, serum progesterone declined from an average of 6 ng/ml to less than 1 ng/ml.

DISCUSSION

Mammary tissue LPL activity is virtually absent during most of pregnancy in non-lactating animals and increases rapidly 24 to 48 hr before parturition in the guinea pig (5,6), rat (7) and cow (8). In this study, plasma lipase activity in control and CB154-treated cows followed a similar pattern (Fig. 1). The higher plasma lipase activity in the mammary vein relative to the tail vessel suggests that the difference in lipase activity between the two vessels is due to LPL released from the mammary gland. This agrees with the findings of Barry et al. (3) in the lactating goat in which the plasma lipase activity was completely inhibited by 0.8 M NaCl—a characteristic of LPL. But, in both tail vessel and mammary vein plasma from lactating cows, we found only an 80% inhibition of plasma lipase activity with 1 M NaCl. This is similar, though, to the 70% reduction in activity we found with plasma LPL purified on heparin-sepharose and assayed without activator (17). The increase in tail vessel plasma lipase activity at the same time as that in the mammary vein suggests that most of the activity in tail vessel plasma also is due to mammary LPL that has not yet been cleared from the blood. This conclusion is supported by the reports showing that adipose tissue LPL declines with onset of lactation (8) and that the other major plasma lipase, hepatic triglyceride lipase (HTGL), is either absent (18) or very low (17,19) in post-heparin plasma of cows.

Prolactin has been shown to increase mammary LPL activity in pseudopregnant rabbits (9) and to re-establish mammary LPL activity after hypophysectomy in lactating rats (10). In this study, infusion of prolactin into CB154 plus prolactin-treated cows was to mimic the normal increase in serum prolactin in the cow at parturition (20). Although plasma lipase activity was not detected until 82 hr after the start of infusion, it was measurable in both cows before the decline in serum progesterone, two days prepartum (Fig. 2). Spooner et al. (11), though, found no increase in mammary LPL activity when prolactin was given to 20-day pregnant rats with high concentrations of serum progesterone; but serum prolactin concentration was not measured and may not have been high enough to effect mammary LPL.

In CB154-treated cows, plasma lipase activity increased after parturition despite low concentrations of serum prolactin. This induction of plasma lipase activity may be caused by the decline in serum progesterone concentration in the presence of low serum prolactin concentration. In 20-day pregnant rats treated with CB154 and $PGF_{2\alpha}$, the serum concentrations of progesterone and prolactin decline and mammary LPL activity increases (11). Djiane and Durand (21) have shown that progesterone blocks the induction of prolactin receptors and prolactin stimulates the formation of its own receptors in the rabbit mammary gland. For the CB154-treated cows, the decline in serum progesterone concentration started two days prepartum and, although low, serum prolactin concentration was not completely suppressed by CB154.

After hydrolysis of serum triglycerides, the probable fate of LPL at the capillary endothelium is to be released into the circulation for catabolism at the liver (22,23). The increased hydrolysis of serum triglycerides by mammary LPL during lactation then would be the cause of the plasma lipase activity measured in this study. This is supported by Shirley (4), who observed that post-heparin plasma lipase activity increased eight-fold after parturition and most of this increase could be attributed to greater plasma lipase activity from the mammary vein. We conclude that the lipase activity in plasma from periparturient cows is mostly due to LPL from the mammary gland and that this activity can be induced prepartum by high serum concentrations of prolactin or at parturition with or without the parturient increase of serum prolactin.

[Received April 6, 1987; Revision accepted December 30, 1987]

Stimulation of Liver Growth and DNA Synthesis by Glucosylceramide

Subhash C. Datta[1] and **Norman S. Radin***
Mental Health Research Institute, University of Michigan, Ann Arbor, MI

The nature of the growth-stimulating effect of glucosylceramide was studied. Mice were injected intraperitoneally with emulsified glucosylceramide and conduritol B epoxide, an inhibitor of cerebroside glucosidase. Within one or two days, the liver grew 18–24%, as reported. Two enzymes involved in DNA synthesis also increased more than the weight. The total liver activity of thymidine kinase increased 46–73%, and the total activity of ornithine decarboxylase increased as much as 101%. It is suggested that elevated liver levels of glucocerebroside stimulate cell proliferation through a relatively direct mechanism.
Lipids 23, 508–510 (1988).

It is evident that the growth of liver and spleen in Gaucher patients, who lack a specific glucohydrolase (EC 3.2.1.45), is far more than can be accounted for by accommodation to the weight of stored glucosylceramide (GlcCer), the enzyme's substrate. The chemical nature of the enlarged organs and the mechanisms of the causational sequence still are obscure. In a study in which we injected mice intraperitoneally over an eight-day period with conduritol B epoxide (CBE), an inhibitor of GlcCer glucosidase, we found significant increases in liver and brain size (9% and 13%, respectively) (1). Presumably, the CBE caused an accumulation of the enzyme's substrate (2) and, therefore, induced a temporary model form of Gaucher disease. In a later study (3), we injected emulsified GlcCer once and found that much of the lipid reached the liver and that a rapid enlargement of the liver ensued, 10–37% within 25 hr. Co-injection of CBE with GlcCer enhanced the growth phenomenon. The enlargement was accompanied by an increase in total DNA, lipid and protein (as well as the glucosidase-activator proteins that are known to accumulate in Gaucher spleen); it was evident that the increase in liver size could not be attributed to edema. The detergent alone did not produce a change in liver weight. We have postulated that GlcCer can induce cell division and growth. The study reported here was directed at clarifying the mechanism by which this occurs.

METHODS AND MATERIALS

Materials. Most of the materials, the mice used and the method for selecting them for each experimental group have been described (3,4). The GlcCer, isolated from Gaucher spleen, was emulsified with 3/4 of its weight of Myrj 52, a low-toxicity nonionic detergent (polyoxyethylene stearate, ICI America Inc.), and injected i.p. into 16-day-old mice (3). Labeled thymidine was from ICN and labeled ornithine was from DuPont NEN.

Assays. Thymidine kinase was measured by following the phosphorylation of [^{3}H]thymidine, 182 cpm/nmol, in a tube containing Tris-Cl$^-$ pH 7.5, ethylenediamine tetraacetic acid (EDTA), mercaptoethanol, adenosine triphosphate (ATP), $MgCl_2$, NaF, bovine serum albumin, creatine phosphate and creatine kinase (5,6). The incubation with liver cytosol was performed for 30 min. The resultant thymidine phosphate was isolated with ion exchange paper.

Ornithine decarboxylase was measured by following the release of [^{14}C]O_2 from L-[1-^{14}C]ornithine (22.9 cpm/pmol) in EDTA, Tris-Cl$^-$ pH 7.4, DTT, pyridoxal phosphate (7, 8), and 2-methylornithine (in half of the tubes). Each assay tube contained the supernatant suspension from centrifugation of liver homogenates at 30,000 g for 25 min.

Protein and DNA were determined as described (3).

RESULTS

In one experiment, thymidine kinase specific activity was determined in the livers of mice injected with GlcCer/Myrj in saline, then (24 hr later) with CBE in saline. A day later, the mice were killed, and the livers were analyzed (Table 1). Control mice received two injections of saline alone. The previous observations, increases in protein and DNA that paralleled liver growth, were confirmed. In addition, a distinct rise in thymidine kinase total activity (46%) was seen.

In another experiment, GlcCer/Myrj and CBE were injected as a mixture once, and the animals were killed 24 or 48 hr later. Thymidine kinase total activity rose 73% in 24 hr and subsided to 43% in 48 hr.

A trial with a single injection of GlcCer/Myrj without CBE produced smaller effects, with a 30% increase in total enzyme activity after 24 hr. No significant rise was seen at seven hr.

In vitro tests were run to determine whether the addition of GlcCer could directly stimulate thymidine kinase. Various amounts of GlcCer emulsion (5, 10, 25 and 50 μg/ml) in Tris buffer were added to the incubation mixture just before the addition of liver enzyme. Incubation for 30 or 60 min, with or without GlcCer, produced similar observed activities. In an experiment with 50 μg/ml of GlcCer, with and without 5 μg/ml of phosphatidylserine (from bovine brain, Sigma Chemical Co., St. Louis, MO), with and without a two-hr preincubation, there was also no significant effect of either lipid. However the phosphatidylserine + GlcCer exerted a small inhibitory effect (about 12%). The phospholipid was tested because it is an activator of GlcCer glucosidase.

Another enzyme noted for its responsiveness to various growth promoters, ornithine decarboxylase (9), showed larger responses in activity to GlcCer and CBE (Table 2). This was done as part of the second experiment, above. Again, the liver increase in weight was seen, similar at the two time points. The total activity of ornithine decarboxylase in the stimulated mouse livers was 101% above controls after 24 hr, 64% above after 48 hr.

Abbreviations: CBE, conduritol B epoxide; DTT, dithiothreitol; EDTA, ethylenediamine tetraacetic acid; GlcCer, glucosylceramide.

TABLE 1

Thymidine Kinase Activity in Mice Injected with Glucosylceramide

Measurement	Controls	Treated	Increase (%)
Body wt. (g/mouse)	6.70 (0.38)	6.65 (0.27)	−0.7
Liver wt. (mg/mouse)	277 (20)	327 (27)	18
Protein in liver (mg)	27.6 (1.6)	31.6 (1.1)	14
DNA in liver (μg)	644 (50)	758 (30)	18
Thymidine kinase (μmol/hr)	1.30 (0.09)	1.90 (0.12)	46

Nine Hsd CF1 mice were injected with GlcCer (250 mg/kg emulsified with Myrj, 188 mg/kg) and, a day later, with CBE (80 mg/kg). Saline was injected into nine controls, and all mice were killed 24 hr later. The thymidine kinase activity shown is μmol/hr of thymidine converted to the monophosphate by the cytosol from one mouse liver, less the blank activity from boiled liver. The numbers in parentheses are standard deviations derived from six values (duplicates from three groups of three pooled livers) or nine individual values in the case of the weights. All increases were statistically significant by Student's t-test ($p < 0.005$).

TABLE 2

Ornithine Decarboxylase Activity in Mice Injected with GlcCer and CBE

Measurement	Controls	Treated	Increase (%)
Body wt. 24 hr later (g)	6.71 (0.77)	6.78 (0.46)	0
Body wt. 48 hr later (g)	6.57 (0.66)	6.95 (0.96)	6
Liver wt. 24 hr (mg)	278 (25)	342 (27)	23*
Liver wt. 48 hr (mg)	268 (34)	333 (55)	24*
Ornithine decarboxylase			
24 hr later (nmol/hr)	400 (21)	805 (55)	101*
48 hr later (nmol/hr)	387 (39)	636 (75)	64*

*$p < 0.005$.

The protocol was similar to that shown in Table 1, but both drugs were injected together at time zero, and the animals were killed 24 hr or 48 hr later. Standard deviations are shown in parentheses. Decarboxylase activity shown is the amount of ornithine decarboxylated by one liver in one hr, corrected for the blank activity in the presence of decarboxylase inhibitor.

DISCUSSION

We have shown that an emulsion of GlcCer acts on the liver to stimulate or increase the amount of thymidine kinase, a major enzyme of DNA synthesis (10). The mechanism for the kinase stimulation may not be through a direct action on the enzyme, as indicated by the lack of effect in vitro. However, the activation phenomenon may require other factors that are needed for in vitro stimulation.

The increase in ornithine decarboxylase activity that we observed is consistent with the reported two-fold increase produced by incubating cells with ganglioside, a glycolipid derived from GlcCer (11). The incubated ganglioside probably was hydrolyzed in part to GlcCer, and the GlcCer injected into our mice presumably was converted in part to ganglioside. It remains to be seen which glycolipid or intermediate between them was the actual stimulator. Ornithine decarboxylase formation is induced, generally, by phorbol diester, which apparently acts also to stimulate phosphorylations by a protein kinase C (12) as well as by a second pathway (9). Both pathways apparently activate the formation of ornithine decarboxylase (13). Gangliosides were reported to stimulate a protein kinase C (14) and to exert a proliferative action on cells such as neuroblastoma (15).

Phorbol diester may act through its stimulating effect on glycolipids, exemplified in the finding that it increased the levels of cerebroside, lactosylceramide and ganglioside GM3 in cultured leukemia cells (16). Both GlcCer and phorbol diester increased interleukin formation by macrophage cells (17).

It has been reported that lysosphingolipids are strong inhibitors of protein kinase C and of phorbol diester binding, and the speculation was offered that the lysolipids are responsible for the pathological features of sphingolipidoses such as Gaucher disease (18). Glucosylsphingosine does accumulate in this disorder (albeit to a low concentration) and might be formed to a certain extent in our GlcCer-loaded mice, but one generally cannot conclude that the inhibition of protein kinase C should lead to cell proliferation and increases in enzymes involved in DNA synthesis. Stimulation of protein kinase C leads to increased levels of ornithine decarboxylase (12,13), and we temporarily could conclude that GlcCer injection produces an increase in the kinase, not an inhibition.

In one experiment, we weighed the mouse spleens and found no significant change in weight after injecting GlcCer. The lack of effect can be attributed to our finding of rapid uptake of the exogenous GlcCer by liver (3). This is consistent with an observation made recently with labeled L-glucosylceramide, an unnatural enantiomer that apparently is unmetabolizable (19).

Omitted in this preliminary study was a control group of mice that had been injected only with detergent, instead of saline. Myrj alone had been found to have no effect on liver weight (3), and it has been found to be replaceable by lecithin for production of GlcCer's growth effect (Datta and Radin, unpublished data). Moreover, our experiment with GlcCer/Myrj without CBE produced a smaller increase in thymidine kinase, a result that is consistent with the assignment of the effect to the lipid rather than to the detergent. GlcCer has been found to enhance the proliferation of Ehrlich ascites carcinoma cells in vivo without the inclusion of detergent (20). While it seems highly unlikely that the detergent is responsible for the interesting increases in enzyme activity reported here, future studies should include a detergent or lecithin control group.

We suggest that GlcCer has mitogenic properties, acting through a relatively direct mechanism. It may function not only as a precursor for nearly all the glycolipids but also to control organ growth in normal animals. The possible roles of GlcCer and/or related glycolipids in cell proliferation and cancer have been discussed more fully (21).

[Received November 16, 1987; Revision accepted February 8, 1988]

Absolute Configuration of 12-Oxo-10,15(Z)-phytodienoic Acid

Mats Hamberg[a,*], **Otto Miersch**[b] and **Gunther Sembdner**[b]

[a]Department of Physiological Chemistry, Karolinska Institutet, Box 60400, S-104 01 Stockholm, Sweden, and [b]Institut für Biochemie der Pflanzen Halle, Akademie der Wissenschaften der GDR, DDR-4020 Halle, Weinberg 3, German Democratic Republic

12-Oxo-10,15(Z)-phytodienoic acid biosynthesized from 13(S)-hydroperoxy-9(Z),11(E),15(Z)-octadecatrienoic acid using a preparation of corn (*Zea mays* L) hydroperoxide dehydrase recently was found to be a mixture of enantiomers in a ratio of 82:18 (Hamberg, M., and Hughes, M.A. (1988) *Lipids 23,* 469–475). In this work, 12-oxophytodienoic acid and (+)-7-iso-jasmonic acid were converted into a common derivative, methyl 3-hydroxy-2-pentyl-cyclopentane-1-octanoate. From gas liquid chromatographic analysis of the (−)-menthoxycarbonyl derivative of methyl 3-hydroxy-2-pentyl-cyclopentane-1-octanoates prepared from 12-oxophytodienoic acid and (+)-7-iso-jasmonic acid, it could be deduced that the major enantiomer of 12-oxophytodienoic acid had the 9(S),13(S) configuration. Therefore, in the major enantiomer of 12-oxophytodienoic acid, the configurations of the side chain-bearing carbons are identical to the configurations of the corresponding carbons of (+)-7-iso-jasmonic acid, thus giving support to previous studies indicating that 12-oxophytodienoic acid serves as the precursor of (+)-7-iso-jasmonic acid in plant tissue.
***Lipids 23,* 521–524 (1988).**

Conversion of 13(S)-hydroperoxy-9(Z),11(E),15(Z)-octadecatrienoic acid (13(S)-HPOT) into a cyclopentenone derivative, 12-oxo-10,15(Z)-phytodienoic acid, was reported by Zimmerman and Feng (1). The enzyme activity responsible for the conversion was detected in a wide variety of plants such as wheat, barley, oat, flax, corn, sunflower and lettuce (2). In subsequent work, Vick and Zimmerman demonstrated that 12-oxophytodienoic acid was a precursor of jasmonic acid (3). The transformation was demonstrated in several plant species and consisted of initial saturation of the Δ^{10} double bond of 12-oxophytodienoic acid catalyzed by a reductase followed by three steps of β-oxidation (4). Jasmonic acid has been suggested to act as a plant hormone because of its growth-inhibitory and senescence-promoting effects (5). Recent studies have shown that an epimer of (−)-jasmonic acid, i.e. (+)-7-iso-jasmonic acid, is produced by higher plants (6,7) and fungi (8). Interestingly, in some systems the growth-inhibitory activity of (+)-7-iso-jasmonic acid appears to be higher than that of (−)-jasmonic acid (7).

The absolute configuration of (−)-jasmonic acid was established by Hill and Edwards (9). 12-Oxo-10,15(Z)-phytodienoic acid has been shown to have the *cis* relationship between its two side chains (10) and to consist of enantiomers of unknown configuration in the ratio 82:18 (11). This paper reports the absolute configurations of the major and minor enantiomers of 12-oxophytodienoic acid.

EXPERIMENTAL PROCEDURES

Materials. 13(S)-[1-^{14}C]HPOT (specific radioactivity, 1.5 kBq/μmol) was prepared by incubation of [1-^{14}C]α-linolenic acid (Amersham, UK) with soybean lipoxygenase as described (12). (+)-7-iso-Jasmonic acid (containing ca. 20% of (−)-jasmonic acid) was isolated from the culture medium of the fungus *Botryodiplodia theobromae* as described (8).

Enzyme preparation. A preparation containing corn hydroperoxide dehydrase was obtained by extraction of defatted corn germ (Bear X8632 hybrid corn, Noble Bear, Inc., Decatur, IL) with potassium phosphate buffer followed by ammonium sulfate precipitation (0–45% saturation) as described (13). Precipitate dissolved in ice-cold 0.1 M potassium phosphate buffer, pH 7.4 (1.6 mg of protein per ml buffer) was used for the incubations.

Preparation of methyl 12-hydroxyphytonoates (trans isomers) from (+)-7-iso-jasmonic acid. Epimeric methyl 12-hydroxyphytonoates with defined stereochemistry at carbons 9, 12 and 13 (**4a** and **4b**) were prepared from (+)-7-iso-jasmonic acid (**1**) as shown in Figure 1.

1 (10 mg; containing ca. 20% of (−)-jasmonic acid) was treated with diazomethane and subjected to catalytic hydrogenation. The product was treated with 10 ml of 1 M KOH in 50% aqueous methanol at 60 C for five hr (8). Material isolated by extraction with diethyl ether was subjected to silicic acid chromatography. Elution with diethyl ether/hexane (2:8, v/v) afforded 6 mg of (−)-9,10-dihydrojasmonic acid (**2**). Thin layer chromatographic analysis of this material showed a single spot (solvent

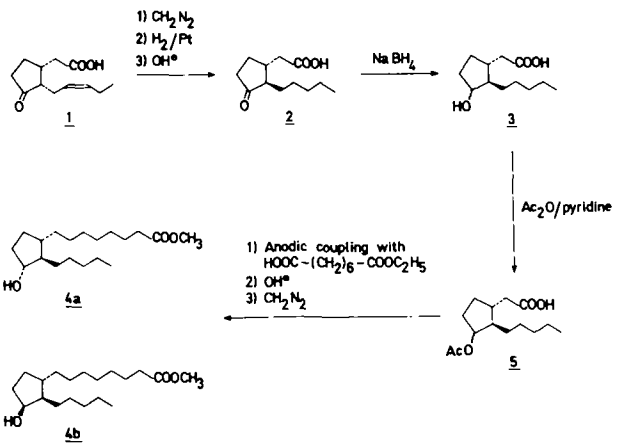

FIG. 1. Preparation of methyl 12(R)-hydroxy-9(S),13(R)-phytonoate (*4a*) and methyl 12(S)-hydroxy-9(S),13(R)-phytonoate (*4b*) from (+)-7-iso-jasmonic acid (*1*).

Abbreviations: 13(S)-HPOT, 13(S)-hydroperoxy-9(Z),11(E),15(Z)-octadecatrienoic acid; MC, (−)-menthoxycarbonyl; Me_3Si, trimethylsilyl; GC-MS, gas chromatography-mass spectrometry; GLC, gas liquid chromatography; HPLC, high performance liquid chromatograpy; TLC, thin layer chromatography.

When absolute configurations of C-9 and C-13 are not specifically indicated, phytonoic acid is used to denote 2-pentyl-cyclopentane-1-octanoic acid in which the two side chains have the *cis* relationship, whereas phytonoic acid (*trans* isomer) denotes 2-pentyl-cyclopentane-1-octanoic acid in which the two side chains have the *trans* relationship.

system, ethyl acetate/hexane/acetic acid (4:6:0.05, v/v/v), R_f = 0.50). An aliquot was treated with diazomethane and analyzed by gas chromatography-mass spectrometry (GC-MS). A major peak due to methyl (−)-9,10-dihydrojasmonate (91%) and a minor peak due to methyl (+)-9,10-dihydro-7-iso-jasmonate (9%) were observed. The mass spectrum recorded on the peak of methyl (−)-9,10-dihydrojasmonate showed prominent ions at *m/e* 226 (M, 3%), 195 (M − 31, 3), 156 (M − 70 [β-cleavage with loss of CH_2=CH-C_3H_7], 38), 153 (M − 73 [loss of ·CH_2-$COOCH_3$], 34), and 83 (100).

2 (5 mg) was dissolved in methanol (5 ml) and treated with sodium borohydride (50 mg) at room temperature for 30 min. An aliquot of the product was treated with diazomethane and subjected to thin layer chromatography (TLC) (solvent system, ethyl acetate/hexane [25:75, v/v]). Two spots due to the methyl esters of 6-hydroxy-9,10-dihydrojasmonic acids epimeric at C-6 (**3**) appeared (R_f = 0.33 and R_f = 0.39). The mass spectrum of the trimethylsilyl (Me_3Si) derivative of the methyl ester of **3** showed prominent ions at *m/e* 300 (M, 4%), 285 (M − 15, 27), 226 (M − 74 [loss of ·CH_2-$COOCH_3$ plus H], 20), 210 (M − 90, 8), and 129 (CH_2=CH-CH=O^+ $SiMe_3$, 100).

3 (ca. 4.5 mg) was acetylated by treatment with acetic anhydride (0.3 ml) in pyridine (0.3 ml) at room temperature for 18 hr. Water (10 ml) was added, and the mixture was stirred at room temperature for four hr. An aliquot of the product was treated with diazomethane and subjected to analysis by gas chromatography-mass spectrometry (GC-MS). Two peaks appeared due to the methyl ester of **5** epimeric at C-6. The mass spectra of the two epimers were virtually identical and showed prominent ions at *m/e* 210 (M − 60 [loss of CH_3COOH], 14%), 197 (M − 73 [loss of ·CH_2-$COOCH_3$], 12), 178 (M − [60 + 32], 10), 150 (36), 136 (100), 80 (33), and 74 (CH_2=C[OCH_3]O^+H, 18).

5 (ca. 4 mg) was dissolved in methanol (12 ml) containing ethyl hydrogen suberate (95 mg). One ml of 0.05 M sodium methoxide in methanol was added, and a current of 0.15 A was passed through the solution for three hr. The reaction mixture was treated with 5% of NaOH at room temperature for 18 hr. Material isolated by extraction with diethyl ether was treated with diazomethane and subjected to silicic acid chromatography. The major by-product from the anodic coupling, dimethyl tetradecanedioate, was eluted with diethyl ether/hexane (5:95, v/v). Elution with diethyl ether/hexane (3:7, v/v) afforded methyl 12-hydroxyphytonoate (*trans* isomer, ca. 2 mg). Preparative TLC (solvent system, ethyl acetate/hexane [25:75, v/v]) afforded the pure epimers **4a** (R_f = 0.51) and **4b** (R_f = 0.58). Aliquots were converted into the Me_3Si derivatives and analyzed by GC-MS. The C-values found for **4a** and **4b** were 19.85 and 20.00, respectively, and the mass spectra showed prominent ions at *m/e* 384 (M, 1%), 369 (M − 15, 15), 337 (M − [15 + 32], 9), 294 (M − 90, 10), 137 (M − [157 + 90] [loss of ·$(CH_2)_7$-$COOCH_3$ plus Me_3SiOH], 7), and 129 (CH_2=CH-CH=O^+SiMe_3, 100).

The absolute configuration of C-9 ("S") and C-13 ("R") of **4a** and **4b** followed from their mode of preparation from **1**, the stereochemistry of which is well-established (8). The configuration of the hydroxyl group at C-12 ("R" in **4a** and "S" in **4b**) followed from recent work that has shown that irrespective of the absolute configuration of C-13, the epimer of methyl 12-hydroxyphytonoate (*trans* isomer), which is more polar on TLC analysis, has the *trans* relationship between the hydroxyl group at C-12 and the pentyl side chain attached to C-13, whereas the less polar epimer has the *cis* relationship between the corresponding substituents (11). Accordingly, **4a** was methyl 12(*R*)-hydroxy-9(*S*),13(*R*)-phytonoate, and **4b** methyl 12(*S*)-hydroxy-9(*S*), 13(*R*)-phytonoate (Fig. 1).

Preparation of methyl 12-hydroxyphytonoates (trans isomers) from 12-oxo-10,15(Z)-phytodienoic acid. Epimeric methyl 12-hydroxyphytonoates (**8a** and **8b**, Fig. 2) were prepared from methyl 12-oxo-10,15(*Z*)-phytodienoate (**6**) as described (11). Briefly, 13(*S*)-HPOT was treated with corn hydroperoxide dehydrase at 0 C for 15 min, and the resulting 12-oxophytodienoic acid isolated as its methyl ester (**6**) by TLC and reversed-phase high performance liquid chromatography (HPLC). **7**, prepared by base-catalyzed isomerization of **6** (2 mg), was subjected to sodium borohydride reduction and catalytic hydrogenation. This treatment resulted in the formation of two epimers that were separable by TLC (solvent system, ethyl acetate/hexane [25:75, v/v]; **8a**, R_f = 0.51; **8b**, R_f = 0.58).

As mentioned above, it recently was found that the relative configuration between the hydroxyl group and the pentyl side chain was *trans* in the more polar epimer (**8a**), whereas the relationship between the corresponding substituents was *cis* in the less polar epimer (**8b**) (11). Accordingly, depending on the absolute configuration of **6**, **8a** may be methyl 12(*R*)-hydroxy-9(*S*),13(*R*)-phytonoate and/or methyl 12(*S*)-hydroxy-9(*R*),13(*S*)-phytonoate. In the same way, **8b** may be methyl 12(*S*)-hydroxy-9(*S*),13(*R*)-phytonoate and/or methyl 12(*R*)-hydroxy-9(*R*),13(*S*)-phytonoate (Fig. 2).

Methods for isolation and stereochemical analysis. TLC was carried out with precoated plates (Kieselgel 60, 0.25 mm) from E. Merck, FRG. Material was located by spraying with 2′,7′-dichlorofluorescein and viewing under UV light. HPLC was performed using a column (300 × 8 mm) of Polygosil C_{18} 5μ and acetonitrile/water (85:15, v/v) at a flow rate of 1.5 ml/min. The absorbancy of the effluent at 222 nm was measured. Gas liquid chromatography (GLC) was performed with an F&M Biomedical gas chromatograph model 402 using a column of 5% QF-1 on Supelcoport. GC-MS was carried out with an LKB 9000S instrument equipped with a column of 3% OV-210 on Supelcoport.

Methods for catalytic hydrogenation and preparation of Me_3Si derivatives were as described (14). Preparation

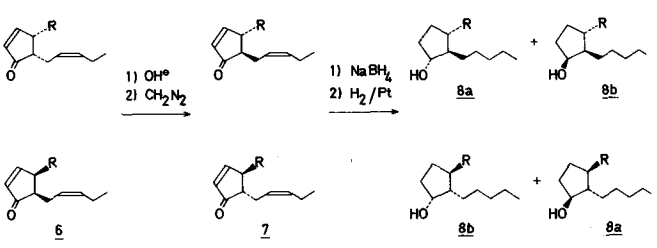

FIG. 2. Preparation of methyl 12-hydroxyphytonoates (*trans* isomers; *8a, 8b*) from methyl 12-oxo-10,15(*Z*)-phytodienoate (*6*). Stereoisomers having the following absolute configurations at C-9 and C-13 are shown: *6*, upper: 9(*S*),13(*S*), lower: 9(*R*),13(*R*); *7*, *8a*, and *8b*, upper: 9(*S*),13(*R*), lower: 9(*R*),13(*S*). R = $(CH_2)_7$-$COOCH_3$.

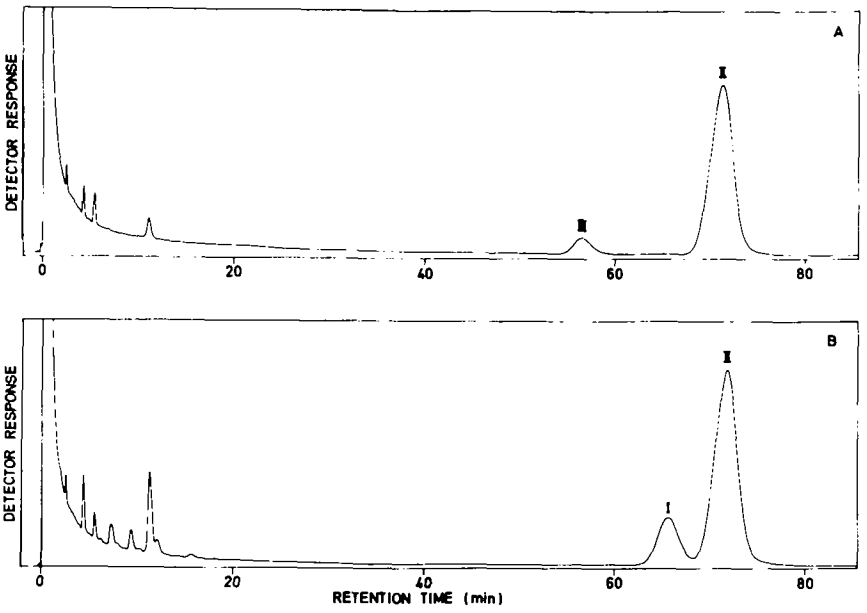

FIG. 3. Gas liquid chromatographic analysis of MC derivatives of *4b* (panel A) and *8b* (panel B). Column, 5% QF-1 on Supelcoport; column temperature, 200 C. I, MC derivative of methyl 12(*R*)-hydroxy-9(*R*),13(*S*)-phytonoate; II, MC derivative of methyl 12(*S*)-hydroxy-9(*S*),13(*R*)-phytonoate; III, MC derivative of methyl 12-hydroxy-9(*S*),13(*S*)-phytonoate.

of (−)-menthoxycarbonyl (MC) derivatives of methyl hydroxyphytonoates were carried out by treating the hydroxy compound (0.05–0.3 mg) with 60 μl of (−)-menthylchloroformate in 40 μl of benzene and 12 μl of dry pyridine at room temperature for 18 hr (15). The MC derivatives were purified by TLC (solvent system, ethyl acetate/hexane [7:93, v/v]) and subjected to gas chromatographic analysis.

RESULTS AND DISCUSSION

In this work, epimeric methyl 12-hydroxyphytonoates (*trans* isomers) of known (**4a** and **4b**) and unknown (**8a** and **8b**) configuration were prepared from (+)-7-iso-jasmonic acid and 12-oxo-10,15(*Z*)-phytodienoic acid, respectively. The epimers were treated separately with (−)-menthylchloroformate, and the resulting MC derivatives were analyzed by GLC. As shown in Figure 3A, the MC derivative of **4b** gave a single peak ("II") confirming that **4b** was optically pure (methyl 12(*S*)-hydroxy-9(*S*),13(*R*)-phytonoate). The minor peak ("III") present in the gas chromatogram was due to the MC derivative of methyl 12-hydroxy-9(*S*),13(*S*)-phytonoate derived from the trace (9%) of (+)-7-iso-jasmonic acid remaining not isomerized after the alkali treatment (see above). Analysis of the MC derivative of **8b**, derived from 12-oxo-10,15(*Z*)-phytodienoic acid, showed two peaks ("II" and "I," ratio 82:18) in agreement with recent work (11) (Fig. 3B). The major peak ("II") coincided with the peak of the MC derivative of **4b** (see Fig. 3; co-chromatography of "II" of the MC derivatives of **4b** and of **8b** was rigorously proved by co-injection of the MC derivatives of **4b** and **8b**). Thus, the major enantiomer of **8b** was methyl 12(*S*)-hydroxy-9(*S*),13(*R*)-phytonoate, and the minor enantiomer (the MC derivative of which gave peak "I") was methyl 12(*R*)-hydroxy-9(*R*),13(*S*)-phytonoate. Analysis of the MC derivatives of **4a** and **8a** gave a similar result, i.e. the MC derivative of the major enantiomer of **8a** co-chromatographed with the MC derivative of **4a** (methyl 12(*R*)-hydroxy-9(*S*),13(*R*)-phytonoate).

The absolute configuration of C-9 of 12-oxo-10,15(*Z*)-phytodienoic acid is unaffected by the treatments shown in Figure 2. Thus, the finding that the configuration of C-9 of the major enantiomers of **8a** and **8b** was "S" coupled with the previous result that the relative configuration of the two side chains of 12-oxo-10,15(*Z*)-phytodienoic acid is *cis* (10) demonstrated that the absolute configurations of C-9 and C-13 of the major enantiomer of 12-oxophytodienoic acid were both "S."

Our finding that the configurations of the chain-bearing carbons of the major enantiomer of 12-oxo-10,15(*Z*)-phytodienoic acid were identical to those of the corresponding carbons of (+)-7-iso-jasmonic acid supports the concept that 12-oxophytodienoic acid serves as the precursor of (+)-7-iso-jasmonic acid in plant tissue (3,4). It was noteworthy, however, that the putative precursor, 12-oxophytodienoic acid, was found to be only 82% optically pure, whereas the product, (+)-7-iso-jasmonic acid, was 100% optically pure. It is possible that 12-oxophytodienoic acid biosynthesized in vivo is optically pure. Another possibility is that 12-oxophytodienoic acid biosynthesized in vivo is, as in this in vitro system, not completely optically pure but that only the major enantiomer can be converted into (+)-7-iso-jasmonic acid. Such a discrimination between enantiomers might be caused by stereospecificity of the reductase that catalyzes saturation of the Δ^{10} double bond of 12-oxophytodienoic acid. Further studies on this problem are in progress and will be reported later.

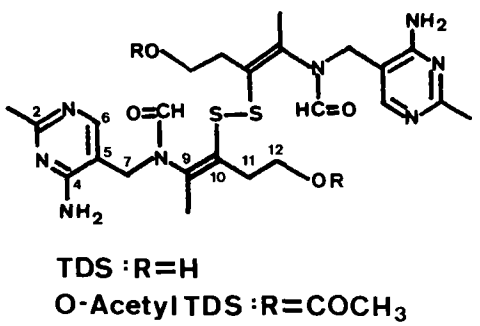
The formation of complexes between thiamine disulfide (TDS) or *O*-acetyl thiamine disulfide (*O*-acetyl TDS) and fatty acid or fatty acid methyl ester in methanol has been studied by fluorescence quenching and ^{13}C NMR relaxation (T_1) measurements. The association constants (K-values) of TDS and *O*-acetyl TDS with fatty acids (from 11:0 to 18:0, and 18:1, 18:2, 18:3 and 20:4) and fatty acid methyl esters have been determined. These values do not depend on either the number of carbon atoms or the degree of unsaturation of the fatty acid. The K-values of TDS and *O*-acetyl TDS with fatty acid were 7.8 M^{-1} and 5.1 M^{-1}, respectively. The K-values of TDS and *O*-acetyl TDS with fatty acid methyl ester were very small. These results show that the -OH moiety in TDS and the -COOH moiety in the fatty acid are necessary for formation of the complex.
***Lipids* 23, 525–527 (1988).**

Many modified thiamine compounds have been synthesized in attempts to increase the pharmacological effect of thiamine (1–3). TDS (thiamine disulfide), an oxidized dimer of thiamine, has been used as an ingredient of pharmaceutical preparations because its absorption and stability are greater than those of thiamine. TDS is readily reduced to thiamine by cysteine, glutathione and other sulfhydryl compounds, so it shows the same biological activity as thiamine in animals.

Complexes of TDS with higher saturated fatty acids were prepared to improve the stability, absorption and taste of TDS in pharmaceutical preparations (4). The molar ratio of TDS to fatty acid in the complexes in the solid state is reported to be 1:6, but the mode of formation of the complexes is unknown.

This paper reports studies on the formation of complexes of TDS with fatty acids in methanol by the fluorescence quenching method and by ^{13}C NMR. The mode of the interaction is discussed.



TDS : R=H
O-Acetyl TDS : R=$COCH_3$

MATERIALS AND METHODS

Thiamine disulfide (hydrated) was purchased from Tokyo Kasei Kogyo Co. (Tokyo, Japan). Stearic acid (18:0), oleic acid (18:1), linoleic acid (18:2), linolenic acid (18:3), arachidonic acid (20:4), undecanoic acid (11:0), lauric acid (12:0), tridecanoic acid (13:0), myristic acid (14:0), pentadecanoic acid (15:0), palmitic acid (16:0) and heptadecanoic acid (17:0) were purchased from Sigma Chemical Co. (St. Louis, MO). All other chemicals and reagents were of guaranteed reagent grade. TDS-fatty acid complexes were prepared by the method of Ueda et al. (4). Fluorescence spectra were recorded at 25 C with a Hitachi MPF-4 fluorescence spectrophotometer. ^1H NMR and ^{13}C NMR spectra were measured with a JEOL GX-270 NMR spectrometer. The spectra were assigned with reference to Kotera (5), Echols and Levy (6) and Gallo and Sable (7). ^{13}C relaxation times were measured by the inversion recovery method, employing a (180°-τ-90°) pulse sequence (8), in which τ is the delay time between the 180° and 90° pulses. Experimental conditions are described in the legends to Table 3.

O-Acetyl TDS was prepared as follows. TDS (1 g) was dissolved in 10 ml of pyridine and stirred for 15 min. Then acetic acid anhydride (1.04 g) was added slowly with stirring at room temperature for 15 min. The mixture was

RESULTS AND DISCUSSION

We used the fluorescence quenching technique to study complex formation, as reported (9). When the TDS-fatty acid complex was dissolved in methanol, the fluorescence intensity of TDS increased as the time proceeded, concomitant with the dissociation of the TDS-fatty acid complex. The excitation and emission spectra of TDS fluorescence in methanol before and after addition of increasing concentrations of fatty acids are shown in Figure 1. Addition of fatty acid to the TDS in methanol solution resulted in a decrease in fluorescence intensity (Ex. 374.0 nm, Em. 423.6 nm), due to interaction of TDS with the fatty acid. Over a wide range of fatty acid concentrations, the reaction conformed to the equation of Stern-Volmer (10): $(F_0 - F)/F = K[Q]$, in which F_0 and F denote the fluorescence intensities in the absence and presence of a fatty acid, respectively, and [Q] the concentration of a fatty acid (Fig. 2). The K-value for the interaction of TDS with fatty acid was calculated to be about 7.8 M^{-1} (Table 1). This K-value did not depend on the number of carbon atoms from 11 to 20 or the degree of unsaturation of the fatty acid.

Addition of a fatty acid methyl ester to TDS in methanol resulted in smaller changes in intensity of fluorescence than addition of a free fatty acid, and the K-values of TDS for fatty acid methyl esters were smaller than those for free fatty acids (Table 2). These results show that the -COOH moiety of the fatty acid interacts with TDS to form a complex.

TABLE 1

Association Constants (K) for Interaction of TDS with Fatty Acids in Methanol Calculated from Stern-Volmer Coordinates

Fatty acid	K(M^{-1})	Fatty acid	K(M^{-1})
11:0	5.9 ± 3.1	17:0	7.2 ± 3.2
12:0	9.6 ± 2.3	18:0	7.3 ± 2.6
13:0	9.6 ± 5.1	18:1	7.0 ± 1.9
14:0	6.4 ± 3.9	18:2	6.4 ± 3.7
15:0	7.9 ± 3.5	18:3	8.8 ± 1.6
16:0	8.5 ± 3.6	20:4	9.2 ± 5.4

TABLE 2

Values of the Constant (K) for Interaction of TDS and *O*-Acetyl TDS with Fatty Acid and Fatty Acid Methyl Ester in Methanol Calculated from Values for Fluorescence Quenching

	K(M^{-1})
TDS + FA	7.8 ± 1.3
TDS + FMe	1.9 ± 0.9
*O*Ac + FA	5.1 ± 1.3
*O*Ac + FMe	2.0 ± 0.8

*O*Ac, *O*-Acetyl TDS; FA, fatty acid; FMe, fatty acid methyl ester.

TABLE 3

Changes in the ^{13}C-Spin Lattice Relaxation Time (T_1)[a] of TDS[b] with Stearic Acid Concentration

Position	TDS carbon (ppm)	Added stearic acid (mg)			
		0	1.0	3.0	5.0
10	135.7	3.07	2.61	2.56	2.30
5	110.1	3.13	3.41	3.03	2.75
12	60.5	0.42	0.41	0.40	0.38
7	40.8	0.32	0.23	0.23	0.19

[a]Sec.

[b]50 mg in 1.0 ml methanol-d_4, 27.0 C.

Pulse delay = 10 sec. Pulse interval = 6.0, 3.0, 2.5, 1.8, 0.8, 0.6, 0.4, 0.2, 0.1 and 0.05 sec.

Using the same method, we found that the K-values of *O*-acetyl TDS for fatty acids were smaller than those of TDS. The K-value of *O*-acetyl TDS for fatty acid methyl ester was quite small and similar to that of TDS (2.0 M^{-1} and 1.9 M^{-1}, respectively). These results suggest that the -OH moiety of TDS interacts with the -COOH moiety of the fatty acid.

We measured the ^{13}C spin-lattice relaxation time (T_1) of each carbon atom of TDS in the complex by ^{13}C-NMR spectroscopy. As can be seen in Table 3, the T_1-values of the carbon atoms at positions 10, 5, 12 and 7 of TDS in methanol were reduced progressively by increasing concentrations of stearic acid, but little change was observed in the T_1-values of other carbon atoms. The reduction in the T_1-values was due to restricted mobility of the carbon atoms in TDS by the formation of a complex. The results obtained by ^{13}C NMR T_1 measurement support those obtained by the fluorescence quenching method.

We conclude from this work that TDS forms a complex with fatty acids in methanol and that formation of this complex is not affected by the number of carbon atoms or the degree of unsaturation of the fatty acid. The -OH moiety in TDS and the -COOH moiety in the fatty acid are concluded to be necessary for this interaction. We now are investigating another mode of interaction of TDS with fatty acids.

[Received June 26, 1987; Revision accepted December 14, 1987]

Purification and Characterization of Fatty Acid-binding Protein from Human Placenta

Tanya Das, Gourisankar Sa and Manju Mukherjea*
Department of Biochemistry, University College of Science, 35, Ballygunge Circular Road, Calcutta 700 019, India

Purification of a cytosolic fatty acid-binding protein (FABP) from developing human placenta has been achieved, and its role in modulating the inhibition of human placental glucose-6-phosphate dehydrogenase (G6PD) by palmitoyl-CoA (PAL-CoA) has been studied. FABP was resolved into three peaks, viz. DE-I, DE-II and DE-III, by DEAE cellulose chromatography. DE-I was almost lipid-free. Presence of endogenous fatty acids in DE-II and DE-III was detected by thin layer chromatography (TLC). Fatty acids were the only detectable lipid component in these fractions. Gas liquid chromatography (GLC) analysis revealed that DE-II binds long chain saturated and unsaturated fatty acids nonspecifically, whereas DE-III is mainly an arachidonic acid carrier. Each of these fractions, viz. DE-I, DE-II and DE-III, has a molecular weight of 14,200 Daltons. Ouchterlony double immunodiffusion studies have confirmed the immunochemical identity of these three fractions of placental FABP. Separation in ion exchanger may be due to their different isoelectric points and varied types of binding affinities. Human placental G6PD was inhibited 50% by 0.03 mM PAL-CoA. The DE-II fraction of FABP enhanced the activity of G6PD in the absence of added PAL-CoA and protected against PAL-CoA inhibition of the enzyme. Such a modulating effect of FABP in this inhibition is attributable to binding of long chain acyl-CoA rather than to a direct effect of FABP on the enzyme itself.
Lipids 23, 528–533 (1988).

The presence of low molecular weight fatty acid-binding proteins (FABP) in the cytosol of various animal tissues was first reported by Ockner et al. (1). FABP appears to be identical with Z protein (2) and sterol carrier protein (3). This protein has been purified from many tissues (4,5). It binds free fatty acids, their CoA derivatives, organic anions and other small molecules (6). In 1985, Gordon et al. (7) found the tissue-specific expression and developmental regulation of two genes coding for rat liver and intestinal FABP; these two proteins were immunochemically unrelated. However, both human and rat liver FABP were reported to be highly homologous (8). Trulzsch and Arias observed that in a specific tissue, FABP may exist in more than one form that differ in isolectric points and binding affinities but are immunochemically identical (9). FABP is also required for ATP/ADP transport (10) across the membranes. Burnett et al. (11) have raised the possibility that this protein affects the metabolic compartmentalization of fatty acids between oxidative and esterification pathways. FABP protects many enzymes of lipid synthesis, e.g. acetyl-CoA carboxylase (12), fatty acid synthase (13), ATP citrate lyase (13), citrate synthetase (14), etc., against inhibition by long chain acyl-CoA. It has been suggested that long chain fatty acids and fatty acyl-CoA may be compartmentalized in the cell and that changes in their distribution might affect these enzymes and lipogenesis out of proportion to any detectable change in their tissue concentration. Jacobs and Majerus (15) and Halestrap and Denton (16) suggested that intracellular compartmentation might be affected in part by their binding to FABP. The present experiments have been designed to purify and characterize FABP from developing human placenta and to investigate the hypothesis that interaction between FABP and long chain acyl-CoAs modulates the activity of glucose-6-phosphate dehydrogenase (G6PD), the key enzyme of the hexose monophosphate (HMP) shunt pathway, which provides NADPH for lipid biosynthesis (17) and is inhibited by fatty acyl-CoA (18).

MATERIALS AND METHODS

12-(9-Anthroyl)stearic acid, palmitoyl-CoA (PAL-CoA), glucose-6-phosphate (G6P), nicotinamideadenine dinucleotide phosphate (NADP), α-lactalbumin, soybean trypsin inhibitor, trypsinogen, carbonic anhydrase, cytochrome c, sodium dodecyl sulfate (SDS), Tris (hydroxymethyl)-amino methane (Tris), diethylaminoethyl (DEAE) cellulose, agarose and 1-ethyl-3(-3-dimethylaminopropyl)carbodimide (EDAC) were purchased from Sigma Chemical Co. (St. Louis, MO). Complete Freund's adjuvant (CFA) and incomplete Freund's adjuvant (IFA) were obtained from Difco Chemicals (Detroit, MI). All other chemicals were of analytical grade and were purchased from local dealers.

Human placentas of gestational ages between 6–30 wk were collected from patients undergoing legal abortion either by suction or via hysterotomy and term placentas were collected at the time of parturition or via Cesarean section from the Department of Obstetrics and Gynecology, National Medical College and Hospital (Calcutta, India). Tissues were collected within 15 min of operation/delivery and kept on ice. Gestational ages were calculated from the period of amenorrhea and by weight and crown-rump length of the fetus (19).

Purification of FABP from human placenta. FABP from human placenta were purified by modification of the procedure published by Das and Mukherjea (20). Placentas were dissected and cut into small segments and rinsed with 0.9% saline to remove blood as much as possible. These segments were then homogenized in 0.01 M Tris-HCl buffer, pH 8.5, by seven passes of a Teflon glass homogenizer. The homogenate was centrifuged for 30 min at 36,000 × g. The supernatant was then spun at 105,000 × g for one hr. The clear cytosol was heated at

*To whom all correspondence should be addressed.

Abbreviations: DEAE, diethylaminoethyl; EDAC, 1-ethyl-3(-3-dimethylaminopropyl)-carbodimide; FABP, fatty acid-binding protein; G6P, glucose-6-phosphate; G6PD, glucose-6-phosphate dehydrogenase; HMP, hexose monophosphate; NADP, nicotinamide-adenine dinudeotide phosphate; PAL-CoA, palmitoyl-CoA; SDS, sodium dodecyl sulfate; Tris, tris (hydroxymethyl)amino methane; CFA, complete Freund's adjuvant; GLC, gas liquid chromatography; IFA, incomplete Freund's adjuvant; PAGE, polyacrylamide gel electrophoresis; TLC, thin layer chromatography.

50 C for 20 min and shaken vigorously with 25% butanol for one min. Then, centrifugation was done at 36,000 × g for 30 min to remove the lipids and denatured proteins. The delipidated cytosol was lyophilized to remove butanol completely. Dry powder thus obtained was dissolved in 0.01 M Tris-HCl buffer, pH 8.5, and incubated with 12-(9-anthroyl)stearic acid dissolved in butanol at 37 C for 30 min. This sample was chromatographed on a Sephacryl S-200 column (2.5 × 60 cm, flow rate 25 ml/hr) equilibrated with the same buffer. Fractions of 4.5 ml each were collected and assayed for protein and 12-(9-anthroyl)-stearic acid. Those corresponding to the second peak were pooled and lyophilized. The dry powder was dissolved in the same buffer and chromatographed on a DEAE cellulose column (1.5 × 10 cm) equilibrated with a linear gradient of NaCl up to 0.3 M in 0.01 M Tris-HCl, pH 8.5. Fractions of 2 ml each were collected and assayed at 280 nm for protein and at 364 nm for 12-(9-anthroyl)-stearic acid in a Hitachi Spectrophotometer (Model No. 200-20). SDS gel electrophoresis was carried out according to the method of Laemmli and Favre (21). In other experiments, placental cytosol was lyophilized without prior heat treatment and butanol precipitation. Dry powder then was dissolved in 0.01 M Tris-HCl buffer, pH 8.5, and chromatographed on a Sephacryl S-200 column (2.5 × 60 cm, flow rate 25 ml/hr) equilibrated with the same buffer. Fractions of 4.5 ml each were collected and assayed for the proteins of placental supernatant.

Lipid analysis. Lipids were extracted from native and butanol-treated samples by the method of Folch et al. (22) and were separated by thin layer chromatography (TLC) (0.25 mm Silica Gel 60 in petroleum ether/diethyl ether/glacial acetic acid, 80:20:1). Appropriate zones were identified by means of standards and were extracted from the chromatogram. For analysis of covalently bound fatty acids, the protein was extracted three times with chloroform/methanol (1:1) and then hydrolyzed in 5.7 M HCl at 110 C for 24 hr under vacuum. Free fatty acids were extracted from the hydrolysate as described above. Fatty acid methyl esters were prepared by heating at 80–90 C for two hr in methanol/benzene/sulfuric acid (86:10:4) (23) and were separated by gas liquid chromatography (GLC) on a 6 ft × ⅛ in column of 10% diethylene glycol succinate on 100–120 chromosorb WHP using a Hewlett Packard Chromatograph equipped with a flame ionization detector. Pure methyl esters were used as standards.

Immunological studies. For raising antibody, the DE-II fraction of FABP was dialyzed extensively against distilled water and lyophilized. The homogeneity of the DE-II preparations was checked by polyacrylamide gel electrophoresis (PAGE) under nondenaturing and denaturing conditions. Monomeric DE-II was found to be very weakly immunogenic, thus this protein was polymerized with EDAC. Rabbits were immunized with two subcutaneous injections of polymerized DE-II in 0.9% saline emulsified in CFA (1:1) given at an interval of 10 days (0.5 mg of DE-II/injection), followed by one injection with IFA. The immunesera was collected about 10 days after the last injection. Specificity of antiserum and immunochemical identity of antigens in various FABP fractions as well as in placental cytosol was assayed by Ouchterlony double immunodiffusion method (24).

Preparation and assay of G6PD. Human placentas were dissected, homogenized in a glass homogenizer in 0.25 M sucrose to obtain 20% homogenate and centrifuged at 105,000 × g for one hr at 0–4 C. The enzyme activity was measured in the cytosolic portion according to the method of Löhr and Waller (25) following the increase in absorbance at 340 nm. Protein was estimated according to the method of Lowry et al. (26).

RESULTS

Purification of FABP. In an earlier communication by us, the presence of FABP in human placenta throughout the gestation has been indicated (20). Purification of FABP from placentas of all gestations is being reported in this

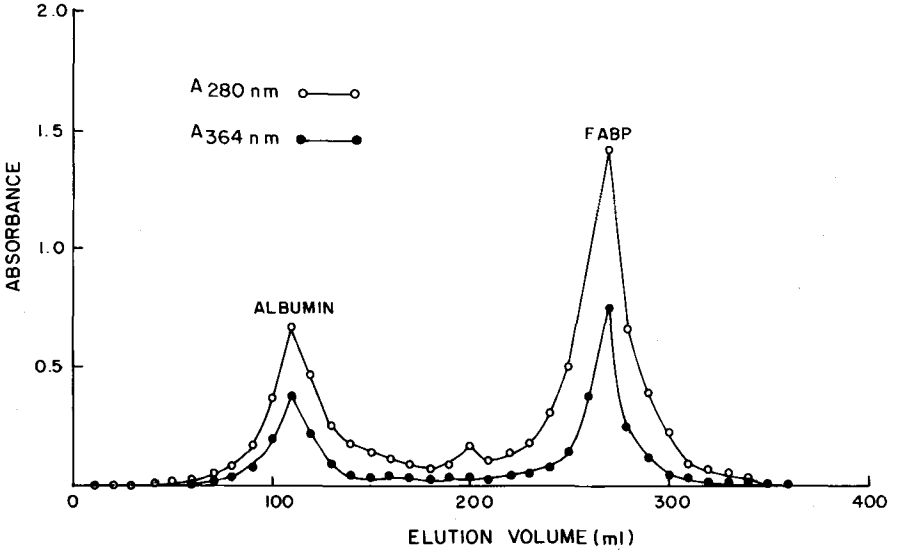

FIG. 1. Gel filtration of human placental cytosolic proteins on Sephacryl S-200. The protein sample (O) after heat treatment and delipidation was charged with 12-(9-anthroyl)stearic acid (●) as described under Materials and Methods and fractionated on a Sephacryl S-200 column (2.5 × 60 cm) equilibrated with 0.01 M Tris-HCl, pH 8.5.

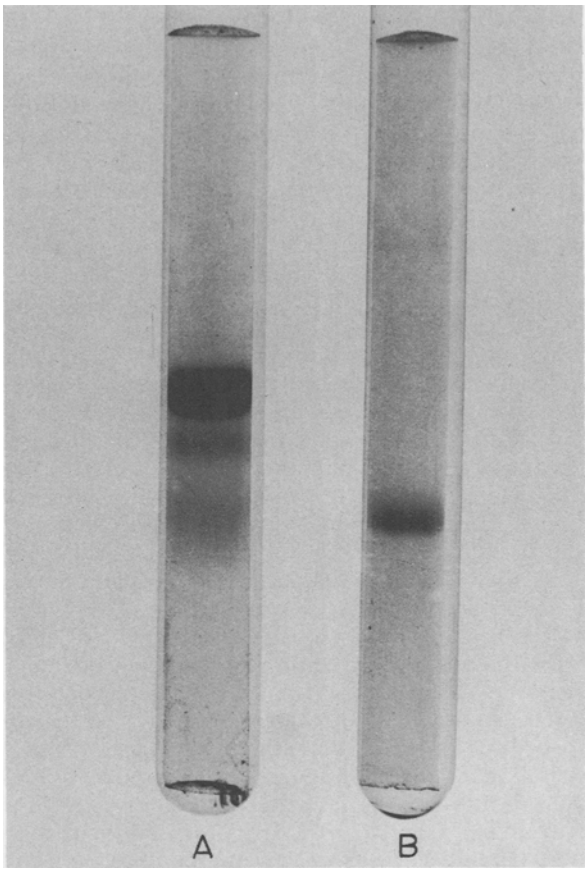

FIG. 2. Ten percent polyacrylamide gel electrophoresis of human placental FABP after Sephacryl S-200 fractionation; (A) under nondenaturing condition; (B) in presence of SDS.

paper. Because an almost similar pattern has been found for FABP in each gestation, results of mid-gestation, i.e. 18–22 wk, are shown here.

When the delipidated cytosolic proteins from human placenta were charged with 12-(9-anthroyl)stearic acid and separated by chromatography on Sephacryl S-200, the fatty acid emerged from the column in two peaks (Fig. 1). The first peak corresponds to serum albumin according to its position. The second peak was due to FABP. These fractions showing three bands in polyacrylamide gel electrophoresis and a single band in polyacrylamide gel electrophoresis in presence of SDS (Fig. 2) were further resolved into three peaks by DEAE cellulose chromatography (Fig. 3). The first of these, i.e. DE-I, was absorbed weakly to the DEAE column and eluted with the equilibrating buffer (0.01 M Tris-HCl, pH 8.5). DE-II and DE-III were eluted with a linear gradient of NaCl up to 0.3 M in the same buffer. DE-I and DE-III showed virtually no binding with 12-(9-anthroyl)stearic acid, but DE-II showed considerable binding. The presence of endogenous fatty acids in DE-II and DE-III (without delipidation or addition of exogenous fatty acid) was detected by TLC after lipid extraction (figure not shown here). GLC analysis revealed that DE-II binds long chain fatty acids nonspecifically, but DE-III is mainly an arachidonic acid binder (Table 1). However, long chain fatty acids were the only detectable lipid component in these fractions and were completely extracted by organic solvent and not detected in the acid hydrolysate of residue proteins. Each of the three fractions gave a single band (Fig. 4) and had an almost similar R_f value on polyacrylamide gel electrophoresis in presence of SDS, which corresponds to the molecular weight of 14,200 Daltons (Fig. 4). When the placental cytosol (without prior heat

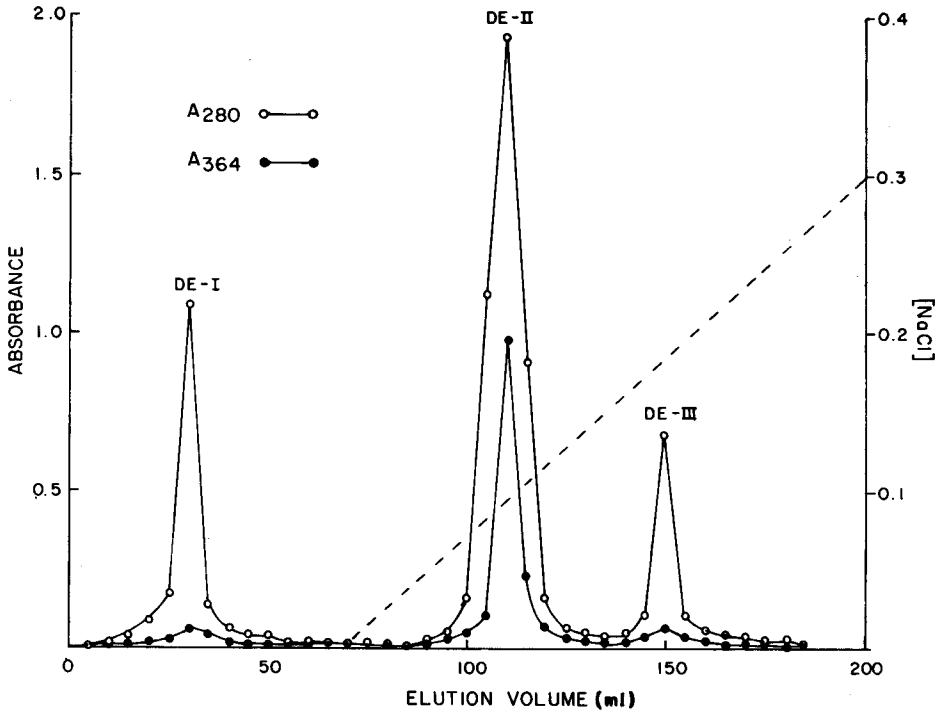

FIG. 3. Chromatography of FABP on DEAE cellulose. Protein concentration (O) and 12-(9-anthroyl)stearic acid (●). Elution was achieved with a linear gradient of NaCl up to 0.3 M in 0.01 M Tris-HCl, pH 8.5.

TABLE 1

Endogenous Fatty Acid Composition of Different FABP Fractions from Human Placental Cytosol

FABP fractions	Bound fatty acids	
DE-I	Virtually lipid-free	
DE-II	Myristic acid	9.62%
	Palmitic acid	19.64%
	Stearic acid	13.99%
	Oleic acid	26.61%
	Linolenic acid	30.12%
DE-III	Palmitic acid	20.52%
	Stearic acid	4.61%
	Oleic acid	10.53%
	Arachidonic acid	64.20%

treatment or butanol precipitation) was chromatographed on Sephacryl S-200, five peaks were obtained (Fig. 5). The fifth peak corresponds to FABP. Endogenous fatty acids were detected in FABP, and in the second peak, which corresponds to serum albumin, by TLC after lipid extraction. The other three peaks were virtually lipid-free. DE-II was employed as an antigen for preparation of an antiserum to FABP. This antiserum produced a single immunoprecipitation line of identity against placental supernatant (Fig. 6A). It can be seen that there were identity reactions between this line and that formed with DE-I, DE-II and DE-III (Fig. 6B, C and D).

Regulation of palmitoyl-CoA inhibition of G6PD by FABP. G6PD activity was found throughout the gestations so far studied. As high activity was associated with 10–15 wk of gestation, further studies have been carried out with tissues of this period. Human placental G6PD was found to be inhibited by PAL-CoA (Fig. 7A). In the experiments shown in curves a, b and c, the reactions were started by the addition of the enzyme. Nearly 50% inhibition was obtained by 0.03 mM PAL-CoA, and almost

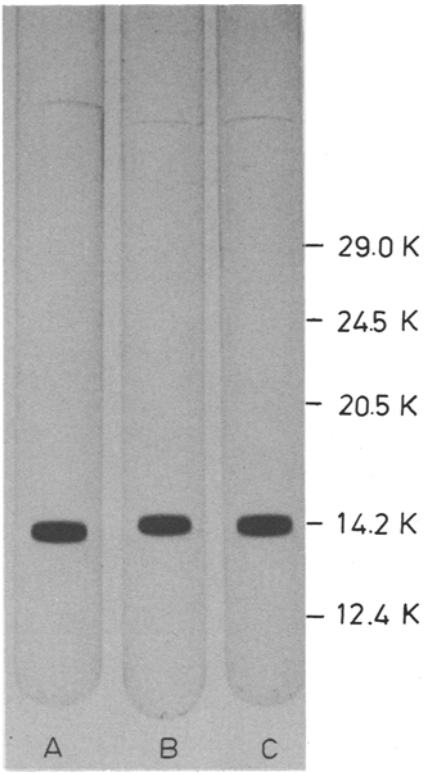

FIG. 4. Ten percent polyacrylamide gel electrophoresis in the presence of SDS. Electrophoresis was carried out at pH 8.3. A, DE-I; B, DE-II; C, DE-III.

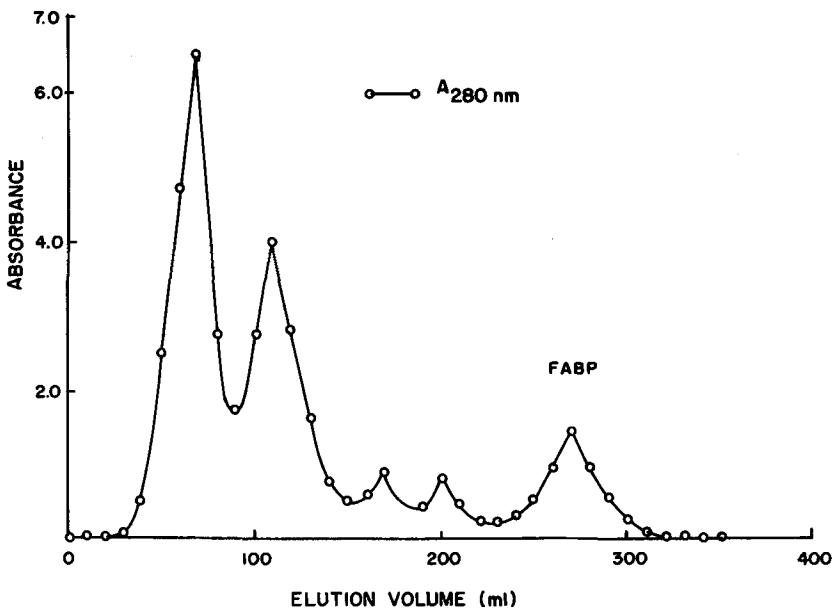

FIG. 5. Gel filtration of human placental cytosolic proteins on Sephacryl S-200. The protein sample (O), without any heat treatment or butanol precipitation, was fractionated on a Sephacryl S-200 column (2.5 × 60 cm) equilibrated with 0.01 M Tris-HCl, pH 8.5.

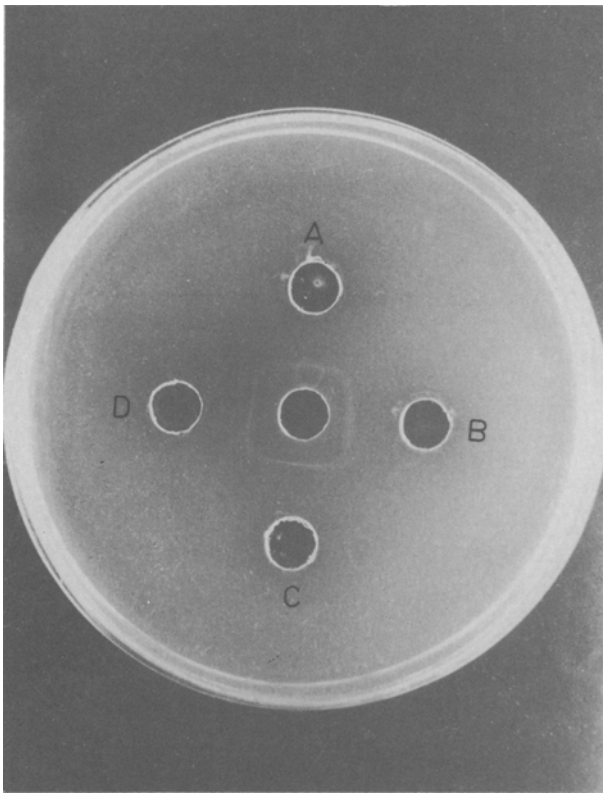

FIG. 6. Ouchterlony double immunodiffusion. Central well contained antisera against DE-II (0.84 mg). A, Human placental supernatant (40 μg); B, DE-I (10 μg); C, DE-II (10 μg); D, DE-III (10 μg).

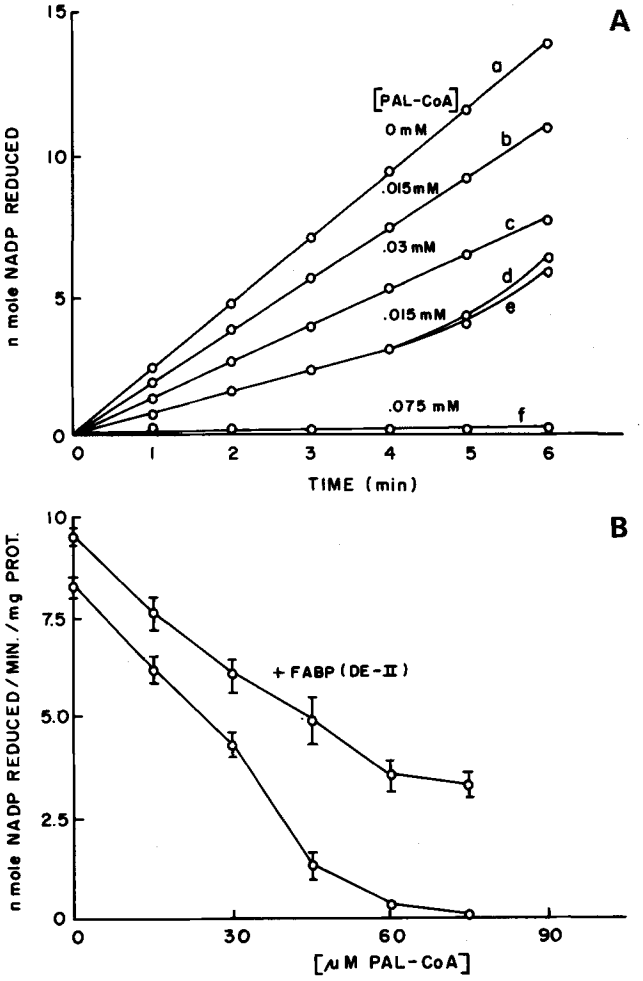

FIG. 7. (A) Inhibition of human placental G6PD by PAL-CoA. The assay mixture contained 0.05 M triethanolamine buffer, pH 7.5, 0.13 mM G6P, 0.1 mM NADP, 0.25 μg/ml of enzyme and PAL—CoA as indicated in a total volume of 3.0 ml. Reaction was started by the addition of enzyme (curves a, b, c and f). The enzyme was preincubated for three min with PAL-CoA and either NADP (curve b) or G6P (curve d), and the reaction was started by the addition of the other substrate. In curve e, the enzyme was preincubated for three min with PAL-CoA alone. (B) Effect of FABP on human placental G6PD activity. Assay mixture contained 0.05 M triethanolamine buffer, pH 7.5, 0.13 mM G6P, 0.1 mM NADP, 0.25 μg/ml enzyme and PAL-CoA as indicated in a total volume of 3 ml. Concentration of FABP was 25 μg/ml. Each point is the mean ± SEM of triplicate experiments.

complete inhibition was obtained with 0.075 mM PAL-CoA (curves c and f, respectively). When the enzyme was preincubated with PAL-CoA and NADP, the extent of inhibition was the same as that shown in curve b. However, when the enzyme and PAL-CoA were preincubated with either G6P alone (curve d) or without any substrate (curve e), inhibition was more severe for the first five min. Thereafter, less inhibition was observed. These results show that NADP but not G6P protects the enzyme against PAL-CoA inhibition.

It is evident from Figure 7B that DE-II reversed the inhibition of G6PD by PAL-CoA. When DE-II was added in absence of any exogenous PAL-CoA, the enzyme was stimulated. Other cytosolic proteins of the placenta, which did not bind endogenous fatty acids, have no effect on the inhibition of G6PD by PAL-CoA.

DISCUSSION

Results of the separation of FABP into three fractions by DEAE cellulose chromatography conform with those reported by Takahashi et al. (27). Human placental FABP can be grouped into at least three distinct fractions with respect to their lipid content (Table 1), i.e. DE-I (almost lipid-free), DE-II (binds long chain fatty acids nonspecifically) and DE-III (binds arachidonic acid mainly). Purification of DE-III from human placenta is of particular importance because arachidonic acid is known to be a common precursor of various prostaglandins, but it cannot be synthesized de novo inside the fetal tissues. Thus, it is mandatory for the fetus to import arachidonic acid from the maternal source through the placenta, and it has been reported that the concentration of this polyunsaturated fatty acid is high in fetal blood (28). DE-I, DE-II and DE-III were found to contain no detectable phospholipids, suggesting that they are not likely to be involved in phospholipid transfer or exchange. These proteins bind ligands noncovalently because long chain fatty acids were completely extracted by organic solvent and not detected in the acid hydrolysate of the residue proteins.

From the Ouchterlony double immunodiffusion studies, it is evident that human placental FABP exists in several immunochemically identical forms, differing in amount

and nature of bound endogenous fatty acids and in isoelectric points. That bound ligands may influence the charge of the carrier molecule is shown by the effect of the bound fatty acid on the pI of serum albumin (29). Other possible explanations for the existence of charge isoforms of FABP are not excluded.

Inhibition of G6PD by PAL-CoA has been proposed as the possible regulatory mechanism for lipogenesis and ketogenesis (13). Because NADP protects the dehydrogenase against PAL-CoA inhibition (Fig. 7A), the binding sites for the two ligands cannot be identical. According to Kawaguchi and Bloch (18), PAL-CoA produces a conformationally altered dehydrogenase with lowered affinity for NADP. The destabilized, coenzyme-depleted tetramer then dissociates to the dimer with exposure of high affinity sites for PAL-CoA. Displacement of PAL-CoA from the inactive enzyme by human placental FABP, which has a high affinity for the inhibitor, regenerates the dehydrogenase tetramer. FABP can reverse the inhibition by removing the inhibitor rather than affecting the enzyme directly. In absence of any exogenous PAL-CoA, G6PD is activated by FABP, indicating the binding of endogenous inhibitors by the latter. These results may explain why these inhibitory effects of long chain fatty acyl-CoA are not seen in intact cells. Such regulation of G6PD by FABP is important because this enzyme is the main source of NADPH for lipid biosynthesis during embryogenesis.

The binding properties and widespread tissue distribution of FABP suggest that it may participate in the potentially critical aspects of cellular physiology and may serve as intracellular analogues of albumin (27), affecting the transport and compartmentation of long chain fatty acids and fatty acyl-CoA inside the cells. Further work is underway to study the structure and function relationship of DE-I, DE-II and DE-III to find out their exact roles in lipid transport and metabolism during human embryogenesis. A possible role in carcinogenesis has been postulated for FABP (30). Hence, characterization of these proteins is of utmost importance for the safety of the unborn child.

Geraniol Interferes with Membrane Functions in Strains of *Candida* and *Saccharomyces*

Martin Bard*, Mark R. Albrecht, Navyash Gupta, Cynthia J. Guynn and William Stillwell
Indiana University-Purdue University at Indianapolis, Department of Biology, 1125 East 38th St., P.O. Box 647, Indianapolis, IN 46223

Geraniol, an olefinic terpene, was found to inhibit growth of *Candida albicans* and *Saccharomyces cerevisiae* strains. Geraniol was shown to enhance the rate of potassium leakage out of whole cells and also was shown by fluorescence polarization to increase *C. albicans* membrane fluidity. Biophysical studies using differential scanning calorimetry, fluorescence polarization and osmotic swelling of phospholipid vesicles demonstrated that geraniol decreased the phase-transition temperature of dipalmitoylphosphatidylcholine vesicles, affected fluidity throughout the bilayer, particularly the central portion of the bilayers, and caused an increase in bilayer permeability to erythritol. Geraniol may have potential use as an antifungal agent.
***Lipids* 23, 534–538 (1988).**

Geraniol, an olefinic terpene isolated from rose and palm oils, is structurally similar to geranyl pyrophosphate, an essential intermediate in the ergosterol biosynthetic pathway (Fig. 1). This similarity suggested that geraniol may be an inhibitor of ergosterol biosynthetic enzymes either involved in geranyl-pyrophosphate formation (geranyl pyrophosphate synthase) or its conversion to farnesyl pyrophosphate (farnesyl pyrophosphate synthase). Many antifungals such as the azoles (econazole, ketoconazole, miconazole) interfere with ergosterol biosynthesis by inhibiting specific steps such as lanosterol demethylation (1,2) or, as in the case of naftifine, inhibit squalene epoxidase (3). Other antifungals such as the azasterols inhibit sterol methylation (4,5). Another category of antifungals, the polyenes, inhibit fungal cells having sterols in their cell membrane. Cell lines in *Candida* and *Saccharomyces* resistant to the polyene antibiotics generally have ergosterol intermediates rather than ergosterol in their cell membranes (6,7).

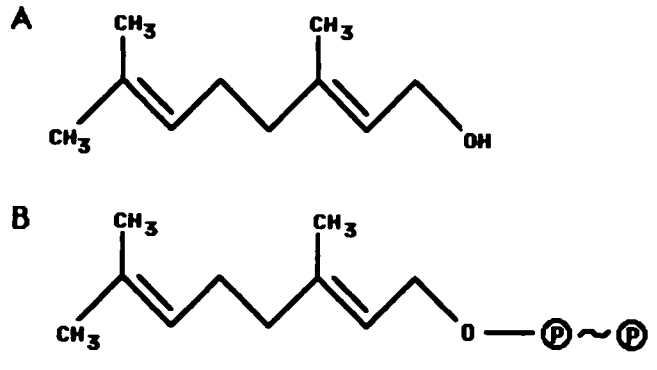

FIG. 1. Structural comparison of (A) geraniol and (B) geranyl pyrophosphate.

In this report, we demonstrate that three clinical isolates of *Candida albicans* and one haploid *Saccharomyces cerevisiae* lab strain are sensitive to the effects of geraniol and that geraniol causes changes in membrane dynamics rather than inhibiting ergosterol biosynthesis. In ergosterol biosynthesis, geranyl pyrophosphate is converted to farnesyl pyrophosphate, and the latter differs from the former in containing an additional isoprenoid unit. Attempts to inhibit growth of several *Saccharomyces* strains using varying concentrations of farnesol (exceeding 5-fold the concentration of geraniol that totally inhibited growth) resulted in no growth inhibition. This suggests that geraniol inhibition is not merely due to the hydrophobicity of the geraniol molecule. Here we compare the effect of geraniol on membrane properties of living cells with its effects on well-defined phospholipid bilayers.

MATERIALS AND METHODS

Yeast strains and media. The three *C. albicans* isolates were A26 (a clinical isolate received from R. Gordee, Eli Lilly & Co., Indianapolis, IN), hOG 357 (an arginine, adenine, methionine auxotrophic strain received from P. Magee, Michigan State University) and ATCC strain 44829 (a clinical isolate mutagenized and selected for adenine auxotrophy). The wild-type, A184D, *S. cerevisiae* strain has been described (8). Yeast cells were grown in a yeast-complete medium (YPD) containing 1% yeast extract, 2% Bacto-peptone, 2% dextrose and 2% agar. Ergosterol was added at 5×10^{-5} M to complete medium from a stock solution of 0.2% ergosterol in Tween 80/ethanol (1:1, v/v). Geraniol was added from a stock solution of geraniol/ethanol (1:1, v/v).

Liposome vesicle preparation and differential scanning calorimetry. Multilamellar vesicles (MLV) comprised of dipalmitoylphosphatidylcholine (DPPC) were made containing between 0 and 20 membrane mol% geraniol by the method of Bangham (9) at 65 C in 100 mM potassium phosphate buffer, pH 7.5, and processed in a "Liposor" lipid vesicle maker (Lidex Technologies, Bedford, MA). The lipid concentration was 100 mg/ml and the weight of samples ca. 6.5 mg. Phase transitions were measured in a Perkin-Elmer Series 7 Differential Scanning Calorimeter.

Fluorescence polarization studies. Fluorescence polarization measurements were made on both DPPC lipid vesicles as well as *C. albicans* whole cells.

Lipid vesicles. MLV were made from DPPC as described above at 10 mg/ml and were sonicated in 20 mM potassium phosphate, pH 7.5, buffer on a Heat Systems W220-F cell disrupter for five min until the solution cleared. The sonicated vesicles were either 100 mol% DPPC or 80 mol% DPPC/20 mol% geraniol. 9-Anthroyloxy-stearic acids labeled at positions 2, 6, 9 or 12 were incorporated into the bilayers during their synthesis at

*To whom correspondence should be addressed.

Abbreviations: AS, anthracene stearic acid; DPH, 1,6-diphenyl-1,3,5-hexatriene; DPPC, dipalmitoylphosphatidylcholine; MIC, minimum inhibitory concentration; MLV, multilamellar vesicles; P, polarization; TMA-DPH, 1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene; YPD, yeast-complete medium.

a ratio of 200 lipids/AS. Polarization measurements were made on a Perkin-Elmer MPF-66 Fluorescence Spectrophotometer at decreasing temperatures between 50 C and 30 C. Excitation was at 361 nm and emission at 446 nm. Temperature in the cuvettes was monitored accurately by a thermoprobe. Polarization values were calculated as described by Chefurka et al. (10) by the equation:

$$P = \frac{I_{vv} - G\,(I_{vh})}{I_{vv} + G\,(I_{vh})}$$

where I represents fluorescent intensity, G is the "grating factor" (I_{hv}/I_{hh}), and h and v refer to the position of the polarizers either horizontal or vertical.

Whole cells. C. albicans strain, hOG 357, was grown overnight to mid-log phase (O.D.$_{660}$ 0.5) in YPD medium, pelleted and washed two times in a 10 mM Tris, pH 7.0, 0.9% NaCl buffer. Cells were resuspended in the same buffer also containing 1% Tween 80 at a final concentration of 4×10^6 cells/ml. The presence of Tween 80, a non-ionic polyoxyethylene detergent containing oleic acid, enhanced geraniol solubility and was included at the same concentration for all cell suspensions. Membrane polarization was determined for the cell membrane interior by 1,6-diphenyl-1,3,5-hexatriene (DPH) and for the aqueous-membrane interface by 1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene (TMA-DPH). Fluorescent labels (43 μM) were dispersed into cell populations using N,N-dimethylformamide as carrier. Cells were preincubated at 37 C for one hr, after which various concentration of geraniol were added. Cells containing fluorescent label and geraniol were further incubated for 90 min. Wavelengths for excitation were 351 nm (DPH) and 358 nm (TMA-DPH) and emission 430 nm (DPH) and 426 nm (TMA-DPH) with experimental temperatures set at 37 C. Polarization (P) values are the average of five separate determinations. All fluorescent labels were purchases from Molecular Probes (Eugene, OR).

Erythritol permeability studies. Egg phosphatidylcholine lipid vesicles containing varying amounts of geraniol (from 0 to 20 membrane mol%) were made by the same method used in the differential scanning calorimetry experiments but at a concentration of 10 mg/ml. The vesicles were rapidly injected into a swelling buffer of 10 mM potassium phosphate and 40 mM erythritol, pH 7.0. Over the time of the measurement (ca. 30 sec), glucose does not cross the bilayer; however, the smaller erythritol molecule does cross down its concentration gradient into the vesicles, causing a hypotonic state. The subsequent water movement results in vesicle swelling, which is measured as a change in absorbance. Lipid vesicles are known to behave as almost perfect osmometers (11), so initial swelling rates (12,13) of the vesicles are an accurate indication of erythritol permeability. Absorbances at 500 nm were recorded in a temperature controlled Beckman DU-8 Computing Spectrophotometer. Results are expressed as initial swelling velocity dl/A/dt% and reported as the average of four to six determinations.

Potassium leakage studies. C. albicans strain, hOG 357, was grown, harvested and resuspended in buffer essentially as described for fluorescence polarization using whole cells except that cells were resuspended at a concentration of 3×10^7 cells/ml. Potassium leakage was measured with a K^+ specific electrode (Microelectrodes, Londonderry, NH) on an Orion 901 Microprocessor Ionanalyzer. After six hr, cells were completely lysed in 3% Triton X-100, and the maximum sequestered K^+ was determined.

RESULTS AND DISCUSSION

Minimal inhibitory concentration (MIC) of geraniol. Yeast cells grown overnight in a YPD (1% yeast extract, 2% peptone, 2% dextrose, and 2% agar) were plated onto YPD plates containing varying concentrations of geraniol at a density of 10^5 cells per plate. Plates were scored after 48 hr, and the results are presented in Table 1. The minimum inhibitory concentration (MIC) of geraniol is defined as that concentration that completely prevents growth after 48 hr. All three *Candida* strains as well as the *Saccharomyces* strain were approximately equally sensitive to geraniol. The numbers in parentheses indicate the MIC in mM concentrations. To determine whether ergosterol supplementation reverses the antifungal effect, plates containing 5×10^{-5} M ergosterol and geraniol were tested. The results with ergosterol supplementation were the same as without ergosterol supplementation, indicating that inhibition of ergosterol synthesis was not the mode of geraniol inhibition or that ergosterol was not taken up from the growth medium. Because liquid YPD cultures innoculated to a visible turbid density when incubated overnight with inhibitory concentrations of geraniol often cleared, this suggested that geraniol may act at the level of the plasma membrane, causing cell lysis.

Lipid vesicle fluidity. To ascertain whether geraniol affects cell membranes by altering bilayers properties, geraniol was incorporated into phospholipid vesicles. Differential scanning calorimetry indicated geraniol broadened and decreased the phospholipid phase transition temperature of the synthetic phospholipid DPPC. Figure 2 demonstrates that increasing concentrations of geraniol from 0 to 20 mol% broadened and decreased the phase transition temperatures of the liposome vesicles 2.2 C indicating that geraniol disorders the bilayers. This suggests geraniol also may have a fluidizing effect on yeast cell membranes.

To test membrane fluidity, fluorescence polarization was employed (14). Anthracene-labeled stearic acids (AS)

[b]Number in parentheses indicates MIC of geraniol in mM concentrations.

have been used to probe the effect of a number of compounds on fluidity as a function of depth in the bilayer (10). Fluorescence polarization measurements also can be used to determine the phase transition temperature of bilayers comprised of synthetic phospholipids (10,15).

The results in Figure 3 show that, as expected, polarization values decreased (relative fluidity increased) from position 2 near the membrane surface to position 12 near the bilayer interior. For all four positions and in the gel and liquid crystalline states, geraniol decreased the P-values (increased fluidity). For DPPC in the liquid crystalline state, the average decrease in P caused by geraniol over the temperature range 50 C to 41 C can be used to compare quantitatively the effect of geraniol at different depths in the bilayer. The values expressed as $\Delta P_{average}$ for the 10 temperatures are: 2 AS, 0.0023; 6 AS, 0.0067; 9 AS, 0.0038; and 12 AS, 0.0041. Clearly, geraniol enhances fluidity at all positions along the chain with the largest effect associated with position 6. This agrees with the structure of geraniol (Fig. 1), which has methyl branches at positions 3 and 7 and so would be expected to disorder bilayers in the central part of the chain more than at either end. These results are in contrast to those for n-alkanols, which mostly perturb the bilayer center (16). In agreement with the differential scanning calorimetry measurements reported in Figure 2, 20 mol% geraniol broadens and decreases the phase transition temperature of DPPC by about 2 C.

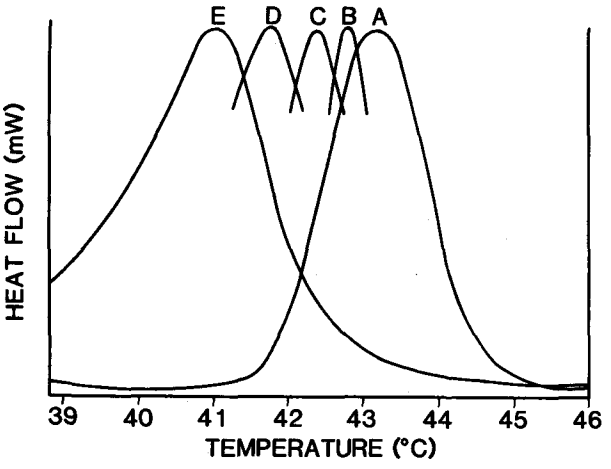

FIG. 2. Effect of geraniol on the phase transition of dipalmitoylphosphatidylcholine vesicles. Geraniol membrane concentration: (A) 0 mol%, (B) 5 mol%, (C) 10 mol%, (D) 15 mol% and (E) 20 mol%.

Cell fluidity. Fluidity also was ascertained by fluorescence polarization with *C. albicans* whole cells. The bilayer interior probe DPH indicated an enhanced membrane fluidity as a function of geraniol concentration (Fig. 4A), while the surface probe TMA-DPH also showed that geraniol enhanced probe motion (fluidity) at the aqueous interface (Fig. 4B). These results confirm those with DPPC lipid vesciles (Fig. 3) and show that geraniol's

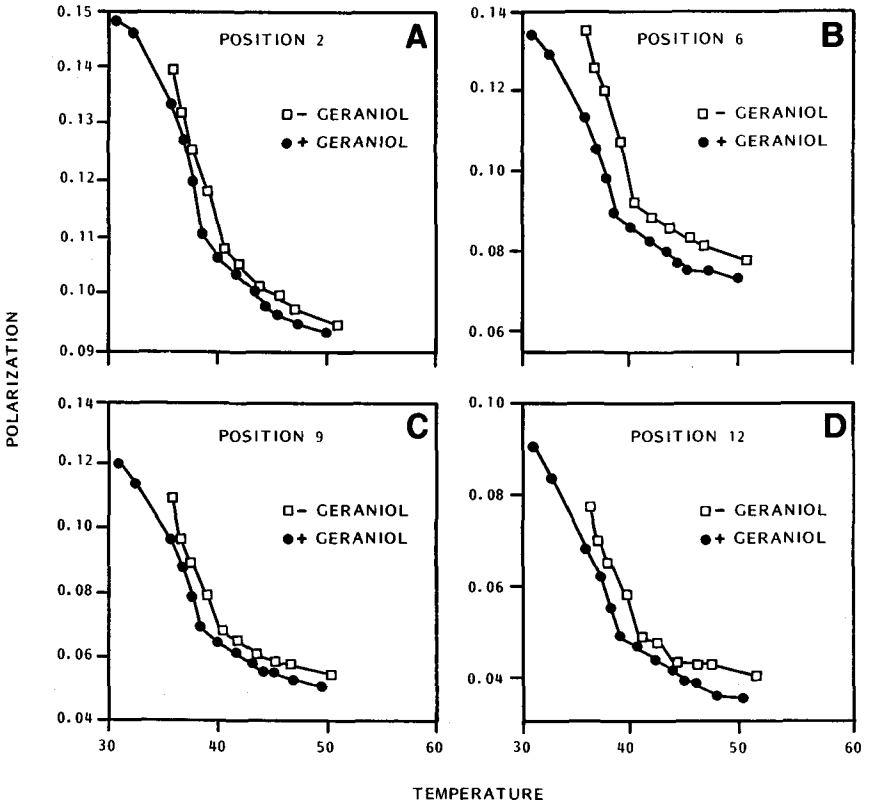

FIG. 3. Effects of geraniol on the polarization of DPPC vesicles as a function of temperature. Geraniol concentration is 20 mol% with respect to DPPC. Fluorescent labels are 2 AS (panel A), 6 AS (panel B), 9 AS (panel C) and 12 AS (panel D). Results, expressed as P, are the average of five determinations and vary 0.0015.

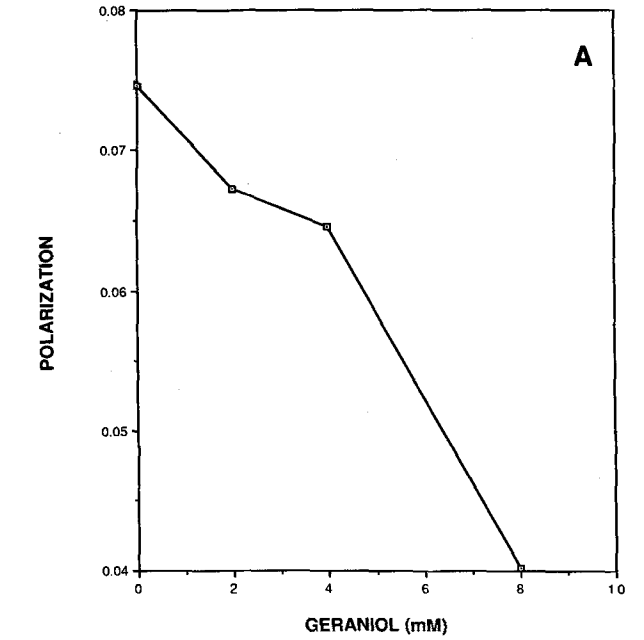
ability to increase bilayer fluidity extends to natural membranes.

Lipid vesicle permeability. A light-scattering technique measuring the permeability of erythritol was used to quantitate the effect of geraniol on general membrane permeability. Geraniol-induced erythritol permeability at different temperatures is shown in Figure 5. Geraniol concentrations are expressed as the mol% geraniol/phosphatidylcholine. Concentrations range from 0% (curve A) to 20 mol% geraniol (curve F). These results also demonstrate that geraniol enhancement of permeability is greater in the more fluid bilayer, that is, at higher temperatures.



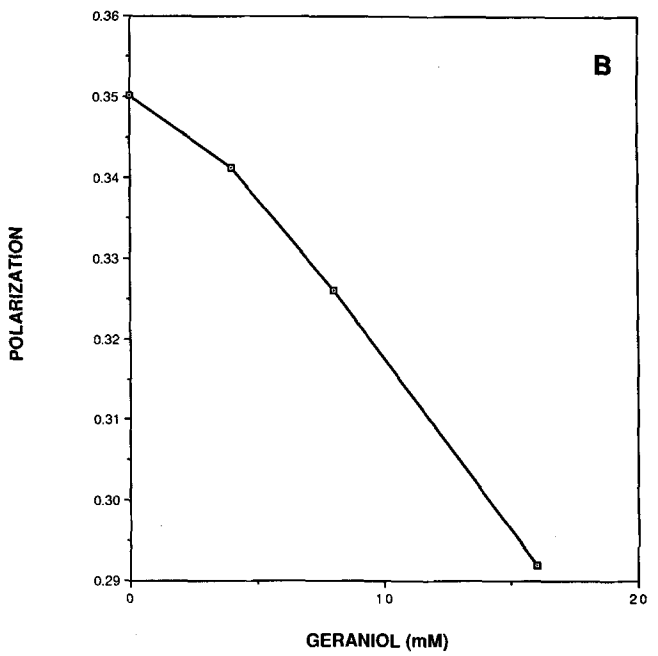


FIG. 4. Effect of geraniol on the polarization of *C. albicans* whole cell membranes. Panel (A) DPH; Panel (B) TMA-DPH. Concentrations of geraniol varied from 0–16 mM.

Potassium leakage from whole cells. The observations that geraniol alters phase transition temperature of liposome vesicles, increases bilayer fluidity and increases liposome permeability to erythritol suggested that the antifungal activity of the molecule also may enhance the rate of solute leakage (K^+) out of whole cells. Results (Fig. 6) are expressed as the percentage of internal sequestered K^+ leaking out of the cell as a function of time. These results indicate that increasing geraniol concentrations do enhance K^+ leakage most markedly in the first two hr. For example, after two hr cells incubated without geraniol showed a 5% K^+ leakage, whereas cells incubated with 12 mM geraniol showed a 28% K^+ leakage.

In conclusion, the experiments presented here on *Candida* and *Saccharomyces* fungal strains, as well as on protein-free phospholipid vesicles, may help to understand the mode of action of geraniol in preventing fungal

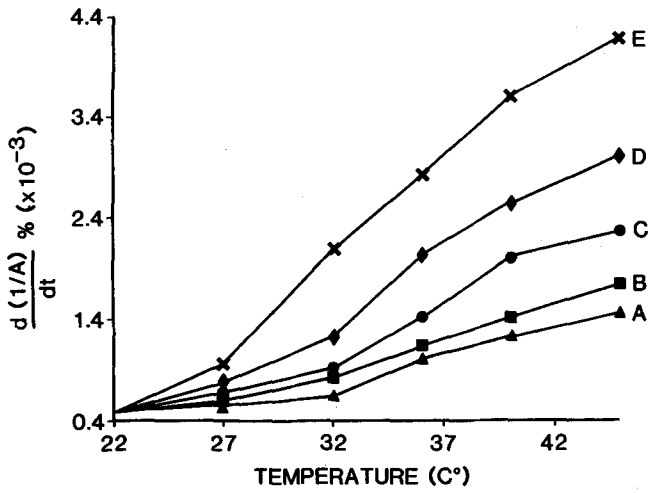

FIG. 5. Effect of geraniol on the permeability of egg phosphatidylcholine vesicles to erythritol. Geraniol membrane concentration: (A) 0 mol%; (B) 5 mol%; (C) 10 mol%; (D) 15 mol%; and (E) 20 mol%.

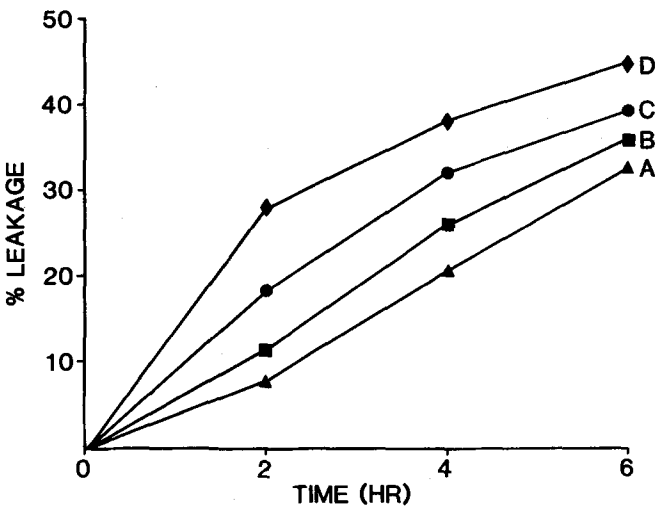

FIG. 6. Effect of geraniol on the leakage of K^+ from *C. albicans* strain hOG 357. Results are expressed as the percentage of initially sequestered K^+ leaking out with time. Geraniol concentration in the bathing solution (10 mM Tris, pH 7.0, 1% Tween 80, 0.9% NaCl). (A) 0 mM; (B) 4 mM; (C) 8 mM; and (D) 12 mM.

growth. Geraniol does not appear to inhibit ergosterol biosynthesis as its primary mode of action but instead appears to partition into membranes where it alters bilayer properties. Upon incorporation of geraniol, membranes become more fluid (as indicated by a broadening and decrease in the phase transition temperature of DPPC vesicles as well as by polarization measurements with AS labels with lipid vesicles and DPH and TMA-DPH measurements on whole cells), while general bilayer permeability is increased (as indicated by vesicle swelling in isomolar erythritol and K^+ leakage from cells).

Cushley et al. (17) have reported similar membrane effects caused by the larger brancher chain alcohol, phytol. This alcohol also broadened and decreased phospholipid phase transitions, decreased membrane order and increased permeability to the cationic NMR shift reagent Pr^{3+}. It was proposed that phytol acts as a membrane-destabilizing agent, increasing membrane permeability. In light of these studies, it is not surprising that geraniol also destabilizes membranes.

Inhibition of cell growth may be the result of altered membranes with the symptomatic loss of cellular potassium. We conclude that the antifungal activity of geraniol resides with its ability to disrupt membrane bilayer structures and, therefore, cellular processes.

The experiments presented here represent an attempt to link biophysical data with biological processes to establish a mode of action of any drug that is thought to be membrane-disruptive. The assessment of geraniol as an antifungal agent for plants or animals remains to be determined.

ACKNOWLEDGMENTS

We thank R. Gordee and P. Magee for making their strains available to us. This work was in part supported by a NSF grant DMB-8607071.

Polyunsaturated Fatty Acids of Serum Lipids in Myocardial Infarction

John W. Crofts[a], Paul L. Ogburn Jr.[b], Susan B. Johnson[c] and Ralph T. Holman[c,*]

[a]Department of Ophthalmology, Henry Ford Hospital, Detroit, MI, [b]Women and Infants Hospital of Rhode Island, Providence, RI, and [c]The Hormel Institute, University of Minnesota, Austin, MN

Two groups of volunteers had blood drawn for serum analysis of fatty acids. The first group was comprised of patients admitted to the hospital with possible myocardial infarction (MI). Blood was drawn at admission and at 12, 24 and 48 hr. These patients were subsequently divided into three groups, those with MI, those without (No MI) and those taking prostaglandin inhibitors (PGI), on the basis of the cardiac enzymes, electrocardiograms and clinical history. A fourth group of Normal non-stressed people was also drawn at 0, 12, 24 and 48 hr for comparison. Fatty acid composition of phospholipids (PL), nonesterified fatty acids (NEFA), triglycerides (TG) and cholesteryl esters (CE) was determined by capillary gas chromatography (GC), and comparisons were made between the MI, No MI, PGI and Normal groups. Total NEFA were significantly elevated in patients admitted for possible MI compared with Normals. Those patients with MI had marginally higher levels of NEFA than the No MI group at each sampling time, but this difference was not statistically significant. The MI, No MI and PGI groups had significantly different fatty acid patterns in NEFA with reduced percentages of arachidonic acid (AA) than controls. The fatty acid patterns in the four lipid classes showed few significant differences comparing the MI, No MI and PGI groups. The regular use of prostaglandin inhibitors before hospitalization for chest pain was associated with a reduced frequency of MI ($p < 0.002$). NEFA levels, nonesterified AA levels and fatty acid patterns in this group did not differ from those patients not taking prostaglandin inhibitors.

Lipids 23, 539-545 (1988).

Myocardial infarction (MI) usually occurs as the result of partial or complete occlusion of one or more coronary arteries. Arachidonic acid (AA, 20:4ω6) metabolism may play a role in this pathology by several mechanisms: vasospasm mediated by thromboxane A_2 (TXA_2) production and prostacyclin (PGI_2) inhibition, platelet clot formation stimulated by TXA_2 due to vascular injury or plaque formation, and vascular occlusion by atherosclerotic plaque caused by vascular endothelial cell injury.

The general elevation of nonesterified fatty acids (NEFA) seen in association with myocardial damage may cause an increase in myocardial oxygen consumption, increased incidence of arrhythmias, and increased size of the infarction (1-4). Elevated NEFA have been shown to stimulate platelet aggregation (5). Thus, elevations of NEFA may contribute to the progression of tissue injury in MI by both increasing tissue oxygen requirements and by promoting vascular occlusion (Fig. 1). Two methods used to decrease the death rate in patients with MI have had some success: the inhibition of TXA_2 production and platelet activation using low-dose aspirin (6,7), and the suppression of circulating NEFA using glucose-insulin-potassium infusions (8).

The following study, which was approved by the University of Minnesota Committee on Human Investigations, sought to clarify the effects of stress and pain on elevation of NEFA with and without MI. Quantities of nonesterified AA in NEFA and fatty acid patterns in NEFA, cholesteryl esters (CE), triglycerides (TG) and phospholipids (PL) were compared in three types of patients: those with symptoms of MI and medically proven MI, those with symptoms of MI, but with no MI, and Normal controls with no symptoms of MI.

METHODS

A group of volunteers had blood drawn for serum analysis of fatty acids. The group was comprised of patients admitted acutely to a small, rural hospital for chest pain with possible MI. Blood was drawn on admission, at 12 hr, at 24 hr and at 48 hr for cardiac enzyme analysis and fatty acid analysis. Timing of each sample depended on admission and, therefore, was random with regard to prandial status. Patients were offered a no-added salt, low-cholesterol diet, either full liquids or solid food, but oral intake varied widely depending on appetite and clinical circumstances from 0 to 2,500 calories per 24 hr. Approximately 30% of caloric intake in either diet was from lipids, with equal amounts of saturated and unsaturated fats. In addition, IV access was maintained with 5% glucose solution until a definitive diagnosis of MI could be excluded and was continued at least 48 hr if MI was found. Intake of IV glucose by this route could vary from 240 to 600 calories per 24 hr. Subsequent to the completion of the fatty acid analyses, this group of patients was sorted into two groups: one in which MI had been confirmed by enzyme studies and electrocardiograms (experimental group = MI), and one that had not experienced MI on the basis of cardiac enzymes (control group = No MI).

A third group was made up of normal, non-stressed health care providers without chest pain and without MI (Normal). The Normal group (n = 10) had blood drawn at four times: 0, 12, 24 and 48 hr. The first and fourth samples were drawn after an overnight fast. The second and the third samples were taken two to three hr postprandial.

Pertinent clinical history for each group was obtained, and special attention was given to medications known to inhibit prostaglandin synthesis. Whenever possible, the use of these drugs was confirmed by direct questioning of the patient or review of outpatient clinic records.

Lipid extraction, methylation and gas chromatography. Serum samples were kept frozen until analysis.

Abbreviations: AA, arachidonic acid; CE, cholesteryl esters; DHLA, dihomogamma linolenic acid (20:3ω6); FAME, fatty acid methyl esters; MI, myocardial infarction; NEFA, nonesterified fatty acids; PGI, prostaglandin inhibitor; PGI_2, prostacyclin; PL, phospholipids; PUFA, polyunsaturated fatty acids; TG, triglycerides; ANOVA, analysis of variance; GC, capillary gas chromatography.

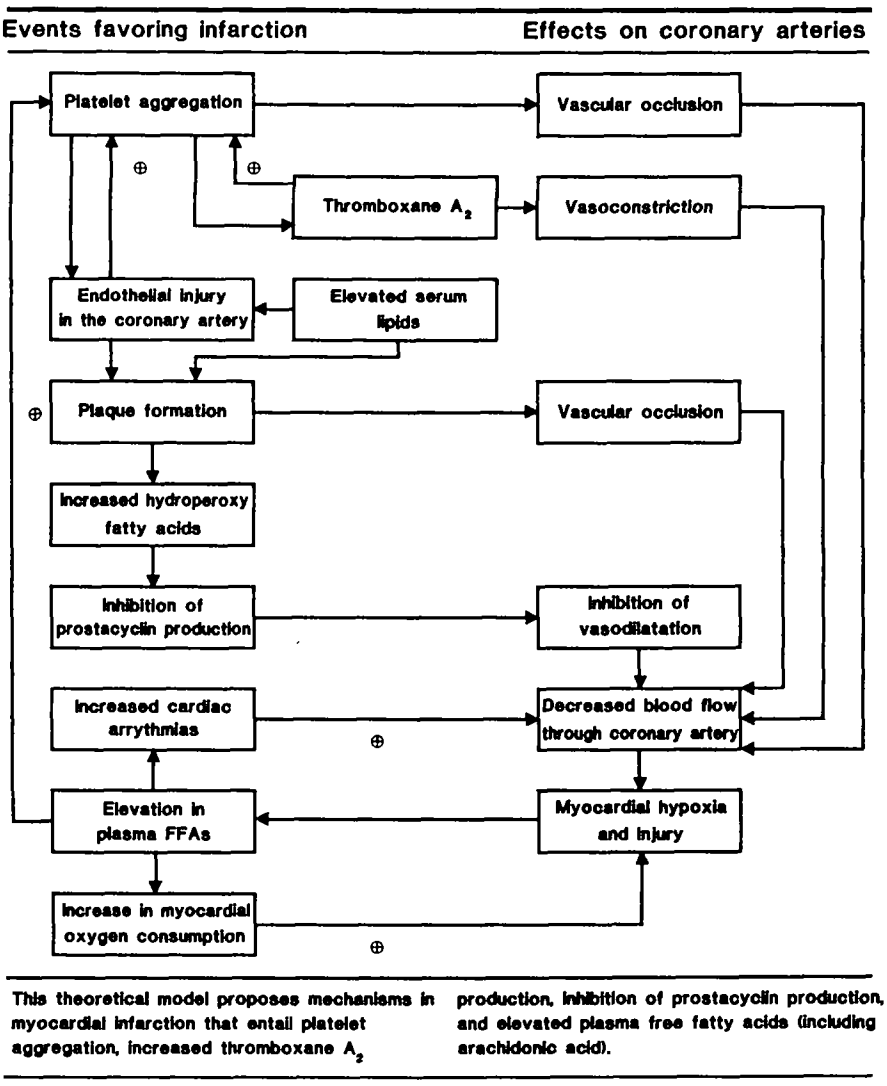

FIG. 1. Proposed mechanism of changes in myocardial infarction. This theoretical model proposes mechanisms in myocardial infarction that entail platelet aggregation, increased TXA_2 production, inhibition of PGI_2, and elevated plasma NEFA (including AA) (11). ⊕ Symbolizes positive-feedback routes.

Heptadecanoic acid (17:0) was added to each sample as internal standard. Lipids from each 2-ml sample were extracted with chloroform/methanol (2:1, v/v). The samples were mixed well and centrifuged. The aqueous layer was drawn off and the chloroform layer filtered to remove the protein. This layer then was dried under a gentle stream of nitrogen and redissolved in 100 μl of chloroform.

The lipid extracts were spotted onto 20 × 20 cm sheets of silicic acid-impregnated ITLC paper (Gelman Sciences, Inc.) and developed in 30–60 C petroleum ether/diethyl ether/acetic acid (90:10:1). The chromatograms were sprayed with 0.1% 2′,7′-dichlorofluorescein solution and illuminated with UV light. The individual lipid classes appeared as distinct bands and were put into glass tubes with teflon-lined caps. These were transesterified with 2 ml of 14% boron trifluoride/methanol (w/v) at 85 C for 1½ hr for PL and CE, and ½ hr for FA and TG. After esterification, the fatty acid methyl esters (FAME) were extracted with petroleum ether (30–60 C), the samples were taken to dryness under nitrogen and redissolved in a minimum of petroleum ether for capillary gas chromatography (GC) analysis.

GC analysis. GC analysis was carried out on a 50 m × 0.2 mm fused silica capillary column coated with FFAP (Scientific Glass Engineering, Austin, TX). The column was temperature-programmed from 190–220 C at 2 C/min, with a final hold of 45 min. The carrier gas was helium, at a flow rate of about 0.68 ml/min. The split ratio was 1:99. Identification of FAME was made by comparison with authentic standards. Peak areas were calculated by a microprocessor. Data were treated by analysis of variance (ANOVA).

RESULTS

Of 58 patients admitted with possible MI, 14 had enzyme-confirmed MI, and 44 did not (No MI). Of these patients, serum samples for lipid analysis were available from 11

48 hr	0.173 ± 0.038 (n = 9)	0.242 ± 0.026 (n = 5)	0.357 ± 0.130 (n = 3)	0.290 ± 0.088 (n = 3)

Values are mean ± SEM (mg/dl).

*$p < 0.05$ compared with Normal and PGI; $p < 0.01$ compared with MI.

patients with MI and 35 patients with No MI. Subsequent to the analyses, it was determined that a subgroup of the No MI group had been treated with anti-inflammatory drugs (n = 19). From this prostaglandin inhibitor (PGI) subgroup, 13 sets of serum samples were available for analysis. None of the MI patients were on chronic antiprostaglandin medications. In some cases, it was impossible to obtain all four serum samples from each patient, or some samples were too small to analyze. These variations in group size are reflected in the summary tables.

Total NEFA measured for the four groups are shown in Table 1. ANOVA showed significant differences among the four groups, Normal, No MI, MI and PGI, at each time of blood sampling. The No MI and MI groups had significantly higher total NEFA than the Normal group at each time period. NEFA levels in the PGI group did not show sustained elevation at 48 hr in contrast with the No MI and MI groups.

The No MI group had significantly lower NEFA than the MI group at 12 hr only ($p < 0.005$, Student's t-test). Linear regression analyses were done of the No MI group and the MI group (total NEFA vs time). For the No MI group, R = −0.032 (95% confidence interval for R = 0.207 to −0.268); and for the MI group, R = −0.048 (95% confidence interval for R = 0.412 to −0.487). These results suggest that total NEFA is independent of time in the No MI and MI groups during the 48-hr interval studied.

Serum AA levels of the NEFA were calculated for each of the study groups (Table 2). There were no significant differences in mean quantities of AA among the groups except that the No MI group had a significant decrease at 24 hr after admission compared with the MI group ($p < 0.01$) and to the Normal and PGI groups ($p < 0.05$) (Table 2). The percentage of NEFA made up by AA was significantly greater in the control samples than in the MI and No MI groups at admission and at 24 hr ($p < 0.01$) (Table 3). The only difference between the MI and No MI groups occurred at 12 hr after admission when the percentage AA was significantly lower in the MI group ($p < 0.05$). Percentage of AA was significantly greater in the PGI group compared with the No MI group at 24 hr only ($p < 0.05$).

Table 4 shows the fatty acid pattern in NEFA for initial fasting samples of controls and the differences from the patterns in the MI, No MI and PGI groups. 16:1ω7 was significantly increased in the MI, No MI and PGI

Values are mean ± SEM in % of total NEFA.

groups. 18:0 was significantly decreased in both the MI and No MI groups. 18:1ω9 was significantly increased in the MI group only. 20:4ω6 was significantly decreased in the MI, No MI and PGI groups. Other individual fatty acids were not significantly different.

Table 5 compares the fatty acid patterns for admission samples in the MI, No MI and PGI groups for each of the major serum lipid classes. For the No MI group compared with the MI group, only 16:1ω7 was significantly elevated in PL, and 14:0 was significantly elevated in NEFA. For the PGI group compared with the MI group, 22:6ω3 was significantly elevated in PL, 18:0 was elevated in NEFA, 18:2ω6 and 20:3ω6 (DHLA, dihomogamma linolenic acid) decreased in NEFA, 18:2ω6 decreased in TG, and 16:0 decreased in CE. Only 22:6ω3 was significantly increased in PL of the PGI group compared with the No MI group. There were no significant differences in the major fatty acids (16:0, 18:0, 18:1ω9, or 18:2ω6) between the MI and No MI groups in any of the four lipid classes. The prostaglandin precursors, 20:3ω6 and 20:4ω6, also were not significantly different in the four lipid classes between the three groups, except 20:3ω6 in NEFA for the PGI group.

None of 19 patients regularly taking prostaglandin inhibitors proved to have MI. Therefore, we compared the MI group and all patients not suffering a heart attack (No MI and PGI groups) with respect to the 10 clinical variables that are listed in Table 6. *The regular use of prostaglandin inhibitors before hospitalization for chest pain was associated with an outcome of No MI to a high level of statistical significance ($p < 0.002$).* The only other variable showing a difference between the two groups was cardiac arrhythmia, which occurred during the course of hospitalization more frequently in the MI group. This difference also was statistically significant. The highest diastolic blood pressure measurement recorded during the hospitalization showed an elevation in the MI group compared with the No MI group, which approaches statistical significance.

In addition, a multivariate analysis was performed to examine the confounding effect of the various covariates on the use of prostaglandin inhibitors in MI. Stepwise logistic regression was used to assess the ability of prostaglandin inhibitors to predict MI in the presence of the nine covariates. The likelihood ratio chi-square results from this stepwise logistic regression analysis indicated that non-use of prostaglandin inhibitors is a statistically significant predictor of MI in the presence of the covariates ($p < 0.01$).

DISCUSSION

This study confirms previous findings that NEFA are elevated in association with MI (1–4). The fact that elevated NEFA are seen in patients with symptoms of MI but without evidence for myocardial damage suggests that this lipolysis probably is mediated through the sympathetic nervous system and is associated with stress. Elevations in NEFA are related to catecholamine elevations in patients with MI (9). The lipolysis caused by catecholamine mobilizes NEFA from adipocyte TG, which are low in AA. This could explain the decreased percentage of AA in the No MI and MI groups. The AA concentration did not change, although the total NEFA increased. Work by McDaniel et al. has shown similar NEFA patterns in patients with MI. When total NEFA values were suppressed by glucose-insulin-potassium infusion, the relative percentage of AA increased (10).

Values are mean ± SEM in % of total fatty acids.

[a]Number of samples, the subgroup of No MI with chronic anti-inflammatory treatment was excluded.

[b]Difference between MI and No MI or PGI extends to $p < 0.05$.

[c]Difference between MI and PGI extends to $p < 0.01$.

[d]Difference between No MI and PGI extends to $p < 0.05$.

TABLE 6

No MI vs MI Groups Compared with Respect to 10 Clinical Variables

Patient variable	No MI (n = 44)	MI (n = 14)	Test	p-Value
Use of prostaglandin inhibitors	19/44	0/14	Fisher's exact test	<0.002[a]
Average age[b]	69 ± 10	68 ± 12	Student's t-test	< 0.59
Sex	24M/20F	5M/9F	Fisher's exact test	<0.36
Arrhythmia	16/42	10/13	Fisher's exact test	<0.02[a]
Diabetes	6/41	0/12	Fisher's exact test	<0.32
Serum triglyceride average (mg/100 ml)[b]	167 ± 113	198 ± 121	Student's t-test	<0.40
Highest blood pressure (mm HG) (diastolic)[b]	88 ± 12	95 ± 15	Student's t-test	<0.07
Treated high blood pressure	16/44	4/14	Fisher's exact test	<0.75
Known coronary artery disease	25/44	7/14	Fisher's exact test	<0.76

[a]Statistically significant.

[b]Mean ± SD.

Patients who are having or have had MI seem to have higher NEFA than those who have symptoms of MI without permanent myocardial damage 12 hr after admission. Whether this difference in NEFA is a result of the MI or contributes to it cannot be answered by this study. However, it should be noted that elevation in blood NEFA has been related to platelet activation, increased infarction size and increased incidence of arrhythmias and death (1-4). Therapy aimed at decreasing NEFA in patients with MI has had some success (8).

Figure 1 shows a theoretical model that may explain how elevated NEFA could promote MI (11). Although serum nonesterified AA was not elevated in the MI patients, it is possible that the elevation in total NEFA may compete for albumin binding sites with AA and result in a local increase in unbound, nonesterified AA. This AA may be more active metabolically and could contribute to platelet aggregation. This may be the mechanism for NEFA elevation causing platelet aggregation described by Gerrard et al. (5). Increase in NEFA associated with fasting and with catecholamine release may explain the temporal association of increased platelet aggregability with the risk of MI and sudden cardiac death seen in the morning hours (12).

The precursors of polyunsaturated fatty acids (PUFA) in the NEFA fraction are the PL of tissue and plasma. The PUFA of the serum or plasma are indicators of the PUFA status of the individual (13), and profiles of these PUFA indicate abnormalities in PUFA metabolism that may occur. Figure 2 shows the PUFA profiles of serum PL, comparing the MI group with the Normal group and the No MI group with Normal group at the time of admission and again at 48 hr. At the time of admission, 20:3ω6 was significantly higher in both the MI and No MI groups. At 48 hr, 20:3ω6 remained high only in the MI group. AA was not significantly altered at the time of admission in either group but was elevated significantly in the MI group at 48 hr. The chain elongation product of AA, adrenic acid (22:4ω6), was normal at admission in both groups, but was very significantly elevated in the No MI group at 48 hr. The 22:5ω6 was elevated in the No MI group at admission and was significantly elevated in both groups at 48 hr. Of the ω3 PUFA, 22:6ω3 was elevated in the No MI group at admission and in both groups at 48 hr. The total ω3 acids in the MI group were 3.45% at admission, not significantly elevated above the Normal group value of 3.13%. They were significantly elevated ($p < 0.05$) at admission in the No MI group compared with the Normal group, 3.95% and 3.13%, respectively. The antithrombotic effects of ω3 acids may have contributed to the protection against cardiac damage in this group (14). The 20:3ω9, an indicator of essential fatty acid deficiency, was elevated significantly only in the No MI group at 48 hr. None of the changes in PUFA indicated deficiencies of ω6 or ω3 fatty acids. The elevation in the prostaglandin precursors, 20:3ω6 and 20:4ω6, in the MI group could have important physiological implications on the extent of myocardial damage present and clinical outcome for the patient.

The clinical observation was made in 1953 that aspirin appeared to protect against MI (15). Numerous studies since have been performed to assess the usefulness of prostaglandin inhibitors in the secondary prevention of MI.

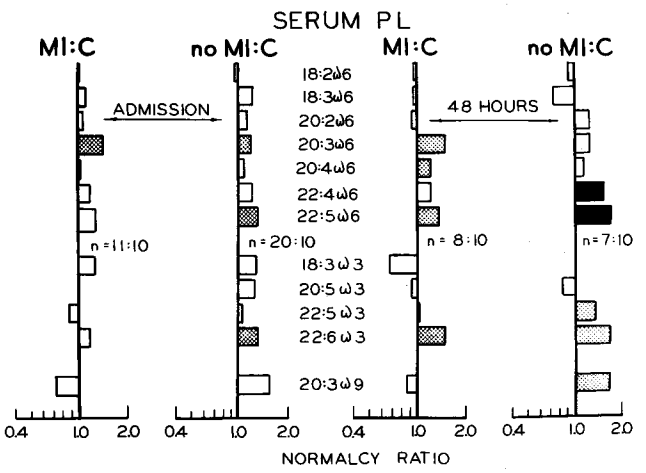

FIG. 2. Polyunsaturated fatty acid profiles for serum PL at admission and at 48 hr for MI and No MI groups. Normalcy ratio is experimental value divided by Normal value. Significance is indicated by shading. Open bars, non-significant; light crosshatch, $p < 0.05$; dark crosshatch, $p < 0.01$; black, $p < 0.001$.

Several studies have shown reduction in the rate of subsequent MI or coronary mortality from PGI (7,16-21). However, two large trials failed to show statistically significant benefit from prophylactic use of these drugs (6,22).

Our results are from an unselected population of patients presenting to an emergency room with chest pain or other clinical criteria requiring admission to rule out MI. There is an improved outcome for those taking a mixed variety of prostaglandin inhibitors (aspirin, ibuprofen, anproxen, prednisone, fenoprofen), most often for arthritis. The dose of these medications placed them in the high-dose prophylaxis category. Beneficial effects of prostaglandin inhibitors are believed to be due to reduced production of platelet TXA_2. Adverse effects may be the result of decreased levels of PGI_2 in the endothelial cell wall (23).

We considered an alternative explanation for our observations. Those taking prostaglandin inhibitors for arthritis might suffer from intermittent chest pain from their arthritis, for which they were admitted, to rule out MI. However, musculoskeletal chest pain is distinct from ischemic chest pain and always is considered in its differential diagnosis, so we think this explanation is unlikely. Coincidental effects from possible confounding risk factors for MI were evaluated as described above and did not account for this association.

In the setting of possible MI in this unselected group of emergency admissions, several clinical indices, some closely linked with coronary artery disease, were of no predictive value in identifying those patients with MI. This observation was true for age, sex and serum triglyceride and cholesterol levels. It was surprising that a prior history of treated diabetes mellitus, hypertension or coronary artery disease was of no value in predicting MI in our series. Our observations underscore the importance of prostaglandin-mediated pathophysiologic mechanisms in MI, but these effects are not mediated through alteration of NEFA levels, including AA, which showed no important difference between the four study groups.

In conclusion, NEFA are elevated in stressed patients admitted for possible MI. Those patients with MI seem to have marginally higher levels of NEFA than those with no MI. The MI, No MI and PGI groups all seem to have significantly different fatty acid patterns (with reduced percentage of AA) in NEFA compared with the Normal group NEFA-AA patterns. The fatty acid patterns in PL, NEFA, TG and CE were significantly different in the MI, No MI and PGI groups in a few fatty acids only. Significant changes in the PL occurred in both MI and No MI groups of patients compared with the Normal group, thereby implicating the effect of stress on fatty acid patterns.

[Received August 28, 1987; Revision accepted February 25, 1988]

Microsomal Desaturation-Elongation of Linoleic Acid Following Parenteral Feeding with Lipid Emulsions in the Rat

Sheila M. Innis* and **Doris E. Yuen**
Department of Paediatrics, University of British Columbia, Vancouver, B.C., Canada V5Z 4H4

The effect of total parenteral nutrition (TPN) with lipid emulsion to supply either 27.5% or 2% total calories on in vitro desaturation-elongation of 18:2(n-6) by liver microsomes was studied in the rat. The emulsion lipid contained ca. 50% 18:2(n-6) plus 8% 18:3(n-3) or 77% 18:2(n-6) plus 0.5% 18:3(n-3). The reaction rate was influenced by the in vitro substrate concentration and inhibited above 50 μmol 18:2(n-6)/mg microsomal protein. At maximum rates of desaturation-elongation, the formation of triene and tetraene (n-6) fatty acids was reduced in rats given either of the two emulsions. The rate of (n-6) pentaene formation was increased in rats given the emulsion with low 18:3(n-3) but not in rats given the emulsion with 8% 18:3(n-3). Analyses of the microsomal lipid indicated increased free cholesterol in all rats that received TPN. Esterified cholesterol was increased only in rats given 27.5% TPN calories as lipid. Microsomal total phospholipids and phospholipid class distributions were not altered by TPN. The data are consistent with reports of reduced levels of long-chain desaturation-elongation metabolites of 18:2(n-6) in tissue phospholipids following infusion of parenteral lipid. The data suggest that the mechanism may include alterations in other metabolic pathways such as cholesterol, in addition to desaturase enzyme activities, and may be influenced by both the quantity and fatty acid composition of the lipid infused. ***Lipids 23,*** **546–550 (1988).**

The composition of diet fat is known to influence membrane structural lipid fatty acid composition and metabolic function (1), as well as lipoprotein (2) and eicosanoid (3) metabolism. Desaturation-elongation pathways for conversion of dietary essential fatty acids, linoleic acid (18:2[n-6]) and linolenic acid (18:3[n-3]), to their more highly unsaturated homologues, which are incorporated into tissue phospholipid and serve as eicosanoid precursors, have been studied extensively (4,5). Competition among C18 (n-6) and (n-3) fatty acids for Δ6 desaturation is well known, as is the inhibition of desaturation caused by various substrates and reaction products (4–9).

Artificial fat emulsions are used widely to supply a major portion of the calories infused during IV nutritional support (total parenteral nutrition, TPN). Commonly used formulations are based on soy oil or safflower oil emulsified with egg phospholipids and contain 45% or more 18:2(n-6) and up to 8% 18:3(n-3) in total fatty acids. Their infusion provides a substantially higher intake of 18:2(n-6) and markedly different fatty acid balance to that encountered in usual human diets. Recent reports have described decreased C20 and C22 (n-6) and (n-3) fatty acids in tissue phospholipids of infants and rats given TPN with lipid emulsion (10,11). Decreased 20:4(n-6) availability also has been suggested to explain the reduced levels of some eicosanoid metabolites found in infants given parenteral lipid emulsions (12). The effects of these emulsions on essential fatty acid metabolism has not been studied directly. Thus, the purpose of the study reported here was to investigate the effect of TPN with different 18:2(n-6) contents on hepatic microsomal desaturation-elongation of 18:2(n-6) in the rat.

Abbreviations: GLC, gas liquid chromatography; TLC, thin layer chromatography; TPN, total parenteral nutrition.

MATERIALS AND METHODS

Materials. [1-^{14}C]Linoleic acid (40–60 mCi/mmol) was from New England Nuclear (Montreal, Quebec). Cofactors used in the enzymatic assay were from Sigma Chemical Co. (St. Louis, MO). Fatty acid methyl esters used as carriers and for gas liquid chromatography (GLC) standards were from Supelco Inc. (Bellefonte, PA) and from NuChek-Prep Inc. (Elysian, MN). The purity of standards and the radiolabeled substrate was confirmed by GLC and argentation thin layer chromatography (TLC), respectively. TPN solutions were prepared as described (13,14) using 50% dextrose, parenteral amino acids (Travenol, 10%, Baxter Labs., Malton, Ontario), vitamins (MVI-12, USV Canada Inc., Mississauga, Ontario) and minerals (Addamel, Pharmacia Canada Inc., Dorval, Quebec). Liposyn (10%) was from Abbott Labs (Montreal, Quebec) and Intralipid (10% Nutralipid) was from Pharmacia. The fatty acid composition of the emulsions and the chow diet has been reported (10); Liposyn and Intralipid contained ca. 77% and 0.5%, and 50% and 8% 18:2(n-6) and 18:3(n-3), respectively. The rat chow contained ca. 4% fat with 34% 18:2(n-6) and 3% 18:3(n-3) (10).

Animals and TPN. Rats (male Wistar, 175–225 g) were surgically prepared for TPN (13) and infused for seven days. The infusate contained ca. 27.5% calories as lipid from Liposyn or Intralipid, or 2% calories from Intralipid with 25.5% calories from additional dextrose, six rats each. The remaining 72.5% calories were supplied by the amino acid-dextrose solution (13,14). Six more rats were sham-operated and allowed free access to Purina rat chow (control). The diets provided ca. 1.4, 1.0, 13.7, and 21.2% calories as 18:2(n-6) and ca. 0.1, 0.2, 2.3 and 0.1% calories as 18:3(n-3) in the control, 2% Intralipid, 27.5% Intralipid and 27.5% Liposyn groups, respectively. The outcome of TPN was similar to previous studies (10,13,15). All rats completed the course of TPN with normal results in plasma tests of liver function and with maintenance of body weight over the infusion period.

Preparation of liver microsomes. The rats were anaesthetized (0900–1000 hr, sodium pentothal, 0.4 mg/kg); the livers excised and immediately rinsed in saline, then in a 0.15 M KCl, 5 mM $MgCl_2$, 0.25 M sucrose, 1.5 mM glutathione, 50 mM potassium phosphate buffer, pH 7.4. Tissue portions were homogenized in 2 vol. buffer, centrifuged, 10,000 g × 20 min and the microsomes recovered from the supernatant by centrifugation, 100,000 g × one hr, without washing (16). All isolation procedures were conducted at 0–4 C. Microsomal protein recovery was

determined by the method of Lowry et al. (17) with bovine serum albumin as the standard.

Desaturation-elongation of 18:2(n-6). Incubations were performed in 1 ml of 0.15 M KCl − 0.05 M KPO_4 buffer (pH 7.0) containing 1.5 mM glutathione, 5 mM ATP, 1.25 mM NADH, 1.25 mM NADPH, 0.3 mM CoA, 0.3 mM malonyl CoA essentially as described by Purvis et al. (18) and using 0.5–3.0 mg microsomal protein. The reactions were started by addition of substrate, 5–200 μmol 18:2(n-6) with 0.1 μCi [^{14}C]18:2(n-6), and continued 20 min at 37 C. They were stopped and saponified with 1.0 ml 20% (w/v) KOH, acidified with 2 N HCl and the fatty acids extracted (19), methylated with methanolic HCl and then dried under N_2. The resulting methyl esters were dissolved in petroleum ether (bp 30–60 C) with a mixture of unlabeled methyl ester carriers (100 μg each) and then separated according to their unsaturation by argentation TLC on Silica Gel G impregnated with 10% $AgNO_3$ (20). The plates were developed three times at −20 C in toluene acetone (95:5, v/v) and the bands containing saturated, mono-, di-, tri-, tetra- and pentaenoic fatty acids visualized under UV light after spraying with 2′7′-dichlorofluorescein (0.1%, w/v). [^{14}C] in each band was quantitated by liquid scintillation spectrometry with quench correction and conversion to dpm. Recovery of radioactivity from the TLC plates was >95%.

Microsomal lipid composition. Lipids were extracted (19) from a known amount of microsomal protein and aliquots taken for determination of total lipid phosphorous (21), total phospholipid fatty acid composition by GLC (10) and free and esterified cholesterol content (22), following their separation on Silica Gel G utilizing petroleum ether/diethyl ether/acetone (85:15:3, v/v/v). Phospholipid classes were quantitated (21) following separation according to Skipski et al. (23).

Data handling. Enzyme activities were calculated as the nmol fatty acid substrate converted per mg protein per min. Because this may underestimate absolute conversion rates to the extent that the labeled substrate was diluted by the microsomal substrate pool, the conversion of 18:2(n-6) to tri-, tetra- and pentaene products also was calculated as percent conversion. Microsomal fatty acid peak areas, weight percentage and μg values from GLC analyses were determined by a chromatography data system (10). Statistical analysis for treatment differences utilized analyses of variance and Duncan's multiple-range test.

RESULTS AND DISCUSSION

Desaturation-elongation of 18:2(n-6) by normal rat liver microsomes. The conversion of C18 fatty acids to higher homologues and their incorporation into tissue lipid involves several complex reactions that potentially may be altered by reaction substrates and/or products. In vitro kinetic analyses have indicated the regulatory importance of desaturation by demonstration that the rate of fatty acid activation to the CoA thioester, acyl-CoA elongation, and transfer and incorporation into lipid products all exceed the rate of the respective desaturation (4,5). Thus, experimental (10) and clinical (11,12) evidence of reduced tissue levels of highly unsaturated metabolites of 18:2(n-6) and 18:3(n-3) following parenteral lipid infusion may suggest inhibition of microsomal desaturation. These studies used a coupled desaturation-elongation assay rather than the more usual study of individual desaturases with single fatty acyl substrates and no elongation cofactors or malonyl-CoA, as more analogous to in vivo metabolism in which n-6 fatty acid substrates for Δ5- and Δ4-desaturation are largely derived from Δ6-desaturation of (dietary) 18:2(n-6).

The total desaturation of 18:2(n-6), derived as the sum of all triene, tetraene and pentaene methyl ester products, together with the rate of triene, tetraene and pentaene formed and remaining in the respective fraction is shown in Figure 1. The Δ6 desaturase represents the first enzyme in the sequence, thus the total activity of this enzyme is reflected by the sum of all desaturation products. The reaction rates were linear with 0.5–3.0 mgm microsomal protein at all substrate concentrations (data not shown) but were markedly reduced at substrate concentrations above 50 μmol. The finding of maximum desaturation-elongation rate at 50 μmol 18:2(n-6)mg/protein agrees with previous specific assays of rat liver Δ6 desaturase (24,25). The reaction rates achieved also are similar to the Δ6-desaturase activities reported by others using similar substrate levels (16,24,26,27). The lower rate of desaturation-elongation at 200 μmol substrate (control group, 0.28 ± 0.07 vs 0.32 ± 0.02 nmol/min/mg protein with 200 vs 50 μmol 18:2(n-6) substrate, respectively) is similar to Δ6-desaturase activity reported by Alam et al. (28) with this substrate concentration.

The distribution of [^{14}C] in fatty acid methyl esters following desaturation-elongation of 18:2(n-6) is shown in

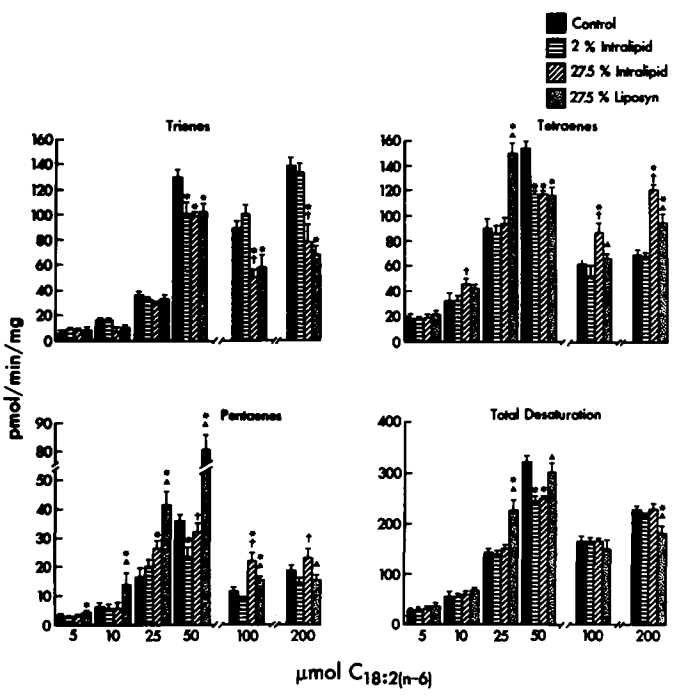

FIG. 1. Desaturation of 18:2(n-6) by rat liver microsomes following seven days TPN with 2% calories from Intralipid or 27.5% calories from Intralipid or Liposyn. The reactions were conducted with 5–200 μmol 18:2(n-6) substrate and 1 mg microsomal protein and performed in triplicate. The results represent mean ± SE for six rats, with significant differences of $p \leq 0.05$ indicated as *, TPN vs control; †, 27.5% Intralipid vs 2% Intralipid; ▲, 27.5% Liposyn vs 27.5% Intralipid.

Figure 2 and reflects the relative activities of the three desaturases studied. The relative activities of Δ6-, Δ5- and Δ4-desaturase with (n-6) series fatty acids has been calculated as 1.0:1.0:0.02, respectively (29), suggesting that the slowest enzyme in the sequence is Δ4-desaturase. Rat liver microsomes have been shown to have very low Δ4-desaturase activity with (n-6) fatty acyl substrates (30). The recovery of over 85% [^{14}C] as triene and tetraene fatty acid methyl esters in these studies (Fig. 2) is consistent with a slow conversion of 22:4(n-6) to 22:5(n-6).

At in vitro substrate concentrations up to apparent saturation (50 μmol 18:2[n-6]), the recovery of [^{14}C] was higher in tetraene than triene methyl esters (Fig. 2). This pattern suggests that the activity of Δ5-desaturase was similar or higher than that of Δ6-desaturase. Previous in vitro work utilizing low 18:2(n-6) and 20:3(n-6) substrate concentrations also have found higher rates of Δ5- than Δ6-desaturation (27,31). In contrast, at substrate concentrations above the apparent reaction optimum the relative distribution of [^{14}C] showed accumulation in triene rather than tetraene methyl esters (Fig. 2), possibly suggesting inhibition of desaturation at the Δ5-desaturation step.

Influence of TPN 18:2(n-6) desaturation-elongation. The maximum rate of 18:2(n-6) desaturation-elongation attained, and the formation of triene and tetraene fatty acids, was decreased in rats that had received 2 or 27.5% TPN calories from Intralipid (Fig. 1). In contrast, the provision of 27.5% TPN calories as Liposyn had no effect on total rates of desaturation-elongation, although the formation of triene and tetraene fatty acids was reduced similarly. The higher rate of total desaturation in the groups given Liposyn compared with the groups given Intralipid was due to a marked increase in the rate of pentaene fatty acid synthesis. This apparent induction of Δ4-desaturation was observed in the assays with microsomes prepared from rats given Liposyn at all nonsaturating 18:2(n-6) substrate levels (Fig. 1). Whether the difference between the emulsions is related to their markedly different 18:2(n-6)/18:3(n-3) ratios (ca. 5.6 and 154 in Intralipid and Liposyn, respectively) is unknown. Diets very low in 18:3(n-3) that produce low tissue levels of 22:5(n-3) and 22:6(n-3) have been associated with increased levels of 22:5(n-6) (32). Definitive evidence of increased Δ4-desaturation of (n-6) fatty acids with such diets is not available. The total calories received as 18:3(n-3) was similar among the control, 2% Intralipid and 27.5% Liposyn groups. Thus, it appears likely that the fatty acid balance rather than absolute intake of 18:3(n-3) may be important.

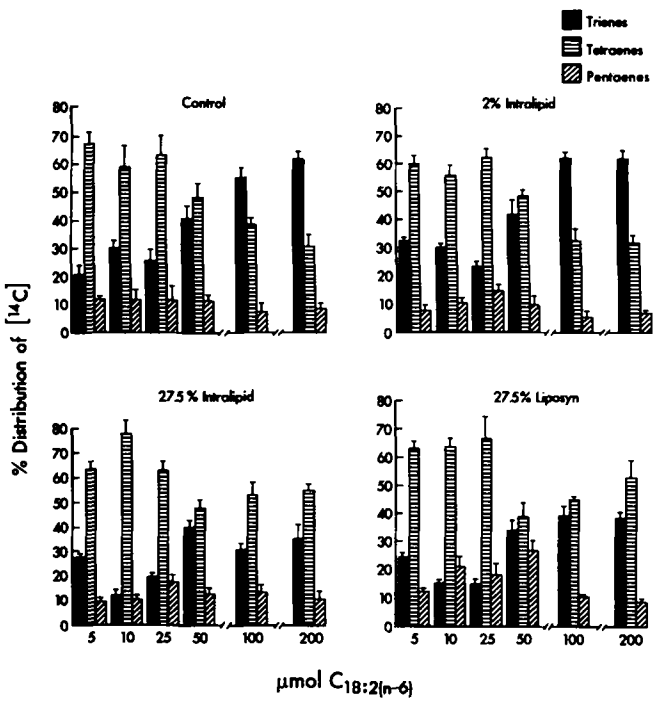

FIG. 2. Recovery of [^{14}C] 18:2(n-6) in triene, tetraene or pentaene fatty acid products expressed as % of total desaturation by rat liver microsomes following seven days TPN with 2% calories from Intralipid or 27.5% calories from Intralipid or Liposyn. The reactions were conducted with 5–200 μmol 18:2(n-6) substrate and 1 mg microsomal protein and performed in triplicate. Results represent means ± SE for six rats.

The distribution of [^{14}C] among triene, tetraene and pentaene methyl ester products in the three TPN groups was similar to that in the control group up to 50 μmol substrate (Fig. 2). In contrast with the control and 2% Intralipid groups this pattern, which suggests higher Δ5-, than Δ6- or Δ4-desaturation, persisted at the higher substrate concentrations in both groups given 27.5% TPN calories as lipid. The difference between the use of 2% and 27.5% calories from parenteral lipid implies the effect was due to the quantity of parenteral lipid provided rather than TPN itself.

Influence of TPN on rat hepatic microsomal lipids. Consideration of the microsomal lipid composition is of interest because of reports that microsomal membrane fluidity may regulate desaturase enzyme activities (33–35), and because phospholipid fatty acids in situ, in addition to fatty acyl-CoA, may serve as substrates for these enzymes (31). Analysis of the microsomal lipid showed increased free cholesterol, and an increased molar cholesterol/phospholipid ratio in all rats that had received TPN, irrespective of its composition or quantity (Table 1). The accumulation of free cholesterol was greater with 27.5% than 2% Intralipid or 27.5% Liposyn. Esterified cholesterol levels were increased and decreased in groups that had received 27.5% and 2% calories as lipid, respectively (Table 1). Phospholipid class distributions were not altered by TPN (control values, mean ± SE as percent total phospholipid, phosphatidylcholine 57.8 ± 2.0, phosphatidylethanolamine 23.6 ± 0.4, phosphatidylserine + phosphatidylinositol 13.8 ± 0.8, sphingomyelin 4.6 ± 0.3).

The elevation of microsomal membrane cholesterol following TPN may involve several mechanisms including altered hepatic lipid metabolism (36) or bile acid excretion (14). This membrane is the site of cholesterol 7α-hydroxylase, which utilizes membrane-free cholesterol for synthesis of bile acid. Whether reduced hepatic bile acid secretion following TPN could impair maintenance of microsomal cholesterol homeostasis is unknown. However, previous studies reported greater reduction of bile acid secretion in rats infused with Intralipid than with Liposyn (14) and thus are consistent with the data in this study, indicating that high levels of Intralipid gave the greatest accumulation of microsomal-free cholesterol (Table 1). Similarly, cholestasis of other etiologies has been shown to result in free cholesterol accumulation in hepatic membranes in this species (37).

The description in previous studies of reduced total hepatic and plasma phospholipid C20 and C22 (n-6) and (n-3) fatty acids in rats (10) and human infants (11) who had received parenteral lipid were not clearly reflected in the microsomal phospholipid fatty acids in this study (Table 2). Rats that had received 2% calories as Intralipid had increased 16:0 and 20:3(n-6) and decreased 18:2(n-6) and 22:3(n-3) levels. Infusion of 27.5% calories from Intralipid or Liposyn increased the microsomal 18:0 and 18:2(n-6) content. Intralipid, but not Liposyn, at this level also reduced the 20:4(n-6) and 22:5(n-3) levels when compared with the control values. The lipid composition of biomembranes is membrane- and tissue-specific and depends on desaturase activities as well as more complex mechanisms, including preferential acylation and deacylation/reacylation reactions (38). Thus, changes in a specific membrane may not reflect desaturase activities or those of other membrane sites. Conceivably, specificity of acylation and remodeling may explain differences between the effects of TPN on microsomal phospholipids (Table 1) and total liver phospholipids (10). The finding that the rate of triene and tetraene fatty acid formation from 18:2(n-6) was reduced under maximum in vitro reaction rate conditions after infusion of 27.5% calories as either Intralipid

TABLE 1

Lipid Composition of Rat Hepatic Microsomes Following Seven Days of TPN

		TPN		
	Control	2% Intralipid	27.5% Intralipid	27.5% Liposyn
Phospholipid (nmol/mg protein)	495 ± 20	433 ± 38	421 ± 19	455 ± 37
Free cholesterol (nmol!mg protein)	45.8 ± 1.0	74.4 ± 3.4[b]	95.6 ± 3.8[b,d]	73.5 ± 4.8[b,e]
Esterified cholesterol (nmol!mg protein)	3.7 ± 0.4	1.5 ± 0.2[b]	6.4 ± 0.8[a,b]	6.7 ± 0.6[b]
Cholesterol/phospholipid (nmol/mol)	0.10 ± 0.01	0.18 ± 0.02[b]	0.24 ± 0.01[b,c]	0.18 ± 0.03[b]

Values given represent means ± SE, n = 6 for all groups.

[a,b]Values for TPN groups are significantly different ($p < 0.05$, 0.01, respectively) from the control.

[c,d]Values for 27.5% Intralipid are significantly different ($p < 0.05$, 0.01, respectively) from the 2% Intralipid group.

[e]Value for 27.5% Liposyn significantly different, $p < 0.01$, from the 27.5% Intralipid group.

TABLE 2

Major Fatty Acids of Rat Hepatic Microsomal Phospholipids Following Seven Days of TPN

Fatty acids (% w/w)		TPN		
	Control	2% Intralipid	27.5% Intralipid	27.5% Liposyn
14:0	0.8 ± 0.2	0.2 ± 0.0[a]	0.2 ± 0.1	0.2 ± 0.1
16:0	20.0 ± 0.6	25.8 ± 0.4[b]	19.1 ± 0.8[f]	19.4 ± 1.0
16:1	1.7 ± 0.3	2.8 ± 1.1	1.7 ± 0.8	0.7 ± 0.3
18:0	25.9 ± 0.6	25.4 ± 1.4	29.4 ± 1.4[a]	31.0 ± 1.5[b]
18:1	11.1 ± 1.4	9.7 ± 1.3	10.0 ± 2.1	7.4 ± 1.1
18:2	13.7 ± 0.7	11.9 ± 1.8	16.6 ± 0.8[a,c]	15.6 ± 0.4[a]
18:3(n-3)	0.3 ± 0.1	0.1 ± 0.1	0.2 ± 0.1	0.1 ± 0.0
20:3(n-6)	0.4 ± 0.0	0.9 ± 0.1[b]	0.4 ± 0.1[d]	0.4 ± 0.1
20:4(n-6)	16.6 ± 1.3	14.3 ± 1.0	13.5 ± 0.3[a]	17.1 ± 1.0[f]
20:5(n-3)	0.3 ± 0.0	0.8 ± 0.3	0.2 ± 0.0	0.1 ± 0.0[a]
22:3(n-3)	0.2 ± 0.0	0.0 ± 0.0[a]	0.2 ± 0.2	0.1 ± 0.1
22:4(n-6)	0.5 ± 0.0	0.4 ± 0.0	0.5 ± 0.2	0.3 ± 0.0[a]
22:5(n-6)	0.1 ± 0.0	0.0 ± 0.0	0.0 ± 0.0	0.3 ± 0.1[e]
22:5(n-3)	0.6 ± 0.1	0.9 ± 0.3	0.4 ± 0.1	0.4 ± 0.0[a]
22:6(n-3)	4.7 ± 0.4	4.6 ± 0.1	4.0 ± 0.8	3.8 ± 0.4

Data given represent means ± SE, n = 6 for all groups.

[a,b]Values for TPN group are significantly different ($p < 0.05$, 0.01, respectively) from the control.

[c,d]Values for 27.5% Intralipid are significantly different ($p < 0.05$, 0.01, respectively) from the 2% Intralipid group.

[e,f]Values for 27.5% Liposyn are significantly different ($p < 0.05$, 0.01, respectively) from the 27.5% Intralipid group.

or Liposyn, however, is consistent with the previous demonstration of reduced hepatic phosphatidylcholine 20:3(n-6) and 20:4(n-6) in similarly treated rats (10). Also of relevance are reports that diet-induced elevation of plasma cholesterol is associated with reduced plasma and liver 20:4(n-6)/18:2(n-6) and 22:6(n-3)/20:5(n-3) (39). The infusion of parenteral lipid is known to lead to accumulation of plasma-free cholesterol (40,41), which appears to extend to liver cell membranes (Table 2). Thus, it is possible that alterations in cholesterol metabolism caused by parenteral lipid emulsions are related to changes in plasma and tissue in (n-6) and/or (n-3) fatty acid levels.

TPN with lipid emulsions continues to be invaluable for the provision of calories to critically ill patients and those with compromised gastrointestinal function. Clinical (11) and animal (10) studies concur in their demonstration of reduced C20 and C22 (n-6) and (n-3) fatty acids in tissue phospholipids following infusion of these products. Although a definitive reason is unknown, it appears likely that it may include altered desaturase enzyme activities and changes in other aspects of hepatic lipid and cholesterol metabolism. The evidence suggests that the mechanism is influenced by both the quantity and fatty acid composition of the parenteral lipid infused.

ACKNOWLEDGMENTS

These studies were supported by grants from the British Columbia Health Care Research Foundation and the Canadian Liver Foundation. S. M. Innis was supported by a Medical Research Council of Canada Scholarship; D. E. Yuen was supported by a University of British Columbia, Faculty of Medicine Studentship. Technical assistance was by Laurie J. Nicol. The assistance of C. Ford and staff in the animal unit is acknowledged.

Surface-active material (SF) was isolated from human lung lavage fluid collected at autopsy employing differential and sucrose density gradient centrifugation. The isolated material showed well-defined electron microscopic structure, consisting of clearly preserved, closely packed vesicles with limiting membranes and inclusion bodies. It showed a very high degree of alkaline phosphatase specific activity and was devoid of other subcellular contaminants. The isolated material also showed a high phospholipid/protein ratio and increasing surface activity when monitored at different stages of purification. It contained 68.5% phosphatidylcholine, 11.5% phosphatidylglycerol and relatively smaller amounts of phosphatidylethanolamine and other individual phospholipid (PL) classes. In addition, cholesterol, unesterified fatty acids, triacylglycerols and other neutral lipids were found. Saturated fatty acids, particularly palmitic acid (16:0), predominated in the major PL fractions. However, various fatty acids of which oleic acid (18:1) constituted a large proportion also are present. Chemical analysis of the material showed that besides lipids and proteins, nucleic acids, sialic acid, hexose, amino sugars, nitrogen and phosphorus were present. The delipidated material showed the presence of three to four proteins as characterized by sodium dodecylsulfate (SDS)-polyacrylamide gel electrophoresis, and gel permeation chromatography on Sephadex G-200 resolved two well-separated peaks. The first fraction contained serum-associated 68 kDa protein, while the second fraction had two apoproteins with molecular weights of 34 kDa and 10 kDa. These two proteins were associated with the SF and they, as well as the whole surface-active material, strongly reacted with the antibody directed against the whole SF in a double-diffusion immunoprecipitation assay. The first Sephadex fraction containing a 68 kDa protein did not produce any precipitation line when reacted against antisera.
***Lipids 23,* 551–558 (1988).**

The lung biosynthesizes a surface-active material called pulmonary surfactant (SF), which lines the surface of the alveoli and prevents collapse or atelactasis due to the pressure differences at air-water interfaces during deflation (1). Chemically, SF is a lipid-protein complex (2) that is required to maintain the normal mechanical properties of the lung and is secreted by type-II epithelial cells in the lung (3). Clinically, insufficient SF production may cause respiratory distress syndrome (RDS) and formation of hyaline membranes (4). Therefore, it is the main cause of mortality and morbidity in prematurely delivered neonates. Not knowing the chemical composition of this material, efforts to study its cellular synthesis, secretion and possible therapeutic approach in RDS have been seriously impeded.

In this paper, we describe a simple method for isolation and purification of SF from human endobronchial lavage fluid collected at autopsy, using a combination of differential and density gradient centrifugation. We also report the results of chemical, immunological and physical analyses of the isolated product. Partial characterization of selected enzymes and the SF-associated apoproteins also are presented. The development of an easy, rapid procedure for large-scale isolation of this unique lipoprotein complex is extremely important for the biophysical and biochemical understanding of its biosynthesis, assembly, secretion and adsorption to the alveolar interfaces. It also is important for developing immunoassay methods for quantitation and prenatal assessment of surfactant and, therefore, lung maturation. Prediction of SF deficiency in the prematurely born neonates will allow timely therapeutic infusion of synthetic surfactants.

MATERIAL AND METHODS

Isolation of pulmonary SF. Adult human lungs of both sexes at autopsy were obtained within two to four hr after death from non-pulmonary causes from the hospital attached to this institute. No patients had alveolar proteinosis, and samples visibly contaminated with blood were discarded. The excised lungs were separately lavaged by infusing chilled buffer A (0.005 M Tris – HCl, pH 7.35, containing 0.15 M NaCl). They were gently massaged, and the buffer was withdrawn by pouring back into a beaker, usually with 60–70% recovery. Thereafter, all the operations were performed strictly at 4 C. Cells and membraneous debris were removed from this crude lavage fluid by centrifugation at 160 × g for 10 min, and the materials suspended in the supernatant were pelleted by further centrifugation at 40,000 × g for two hr in a Sorvall SS-34 rotor. The sediment, a brownish precipitate, was suspended in and osmotically equilibrated with buffer A for two hr. About 30 ml of this suspension were placed in 50 ml centrifuge tubes and underlayered with 10 ml of 0.75 M sucrose, prepared in buffer A. After centrifugation at 18,000 × g for 10 min, the white interface was collected and, after dilution with four vol of buffer A, it was pelleted at 18,000 × g for 30 min. The resultant pellet was suspended in buffer A, and about 10 ml of it was underlayered with 12 ml each of a stepwise gradient consisting of 0.65 and 0.41 M sucrose, prepared in buffer A. The gradients were centrifuged at 75,000 × g for one hr in a SW-28 swinging bucket rotor in a Beckman ultracentrifuge maintained at 4 C. Purified SF appeared as a major band at the buffer A/0.41 M sucrose interface

(fraction I) and a minor very fine band at 0.41 M/0.61 M sucrose interface (fraction II). Both fractions were collected, diluted with four vol of buffer A and pelleted as above. By electron microscopic characterization (EM), glycerophospholipid analysis and surface-active properties (2), fraction I was the major surfactant material and was further characterized.

Surface tension determination. Surface activity of the SF suspensions was measured with a pulsating bubble surfactometer (Surfactometer International, Toronto, Canada), as described by Enhorning (5). A bubble with ambient air was created by withdrawing a small quantity (20 μl) of the SF suspension from the test chamber and the bubble, after being equilibrated for five min at 37 C, was pulstaed between a maximum radius (r_{max}) of 0.55 mm and a minimum radius (r_{min}) of 0.40 mm for one min. Surface tensions were calculated from the pressure tracings on a strip chart recorder, by a pressure transducer using the Laplace equation: $\Delta P = -2\sigma/r$, in which P, σ and r refer to the pressure drop, surface tension and radius of the spherical bubble, respectively (6).

Chemical analysis. Lipids were extracted from the isolated SF following the standard procedure of Folch et al. (7). The extracted total lipid was quantitated by gravimetry (8) and also following the method of Frings and Dunn (9), using olive oil as the standard. The neutral lipids and phospholipids (PL) from the total lipid were separated by batch chromatography on silicic acid column following the method of Vance and Sweeley (10). Individual PL were separated by single-dimensional thin layer chromatography (TLC) at room temperature on Silica Gel G and was developed by the development system of Mitnick et al. (11). For analytical purposes, the plates were exposed to I_2 vapor and marked. Amounts of individual PL were estimated in the scraped silica gel by phosphorus analysis (12) and computed with an average mol wt. of 775. Neutral lipids also were separated by TLC on Silica Gel G, using the solvent system, petroleum ether/diethyl ether/glacial acetic acid (90:10:1, v/v/v). Cholesterol and unesterified fatty acids were quantitated by the standard methods of Zak (13) and Novak (14), respectively. Cholesterol also was quantitated by gas liquid chromatography (GLC), using cholestenone as the internal standard. Triglyceride was quantitated by glycerol analysis (15), using glycerol trioleate as the standard.

Protein was determined by the modified sodium dodecyl sulfate (SDS)-Lowry procedure using crystallized bovine serum albumin as the standard (16). Nitrogen was analyzed by the method of Lang (17). Hexose and hexosamine were determined by the method of Sheflar (18). Equal amounts of D-mannose and D-galactose served as the hexose standard while D-glucosamine and D-galactosamine for hexosamine. Nucleic acids (DNA and RNA) were extracted by the method of Schneider (19). DNA was determined by the method of Burton (20), using calf thymus DNA as the standard, while RNA was estimated spectrophotometrically following the method of Munro and Fleck (21), utilizing the molar extinction coefficient of RNA at 260 nm. Sialic acid was estimated after acid hydrolysis following the method of Warren (22), and N-acetyl neuraminic acid was used as the standard. All chemical analyses were done in quadruplicate or more.

GLC of the methyl esters of fatty acid moieties of individual lipid classes was done after transesterification (23). GLC was performed with a Hewlett Packard instrument, using a column packed with EGSS-X on chromosorb with heptadecanoate as internal standard. The chromatographic conditions used were injection temperature 250 C, isothermal column temperature 186 C and nitrogen carrier gas at 54 lb/in.^{2}. The column was standardized using fatty acid methyl ester standards (Applied Science Laboratories, State College, PA), and the identification of unknown methyl esters was based upon a comparison of retention times of standards and the unknown. The chromatograms were directly encoded on punch cards, and the relative weight percentage of each methyl ester was calculated by computer integration of the areas under each curve. Fatty acids of PL classes were transesterified and transmethylated according to Metcalfe et al. (24). Fatty acid analysis was done in duplicate.

Enzyme assays. Glucose-6-phosphate phosphohydrolase was assayed following the method of Freedland and Haprer (25); the liberated phosphorus was estimated by either the method of Fiske and Subbarow (26) or Chen et al. (27), using potassium dihydrogen phosphate as the standard. Acid phosphatase and alkaline phosphatase (AKP) activities were assayed as described by Bergmeyer (28), using p-nitrophenyl phosphate as the substrate, and the liberated p-nitrophenol was mesaured at 419 nm. ($Na^+ + K^+$)-dependent ATPase estimation was carried out according to Quigley and Gotterer (29), and the enzyme activity was obtained by subtracting ouabain insensitive ATPase from the total ATPase. 5′-Nucleotidase was assayed according to Heppel and Hilmoe (30). β-N-acetyl glucosaminidase was estimated following the method of Sugden and Lazou (31). NADPH-cytochrome C reductase was estimated by the method of Mazel (32). Reduction of cytochrome P450 was followed spectrophotometrically at 550 nm and an extinction coefficient of 19.1 mM^{-1}/cm of the reduced form was utilized to calculate the enzyme activity. Succinic dehydrogenase was assayed following the method of Kun and Abood (33). For all enzyme analyses, SF samples were suspended in 0.1% Triton X-100 before the enzyme assay.

Isolation of SF-associated apoproteins. SF is dialyzed against 5 mM ethylenediamine tetraacetic acid (EDTA) in water for 24 hr, and the dialysate was lyophilized. The lyophilized material was delipidated according to Scanu et al. (34). Ethanol/ether (1:3, v/v) at −20 C was added to the dry powder and the lipids extracted overnight at −20 C. The protein precipitated as a fine white powder, which was pelleted by centrifugation at 10,000 × g for 30 min. The precipitate was reextracted twice more, first with 1:3 (v/v) ethanol/ether for four hr, followed by ether for four hr at −20 C. Both the supernatants and the precipitates were analyzed for their PL and protein contents. The precipitate was dried under a N_2 stream and suspended in buffer B (0.05 M sodium borate, pH 9.0, containing 0.1% SDS). The suspension was sonicated with a probe-type sonicator (MSE) with moderate power setting (12 amplitude microns) in an ice-water environment for 10 min and then centrifuted at 40,000 × g for one hr. The clear supernatant was used for sephadex gel filtration chromatography and polyacrylamide gel electrophoresis.

Sephadex gel filtration chromatography. Proteins were chromatographed on columns of sephadex G-200 (40–120 μm dry bead diameter, Pharmacia, Piscataway, NJ),

equilibrated with buffer B using a 90 × 2.5 cm (i.d.) column having a bed volume of 450 ml and a void volume of 150 ml as determined with blue dextran. They were eluted with buffer B at a flow rate of 25 ml/hr, monitored by UV absorption at 280 nm, and a 5 ml fraction of each was collected.

Polyacrylamide gel electrophoresis. Polyacryamide disc gel electrophoresis of the apoprotein was done in 10% acrylamide gels, uniformly in buffer B, essentially following the method of Weber and Osborn (35) at a constant current of 5 mA per gel. About 100 μg protein in 100 μl vol was applied in 0.2% SDS solution with 0.05% bromophenol blue as the tracking dye and 5 μl of 2-mercaptoethanol. After the electrophoresis was completed, the gels were treated with 10% trichloroacetic acid for 30 min, stained with 0.25% Coomassie blue in 50% methanol for four hr and destained overnight by diffusion in 10% acetic acid in water.

Electron microscopy. Pellets of SF were fixed for one hr with 3% glutaryldehyde in 0.1 M sodium phosphate buffer, pH 7.4, at room temperature and then post-fixed in 1% OsO_4 in the same buffer for one hr at 4 C, followed by several changes of 100% alcohol at room temperature. Pellets were infiltrated with a 1:1 (v/v) mixture of epon and propylene oxide at room temperature with constant shaking for one hr, followed by shaking overnight in 4:1 (v/v) mixture of the same. They subsequently were embedded in pure epon, and ultrathin sections were cut in a LKB Loba ultramicrotome, stained with lead citrate and uranyl acetate and finally examined with a Jeol 1200 XE electron microscope. The EM procedure was based on the method of Collet (36).

Immunological analysis. Antibodies directed against the purified surface-active material were obtained from New Zealand white rabbits by injecting intramuscularly at multiple sites in the hindquarters and footpads of rabbits 10 mg of SF mixed with 2 ml of complete Freund's adjuvant. The animals were reinjected with 1 mg of SF without adjuvant, one, two and three wk after the initial injection. If needed, the animals were fortified with 0.2 mg protein injected intravenously. Blood was collected from the ear vein four wk after the first injection and then weekly while the antibody titers remained high. The antiserum was separated by centrifugation and adsorbed for 60 min at 37 C against pooled human serum by mixing one drop of human serum with 1 ml of rabbit antiserum to remove antibody activity that reacted with this substance. The resulting precipitate was removed by centrifugation at 5,000 × g for 20 min, and the adsorption was repeated by mixing one drop of human serum in a 1:10 dilution (serum/normal saline, v/v) with 1 ml of antiserum incubated at 37 C for 60 min to separate the precipitate. The adsorption was repeated with human serum in a 1:100 dilution until no precipitate was visible. The antigen, suspended in solution containing 0.2% SDS, was studied using a double diffusion precipitation reaction in 0.75% agarose gels (Biorad Laboratories, Richmond, CA) following the procedure of Clausen (37). The gels were swollen in 0.05 M sodium barbital buffer, pH 8.0, containing 0.05% of SDS, and the reactions were carried out at room temperature in a moist atmosphere for 48 hr. The precipitation patterns were clearly visible after staining with Coomassie blue and then photographed with suitable backlighting.

Unless otherwise noted, analytical reagent-grade chemicals were used in all the experiments without further purification. Solvents were redistilled before use. The standards used in each of the analyses were specified by the manufacturers as being chromatographically homogeneous.

RESULTS

As reported in this paper, a SF fraction from human lung lavage fluid collected at autopsy is isolated and purified free of other subcellular contaminants such as mitochondria, lysosomes, endoplasmic reticulum and type-II cell plasma membranes. A low-power EM photomicrograph of the isolated material (Fig. 1) shows a considerable degree of purity with no apparent contamination. The fraction consists of membranous vesicles, lamellar structures and sheets of membranous materials. Vesicles with well-preserved limiting membranes and inclusion bodies are observed.

The chemical compositions of SF are given in Table 1. It is comprised almost entirely of lipid and protein with

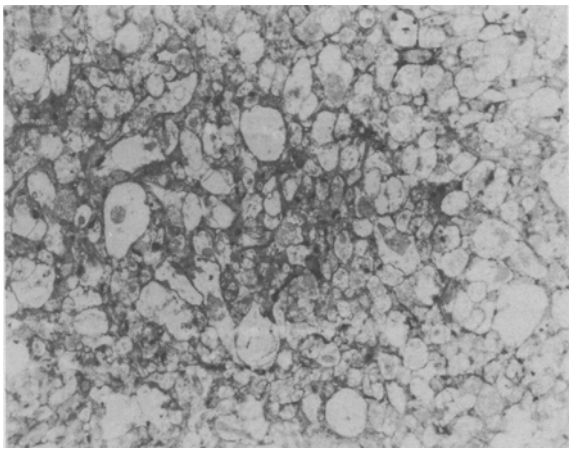

FIG. 1. Electron micrograph of surfactant isolated and gradient purified from adult human lung lavage (×3000).

TABLE 1

Chemical Composition of Human Pulmonary Surfactant

Chemical constitutent	mg/ml	% of dry wt
Dry wt (gravimetry)	10.90 ± 0.003	—
Protein	2.185 ± 0.012	20.04
Total lipid	7.99 ± 0.11	73.30
DNA	0.022 ± 0.002	0.20
RNA	0.061 ± 0.0003	0.55
Phosphorus	0.218 ± 0.006	2.0
Total sialic acid	0.0573 ± 0.0008	0.52
Hexose	0.174 ± 0.011	1.59
Hexosamine	0.046 ± 0.004	0.42
Nitrogen	0.379 ± 0.009	3.47

Results are mean ± SD of four to six observations. Whole lungs of either sex weighing between 700–1000 g were lavaged with 3 l of chilled buffer, with the average recovery of 60–70% of lavage fluid (ca. 2 l), which was processed for purification of SF. The isolated material finally was suspended in 5 ml of the buffer, and an aliquot was taken for determination of dry mass by gravimetry and also for analyzing each of the chemical constituents reported here and in the subsequent tables.

only small amounts of hexose, hexosamine, nucleic acids and sialic acid. The total lipid constitutes 73.34% of the SF dry wt., while the protein present is about 20%. About 2% phosphorus and 3.5% nitrogen also are present in the material. Lipid compositions of the isolated fraction (Table 2) show that PL constitutes more than 78% of the total lipid weight. Among the individual PL classes, phosphatidylcholine (PC) constitutes about 69% of total PL and phosphatidylethanolamine (PE) and phosphatidylglycerol (PG) are 8% and 11%, respectively. Lysophosphatidylcholine, phosphatidylinositol (PI) and sphingomyelin constitute relatively minor components of the total PL. Six neutral lipid fractions also can be identified by chemical analyses. These are cholesterol, cholesteryl ester, unesterified fatty acids and mono-, di- and triacylglycerol. Mono- and diacylglycerols in extremely small amounts also are detected by GLC constituting less than 1% of the total lipid. A seventh component migrating with mobility less than cholesterol has been isolated by TLC, but its identity cannot be established. A negligible amount of lipid-bound sialic acid also is present in the form of gangliosides, but cannot be quantitated by conventional chemical analysis.

Fatty acid compositions of the isolated PL classes are shown in Table 3. The predominant fatty acid of PC and PG is palmitic acid (16:0), while oleic acid (18:1) is the

Total unsaturated	29.5	72.3	44.5	54.3
Saturated/unsaturated	2.36	0.35	1.24	0.77

Results are mean of two independent observations.

main fatty acid present in the PE and PI fractions. Interestingly, 16:0 and 18:1 are quantitatively the next highest fatty acid components of PE/PI and PC/PG, respectively. A large variety of fatty acids differing in carbon number, chain length and number of double bonds are present in these PL fractions, ranging from 14:0 to 22:6. Saturated fatty acids consist of about 69.9 and 55.5% weight composition of total fatty acids for the two most important PL classes of surfactant, i.e. PC and PG, while PE and PI are more unsaturated.

Enzymatic analysis of SF indicates that it contains a very high specific activity of AKP (Table 4), but acid phosphatase activity is almost nonexistent. A number of subcellular marker enzymes also are assayed in the surfactant. There are negligible activities of lysosomal hydrolases such as β-N-acetyl glucosaminidase and microsomal markers like glucose-6-phosphatase and NADPH-cytochrome C reductase. Mitochondrial-specific succinic dehydrogenase and plasma membrane associated enzymes like $(Na^+ + K^+)$-dependent ATPase and 5′-Nucleotidase are not detected. These results suggest that our SF-enriched fraction apparently is not contaminated by endoplasmic reticulum, mitochondria, lysosomes or type-II cell plasma membranes and substantiate the EM observations.

Isolation of SF material is monitored systematically at each step of centrifugation by using PL/protein ratio, AKP-specific activity and surface activity of the isolated material as indications of purity. As shown in Table 5, the isolated surfactant from the stepwise gradient centrifugation step (75,000 × g sucrose density) represents considerable purity (× 196) based on the PL/protein ratio and 450-fold purity based on the AKP-specific activity compared with the initial lung lavage fluid. Additional centrifugation in a discontinuous sucrose density gradient does not significantly alter the ratio of PL to protein or AKP specific activity and, therefore, does not increase the purity but actually results in more than 60% loss of the purified sample and thus is avoided.

During delipidation, the substance precipitating in the ether/ethanol solution contains about 10% of the recovered phosphorus and more than 90% of the recovered proteins. The supernatant contains the remaining phosphorus but little or no amount of protein. The polyacrylamide gel electrophoresis in 10% acrylamide of the total protein is shown in Figure 2. There are three major components stained with Coomassie blue and one or two minor bands. The molecular weight assignments are based on comparison of the mobilities of protein standards with those recovered from the SF. The major components show molecular weight of about 68,000, 34,000 and 10,000 daltons. Sometimes, a high molecular weight material (>100,000) also is seen at the top of the gel, representing aggregated protein and probably not associated with SF. Gel filtration chromatography of these

Results are means of three observations. Isolation steps are carried out with 100 ml of initial lavage fluid.

proteins using Sephadex G-200 results in two separate fractions (Fig. 3). The first fraction contains mostly 68 kDa protein, which has identical electrophoretic mobility with serum albumin, while the second fraction eluted from the column contains 34 kDa and 10 kDa proteins that represent non-serum components. They also show the maximum surface activity and are consequently the proteins of particular interest in this study.

The results of a double diffusion immunoprecipitation in 0.75% agarose gel are shown in Figure 4A. The center well contains the antiserum directed against the whole surfactant that has been adsorbed against pooled human serum. The outer wells contain (1) purified and delipidated whole human lung lavage surface-active material, (2) peak II of Sephadex G-200 gel filtration chromatography of the isolated and delipidated SF and (3) peak I of the same. Both, whole SF and the material in the second Sephadex fraction, give one strong precipitation line with the antiserum. Figure 4B shows the immuneprecipitin reaction when two different dilutions of the antigen are used. Wells 1 and 3 contain 1:3 dilution of the surface-active material to normal saline while wells 2 and 4 represent 1:4 dilution

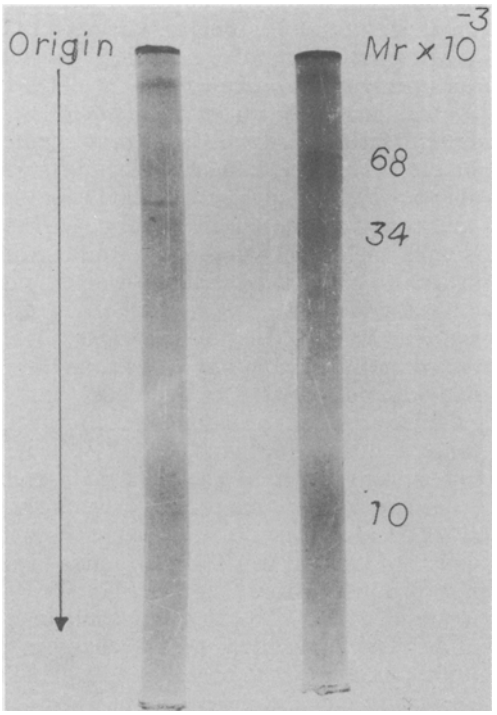

FIG. 2. Analysis of surfactant associated proteins by SDS-polyacrylamide gel electrophoresis. Electrophoresis is done in 10% acrylamide gels, using 0.05 M sodium borate buffer, pH 9.0, containing 0.1% SDS. The two gels indicate the independently isolated surface-active materials from bronchoalveolar lavage fluid of two different sets of lungs. The isolated materials are lyophilized and delipidated before electrophoresis.

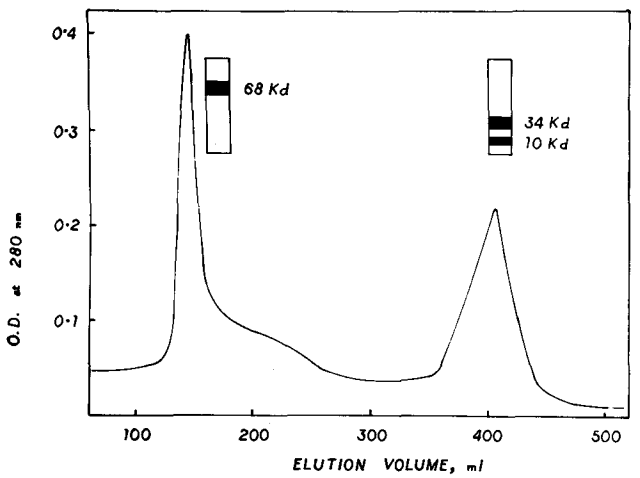

FIG. 3. Results of Sephadex G-200 gel filtration and polyacrylamide gel electrophoresis of proteins from human lung surface-active material. Gel filtration studies are carried out twice, and a representative result is shown.

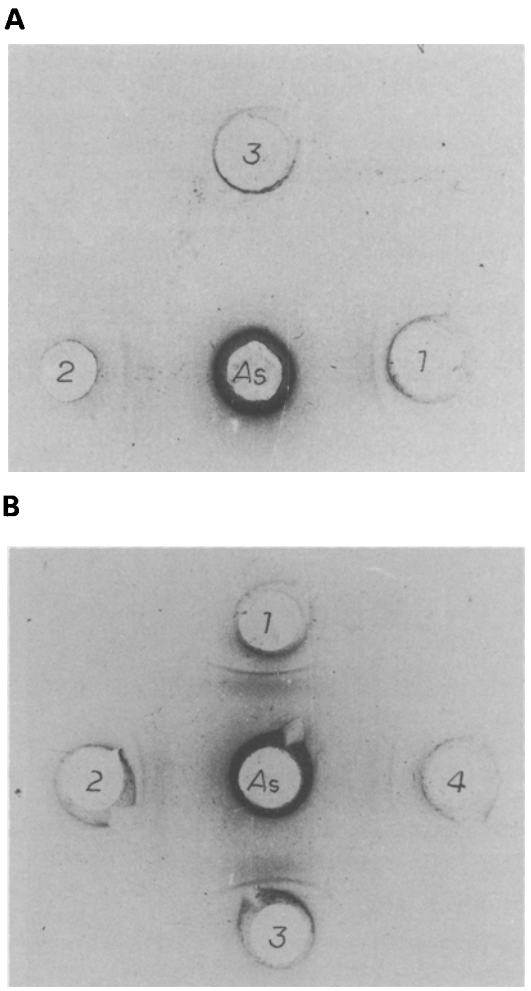

FIG. 4. (A) Double-diffusion immunoprecipitation in 0.75% agarose gel of lung surface-active material. (1) Purified surfactant from human lung lavage, (2) Peak II of the gel filtration chromatography, and (3) Peak I of the same. Center well contains antiserum against surfactant extensively adsorbed against pooled human serum. (B) Immune precipitin reaction with two different dilutions of the surface-active material. Center well contains antiserum against surfactant extensively adsorbed against human serum. 1 and 3 contain 1:3 (SF to normal saline) diluted surface-active material, whereas, 2 and 4 contain 1:4 dilution of the same. The surface-active material used is that purified through the 75,000 × g stepwise sucrose density gradient step (Fraction-I).

of the same. No diffusion of the pulmonary surface-active material takes place in agarose unless a dispersing agent such as SDS in 0.05% concentration is added to the gel.

DISCUSSION

In this work, SF from human lung lavage fluid have been isolated, and their biochemical, morphological and immunological compositions are characterized. Some investigators have developed a method to isolate lung SF from tissue homogenates (38,39). However, the risk of contamination using these methods is much higher because the lung tissue contains numerous cell types (40). Our method involves low-speed centrifugation for removal of cellular debris, followed by high-speed centrifugation and final purification by gradient centrifugation. The major advantage of the procedure, apart from the use of a single-step sucrose gradient in an ultracentrifuge, is that the centrifugation time is much shorter than most of the methods published before. Such combinations of differential and density gradient centrifugations yield SF fractions that are far more enriched based on phospholipid to protein ratio, AKP specific activity and surface activity than the crude lavage fluid. Our EM and marker enzyme data also establish the purity of the material, free of other lung subcellular contaminants. Presence of high concentrations of AKP in the isolated material leads us to believe that insoluble AKP probably is secreted from the lung lamellar bodies, and they can be used as potential markers for studies on synthesis and secretion of pulmonary SF. Tubular myelin-like figures, as observed by others in the ultrastructural studies of SF, are absent in our material (41,42) possibly because our isolation buffer did not contain Ca_{2+}, which tends to stabilize ordered lattice structures.

The chemical composition of pulmonary surface active material has been investigated in experimental animals in several laboratories (43) and there is general agreement that it is rich in PL, especially dipalmitoyl phosphatidylcholine (DPPC). Whether the protein associated with it qualifies it as a lipoprotein has been debated. Even after delipidation, the protein precipitated in ethanol/ether still retains 10% phospholipids. In the presence of PL, the surfactant-associated apoproteins migrate as a broad, blurred band in our electrophoretic experiments. PL analyses of the isolated SF show that the major components are either zwitterionic (PC) or acidic (PG), and, therefore, the firm association of PL-protein may occur through divalent cation linkage, hydrophobic interactions or both. Preponderance of the saturated fatty acid, palmitic acid, in these two PL of SF is confirmed by GLC analysis. Substantial amounts of monoenoic PL and neutral lipids also are present in SF. The functions of these lipids are not certain, but they do lower the temperature of an endothermic phase change or transition, called melting in synthetic lipid mixtures containing DPPC, which may be essential to the velocity of adsorption rates that are required in the alveolar lining.

The isolated material also contains two nonserum proteins of 34 and 10 kDa, respectively, which give a partial identity reaction with antiserum directed against the whole SF. Recently, there have been reports of the presence of a very low molecular weight protein, 5–6 kDa, in the lung surfactant system (44–46), which also is found to be chloroform-soluble. However, our method of isolation, delipidation and protein analysis by gel electrophoresis may exclude the presence of this extremely hydrophobic protein. SF apoproteins apparently function by promoting the formation of a surface active monolayer from bilayer lipids through a lipid-lipid interaction (46). However, the precise mechanism by which they influence lipid structures and/or mobility is not known. The immuno properties of these proteins will be used as a basis for a quantitative assay of surface-active material in small lung samples obtained by biopsy in further experiments to investigate the metabolism of SF and in samples of tracheal or amniotic fluid. The ultimate goal of this useful technique will be the prenatal assessment of lung maturity. Our method of isolation also can be used in large-scale isolation of SF required for therapeutic use in RDS of the neonates.

[Received May 5, 1987; Revision accepted February 8, 1988]

Promotion of Iron-induced Rat Liver Microsomal Lipid Peroxidation by Copper

Jeffrey K. Beckman*, Stephen M. Borowitz, Harry L. Greene and Ian M. Burr
Department of Pediatrics, Division of Gastroenterology and Nutrition, Vanderbilt University School of Medicine, Nashville, TN

Although copper has been demonstrated to promote lipid peroxidation in a number of systems, the mechanisms involved have not been fully defined. In this study, the role of copper in modifying lipid peroxidation has been explored in rat hepatic microsomes. In an in vitro system containing reduced glutathione (GSH, 200 μM) and Tris buffer, pH 7.4, cupric sulfate (1–50 μM) potentiated lipid peroxidation induced by ferrous sulfate (10 μM) but was unable to elicit peroxidation in the absence of iron. Higher levels of cupric sulfate (100 μM or greater) were inhibitory. The nature as well as the extent of the peroxidative response of microsomes to cupric sulfate were dependent on glutathione levels in addition to those of iron. Cupric sulfate (100 μM) strongly potentiated ferrous ion-induced lipid peroxidation in the presence of 400–800 μM GSH, while it inhibited peroxidation at lower levels of GSH (0–200 μM) and did not affect ferrous ion-induced peroxidation with glutathione levels of 3–10 mM.

The potentiating effect of copper on ferrous ion-induced lipid peroxidation was further explored by investigating: (1) potential GSH-mediated reduction of cupric ions; (2) potential copper/GSH-mediated reduction of ferric ions (formed by oxidation during incubation); and (3) possible promotion of propagation reactions by copper/GSH. Our results indicate that cupric ions are reduced by GSH and thus are converted from an inhibitor to an enhancer of iron-induced lipid peroxidation. Cuprous ions appear to potentiate lipid peroxidation by reduction of ferric ions, rather than by promoting propagation reactions. Iron (in a specific Fe^{+2}/Fe^{+3} ratio) is then an effective promoter of initiation reactions.
Lipids 23, 559–563 (1988).

Iron is an active agent throughout the reaction sequences involved in microsomal lipid peroxidation. Specific iron chelates promote the initiation phase of peroxidation, while other iron chelates are thought to act as propagators (1,2). The role of copper in lipid peroxidation is less defined. Hochstein et al. (3) demonstrated the formation of fluorescent chromolipids in human erythrocytes exposed to cupric sulfate. They suggested that cupric ions are reduced by membranous sulfhydryl groups (regenerated by reduced glutathione [GSH]) and subsequently react with molecular oxygen to yield superoxide anions which in turn promote peroxidation. Ding and Chan (4) described copper catalyzed lipid peroxidation in erythrocyte membranes following generation of membranous lipid hydroperoxides by exposure to ultraviolet light. Hydroperoxides were essential for this peroxidative response to copper, suggesting that copper promotes the degradation of lipid hydroperoxide and thus promotes the propagation phase of the peroxidation mechanisms.

In contrast with these findings, Wittig and Steffen reported that cupric ions inhibit NADPH-dependent rat liver lipid peroxidation (5). The inhibition of microsomal lipid peroxidation by copper paralleled a similar effect of 100,000 × g supernatant (containing equivalent concentrations of copper).

As part of an effort to define agents that act as initiators and/or propagators of lipid peroxidation, we have explored the effect of copper on basal and ferrous ion-initiated peroxidative responses.

EXPERIMENTAL

Materials. ADP, bathocuproine, cytochrome c (Type III from horse heart), GSH, 2-thiobarbituric acid (TBA) and xanthine were obtained from Sigma Chemical Co. (St. Louis, MO). Ferric chloride and ferrous sulfate were purchased from Aldrich Chemical Co. (Milwaukee, WI). Cupric sulfate was purchased from Merck and Co. (Rahway, NJ).

Enzymes. Bovine erythrocyte superoxide dismutase (SOD) (EC 1.15.1.1) was obtained from Miles Biochemical (Elkart, IN). Xanthine oxidase (EC 1.2.3.2) was purchased from Sigma Chemical Co.

Preparation of microsomes. Liver microsomes were prepared from 20 g of tissue from a 10% homogenate in 0.15 M KCl, 10 mM Tris buffer, pH 7.4, by performing differential centrifugation. The pellet obtained by centrifuging the 20,000 × g supernatant at 100,000 × g was resuspended in homogenization buffer (5–10 mg protein/ml) and assayed for protein content (6).

Preparation of oxidized and control phospholipid liposomes. Phospholipid hydroperoxides were prepared from egg phosphatidylcholine (Type III E, Sigma Chemical Co.) using soybean lipoxygenase-1 and incubating one hr at pH 9.0 in the presence of 10 mM deoxycholic acid as described by Eskola and Laakso (7). The extent of formation of phospholipid hydroperoxide was monitored by U.V. absorbance (232–235 nm) using a molar coefficient of 27,000 M^{-1} cm^{-1} (8). Chloroform/methanol solutions of oxidized and unoxidized phosphatidylcholine were combined such that 10% of the phospholipid was oxidized. Following evaporation of organic solvents, phospholipid liposomes were prepared by sonication in water to a concentration of 1 mM phosphatidylcholine. Control phospholipid liposomes were prepared in the same manner omitting the phospholipid hydroperoxide and substituting unoxidized phospholipid.

In one experiment, liposomes were prepared from the total (neutral plus polar) lipids of liver microsomes by sonication at their original concentration in homogenization buffer. An Aminco-Bowman spectrofluorometer was used with a relative intensity of 1.0 being defined as a reading of 10 on sensitivity setting 10. Standard solutions yielded relative intensities of 0.9, 1.7, 3.25 and 6.1 for 0.5,

Abbreviations: ADP, adenosine 5′-diphosphate; GSH, reduced glutathione; SOD, superoxide dismutase; TBA, 2-thiobarbituric acid.

1.0, 2.0 and 4.0 nmol of malondialdehyde. More intense samples were diluted 10:1 in butanol before reading.

Other assays. Cuprous copper was detected by measurement of complex formation with bathocuproine (11). Ferrous iron was detected by measurement of reactivity with 1,10-phenanthroline (12).

RESULTS

Cupric sulfate (1–50 μM) potentiated ferrous ion-promoted lipid peroxidation in a system consisting of rat liver microsomes in 100 mM Tris buffer, pH 7.4, containing 200 μM GSH and ferrous sulfate (10 μM) (Fig. 1). However, copper did not induce peroxidation in the absence of iron (Fig. 1). Higher levels of copper (100, 200 μM) inhibited iron-induced lipid peroxidation. A temporal study of ferrous ion-induced lipid peroxidation in the presence and absence of copper/GSH showed the potentiation of peroxidation by 10 μM copper developed after a lag period during which time the peroxidative response to iron alone was rapid (Fig. 2). In the presence of copper/GSH, iron-induced peroxidation continued for a longer period before plateauing. In these initial investigations, adenosine 5′-diphosphate (ADP) (1 mM) was included in reaction mixtures to promote iron-induced peroxidation (1). We determined that in our system, the effect of ADP was a minor (less than 15%) enhancement of both the iron and copper/iron peroxidative responses and did not add ADP in subsequent investigations except where particularly noted. GSH was included in reaction mixtures to facilitate possible redox cycling reactions (3). The dependency of the peroxidative response to copper (in the presence of iron) on GSH is demonstrated in Figure 3. Cupric sulfate was ineffective in the absence of GSH and higher levels of copper (100 μM) inhibited iron-induced peroxidation. At glutathione levels of 400–800 μM, copper-promoted potentiation of ferrous ion-elicited lipid peroxidation was optimal, and higher levels of copper (100 μM) now strongly enhanced the peroxidative response. Cupric sulfate was ineffective, however, in modifying peroxidative responses to iron in the presence of 3–10 mM GSH.

The peroxidative response of microsomes to copper/iron was tested in a 5 mM phosphate buffer (pH 7.4) to investigate possible artifacts due to the use of Tris buffer. Initial results indicated that copper was ineffective in phosphate buffer. Chelation of copper with ADP (10 × concentration in an aqueous solution) before its addition to reaction mixtures resulted in potentiation of iron-induced peroxidation comparable to that seen in Tris buffer (with or without ADP) (data not shown). A similar chelation of iron with ADP did not allow copper induced potentiation of lipid peroxidation in phosphate buffer.

Reduction of cupric ions to the cuprous form by glutathione (400 μM) was demonstrated by measuring complex formation with bathocuproine (Fig. 4) and thus conceivably is involved in copper-promoted peroxidation.

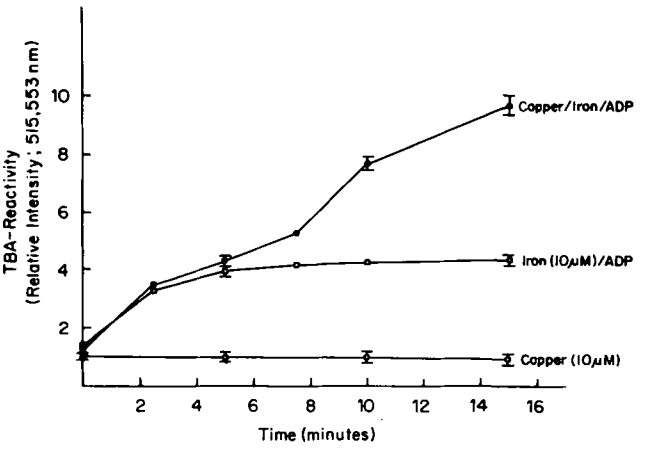

FIG. 2. The time dependency of copper/iron-induced lipid peroxidation. Rat liver microsomes were exposed to cupric sulfate (10 μM) (○), to ferrous sulfate (10 μM) (□) or to the combination of cupric sulfate and ferrous sulfate (same concentration as above) (●) for the indicated duration in the presence of glutathione (200 μM), ADP (1 mM) and 100 mM Tris buffer (pH 7.4) at 37 C. Lipid peroxidation was assessed by a spectrofluorometric measurement of TBA-reactivity. Brackets denote the SEM of four observations.

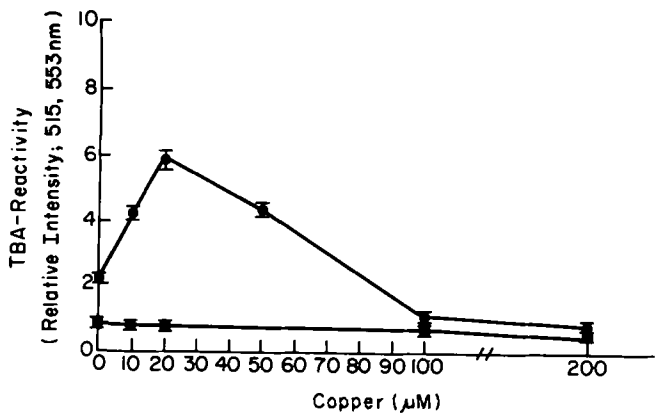

FIG. 1. The effects of copper on basal and iron-promoted microsomal lipid peroxidation. Rat liver microsomes were exposed to the indicated concentration of copper for 15 min at 37 C in the presence of 200 μM GSH in 100 mM Tris buffer (pH 7.4) and (■) no additional agent or (●) ferrous sulfate (10 μM). Lipid peroxidation then was assessed by spectrofluorometric measurement of TBA-reactivity. Brackets denote the SEM of four observations.

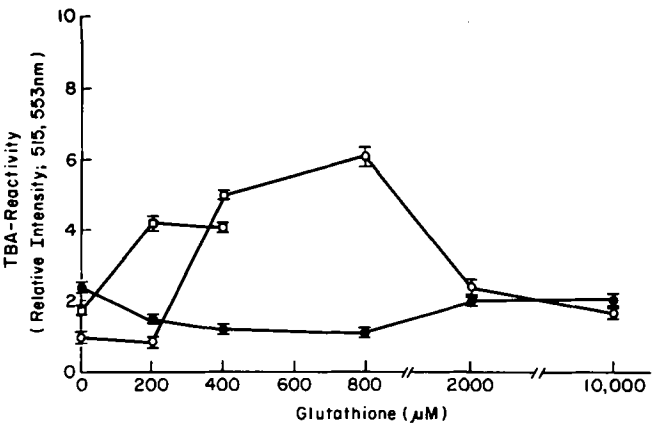

FIG. 3. The GSH dependency of cupric ion-induced lipid peroxidation. Rat liver microsomes were exposed to ferrous sulfate (10 μM) and either no additional metals (●) or to cupric sulfate (10 μM) (□) or cupric sulfate (100 μM) (○). GSH was included in reaction mixtures at the indicated concentration. Lipid peroxidation was assessed as described above. Brackets denote the SEM of four observations.

A possible mechanism for cupric sulfate/GSH-promoted peroxidation is that iron, oxidized to the ferric form during the course of incubation, is reduced by cuprous ion (a thermodynamically feasible process) and may exert an amplified peroxidative response. In microsome-free incubation media, rapid oxidation of ferrous ion was demonstrated (by measurement of phenanthroline reactivity), while the co-presence of both cupric ions and glutathione (but not individually) spared ferrous ion levels (Fig. 5). Following complete oxidation of 20 μM ferrous ion, partial regeneration (29% in 5 min) was demonstrated by subsequent exposure to cupric sulfate (100 μM) and glutathione (400 μM), while the individual agents were either without effect or accelerated the rate of oxidation. Copper/GSH at these levels did not yield a measurable ferrous ion-like response (phenanthroline reactivity).

Copper (100 μM)/GSH (400 μM) promoted microsomal lipid peroxidation when ferric chloride was used as a source of iron (relative intensity = 9.6 ± 0.5 following a 10-min incubation, n = 4), while GSH alone was ineffective (relative intensity = 0.8 ± 0.3, n = 4).

Potential involvement of enzymes in the peroxidative response of membranes to copper/GSH/iron was explored by substituting liposomes, prepared from an extract of microsomal lipid, for microsomes in peroxidation reaction mixtures. A qualitatively similar pattern of lipid peroxidation resulted; TBA-reactivity for reaction mixtures containing the peroxidative stimuli of ferrous ion (10 μM)/GSH (400 μM) was 3.8 ± 0.9 (relative intensity; n = 4 each group) compared with the copper (100 μM)/GSH/iron peroxidative response of 6.6 ± 0.5 ($p < 0.001$) and the copper (100 μ)/GSH (400 μM) response of 0.6 ± 0.07 ($p < 0.001$).

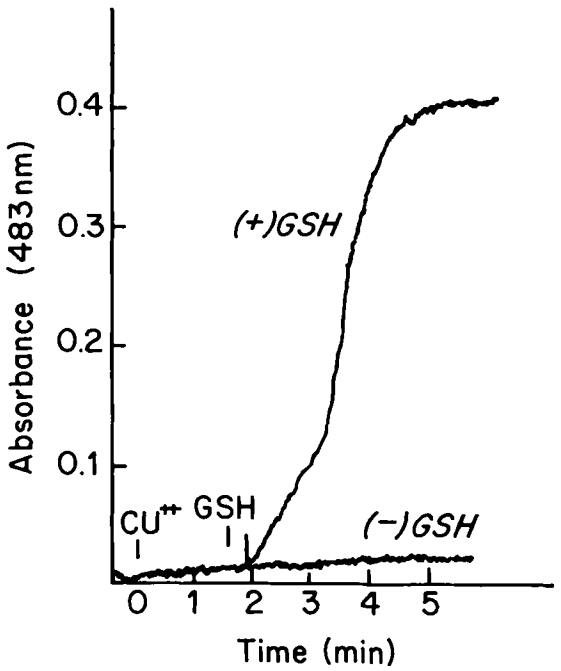

FIG. 4. GSH-mediated reduction of cupric ion. Formation of cuprous ion from cupric sulfate (100 μM) was measured spectrophotometrically at 483 nm by the formation of a complex of cuprous ion and bathocuproine (250 μM). Glutathione (400 μM) was added as indicated by the arrow. Controls (glutathione without copper) did not affect baseline absorbance.

To investigate whether copper/GSH was enhancing peroxidation by promoting propagation reactions, liposomes were prepared from fresh solutions of phosphatidylcholine (control liposomes) and from phosphatidylcholine liposomes containing 10% phosphatidylcholine hydroperoxide (oxidized liposomes). Ferrous sulfate (10 μM) promoted the formation of TBA-reactive material following incubation with oxidized liposomes, while much lower levels resulted using control liposomes. This

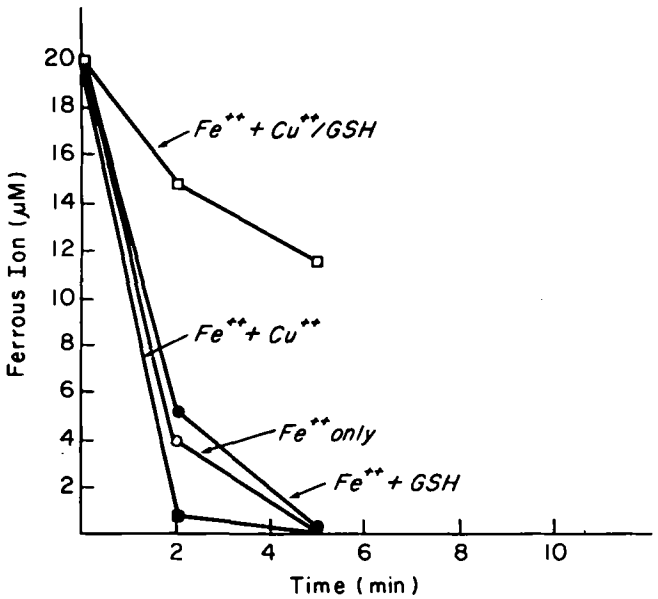

FIG. 5. Oxidation of ferrous ion during incubation at 37 C; sparing effect of copper/GSH. Ferrous sulfate (20 μM) was incubated at 37 C for the indicated duration in the presence or absence of combinations of GSH (400 μM) and cupric sulfate (100 μM) as indicated. Ferrous ion levels then were assessed by measurement of phenanthroline reactivity. Brackets denote the SEM of six samples.

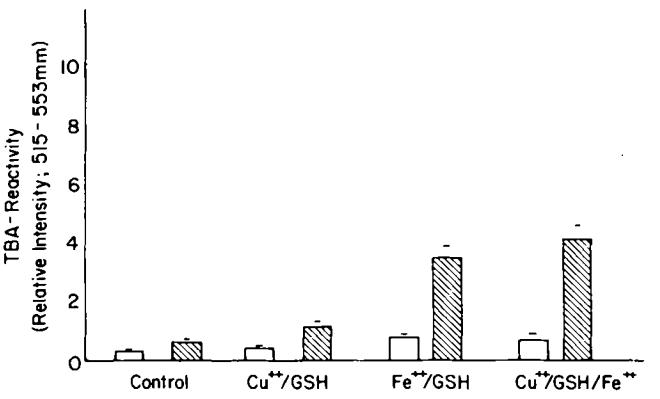

FIG. 6. Propagation of liposomal lipid peroxidation by copper and iron. Phosphatidylcholine liposomes were prepared with from egg phosphatidylcholine to which 10% phosphatidylcholine hydroperoxides were added (cross-hatched bars) or without the addition of hydroperoxides (controls, open bars). Liposomes (200 nmol/0.5 ml) were incubated in 50 mM Tris buffer (pH 7.4), with combinations of cupric sulfate (Cu^{++}, 100 μM), glutathione (GSH, 400 μM) and ferrous sulfate (Fe^{++}, 10 μM) as indicated. Lipid peroxidation was then assessed by spectrofluorometric measurement of TBA-reactivity. Brackets denote the SEM of four observations.

supports the concept that enhanced peroxidation resulted from propagation reactions (Fig. 6). By contrast, copper (50 μM)/GSH (400 μM) promoted much less peroxidation in either liposome preparation (Fig. 6).

DISCUSSION

The mechanisms of lipid peroxidation involve distinct phases of initiation (production of catalytic levels of lipid hydroperoxide accompanied by low levels of TBA-reactive end-products) and propagation (degradation of the primary lipid hydroperoxides to form reactive radicals that re-initiate peroxidation and generate additional hydroperoxide as well as end-products) (1,2). Iron functions in both the initiation and propagation phases with ADP/ferrous ion, serving primarily as an initiator and other iron chelates, including perhaps cytochrome P450-ferric ion serving as propagators. Our results suggest that in an iron-initiated system, cupric sulfate in the presence of GSH serves to augment lipid peroxidation of rat liver microsomes by a mechanism that likely involves oxidation/reduction reactions.

The potentiation of iron-induced lipid peroxidation by copper was highly dependent on the level of GSH. Cupric sulfate (100 μM) inhibited lipid peroxidation in the presence of low levels (0–200 μM) but strongly potentiated peroxidation with 400–800 μM GSH and was without effect with 2–10 mM GSH. Lower levels of copper (10 μM) effectively potentiated iron-induced peroxidation in a somewhat extended dose range (100–400 μM) of GSH. We hypothesize that GSH is required to reduce cupric ions to the cuprous form and by so doing transform copper from an inhibitor to a positive modifier of iron-induced peroxidations. Formation of cuprous ion during incubation of cupric sulfate with GSH (but not without GSH) was demonstrated by complex formation with bathocuproine supporting this contention.

Glutathione thus may promote copper-potentiated lipid peroxidation despite GSH being an inhibitor of iron-induced peroxidation (13). High level (2–10 mM) of GSH may directly reduce iron (14) and, in this manner, may promote in vitro peroxidation. Copper was ineffective as a potentiator of lipid peroxidation in the presence of these GSH levels, suggesting that cuprous ions may augment peroxidation by a similar mechanism involving iron reduction. Measurement of ferrous ion levels by the phenanthroline assay indeed revealed that ferrous ions rapidly are oxidized during model incubations and that cupric sulfate in the required presence of GSH slowed the rate of decline of ferrous ion. Regeneration of ferrous ion from media in which iron had been completely oxidized similarly was demonstrated. Further support for the role of copper/GSH in the reduction of iron was obtained by using ferric chloride as an iron source in assays of microsomal lipid peroxidation as the resulting level of TBA-reactivity was comparable with that obtained with copper/GSH/ferrous sulfate.

Recent studies support the concept that both oxidized and reduced iron are required for initiation reactions (15–17). A lag period was noted for peroxidative response to copper (in the presence of ferrous ion), which may reflect the rapid oxidation of Fe^{2+} and the subsequent regeneration of ferrous ion and formation of a ratio of Fe^{3+}/Fe^{2+} active for peroxidation. Bucher et al. (16) similarly noted lag periods for reduced iron chelates that were eliminated by the addition of chelates of oxidized iron supporting the contention that both forms of iron are required.

It is conceivable that cupric ions might function as a source of oxidized metal in addition to promoting the reduction of iron. The inhibition by cupric ions of ferrous sulfate promoted peroxidation (in the absence of GSH) would argue against such a role for copper in this system.

Inhibition of microsomal lipid peroxidation by GSH has been attributed to a glutathione-dependent microsomal protein (18) as well as numerous GSH-dependent cytosolic proteins that may be adherent to the microsomal preparation (19–21). An hypothesis that copper was promoting iron-induced peroxidation by inhibiting a component of the cytosolic defense is unlikely because liposomal membranes exhibited a similar peroxidative response.

Cuprous ions added to hydrogen peroxide (a product of phagocytic cell activities) generate reactive oxygen species including hydroxyl radicals (22). However, in biological systems copper is tightly bound to protein, including most notedly ceruloplasmin and albumin (23). Evidence has indicated that hydroxyl radicals may be generated by protein-bound copper and that such hydroxyl radicals will react rapidly at their site of generation to cause site-specific protein damage (24). It is unlikely that hydroxyl radicals are involved in the peroxidative response to copper, however, as microsomes contain protective enzymes (catalase, glutathione peroxidases) that should limit the availability of hydrogen peroxide and, in any event, in systems in which the generation of hydroxy radicals was certain, it was demonstrated that hydroxyl radicals do not participate in iron-dependent peroxidation of phospholipid liposomes (17,25). Minotti and Aust have demonstrated that the initiation of lipid peroxidation by Fe^{2+} and hydrogen peroxide is not mediated by the generated hydroxyl radicals, but is alternatively linked to H_2O_2-mediated oxidation of iron and requires both reduced and oxidized forms of iron (17).

The use of a phosphate buffer in place of Tris necessitated the chelation of copper with ADP before addition to peroxidation reaction mixtures to obtain a comparable potentiation of peroxidation. Thus, it appears that complexed rather than free copper is involved in this peroxidative response. The lack of requirement for ADP with Tris buffer may be due to an alternative Tris-copper complex, the formation of which has been suggested (26).

Our data suggests that the reduction of iron plays a major role in the potentiation of lipid peroxidation by cuprous ions. We investigated on alternative mechanisms by which cuprous ion may act as promoter of propagation reactions by studying peroxidation of phospholipid liposomes with and without phospholipid hydroperoxide. Ferrous sulfate effectively propagated the peroxidation of the oxidized liposomes, while control liposomes, which lacked sufficient hydroperoxide initiator, were peroxidized to a much lesser degree. Propagation thus could be evaluated in this system largely independent of initiation. Copper/GSH was not as effective a promoter of propagation as iron or copper/GSH/iron, indicating that the primary role of copper in the potentiation of iron-induced peroxidation is to provide enough reduced iron (and an optimal Fe^{2+}/Fe^{3+} ratio) for initiation reactions to proceed rather than to promote propagation reactions.

Serum Lipids in Spontaneously Hypertensive Rats and Sprague-Dawley Rats Fed Menhaden Oil

T.R. Kingsley[a,b,*] and **D.L. Snyder**[b]
[a]Indiana University School of Medicine, South Bend Center, and Lobund Laboratories, and [b]Notre Dame University, Notre Dame, IN

Dietary n-3 fatty acids, abundant in fish oil, exert a variety of effects that attenuate cardiovascular disease. In this study, we assessed the effect of fish oil (menhaden oil) on the serum lipid profile in hypertensive and normotensive rats. Spontaneously hypertensive rats (SHR) or Sprague-Dawley rats (SD) were fed either standard powdered diet (L-485), or L-485 + 5% menhaden oil (MO) or L-485 + 5% corn oil (CO) from weaning through eight months of age. Systolic blood pressure (BP) was periodically determined on SHR. Serum lipid profiles were performed at eight months on samples taken from the exposed hearts of anesthetized, fasted rats. SHR, compared with SD (diets combined) had significantly lower triacylglycerols (TG), higher cholesterol (CHOL), higher high density lipoprotein cholesterol (HDL CHOL), higher low density lipoprotein cholesterol (LDL CHOL), and a higher LDL:HDL ratio. Comparisons among diets (strains combined) revealed that rats fed MO had the lowest values for TG, CHOL, LDL and LDL:HDL; HDL did not vary with diet. SHR were less responsive to diet-induced changes than were SD; no decrease in TG, LDL or LDL:HDL was observed in SHR, nor was degree of hypertension altered in SHR by the MO or CO diet. In summary, MO is more effective than CO in shifting the lipid profile of rats toward one that is less atherogenic. However, the SD rat is more susceptible to diet-induced lipid modification than is the SHR.
Lipids 23, 564-567 (1988).

The relationship between the composition of dietary lipids and the development of cardiovascular disease is the subject of intense research interest. High dietary intake of saturated fatty acids and cholesterol, combined with genetic and other undefined factors, seem to contribute to the development of atherosclerosis and, perhaps, hypertension (1). Increased consumption of the polyunsaturated fatty acids found in marine fish oils (the n-3 polyenes, or linolenic acid derivatives) has been found to have a variety of beneficial effects. Early reports revealed a low incidence of cardiovascular disease among Eskimos who consume large amounts of these oils (2). The n-3 polyenes decreased platelet aggregation (3-5), and reduced levels of cholesterol and triacylglycerols in humans (6-9) and laboratory animals (10-12).

We used the spontaneously hypertensive rat (SHR) to examine the effect of chronic ingestion of marine fish oils on subjects prone to cardiovascular disease. This strain, derived from the Kyoto-Wistar (13), exhibits severe hypertension that begins to develop at four wk, and that is accompanied by vascular pathology similar to that found in humans (13-16). A moderate amount (5%) of fish oil was added to the diet of SHR and of normotensive Sprague-Dawley rats from weaning (4 wk) through eight months of age. We analyzed the effects on the lipoprotein profile of both strains, and monitored the development of hypertension in the SHR.

METHODS

Experimental design. The main purpose of these experiments was to assess various effects of the addition of n-3 polyenes to the diet of rats prone to hypertension and vascular disease (SHR), and compare them with the effects of the same diet on rats that exhibit no tendency to such pathology. For comparison with SHR, we selected the Lobund Sprague-Dawley rat (SD), a strain that has been observed through 56 generations of breeding at Lobund, and has shown no tendency towards cardiovascular disease. Rats were weaned at four wk of age, at which time they were weighed and distributed into groupings that would produce a similar mean weight for each group before initiation of treatment. One group was fed a diet supplemented with menhaden oil (MO) (a marine oil rich in n-3 polyenes); a second group was fed a diet supplemented with an equivalent amount of corn oil (CO) as a control; a third group was maintained on the stock diet utilized by Lobund Laboratories (L-485) to provide an evaluation of baseline values for both strains, before the addition of oils. All rats were maintained on the diets from 4 to 35 wk. This extended period was necessary to allow adequate time for the development of cardiovascular lesions in SHR, which generally are not apparent before eight months. Systolic blood pressure (BP) and body weight (BW) were measured on SHR initially, then at two-wk intervals through 12 wk (the period of rapid increments in BP); afterwards, measurements were made at monthly intervals. All rats were killed at 35 wk of age, and blood and tissue samples were taken for evaluation.

Animals. Animals were obtained from the inbred colony at Lobund Laboratory. Original SHR stock had been obtained from the Laboratory Supply Co. (Indianapolis, IN). They were given unchlorinated tap water and housed in plastic boxes on Sani-cel bedding, in air- and humidity-controlled rooms, with a 12-hr light and dark cycle.

Diet. Before weaning, all animals were fed L-485, a natural grain diet supplemented with vitamins and minerals (Table 1) (17). After weaning, rats were maintained either on powdered L-485, or on powdered L-485 supplemented with 5%, by weight, menhaden oil (MO) (Zapata Haynie Corp., Reedville, VA) or 5% CO. A complete listing of the fatty acid composition of each diet is provided in Table 2. Rats were fed ad libitum. Food containers were emptied and replenished every 48 hr to prevent the ingestion of the toxic oxidation products of MO.

Determination of serum lipids. Triacylglycerols (TG), cholesterol (CHOL), HDL CHOL and LDL CHOL were determined in serum of rats fasted overnight. Blood samples were taken from the exposed hearts of ether-anesthetized rats and allowed to clot for 30 min before centrifugation. Some serum samples were frozen before analysis. Analysis of all samples was performed at the South Bend Medical Foundation (SBMF), South Bend, IN, using standard clinical procedures. TG were measured by a modification of the procedure of Levy and Frederickson, which is based upon depletion of NADH after a series of reactions in which TG are the initial substrate (18). CHOL measurements were done by a procedure based upon the oxidation of quinoneimine (19). Measurement of HDL CHOL was performed after precipitation of LDL and VLDL by dextran sulfate and magnesium chloride; HDL CHOL was then measured by the above method for CHOL (19). LDL CHOL was calculated according to the equation:

LDL CHOL = Total CHOL − HDL CHOL − (triacylglycerols/5).

Blood pressure determinations. Systolic blood pressure (BP) was evaluated by the tail cuff method, using the IITC Model 59 amplifier, which does not require preheating of the animal.

Statistical analysis. Data were analyzed using the Statistical Analysis System (SAS) software package (20) on the University of Notre Dame's IBM 3033 mainframe computer. A two-factor design (strain and diet) for analysis of variance (ANOVA) was performed individually on each serum lipid component, blood pressure and body weight, using the general linear model (GLM) program from SAS. Strain had two treatments: SHR and SD. Diet had three treatments: L-485, MO and CO. The GLM program compensates for unequal sample sizes. In each ANOVA procedure, a single error mean square is used to calculate a separate F-statistic for the overall model, the strain, the diet and the interaction between diet and strain treatments. Duncan's multiple-range test was used to distinguish between treatments within a factor when the GLM procedure indicated that a factor or interaction had a significant effect on the parameter being analyzed. Significance was set at 0.05. Values are expressed as Means ± SE.

RESULTS

Data from the blood lipid analyses, as well as body weight and blood pressures determined at 35 weeks of age are summarized in Table 3.

Body weight. SD rats had significantly higher body weight than SHR (459 vs 409 g), although the weight of SHR fed L-485 exceeded that of SD fed L-485 (381 g vs 354 g). With strains combined, the weight of rats fed MO was equivalent to those fed CO (452 g vs 445 g), and exceeded that of rats fed L-485 (367 g).

Blood pressure. Apparent diet-related BP differences in SHR were not significant (MO = 215.6, CO = 221.7, and L-485 = 225.8 mm Hg).

Triacylglycerols. Serum TG levels were affected by strain and diet. ANOVA showed that SHR had significantly lower serum TG than SD. Rats fed MO had significantly lower serum TG than rats fed CO or L-485. There was no interactive effect between strain and diet.

TABLE 3

Effect of Dietary Oil on SHR and Sprague-Dawley Rats*

	Body weight (g)	Systolic BP (mmHg)	Triacylglycerols (mg/dl)	Cholesterol (mg/dl)	HDL (mg/dl)	LDL (mg/dl)	LDL:HDL
SD/CO (N = 6)	495.3 ± 17.1[a]	—	90.5 ± 11.6[a,b]	74.0 ± 3.7[b,c]	46.0 ± 2.8[b]	9.9 ± 3.8[b]	0.2[b,c]
SD/MO (N = 6)	509.3 ± 21.6[a]	—	74.5 ± 7.5[b]	63.2 ± 2.3[c]	42.5 ± 1.5[b,c]	5.8 ± 1.4[b]	0.1[c]
SD/L-485 (N = 5)	354.2 ± 18.5[c]	—	104.2 ± 17.5[a]	78.0 ± 2.2[b]	36.0 ± 2.0[c]	21.2 ± 2.7[a]	0.6[a]
SHR/CO (N = 10)	415.4 ± 5.4[b]	221 ± 4	41.7 ± 5.2[c]	84.2 ± 2.4[b]	48.5 ± 2.9[b]	27.3 ± 1.7[a]	0.6[a]
SHR/MO (N = 10)	417.7 ± 5.1[b]	215 ± 2	22.8 ± 3.2[c]	74.1 ± 3.1[b,c]	47.9 ± 3.1[b]	21.7 ± 2.6[a]	0.5[a]
SHR/L-485 (N = 5)	380.6 ± 13.6[b,c]	225 ± 2	26.4 ± 5.5[c]	97.4 ± 7.2[a]	65.8 ± 3.0[a]	26.4 ± 4.1[a]	0.4[a,b]

*Data from rats at age 35 wk, after maintenance on diet from age four wk.

All values are mean ± standard error; values with the differing superscript are significantly different ($p < .05$) as determined by Duncan's multiple-range test after two-factor analysis of variance.

Cholesterol. Serum CHOL levels were affected by strain and diet. ANOVA showed that SHR had significantly higher serum CHOL than SD, but the difference was small, relative to that seen for TG. SHR values were higher on each of the diets. Rats fed MO had significantly lower serum CHOL levels than rats fed CO or L-485. MO lowered CHOL in both strains, but there was no interactive effect between strain and diet.

HDL cholesterol. Serum HDL CHOL levels were affected by strain but not by diet. ANOVA showed that SHR had significantly higher HDL CHOL than SD. SHR fed L-485 had significantly higher HDL CHOL levels than all other groups.

LDL cholesterol. Serum LDL CHOL levels were affected by strain and diet. ANOVA showed that SHR had significantly higher serum LDL CHOL than SD. MO reduced serum LDL CHOL levels. There was no interactive effect between strain and diet.

LDL/HDL ratio. The ratio followed the same pattern as serum LDL. ANOVA showed that SHR had a ratio significantly higher than SD rats. MO reduced the ratio. SD rats fed MO or CO had a ratio that was significantly lower than other groups.

DISCUSSION

The data presented compare values for blood lipids in a strain of rat that exhibits hypertension (SHR), with blood lipids in an unrelated strain that is not susceptible to hypertension (SD). A survey of values obtained by others reveals considerable variation in levels of CHOL and TG for rats maintained on unmodified diets: CHOL values ranged between 28.4–79.9 mg/dl for SHR, and 40.2–83.2 mg/dl for other strains (1,21–23); TG values of 40.2 mg/dl (1) and 96.0 mg/dl (21) for SHR, and 40.0 mg/dl (23) and 63.2 mg/dl (1) for other strains have been obtained. SHR maintained on our stock diet, L-485, had somewhat higher CHOL (97.4 mg/dl) and lower TG (26.4 mg/dl); SD had CHOL of 78.0 mg/dl, but TG levels were somewhat higher than previously observed (104.2 mg/dl) (Table 3). Variations in the stock diets as well as in techniques for measurement of serum lipids could account for the wide ranges of values reported for a given strain. It should be noted that the fatty acid (FA) content of L-485 is derived entirely from vegetable sources (Table 1), and consists of approximately equal parts monounsaturated FA (oleic acid) and polyunsaturated FA (primarily linoleic acid) (Table 2). Such a diet might be expected to minimize values for CHOL and TG.

A comparison of the SHR lipid profile to that of the SD reveals that, irrespective of diet, the SHR has lower serum TG but higher CHOL, HDL CHOL, LDL CHOL, and a higher LDL:HDL ratio. Apart from the unexpectedly low level of TG, the lipid profile presented in the SHR is consistent with the atherogenesis observed in the strain, and implies that the SHR may exhibit fundamental differences in lipid metabolism that contribute to their cardiovascular pathology.

Addition of dietary fats rich in either linoleic or linolenic acid has been reported to lower both cholesterol and triacylglycerols, the linolenic acid source (fish oil) being more effective (11,24). We observed a similar trend. Enrichment of stock diet with either CO or MO lowered both TG and CHOL in SD, with MO eliciting a greater effect. A similar pattern was observed in SHR with respect to CHOL levels; however, neither diet supplement lowered TG in SHR. With respect to HDL and LDL levels, SD responded to either oil supplement with an increase in HDL and a decrease in LDL, and a consequent reduction in the HDL:LDL ratio. MO was somewhat more effective than CO in this regard. The SHR, however, was again less responsive to the effects of either oil supplement. Both oils elicited a decrease in HDL and no change in LDL, resulting in a slight increase in the LDL:HDL ratio. This ratio, generally regarded as an indicator of atherogenic potential (atherogenic index), thus remains high in SHR, following long-term addition of either linoleic or linolenic acids to their diet. Because SD, exposed to the same diet regimen, experienced a marked reduction in this index, there appear to be fundamental differences in lipid metabolism between the strains, resulting in high LDL levels in SHR despite diet modification.

Addition of MO to the diet of SHR and stroke-prone SHR (SPSHR) has been shown to attenuate the development of hypertension (25). Others have shown that supplementation of the SHR's diet with linoleic acid, a major constituent of CO, did not alter BP (26). We did not observe a BP difference between SHR fed CO vs MO (Fig. 1). At 35 weeks of age, BP was slightly, not significantly, lower in rats fed either CO or MO compared with rats fed control, L-485, diet. The stronger hypotensive

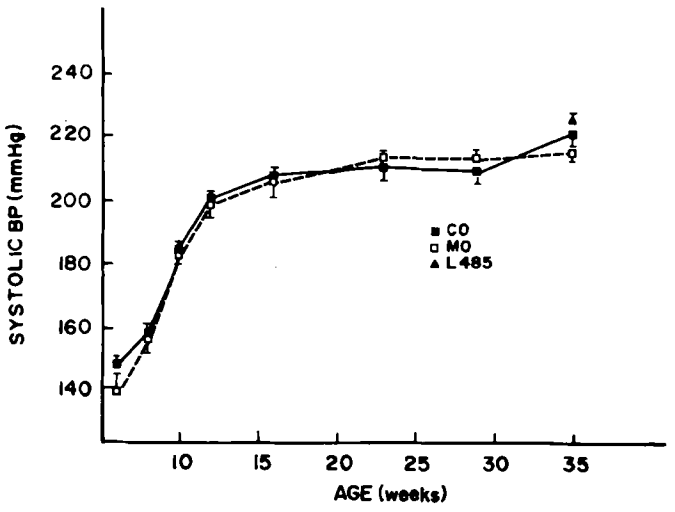

FIG. 1. Systolic blood pressure of SHR maintained on diets with differing dietary oil composition. SHR were fed either stock diet (L-485), L-485 + 5% menhaden oil (MO) or L-485 + corn oil (CO) from 4-35 wk of age. Values are mean ± S.E.

effect of MO in the previous study may be due to differences in experimental design. In that study, dietary lipid amounted to a total of 5%, either in the form of CO, or a combination of 1% CO + 4% MO. The authors speculated that this diet may have changed the ratio of n-6/n-3 fatty acids in the diet sufficiently to modify prostaglandin metabolism in a way that affected blood pressure. In our study, 5% CO or MO was added to a basic diet that already contained ca. 5% fatty acids (Table 1), primarily as soybean oil and corn oil. The superimposition of MO onto this basic diet did not result in significant BP reduction in SHR.

In summary, addition of either 5% CO or 5% MO to the diet of rats maintained on a stock diet of L-485 tends to shift the blood lipid profile towards one that is less atherogenic. MO is more effective than CO in reducing serum TG, CHOL and LDL. The SHR rat, which is genetically susceptible to hypertension and vascular pathology, is less responsive to the effects of the added lipids than the SD, exhibiting only a moderate decline in CHOL following MO, and no decline in LDL or the LDL:HDL ratio. Hypertension is not significantly ameliorated by the addition of MO to the diet. We conclude that in an animal genetically inclined toward vascular disease and hypertension, addition of MO to a diet already low in cholesterol and unsaturated fatty acids has little beneficial effect.

Free Radicals, Antioxidants, Skin Cancer and Related Diseases

Symposium held at the 78th AOCS Annual Meeting in New Orleans, Louisiana, May 1987

Introduction to the Symposium

K.M. Schaich[a] and **H.S. Black**[b,1,*]

[a]Medical Department, Brookhaven National Laboratory, Upton, NY 11973, and [b]Veterans Administration Medical Center and Department of Dermatology, Baylor College of Medicine, 2002 Holcombe Blvd., Houston, TX 77030

The following four papers were part of a symposium on "Free Radicals, Antioxidants, Skin Cancer and Related Diseases" presented at the 78th Annual Meeting of the American Oil Chemists' Society. Although the symposium originally was designed to provide a forum for the continuing documentation of oxygen- and lipid-free radical associations with cancer and diseases of the skin, it was expanded to include some papers considering the molecular mechanisms whereby the effects observed clinically could occur. Interchange between basic and clinical researchers was expected to identify specific reactions that may cause or modify pathological processes in the complex milieu of cells and stimulate interest in using fundamental (bio)chemical research to help understand the interrelationships between free radicals, lipid oxidation, and the clinical and pathological phenomena described in papers of this symposium.

Some general background is necessary to provide the common thread connecting what may seem to be widely varying, even unrelated, research topics. Within the past decade, a considerable amount of data has been accumulated documenting the association of free radicals (particularly those derived from oxygen) and lipid oxidation with a wide variety of oxidative cytotoxicities in vivo (1) and with carcinogenesis (2,3), particularly in the promotion and progression phases of the latter (4,5). However, the precise roles of oxygen radicals and lipid oxidation in biological damage remain controversial.

That hydroxyl radicals ($OH^{\cdot}$) are very reactive and have one of the highest-known oxidation potentials is universally recognized, and much pathology is suspected of arising from this radical species that is produced in tissues primarily via metal-driven reduction of H_2O_2. However, precisely because of their high reactivity, $OH^{\cdot}$ are largely non-specific in their attack on molecules and their efficiency in terms of measurable specific damage often is low. Hence, even though production of $OH^{\cdot}$ concurrently with the development of a wide range of pathologies has been amply documented, unequivocal attribution of specific molecular or cellular changes to $OH^{\cdot}$ reactions remains difficult and, indeed, has been the subject of much controversy.

Lipid oxidation, too, has been found to occur universally in biological systems, but its precise role in specific pathologies remains unclear. Is lipid oxidation merely a result of other primary oxidations, or are alkoxyl and peroxyl-free radicals from oxidizing lipids active agents broadcasting oxidative damage? Classical biochemistry has held that oxidizing lipids contribute only indirectly to pathological processes by disrupting the packed-chain organization of membranes leading to leakiness (6,7) and/or by overwhelming cellular antioxidant defenses (8) and oxidizing the electron transport cytochromes b_5 and P-450 as well (7,9), thus allowing the unchecked progression of other oxidative reactions that normally either would not occur or would be reparable. However, in a number of pathologies lipid oxidation has been measured in cells in which no concurrent development of leakiness or depletion of antioxidant capacity occurs. Thus, the importance of these indirect mechanisms, alone, to the destructive effects of oxidizing lipids in vivo remains uncertain.

Alternatively, essential structural or functional biomolecules may be damaged directly by co-oxidation with lipids. For some years, there has been interest in the mechanisms of these reactions (10–13), and co-oxidation of critical cellular molecules, particularly proteins and nucleic acids, is considered by some researchers to be a key mechanism accounting for the biological effects of oxidizing lipids (6,14–16). Intermediate alkoxyl and peroxyl radicals of lipid oxidation react with proteins, forming protein radicals and leading to destruction of amino residues in active sites, chain scission or peptide polymerization. Some of the final breakdown products of lipid oxidation, particularly malonaldehyde, lead to co-molecular crosslinking and formation of fluorescent pigments. Enzyme destruction by oxidizing lipids also has been well-documented (6,17).

Because of the known relationship of $OH^{\cdot}$ to radiation-induced cytotoxicity and genetic damage, their potential contribution to the development of cancers is taken for granted. On the other hand, how may the reactions of oxidizing lipids relate to cancer, one of the major foci of this symposium? Lipid-mediated co-oxidation of key proteins may influence carcinogenesis epigenetically. Initiation of carcinogenesis may be affected if proteins involved in activation or detoxification of toxic agents are co-oxidized, and promotion and progression may be altered similarly when the proteins co-oxidized are those involved in replication or repair of genetic material (resulting in destabilization of gene regulation) or those controlling the replication of cells generally, thus priming cells for transformation and progression (4,18).

It now is clear that oxidizing lipids also may exert direct genetic influences on carcinogenesis as co-oxidations occur with nucleic acids. Radiomimetic free radical formation (13) and oxidative breakdown as well as lipidoxyl adduct formation in pyrimidine bases incubated with oxidizing methyl linoleate have been observed (K. M. Schaich and D. C. Borg, unpublished data), and a number of Japanese scientists have reported single-strand breaks induced in DNA by methyl linoleate hydroperoxides in model systems (19,20) and in cultured human fibroblasts (21). Strand breaks and loss of plasmid-transforming activity also were found in DNA incubated with oxidized

[1]Symposium chairman.

microsomal lipid in liposomes (22). This activity required redox-active metals (Cu or Fe) and was inhibited by catalase, tocopherol and glutathione peroxidase but not by conventional water-soluble $OH^{\cdot}$ scavengers. Thus, lipid hydroperoxides and metal-mediated reactions in the lipid rather than aqueous phases were implicated in the DNA damage.

In considering oxidizing lipids as potential destructive agents in vivo, however, it must be remembered that lipid oxidation is a normal result of cell metabolism and tissue aging, and a variety of defenses—including glutathione peroxidase, tocopherols and membrane endocytosis—constantly are operative to control the steady-state levels of toxic hydroperoxides (7). Thus, pathological lipid oxidation requires some agents or processes capable of initiating this oxidation at levels that will provide a flux of lipid free radicals and/or other reactive oxidation products sufficient to overwhelm the rather efficient antioxidative mechanisms normally operative in vivo, and this is where free radicals from oxygen and other sources may be very important. Indeed, recognizing the critical role of initiation, papers in this symposium investigate a number of initiators that may operate physiologically, including radiation (ionizing, ultraviolet, visible light with photosensitizers); free radicals (e.g. from the metabolism of drugs and other chemicals); the "active" oxygen species $^1O_2$, H_2O_2, $O_2^{\cdot-}$, $OH^{\cdot}$; and metals. Moreover, considerable literature is accruing that strongly implicates free radicals and active oxygen species in the promotion and/or progression stages of carcinogenesis (23). This aspect of radical involvement plays an equally important role in expression of the cancerous state.

While much has been learned about the association of oxygen free radicals and of lipid oxidation with certain diseases and cancers, it is obvious that living systems are extremely complex with many reactions occurring simultaneously, and much detailed study still is needed to untangle the specific effects and relative contributions of particular damaging agents. This symposium, hopefully, contributed to a better understanding of these complicated interactions.

Fenton Reactions in Lipid Phases[1]

K.M. Schaich* and **D.C. Borg**
Medical Department, Brookhaven National Laboratory, Upton, NY 11973

Metal catalysis of membrane lipid oxidation has been thought to occur only at cell surfaces. However, conflicting observations of the pro-oxidant activity of ferric (Fe^{3+}) vs ferrous (Fe^{2+}) forms of various chelates have raised questions regarding this dogma. This paper suggests that the solubilities of iron complexes in lipid phases and the corresponding abilities to initiate lipid oxidation there, either directly or via Fenton-like production of reactive hydroxyl radicals, are critical determinants of initial catalytic effectiveness.

Partitioning of Fe^{3+} and Fe^{2+} complexes and chelates into bulk phases of purified lipids was quantified by atomic absorption spectroscopy. mM solutions of iron salts partitioned into oleic acid at levels of about micromolar. Ethylenediamine tetraacetic acid (EDTA) and diethylenetriaminepentaacetic acid (DTPA) chelates were somewhat less soluble, while adenosine diphosphate (ADP) chelates, and ferrioxamine were soluble as chelates at greater than 10^{-5} M. Solubilities of all iron compounds in methyl linoleate were 10- to 100-fold lower.

To determine whether Fenton-like reactions occur in lipid phases, H_2O_2 and either Fe^{2+} or Fe^{3+} and a reducing agent were partitioned into the lipid along with the spin-trap 5,5-dimethyl-1-pyrroline-N-oxide (DMPO), and free radical adducts were recorded by electron paramagnetic resonance (EPR). Hydroxyl radicals ($OH^{\cdot}$) adducts were observed in oleic acid, but in lipid esters secondary peroxyl radicals predominated, and the presence of $OH^{\cdot}$ adducts was uncertain.
***Lipids 23,* 570-579 (1988).**

In the past few years, considerable attention has been given to the involvement of hydroxyl radicals ($OH^{\cdot}$), oxidizing lipids and metal ions in oxidative damage in living tissue and food systems. However, the causal relationships linking these three species to each other and to specific damage in cells have not been clarified.

Iron is a well-known catalyst of lipid oxidation, and it is also a critical reactant necessary for the non-radiolytic production of $OH^{\cdot}$ via the classical Fenton reaction, i.e. where -L represents ligand(s),

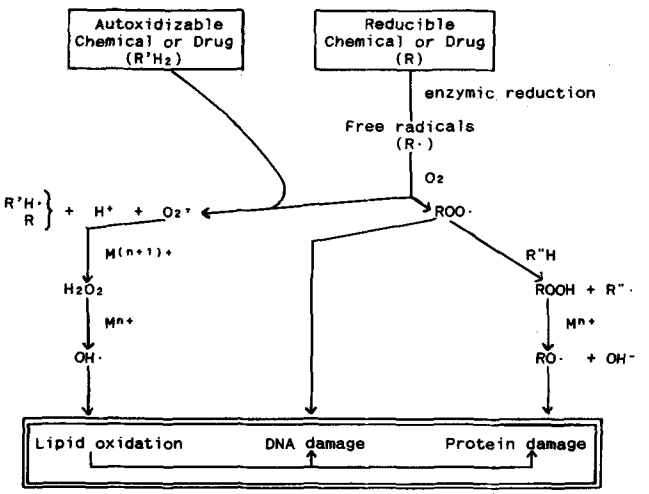
$$Fe^{2+}\text{-L} + H_2O_2 \rightarrow Fe^{3+}\text{-L} + OH^{\cdot} + OH^{-}$$

Because the non-heme redox-active iron driving this reaction is a trace constituent and there are impressive antioxidant defenses in cells, iron is most effective in initiating biological oxidations when Fe^{3+} can be recycled to Fe^{2+} by various reducing agents,

$$Fe^{3+}\text{-L} + O_2^{\cdot-}, GSH, etc. \rightarrow Fe^{2+}\text{-L} + O_2, GS^{\cdot}, etc.$$

and thus can be used catalytically to produce damaging fluxes of $OH^{\cdot}$. While it certainly is clear that the highly reactive $OH^{\cdot}$ so produced can initiate many reactions, including lipid oxidation (1-5), it is not universally accepted that the latter reaction occurs in complex biological systems.

Because many reaction sequences may occur simultaneously in cell systems or in tissues under oxidative attack (Scheme 1), the presence of oxidizing lipids may be either an effect of other free radical reactions (e.g. $OH^{\cdot}$) or it may be the cause of further molecular or cellular damage. Often the distinction is not clear. The problem of determining the causative species and the precise reaction loci of oxidative damage is further confounded by the similarity in the final expression of damage resulting from different oxygen radicals. For example, it is difficult to differentiate between effects of $OH^{\cdot}$ vs those of lipid oxyl radicals in complex biological systems. Indeed, the



SCHEME 1. Simplified scheme showing major reactive species in the pathways leading to oxidative damage to lipids, proteins and DNA in cells and tissues. Free radicals (R$^{\cdot}$) may be produced initially by either autoxidation or enzymatic reduction of suitable substrates. These radicals then may reduce O_2 to the superoxide radical anion, $O_2^{\cdot-}$, or add oxygen to form peroxyl radicals (ROO$^{\cdot}$). Metals participate as obligate reductants of H_2O_2 (usually from $O_2^{\cdot-}$ disproportionation) and organic hydroperoxides (ROOH), converting them to hydroxyl radicals ($OH^{\cdot}$) and alkoxyl radicals (RO$^{\cdot}$), respectively. These two radical species, along with ROO$^{\cdot}$, then attack critical biomolecules. When the reaction is with membrane lipids, chain reactions of lipid autoxidation ensue, and the lipid alkoxyl (LO$^{\cdot}$) and peroxyl (LOO$^{\cdot}$) radicals formed therein also can attack DNA and proteins near the site of initial $O_2^{\cdot-}$, ROO$^{\cdot}$ or RO$^{\cdot}$ reaction. The LO$^{\cdot}$ and, especially, the more stable LOO$^{\cdot}$ reaction products also can migrate some distance away to initiate additional foci of lipid chain peroxidation or to react with DNA and proteins there. Neither all intermediate steps nor all side reactions are represented, and protons and/or charges are not balanced in some reactions as written.

literature is replete with contradictory claims regarding the production, activity and effects of $OH^{\cdot}$ and lipid oxidation.

At least part of the difficulty in determining the interrelationships between $OH^{\cdot}$, lipid oxidation and cell damage may lie in common experimental approaches to the problem. Typically cells, sub-cellular components or liposomes are suspended in media in which Fenton components or other $OH^{\cdot}$-generating reactants are added externally or are generated in the cytosol, and then lipid oxidation or damage to protein, DNA, etc. is monitored. In most of these studies, lack of inhibition of lipid oxidation or other damage by water-soluble $OH^{\cdot}$ scavengers or metal chelators is taken as evidence that $OH^{\cdot}$ are not involved in the processes.

Similarly, in attempts to determine the mutagenicity/carcinogenicity of lipid hydroperoxides, the typical approach has utilized LOOH added to the media external to mammalian cells or Salmonella tester strains in the Ames mutagenesis assay. The failure to produce DNA strand breaks in cells or mutagenic responses in the Ames test has been interpreted as lack of toxicity or involvement in initiation or promotion of cancer by LOOH, even though in such cases the peroxides would not be expected to reach the nucleus intact, given their metabolism by cellular glutathione peroxidase or decomposition by redox-active metals (6).

We feel that in both these situations the critical site of reaction, namely, the lipid phases of membranes, has been missed. Because $OH^{\cdot}$ are extraordinarily reactive, they do not survive for more than a few collisions following their formation, and thus their reactions are intrinsically site-specific, i.e. characterized by whatever potential substrates are within 10 or a few 10s of Angstroms of where the $OH^{\cdot}$ are produced (4,7). This implies that Fenton-generated $OH^{\cdot}$ must react at the sites where iron is bound, and for effective initiation of lipid oxidation this means on the membrane surface or within the lipid environment.

The shallow penetration of a lipid bilayer that would be expected before the highly electrophilic and nonselective $OH^{\cdot}$ react provides good reason to question whether $OH^{\cdot}$ generated externally could penetrate to the hydrophobic membrane interior where the lipid chains are confined. There is evidence that iron on the membrane surface can lead to the production of some effective initiator of lipid peroxidation because iron/ascorbate reactions that are prolific sources of $OH^{\cdot}$ lead to liposome oxidation when the membrane's surface charge is neutral or negative, and iron ions are not repelled from contact or binding. This does not occur when the surface charge is positive (8). Similarly, Girotti concluded that displacement of iron from membrane-binding sites by zinc accounted for most or all of the antioxidant ability of zinc ions to protect erythrocyte ghosts from undergoing lipid peroxidation in media containing soluble Fenton systems (9).

Although there is substantial inferential evidence to support the lipid phases of membranes as the site both for Fenton-type $OH^{\cdot}$ formation in the primordial initiation of lipid oxidation and for subsequent reactions of lipid-oxyl radicals with proteins and DNA, there is little direct experimental evidence in support of that notion. Hence, we reasoned that it was important to determine experimentally whether Fenton-like formation of $OH^{\cdot}$ can occur in the lipid phase of a model system, whether $OH^{\cdot}$ so generated can initiate the free radical chains of lipid autoxidation, and if so, whether these reactions also occur in real membranes. Data demonstrating Fenton reactions in lipids phases are presented here.

MATERIALS AND METHODS

Reagents. Oleic acid was stored at room temperature, sealed, as obtained from Baker. Methyl linoleate, oleate and laurate (NuChek Prep) were stored under vacuum at −20 C. Ferrous and ferric ammonium sulphate, chloride, sulphate and oxalate were reagent grade. 1.10:1.00 (chelator/metal) chelates were prepared immediately before use by reacting ferric or ferrous ammonium sulphate with desferrioxamine (DFO) (Desferal mesylate, Ciba-Geigy), adenosine diphosphate (ADP), ethylenediamine tetraacetic acid (EDTA), diethylenetriaminepentaacetic acid (DTPA) or sodium citrate. Hydrogen peroxide solutions (10^{-1} to 10^{-3} M) were prepared daily by dilution of a stock solution (Apache Ultrapure) that had been distilled in Vycor (gift of B.H.J. Bielski, Chemistry Dept., Brookhaven National Laboratory, Upton, NY). Concentrations were determined by the KI/molybdate/phthalate method of Allen (10). 10% (w/v) aqueous stock solutions of hydroxylamine hydrochloride (reagent grade), prepared daily, were demetalled by bathophenanthroline (11) and diluted as required. The spin trap 5,5-dimethyl-1-pyrroline-N-oxide (DMPO) (Aldrich Chemical Co., Milwaukee, WI) was filtered over activated charcoal in the dark and dissolved in lipid or used directly. All solutions were prepared in water which had been purified in a Milli-Q water purification system (Millipore, minimum acceptable resistivity 12 megohms/cm), then degassed under vacuum and sparged with high-purity argon. Prepared reagents were maintained under argon until and, in most cases, during reactions and analyses. Only acid-washed glassware was used.

Partitioning of Fenton reactants into lipid phases. To effect the partitioning, equal volumes of reactants—H_2O_2, iron complexes or reducing agents (usually hydroxylamine)—were individually vortexed for two min (usually under argon) with the lipid to be studied, and the phases were separated by centrifugation.

Analysis of lipid phases. Iron partitioned into lipid phases was quantified by atomic absorption spectroscopy (Instrumentation Laboratory 551) using a graphite furnace with deuterium arc background correction. Aliquots of lipid phases were diluted 1:5 in tetrahydrofuran, and 10 μl samples were deposited in the graphite cuvette by means of a Fastac 254 autosampler. Heating and atomization sequences were programmed and controlled electronically (Instrumentation Laboratory flameless atomizer 555). Iron standards for determination of standard curves were prepared by diluting a 1000 ppm stock iron solution (12) in tetrahydrofuran and then mixing four parts of these dilutions with one part lipid (oleic acid or methyl linoleate as required) for analysis.

Fenton reactions in lipid phases. To detect radicals too short-lived or too low in concentration for direct detection by electron paramagnetic resonance (EPR), the spin-trapping technique was used, in which nitrone or nitroso compounds react with unstable radicals to give more stable nitroxide radicals. The resulting spectra frequently have characteristic features for each spin trap and can

provide information about the original radical(s) forming the adducts (2). The spin trap DMPO was dissolved directly in neat fatty acids or esters, and H_2O_2, iron compounds and hydroxylamine were separately partitioned into the same lipids in the manner described above. In most cases, both starting solutions and the lipid phases were sparged and maintained under argon to limit secondary peroxyl radical formation and background lipid oxidation. To start the reaction, aliquots from each of the lipid phases were mixed and transferred immediately to an aqueous flat cell, where subsequent radical production was monitored by EPR. During the course of these experiments, DMPO was found to be unstable when dissolved in the esters for several hours, even under argon. Thus, in subsequent studies, aliquots of neat DMPO were added directly to the Fenton reaction mixtures prepared as described above.

EPR analyses were conducted using a Varian E-12 EPR spectrometer equipped with a TE102 cavity and E-101 X-band (9.5 GHz) microwave bridge. The spectrometer is interfaced with a MassComp MC-5500 computer, which controls data taking and provides data storage and analysis as well as signal averaging of the 30-sec field scans routinely used. All scans reported in this study were 100 gauss; magnetic fields were calibrated with Fremy's salt (peroxylamine disulphonate). Hyperfine splitting constants were determined using computer simulations.

RESULTS AND DISCUSSION

In assessing the potential for Fenton reactions in lipid phases and consequential lipid oxidation, three questions must be answered: 1) Can all the reactants (hydrogen peroxide and ferrous iron or ferric iron and a reducing agent) penetrate a membrane or a lipid phase? 2) If so, does the reaction "go" in a lipid, hydrophobic environment? 3) Does a Fenton reaction in a hydrophobic environment initiate autoxidation of lipids or does any interaction with lipid remain limited to the original reaction site?

To answer these questions, model systems consisting of bulk lipids with the various reactants partitioned into them were used. Although bulk lipids are weak surrogates for structurally organized membrane bilayers with hydrophobic centers of oriented lipids, exterior polar headgroups and, in cells, external glycoprotein filaments, they may provide experimental access to environments with hydrophobicity comparable to membrane interiors. Furthermore, use of relatively simple, well-defined model systems can provide information about phase specificity and competitive kinetics that may contribute considerably to elucidating what happens when similar reactions occur in the complex milieu of cells.

Earlier work had shown differences in the proticities of bulk lipids: bulk oleic acid is weakly protic and its methyl ester and that of linoleic acid are aprotic when judged by the specific reactions of superoxide with stilbene dibromide in aprotic versus protic media (5). It was assumed that the proticity of membrane interiors might resemble that of esters, but since little data on metal solubilities in lipids was available, both bulk fatty acids and lipid esters were studied with the expectation that eventually comparisons of solubilities and/or binding of metals to different lipid classes would provide some insight regarding metal localization in membranes.

Hydroxylamine, although not very physiological, was chosen for three reasons: it is reasonably lipophilic; it was expected to be effective as a reducing agent for all the chelates to be tested (particularly ferrioxamine with a redox potential of −0.42 V vs NHE) (13 and Schaich, K.M., Linkous, C., and Borg, D.C., unpublished data); and it was expected to introduce fewer complications in the spin-trapping reactions than the more physiological reducing agents ascorbic acid, cysteine and glutathione. Ascorbic acid was unsuitable for these studies because it cannot reduce ferrioxamine (4) and it does reduce DMPO and its adducts (14). Also, as an anion it does not enter membranes or lipid phases (15). The thiols do not reduce ferrioxamine either, and they form radicals themselves and complex with oxidizing lipids in the presence of ferric iron (16).

(Question 1) Solubilities of Fenton reactants in lipid phases. Initial results using the partitioning technique indicated that mM solutions of iron salts and some low molecular weight complexes partition from water into protic oleic acid at concentrations of about μM or less (Table 1). These concentrations are 1000× or more greater than can be accounted for merely by the solubility of water in oleic acid. The recognized ability of oleic acid to complex iron may have facilitated apparent partitioning of the salts, but it is unlikely that oleic acid could compete with the strong binding of iron by the ADP chelates and ferrioxamine, which, as suggested by optical absorption spectra, partition as chelates into lipid. The resulting concentrations of ADP chelates or ferrioxamine are comparable with or greater than those of the iron salts, i.e. μM or higher for oleic acid. Iron solubilities in aprotic methyl linoleate were substantially lower, with mM solutions partitioning to final concentrations of about 10^{-7} M in the ester.

In these experiments, high concentrations of aqueous iron were used to assure that concentrations partitioned into the lipid could be detected with accuracy. Studies determining the dependence of iron solubilization in lipid on aqueous iron concentrations have not yet been completed, so it is not known whether the values reported here

represent true partitioning as opposed to saturation levels of iron in these lipids. Nevertheless, even 30-fold dilutions of the sub-μM iron solubilized in methyl linoleate is sufficient to fuel Fenton reactions, as will be shown later.

Contrary to what had been expected, at these aqueous concentrations the valence of the metal did not affect the solubility in lipid except for ADP chelates, where the ferric form was more lipophilic, and citrate complexes, where more iron was solubilized from the ferrous form. Because citrate binds Fe^{2+} only weakly (17), it is likely that the iron from those complexes partitioned as the ammonium sulfate salt, whereas ferric citrate is an anion (18) and thus should partition with difficulty into a hydrophobic phase. However, there presently is no obvious explanation for the behavior of the ADP chelates.

As was expected from their anionic character, EDTA and DTPA chelates have very low lipid solubility. Indeed, this low solubility combined with high binding constants for iron makes these two chelators reasonably efficient demetalling agents when the partitioning procedure is used in reverse with oleic acid and with various oils (Schaich, K. M. and Borg, D. C., unpublished data).

H_2O_2 partitioned into lipid less efficiently than did iron (Fig. 1), the partition coefficients being 1 to 2 $\times$ 10^{-3}. These coefficients are not inconsistent with those reported for H_2O_2 in chloroform (19), considering the very short equilibration period in this study. Partitioning seemed to depend on the concentration of H_2O_2 in the aqueous phase, although the apparent decreased partitioning with increasing dilution of H_2O_2 may have resulted in part from greater instability of the dilute aqueous H_2O_2 during the partitioning procedure.

Solubilization of hydroxylamine in both fatty acids and esters occurred, as was evident in spin-trapping experiments, but could not be quantified. While hydroxylamine is known to form hydroxamic acids with fatty acid esters (20), the reaction was not expected to be a complication in this experiment because it requires strongly alkaline conditions and high concentrations of hydroxylamine (21). Hydroxylamine concentrations in these reactions were limited to prevent reduction of the spin traps and the adducts. No products absorbing in the 500–560 nm range were detected.

(Question 2) Does the Fenton reaction "go" in a lipid environment? It has been shown that reactants necessary for a Fenton reaction solubilize in bulk lipids. Fenton kinetics in lipid phases now become important for assessing the potential biological significance of these reactions.

The technique of spin trapping was used to answer this question. When Fenton reactions, either with Fe^{2+} or with Fe^{3+} and a reducing agent, were run in protic oleic acid with DMPO, a four-line signal similar to that expected for the $OH^{\cdot}$ adduct was produced (Fig. 2). The splitting constants for the nitrogen (A_N) and β-hydrogen (A_H) were not equal, and thus the ratios of the line intensities were not 1:2:2:1 as seen with the $OH^{\cdot}$ adduct in water. The lower polarity of the neat lipid should decrease the splitting constants relative to those observed in water, and the splitting constants observed in oleic acid are comparable with those reported for $OH^{\cdot}$ adducts of DMPO in other organic solvents of low polarity (22), which gave six-line spectra. In this case, however, the broadening of spectral lines (i.e. increase in spectral linewidths) resulting from the high viscosity of the oleic acid is sufficient to cause overlaps in pairs of the four center lines so that an intrinsic six-line spectrum presents as a four-line first derivative spectrum with almost equal line heights, as

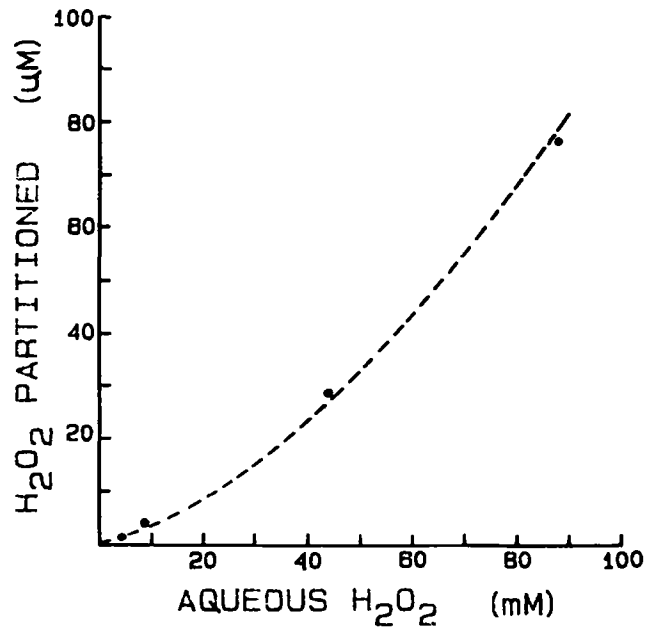

FIG. 1. Partitioning of H_2O_2 into oleic acid as a function of H_2O_2 concentrations in the aqueous phase.

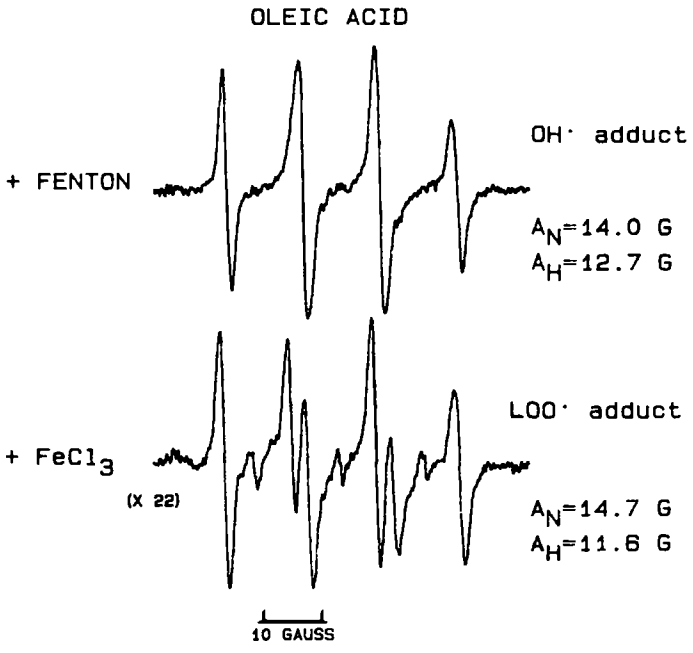

FIG. 2. Typical EPR spectra of DMPO free radical adducts in oleic acid. Top: spectrum assigned to $OH^{\cdot}$ adduct, which appeared immediately following Fenton reactions with either Fe^{2+} or Fe^{3+} plus hydroxylamine. Instrument settings: microwave power, 5 mW; modulation amplitude, 0.8 G.; gain, 3,200; time constant, 0.01 sec. Bottom: spectrum of peroxyl radical adducts obtained when $FeCl_3$ was added to oleic acid to initiate autoxidation. Instrument settings: modulation amplitude, 0.5 G.; gain, 10,000; otherwise as above.

verified by computer simulation. Thus, the assignment of this signal to $OH^{\cdot}$ adducts in oleic acid is reasonable, even though conclusive identification will require isolation and analysis of this adduct.

The signal intensities but not the line patterns were altered by moderate variations in reactant concentrations, which further indicates that primary rather than secondary radicals were being trapped under the reaction conditions of this study. Decreasing the spin-trap concentration did not increase detection of secondary lipid radicals. However, subsequent investigations have shown that when 10-fold higher iron concentrations are present, the reducing capacity of the hydroxylamine is exceeded and/or the reduction of the iron is slower than the direct reaction of ferric iron with oleic acid; in this case, iron-induced peroxyl radicals rather than $OH^{\cdot}$ are trapped.

DMPO dissolved in fresh samples of oleic acid gave no EPR signals. If oleic acid was incubated with ferric iron before DMPO was added, a lipid peroxyl radical was trapped (Fig. 2, lower trace); and if organic reducing agents such as glutathione were used or if small amounts of alcohol were present during the reaction, radicals formed by $OH^{\cdot}$ attack on them also were trapped. Ferrous iron alone in oleic acid gave no signal unless oxygen was present, in which case the $OH^{\cdot}$ adduct slowly grew in as the Fe^{2+} autoxidized and produced H_2O_2. Thus, at least qualitatively the Fenton reaction system in this lipid behaves as would be expected from classical lipid oxidation chemistry.

It is possible to follow the changes in $OH^{\cdot}$ adduct concentrations with time by fixing the magnetic field on one of the center lines of the EPR signal, and this technique was used to monitor Fenton-like reactions of ferric iron: "free" as $FeCl_3$, and chelated by ADP, EDTA and DTPA. Results are presented in Figure 3.

Of the three chelates, ADP supported Fenton kinetics in oleic acid at rates approaching that of the ferric salt, while EDTA and DTPA chelates reacted much more slowly and provided lower total adduct concentrations. There are three possible explanations for these differences: the absolute concentrations of chelates partitioned into the oleic acid were not the same, as was indicated by the AA data; EDTA and DTPA are known to react rapidly with $OH^{\cdot}$ and may have competed with DMPO for the hydroxyl radicals as they were formed close to the chelates; or the relative redox characteristics of the three chelates may be different in oleic acid than in water. Probably all of these factors contributed to the observed behavior.

That initial signal intensities for $FeCl_3$ were higher than those of the chelates reflects the greater extent of reaction that occurred within the approximately 10 sec required to transfer reaction mixtures by hand to the EPR cavity. That EDTA and DTPA chelates gave detectable $OH^{\cdot}$ production at all, despite the negligible iron concentrations detected by AA in the partitioning experiments, indicates that even sub-μM iron is sufficient to drive a Fenton reaction and/or possibly that contaminating traces of iron or other redox-active metal were present despite care taken to remove them.

Kinetics of the ferrioxamine-driven Fenton reaction in oleic acid could not be compared directly with the Fenton kinetics of those of the other chelates. Because ferrous complexes of DFO are unstable in the presence of oxygen and oxidize to ferrioxamine almost instantaneously in the presence of oxygen, the Fenton and trapping reactions with this chelate had to be performed on a vacuum manifold; samples were subsequently withdrawn from the manifold and analyzed by EPR. Hydroxylamine reduction of ferrioxamine was slow in oleic acid, but when this reaction was allowed to proceed before the addition of H_2O_2 and DMPO, a four-line adduct signal identical to that produced by the other chelates and by iron salts was observed.

When the reactions were run in aprotic lauric, oleic or linoleic methyl esters instead of the more protic acids, the expected four-line signal of hydroxyl radicals could not be detected. The signals obtained grew in more slowly than did the $OH^{\cdot}$ adducts in oleic acid, and consisted of mixtures of radical adducts (Fig. 4), the major components of which gave A_N's about 12–13.5 G and A_H's about 10–11 G. These splittings are substantially lower than those reported for $OH^{\cdot}$ adducts in organic solvents (22) but are nearly identical to those reported for lipid peroxyl radical adducts in toluene (23,24). Thus, spectral components having parameters in the range noted have been assigned to $LOO^{\cdot}$ adducts.

The $OH^{\cdot}$ adduct of DMPO in fatty acids or esters has not been reported previously, so what the spectra should look like can only be surmised from comparisons with known $OH^{\cdot}$ adducts in organic solvents of similar polarity. If the spectra of $OH^{\cdot}$ adducts in methyl linoleate and oleic acid are similar, only traces of $OH^{\cdot}$, if any, were evident in the complex spectra in methyl linoleate. If, on the other hand, the spectra of $OH^{\cdot}$ adducts in linoleate are comparable with those in ethyl acetate, benzene, or toluene (22), $OH^{\cdot}$ adducts always may be present as a

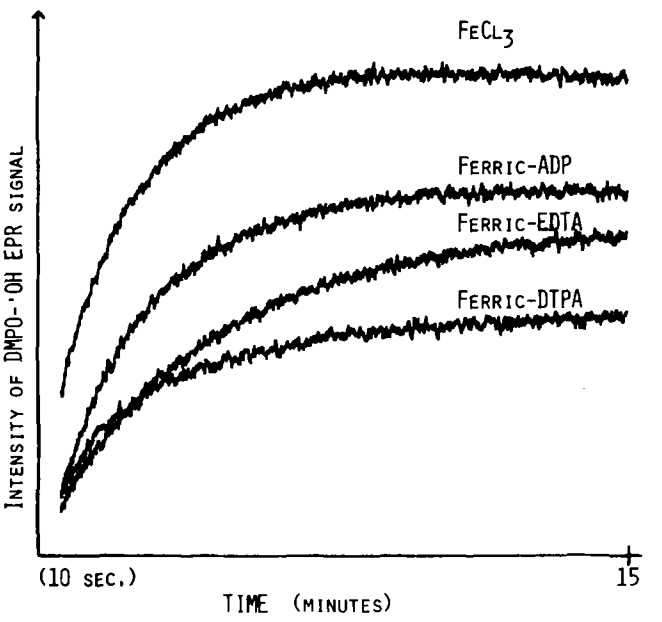

FIG. 3. Effects of iron complexation on kinetics of Fenton reactions in oleic acid: production of DMPO-$OH^{\cdot}$ adducts by Fe^{3+} "free" as its chloride salt and chelated by ADP, EDTA or DTPA. Reaction concentrations: DMPO, 44 mM; H_2O_2, 30 μM; iron compounds, as partitioned into oleic acid from 10^{-4} M aqueous solutions; plus hydroxylamine. Instrument settings: microwave power, 5 mW; modulation amplitude, 0.5 G.; gain, 8,000; time constant, 0.03 sec.

background component, contributing to the complexity and overlap of lines in the observed spectra. Indeed, computer simulations suggested that a component with $A_H \sim 12$ G and $A_H \sim 11$ G could be a component of nearly all spectra from the esters. This signal was clearest in EPR spectra from laurate and from Fe^{2+}-Fenton reactions in linoleate; in both of these situations, greater production or stability production of OH· adducts would be expected. Therefore, it is possible that this component is the OH· adduct, and attempts to isolate and identify this component conclusively are underway.

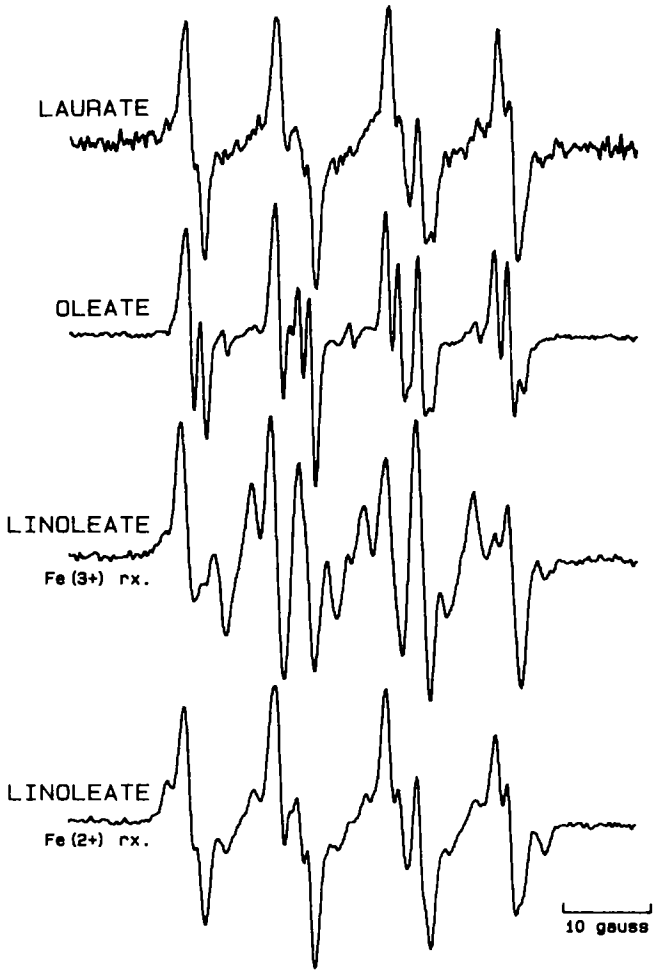

FIG. 4. Representative spectra produced during Fenton reactions in lipid esters containing hydroxylamine and 44 mM DMPO. Methyl laurate: reaction time, five min. Estimated reaction concentrations: H_2O_2, 19 μM; Fe^{3+}, 0.5×10^{-7} M. Main components: 1) $A_N = 12.82$, $^{\beta}A_H = 10.70$, A_N, $^{\gamma}A_H = 1.3$ G. (LOO· adduct); 2) $A_N = 12.1$, $^{\beta}A_H = 11.2$, $^{\gamma}A_H = 1.3$ G (unknown species). Methyl oleate: reaction time, 18 min. Estimated reaction concentrations: H_2O_2, 26 μM; Fe^{3+}, 0.1×10^{-7} M. One identified component: $A_N = 12.62$, $^{\beta}A_H = 10.25$, $^{\gamma}A_H = 1.4$ G. (LOO· adduct). Methyl linoleate (Fe^{3+}-Fenton): reaction time, 25 min. Estimated reaction concentrations: H_2O_2, 38 μM; Fe^{3+}, 0.2×10^{-7} M. Two components identified: 1) $A_N = 13.4$, $^{\beta}A_H = 10.4$ G. (unknown species); 2) $A_N = 12.82$, $^{\beta}A_H = 6.65$, $^{\gamma}A_H = 2.20$ G (LO· adduct). Methyl linoleate (Fe^{2+}-Fenton): reaction time, 7.5 min. Estimated reaction concentrations: H_2O_2, 38 μM; Fe^{2+}, 0.5×10^{-7} M. Instrument settings for all spectra: microwave power, 5 mW; modulation amplitude, 0.25 G.; gain, 8,000–10,000; time constant, 0.03 sec.

OH·-induced lipid alkyl radicals surely are being produced in these reaction systems, but it may be very difficult to trap them because these radicals react with oxygen so much faster ($k = 10^9$/M/sec) (25) than they are trapped by DMPO ($k = 10^6$/M/sec) (see review in Ref. 2). Increasing the rigor of deoxygenation with inert gases increased the radical yields and decreased oxygen line broadening, thus improving the resolution of the spectra, but it did not enhance trapping of OH· or alkyl radicals. Because of the solubility of oxygen in bulk lipids, they are extremely difficult to deoxygenate completely. Thus, trapping the initial lipid alkyl radicals may require running the reaction on a vacuum manifold to limit sufficiently the competition from oxygen or else may require utilizing a spin trap, such as nitrosobutane, which forms adducts with alkyl radicals much faster than does DMPO.

With all the esters, the DMPO adduct signals changed with time, indicating changes of radical species and varying proportions of different radicals. Methyl laurate adducts were most stable over time and required all Fenton reactants for production. As would be expected, with increasing unsaturation of the lipid, adduct mixtures became less stable and more sensitive to concentrations of Fenton reactants, particularly iron. Pulse radiolysis studies (25,26) have shown that initial OH· attack on methyl linoleate occurs indiscriminantly along the hydrocarbon chain, and that subsequent intramolecular migration of the radicals or, more likely, secondary hydrogen abstractions from other lipid molecules results in radicals and peroxides at the expected 9 and 13 carbon positions. It is likely that some of the spectral changes observed here reflect a similar process.

As in all spin-trapping experiments, caution must be exercised in interpretation of results. Both the signal intensities and adduct mixtures were quite sensitive to reactant concentrations, as shown for methyl linoleate in Figure 5. This may be expected because changing the levels of any of the Fenton reactants should alter the course of secondary branching reactions of oxidation chains, and the mix of radicals available for trapping would be altered correspondingly. In particular, high concentrations of iron (e.g. approaching μM) altered initial peroxyl radicals or their adducts so that artifactual four-line spectra similar to that of the OH· adduct were sometimes produced, either by direct attack on DMPO ($A_N = 14.98$ G, $A_H = 14.78$ G) or by conversion of peroxyl radicals or their DMPO adducts ($A_N = 14.64$ G, $A_H = 14.33$ G, see trace [E] in Figure 6). The splitting constants of these spectra are larger than would be expected for a bona fide OH· adduct in this solvent, so they are likely to arise from DMPO decomposition reactions, of which ring scission is known to produce four-line spectra resembling OH· adduct spectra (27). Similarly, when insufficient hydroxylamine was present in the reaction mixture, radicals from ferric iron-initiated lipid oxidation were trapped (c.f. trace [D], Fig. 5). While similar to the spectra obtained from full Fenton reactions, spectra from iron-dominated reactions showed altered proportions of some components and the absence of other components. Finally, a triplet ($A_N \sim 14.5$ G) was produced in systems with high iron or with long incubations; it is a nitroxide radical formed by the oxidation of DMPO.

It seems certain that Fenton processes rather than propagation reactions involving preformed lipid hydro-

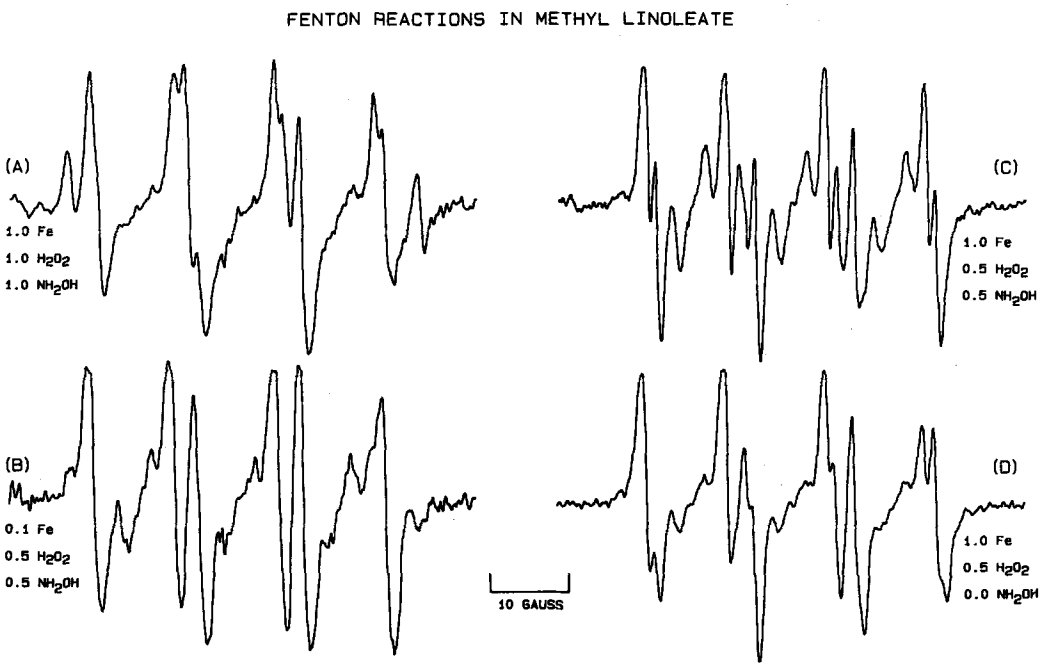

FIG. 5. Effects of varying reactant concentrations on Fenton reactions in methyl linoleate. Concentrations given are relative to (A): Fe^{3+}, 10^{-7} M; H_2O_2, 26 μM; NH_2OH, as partitioned from a 10% solution. (A) has a four-line signal with A_N = 14.98, βA_H = 14.78 G, and a component of unknown identity (X·), A_N = 13.4, βA_H = 10.4 G. The other three spectra have various mixtures of predominately X· and LOO· (A_N = 12.82, βA_H = 10.42, γA_H = 2.2 G), with lesser amounts of LO· (A_N = 12.82, βA_H = 6.65, γA_H = 2.2 G). Instrument settings comparable to those given in Figures 4 and 6.

peroxides were the dominant reactions being observed. DMPO adducts that had been identified as LO· adducts in other reaction systems either were not detected or were very weak background components when Fenton reactions were used as initiators in the esters. Peroxides were not detectable iodometrically in methyl oleate and linoleate after the partitioning step, and in incubations without Fenton reagents peroxyl adducts required substantially longer (days) to accumulate than the times typically monitored in the EPR experiments (minutes). Furthermore, variable low levels of peroxides (usually peroxide values less than 10) did not affect the spectra obtained with oleic acid, but using pre-oxidized lipid esters (e.g. peroxide values about 100 or higher) did alter the radical species trapped, particularly with methyl linoleate. DMPO added to pre-oxidized linoleate and Fenton reactions run with pre-oxidized linoleate (Fig. 6) both gave composite spectra different from those obtained in virgin (unoxidized) linoleate but similar to some spectra observed if the Fenton reactions in virgin linoleate were allowed to progress for long periods (e.g. 20 to 30 min, as in trace [C], Fig. 5). Computer simulations were used to decompose typical spectra obtained from a Fenton reaction in oxidized linoleate; this technique indicated at least three components.

One of these components had EPR hyperfine coupling constants (A_N = 12.62, βA_H = 10.27, γA_H = 1.47 G) characteristic of DMPO peroxyl adducts, although the splittings were better resolved than usual. This signal most likely results from adducts of the 9-peroxyl and/or 13-peroxyl radicals of methyl linoleate, which predominate during normal autoxidation and should not differ in their EPR spectra. The other species was present at concentrations, relative to those of the more ubiquitous peroxyl adducts, which varied with reaction time. It had a narrower beta proton splitting (A_N = 12.82, βA_H = 6.65 G) and a somewhat wider γ-proton splitting (γA_H = 2.2 G), suggestive of hyperfine spectra documented for alkoxyl radicals (2,23), and nearly identical spectra recently have been attributed to alkoxyl radicals of methyl linoleate in toluene following metalloreductions of lipoxygenase-generated hydroperoxides (24) and in freon following ozonization (28). This alkoxyl component, which should be produced only in secondary reactions of ferrous reactants with LOOH, was either absent or present only as very weak background when Fenton components were reacted in unoxidized linoleate.

The third component, a six-line spectrum with splitting constants (A_N = 13.4, A_H = 10.4 G) slightly higher than those of LOO· adducts, also was observed under other reaction conditions. Moderate to high iron concentrations, the presence of oxygen, and low-level pre-oxidation of the linoleate all seemed to increase the contribution of this species. One speculation is that this signal arises from epoxy-peroxyl radicals formed by rearrangement of alkoxyl radicals to epoxyallylic radicals that then react with O_2 (16,29). However, further work is needed to conclusively identify this radical as well as to clarify which radical species are favored under various reaction conditions.

Why could there be such differences in the Fenton reactions and/or spin-trapping of radicals in fatty acids vs their esters? Because the concentrations of iron partitioning into the esters were lower than for the acids, it is

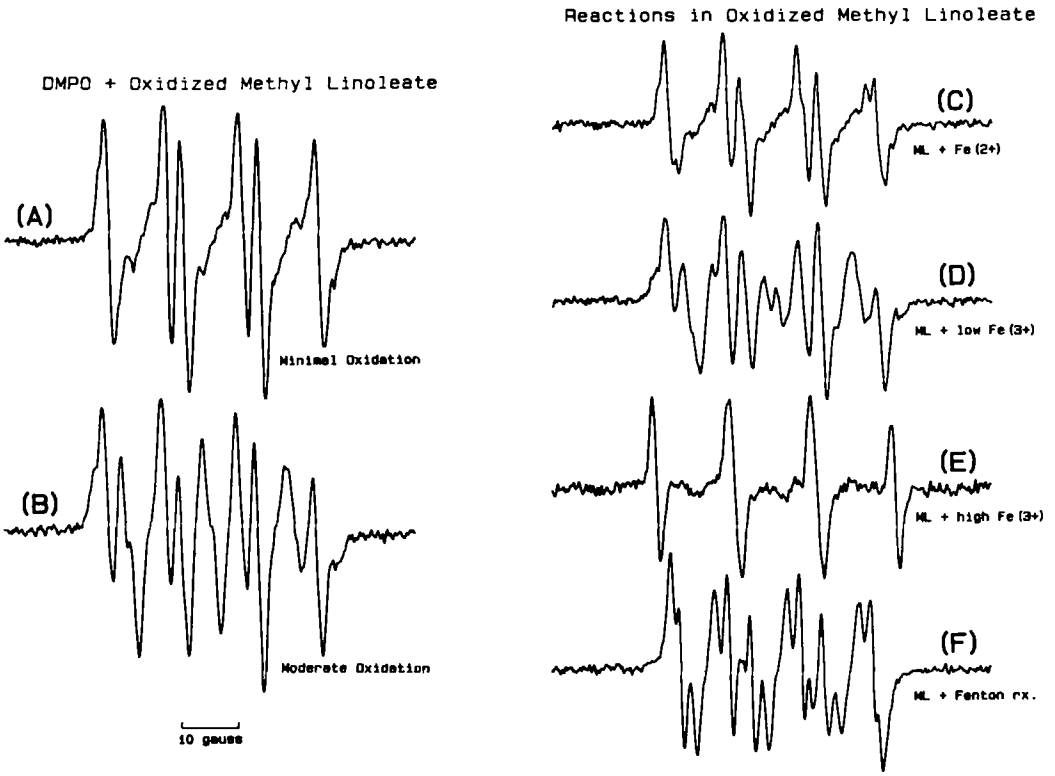

FIG. 6. Representative spectra of DMPO adducts produced by oxidizing methyl linoleate (ML) and by Fenton reactions in preoxidized ML. (A) First signal detected when ML was allowed to oxidize in the presence of DMPO (117 mM). Reaction time, approximately one day. Two identified components: 1) $A_N = 13.9$, $^{\beta}A_H = 10.9$ G (unknown species); 2) $A_N = 12.1$, $^{\beta}A_H = 11.2$, $^{\gamma}A_H = 1.3$ G (unknown species). Gain, 12,500; modulation amplitude, 0.4 G. (B) Adducts produced when DMPO was reacted with pre-oxidized ML (PV > 300). Two identified components: 1) $A_N = 13.4$, $^{\beta}A_H = 10.4$, $^{\gamma}A_H = 0.8$ G (unknown species); 2) $A_N = 14.6$, $^{\beta}A_H = 1.5$ G (unknown species). Gain, 12,500; modulation amplitude, 0.25 G. (C) Adducts from reaction of Fe^{2+} (0.05×10^{-7} M) with minimally oxidized ML (as in A). Main component: $A_N = 13.9$, $^{\beta}A_H = 10.9$ G. Gain, 10,000; modulation amplitude, 0.25 G. (D) Adducts from reaction of Fe^{3+} (0.05×10^{-7} M) with minimally oxidized ML. Reaction time six min. Three components: 1) $A_N = 13.6$, $^{\beta}A_H = 10.2$, $^{\gamma}A_H = 1.5$ G ($g = 2.0078$); 2) $A_N = 13.5$, $^{\beta}A_H = 10.1$ G ($g = 2.0068$); 3) $A_H = 14.6$, $^{\beta}A_H = 1.5$ G. All species unknown. Gain, 10,000; modulation amplitude, 0.4 G. (E) Adducts from reaction of Fe^{3+} (0.1×10^{-7} M) with ML oxidized as in (B). Reaction time, 15 min. $A_N = 14.64$, $^{\beta}A_H = 13.33$ G (from decomposition of DMPO or an adduct). Gain, 10,000; modulation amplitude, 0.25 G. (F) Adducts from Fenton reaction in minimally oxidized ML (as in A). Estimated reaction concentrations: DMPO, 215 mM; H_2O_2, 25 μM; Fe^{3+}, 0.1×10^{-7} M; plus hydroxylamine. Signal contains at least three components: 1) $A_N = 12.62$, $^{\beta}A_H = 10.27$, $^{\gamma}A_H = 1.47$ G ($LOO^{\cdot}$); 2) $A_N = 12.82$, $^{\beta}A_H = 6.65$, $^{\gamma}A_H = 2.20$ G ($LO^{\cdot}$); 3) $A_N = 13.4$, $^{\beta}A_H = 10.4$ G (unknown). Gain, 6,300; modulation amplitude, 0.1 G. Microwave power for all samples was 5 mW.

possible that Fenton reactions in the esters occurred at levels too low for efficient trapping of the primary $OH^{\cdot}$ in comparison with trapping of the secondary lipid peroxyl radicals. Alternatively, the Fenton reaction itself may proceed more slowly in aprotic media than in the protic oleic acid or in aqueous solutions. Some preliminary studies of Fenton kinetics in lipids suggest that reduction of iron is the rate-limiting step, that this step may be slower in lipid esters than in acids, and that the solubility of hydroxylamine in lipid esters may be a second critical factor affecting the overall balance of reactions in lipid esters. All of these possibilities are under investigation.

The differences in the iron solubilities and trapping patterns in oleic acid vs those in aprotic esters have some interesting implications: are there specific regions of membranes where Fenton reactions may be facilitated and are there specific preferential targets for reaction with $OH^{\cdot}$ in membranes, where most fatty acids are present as esters? Also, in pathological conditions with elevated free fatty acid levels in membranes, do the fatty acids increase iron uptake and thus predispose those membranes to potential oxidative destruction?

(Question 3) Do Fenton reactions occurring within lipid phases initiate the chain reactions of lipid autoxidation? The spin-trapping experiments suggested qualitatively that Fenton-initiated oxidation does proceed at rates considerably faster than uncatalyzed autoxidation, and subsequent experiments have provided quantification of the effects. However, the autoxidation kinetics depend in a complex manner on the form of iron complexation, both the absolute and the relative concentrations of all the

reactants (including oxygen), and the particular property measured. This work will be presented elsewhere.

Finally, in partial answer to question c posed at the close of the introduction, experiments with red cell ghosts and with liposomes have suggested that Fenton reactions occur in lipid phases of membranes (30) as well as in bulk lipids, although the form(s) and localization of the iron in the membranes have not been determined. These observations, while preliminary, nevertheless reinforce the lesson proffered by the model system studies reported here: i.e., H_2O_2, some iron complexes and DMPO all penetrate lipid phases, so membrane-localized reactions of these reagents must be expected in addition to, or perhaps even in place of, aqueous phase reactions.

SUMMARY

In summary, intramembranous formation of $OH^{\cdot}$ and initiation of lipid oxidation via Fenton reactions in the lipid phases of membranes in vivo certainly appears feasible. Clearly all the makings for compartmentalized Fenton reactions are present, and $OH^{\cdot}$ is produced in model systems using bulk lipids. Granted, these model systems do not mimic physiological conditions directly. However, the proofs-of-principle established in these chemical models should hold in vivo for cells and tissues in which H_2O_2 is being produced provided that appropriately complexed nonheme iron is available and endogenous reducing sources can replace the hydroxylamine used in the models.

Indeed, the makings for membrane-bound Fenton reactions should be available in vivo. Although little is known regarding the concentrations, endogenous ligands and cellular localization of redox-active nonheme iron, iron is known to traverse membranes by both energy-requiring and energy-independent mechanisms (31). Our solubility data certainly support the potential for the latter via passive diffusion, with accumulation of catalytically meaningful concentrations. Redox cycling of iron in membranes may be effected by thiols, by many reducing radicals (including $O_2^{\cdot-}/HO_2^{\cdot}$), and by a number of reductases (32,33). Furthermore, most of the H_2O_2 in cells, e.g. 60% or more of that produced in rat hepatocytes, is produced by membrane-bound multi-enzyme redox systems (34), and H_2O_2 produced elsewhere diffuses through membranes (35) nearly as freely as water (36).

Nevertheless, it must be emphasized that the effects resulting from Fenton reactions in membranes ultimately will be determined by the microenvironment where the redox-active metal is bound—by the character of the nearby lipid and the presence of other potential targets such as DNA or embedded proteins. Sub-μM concentrations of iron (or copper) dissolved in the hydrophobic regions of membrane lipid bilayers most likely will initiate free radical chains of lipid autoxidation, which then may proceed to damage proteins or DNA. Usually low concentrations of redox-active metal in lipid will augment lipid peroxidation in a catalytic manner. However, when the metal is bound within a few angstroms of embedded macromolecules, $OH^{\cdot}$ may attack them directly in preference to initiating a chain reaction in more distant lipid molecules of the membrane, and in such cases lipid oxidation may be decreased by the Fenton chemistry or not observed at all. Furthermore, as we recently have discussed elsewhere (37,38), it is important to keep in mind that when high concentrations of iron are used in various model systems, the metal may become a stoichiometric rather than a catalytic reactant and also may exhibit dominant chain termination behavior that is not seen at all at physiological concentrations. Observations in multiphase or compartmentalized systems will be open to misinterpretation if due consideration is not given to these possibilities.

ACKNOWLEDGMENTS

The authors thank Raymond Stoenner, Chemistry Department, Brookhaven National Laboratory, for the use of his atomic absorption spectrometer. This research was carried out under the auspices of the U.S. Department of Energy under contract No. DE-AC02-76CH00016.

Ascorbate-enhanced Lipid Peroxidation in Photooxidized Cell Membranes: Cholesterol Product Analysis as a Probe of Reaction Mechanism[1]

Gary J. Bachowski, James P. Thomas and **Albert W. Girotti***
Department of Biochemistry, Medical College of Wisconsin, Milwaukee, WI 53226

Cholesterol was used as an in situ probe for studying mechanisms of lipid peroxidation in isolated erythrocyte membranes subjected to different prooxidant conditions. The membranes were labeled with [^{14}C]cholesterol by exchange with prelabeled unilamellar liposomes and photosensitized with hematoporphyrin derivative. Irradiation with a dose of blue light resulted in thiobarbituric acid-detectable lipid peroxidation that was increased markedly by subsequent dark incubation with 0.5–1.0 mM ascorbate (AH^-). Ascorbate-stimulated lipid peroxidation was inhibited by EDTA, desferrioxamine (DOX) and butylated hydroxytoluene (BHT), suggesting that the process is free radical in nature and catalyzed by membrane-bound iron. Thin layer chromatography and radiometric scanning of extracted lipids from photooxidized membranes revealed that the major oxidation product of cholesterol was the 5α-hydroperoxide (5α-OOH), a singlet oxygen adduct. Post-irradiation treatment with AH^-/Fe(III) resulted in an almost-total disappearance of 5α-OOH and the preponderance of free radical oxidation products, e.g. 7-ketocholesterol, the epimeric 7α-/7β-hydroperoxides (7α-/7β-OOH) and their respective alcohols (7α-/7β-OH). EDTA, DOX and BHT inhibited the formation of these products, while catalase and superoxide dismutase had no effect. These results are consistent with a mechanism involving 1-electron reduction of photogenerated hydroperoxides to oxyl radicals, which trigger bursts of free radical lipid peroxidation. Though generated in this system, partially reduced oxygen species, viz. superoxide, hydrogen peroxide and hydroxyl radical, appear to be relatively unimportant in the autoxidation process. *Lipids 23,* 580–586 (1988)

Cholesterol products that arise from ionizing radiation, photodynamic action and other oxidative reactions have been well-characterized in simple systems, i.e. organic solvents and artificial lipid membranes (liposomes) (1–6). With systems of this type, it has been possible to use cholesterol as a mechanistic probe for distinguishing, e.g. between singlet oxygen ($^1O_2$)-driven reactions and free radical-driven ones. We recently have advanced this area of investigation (7) by showing that cholesterol in a natural plasma membrane, the human erythrocyte ghost, can be exploited in similar fashion (8–10). Thus, two major products of oxygen radical attack, 3β-hydroxycholest-5-ene-7α-hydroperoxide (7α-OOH) and 3β-hydroxycholest-5-ene-7β-hydroperoxide (7β-OOH) generated during xanthine/xanthine oxidase treatment, were distinguished from the characteristic $^1O_2$ product, 3β-hydroxy-5α-cholest-6-ene-5-hydroperoxide (5α-OOH) generated by porphyrin-sensitized photooxidation. Structures of these compounds are shown in Figure 1. We now demonstrate that cholesterol can be used to detect switching from predominantly $^1O_2$-dependent lipid peroxidation to free radical-mediated peroxidation when membranes are first photooxidized in the presence of hematoporphyrin derivative (HPD) and then exposed to the electron donor ascorbate. Quantitation of these effects was made possible by tracking the products of radiolabeled membrane cholesterol.

MATERIALS AND METHODS

Materials. Freshly drawn human blood from anonymous donors was obtained from the Blood Center of Southeastern Wisconsin and used within one week. Unsealed erythrocyte membranes (white ghosts) were prepared by hypotonic lysis, followed by centrifugation and washing in lysing buffer and final resuspension in PBS (11). Total membrane protein was determined according to Lowry et al. (12) using serum albumin as the standard. During storage at 4 C, stock suspensions were blanketed with argon to minimize autoxidation. [4-^{14}C]cholesterol, 40–60 mCi/mmol in benzene, was obtained from Research Products International (Mount Prospect, IL). Hematoporphyrin derivative (HPD) was prepared according to Gomer and Dougherty (13) and partially purified by gel exclusion chromatography on Bio Gel P-10 (14). The rapidly eluting, relatively hydrophobic fraction, designated HPD-A, was used for membrane photosensitization. This fraction is enriched in tumor-localizing porphyrin aggregates that are under investigation in

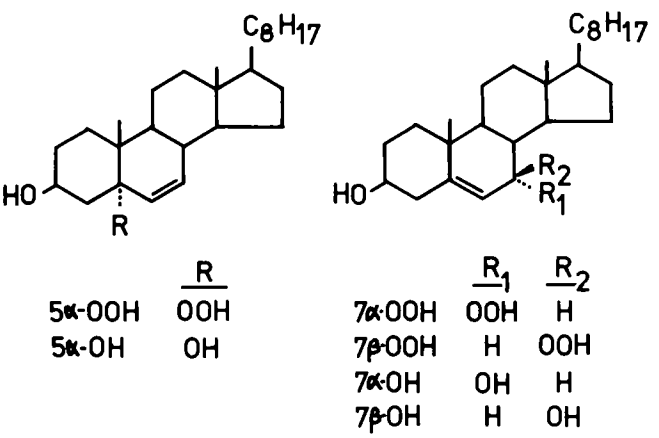

FIG. 1. Major cholesterol products derived from singlet oxygen and free radical oxidation.

Abbreviations: AH^-, ascorbate; BHT, butylated hydroxytoluene; DOX, desferrioxamine; HPD, hematoporphyrin derivative; LOOH, lipid hydroperoxide; PBS, phosphate-buffered saline; TBA, thiobarbituric acid; TBARS, thiobarbituric acid reactive substance(s); TMPD, N,N,N′,N′-tetramethyl-p-phenylenediamine; 5α-OH, 5α-cholest-6-ene-3β,5-diol; 5α-OOH, 3β-hydroxy-5α-cholest-6-ene-5-hydroperoxide; 7α-OH, cholest-5-en-3β,7α-diol; 7α-OOH,3β-hydroxycholest-5-en-7α-hydroperoxide; 7β-OOH, 3β-hydroxycholest-5-en-7β-hydroperoxide; 7β-OH, cholest-5-en-3β,7β-diol; 7-one, 3β-hydroxycholest-5-en-7-one.

connection with photodynamic therapy (15). HPD-A preparations in PBS were stored at −20 C until used. Porphyrin concentrations were determined spectrophotometrically, as described (14). Cholesterol, 7-ketocholesterol, egg yolk phosphatidylcholine, Cu/Zn superoxide dismutase, catalase (thymol-free), butylated hydroxytoluene, and 2-thiobarbituric acid were from Sigma Chemical Co. (St. Louis, MO), while sodium ascorbate was from BDH Chemicals (Poole, England). All other chemicals were of the highest purity available, and all aqueous solutions were prepared with deionized, glass-distilled water.

Radiolabeling of membranes. Immediately before use, [^{14}C]cholesterol plus carrier (~300 μg total; see below) was separated from any pre-existing oxidation products by thin layer chromatography (TLC) on Silica Gel-60 plates, using heptane/ethyl acetate (1:1, v/v) as the solvent system. The cholesterol zone was located by radioscanning (see below), recovered by scraping, and washed with chloroform/methanol (2:1, v/v). After centrifugation to remove gel particles, the extract was dried under argon. Cholesterol-labeled erythrocyte membranes were prepared by exchange with labeled unilamellar liposomes as follows (16). Egg phosphatidylcholine (1 μmol) and purified cholesterol (0.8 μmol, including 5-10 μCi of [^{14}C]cholesterol) were dissolved in chloroform/methanol (2:1, v/v), and the solvent was removed by flushing with argon. The cholesterol/phospholipid ratio was chosen so as to approximate that of the erythrocyte membrane (16). The lipids were suspended in PBS by vortexing for 0.5–1 min, allowed to stand for 30 min on ice, and then sonicated under a stream of argon, using a Branson Sonifier with microtip (approximately ten 30-sec doses at 30% full power, with interim chilling periods). Suspensions then were centrifuged at 27,000 × g for 10 min to remove any probe particles or large lipid aggregates. The liposomes in the supernatant fraction were mixed with ghost membranes and incubated in the presence of 2 mM azide and under argon for periods of up to 48 hr at 37 C. Ghost membrane cholesterol was typically in 15- to 20-fold excess over liposome cholesterol. Using the 48 hr-value as an end point, we found that exchange was undetectable after 3 hr and approximated 40% after 20 hr. After incubation, the ghosts were washed with 10 volumes of PBS and centrifuged at 17,000 × g for 15 min. This was repeated five to six times to ensure complete removal of liposomes and azide. The ghosts were resuspended to a final working concentration of 1 mg protein/ml (~2×10^9 ghosts/ml).

Experimental conditions. Radiolabeled ghosts were sensitized with HPD-A, transferred to a pair of thermostatted beakers (45 mm diameter) at 10 C, and irradiated from above with filtered blue light (transmittance maximum ~420 nm) (7). The suspensions were stirred continuously at a slow rate to ensure uniform light exposure. Fluence rates (W/m^2) were measured with a radiometer (Yellow Springs Instruments, Yellow Springs, OH). After a given dose of irradiation, the membranes were recovered for subsequent incubation with AH^- (without or with other additions) in the dark. These reactions were carried out at 37 C in four-place Stirrer Baths (Yellow Springs Instruments). Samples were removed for measurement of lipid peroxidation and/or TLC analysis immediately after irradiation and after one or more intervals of post-irradiation incubation.

Assessment of lipid peroxidation. Peroxidation of unsaturated lipids (excepting cholesterol and monoenoic and dienoic phospholipids) was measured by thiobarbituric acid assay, as described previously (18,19). Absorbance readings at 532 nm were converted to TBARS values for malonaldehyde and other carbonyl by-products, using an extinction coefficient of 147,000 $M^{-1}cm^{-1}$.

Chromatographic procedures. TLC separations of cholesterol photoproducts and autoxidation products were carried out in essentially the same manner as described (8). It was essential that EDTA or DOX be added to experimental samples before lipid extraction to prevent LOOH decomposition. Extracted lipids were either chromatographed directly or after borohydride reduction of hydroperoxides to their relatively stable alcohols. Stock solutions of 50 mM $NaBH_4$ in methanol/10 mM NaOH were prepared immediately before use and added in five-fold molar excess over total cholesterol. After 15 min incubation at room temperature, solvent was evaporated and the lipid residues were taken up in 10 μl of cold chloroform/methanol for application to TLC plates. Authentic 7-ketocholesterol and its borohydride reduction products, 7α-OH and 7β-OH, were used as standards for identifying free radical reaction products. Authentic 5α-OOH and its borohydride product 5α-OH were obtained by photooxidizing membranes with rose bengal, a well-known photogenerator of $^1O_2$ (20). Chromatography was performed on Silica Gel-60 F_{254} plates of 0.25-mm thickness (EM Science, Cherry Hill, NJ), using a single irrigation of heptane/ethyl acetate (1:1, v/v). Phospholipids remained at the origin in this system and therefore did not interfere with the colorimetric detection of cholesterol products (see below). Immediately after development, the plates were either sprayed with TMPD to detect peroxides, or scanned for radioactivity, using a RTLC Scanner (Model RS) equipped with a data processing system (Radiomatic Instruments, Tampa, FL). Subsequent to scanning, the plates were sprayed with 50% H_2SO_4, warmed briefly to visualize cholesterol and its various oxidation products (21) and finally photographed.

Other methods. Ascorbate was determined spectrophotometrically by measuring the reduction of Fe(III) [o-phenanthroline]$_2$ at 515 nm (22,23). Calculations were based on an extinction coefficient of 23,000 $M^{-1}cm^{-1}$ (2-electron oxidation of AH^-). Determinations were started immediately after removing samples from reaction vials. When present in assay mixtures, membranes were pelleted in a microcentrifuge, and the supernatant fluids were used for absorbance measurements.

RESULTS

Ascorbate-driven lipid peroxidation. As shown in Table 1, exposure of HPD-A-sensitized erythrocyte ghosts to a one-hr light dose resulted in a low level of TBA-detectable lipid peroxidation (~1 nmol TBARS/mg protein), which reflects free radical processes (24). Most of this reactivity probably originated from degradation of $^1O_2$-derived hydroperoxides during the assay because HPD-A has been shown to be a more efficient sensitizer of Type-II ($^1O_2$) photochemistry than Type-I (free radical) photochemistry in this system (below and [10]). Incubation of the photoperoxidized membranes with 0.5 mM AH^-/0.05 mM Fe(III) in the dark caused a strong burst of lipid

[a]Membranes (2 mg protein/ml in PBS) were sensitized with HPD-A (15 μg/ml) and irradiated for one hr at 10 C (fluence rate ~25 W/m²). The standard reaction mixture in subsequent dark incubations consisted of photooxidized membranes (1 mg protein/ml), AH^- (0.5 mM), and $FeCl_3$ (0.05 mM) in PBS at 37 C. In separate experiments, as indicated, the following were included: EDTA (0.06 mM), DOX (0.06 mM) or BHT (0.05 mM); or $FeCl_3$ was omitted. A control containing nonirradiated membranes, AH^- and $FeCl_3$ was incubated alongside. At the indicated times, samples were withdrawn for determination of thiobarbituric acid reactive substances (TBARS). All absorbance readings were corrected for the zero-time reading of the control. Numbers with ± designations are means ± deviation of values from duplicate experiments. —, Not determined.

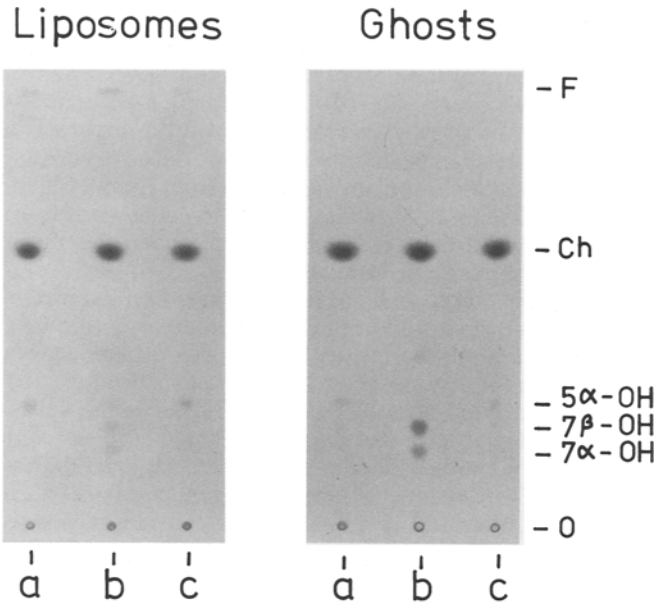

FIG. 2. Post-irradiation effects of ascorbate on cholesterol in liposomes (left) and erythrocyte ghosts (right). Preparations of [^{14}C] cholesterol-labeled liposomes and ghosts were sensitized with 5 μg/ml of HPD-A and irradiated for one hr at 10 C (fluence rate ~100 W/m²). Ghost protein was 1.0 mg/ml, corresponding to 0.7 mM phospholipid and 0.55 mM cholesterol. Liposomal lipid was approximately the same, i.e. 0.7 mM egg phosphatidylcholine and 0.5 mM cholesterol. After irradiation, the membranes were incubated for one hr at 37 C in the presence of 1 mM AH^-/10 μM $FeCl_3$ (lane b); and 1 mM AH^- /10 μ $FeCl_3$/50 μM DOX (lane c). Lane a represents irradiated membranes that were incubated one hr with $FeCl_3$, but without AH^-. Lipid extracts were reduced with $NaBH_4$ before chromatographing. Sample loads (as starting cholesterol): ~80 μg per lane. O, origin; Ch, cholesterol; F, solvent front. Spots were visualized by spraying with 50% H_2SO_4 and had the following colors: magenta (Ch); blue (5α-OH, 7α-OH, 7β-OH); gray (component between 5α-OH and Ch). Radioscans of lanes a–c (ghosts) are shown in Figure 3.

peroxidation that leveled off at approximately 30 nmol TBARS/mg protein after 40–50 min. Similar incubation of a non-photooxidized control produced no significant peroxidation, despite the fact that hydroxyl radical (OH^-), a powerful oxidant, was generated in the aqueous compartment under these conditions (23). When AH^- was omitted from the standard reaction mixture (Table 1), peroxidation remained at the starting level, indicating that Fe(III) alone could not support the reaction. The radical scavenger BHT and the chelators EDTA and DOX, which respectively stimulate and suppress iron redox cycling (25), all acted as strong inhibitors, suggesting that the reaction was free radical in nature and catalyzed by membrane-bound iron. The lower level of peroxidation observed without added iron (~8 nmol TBARS/mg at 50 min) is attributed to endogenous metal. These results are similar to earlier ones involving photooxidative priming by other sensitizers (26) and support the idea that AH^--stimulated lipid peroxidation in this system occurs via LOOH-dependent initiation (27). A similar mechanism has been proposed for reactions in which AH^- is present throughout the irradiation period (17).

Cholesterol oxidation products. Additional insights into the reaction mechanisms involved in these processes were obtained by identifying cholesterol oxidation products. TLC results obtained with [^{14}C]cholesterol-containing unilamellar liposomes and erythrocyte ghosts are shown in Figure 2. HPD-A-sensitized photooxidation (lanes a) afforded a major product that, on borohydride treatment, comigrated with the product obtained from rose bengal-sensitized photooxidation (10), and thus was identified as 5α-OOH (Fig. 1). This clearly indicates that Type-II photochemistry was dominant. In addition to 5α-OOH, small amounts of 7α-OOH and 7β-OOH must have been formed, as evidence by the presence of 7α-OH and 7β-OH. None of the diols (5α-OH, 7α-OH, or 7β-OH) were detected without borohydride treatment (see below). As indicated (8), the free radical-derived 7-OOH epimers could have arisen via a low level of Type-I photochemistry, allylic rearrangement of 5α-OOH (28), light-independent autoxidation or some combination of these processes. Some rearrangement may have occurred during post-irradiation incubation of the samples in lanes a, but this was not assessed by comparing with non-incubated samples. Also, the membrane-bound state of HPD-A (10) might have favored at least some bona fide Type-I chemistry, e.g. by electron transfer from unsaturated lipid to excited state porphyrin (8). The relative importance of these pathways has not yet been established. Incubation of photoperoxidized membranes with AH^- plus Fe(III) caused striking changes, both qualitative and quantitative, in the cholesterol product profile of liposomes as well as ghosts (Fig. 2, lanes b). For example, 5α-OH was greatly diminished (barely detectable in the ghosts) and relatively large amounts of 7α-OH/7β-OH were now evident, along with an unidentified species migrating between 5α-OH and cholesterol. The 7-diols were assigned on the basis of comigration with the reduction products of a 7-ketocholesterol standard, 7β-OH being the more abundant product (28). The appearance of 7-diols during AH^-/iron treatment clearly reflected the large burst of free radical lipid peroxidation that was observed by TBA assay (Table 1).

Formation of radical-derived products was absolutely dependent on AH^- and iron because DOX prevented the reaction (lanes c), and Fe(III) alone was ineffective. No significant amounts of 7α-/7β-OH were detected when nonirradiated membranes were exposed to AH^- and iron (not shown), which is consistent with TBARS formation being negligible under these conditions (Table 1). That a natural membrane responded similarly (albeit not identically) to an artificial bilayer in this system (Fig. 2) suggests that phospholipids per se provide the necessary sites of iron-binding and AH^- interaction, and proteins are not required. Small differences in the effect of AH^- on photooxidized liposomes and ghosts under identical reaction conditions (compare amounts of 7α-/7β-OH in lanes b, Fig. 2) could easily reflect differences in the cholesterol environment of the two membranes.

Radioscans of labeled cholesterol products from the ghost membrane experiment described in Figure 2 are shown in Figure 3. The photooxidized control (Scan A) exhibits a major peak at R_F 0.29, which coincides with the 5α-OH spot shown in Figure 2 and contains ~4% of the total radioactivity. Lesser amounts of 7α-OH (R_F 0.17) and 7β-OH (R_F 0.24) also are evident (3% and 1%, respectively). The broad peak near the origin represents an artifact of borohydride treatment that was observed as background noise in all samples, including nonirradiated samples. Treatment with AH^-/iron (Scan B) resulted in a large increase in the 7-diol peaks and decrease in the 5α-OH peak, which correspond qualitatively to the changes observed using colorimetric detection. Intensification of the peak at the origin suggests the presence of a relatively polar product that overlaps with background material (see below). An additional component (R_F 0.41; unassigned) coincides with the gray spot observed on the sprayed plate (Fig. 2). A similar product was observed in xanthine/xanthine oxidase-treated ghosts, which undergo oxyradical-dependent lipid peroxidation (8). That DOX could abolish the effects of AH^-/iron is further illustrated by Scan C, which shows a product profile that is virtually identical to that of the control (Scan A).

Radioscans taken from experiments similar to those described in Figures 2 and 3, but without borohydride treatment prior to TLC are shown in Figure 4. In this case, we were able to detect radiolabeled hydroperoxides of cholesterol as well as diols and other products (e.g. 7-one) generated during AH^--stimulated lipid peroxidation. The shift in product distribution when photoperoxidized membranes were reacted with AH^- is again strikingly evident when Scan B (before AH^-) is compared with Scan C (after AH^-/iron). The Scan B peak at R_F 0.36 (~10% of the applied radioactivity) consisted mainly of 5α-*OOH* because 5α-*OH* was the most abundant product after $NaBH_4$ treatment. In Scan C, 5α-OH (R_F 0.27) is barely evident (<1%) while 7α-OH (R_F 0.17; 4%) and 7β-OH (R_F 0.23; 2%) are relatively prominant. Additional products ascribed to free radical reactions are observed at the origin and at R_F 0.44 but are not identified. The

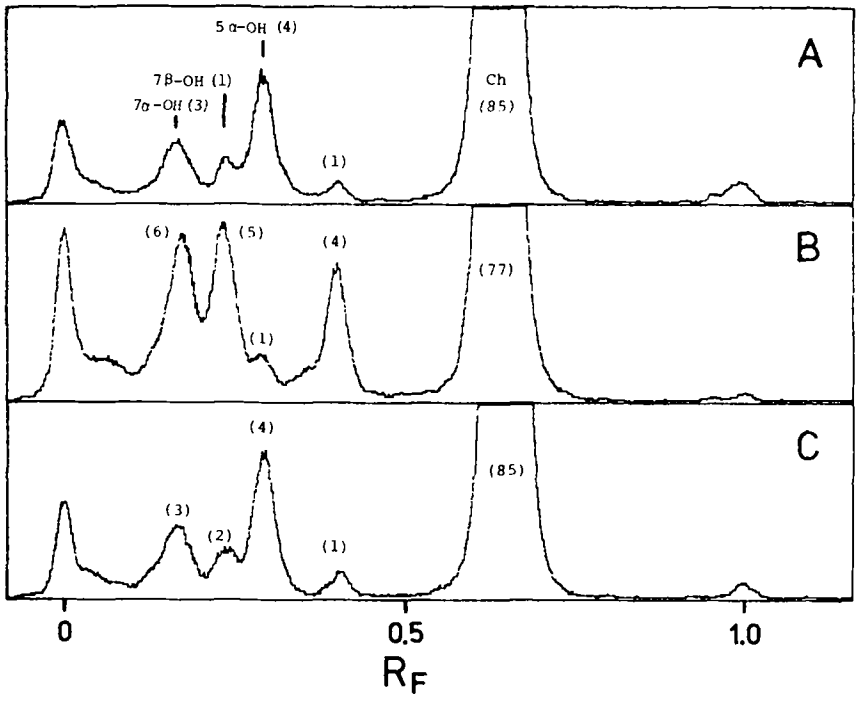

FIG. 3. Radioscans of cholesterol oxidation products from [^{14}C]cholesterol-labeled ghosts. The scans were performed on the same TLC plates as shown in Figure 2, but before H_2SO_4 spraying. (Samples were reduced with $NaBH_4$ before analyzing.) (A) photooxidized control incubated with Fe(III), without AH^-; (B) photooxidized ghosts incubated with 1 mM AH^-/10 μM Fe(III); (C) photooxidized ghosts incubated with 1 mM AH^-/10 μM Fe(III)/50 μM DOX. Sample load per lane: ~80 μg, as starting cholesterol (~2,600 cpm). Product yields (as percent total radioactivity) are shown in parentheses.

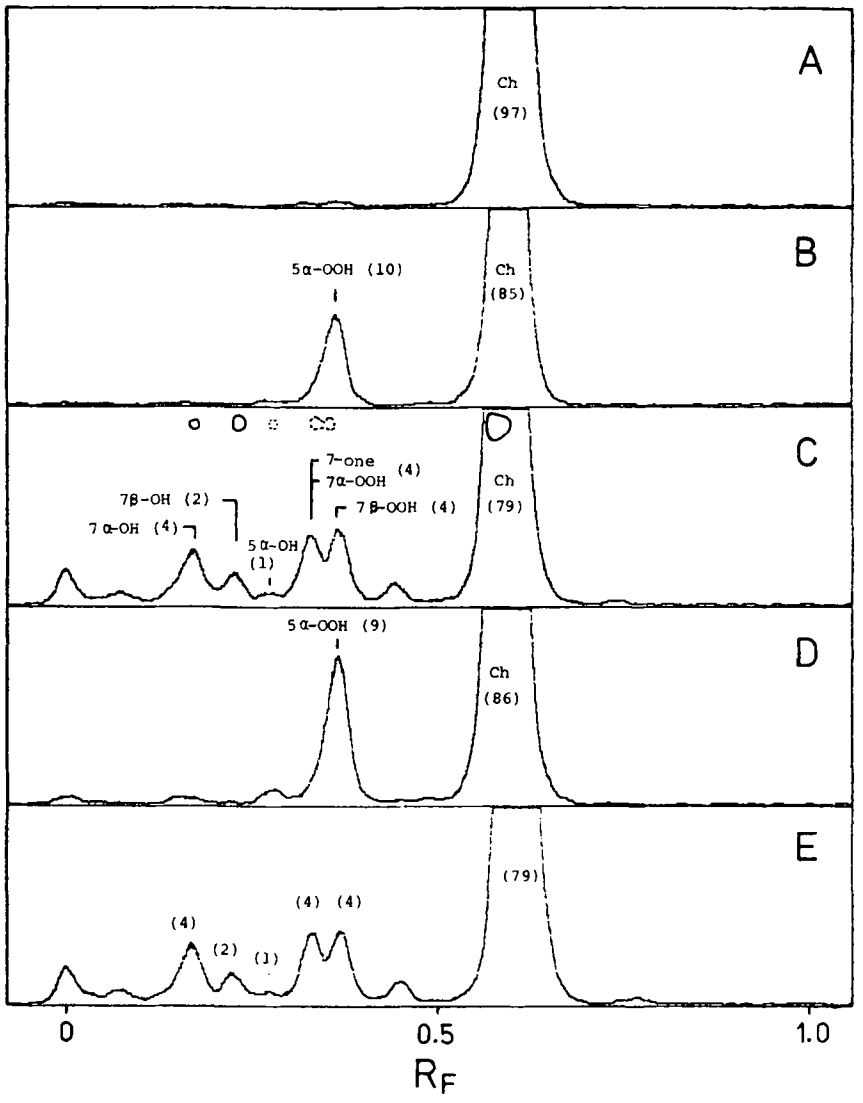

FIG. 4. Photoperoxidation of [^{14}C]cholesterol-labeled ghosts: radioscans of labeled products after exposure to ascorbate. (Samples were not reduced with borohydride before chromatographing.) The ghosts (0.5 mg protein/ml in PBS) were sensitized with HPD-A (5 μg/ml), irradiated for one hr (Fig. 2) and then dark-incubated for one hr in the presence of 1 mM AH^-/10 μM $FeCl_3$ plus the following additions: none (C); 50 μM EDTA (D); 30 μg/ml catalase (E). (A) is a 2-hr dark control; (B) is an irradiated sample before AH^- treatment. Sample load per lane: ~40 μg, as starting cholesterol (~1,200 cpm). The overlay in lane C shows spots detected with H_2SO_4. Product yields (as percent total radioactivity) are shown in parentheses.

poorly resolved doublet migrating slightly ahead of 5α-OH consists mainly of 7α-OOH and 7β-OOH (visualized by TMPD spraying and tentatively assigned as shown) plus the 7-one, which was detected by fluorescence (21). EDTA, like DOX, inhibited these reactions, as evidenced by Scan D resembling Scan B. As indicated above, this effect probably was due to chelation and removal of iron from the membrane surface, which prevented LOOH decomposition. On the other hand, catalase had no effect on the reaction (Scan E), which is consistent with the enzyme's inability to inhibit TBARS formation (17,26). Therefore, even though H_2O_2 was generated in this system and served as a precursor of $OH^\cdot$ (23), neither of these species could have been involved in the transformations described.

The cholesterol products shown in Scan B (Fig. 4) comprised part of the overall population of lipid hydroperoxides generated by photooxidation. We estimated the percentage content of cholesterol products as follows. Iodometric analysis (26) of the irradiated membranes indicated that the bulk concentration of total LOOHs (derived mainly from phospholipids and cholesterol) was 115 ± 3 μM (mean ± deviation of two determinations). Based on percentage radioactivity (corrected for 2–3% background), the yield of cholesterol hydroperoxides in Scan B was estimated to be ~38 μM. Thus, ~32 mol % of the LOOH population existed as cholesterol hydroperoxides. This figure assumes, of course, that [^{14}C]cholesterol underwent uniform exchange with membrane cholesterol and that the labeled products were representative

of the entire reactive population. Since cholesterol constitutes about 45 mol % of the erythrocyte membrane lipid (16), these data suggest that the sterol was less reactive toward photooxidation than the phospholipids. However, the difference in these values is not as great as might have been expected, considering the fact that $^1O_2$ has been shown to react with the methyl esters of linoleic, linolenic and arachidonic acids approximately 2×, 3× and 4× faster, respectively, than it reacts with cholesterol (29).

Ascorbate oxidation. Figure 5 shows AH^- decay during the incubations described in Figure 4. As can be seen, AH^- loss in the presence of membranes was accelerated considerably after photoperoxidation, confirming that LOOH-dependent oxidation of AH^- was taking place. In contrast to its effects on lipid peroxidation, EDTA stimulated AH^- oxidation, which is in agreement with previous observations (23). BHT, on the other hand, inhibited the reaction, which is consistent with the fact that this antioxidant suppressed TBA-detectable lipid peroxidation (Table 1). The protective effect of catalase is attributed to a small contribution to H_2O_2-dependent reactions to AH^- oxidation.

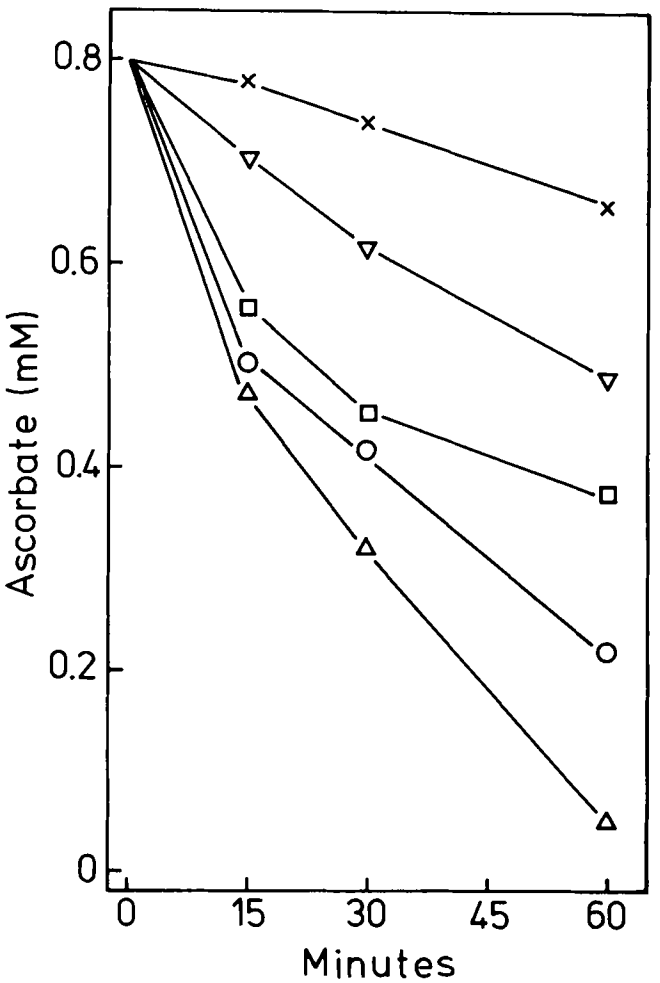

FIG. 5. Ascorbate loss during incubation with photoperoxidized membranes. Data are taken from the experiment described in Figure 4. The photooxidized ghosts were treated with AH^-/iron (○), or AH^-/iron plus the following: 50 μM EDTA (△); 30 μg/ml catalase (□); 0.2 mM BHT (▽). A control with nonirradiated membranes was run alongside (×).

DISCUSSION

The observed effects of AH^- on membranes containing preexisting LOOH is an example of hydroperoxide-dependent initiation of lipid peroxidation (27). The following reaction scheme is proposed to explain these effects (where LOOH, L·, LOO· and LO· are lipid hydroperoxide, alkyl radical, peroxyl radical and oxyl radical, respectively, and $AH^{\cdot}$. is ascorbate radical).

$$AH^- + Fe(III) \rightarrow A^{\cdot} + H^+ + Fe(II) \quad [1]$$

$$LOOH + Fe(II) \rightarrow LO\cdot + OH^- + Fe(III) \quad [2]$$

$$LH + LO\cdot \rightarrow L\cdot + LOH \quad [3]$$

$$L\cdot + O_2 \rightarrow LOO\cdot \quad [4]$$

$$LH + LOO\cdot \rightarrow L\cdot + LOOH \quad [5]$$

$$O_2 + Fe(II) \rightarrow O_2^- + Fe(III) \quad [6]$$

$$AH^- + H^+ + O_2^- \rightarrow A^{\cdot} + H_2O_2 \quad [7]$$

$$H_2O_2 + Fe(II) \rightarrow OH\cdot + OH^- + Fe(III) \quad [8]$$

Cholesterol and phospholipid hydroperoxides generated primarily by $^1O_2$ attack during porphyrin-sensitized photooxidation undergo iron-catalyzed reduction to oxyl radicals (Eqs. 1 and 2), which subsequently trigger waves of free radical lipid peroxidation (Eqs. 3–5). In this scheme, AH^- exacerbates the membrane-damaging effects of photosensitized peroxidation by reducing Fe(III) in the midst of reactive LOOH. Previous work has shown that iron-catalyzed autoxidation of AH^- in a system of this type ultimately gives rise to OH· (Eqs. 1, 6–8), which can be detected in the aqueous compartment with OH· traps (23). As indicated earlier (17,26), however, and confirmed here, OH· generated in this way (whether in the medium or on the membrane itself) has little to do with AH^--stimulated lipid peroxidation, presumably because LO· is a much more effective initiator. This derives from the fact that catalase inhibited the oxidation of OH· traps (23), but had no effect on post-irradiation lipid peroxidation (Table 1) or formation of 7α-/7β-OOH and other radical-derived products (Fig. 4).

In addition to 7α-OOH and 7β-OOH, we were able to detect 7-one by virtue of its characteristic fluorescence on ultraviolet excitation (21). As suggested in previous studies on simpler systems (28,30), the ketone may have arisen via disproportionation reactions involving two 7-peroxyl radicals or two 7-oxyl radicals (Eqs. 9 and 10, where L_2O_4 and L_2O_2 are postulated tetroxide and dioxide intermediates, and LO is the ketone). Heteroreactions involving 7-peroxyl or 7-oxyl radical and a different lipid peroxyl or oxyl radical may also have taken place.

$$2\ LOO\cdot \rightarrow [LOOOOL] \rightarrow LOH + LO + O_2 \quad [9]$$

$$2\ LO\cdot \rightarrow [LOOL] \rightarrow LOH + LO \quad [10]$$

This and the preceding study (8) represent the first real examples of how cholesterol in a natural membrane can be exploited as a reporter lipid for monitoring changes in oxidant chemistry. Numerous earlier investigations by Smith (4) and others (1–3,5,6) on cholesterol oxidation in homogeneous solution (organic solvents) and in organized media (micelles and liposomes) have provided an important background for this work. These findings improve our understanding of how AH^- and other iron reductants

might exacerbate the cytotoxic effects of photosensitizing dyes and drugs (17). In addition, they suggest new approaches for enhancing the therapeutic potency of HPD and other antineoplastic photosensitizers (15).

ACKNOWLEDGMENTS

Leland Smith provided helpful information about cholesterol product analysis; John Lech, Department of Pharmacology/Toxicology at this institution, provided use of the RTLC Scanner. This work was supported by Grant DCB-8501894 from the National Science Foundation.

Sunlight, Melanogenesis and Radicals in the Skin[1]

Miles R. Chedekel* and **Lisa Zeise**
Division of Environmental Chemistry, School of Hygiene and Public Health, The Johns Hopkins University, Baltimore, MD 21205

Melanocytes are cells of neural crest origin residing at the dermal-epidermal juncture. They produce specialized organelles called melanosomes within which the biochemical processes of melanization occurs. UV radiation is capable of inducing melanogenesis and, during the biosynthesis of melanins, several of the putative precursors "leak out" of the melanosome and can be detected in the skin, serum and urine of individuals undergoing active melanogenesis. Most notable are the cysteinyldopas (formed by nucleophilic addition of cysteine to dopaquinone) and several dihydroxyindoles (formed by intramolecular cyclization of dopaquinone). These catechols often are methylated in the melanocyte to afford a mixture of the monomethoxy derivatives and, in some cases, the dimethoxy species.

Recent investigations in our laboratories have demonstrated that the cysteinyldopas, dihydroxyindoles, and their various methylated derivatives are photochemically unstable. Irradiation with biologically relevant ultraviolet radiation (i.e. wavelengths >300 nm) results in the rapid destruction of the precursors/metabolites and the production of a variety of free radical species. The photochemistry and potential photobiological significance of melanogenic intermediates is discussed.
Lipids 23, 587-591 (1988).

Melanin is an ubiquitous biopolymer of quinone and hydroquinone monomer units found throughout the animal and plant kingdoms. In animals, it contains concentrations of metal ions and free radicals under most known conditions and is largely responsible for pigmentation. In fact, melanins are the only pigments apart from hemoglobin in the blood that are synthesized and used extensively by mammals. The amount, type and distribution of melanin in keratinocytes determines hair and skin pigmentation and is largely responsible for basic photoprotection.

Specialized dendritic cells of neural crest origin known as melanocytes produce and package human epidermal melanin pigments. These cells reside at the dermal/epidermal junction and together with the surrounding keratinocytes form a unit that is called the epidermal melanin unit. Within these units, the average ratio of melanocytes to keratinocytes is 1:36, but it varies in different parts of the body. Melanin formation occurs in melanosomes, which are subcellular organelles transferred to keratinocytes via the dendritic processes during pigmentation. The size of the individual melanosomes dictates their distribution within keratinocytes. Melanosomes smaller than 0.8 μm are found in groups of two or more within the keratinocytes in membrane-limited vesicles called "melanosome complexes" in Caucasoids and Mongoloids, while melanosomes larger than 0.8 μm are packaged singly within the keratinocytes in membrane-limited vesicles in Negroids. Once the keratinocytes are full of melanosomes, they are pushed towards the surface of the skin where they die and ultimately are sloughed off.

Proteins sequestered from the smooth and the rough endoplasmic reticula, the Golgi apparatus and the Golgi-associated endoplasmic reticulum of melanocytes are deposited into initially unpigmented membrane-limited vesicles called premelanosomes. As the melanosome translocates to the tips of the dendrites, pigment formation slowly occurs and is nearly complete when transfer of the melanosome to the keratinocyte takes place (see Fig. 1). Delayed tanning is stimulated by the UVB component of sunlight and encompasses melanosome formation, pigment production and melanosome transfer. The detailed photobiological mechanisms of sunlight induced melanogenesis are not clearly understood.

Melanins and photoprotection. Regardless of melanin's original evolutionary function, there is little doubt that it photoprotects the skin of present-day humans (2). In their 1974 paper, "The role of natural photoprotective agents in human skin," Pathak and Fitzpatrick concluded, "Melanin and the distribution of melanosomes in the epidermis are the single most important factors in the protection of human skin from the effects of ultraviolet light." Other investigators have substantiated this view over the past 30 years (3-8). Pathak and Fitzpatrick also proposed a variety of mechanisms to explain how melanins accomplish this photoprotection, including the filtering and attenuation of impinging radiation by scattering, absorption and subsequent dissipation (as heat),

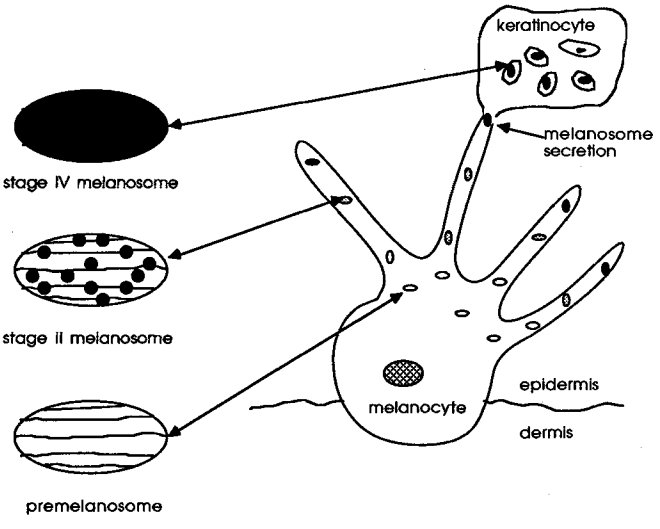

FIG. 1. Schematic representation of melanosome migration and melanization within the melanocyte and transfer to a keratinocyte.

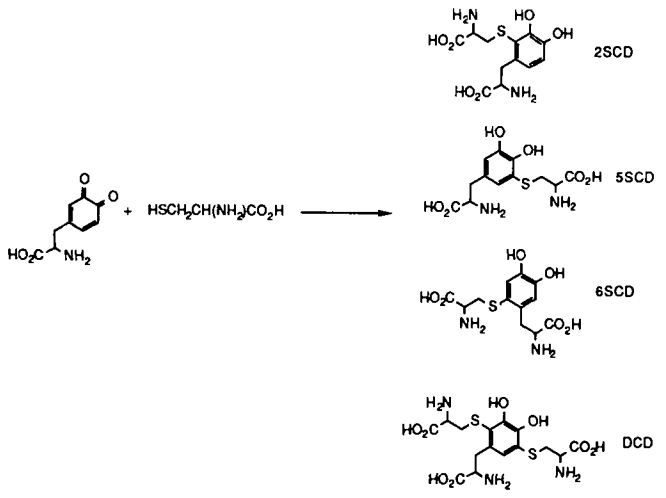
absorption accompanied by redox reactions and absorption accompanied by electron transfer processes.

When considering normal, physiological and pathological effects of sunlight on human skin, differences in genetic background must be considered. For example, Negroes are much less susceptible to general actinic damage and UV-induced skin cancer than dark-complexioned Caucasians who are less susceptible than fair-skinned Caucasians. The morphology of Caucasian vs Negro epidermal melanosomes may cause much of the difference between the respective melanins. In Caucasian skin, the "melanosome complexes" are taken up by lysosomes and decomposed during passage of the host keratinocyte to the surface (9), unlike the larger, single, melanosomes of the Negro. Thus, while the horny layer in Negro skin contains intact melanosomes that effectively protect the underlying layers of living cells, this layer in Caucasians possesses little more than a dust of melanin.

Melanin metabolites. Raper was the first to postulate that indole derivatives are formed as intermediates in melanization (10). These derivatives arise from the oxidation of the 1,4-addition product of tyrosinase-generated dopaquinone (10,11). Derived forms of the two types of dihydroxyindoles formed during eumelanogenesis, i.e. 5,6-dihydroxyindole (DHI) and 5,6-dihydroxyindole-2-carboxylic acid (DHICA), have been experimentally implicated to form the heteropolymer eumelanin, along with dopa, dopaquinone or both (12,13).

Prota and Nicolaus conducted in vitro studies of pheomelanin biochemistry, which demonstrated that the precursors of pheomelanin are nucleophilic addition products of cysteine and tyrosinase-generated dopaquinone (14, 15). 5-S-cysteinyldopa (5SCD) (16), the major product of this reaction, was chemically synthesized and characterized to enable great strides to be taken in pheomelanin chemistry and melanocyte biochemistry. Two-S- and 6-S-cysteinyldopa, natural 5 SCD isomers and the di-addition product, 2,5-S,S′-dicysteinyldopa (DCD) (see Scheme 1) also are formed in melanosomes (17,18). The two chemically distinct biopolymers, eu- and pheomelanin, appear to occur as an intimate mixture in the human epidermis (19).



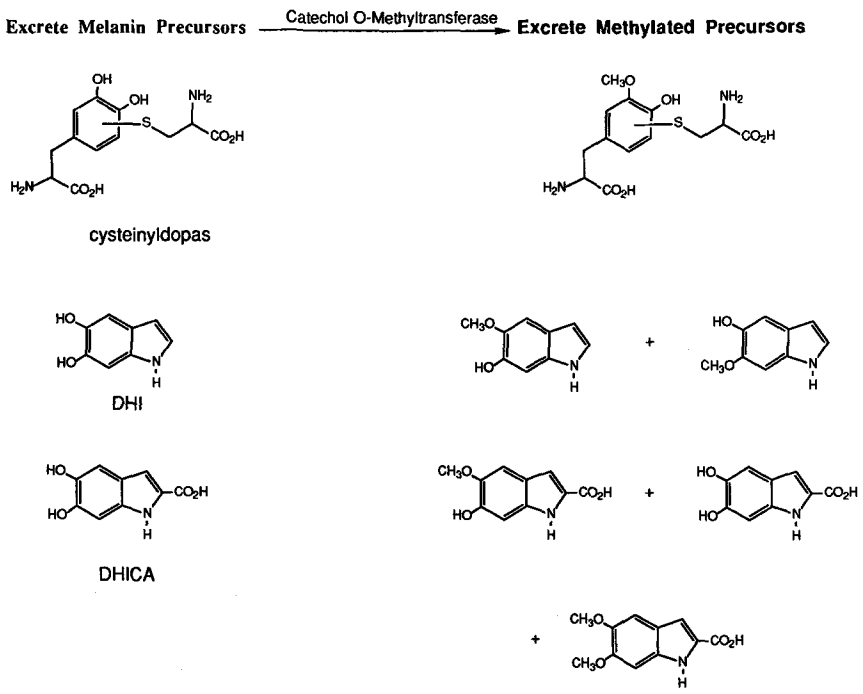
SCHEME 1. Formation of cysteinyldopas from dopaquinone and cysteine.

Detection of free dihydroxyindoles and cysteinyldopas in the urine and serum of normal humans and melanoma patients indicated their escape from the melanocyte during polymerization (20). DHI and DHICA may be O-methylated by the action of catechol-O-methyl transferase (COMPT) in the melanocyte, like many catechols, to respectively yield the 6-monomethoxyindole-2-carboxylic acid (6HMICA), 5-monomethoxyindole-2-carboxylic acid (5HMICA) and 5,6-dimethoxyindole-2-carboxylic acid (DMICA) positional isomers (Scheme 2) (21–25). Similarly, cysteinyldopas catabolized by O-methylation and/or glucuronide and sulfate conjugation (26) appear to represent detoxification products that are not cytotoxic.

The role of cysteinyldopas and indole metabolites as biochemical markers of melanocyte function and malignant melanoma have been facilitated by recent developments in their syntheses and analyses. These investigations revealed that 5SCD urine concentrations in healthy humans increase with exposure to sunlight (27), with individuals of Celtic origin exhibiting the most marked increases (28). Subsequently, exposure to both ultraviolet light in the A region, 400–320 nm (320–280 nm or <280 nm) UVA (29) and UVB (30) light was shown to increase 5SCD serum concentrations in healthy individuals. Additionally, psoriatic patients treated with 8-methoxypsoralen plus UVA (PUVA) therapy (i.e. 8-methoxypsoralen and UVA light) increased serum concentrations of 5SCD and 6HMICA (31,32). The latter metabolite was suggested to mark melanogenic activity more specifically by Rorsman and his colleagues, because albino animals found to contain measurable levels of 5SCD were devoid of 6HMICA (33).

So, the melanocytic amino acid 5SCD and indolic metabolites have been useful biochemical markers of normal and pathological melanocyte function (20). Controlled light exposure or PUVA generally leads to a 100–300% increase in 5SCD serum levels (relative to normal serum levels in the range of 4–16 nmol/l) (29); however, the local concentrations in the skin and especially in the melanocyte may be much higher. From these studies, it may be postulated that a variety of environmental insults may activate melanocytes to cause an increase in both the production of melanin precursors and metabolites.

Melanogenic metabolite photochemistry. UV radiation-induced oxidation of melanogenic catechols, such as that of dopa to dopachrome and ultimately to melanin, first was described by Arnow (34). Felix and Sealy confirmed the purported free radical nature of catecholamine photochemistry spectroscopically by using ESR (35,36). Steady-state electron spin resonance (ESR) spectra of the corresponding o-semiquinones were generated by continuous-wave photolysis of a number of catechols and catecholamines. Because o-semiquinones may arise from catechols, either via photoionization or by phenolic O-H bond homolysis, ESR spin trapping with the spin trap 5,5-dimethyl-1-pyrolline *N*-oxide (DMPO) was employed to scavenge hydrated electrons, hydrogen atoms or both produced during dopa photolysis (37). This study demonstrated that although dopa undergoes both photoionization and bond homolysis upon irradiation at neutral pH, the former predominates over the latter pathway by an estimated 2.6-fold.



SCHEME 2. Formation of methylated melanin metabolites.

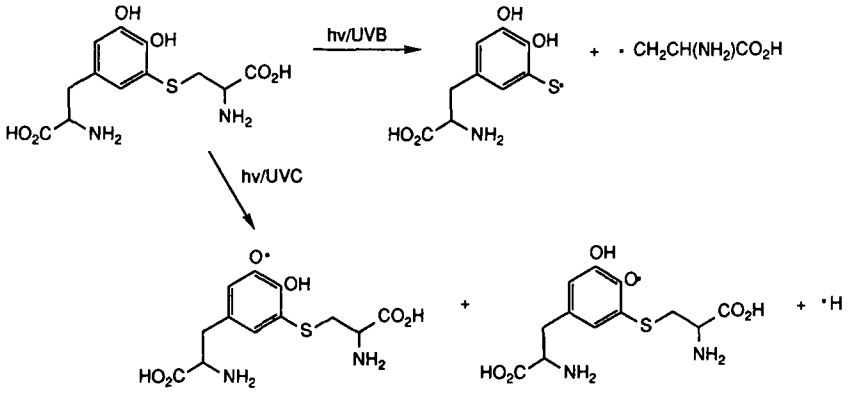
Laser flash photolysis was used to observe directly catechol photoionization for the first time (38). Photoionization of dopa allowed the direct spectroscopic observation of an hydrated electron, indicating the quantum yield for the process to be 9.1%. Absorption spectra, extinction coefficients and rate constants for formation and decay of transients produced upon pulse radiolytic one-electron oxidation of dopa and the cysteinyldopas were used to investigate the photochemistry of the catechols (39,40). Because flash photolysis of dopa yielded a quantum yield of hydrated electron corresponding only to approximately half the yield of dopasemiquinone (19.6%), dopa photoionization and phenolic O-H bond photohomolysis are implicated as being equally efficient processes. The estimated predominance of dopa photoionization over O-H photohomolysis by Kalyanaraman and coworkers is based on an indirect observation of $e^-_{aq}/H^\cdot$ formation, rather than a more accurate, direct observation of e^-_{aq} and dopasemiquinone formation. The rapid disproportionation of dopasemiquinone to form dopaquinone and dopa was demonstrated by Land et al. The subsequent decay of dopaquinone to form dopachrome proceeds via a base-catalyzed unimolecular cyclization (38).

Laser flash photolysis of the pheomelanin precursors 5SCD and DCD yielded fewer hydrated electrons from the cysteinyldopas than from dopa; ($\phi_{photoionization}$ = 1.2% and <0.5%, for 5SCD and DCD, respectively) (38). Markedly different peak wavelengths and spectral shapes were exhibited by the initial flash photolysis transient absorption spectra of 5SCD and DCD compared with semiquinones produced by pulse radiolysis (41). Thus, photohomolytic pathways were implicated as the primary photochemical events in 5SCD photolysis (Scheme 3) (38). Further investigation of these radical pathways have used ESR spin-trapping techniques for continuous wave photolysis experiments.

By continuous wave, 5SCD was found to be about one order of magnitude more photolabile than dopa using 254 nm radiation, and quantum yields for photodestruction were 6.8 ± 0.5% for 5SCD and 0.9 ± 0.1% for dopa (42). Evidence for production of both the hydrated electron and the hydrogen atom was provided by ESR spectra of 280 nm photolysis of dopa in argon- and N_2O-saturated solution of DMPO. These findings corroborate ESR spin trapping results obtained by Kalyaranaman et al. (37) and laser flash photolysis results of Land et al. (38).

Photolysis of 5SCD with 290 nm radiation in the presence of DMPO gave rise to an ESR spectrum unlike dopa and characteristic of a carbon-centered DMPO spin adduct, whereas shorter wavelength light (i.e. 260 nm) afforded a spectrum consisting of the predominant carbon-centered spin adduct as well as the DMPO-hydrogen adduct (42). Because N_2O-saturation did not affect the DMPO-H adduct signal observed during UVC photolysis of 5SCD, the adduct was thought to arise primarily from hydrogen atoms and not the hydrated electron. Model compounds used for further investigations suggested that the carbon-based radical probably did not arise from the dopa alanyl side chain. Subsequently, photolysis of 5SCD in the presence of MNP yielded an ESR spectrum indicative of the MNP-alanyl radical adduct. Thus, the homolytic cleavage of the S-CH_2 bond of the cysteinyl side chain generating both alanyl and thiyl radicals was confirmed (see Scheme 3) (42).

Melanin-like polymeric substances were formed by subjecting dopa or cysteinyldopas to prolonged photolysis. Dopaquinone was produced photochemically from dopa to suggest that the indolic compounds generated by both intramolecular cyclization of the dopaquinone and the tyrosinase-catalyzed polymerization of dopa to eumelanins are similar (43). The photochemical behavior of melanogenic indole intermediates and metabolites did



SCHEME 3. Formation of free radicals following UVB and UVC irradiation of 5SCD.

not receive much attention until recently. De Mol and coworkers investigated the photoproducts formed during catecholamine photolysis (44), and found melanin-like compounds were formed when 5,6-dihydroxy-N-methylindole was irradiated. The investigation of free radical production from DHI in the presence of zinc by Felix and Sealy (36) yielded an ESR spectrum during 254-nm irradiation. The spectrum was assigned to the metal complex of the indolesemiquinone, which suggests that photoionization, phenolic O-H bond homolysis or both may occur in DHI.

Further characterization of the photochemical behavior of the melanogenic indole intermediates and metabolites DHI, DHICA and 6HMICA included a comparison of the relative photolability of the indoles by determination of their quantum yields for destruction by broad-band 300 nm radiation (45,46). The rank order of photolability was found to be DHI > DHICA > 6HMICA ($\phi = 4.9 \pm 0.8\%$, $3.3 \pm 0.3\%$, and $1.9 \pm 0.3\%$, respectively). Continuous-wave photolysis of these indoles monitored by UV-visible difference spectroscopy revealed isosbestic points for all three indoles, which suggests an initial conversion of the indoles to a single photoproduct. The photoproducts of the indole-2-carboxylic acids are stable for minutes to hours before polymerizing, while the analagous DHI photoproducts form highly colored substances much more rapidly.

To characterize further the mechanics of the photochemistry, these melanogenic indoles were studied using ESR spin-trapping techniques (45). Photolysis of DHI with 300-nm radiation in argon- and N_2O-saturated DMPO solutions provided evidence that hydrated electrons and hydrogen atoms were produced. Thus, DHI and dopa seem to have similar photochemistry involving both photoionization and X-H bond homolysis. In contrast, photolysis of DHICA and 6HMICA in the presence of the spin-trap DMPO yielded ESR spectra, which consisted of two spin adducts: the DMPO-hydrogen adduct and a six-line spectrum characteristic of a carbon-centered radical adduct. The DMPO-H adduct was not quenched by N_2O, suggesting that this adduct originates not from the hydrated electron but from the hydrogen atom. Further ESR experiments attempted with several nitrone and nitroso spin trapping reagents were unable to characterize the carbon-based DMPO adducts observed with DHICA and HMICA (45).

The ESR spin trapping experiments detailed above indicate that for DHI, photoionization is an efficient process for DHI but some photohomolysis also may occur, leading to the production of hydrogen atoms. However, the hydrogen atom may be produced via two alternative photohomolytic cleavages on a catecholic indole: O-H bond fission, or N-H bond fission (38,39).

In summary, we have demonstrated that irradiation of a class of endogenous photosensitizers, melanogenic metabolites, gives rise to a number of reactive free radicals. The types of cellular damage promoted by these radicals depend on the rate constants of reaction with cellular biomolecules, the accessibility of these radicals to cellular biomolecules and the concentration of the radicals and biomolecules of interest within a specific cellular environment. While plasma levels of melanogenic metabolites range from 4–16 nmol/l in humans (47), local concentrations in the skin, and particularly in actively pigmenting melanocytes, undoubtedly are much higher. Indeed, we recently have calculated the content of 5-S-cysteinyldopa within actively pigmenting melanoma cells based on data from Rorsman and coworkers (personal communication) and found concentrations to be as high as 200 μM. It is unknown whether melanogenic metabolites localize within intracellular environments; however, it is tempting to speculate that the more hydrophobic methylated metabolites may localize in the lipid portion of biomembranes. Previous studies of light-induced reactions of melanin precursors indicated that several critical cellular components including DNA, proteins and lipids are possible targets (48–51).

The reactivity of the hydrated electrons and the hydrogen atom with various biomolecules is well-known from studies of aqueous radiochemistry. These two radical species have very high reaction rate constants with DNA and various amino acid moieties found in proteins, including aromatic amino acids, the protonated histidyl residue, sulfhydryl and disulfide bonds, as well as the peptide bond carbonyl (52–54). Hydrated electrons and hydrogen atoms also react rapidly with carbon-carbon double bonds such as those found in polyunsaturated fatty acids. In the presence of oxygen, these may lead to long-lived peroxy radicals (55,56). If these photoreactions occur in vivo, our studies suggest a possible role for melanogenic metabolite photolysis in acute solar responses of human skin such as erythema, as well as in sequellae

of chronic solar exposure including premature aging and carcinogenesis.

Reactive Oxygen in the Tumor Promotion Stage of Skin Carcinogenesis[1]

Susan M. Fischer*, Gregory S. Cameron, James K. Baldwin, Daniel W. Jasheway and Kelly E. Patrick
University of Texas System Cancer Center, Science Park-Research Division, Box 389, Smithville, TX 78957

Exposure of isolated SENCAR mouse epidermal cells to the tumor promoter 12-0-tetradecanoylphorbol-13-acetate (TPA) in vitro resulted in the production of oxidant species detected as chemiluminescence. This oxidant response can be inhibited by superoxide dismutase and copper complexes but not catalase or scavengers of hydroxyl radical or singlet oxygen, suggesting that the oxidant is superoxide anion. Inhibitors of various parts of the arachidonate cascade affect the TPA-induced oxidant response in a manner that corresponds to their effects on in vivo tumor promotion experiments. Agents that inhibit lipoxygenase activity, i.e. nordihydroguaiaretic acid, benoxaprofen, but not agents that are cyclooxygenase inhibitors, i.e. indomethacin, are effective in suppressing the oxidant response to TPA. Phospholipase C but not phospholipase A_2 or D produced an oxidant response kinetically similar to that elicited by TPA. The inhibitors of TPA-induced oxidants inhibited the phospholipase C response to the same extent, suggsting that TPA and phospholipase C may produce an oxidant species through a common mechanism, via phospholipid turnover-protein kinase C activation. The relevance of oxidant production to the tumor promotion process is suggested by the ability of exogenous xanthine/xanthine oxidase, a superoxide anion-generating system, to induce ornithine decarboxylase, a characteristic of TPA-treated cells. In addition, oxidant production is significantly lower in cells from the TPA-promotion resistant C57BL/6J mouse. These studies provide further support for a role for reactive oxygens in the tumor promotion process.
Lipids 23, 592-597 (1988).

Experimental chemical carcinogenesis studies in animals are valuable in identifying those biological events or agents that play either an essential or modulatory role in the development of tumors. Mouse skin has proven to be one of the best model systems for studying the multistage nature of carcinogenesis (1-3). Skin tumors can be induced readily by the sequential application of a subthreshold dose of carcinogen, operationally referred to as the initiation stage, followed by repetitive treatment with a noncarcinogenic tumor promoter (promotion stage). This second stage, promotion, most often is accomplished by using the phorbol diester 12-0-tetracecanoylphorbol-13-acetate (TPA), although a variety of agents have been identified as skin tumor promoters, including benzoyl peroxide, dihydroteleocidin, anthralin and its derivative chrysarobin (4,5).

The mode of action of TPA has been under investigation for numerous years, but elucidation of its mechanism(s) has been hampered in part by TPA, as well as other promoters, causing a plethora of morphological and biochemical responses in the skin (4,6). One of the prominent responses, inflammation and vascular permeability changes, (7) have provided the basis for inquiry into the role of mediators of these events in the promotion process. The particular mediators under investigation by this and other laboratories are arachidonic acid metabolites (8-11) and activated oxygen species (12).

Substantial evidence (reviewed in Ref. 12) that suggests that the generation of free radicals, such as superoxide anion and hydroxyl radical, may be involved in tumor promotion has been accumulating in the last few years. The most direct evidence comes from the work of Slaga et al. (13) in which free radical generating compounds, such as benzoyl peroxide, lauroyl peroxide and chlorperbenzoic acid were shown to be complete tumor promoters. Indirect evidence comes from studies demonstrating that various antioxidants are inhibitors of TPA tumor promotion; butylated hydroxyanisole (14), vitamin E and vitamin C (15), dimethylsulfoxide (14) and the superoxide dismutase (SOD) mimetic copper II diisopropylsalicylic $acid)_2$ (Cu DIPIS) (16) have been shown by Kensler and Trush (17) and Kozumbo et al. (18) to inhibit tumor promotion. Butylated hydroxyanisole and CuDIPS also have been reported to inhibit TPA-induced ornithine decarboxylase (ODC) activity. In addition, Solanki et al. (19) found that application of TPA to mouse skin resulted in a substantial decrease in the endogenous levels of SOD and catalase, the major detoxification enzymes for superoxide and H_2O_2 respectively. Numerous in vitro studies have been performed as well, particularly with polymorphonuclear leukocytes, on the generation of excited oxygen species by TPA (20-24).

These studies raised the question of whether TPA-induced oxidant generation in the skin is attributable to the inflammatory cell infiltration of the dermis or if TPA can induce an oxidant response in epidermal cells as well. Our laboratory has undertaken to address this question and the sequel issues of the identity, metabolic source and biological activity of the oxidants(s), and the essential nature of oxidant production to the tumor promotion process. This paper describes the approaches that we have taken to these problems and presents the results of investigations (11,25-27) and on-going studies.

METHODS

Animals. Female and male SENCAR mice were obtained from NCI (Frederick, MD). SSIN (inbred SENCAR) mice are bred at this facility. Male and female C57BL/6J mice were purchased from Jackson Laboratories (Bar Harbor, ME).

All strains of mice were bred at this facility to minimize any influences due to differences in diet and environment.

[1]Presented at the symposiumm on "Free Radicals, Antioxidants, Skin Cancer and Related Diseases" at the 78th Annual Meeting in New Orleans, LA, May 1987.

Abbreviations: CL, chemiluminescence; CuDIPS, copper II (3,4-diisopropylsalicylic $acid)_2$; HA-1004, N-(2-quanidinoethyl)-5-isoquinoline sulfonamide HCl; H-7; 1-(5-isoquinoline sulfonyl)-2-methyl piperazine dihydrochloride; ODC, ornithine decarboxylase; SOD, superoxide dismutase; TPA, 12-0-tetradecanoylphorbol-13-acetate.

Newborn mice from these parental stocks were used in these studies.

Chemiluminescence (CL) measurements. Epidermal cells were isolated from the newborn mice by trypsinization (24). The absence of leukocyte contamination was monitored as described (25). Chemiluminescence of 1×10^7 epidermal cells was measured as described (25) using an LKB Rackbeta Model 1218 ambient temperature liquid scintillation counter set in the CL mode. The assay was carried out in 7-ml glass minivials by adding the cells to 3 ml of Dulbecco's phosphate-buffered saline containing 5 mM glucose and 1 μg/ml luminol. After determining the background CL of each vial, solvent or test agent was added to start the reaction. The CL was monitored continuously for up to 30 min at 10-sec intervals. Either saline, ethanol or dimethylsulfoxide was used as the solvent for all the agents; due to the quenching activity of the latter two, the amount used was never more than 10 μl per 3-ml assay. Results are expressed as counts/unit time and the data expressed as either peak response or temporal curves.

ODC activity. Twenty-four-hr-old primary cultures of epidermal cells were treated for seven hr with either 1 μg/ml TPA and/or inhibitors at the given doses, 0.1 units/ml phospholipase C and/or inhibitors at the given doses or 10 μg/ml xanthine and 0.45 units/ml xanthine oxidase and/or inhibitors at the given doses. The medium then was discarded and a 12,000 × g centrifugation performed following homogenization of the scraped cells. The supernatant was used to determine enzyme activity measured as the release of $^{14}CO_2$ from [^{14}C]-L ornithine, as described (28) and the total protein measured by the Bio-rad Coomassie blue reaction.

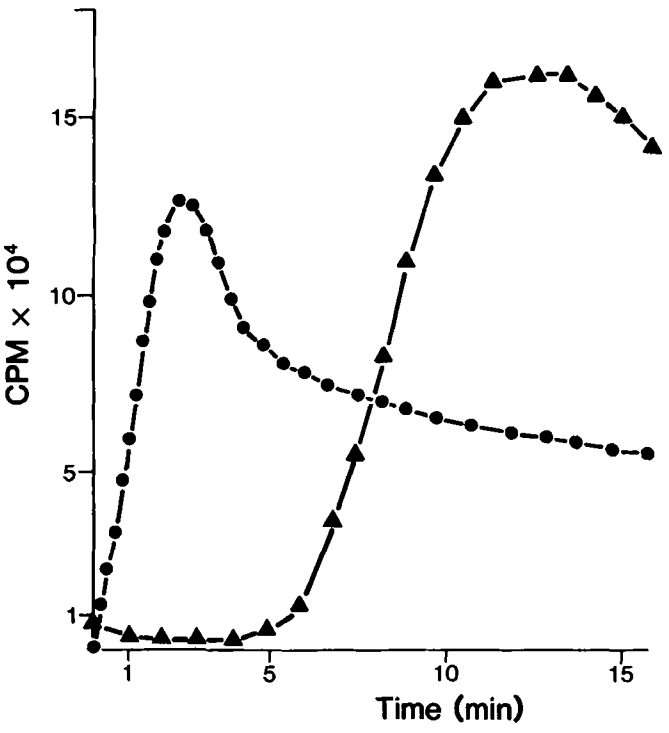

FIG. 1. Comparison of the chemiluminescence response to TPA of human PMN and mouse epidermal cells. Epidermal cell assay required the use of luminol, ●, 100 ng/TPA added to 10^7 PMN; ▲, 100 ng/ml TPA added to 10^7 epidermal cells. No response seen with solvent controls (acetone).

RESULTS AND DISCUSSION

TPA-induced oxidant generation in epidermal cells. One of the major obstacles in the detection of reactive oxygen species in nonleukocytes is the lack of sensitivity of available methods or assays for such detection. For this reason, these studies on epidermal cells used a modification (25) of a chemiluminescence (CL) assay described by Kensler et al. (21) for measuring reactive oxygen production in polymorphonuclear leukocytes. The chemiluminescence enhancer luminol is an absolute requirement for the assay for epidermal cells but not for polymorphonuclear leukocytes, suggesting that the level of oxygen radicals produced is considerably less (approximately 10,000-fold) than in leukocytes. The extremely low level of oxidant production by the epidermal cells probably accounts for the negligible cytochrome C reduction seen in that assay (25). The CL response of epidermal cells to TPA, shown in Figure 1, also is different kinetically from that seen with polymorphonuclear leukocytes. The epidermal cell response to TPA produces a distinct rise after five min, rapidly reaches a peak by 15 min and slowly tapers off over the next 30 min or more. The magnitude of the response correlates with the dose of TPA as well as the number of cells used in the assay (25). In addition, a series of phorbol esters with different promoting abilities produced corresponding CL responses (25).

Oxidant identification. The approach taken to identify the oxidant species responsible for the CL response to TPA was to include in the assay known scavengers with specificites for particular reactive species. For example, the contribution of the superoxide anion to CL may be direct or indirect (29), but an indication of its participation can be determined through the use of SOD, an enzyme specific for the dismutation of this radical (29). As shown in Figure 2, inclusion in the CL assay of either SOD, the SOD-mimetic CuDIPS or $CuSO_4$ nearly negated the TPA-induced CL response. On the other hand, neither catalase, which breaks down H_2O_2, nor mannitol or sodium benzoate, scavengers of hydroxy radicals, inhibited CL to any appreciable extent. The singlet oxygen scavengers histidine or diazobicyclooctane also had no suppressive effect. These data suggest that the species responsible for the majority of the observed CL response is superoxide anion. Because the CL assay measures extracellular or cell-membrane surface oxidants and because SOD presumably does not enter the cell, it is concluded that the superoxide is generated in the membrane.

Metabolic source. The insertion of molecular oxygen into arachidonic acid and subsequent rearrangements and metabolism produce reactive oxygen species and the hydroperoxides of the fatty acid. Because epidermal cells have been shown to produce prostaglandins and other arachidonate metabolites in response to TPA, it was anticipated that inhibitors of various parts of the arachidonate cascade would affect the magnitude of the TPA-induced oxidant response. As indicated in Table 1 and described in detail by Fischer and Adams (25), the effect of these inhibitors depends upon the particular pathway against which they are effective. Those inhibitors that are

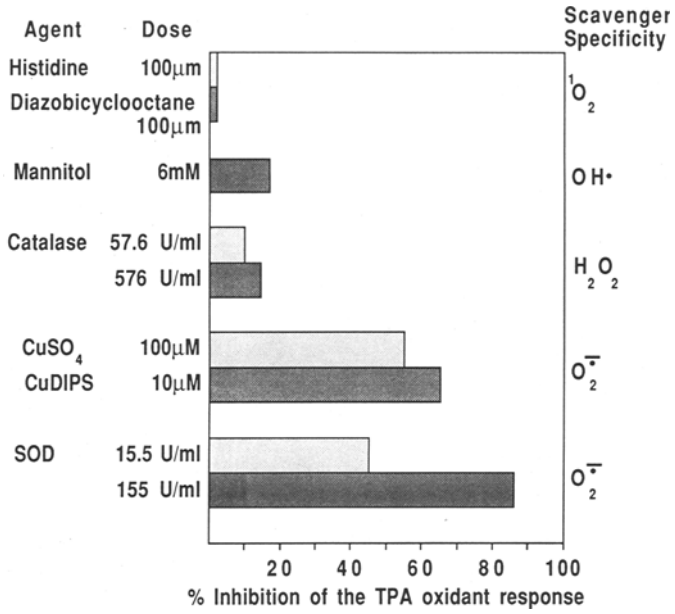

FIG. 2. Effect of free radical modifiers on the chemiluminescence of TPA-treated epidermal cells. 10^7 epidermal cells were used in each assay; the cpm at the peak of the response were used to determine the percentage of the TPA-alone response.

TABLE 1

Effect of Inhibitors of Arachidonic Acid Metabolism on TPA-stimulated Chemiluminescence in SENCAR Epidermal Cells

Agent	Dose (μM)	% TPA CL response	Effect on promotion

predominantly lipoxygenase inhibitors, such as benoxaprofen, or inhibit both cyclooxygenase and lipoxygenase, such as phenidone, are effective in diminishing the TPA-induced CL response. However, cyclooxygenase inhibitors, i.e. indomethacin, are not inhibitory. This data correlates well with both their effect on tumor promotion (9,30,33) and their effect on TPA-induced DNA synthesis in vivo and in vitro (34).

Because the above study suggested that a source of the TPA-stimulated oxidant was arachidonic acid metabolism via the lipoxygenase pathway, the question arose as to the mechanism of arachidonate release from phospholipids. Free arachidonate can result from either phospholipase A_2 activity or phospholipase C activity followed by diacylglycerol lipase action. This latter pathway is of particular interest because TPA both competes for diacylglycerol binding and activation of protein kinase C, as described by Nishisuka (35), and can increase diacylglycerol production in mouse epidermal cells through what is presumed to be phospholipase C activity.

To determine whether a particular phospholipase activity is involved in the TPA-induced CL response, different types of phospholipases were compared for their ability to induce CL in mouse epidermal cells. As shown in Figure 3, and described by Fischer et al. (26), a CL response can be induced only by phospholipase C and most notably when this enzyme is isolated from *Clostridia perfringens.* Kinetically, this response differs from TPA-induced CL in that it typically occurs several minutes earlier than the TPA response. Concomitant treatment with TPA and phospholipase C results in a partial, but not complete, additivity. The phospholipase C response is suppressed, and to nearly the same extent, by the same agents that inhibit the TPA response (26). Because neither exposure

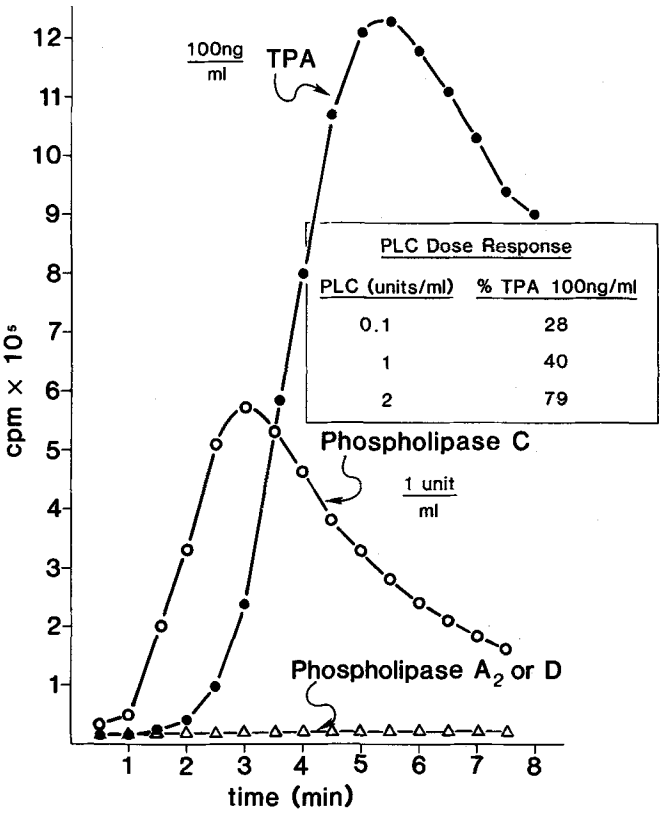

FIG. 3. Comparison of different phospholipases in their ability to induce chemiluminescence in mouse epidermal cells. Phospholipases at doses of 1–100 units/ml were included in the assay (in the absence of TPA) as possible chemiluminescence inducing agents.

to phospholipase A_2 (from any source) or exogenous arachidonic acid (with or without TPA) results in a CL response, an argument can be made against arachidonic acid metabolism as the source of the oxidant. Previous work (data not presented) has demonstrated that epidermal cells readily metabolize exogenous arachidonate and both phospholipase A_2 and C treatment results in the release of arachidonate from prelabeled epidermal cells. Because only phospholipase C produces a CL response, it appears that the oxidant is generated through the phospholipid-diacylglycerol-protein kinase C pathway, shown in Figure 4. It is possible that protein kinase C activates oxidative enzymes such as NADPH oxidase and that this or other oxidases are the source of the superoxide anion. This suggestion stems from the demonstration that in stimulated inflammatory cells such as neutrophils, NADPH oxidative metabolism is a source of reactive oxygens, particularly superoxide anion (22).

To pursue this hypothesis, studies with protein kinase C inhibitors were carried out using both the CL assay and the induction of ornithine decarboxylase (ODC), a known protein kinase C-mediated event (36). Two pairs of compounds were selected such that each was comprised of a protein kinase C inhibitor and its reportedly inactive analog, used to control for any nonspecific effects (37, 38). With the first pair, the inhibitor palmitoylcarnitine (100 μM) inhibited TPA-induced ODC by 50% and phospholipase C-induced ODC by 74% as indicated in Table 2. The negative analog acetylcarnitine was without activity. With the second pair of compounds, the inhibitor H-7 (100 μM) completely inhibited both TPA and phospholipase C-induced ODC; at the same dose, the negative analog HA-1004 had no effect. When these agents were included in the CL assay, similar results were seen: 100 μM palmitoylcarnitine or H-7 but not acetylcarnitine or HA-1004 almost completely suppressed the CL response to either TPA or phospholipase C. These results suggest that the oxidant response to both TPA and phospholipase C is mediated, at least in part, by protein kinase C.

TABLE 2

Effects of Protein Kinase C Inhibitors on TPA- and Phospholipase C-induced Chemiluminescence and Ornithine Decarboxylase Activity

Inducing agent	Inhibitor (dose, μM)	% Inhibition of CL	% Inhibition of ODC
TPA	H-7 (10)	44	N.D.
	H-7 (50)	N.D.	46
	H-7 (100)	95	100
	HA-1004 (100)	0	0
	PC (10)	30	N.D.
	PC (100)	100	60
	AC (100)	13	0
Phospholipase C	H-7 (10)	27	20
	H-7 (100)	100	100
	HA-1004 (100)	0	0
	PC (10)	65	N.D.
	PC (100)	100	98
	AC (100)	0	20

Mouse epidermal cells were isolated and used either directly in the chemiluminescence (CL) assay or cultured and used in the ornithine decarboxylase (ODC) assay.

H-7, 1-(5-isoquinoline sulfonyl)-2-methylpiperazine dihydrochloride; HA-1004, N-(2)guanidinoethyl)-5-isoquinoline sulfonamide HCl; PC, palmitoylcarnitine; AC, acetylcarnitine; N.D., not determined.

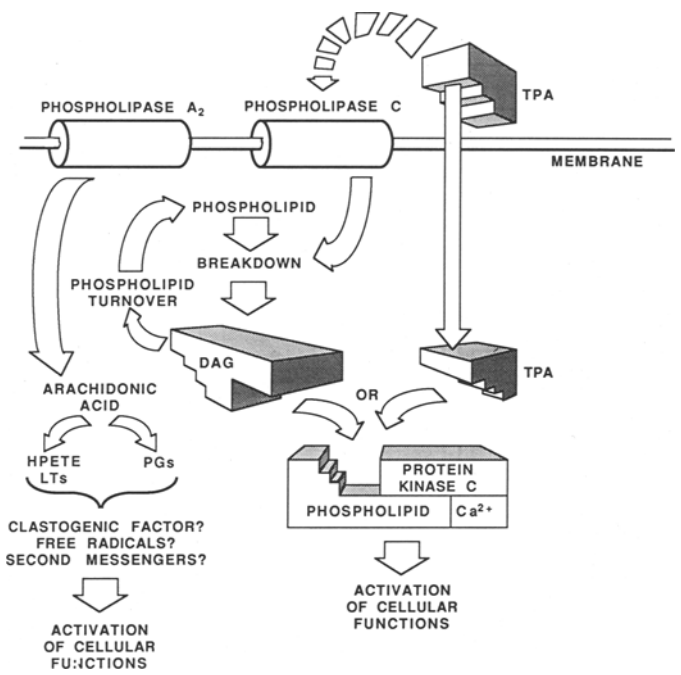

FIG. 4. Relationship of TPA and its protein kinase C receptor to phospholipid metabolism and arachidonate release.

Biological activity of superoxide anion. Two approaches were taken to determine whether superoxide anion production in response to TPA plays a role in subsequent cellular processes. If particular TPA-induced events are mediated by oxidants, specific scavengers or antioxidants should diminish these responses; in addition, exogenous addition of oxidants such as superoxide anion to epidermal cells should elicit some of these events. The event chosen for study was the induction of ODC, believed to be important in tumor promotion since inhibition of this induction is associated with inhibition of promotion (4,6). The work of Kensler et al. (16) in which the SOD mimetic CuDIPS was shown to inhibit TPA-induced ODC, suggested that superoxide is involved in ODC induction. To test this more directly, we treated cultured epidermal cells with xanthine/xanthine oxidase, a superoxide anion-generating system, in the presence or absence of SOD. As indicated in Figure 5, xanthine/xanthine oxidase induced ODC significantly, although only to about half of the level that can be achieved with TPA. Inclusion of SOD inhibited either xanthine/xanthine oxidase- or TPA-induced ODC by approximately 50%. These results suggest that oxidants generated in response to TPA treatment partially mediate the induction of ODC. The lack of a more complete inhibition may be due to the presence of further metabolites of superoxide, specifically H_2O_2. It is not known if a combination of catalase and SOD would produce a more substantial inhibition.

Oxidants and tumor promotion. To determine whether the magnitude of the TPA-induced oxidant response is

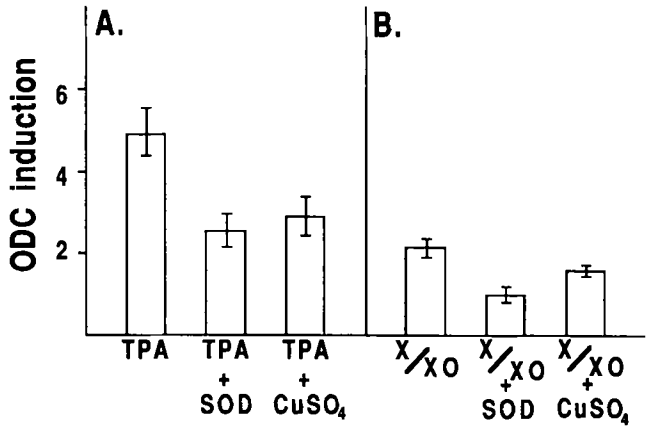

FIG. 5. Effects of superoxide anion dismutating agents on either TPA or xanthine/xanthine oxidase (x/xo) induced ornithine decarboxylase (ODC) induction. ODC activity measured as net nmol CO_2/mg protein/hr was determined seven hr after treatment with either 1 μg/ml TPA (panel A) or 60 μg/ml xanthine plus 0.45 units/ml xanthine oxidase (panel B) in the presence or absence of 155 units/ml SOD or 250 μM $CuSO_4$. Treatment groups of six to eight epidermal cultures were used to determine the mean ± s.e.m. Inhibition by SOD and $CuSO_4$ is significant ($p < .01$, Student's t-test).

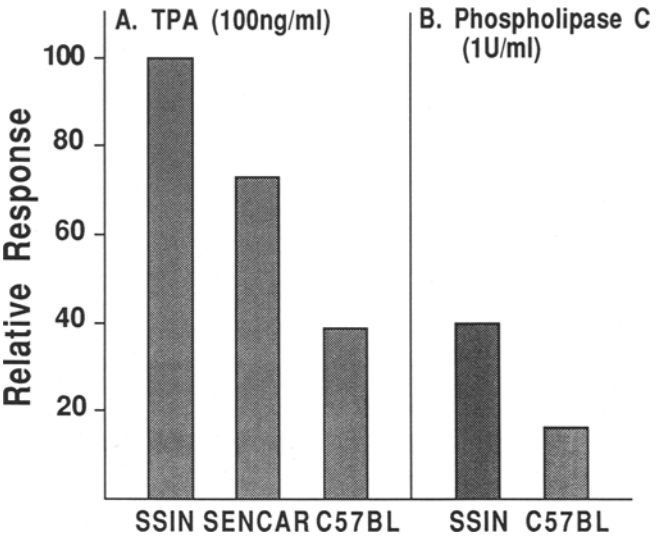

FIG. 6. Comparison of the chemiluminescence response in epidermal cells from SSIN, SENCAR and C57BL/6J mice. Epidermal cells (10^7) from each of the strains of mice were stimulated with either 100 ng/ml TPA (panel A) or 1 unit/ml phospholipase C in the chemiluminescence assay. The peak response, SSIN treated with TPA, was used to determine relative responses of the other groups. The experiments were repeated two to three times and the replicate variation within an experiment was <15%.

relevant to the tumor promotion process, several strains of mice with known sensitivities to TPA as a promoter were compared. Of particular interest is the difference in sensitivity to promotion between SENCAR and C57BL/6J mice: the latter essentially are refractory to TPA promotion, although sensitive to benzoyl peroxide promotion (39). Therefore, it was hypothesized that while the C57BL/6J are able to respond to radicals, TPA may not induce radical production to the same extent as in TPA-sensitive strains of mice. In addition to the above mice, the SSIN, an inbred strain of SENCAR that is more sensitive to TPA (40), also were compared. As shown in Figure 6 and described by Fischer et al. (27), the mice can be ranked SSIN > SENCAR > C57BL/6J on the basis of the magnitude of the CL response to TPA. Lewis and Adams (41,42) have shown that arachidonic acid metabolism and H_2O_2 release from macrophages of SENCAR is greater than from C57BL/6 mice and that the dermal inflammatory response to TPA is greater in SENCAR mice. These correlations between TPA promotion sensitivity and oxidant generation argues in favor of a role for reactive oxygens in the promotion process.

The above studies indicate that the tumor promoter TPA can cause the production of reactive oxygen species, principally superoxide, in mouse epidermal cells. The oxidant is believed to be superoxide and may at least partially mediate some of the effects of TPA. The generation of the same oxidant by phospholipase C suggests that the phospholipid turnover-protein kinase C signaling mechanism may be involved. This is further supported by the finding that specific protein kinase C inhibitors suppress both TPA and phospholipase C induced oxidant response and induced ornithine decarboxylase activity. A correlation was observed between strains of mice with respect to TPA-induced oxidant response and tumor promotion sensitivity. Collectively, these data suggest a strong link between the generation of an oxidant species and at least some aspects of tumor promotion. Clearly, more work is needed to determine the mechanisms involved (i.e., altered redox status in the cell, oxidation of molecules including DNA) and the extent to which oxidant generation is essential to tumor promotion.

METHODS

Biopsy Method for Human Adipose with Vitamin E and Lipid Measurements

Garry J. Handelman[a,*], William L. Epstein[b], Lawrence J. Machlin[c], Frederik J.G.M. van Kuijk[d] and Edward A. Dratz[d]

[a]Department of Biochemistry, Tufts University, Health Sciences Campus, Boston, MA 02111, [b]University of California, San Francisco, CA 94143, [c]Hoffman-La Roche, Inc., Nutley, NJ 07110, and [d]Department of Chemistry, Montana State University, Bozeman, MT 59717

An adaptation of the needle biopsy procedure of Beynen and Katan for human adipose tissue, which yields 2–10 mg adipose samples, is described and evaluated. Micromethods are presented for the analysis of α-tocopherol, cholesterol and fatty acids in each adipose specimen. The needle biopsy procedure, which uses a Vacutainer to create suction, is compared with a punch biopsy method. The needle biopsy is rapid (6 samples/hr), simple and unobjectionable to the subjects, and provides samples with reproducible ratios of cholesterol and α-tocopherol. Unlike the punch biopsy, the needle biopsy reliably obtains specimens with a lipid composition typical of adipocytes. The needle biopsy method is adaptable to nutritional studies of tocopherol and fatty acid metabolism in adipose, and to studies of hazardous compounds stored in adipose. The linoleic acid content of adipose from residents of the West Coast was found to be considerably higher than values reported earlier. The adipose fatty acid data indicate an increase in human adipose linoleate when compared with earlier reports and suggest a trend toward increasing linoleic acid in the American diet.
Lipids 23, 598–604 (1988).

Evaluation of long-term nutritional status using adipose tissue biopsy has definite advantages for several nutrients over measurement of plasma levels. The adipose levels may provide a useful indication of a long-term average intake for many fat-soluble nutrients. Plasma levels of both unsaturated fatty acids (1) and α-tocopherol (2,3) change very rapidly in humans following change in dietary intake, reaching a new steady-state level in a few days to a week. However, adipose fatty acids in humans take several years to reach new steady-state following dietary change (1,4). Adipose α-tocopherol levels have been shown to respond slowly to dietary change in experimental animals (5,6). Other compounds with a slow turnover in adipose tissue include certain pesticides (7) and halogenated hydrocarbons (8), and adipose levels may indicate effective exposure to many fat-soluble toxic compounds.

There has been considerable interest in measuring adipose tocopherols in human subjects. McMasters et al. (9,10) carried out an analysis of a large number of subjects and examined the effects of dietary α-tocopherol supplements. However, their vitamin E-analysis method had low sensitivity and necessitated taking ca. 1 g surgical fat samples, which is not practical for many studies. Bieri and Poukka Evarts (11) measured tocopherols in autopsy fat, and this work also employed large adipose samples.

More recently, Kayden et al. (12,13) carried out investigations of tocopherol metabolism in human adipose and established that human adipose tocopherol levels are depressed in abetalipoproteinemia and other malabsorptive states. These workers also carried out small-scale trials of the effects of dietary tocopherol supplements on adipose α-tocopherol levels. Kayden et al. utilized the original needle biopsy procedure of Hirsch et al. (1) and used sensitive HPLC techniques for tocopherol measurements.

Needle-biopsy procedures are preferred to more invasive surgical or punch procedures because of speed, lack of discomfort and absence of any suture or scar afterward. Newer microchemical techniques using HPLC or GC/MS have the sensitivity needed to carry out biochemical measurements on the small samples provided by needle biopsy. To facilitate long-term studies of α-tocopherol turnover in human adipose, a simplification of the recently published needle biopsy procedure of Beynen and Katan (14) was developed and tested. An earlier version of this method also was described by Christakis (15). Micromethods to measure tocopherols and the lipid denominators cholesterol and fatty acids also were developed to utilize the milligram adipose samples obtained.

EXPERIMENTAL

Adipose biopsy. Several methods of obtaining human adipose fat were explored. The first approach was the needle biopsy method as originally described by Hirsch et al. (1). This method, which uses saline injection and a large hypodermic syringe to create suction, was slow and fatiguing to use and frequently yielded only 0.5 mg of adipose or less, which is insufficient for the biochemical analyses described in this report. While it may have been possible to improve the performance of the Hirsch method with practice, a method that could be more easily mastered was desired.

A conventional skin biopsy punch (16), using a small 2-mm punch, also was evaluated for adipose sampling because it is easy to obtain specimens of 2 mg or more. Specimens initially were determined to be "fat" by visual observation. About 20 specimens were collected with this method and analyzed. However, it was found that about one-half of the specimens contained virtually no triglyceride. A 22.5-power dissecting microscope then was used to examine specimens in more detail. Many specimens were observed through the microscope and found to consist of a large cluster of fat cells, with pieces of skin or connective tissue adhering to some specimens. The nonadipose tissue was removed by dissection, and the remaining cluster of cells (with a bunch-of-grapes appearance) was thought to be pure fat. This method was easy and rapid but not quite satisfactory. The dissected punch biopsies usually provided adequate triglyceride, but the specimens frequently contained cholesterol far in excess of the normal range for adipocytes (1–2 μg cholesterol/mg triglyceride) (17), which indicated skin contamination.

Abbreviations: BHT, butylated-hydroxy-toluene; TMS, tetramethylsilane; GC, gas chromatography; HPLC, high performance liquid chromatography.

Finally, the needle biopsy method of Beynen and Katan (14) was used. This method uses a Vacutainer to create suction. With a Vacutainer adapter, we found that the special needle specified by Beynen and Katan was not required, and any standard hypodermic needle could be used. In the work described here, a 1.5-inch, 16-gauge needle, a Vacutainer adapter (American Scientific Products #B3035-10, McGaw Park, IL), a Vacutainer holder, and a 20-cc "red-top" (no anticoagulant) Vacutainer are employed to obtain the adipose biopsies. The sampling area is infiltrated with 1–2 ml of Xylocaine (1% containing 1:100,000 epinephrine), using a 27-gauge needle. The 16-gauge biopsy needle is inserted at a 45-degree angle into the anaesthetized subcutaneous fat pad, just below the dermal interdigitation, and the Vacutainer is engaged. The needle is moved forward and backward 1–2 cm to disrupt fatty tissue. This motion is continued as the entire unit is slowly withdrawn from the skin. If blood oozes from the puncture site, hemostasis is accomplished by a pressure dressing. Otherwise it is simply covered with a Band-aid for 24–48 hr. No visible scar develops, and the test site is recognizable only by a very slight alteration in normal pigmentation at two wk. Two months after the test, the site is no longer visible.

Beynen and Katan did not use anaesthetic in their needle biopsy procedure (14), whereas our subjects found that local anaesthetics were highly desirable.

Usually the fat is lodged into the upper part of the Vacutainer adapter and is collected by back-flushing the adapter with saline into a dish (Fig. 1). By this means, 2–10 mg of fat typically is collected. Repeat samples usually can be collected through the same skin puncture.

When upper-arm and waist adipose tissue are sampled with this procedure, a more shallow needle angle (20–30 degrees) is employed so that the superficial area of subcutaneous fat is sampled. These sites are somewhat more difficult to biopsy but give satisfactory and reproducible results.

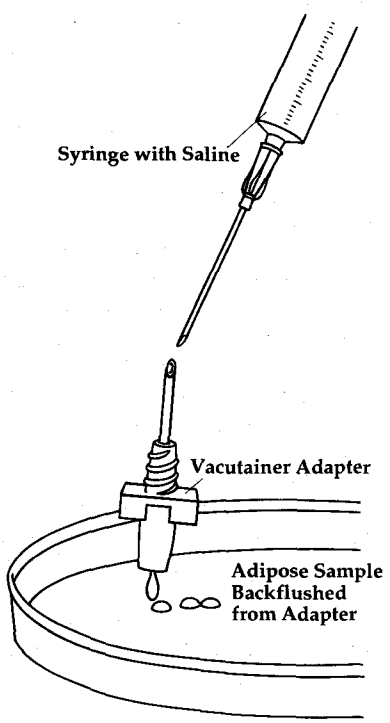

FIG. 1. Technique of recovering adipose biopsy samples from the hub of the Vacutainer adapter, where it usually is lodged.

In the data given in this study, replicate samples (within-day and between-day) always were taken from the same site on each subject.

Human subjects. Healthy adult males, ages 21–60, were recruited for this study from the San Francisco Bay area. An informed consent procedure was followed. The protocol was approved by the human subjects committee, University of California School of Medicine, San Francisco, CA. The subjects were instructed to adhere to their normal diets for the period of the study. Seven of the nine subjects in this study were administered a food-frequency questionnaire to determine dietary intake of lipids as considered in the discussion. The questionnaire used recently was validated by Willett et al. (18).

Reagents for biochemical analysis. Cholesterol (>99%), pentadecanoic acid (15:0, >99%) and fatty acid methyl ester standards are obtained from Alltech/Applied Science (Deerfield, IL). Sylon BFT, 5β-cholestan-3β-ol and BCl_3/methanol (15%, w/v) are from Supelco (Bellefonte, PA). Pyridine (silylation grade) is from Pierce (Rockford, IL). Pyrogallol is from Matheson-Coleman-Bell (Cincinnati, OH). α-Tocopherol is from Sigma Chemical Co. (St. Louis, MO). Tocol was a gift from Hoffman-La Roche, Inc. (Nutley, NJ). These materials were used without further purification. H_2O is distilled in glass, deionized and charcoal-filtered. Hexanes are redistilled, reagent-grade. Ethanol is 200 proof, redistilled, USP-grade (Publicker, Linfield, PA). Methanol for liquid chromatography is high performance liquid chromatography (HPLC) grade (Fisher, Fairlawn, NJ). All solutions in organic solvents contain 50 μg/ml butylated-hydroxy-toluene (BHT).

The stock solutions of cholesterol, 5β-cholestan-3β-ol, tocol (in hexanes) and 15:0 fatty acid (in ethanol) are prepared by weighing of the material. The stock solution of α-tocopherol (in hexanes) is prepared spectrophotometrically using its molar extinction of 3170 at 292 nm (19). These stock solutions are stored tightly capped at −20 C and are stable for at least one yr.

The 15:0 internal standard solution in EtOH is dispensed with a 100 μl positive displacement SMI Micropettor (American Scientific Products, McGaw Park, IL). The standard solutions in hexane (chilled in an ice bath) are dispensed with a Pasteur pipette coupled through a section of Tygon tubing to a Gilson Pipetteman automatic pipettor. The pipettor is calibrated with a balance to deliver exactly 0.66 g of chilled hexanes (density, 20 C, hexanes = 0.66). Each pipetting method was found to have precision of better than 1% for these standard solutions.

Biochemical analysis: procedure. After collection, the sample is stored at −80 C in 1 ml of ethanol with 0.1% pyrogallol, in an 8-ml borosilicate glass vial closed with a Teflon-lined cap (#2390-H32, Arthur H. Thomas, Philadelphia, PA) and analyzed within six months of collection. These storage conditions were chosen because it was determined that α-tocopherol in plasma is stable under such conditions for at least six months.

It is difficult to directly evaluate human adipose biopsy storage conditions because duplicate samples are not completely uniform. However, the α-tocopherol/γ-tocopherol

ratio is highly reproducible even over time if subjects do not make large dietary changes (Handelman, Epstein and Dratz, unpublished data). We have observed that α-tocopherol is more sensitive to degradation than γ-tocopherol, and treatments that decompose tocopherols tend to change the α/γ ratio (unpublished results). It was found that the α-tocopherol/γ-tocopherol ratio is stable in adipose biopsy samples for at least eight months, which suggests that both tocopherols are fully stable under these conditions.

For analysis, 100 μl of 10% pyrogallol in EtOH, 100 μl of 15:0 fatty acid (10 mg/ml EtOH) and 100 μl of 30% aqueous KOH are added to the sample vial. The vial with the Teflon-lined cap is vortexed and placed in a heating block at 70 C to saponify the glycerides. At five min, the vial is taped to prevent the cap vibrating off, inverted and vortexed to bring into solution any bits of fat that might have stuck to the wall of the vial during specimen collection. Specimens then are heated at 70 C for an additional 25 min.

Vials are removed from the heating block, allowed to cool, 1.2 ml of H_2O added, followed by thorough mixing. Then 1 ml of hexane, containing both tocol (1 μg/ml) and 5β-cholestan-3β-ol (6 μg/ml) as internal standards, is added, followed by 3 ml more hexane. The vial is vortexed for 30 sec, centrifuged at 800 g for 30 sec, and the supernatant layer transferred to a clean vial. The supernatant then is split into two unequal fractions: about 1/4 for vitamin E analysis, the rest for cholesterol analysis.

For tocopherol analysis, the first supernatant aliquot is evaporated under nitrogen at 40 C, 60 μl MeOH added, and 20 μl is analyzed by reverse-phase HPLC with fluorescence detection on a Perkin-Elmer 650-LC fluorescence detector with excitation at 295 nm and emission at 340 nm (2). One hundred percent MeOH is used as mobile phase, and an Alltech C18 10μ column is employed.

For cholesterol analysis, the second supernatant aliquot is evaporated, 50 μl of a 1/1 mixture of Sylon-BFT/pyridine is added, and the sample heated at 80 C for 30 min to form the silyl derivatives. Rubber gloves are advised for steps at which contamination of samples with flakes of skin might be a problem, because skin contains relatively large amounts of cholesterol and other sterols (20), and the procedure is optimized to analyze ca. 1 μg of cholesterol or less. The sample is cooled, and the reagent evaporated under a stream of nitrogen. The sample is redissolved in 40 μl of pure 100% Sylon-BFT, and a 2 μl volume is analyzed by gas chromatography (GC) at 250 C with a flame ionization detector on a packed SE-30 column (2 m length × 2 mm i.d.) with nitrogen carrier gas at 20 cc/min flow rate. The nitrogen carrier gas used for the GC analysis must be passed through a gas-drier before the GC, otherwise residual moisture in the carrier gas will tend to hydrolyze the TMS derivatives at the high temperature on the column.

Most laboratories prepare tetramethylsilane (TMS) or other derivatives of cholesterol for GC analysis because of problems with degradation of underivatized cholesterol on the GC column (21,22). However, recent reports have employed GC analysis of underivatized cholesterol (23,24). Cholesterol is poorly soluble in Sylon-BFT alone, and a 1/1 mixture of Sylon-BFT/pyridine is used in this work for preparation of silyl derivatives. Pyridine, however, gives a very long solvent front on the gas chromatograph. Therefore, the volatile derivatization mixture is evaporated under a stream of nitrogen, and the TMS derivatives are completely dissolved in pure Sylon-BFT. The Sylon-BFT gives a very short solvent front under the gas chromatographic conditions employed.

For analysis of fatty acids, the lower layer from the saponification is acidified with HCl (4 drops of conc. HCl is sufficient to cause a strong acid reaction in the lower layer). The fatty acids then are extracted with 4 ml of hexane. A portion of the hexane extract is derivatized with BCl_3/MeOH, and the methyl esters are analyzed by GC on a SP-2340 column, with temperature programming, as described by Stone et al. (25). The percentage of each fatty acid in the specimen is obtained. Each peak is identified from its retention time by comparison with the fatty acid methyl ester standards. To determine total triglyceride in the specimen, the total fatty acid mass is multiplied by 1.05 to adjust for glycerol lost during saponification.

For quantitation of fatty acid methyl esters, a digital integrator and peak area measurements are employed. For cholesterol and tocopherol analyses, relative peak heights are utilized. The fatty acid analysis is calibrated by the 1.0 mg of 15:0 added at the start of the procedure. For calibration of tocopherol and cholesterol values, a stock solution of α-tocopherol, 700 ng/ml and cholesterol, 6.0 μg/ml is prepared in hexanes and stored at −20 C. One ml of this is dispensed at step 2, evaporated, 100 μl of 10% pyrogallol in EtOH and 1 ml of EtOH added, and the vial is carried through the analysis with the rest of the samples. This calibration is carried out in duplicate. A reagent blank also is carried through the procedure.

Because α-tocopherol elutes shortly after cholesterol on packed GC columns, the observed peak generally contains contributions from both components. However, because of partial separation, the α-tocopherol contribution to the peak height is quite small. With the GC system employed here, 0.1 μg of α-tocopherol analyzed with 1.0 μg of cholesterol increased the cholesterol peak height by only 2%, whereas errors in cholesterol estimation due to tocopherol overlap can be quite large if peak areas are used.

Tocol can be added before the saponification step, because it is not attacked by saponification if 1% pyrogallol is present. However, the 5β-cholestan-3β-ol must be added after the sample is cooled and diluted with water; otherwise, this compound is modified during the saponification to produce a split peak on the GC. Both standards were routinely added after saponification is complete. The determination of the total fatty acid content and the ratio of the 18:2/total fatty acids are not affected by saponification as compared with a direct quantitative transesterification with BCl_3/methanol.

Because the adipose is inherently nonhomogeneous, the precision of these methods was determined using aliquots of a pool of frozen human plasma and was found to be generally equal to or better than 2% for α-tocopherol and cholesterol. For the total fatty acid measurements and the percentage of major fatty acids in the specimen, 4% or better precision typically was achieved.

RESULTS

α-Tocopherol, cholesterol, triglycerides and linoleic acid in adipose tissue. Table 1 gives cholesterol/triglyceride,

TABLE 1

Biochemical Parameters of Adipose (from Buttock) from Different Subjects

Subject	Wt/wt ratios			% 18:2 in TG
	Chol/TG(× 10^3)	α-Toc/chol	α-Toc/TG(× 10^3)	
A	1.71	.242	.413	22.0
B	1.59	.139	.221	15.9
C	1.57	.197	.278	17.6
D	1.90	.314	.598	21.0
E	1.98	.341	.677	17.1
F	1.69	.148	.250	17.3

Chol, cholesterol; TG, triglyceride; α-Toc, α-tocopherol.

α-tocopherol/cholesterol, α-tocopherol/triglyceride and linoleic acid (as percentage total fatty acids) for adipose samples taken with needle biopsy from the buttock of nine adult subjects. Most specimens had a ratio of cholesterol/triglyceride in the range of 1.5–2.0 μg/mg and were concluded to be true fat. Previous reported values (mean ± SD) for various groups include 1.36 ± 0.64 μg cholesterol/mg wet wt. adipose (26), 2.08 ± 0.05 μg cholesterol/mg dry wt. adipose (27), 1.47 ± 0.23 μg cholesterol/mg adipose lipid (17), and 1.86 ± 0.53 μg cholesterol/mg triglyceride (12). Occasional subjects (subject G) were outside this range but were found to have a highly reproducible value (Fig. 2). The mean ratio of α-tocopherol/triglyceride was 402 ± 154 μg/g triglyceride, which is comparable with values reported by Kayden et al. (12). The mean wt/wt ratio of α-tocopherol to cholesterol was 0.213 ± 0.0076.

Linoleic acid. As predicted from the results of Hirsch et al. (1) and others (4,28), the percentage of linoleic acid in specimens from each subject showed little or no change between clinic visits over the time frame of this study (several weeks to months). The 18:2 content is expressed in Table 1 as percentage of the six major fatty acids in human adipose, 14:0, 16:0, 16:1, 18:0, 18:1 and 18:2. For most specimens, these are greater than 95% of the total. The mean linoleic acid from subjects in this study was 18.2% of total fatty acids.

Cholesterol/triglyceride ratios. The punch biopsy and needle biopsy samples described above were evaluated for their cholesterol and triglyceride content, and it was found that only the needle biopsy procedure reliably provided specimens with lipid characteristics appropriate for adipose tissue. Cholesterol/triglyceride ratios in samples collected by punch biopsy are compared with samples collected by the modified needle biopsy in Figure 2. Although all the punch biopsy samples appeared to consist of pure adipocytes on microscopic examination, Figure 2 shows that 20% of the samples collected by punch biopsy had a very aberrant ratio of cholesterol/triglyceride, indicating the presence of non-adipose tissue. Even the punch biopsy samples with the lower, more normal values of cholesterol/triglyceride ratios showed rather large scatter in this ratio.

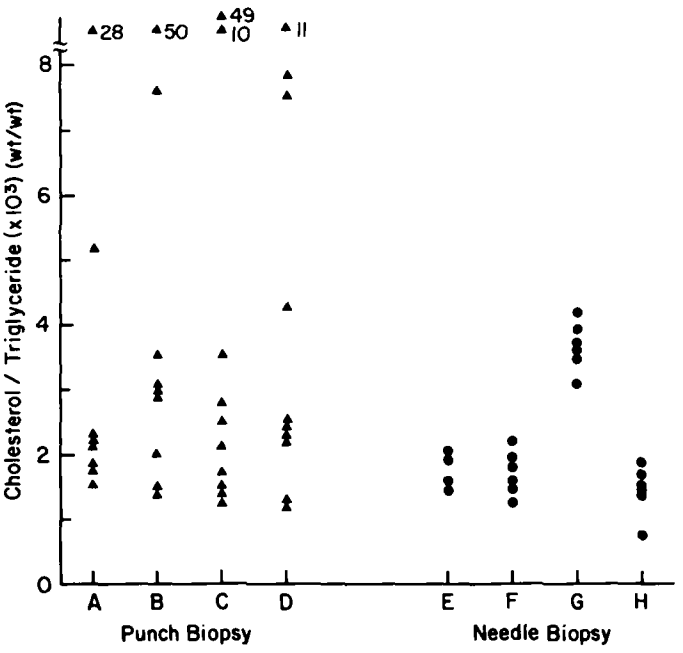

FIG. 2. Cholesterol/triglyceride ratios for human adipose samples collected from the buttock by punch biopsy (▲) and by needle biopsy (●), with multiple sampling from the same subjects. The different subjects are denoted by capital letter codes.

Extreme values of the cholesterol/triglyceride ratio are not observed with the modified needle biopsy method, and the values for each subject cluster more tightly compared with the punch method, as shown in Figure 2. Subject H had one low and unexplained value of cholesterol/triglyceride. All the values for subject G are reproducibly in the range of three to four parts cholesterol/1000 parts triglyceride, and we believe this high value is the normal state for this subject.

Comparison of reproducibility of the punch biopsy and needle biopsy methods. The key parameters evaluated in this investigation are the ratios of α-tocopherol to the two different denominators available, cholesterol and triglyceride. A reliable method would obtain reproducible results for the ratio α-tocopherol/denominator when sampling an individual subject at the same site on the same day. The reproducibility of the punch and needle biopsy methods for each denominator were evaluated from an analysis of a substantial number of within-day replicate samples collected from a number of subjects (data not shown). For 14 sets of replicates collected with the punch biopsy, the mean within-day difference for the α-tocopherol/cholesterol ratio was 44.6% and for the α-tocopherol/triglyceride ratio, the mean difference was 26.0%. For 10 sets of replicates collected with the needle biopsy, the mean difference in α-tocopherol/cholesterol ratio was 8.8%, which was the most reproducible parameter found in replicate sampling of the same subject, and the mean difference in α-tocopherol/triglyceride ratio was 15.8%.

Variation in α-tocopherol/cholesterol and α-tocopherol/triglyceride ratio on replicate sampling at different sites. The development of the needle biopsy method provided reproducible values of the ratio of tocopherol/denominator

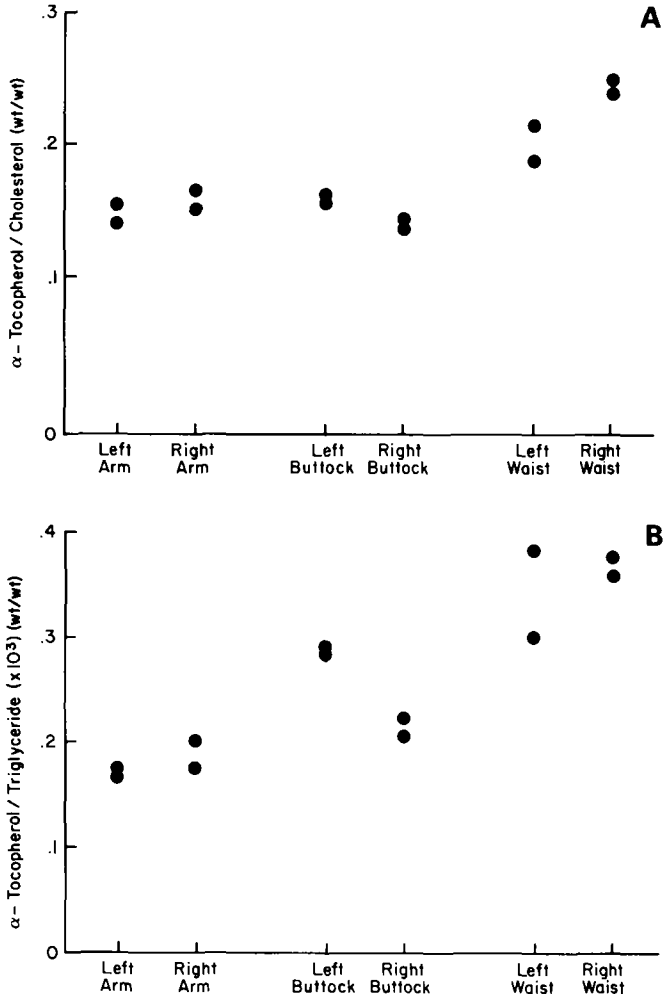

FIG. 3. (A) Human adipose α-tocopherol/cholesterol ratios determined by duplicate sampling with needle biopsy of one subject on same day at different anatomical sites. (B) Human adipose α-tocopherol/triglyceride ratios determined by duplicate sampling with needle biopsy of same subject as in A on the same day at different anatomical sites.

for within-day replicate sampling of individual subjects, using the cholesterol denominator. Once this was established, we evaluated the anatomical variation of the α-tocopherol/lipid ratios at different sites on the same subject. One subject was sampled at six sites, in duplicate on right and left upper arm, right and left buttock, and right and left waist, using the needle biopsy. Figure 3A shows the α-tocopherol/cholesterol ratios for this subject at each site, and Figure 3B shows the α-tocopherol/triglyceride ratios. The reproducibility of duplicate samples shows that a reliable biopsy procedure has been established. In this subject, the waist fat has substantially more α-tocopherol (per weight cholesterol or per weight triglyceride) than the other sites.

DISCUSSION

The methods described were developed with the primary goal of following the uptake and turnover of α-tocopherol in human adipose tissue using deuterated tocopherol in future experiments. This information is required to evaluate the use of adipose tocopherol for assessment of the average long-term vitamin E status in humans. Tissue was taken from subjects as often as twice a month, with two (or more) samples taken per subject per clinic visit. The Hirsch procedure (1) was found to be time-consuming and fatiguing to use for the physician. It led to an effective limit of five to eight samples per half-day session, and furthermore, it often failed to yield adequate amounts of tissue for the work described here. The conventional biopsy punch, which takes a 2-mm core, was unacceptable to the subjects when used frequently because it leaves small scars. The punch biopsy method (16) was investigated because it is a simple and facile procedure, and many dermatologists have experience with it; however, the unreliability of using punch biopsies for biochemical adipose sampling should be emphasized. With the punch method, specimens that have a lipid profile not at all characteristic of adipose often are obtained. Fat collected from very near the dermis may be contaminated with skin components, which are known to be high in cholesterol (20), and this caused a large variation in the α-tocopherol/cholesterol ratio.

The method pioneered by Beynen and Katan (14), which combines needle biopsy and a Vacutainer to create suction, proved very satisfactory with simple modifications. The modified needle biopsy method has entailed no objections from the subjects, especially because it leaves no scar. Specimens collected with the needle biopsy consistently have been biochemically normal for adipose as classically described from adipose obtained by surgical means. The needle biopsy method provides quite ample amounts of tissue (2–10 mg, in most cases) for analysis by the microchemical assays described in Experimental. This method is now a simple and routine procedure in our ongoing investigations of human adipose tissue.

There are several modifications to the method of Kayden et al. (12) for biochemical analysis of α-tocopherol and other components in microbiopsies. This method employed tocol as internal standard, and no internal standard was used before (12). This method uses internal standard GC for cholesterol, and fatty acid analysis carried out simultaneously on the same small specimens. We used pyrogallol to protect α-tocopherol during saponification, whereas ascorbic acid (12) was not reliable for this procedure in our hands. However, it has been noted that some lots of pyrogallol may not yield reliable results (29), so each batch of pyrogallol should be checked to ensure that it protects vitamin E during saponification.

The cholesterol/triglyceride ratio on each specimen is useful because it validates that a true adipose sample has been obtained. We hypothesize that both cholesterol and triglyceride levels in adipose are relatively stable over time in subjects who are not gaining or losing weight and that each may be useful as a denominator to express tissue levels of other adipose constituents. This hypothesis is being explored in more studies. The ratio α-tocopherol/cholesterol appears most promising in long-term studies of α-tocopherol turnover in adipose. Our laboratories are carrying out studies of long-term turnover of α-tocopherol and other tocopherols in adipose and are evaluating the effects of dietary supplementation on these parameters.

We used a food-frequency questionnaire (18) to evaluate the lipid nutritional status of most of our subjects. The

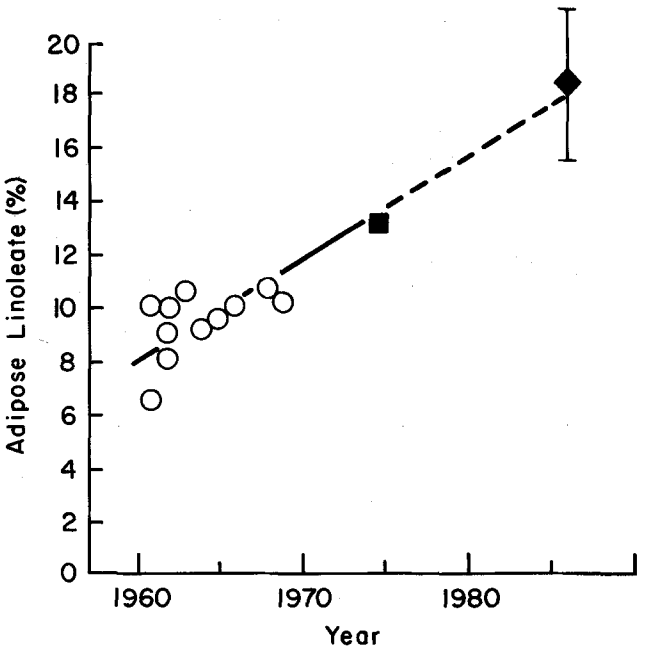

FIG. 4. Human adipose linoleate as percentage of major fatty acids reported from 1961 to 1975, compared with the average value determined in this study. (○), Data summarized by Insull and Bartsch (30); (■), data from Witting and Lee (31); (◆), this study.

food frequency questionnaires were scored by W. C. Willett's laboratory at Harvard University. The diet analysis yielded several parameters that are suitable for identifying individuals who modify their lipid nutrition away from the norm: percentage calories as fat, percentage total dietary fat as linoleic acid, and cholesterol/Kcal diet. Health-conscious individuals would be expected to have a lower cholesterol/Kcal, lower percentage calories as fat and higher percentage total fat as 18:2. This study group had essentially the same percentage calories as fat and percentage total dietary fat as linoleic acid as the Willett normal population. This study group had slightly higher cholesterol/Kcal diet than the Willett population. Therefore, it may be concluded that the subjects in this study showed no significant tendency to reduce fat intake or to increase percentage linoleic acid compared with a control population.

The findings in this study with percentage 18:2 in adipose, taken with earlier data, suggest that important demographic dietary trends may be occurring in American populations. Insull and Bartsch (30) summarized adipose fatty acid data from 11 studies of Americans carried out between 1960 and 1967. The average 18:2 was 9.5% of the major fatty acids. Witting and Lee (31) in 1974 found that 18:2 was 13% of major fatty acids in adipose. In the present study group, 18:2 was 18.2% of major fatty acids. Witting and Lee pointed out a striking increase in adipose 18:2 from the early 1960s to 1974. The same trend has been noted in the U.S. for the years 1958–1975 purely from literature data (32). The data from this study fits smoothly on with this trend, as shown in Figure 4, and extends the data for 10 years. This finding suggests a substantial, continuing increase in 18:2 in the American diet. This trend is consistent with a reported increase in vegetable fat consumption in the U.S. from 25% of total dietary fat in 1947–1949 to 42% of total dietary fat in 1980 (33). Such an increase may be significant, because 18:2 has been suggested as a risk factor for increased peroxidative damage to tissues (34). This suggests that a larger group of Americans should be sampled periodically, so that long-term trends in adipose fatty acids can be followed in a larger population.

Adipose collected from the waist appeared different in composition from adipose collected from arm and buttock (Fig. 4), although this point was not investigated in detail. Klein et al. (35), using the marker methyl-tetradecanoic acid to compare fatty acid turnover rates at these three sites, found that turnover was more rapid at the waist. Comparison of the ratios of α-tocopherol to cholesterol and to triglyceride at anatomical sites other than the buttock may warrant further investigation.

The biopsy method as described may have broader applications. The method might be suitable for evaluating the change in the ratio of cholesterol/triglyceride in adipose over time, which is of interest in studying the effects of certain weight-loss protocols (17). It may be suitable for the study of the metabolism and turnover of other fat-soluble vitamins, such as retinol and carotenoids, and for the study of fat-soluble drugs, exogenous fat-soluble compounds, such as environmental pollutants (7,8), and certain hormones, such as pregnancy and lactation hormones. As discussed by Erickson (36), the protocol described may be applicable to the analysis of PCBs in adipose tissue. The adipose is a useful indicator storage site for toxic lipid peroxides (34,37), which might be correlated with disease states (38) using new, highly sensitive and specific assay procedures for lipid peroxides (39,40).

Use of a Fluorescent Radiolabeled Triacylglycerol as a Substrate for Lipoprotein Lipase and Hepatic Triglyceride Lipase

Nicole Dousset*, Anne Negre, Robert Salvayre, Pierre Rogalle, Quoc Quan Dang and Louis Douste-Blazy
INSERM Unite 101, Biochimie des Lipides, Hôpital Purpan, and Laboratoire de Biochimie Medicale, Faculte de Medecine Purpan, Toulouse, France

A fluorescent radiolabeled triacylglycerol has been synthesized by using a fluorescent fatty acid (pyrene decanoic acid) and a radiolabeled oleic acid. This analog of the natural substrate, 1(3)pyrene decanoic-2,3 (1,2)-dioleoyl-*sn*-glycerol, has been tested as substrate for determining lipoprotein lipase and hepatic triacylglycerol lipase activities in post-heparin plasma. Optimal conditions for the determination of the two post-heparin plasma lipases were similar to those using radiolabeled triolein. Using this substrate, both post-heparin lipases exhibited their characteristic properties (pH optimum and effect of inhibitors) and attacked external ester bonds (1 or 3) containing pyrene decanoic and oleic acids at a similar rate. *Lipids 23,* 605–608 (1988).

Two kinds of lipase, lipoprotein lipase (EC 3.1.1.34) and hepatic triacylglycerol lipase (EC 3.1.1.3), are released into plasma when heparin is intravenously administered. Both enzymes play important roles in the metabolism of lipoproteins: LPL in the degradation of triglycerides of triglyceride-rich lipoproteins, such as chylomicrons and VLDL, and H-TGL in the hydrolysis of triacylglycerols of intermediate-sized particles (1). These lipolytic enzymes exhibited the same substrate specificity (against long-chain triacylglycerols) and also a similar stereospecificity on external (1 or 3) acyl ester bonds of triacylglycerol (2–5). Thus, as emphasized by Baginsky (6) the direct determination of each activity needs the use of either effectors or antibodies or separation on a heparin-sepharose column (but this latter method is not useful for routine determinations) (7–10).

Post-heparin lipolytic activity commonly is measured with radioisotopically labeled substrate (11). Colorimetric techniques involving the determination of free fatty acids have been reported (12). Another assay described the use of a dansyl fluorescent lipid to follow the reaction of lipoprotein lipase (13). Finally, a recent study used 1,2-dipalmitoyl-3-β-2-furylacryloyltriacylglycerol as a chromophoric substrate (14).

In this paper, we report a new fluorometric method for determining lipoprotein lipase and hepatic triacylglycerol lipase in post-heparin plasma. Fluorometric assays of lipases such as pancreatic lipase (15) and lysosomal acid lipase (16) have been used successfully. We have evaluated this sensitive and specific method for determining post-heparin plasma activities and compared the results with those of radioactive method.

Abbreviations: LPL, lipoprotein lipase; H-TGL, hepatic triacylglycerol lipase; $P_{10}OOG$, 1(3)pyrene decanoyl-2,3(1,2)-dioleoyl-*sn*-glycerol; VLDL, very low density lipoproteins.

MATERIALS AND METHODS

Chemicals. Tri[9,10-^{3}H]oleoylglycerol was obtained from Amersham (Les Ulis, France), [9,10-^{3}H]oleic acid was from NEN (Dreieich, FRG), 10-(1-pyrene)-decanoic acid, triolein, lysophosphatidylcholine and albumin free fatty acids were obtained from Sigma Chemical Co. (St. Louis, MO). Heparin (5,000 U/ml) was purchased from Roche (Paris, France).

We synthesized the fluorescent radiolabeled substrate 1(3)-pyrenedecanoyl-2,3(1,2)-di[9,10-^{3}H]oleoylglycerol ($P_{10}OOG$) using a three-step method including a process of esterification of (R)-(+)-2,2-dimethyl 1,3-dioxolane-4-methanol by 25 μmol of pyrene decanoic acid (17) followed by the hydrolysis of the ketal function (18) and the esterification of the obtained monoglyceride by 50 μmol of [9,10-^{3}H]oleic acid (17). The product was purified by thin layer chromatography using a solvent system of light petroleum/diethyl ether (80:20, v/v); the purity and the structure of the compound were tested by gas chromatography (after hydrolysis and methylation) and by proton nuclear magnetic resonance spectroscopy.

Plasma samples. Post-heparin plasma was prepared from rabbit blood drawn 10 min after IV administration of 175 IU heparin per kg body weight. Plasma was kept frozen (−20 C) until use.

Enzyme assays. We have used the specific assays of lipoprotein lipase and hepatic lipase activities described by Nilsson-Ehle and Ekman (19). These authors employed a combination of the differential catalytic properties of the lipases to selectively measure one in the presence of the other. Under these optimal conditions, we compared our fluorescent radiolabeled triacyglycerol with the radiolabeled triolein (used as reference method).

Assay for hepatic triacylglycerol lipase (H-TGL). Labeled triacylglycerol (35 nmol) and unlabeled triolein (7.92 μmol) were mixed with 0.6 μmol lysophosphatidylcholine. After removal of solvents under a stream of nitrogen, 1.8 ml of 0.2 M Tris-HCl buffer (pH 9.0) and 1.2 ml 1% (w/v) bovine serum albumin in the same buffer were added. The mixture was sonicated with a Branson sonifier in 30-sec intervals for a total of three min and used as a substrate. The standard H-TGL assay contained 0.1 ml buffered substrate and the enzyme solution (post-heparin plasma adjusted to 1 M NaCl by adding an equal volume of 2 M NaCl) in a final volume of 0.2 ml. After incubation (30 min at 37 C), the liberated fatty acids were selectively extracted using the method of Belfrage and Vaughan (20). After mixing and centrifuging, we measured the liberated fatty acid extracted in the upper aqueous phase radiometrically (19) and fluorometrically with a Jobin-Yvon JY 3C spectro fluorometer (excitation 342 nm, emission 398 nm) calibrated by using a standard of P_{10} fatty acid prepared in the assay conditions.

Assay for lipoprotein lipase (LPL). The substrate was prepared by sonicating a mixture of 35 nmol labeled triacylglycerol, 7.92 μmol unlabeled triolein, 0.6 μmol

lysophosphatidylcholine and 2.4 ml 0.2 M Tris-HCl (pH 8.0) buffer. After sonication, 0.3 ml plasma as source of apo CII but devoid of lipase activity and 0.3 ml 4% (w/v) bovine serum albumin in 0.2 M Tris-HCl (pH 8.0) buffer were added and the substrate shaken on a vortex mixer for 15 sec. The standard assay contained 0.1 ml substrate, 0.075 M NaCl and enzyme in a final volume of 0.2 ml. After incubating for 30 min at 37 C, the liberated fatty acids were extracted and determined as indicated for H-TGL assay.

Test of inhibitors. To discriminate between LPL and H-TGL activities in the whole post-heparin plasma, we have utilized the classical inhibitors of LPL (1 M NaCl) and of H-TGL (50 mM SDS). These inhibitors were preincubated with the post-heparin plasma in the optimal conditions defined by Nilsson-Ehle and Ekman (19) and Baginsky (6) (experimental details are in Table 1).

Enzymatic activities by the radioactive method were calculated as described by Nilsson-Ehle and Schotz (11). Lipase activities by the fluorometric method were measured using a standard of P_{10} fatty acid. One mU of enzyme activity was defined as the amount of the enzyme in 1 ml of enzyme preparation, which released 1 nmol fatty acid per min at 37 C.

RESULTS

$P_{10}OOG$, the synthetic fluorescent analog of natural triacylglycerol, is hydrolyzed by LPL and H-TGL. Therefore, it can be used as a substrate for determining the lipase activities in post-heparin plasma.

Enzyme activity was directly proportional to the amount of post-heparin plasma up to 10 µl for both enzymes (Fig. 1). In the standard assay, we generally used 10 µl of plasma as enzyme source.

Kinetic curves of substrate hydrolysis vs time were linear for at least 60 min at 37 C (Fig. 2).

These enzymes showed similar optimum pH and activity with either the fluorescent $P_{10}OOG$ or the radiolabeled triolein as substrate (Fig. 3). The pH profile of the hydrolysis of both substrates showed one peak of lipolytic activity with an optimum at pH 9.0 for H-TGL (Fig. 3A). LPL assay had a pH optimum of about 8.0 using either substrate (Fig. 3B).

The sodium dodecyl sulfate and sodium chloride were controlled to affect the activity of H-TGL and LPL differently. Lipase activity of post-heparin plasma measured

TABLE 1

Effect of NaCl and Sodium Dodecyl Sulfate on Lipase Activities in Post-Heparin Plasma

Treatment of plasma	Enzymatic activity (% of control)	
	H-TGL assay	LPL assay
Control	100	100
NaCl, 10 min at 26 C[a]	100	25
NaCl, 10 min at 37 C[a]	110	15
SDS, 60 min at 26 C[b]	6.9	61
SDS, 60 min at 26 C and 1 M NaCl	—	10

[a]Duplicate samples of post-heparin plasma (100 µl) were diluted to 1 ml with 0.15 M NaCl. To 100 µl of diluted plasma 100 µl 2 M NaCl was added according to Nilsson-Ehle and Ekman (19).

[b]Post-heparin plasma was preincubated with 50 mM sodium dodecyl sulfate in 0.2 M Tris-HCl buffer, pH 8.2 during 60 min at 26 C according to Baginsky (6).

Experiments were done in duplicate.

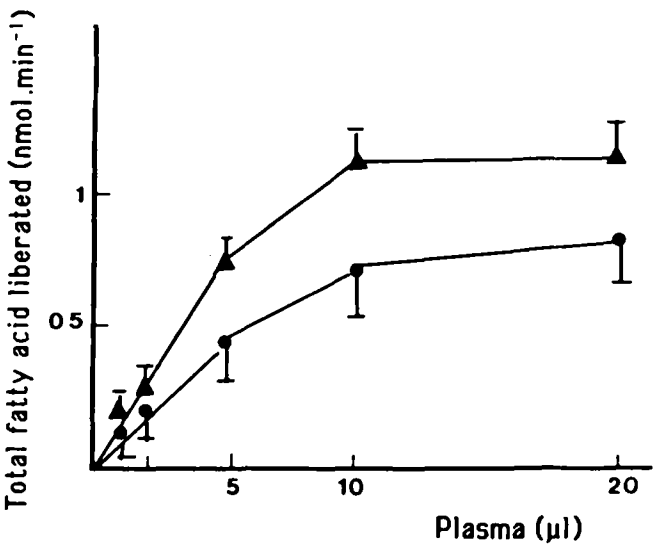

FIG. 1. Hydrolysis of $P_{10}OOG$ by hepatic triacylglycerol lipase (▲) and lipoprotein lipase (●) when increasing amounts of enzyme source (post-heparin plasma) in the standard assay conditions described in Material and Methods. Average and range (bars) of five experiments.

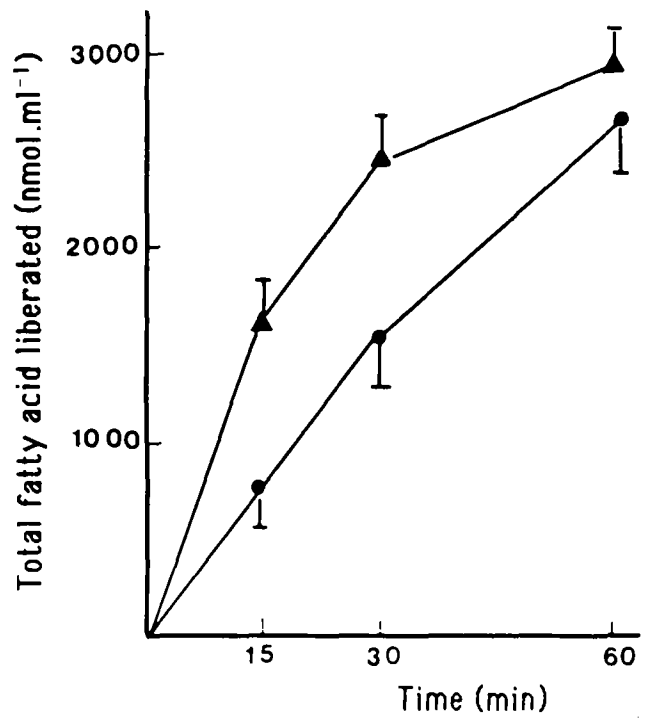

FIG. 2. Hydrolysis of $P_{10}OOG$ by hepatic triacylglycerol lipase (▲) and lipoprotein lipase (●) as a function of time. Enzyme activities were assayed under standard assay conditions reported in Material and Methods. Average and range (bars) of five experiments.

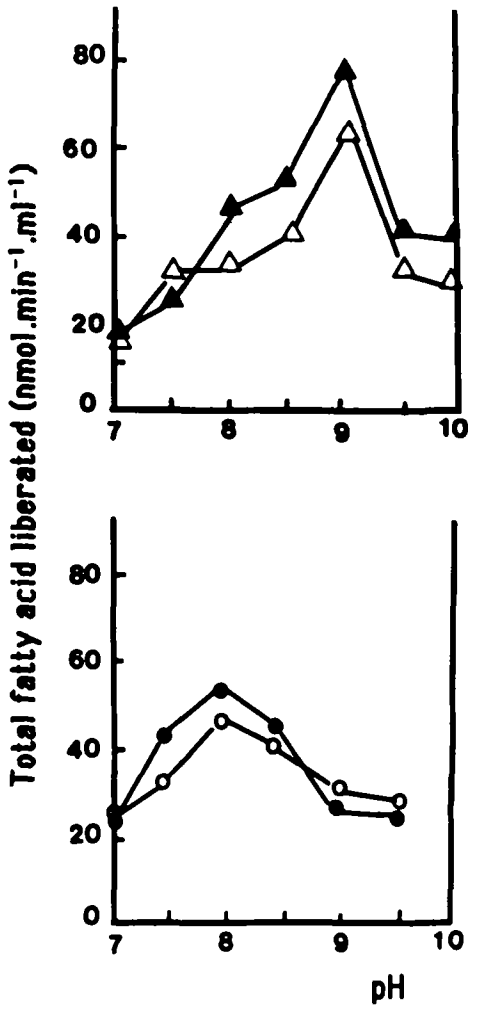

FIG. 3. Effect of pH on hepatic triacylglycerol lipase (upper) and lipoprotein lipase (lower) activities. Enzyme assays were performed as indicated for the standard assays but using various 0.5 M Tris-HCl buffers (pH varying between 7 and 10). Using fluorescent $P_{10}OOG$ (filled symbols), and radiolabeled triolein (open symbols), the enzyme activities were expressed as total fatty acid liberated (nmol/min/ml).

with LPL assay showed an almost complete inhibition by addition of 1 M NaCl (final concentration) to the assay (Table 1), a well-known characteristic of LPL activity. On the contrary, the lipase activity measured with H-TGL assay was unaffected by NaCl (Table 1). On the other hand, preincubation of post-heparin plasma with 50 mM sodium dodecyl sulfate during 60 min at 26 C suppressed the H-TGL activity (Table 1). However, we also have noted that inhibition of LPL activity can occur. As a control that the activity remaining after SDS treatment is really LPL, we have tested the inhibition of this enzyme activity by 1 M NaCl. As expected, this activity was almost completely inhibited, therefore demonstrating that it was only due to LPL.

We have compared in the synthetic substrate the liberation rate of pyrene decanoic and oleic acids as a function of time (Table 2). The results showed that the time course of substrate hydrolysis by LPL and H-TGL is the same regardless of the fluorescent or the radioactive moiety considered.

TABLE 2

Hydrolysis of Synthetic Substrate: Comparison of the Liberation Rate of Pyrene Decanoic and Oleic Acids

	Fluorescence		Radioactivity	
Time	LPL	H-TGL	LPL	H-TGL
15 min	702	1701	605	1876
30 min	1549	2535	1459	2285
60 min	2640	2956	2562	3026

The data are expressed as nmol total fatty acid released by 1 ml plasma. Experiments were performed in triplicate.

DISCUSSION

This paper demonstrates that the two post-heparin lipases that split the ester linkages of natural substrates (11) also hydrolyze the synthetic fluorescent analog of the natural substrate ($P_{10}OOG$). Using this substrate, pH profiles were quite similar to those observed using trioleoylglycerol as substrate (Fig. 3); these results were quite consistent with the pH optima reported in the literature (19). Lipoprotein lipase rapidly hydrolyzes synthetic substrate prepared as described by Nilsson-Ehle and Ekman (19). Specific measurements of this lipase activity can be performed at pH 8.0, at 0.15 M NaCl and in the presence of plasma, adding apolipoprotein CII as activator (21). Hepatic triacylglycerol lipase activity can be measured selectively using the synthetic substrate in 0.2 M Tris-HCl (pH 9.0) containing 1 M NaCl.

H-TGL differs in a number of aspects from the lipoprotein lipase. In fact, sodium chloride and sodium dodecyl sulfate affect the activity of H-TGL and LPL differently. H-TGL is not inhibited by NaCl and not stimulated by apolipoprotein CII. These data are in good agreement with those reported in literature (19,22,23) with natural substrate. H-TGL activity is suppressed by preincubation with SDS, in agreement with the results of Baginsky and Brown (8). We also noted that LPL activity is decreased by preincubation of plasma with SDS. Elsewhere, it is noteworthy that SDS also partially inhibits the activity measured by LPL assay (39%). This is quite consistent with the data reported by Baginsky (6), who suggests that this apparent inhibition could be due to the inactivation of H-TGL, which interferes in LPL assay. However, in our assay conditions, a partial inhibition of LPL by SDS cannot be absolutely excluded.

These results concerning the liberation rate of pyrene decanoic and oleic acids as a function of time demonstrate that ester linkage containing P_{10}-fatty acid is hydrolyzed similarly to that containing the radioactive oleic acid. These results suggest that only external (i.e. 1 or 3) ester bonds are attacked by both lipases in agreement with previous reports (2-5). It also is noteworthy that the presence of pyrene nucleus does not hinder the interaction of the synthetic $P_{10}OOG$ with the enzymatic sites of both lipases, as demonstrated by the similar liberation rates of P_{10} and oleic acid from the doubly labeled substrate (Table 2).

Finally, we emphasize that the assay utilizing the fluorescent radiolabeled $P_{10}OOG$ exhibits a good sensitivity

(limit of detection was around 1 nmol/min/ml in the used conditions), much better than that of the assays utilizing chromophoric substrates (24). Thus, the fluorescent substrates can be used diluted many fold (300-fold in our assay) with the natural substrate, thereby considerably reducing the amount of the substrate analogue used in the reaction mixture.

In conclusion, the use of synthetic fluorescent triacylglycerol in the presence of natural triacylglycerol provides an easy, convenient assay system for estimating hepatic lipase and lipoprotein lipase activities.

[Received July 20, 1987; Revision accepted February 8, 1988]

A Simplified Approach to the Analysis of Subclasses of Phospholipids: Application to Human Platelets

Indira Vishnubhatla[a], Morris Kates[a,*] and George A. Adams[b]

[a]Department of Biochemistry, University of Ottawa, Ottawa, Canada K1N 9B4, and [b]Ottawa Center, Canadian Red Cross Society, Blood Transfusion Service, 85 Plymouth St., Ottawa, Canada K1S 3E2

A procedure for the determination of the proportions of diacyl, alkenylacyl and alkylacyl subclasses of glycerophospholipids was developed. The procedure involves: (1) acid methanolysis of the phospholipid followed by Bligh/Dyer extraction of fatty acid methyl esters (FAME) derived from acyl chain types, dimethylacetals (DMA) derived from alkenyl ether chain types, and lysoalkyl phosphatidic acids (lysoalkyl-PA) derived from alkyl ether chain types; and (2) subsequent acetolysis to convert the lysoalkyl-PA to monoalkyl glycerol diacetates (MAGD). GLC analysis and quantitation (using internal standard, 21:0 FAME) of FAME, DMA and MAGD allowed calculation of the proportions of the three molecular subclasses. The methanolysis/acetolysis procedure gave an overall mean phospholipid recovery of 95 ± 3%. Analysis of the major phospholipids in four separate preparations of fresh resting human platelets by this procedure showed the following range of molecular subclasses: phosphatidylcholine (PC), 86–92 mol % diacyl, 6–10 mol % alkylacyl and 2–3 mol % alkenylacyl; and phosphatidylethanoline (PE), 39–60 mol % diacyl, 5–8 mol % alkylacyl and 34–55 mol % alkenylacyl. The results of these subclass analyses were in general agreement with those reported in the literature.
***Lipids 23,* 609–614 (1988).**

Platelet phospholipids consist of complex mixtures of molecular species of diacyl, alk-1-enyl, and alkylacyl subclasses; the relative proportions of these subclasses vary with the phospholipid component and the animal species involved and differ from other blood cell types (1–4).

Conventional methods of analysis of phospholipid subclasses employ cleavage of alk-1-enyl groups by exposure to HCl fumes (2–4) or treatment with mercuric chloride solution (5,6), followed by thin layer chromatography (TLC) separation of the aldehyde and lysophospholipid products and the unreacted diacyl and alkylacyl phospholipids; quantitation of the lyso-PL by P-analysis gives the alk-1-enyl class content. Phospholipase C hydrolysis of the unreacted diacyl and alkylacyl phospholipids, followed by acetylation of the diradylglycerol products, separation by TLC, and quantitation by gas liquid chromatography (GLC) of the derived FAME gives the diacyl and alkylacyl subclass contents (2–4,7,8). In a variation of this approach (9), the diacyl subclass is first selectively hydrolyzed by a special phospholipase A_1, and the alk-1-enylacyl class is hydrolyzed by exposure to HCl fumes; quantitation of the TLC separated lyso-PL from phospholipase A_1 treatment, the lyso-PL from HCl treatment and the unreacted alkylacyl-PL gives the contents of diacyl, alk-1-enylacyl and alkylacyl subclasses, respectively.

A different approach has been developed (10) in which the total lipid is first reduced with $LiAlH_4$ to yield a mixture of alkylglycerols, alk-1-enyl glycerols and alcohols, which after acetylation with radiolabeled acetic anhydride is resolved into the three lipid molecular classes by TLC and quantitated by radioscanning of the TLC plate. The alkyl and alkenyl ether chain composition is determined by GLC after treatment of the acetyl derivatives with hydrochloric acid in diethyl ether to liberate the aldehyde groups. In a variation (11,12) of the $LiAlH_4$ reduction procedure, the alkenylglycerols are converted to alkyl dioxanes, and the alkylglycerols to isopropylidene derivatives, which then are quantitated by GLC using 1,1-dimethoxyheptadecane and 1-O-heptadecylglycerol, respectively as internal standards carried through the procedure.

Molecular species composition within each of the three subclasses of an individual phospholipid (PL) has been determined by phospholipase C hydrolysis, separation of the diradylglycerols (as such or as acetates) according to their degree of unsaturation by argentation TLC, and identification and quantitation of the molecular species by GLC analysis (with internal standard) of the derived fatty acid methyl esters (FAME), dimethylacetals (DMA) and alkylglycerols (4,7,8,13). More sophisticated procedures for analysis of phospholipid subclasses and their molecular species involve modification of the phospholipid by phospholipase C hydrolysis, followed by chemical derivatization (acetate or benzoate, *tert*-butyldimethylsilyl [*t*-BDMS] or trimethylsilyl [TMS] ether) of the diradylglycerol products and resolution and quantitation of the derivatized molecular species by GLC (14), gas chromatography-mass spectrometry (GC-MS) (15–19) or high pressure liquid chromatography (HPLC) (2,15,16, 20,21,23) with or without prior TLC (22) or HPLC (23) separation of the molecular subclasses.

In a study on changes in platelet lipid composition during storage, the need arose for a relatively simple procedure for analysis of molecular classes that could be used for multisample analysis within a reasonable time period. Therefore, we have developed a chemical method based on two well-known lipid degradative reactions that avoids TLC separation of degradation products. The method will provide the molecular class composition of a phospholipid as well as the overall acyl, aldehyde and alkyl chain composition, but not the radyl chain composition of each class.

In this procedure (Scheme 1), the phospholipid sample is first subjected to acid methanolysis and then to acetolysis (7). Methanolysis produces FAME and DMA from the acid sensitive acyl ester and vinyl ether groups, respectively, and lysoalkyl phosphatidic acids (lysoalkyl-PA)

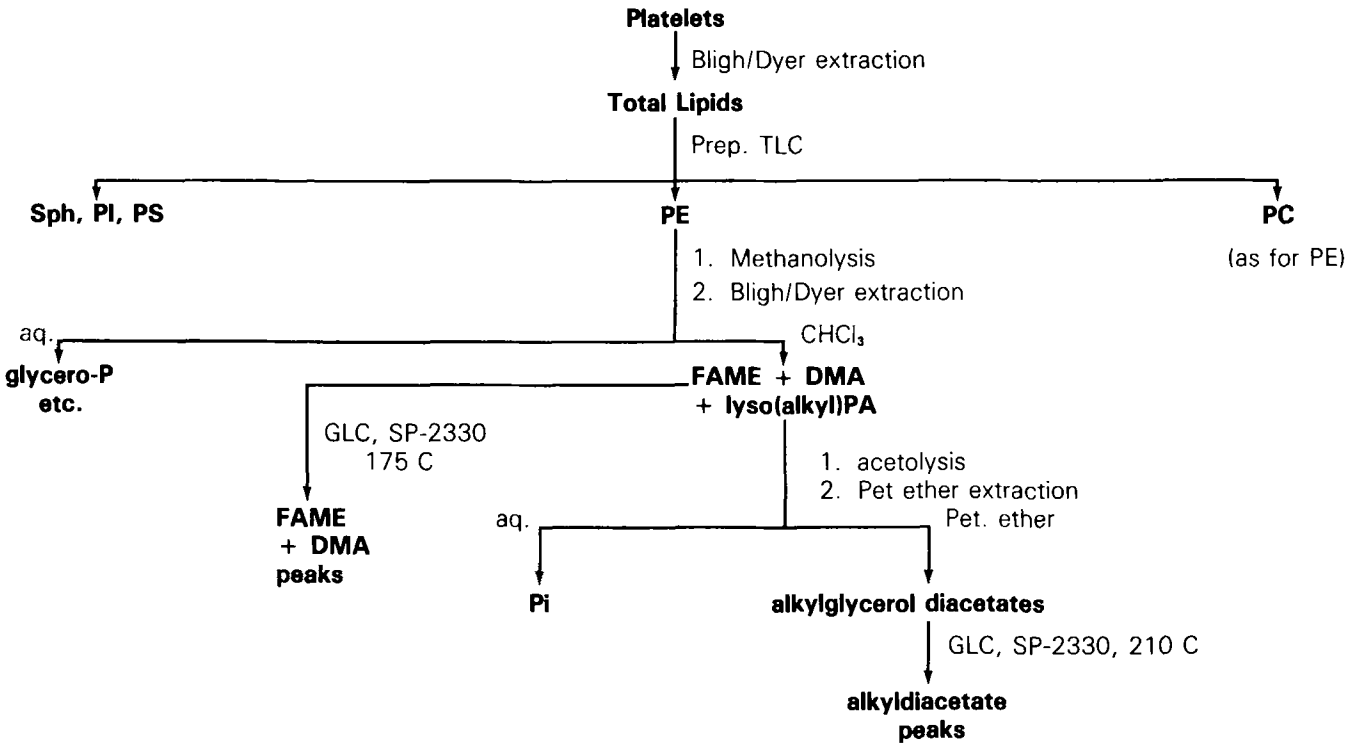

SCHEME 1. Procedure for analysis of molecular subclasses of phospholipids.

from the alkylacyl phospholipids. These products are extracted into chloroform in a Bligh-Dyer partition (24,25), and the FAME and DMA are quantitated by GLC. The lysoalkyl-PA are then derivatized by acetolysis (7) to monoalkyl glycerol diacetates (MAGD) and quantitated by GLC.

In this paper, we demonstrate the feasibility of this methanolysis/acetolysis procedure with authentic standard phospholipids, and its application to the analysis of phospholipid molecular classes and chain type composition in resting platelets from humans.

MATERIALS AND METHODS

All solvents were glass-distilled before use. All other chemicals were of reagent grade unless otherwise specified. Methanolic-HCl (0.6 N) was prepared by diluting 5 ml of concentrated HCl to 100 ml with methanol.

FAME standards were from NuChek (Elysian, MN). DMA were prepared from the sodium bisulfite-adducts of palmitaldehyde and stearaldehyde (K+K Lab Inc., Plainview, NY) by heating at 75 C in a closed screw-capped tube in 4.5 ml of 0.6 N methanolic-HCl for one to two hr followed by addition of 0.6 ml of 8 N aqueous NaOH, further heating at 75 C for one hr, and extraction of the DMA with petroleum ether (25). Purity of the DMA was checked by TLC (Rf, 0.36 in petroleum ether/ethyl ether, 9:1, v/v). GLC analysis showed that the TLC pure palmitaldehyde DMA sample contained ca. 90% 16:0 DMA with 1-2% each of 14:0, 14:1, 16:1, 18:0 and 18:1 DMA; the stearaldehyde DMA sample contained ca. 89% 18:0 DMA with 1-2% each of 14:0, 16:0, 16:1, 18:1 and 20:0 DMA.

MAGD standards were prepared by acetylation (7) of chimyl (16:0), batyl (18:0) and selachyl (18:1) alcohols (Western Chemical Industries Ltd., Vancouver, BC). The MAGD standards were checked for purity and characterized by TLC, GLC and mass spectrometry.

PAF (1-O-hexadecyl-2-acetyl-3-glycerophosphocholine) and plasmalogen phosphatidylethanolamine (PE) (bovine brain) were purchased from Sigma Chemical Co. (St. Louis, MO). Plasmalogen PE was partially hydrogenated with PtO_2 as catalyst (25) to form a mixture of alkylacyl, alkenylacyl and diacyl subclasses. Plasmalogen content was estimated by vinyl ether (iodometric) assay (25).

Preparative and analytical TLC plates were obtained from Whatman Chemical Separation Inc. (Clifton, NJ). The glass columns for GLC were packed with 10% SP 2330 on 100/120 Chromosorb W AW (Supelco, Bellefonte, PA).

Preparation of platelets. Human venous blood was collected from donors (Canadian Red Cross, Ottawa Center, Blood Transfusion Service) into citrate-phosphate-dextrose-adenine (CPDA-1) anticoagulant. The fresh platelet-rich plasma (PRP) was prepared by centrifugation of whole blood at 150 × g at 22 C for 15 min. The platelets were pelleted by a second spin at 3000 × g for 10 min, washed three times according to the procedure of Mustard et al. (26) and suspended in Tyrodes buffer (5 ml). The platelet concentration (6-12 × 10^9 cells/ml) was determined by electronic particle counting (Coulter Inc., Hialeah, FL). Differential staining and counting revealed the presence of one lymphocyte per 1600 platelets (0.06%); no neutrophils were detected in the final platelet preparation. One preparation of pooled platelets (preparation 1) and three platelet preparations from separate individuals (preps. 2-4), collected at different times, were analyzed.

Extraction and fractionation of platelet lipids (Scheme 1). Cellular lipids were extracted from fresh platelets by the method of Bligh and Dyer (24) as modified by Kates

(25). Total lipid content of platelets was found to be in range 30–60 μg per 10^8 cells, and total lipid P was 45 ± 9 nmol per 10^8 cells. The choline and ethanolamine glycerophospholipids were separated by preparative TLC using the solvent system chloroform/methanol/ammonia/water (70:30:4:1) (27), with double development. After detection of standard markers with I_2 vapor or Rhodamine 6G, the phosphatidylcholine (PC) and PE bands were eluted from the plates with chloroform/methanol (1:1), partitioned into chloroform, and the chloroform phases were taken to dryness under a stream of nitrogen (25). The residual phospholipids were dissolved in chloroform, to a known volume, and aliquots were taken for P-analysis, TLC to check purity, and subclass analysis. Phospholipid phosphorus was determined by a modification (25) of the method of Bartlett (28).

Determination of diacyl, alkenylacyl and alkylacyl subclass composition of phospholipids (Scheme 1). (1) The methanolysis procedure (25) was as follows: to an aliquot of the chloroform solution containing 1–2 mg of total lipid or 1.3–2.5 μmol of PE or PC fraction in a 20 ml screw-capped (Teflon-lined) test tube was added a known quantity (0.5–1.0 μmol) of internal standard, methyl heneicosanoate (21:0 FAME). The solvent was evaporated under a stream of nitrogen; 4.5 ml of 0.6 N methanolic-HCl was added, and the tube was stoppered and heated for one to two hr at 75 C in a temperature-controlled block heater. After addition of 4.0 ml of water and 4.5 ml of chloroform and centrifugation, the lower chloroform phase was removed, and the upper phase was washed three times with chloroform. The pooled chloroform phases were diluted with benzene and concentrated under a stream of nitrogen. The residual lipids (FAME, DMA, lysoalkyl-phosphatic acid [PA]) were made to a known volume in chloroform, and appropriate aliquots were taken for GLC analysis. The FAME and DMA were analyzed by GLC (in presence of lysoalkyl-PA, which are retained on the column) on a glass column (2 m × 4 mm) of 10% SP2330 at 165 C, 175 C or 195 C depending on the batch of SP2330 used (injector and detector temperatures were 45 C and 50 C, respectively, above the column temperature), and quantitated using the previously added 21:0 FAME as internal standard (25). GLC peak areas were determined by the method of Carroll (29).

(2) The acetolysis procedure (Scheme 1 and ref. 7) was as follows: the remainder of the chloroform phase of the methanolysate described above, containing lysoalkyl-PA + DMA + FAME, after removal of the solvent under a stream of nitrogen was acetolyzed in a screw-capped (Teflon-lined) test tube with 1 ml of acetic acid/acetic anhydride (3:2) at 150 C for 48 hr. To the cooled tube, 4.5 ml of methanol and 0.5 ml of water were added, and the MAGD formed from lysoalkyl-PA, along with remaining FAME and DMA were extracted with three to four portions (5 ml) of petroleum ether. The combined extracts were evaporated under a stream of nitrogen, and the residual lipids were dried in a dessicator over KOH in vacuo and made up to a known volume in chloroform. An aliquot was analyzed for MAGD by GLC at 210 C on a column (2 m × 4 mm) of 10% SP2330 and quantitated using the previously added 21:0 FAME as internal standard (25). Overlapping of FAME with DMA or MAGD may be checked by GLC of the mixture after saponification to remove FAME (25). Replicate analyses included all the steps of the methanolysis and acetolysis procedures.

Molecular subclass calculation. The proportions of molecular classes (mol %) was calculated from the total moles of FAME and DMA obtained by methanolysis and total MAGD obtained by acetolysis, as determined by GLC with 21:0 FAME internal standard, as follows:

$$\text{mol \% diacyl class} = \frac{\Sigma \text{ mol FAME} - \Sigma \text{ mol DMA} - \Sigma \text{ mol MAGD}}{\Sigma \text{ mol FAME} + \text{DMA} + \text{MAGD}} \times 100$$

$$\text{mol \% alkenylacyl class} = \frac{2 \times \Sigma \text{ mol DMA}}{\Sigma \text{ mol FAME} + \text{DMA} + \text{MAGD}} \times 100$$

$$\text{mol \% alkylacyl class} = \frac{2 \times \Sigma \text{ mol MAGD}}{\Sigma \text{ mol FAME} + \text{DMA} + \text{MAGD}} \times 100$$

Recoveries of 1-O-alkyl-2-acyl-, 1-O-alkenyl-2-acyl, or 1,2-diacyl phospholipid classes, as percentages of total PL were checked as follows:

$$\text{mol \% diacyl PL} = \frac{\Sigma \text{ mol FAME} - \Sigma \text{ mol DMA} - \Sigma \text{ mol MAGD}}{2 \times \text{mol PL}} \times 100$$

$$\text{mol \% alkenylacyl PL} = [\Sigma \text{ mol DMA/mol PL}] \times 100$$

$$\text{mol \% alkylacyl PL} = [\Sigma \text{ mol MAGD/mol PL}] \times 100$$

Mol PL was determined by phospholipid phosphorus analysis (25). Statistical evaluation of the data was done by the paired Student's t-test (30).

RESULTS AND DISCUSSION

Standardization of methanolysis/acetolysis procedure. The methanolysis and acetolysis reactions that form the basis of the present method (Scheme 1) were checked for efficiency of separation and recovery of FAME, DMA and MAGD by GLC analysis. After subjecting a known mixture of authentic standard FAME (14:0, 16:0, 16:1, 18:0, 18:1) and DMA (16:0, 18:0) to the methanolysis step, GLC analysis on SP2330 at 175 C with internal standard (21:0 FAME) showed complete resolution of the DMA from the FAME (checked also by GLC analysis of the mixture after saponification to remove FAME) with a recovery of each FAME component in the range 96.9 ± 3.5%; recovery of the DMA components was in the range 99.1 ± 3.1% after correction for the detector response (25) relative to the 21:0 FAME standard (for 16:0 DMA the relative response was 0.722, 0.649 and 0.678 at 165 C, 175 C and 195 C, respectively; and for 18:0 DMA, 0.848, 0.755 and 0.775 for the same temperatures, respectively). Essentially the same recovery of the DMA (99 ± 3%) was obtained at column temperatures of 165 C and 195 C as for column temperature 175 C given above. These results show that under the GLC conditions used, little or no breakdown of the DMA, relative to the internal standard, takes place on a SP2330 column in the temperature range 165–195 C.

GLC analysis on SP2330 at 210 C of a known mixture of authentic standard MAGDs, after subjection to the acetolysis step, showed good separation (ret. rel. to 21:0 FAME: 16:0 MAGD, 4.81; 18:0 MAGD, 7.68; 18:1

MAGD, 8.89) and recovery of each component in the range 99.1 ± 0.5%. The corrected detector response relative to 21:0 FAME thus was close to 100%.

The efficiency of the methanolysis procedure for formation and extraction of the lysoalkyl-PA formed from alkylacyl phospholipids (Scheme 1) was checked with a known amount (27.8 μg P) of standard platelet-activating factor (PAF) (1-*O*-hexadecy-2-O-acetyl-*sn*-glycerophosphorylcholine). Virtually all of the lipid-P (96.6 ± 0.6%) appeared in the chloroform phase as lysoalkyl-PA (Rf, 0.44 and 0.03 on Silica Gel H in solvent systems chloroform/methanol/acetic acid/water, 25:15:4:2, and chloroform/methanol/ammonia/water, 70:30:4:1, respectively) and negligible amounts (2.5 ± 0.1%) were retained in the methanol-water phase of the Bligh-Dyer extraction.

The conditions for the acetolysis procedure (essentially those of Renkonen [7]) were checked by subjecting the chloroform-soluble fraction of the methanolysis products of PAF to the acetolysis procedure (Scheme 1) and analyzing the MAGD formed by GLC on SP2330 at 210 C with the internal standard (21:0 FAME). All of the lysoalkyl-PA phosphorus (99.1 ± 0.6%) was found to be liberated into the aqueous phase of the acetolysate and recovery of the MAGD (1-*O*-hexadecyl glycerol diacetate) was 99.5 ± 0.1%. The optimal time of the acetolysis reaction also was checked with the standard PAF substrate and found to be 48 hr at 150 C, as reported by Renkonen (7).

The methanolysis/acetolysis procedure then was applied to the analysis of samples of unhydrogenated and partially hydrogenated bovine brain plasmalogen PE. Optimal conditions for the acetolysis reaction were found to be the same as for PAF (48 hr at 150 C) and good separation and recovery of the FAME, DMA and MAGD formed was obtained (95 ± 3%). The alkenylacyl subclass content (24.1 ± 0.9 mol %) in the unhydrogenated sample calculated from the GLC data was in good agreement with that calculated from the vinyl ether assay (23.7 ± 1.0 mol %); no alkylacyl subclass was detected by the methanolysis/acetolysis procedure. The contents of diacyl, alkenylacyl and alkylacyl subclasses in the partially hydrogenated sample (75.8 ± 2.8, 7.5 ± 0.3 and 16.6 ± 0.6 mol %, respectively) corresponded well with the respective contents calculated from the vinyl ether assay (76.3 ± 1.8, 7.0 ± 0.8 and 16.7 ± 1.8 mol %).

Analysis of human platelet phospholipid subclasses. The overall phospholipid composition of fresh resting pooled platelets (preparation 1), as determined by P-analysis of TLC-separated components (PC, PE, SPH + PS + PI), was found to be in good agreement with the results reported by other workers (2,5,12,13,31-34) (Table 1).

The methanolysis/acetolysis procedure then was applied to the analysis of molecular subclasses of the PC and PE components. Data are given in Table 1 for one preparation (prep. 1) of platelets from pooled blood and for three preparations from separate individuals (preps. 2-4), collected at different times. The major phospholipid, PC, contained mainly the diacyl class (range for the four preparations, 86-92 mol %) with significant proportions of alkylacyl subclass (range, 7-10 mol %), and only small proportions of alkenylacyl subclass (2-3 mol %). In contrast, PE contained much lower proportions of diacyl subclass (39-60 mol %), somewhat lower proportions of alkylacyl subclass (5-8 mol %) and much higher but variable contents of alkenylacyl subclass (34-55 mol %). The values for diacyl and alkylacyl classes in PC appear to be fairly constant for different platelet preparations and are in reasonable agreement with the corresponding values (82, 94% diacyl; 10, 4.5% alkylacyl) reported by Mueller et al. (2) and Natarajan et al. (12), respectively.

In contrast, the alkenylacyl content of PE was quite variable, ranging from 34% to 55%, the higher value agreeing with that reported by Mueller et al. (2) and the lower value with that of Mahadevapa and Holub (13). The alkenylacyl content of PC, however, was consistently lower than that reported by Mueller et al. (2) but somewhat higher than that of Natarajan et al. (12). Previous workers (5,6,12,13,31,32,35,36) using different analytical procedures also have reported a wide range of values (30-60%) for the alkenylacyl content in human platelet PE and a restricted range (trace to 3%) in platelet PC. The alkenylacyl contents found here (Table 1) thus fall

TABLE 1

Overall Phospholipid Composition and Molecular Subclass Composition of the PC and PE Components of Fresh Resting Platelets[a]

Component and subclass	Present study				Ref. 2	Ref. 12	Ref. 13
	Prep. 1 (n = 3)	Prep. 2 (n = 2)	Prep. 3 (n = 2)	Prep. 4 (n = 2)	(n = 3)	(n = 3)	(n = 4)

within the range of values reported (2,5,12,13,31,32,35,36) and may reflect biological variations (due to dietary differences) rather than metholological deficiencies. The alkylacyl content of PE found here (5–8%) was somewhat higher than the values (3.5 and 1.7%) reported by Mueller et al. (2) and Natarajan et al. (12), respectively, but may be due partly to the fact that some of the data of Natarajan et al. (12) were obtained with three-day-old platelets. We have found that stored platelets have lower alkylacyl PE and PC contents than fresh platelets (Vishnubhatla, Kates and Adams, unpublished data).

The fatty acyl, alkyl and alk-1-enyl chain distribution of platelet PC and PE from preparations 2–4 are shown in Table 2. The major fatty acid residues in both PE and PC were 16:0, 18:0, 18:1, 18:2 and 20:4 in general agreement with previous reports (2,5,6,13,31–36). The alkyl ether chains of PC consisted mainly of 14:0, 16:0, 18:0 and 18:1 with small amounts of 14:1, 20:0 and 20:1 (Table 2). Mueller et al. (2) found 16:0, 18:0 and 18:1 as major alkyl ether chains plus small amounts of 20:0 in PC, but Natarajan et al. (12) found only 16:0, 18:0 and 18:1 chains. The major alkyl ether chains found in PE were 14:0, 16:0, 18:0 and 18:1 with lower amounts of 14:1 and 18:2 and traces of 20:0 and 20:1 (Table 2). Natarajan et al. (12), however, found only 16:0, 18:0 and 18:1 alkyl chains in PE.

Analysis of alk-1-enyl chain distribution of the PC indicated that the major chains were 16:0, 18:0 and 18:1 with small amounts of 16:1 (Table 2). Mueller et al. (2) have reported 18:0 (52%) and 16:0 (34%) as major chains with 18:1 and 18:2 as minor components, while Natarajan et al. (12) report the presence only of 16:0, 18:0 and 18:1 chains. PE alk-1-enyl chain composition showed major amounts of 16:0, 18:0 and 18:1 with small amounts of 20:0 (Table 2). Mahadevappa and Holub (13), Mueller et al. (2) and Natarajan et al. (12) found the same major alkenyl chains (16:0, 18:0 and 18:1), but small amounts of 18:2 (2,12), and 20:0 and 20:1 (12) also were reported.

Thus, fatty acyl residues show little variability in composition in the various platelet preparations studied here and elsewhere, but there appears to be more variability in the ether-linked aldehyde and alkyl chain compositions (Table 2) and some inconsistencies with the literature values. However, it should be noted that there are discrepancies also in the alkyl and alk-1-enyl chain compositions reported in the literature (2,12,13). We have observed several unidentified peaks on GLC analysis of the MAGD, which may partly account for some of the discrepancies. Further studies using capillary column GLC-mass spectrometry are necessary to identify these peaks and to check the identity of the MAGD and DMA.

The procedure described here for phospholipid subclass analysis was found to be well-suited for replicate and multisample analysis, on the level of 1–2 μmol, with a reproducibility of ±2–3%, ±5–7%, and ±5–8% for diacyl, alkenylacyl and alkylacyl subclasses, respectively, and within a reasonable time period (7–10 days for 3–4 samples in duplicate). At the same time, the procedure also gives data on the hydrocarbon chain type and chain length for fatty acid, aldehyde and alkyl group constituents of phospholipids. It should prove useful as an adjunct to the more sophisticated procedures for molecular subclass and species analysis of phospholipids by HPLC (2,15,16,20–23) and GC-MS (15–19) methods, to provide a relatively simple assessment of molecular subclasses in a particular phospholipid.

ACKNOWLEDGMENTS

This work was supported by grants from the Natural Sciences and Engineering Research Council of Canada and the Medical Research Council of Canada. We thank Peggy Robinson, Christiane Hallee and Sonia Swenson for technical assistance in preparation of platelets. This paper forms part of a thesis submitted by I. Vishnubhatla to the School of Graduate Studies, University of Ottawa, Ottawa, Canada, in partial fulfillment of the requirements for the M.Sc. degree.

Modification of the Fatty Acid Composition of L1210 Leukemia Subcellular Organelles

C. Patrick Burns*, James A. North, Craig J. Mossman and Leah M. Ingraham
Department of Medicine, University of Iowa College of Medicine, Iowa City, IA 52242

We have examined the extent to which it is possible to modify the fatty acid composition of subcellular organelles of L1210 leukemia cells. A polyunsaturated fatty acid, docosahexaenoic acid, or a monounsaturated fatty acid, oleic acid, were added to the culture media. After 48 hr, the cells were ruptured and the subcellular fractions isolated. Fatty acid analysis revealed that nuclei, mitochondria, plasma membranes and microsomes of the cells grown in media supplemented with docosahexaenoic acid contained increased amounts of polyenoic fatty acids, mean number of double bonds and docosahexaenoic acid compared with cells grown in oleic acid. We conclude that it is possible to experimentally modify the lipids of multiple intracellular structures of L1210 cells by the addition of fatty acids to the growth media.
***Lipids 23,* 615–618 (1988).**

It is well-established that it is possible to modify the fatty acid composition of the total cellular phospholipids and plasma membranes of the L1210 murine leukemia cell (1,2) and other neoplastic cells (3,4). Experimental modification can be brought about in vitro by the addition of supplemental fatty acids to the culture media (4,5) or in vivo by lipid-supplementing the diets fed to tumor-bearing host animals (2,3). Normal tissues of animals and humans also can be altered by dietary supplementation (6,7). The biologic implications and therapeutic potential of such alteration recently have been reviewed (8,9). However, much less information is available about the potential for lipid alteration of subcellular organelles such as nuclei, mitochondria and microsomes. Therefore, we have undertaken a study of the extent of fatty acid modification of four intracellular organelles isolated from cells incubated in media supplemented with fatty acids known from previous studies in our laboratory to affect the fatty acid composition of total cellular phospholipids.

METHODS

Fatty acid modification. L1210 murine leukemia cells were grown in suspension culture in medium consisting of RPMI 1640 (Grand Island Biological Co., Grand Island, NY), 5% fetal bovine serum (KC biologicals Inc., Lenexa, KS), with gentamicin sulfate (40 μg/ml) at 37 C in a humidified atmosphere of 5% CO_2/95% air. Modification of the fatty acid composition was accomplished as described (5,10). Briefly, the cells were grown for 48 hr in medium supplemented with 32 μM docosahexaenoic acid (22:6; number of carbon atoms:number of double bonds) or oleic acid (18:1) (NuChek Prep., Inc., Elysian, MN). The fatty acid composition of the nuclear, mitochondrial, plasma membrane and microsome fractions, were determined using gas chromatography as described (2).

Subcellular fractionation. L1210 cells were disrupted and the fractions separated using the Method I of Tsai et al. (11) except for the following modifications: (a) cells suspended in homogenizing fluid were passed through a 25-gauge needle (30 strokes) for disruption. (b) The pellet and supernatants combined from two consecutive centrifugations of homogenate at 1300 × g for one min were utilized. (c) Both discontinuous gradients were made by placing 14 ml of 30% sucrose over 7 ml of 45% sucrose. Aliquots were taken at each step of the procedure and saved for subsequent enzyme activity and DNA content.

Chemical methods. 5′-Nucleotidase was determined through use of radiolabeled substrate (12). Assays of NADPH cytochrome C reductase (13) and succinic acid dehydrogenase activity (14), DNA content (15) and protein (16) also were determined on each relevant fraction.

RESULTS

Characterization of subcellular fractions. Aliquots of each interface and layer of the final gradient were taken for determination of protein, DNA, 5′-nucleotidase, succinic acid dehydrogenase and NADPH cytochrome C reductase. These fractions included the total homogenate, post-nuclei homogenate (supernatants of two 1,300 × g centrifugations), nuclei (pellet of second 1,300 × g centrifugation), membrane (interface between 10% and 30% layers of sucrose gradients after 23,000 × g ultracentrifugations), mitochondria (interface between the 30% and 45% layers plus the 45% layer of sucrose gradients after 23,000 × g ultracentrifugation), microsomes (30% layer) and cytosol (10% layer). The results for the most pertinent seven fractions are shown in Table 1. The nuclear fraction contained 68% of the DNA in the homogenate and 81% of the total DNA recovered in nuclei plus post-nuclear fractions. About half of the protein (54%) was recovered in the cytosol; there were smaller amounts in other fractions, especially the nuclei and mitochondria. 5′-Nucleotidase, a plasma membrane marker for murine cells, was enriched 19-fold in the membrane fraction (10/30% interface) and eight-fold in the microsomes. Succinic acid dehydrogenase, which is a mitochondrial marker, was enriched 17-fold in the mitochondria fraction (30/45% interface plus 45% layer), and three-fold in the microsomes. NADPH cytochrome C reductase, a microsomal marker, was enriched six-fold in the microsomes and 2.5-fold in the plasma membrane fraction. We conclude from this enzymatic and DNA data that our subcellular fractionation procedure yielded fractions that were individually enriched in nuclei, mitochondria, plasma membrane or microsomes.

[b]Among the individual fatty acids, the amounts of 16:0, 18:0, 18:1, 18:3 and 22:6 for the nuclei, 16:0, 18:1, 18:3, 20:5, and 22:6 for the mitochondria, 16:0, 18:0, 18:1, 18:3, 20:5 and 22:6 for the membranes and 18:0, 18:1, 18:3 and 22:6 for the microsomes are significantly different for 22:6- vs 18:1-supplemented cells ($p < 0.05$).

[c]Includes small amounts of 12:0, 14:0, 20:3, 22:4 and unidentified fatty acids.

[d]Significantly different values ($p < 0.05$) for 22:6- vs 18:1-supplemented cells were found for the amounts of saturates, monoenoics, polyenoics, mean number of double bonds and mean chain length for the nuclei, monenoics, polyenoics, mean number of double bonds and mean chain length for the mitochondria, saturates, monoenoics, polyenoics, mean number of double bonds and mean chain length for the plasma membranes and saturates, monoenoics, polyenoics, mean number of double bonds and mean chain length for the microsomes.

N.D., not detected.

Fatty acid composition. We have shown that the medium fatty acid supplementation techniques used in this paper result in enrichment of the L1210 cellular phospholipids in the supplemented fatty acid (5,17). In this study, we determined the fatty acid composition of selected subcellular fractions of the 22:6- and 18:1-enriched leukemia cells to allow comparison of fatty acid enrichment (Table 2). There was considerable modification of the fatty acid composition of all four fractions studied. Each of the subcellular fractions of the cells grown in 22:6-supplemented media were enriched in 22:6. This enrichment ranged from 17% of the total fatty acids in the microsomes and was the greatest, 40%, in the mitochondria. This compares with only 0–2% 22:6 in the 18:1-supplemented cells. Conversely, the cells grown in 18:1-supplemented media contained 58–66% 18:1 compared with only about half that much in the organelles of the 22:6-supplemented cells. The organelles of the

22:6-supplemented cells contained more palmitic acid (16:0) but less linolenic acid (18:3). These changes in the individual acids resulted in more polyunsaturation and greater mean number of double bonds in the 22:6-supplemented cells and more monounsaturation in the 18:1-supplemented cells. Noteworthy was the observation that the mitochondria contained only 2% and 5% stearic acid (18:0) compared with 20% and 13% in plasma membranes, regardless of fatty acid supplementation.

DISCUSSION

The important finding of this study is that it is possible to modify the fatty acid composition of multiple intracellular organelles. It is well known that substantial differences in the composition of total cellular phospholipids and of plasma membranes can be produced in vivo and vitro (8). In contrast, there is only limited information on experimental alteration of other subcellular fractions. For example, there has been a study on the modification of the lipids of nuclei. Awad and Spector reported that the nuclear lipids of the Ehrlich ascites tumor cell were altered by feeding the tumor-bearing mice diets rich in either coconut or sunflower oil (18). These changes were qualitatively similar to those that the investigators had reported earlier in the plasma membranes of the same cell type, but were quantitatively somewhat less (19). There also have been reports regarding the experimental modification of the cellular microsomes of human Y79 retinoblastoma cells (4,20). There was considerable enrichment of the fatty acids of microsome lipids with 18:1, arachidonic acid (20:4), 18:3 or 22:6 added to the culture medium. However, these studies did not separate microsomes from plasma membranes so that the crude microsomal fraction that was studied contained both endoplasmic reticulum and plasma membranes. In our study, the extent of enrichment of the L1210 microsomes grown in 22:6 was only 17% of the total fatty acid compared with a greater percent enrichment of 26–41% in the other subcellular fractions. It is interesting to note that this is similar to the 15% enrichment of microsomal membranes of the Y79 cells (20). These studies taken together suggest that the endoplasmic reticulum contained in the microsomal fraction may be perturbed by these fatty acyl substitutions to a lesser extent than plasma membranes.

Dietary-induced alteration in mitochondrial fatty acids of the kidney, liver, heart and other tissues of normal animals also has been demonstrated (21,22). Similarly, the addition of linoleic acid (18:2) supplements to the medium of cultured mouse fibroblasts resulted in an increase in the mitochondrial linoleic acid (18:2) from not detectable to 33% of the total fatty acids (23). In our study, the degree of insertion of the supplemented fatty acid was somewhat greater in the case of the mitochondria as compared to the nuclei. This could be related to the active role of the mitochondria in oxidative metabolism. We have demonstrated that multiple organelles of the L1210 cell can be modified experimentally with respect to fatty acid composition. The alterations of separated fractions are generally similar. However, the extent of polyunsaturated fatty acid insertion into microsomes was somewhat less, and into mitochondria somewhat more, than plasma membranes and nuclei. The changes that we were able to bring about in the L1210 subcellular fractions in tissue-cultured cells demonstrate that our model can be utilized to study the effects of lipid modification on multiple cell structures.

It is known that 18:1-enriched cells are similar in fatty acid composition and physical properties to unmodified L1210 cells (5). These 18:1 cells, therefore, represent a control cell for comparison with the polyunsaturated-rich cells. We did not study the organelles of unmodified L1210 cells, because such a comparison of modified and unmodified cell fractions would not take into account that only one of the cell types would have been exposed to exogenous fatty acid. We studied intact organelles. It is likely that the major specific site of the fatty acid alteration is the phospholipid-rich membranes of the organelles. However, it would be technically difficult to obtain a pure membrane fraction from the organelles in sufficient quantities for analysis.

These results demonstrate that experimental fatty acid alteration affects more than just plasma membranes exposed directly to the lipids in the supplemented medium. Intracellular structures including mitochondria and nuclei also are modified. It is possible that the fatty acid changes that we have found might be partially or fully compensated by changes in content or type of other lipids of the organelle. However, such was not the case for plasma membranes (8,9). The general nature of the changes provides a rationale for resultant broad functional changes within the cell. Even though most of the biologic effects of fatty acid modification described to date can be related to plasma membranes (8,9), it seems likely that there are also undiscovered consequences relating to mitochondria or nuclear function.

[Received December 31, 1987; Revision accepted February 12, 1988]

Composition and Physical State of Phospholipids in Calanoid Copepods from India and Norway

T. Farkas[a,*], **T. Storebakken**[b] and **N.B. Bhosle**[c]

[a]Biological Research Center, Hungarian Academy of Sciences, H-6701 Szeged, Hungary, [b]Institute of Aquaculture Research, The Agricultural Center of Norway, N-1432 As-NLH, Norway, and [c]National Institute Oceonography, Dona Paula, Goa-403004, India

The fatty acid composition and physical state of isolated phospholipids obtained from marine copepods collected on the Southwest coast of India *(Calanus ssp.)* and the West coast of Norway *(Calanus finmarchicus)* were investigated to compare the adaptation of membrane lipids with seawater temperatures. Phospholipid vesicles obtained from the tropic copepods proved more rigid than those from *C. finmarchicus*, as assessed by diphenylhexatriene fluorescence polarization techniques. In each case, there were two breaks present on the fluorescence polarization vs 1/T plots, suggesting that the onset and completion of phase separation to occurred above 0 C. For the tropic copepods, the onset of phase separation roughly corresponded to the ambient water temperature, while for *C. finmarchicus* some discrepancies were observed, depending on the time of the year. Phospholipids in copepods from both habitats contained more than 50% unsaturated fatty acids, the animals from Norway containing slightly higher amounts. The data indicate an adaptation of membranes to temperature.
***Lipids 23,* 619–622 (1988).**

Most of our knowledge concerning adaptation of the composition and physical state of membranes to temperature in higher eukariotic systems is derived from observations made on freshwater organisms (1,2). The majority of these investigations demonstrate an inverse relationship between the unsaturation of the constituent phospholipids and temperature (1,3–6), and also a varying degree of homeoviscosus response of membrane physical state to the temperature (7,8). Fatty acids are regarded as the most important factors controlling the physical state of these structures. A major difference between freshwater and marine species is the high level of long-chain polyunsaturated fatty acids in the latter. This should render their membranes more fluid. Based on the data available (2,9,10), the question remains whether they are able to control fatty acid composition according to temperature, by homeoviscosus adaptation. The oil sardine, *Sardinella longiceps,* responded by an increase in the level of docosahexaenoic acid and a decrease of saturated fatty acids when the temperature decreased from 30–31 C to 25–26 C from summer to winter (11). Absence of seasonal variation of phospholipid fatty acids was noted with two marine clam species (12) and with shrimp (13) as well as with *Porphyra yezoensis* exposed to cold for a prolonged time (14). However, in these investigations there was no direct determination of the effect of temperature on the fluidity of membrane phospholipids. In this study, the fatty acid composition and the physical state of phospholipids obtained from marine calanoid copepods collected, respectively, from tropic and temperate seas was investigated.

Abbreviations: BHT, butylated hydroxytoluene; DPH, 1,6-diphenyl 1,3,5-hexatriene; P, fluorescence polarization.

MATERIALS AND METHODS

Animals. Calanus finmarchicus were collected at the West coast of Norway, at Austevoll (60°7′N, 5°13′E), and Stangvik Fjord (62°48′N, 8°26′E), on April 13, and November 26, 1984, respectively. The water temperature was near 10 C in both cases. Calanoid copepods *Calanus ssp.)* also were collected on the West coast of India. One sample originated from the coastal waters off Bombay, collected one km offshore of the Gateway of India (19°00′N, 72°45′E), on February 16, 1981. Another sample was collected at Dona Paula, Goa (15°N, 72°48′E), on January 20, 1986. The surface temperatures were 26 C and 25 C, respectively. No species were identified from the samples collected in India. The copepods originating from the Bombay area were large specimens resembling the size of *C. finmarchicus* Stage V, while those collected at Dona Paula were considerably smaller. The hauls of *C. finmarchicus* were almost 100% copepods, while those made in India were 90–95% copepods with some contaminating decapod larvae.

Analysis of lipids. The animals were fixed in chloroform/methanol (2:1, v/v) containing 0.01% butylated hydroxytoluene (BHT) and frozen until transferred to the laboratory. The Folch procedure (15) was used to extract the total lipids. Phospholipids were separated by silicic acid column chromatography using chloroform to remove the neutral lipids and methanol to obtain the phospholipid fraction. The polar head group composition of the latter was determined according to Rouser et al. (16).

Phosphatidylcholine and phosphatidylethanolamine were separated for further analysis by preparative thin layer chromatography using chloroform/methanol/water (65:25:4, v/v/v) as solvent. Identification of the spots was by comparing the R_f values to those of known standards (Supelco, Bellefonte PA). The spots were detected by spraying the plates with 0.05% 8-anilino-1-naphtalene sulfonic acid in 50% methanol and viewed under UV light. Total or individual phospholipids were transmethylated in the presence of 5% HCl in absolute methanol at 80 C in sealed vials for 2.5 hr. A Hitachi 263-80 type gas chromatograph connected to a Hitachi M263 data processor was used to separate the fatty acid methyl esters. The polar phase was 10% Carbowax 20M on 100–120 mesh Supelcoport in 2 m long stainless steel columns (3 mm i.d.). The oven temperature was programed to rise linearly from 180 to 215 C, at 1 C/min. Each run was made in triplicate, and the error was not more than 1% in the case of the major fatty acids such as 22:6(n-3).

Fluorescence polarization. Phospholipid vesicles were prepared and labeled with 1,6-diphenyl 1,3,5-hexatriene (Sigma Chemical Co., St. Louis, MO) as described by Montaudon et al. (17). A Perkin Elmer Model 44A fluorescence spectrophotometer equipped with a polarization accessory and fitted with a temperature regulation unit was used for the measurements. The excitation wavelength was 370 nm, and the fluorescence emission

was monitored at 420 nm. Fluorescence polarization (P) was calculated from the equation, $P = I_{vv} - I_{vh}/I_{vv} + I_{vh} \cdot Z$, in which I_{vv} and I_{vh} are the fluorescence intensities measured with emission analyzer parallel or perpendicular, respectively, to the polarization of the detection system for vertically and horizontally polarized light.

RESULTS AND DISCUSSION

Figure 1 presents a Vant Hoff's representation of 1,6-diphenyl 1,3,5-hexatriene (DPH) fluorescence polarization, P, of vesicles of phospholipids prepared from marine calanoid copepods collected either in the North Atlantic or in tropic seas. Lower P-values represent more fluid structures. From these data, it may be inferred that the most fluid membranes were present in *C. finmarchicus* collected in the spring and the most rigid ones in the copepods inhabiting the tropic seas. *C. finmarchicus* sampled in early fall revealed values in between these two extremes. In addition, there are two distinct breaks in the curves on the P vs 1/T plots. The break at the higher temperature indicates onset, while that at the lower temperature indicates completion of phase separation of these phospholipids. The sea water temperature at the time of collecting *C. finmarchicus* was about 10 C but varied between 2 and 20 C during the year. The temperature in the tropic seas was about 25–26 C at the time of sample collecting and varied from 25 to 30–31 C during the year. The temperature at the onset of phase separation of phospholipids from each sample was close to the temperature at which the organism lived, except in the *C. finmarchicus* collected in the fall. However, it should be remembered that the above values for phospholipid vesicles might be modulated if other membrane constituents (proteins, sterols, etc.) also were present.

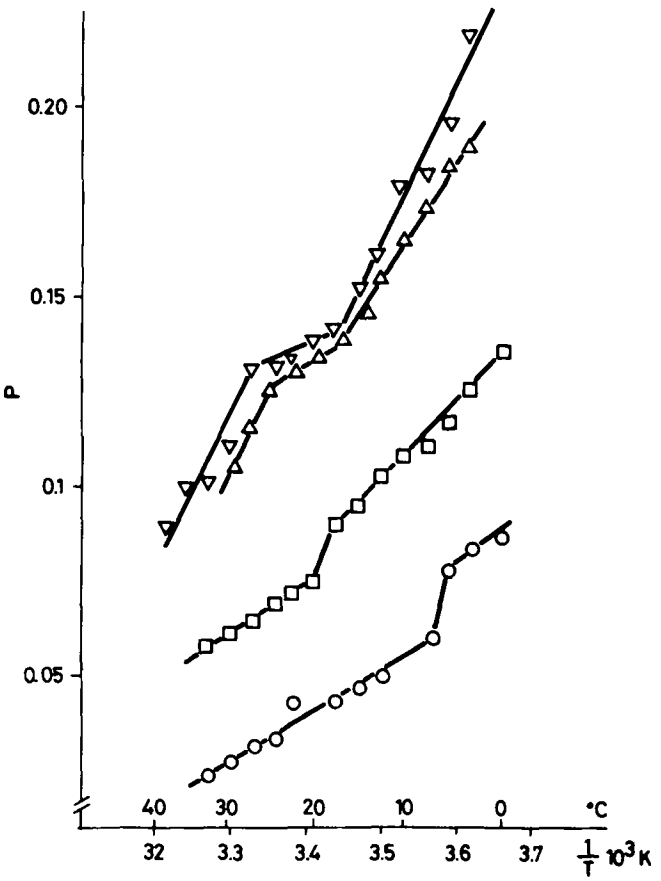

FIG. 1. Temperature dependency (1/T) of DPH fluorescence polarization (P) in phospholipids of marine calanoid copepods. *Calanus spp.* were collected at Dona Paula, Goa (—∇—) and Bombay (—△—) at the Southwest coast of India, while *C. finmarchicus* were collected at the West coast of Norway in the fall (—□—) and in the spring (—○—), respectively.

The observation that the temperature at onset of the phase separation of the membrane lipids coincides with growth temperature has been made with other poikilotherms (10,18–20), but it is not documented as a general phenomenon (7,21). Cossins and Prosser (18) reported that the onset of phase separation of phospholipids from synaptosomal membranes of arctic sculpin adapted to 0 C occurred at 5 C while that for goldfish acclimated at 5 C occurred at 10 C. It can be inferred from Figure 1 of Prosser and Cossin's paper that phospholipids of synaptosomal membranes of goldfish adapted at 25 C show phase separation around the growth temperature (18). In a current study of liver phospholipids of the carp, *Cyprinus carpio L.*, we found that the onset of phase separation of phospholipids of summer-adapted fish occurred around 25 C, while that of winter-adapted fish occurred around 6 C (unpublished observations). In earlier work on the freshwater copepod *Cyclops vicinus*, we also found that phase separation temperatures were similarly related to the actual growth temperature (10). Although the water temperature at the time of collecting *C. finmarchicus* was the same in the fall and the spring (10 C), the higher polarization value and phase separation temperature of phospholipids of the fall sample may suggest that the fall specimens retained a "summer" state in their lipids.

Whether marine species similar to *C. vicinus* can regulate the physical state of their phospholipids according to the temperature or whether they lack this property, like the freshwater crustacean *Daphnia magna*, requires further investigation. Some freshwater crustaceans and fish are exposed to fluctuation in their environmental temperature. In cases of tropic seas, this is less pronounced. Judging from the temperature range at which the phase separation occurs, it may be inferred that *C. finmarchicus* can tolerate less changes in the water temperature than the copepods in the tropic seas.

Spring-collected *C. finmarchicus* did not survive exposure to 20 C longer than two hr, and copepods collected at Dona Paula lost their swimming activity but did not die when exposed to 17 C for six hr (unpublished observations). Because the former can be regarded as a cold stenothermic and the latter as a warm stenothermic species, it is tempting to speculate that this is at least partially related to the phase behavior of their membranes.

Table 1 shows that the above differences in the phase behavior are not easily explained by the fatty acid composition of the phospholipids. An inverse relationship between environmental temperature and fatty acid unsaturation also was observed in this case. This was due mainly to a higher level of docosahexaenoic acid in phospholipids of *C. finmarchicus*. Despite these differences,

[a]*Calanus ssp.*, Dona Paula, Goa.
[b]*C. finmarchicus*, spring.

the spring-collected *C. finmarchicus* and the copepods collected at Dona Paula showed similar saturated to unsaturated ratios but great differences in the phase behavior of their phospholipids. Moreover, the two samples of copepods from the tropic seas showed differences in phospholipid fatty acid compositions as well as in the saturated to unsaturated fatty acid ratios, although the P-values and the phase separation temperatures were almost identical (Fig. 1). Thus, it is highly probable that control occurs at a level beyond the overall distribution of fatty acids in phospholipids. Table 2 shows that the phospholipids of copepods from tropic seas were poorer in sphingomyelin and phosphatidic acid, and richer in phosphatidylethanolamine than those in *C. finmarchicus*. Phosphatidylcholines in spring-collected *C. finmarchicus* contained more polyunsaturated acids (82% vs 62%) and had a lower saturated-to-unsaturated fatty acid ratio (0.15 vs 0.38) than those of the tropic copepods (Table 3). Even though phospholipids were not separated according to molecular-species composition, one could expect that diunsaturated phospholipids would be present whenever the level of total unsaturated fatty acids exceeds 50 mol %. As shown in Table 3, the phosphatidylcholines and phosphatidylethanolamines were richer in diunsaturated phospholipids than were the phospholipids of copepods in the tropic seas (32% vs 12% and 17% vs 11%, respectively), and this could explain the observed differences in the P-values (Fig. 1). Because the phase separation temperature of 1-palmitoyl,2-docosahexaenoyl phosphatidylcholine is about −10 C (22) and that of diunsaturated molecules is even lower, phospholipids of marine copepods should exhibit lower phase-separation temperatures than those observed. Phospholipids of these copepods behave similarly to those of the bovine retinal rod outer segment membranes. Although the latter are as rich in polyenes as the phospholipids of copepods investigated here, they too contain fair amounts of supraenes (dipolyunsaturated phospholipids) (23,24) and exhibit phase-separation temperature between 15 and 5 C (25).

It has been proposed that this results from a precise balance between disaturated and diunsaturated phospholipid molecules (25). The differences demonstrated in physical parameters of phospholipid vesicles indicate an adaptation of membrane physical states to temperatures.

ACKNOWLEDGMENTS

We thank S. K. Chakraborty, Central Institute of Marine Fisheries, Bombay, India, for making possible the collecting of marine copepods. Thanks go also to E. Lehoczki (Jozsef A. University, Szeged, Hungary) for help in fluorescence polarization measurements.

Improved survival to endotoxin has been demonstrated in rats pretreated with cyclooxygenase inhibitors or made essential fatty acid deficient, implying that excessive ω6 fatty acids, possibly through their eicosanoid products, contribute to mortality. Following endotoxin administration, we also have shown improvement in survival with oral diets supplemented with fish oil. This study sought to explore whether parenteral fish oil ameliorates the adverse impact of endotoxin.

Male Hartley-strain guinea pigs were obtained at a body weight of 500 g and fed a normal laboratory diet. Central venous lines through which the animals received either a 10% safflower oil emulsion (n = 11) or a 10% fish oil emulsion (n = 11) during two, 24-hr periods separated by two days were inserted. Two days after the second infusion, endotoxin (0.35 mg/100 g b.w.), was given intraperitoneally, and survival was noted. The animals received a total of 25.4 g of IV fat per kg b.w., including 5.3 g of eicosapentaenoic acid per kg b.w., for the fish oil group.

From six hr after endotoxin through four days, there was better survival in the fish oil group ($p < .006$). Final mortality showed 7/11 fish-fed vs 2/11 safflower-fed animals surviving. We conclude that the administration of parenteral fish oil, even for a brief time, can have a profound effect on subsequent survival to endotoxin.
Lipids 23, 623–625 (1988).

Endotoxic shock involves activation of platelets and leukocytes (1). Investigations have shown enhanced survival to endotoxin when the effects of the vasoactive prostanoids thromboxane A_2 and prostacyclin I_2 have been inhibited through either decreased production or blocked action (2,3). Methods used to arrive at this common physiologic end-point include essential fatty acid deficiency, pretreatment with the cyclooxygenase inhibitors indomethacin or ibuprofen, or with the thromboxane synthetase inhibitor imidazole or by the use of 13-azaprostanoic acid, a thromboxane antagonist (2,3).

Fish oils contain eicosapentaenoic acid (EPA), a long chain polyunsaturated fatty acid of the ω3 family. As a substrate for cyclooxygenase in platelets, it forms thromboxane A_3, a vasoconstrictor like thromboxane A_2, but not a platelet aggregator (4,5). Likewise, in endothelial cells, EPA serves as substrate for prostacyclin I_3, which is similar to prostacyclin I_2 as a vasodilator and platelet anti-aggregator (5). This shifts the overall balance towards lessened clotting, manifested by prolonged bleeding times (6) and decreased thromboxane production (7).

Fish oils also have been shown to dampen leukocyte function (8). Lee and colleagues (8) showed decreased chemotaxis and decreased production of leukotriene B4 in neutrophils obtained from human subjects taking supplemental fish oil. This leukocyte inhibitory effect from dietary fish oil may be another mechanism through which survival to endotoxin challenge could be modulated.

We recently have shown (9) enhanced survival to an LD_{50} of endotoxin in animals orally fed fish oils for a six-wk period. We considered the hypothesis that fish oils would be protective against endotoxic shock by utilizing an IV preparation of fish oil given over several days.

METHODS

Animals. Male Hartley strain guinea pigs were obtained at a weight of 500 g from the Elm Hill Breeding Laboratories (Chelmsford, MA). They were housed in plastic cages with pine shavings on a 12-hr light and 12-hr dark cycle with the temperature controlled at 23 C and the relative humidity between 50–55%. This study met with the approval of the Institutional Animal Care and Use Committee of the New England Deaconess Hospital.

Study protocol. The animals were allowed a normal laboratory guinea pig diet (Agway Inc., Syracuse, NY), ad libitum, throughout the study. One wk after arriving, the animals underwent central vein catheterization. While anesthetized, a 0.025 in. (i.d.) × 0.037 in. (o.d.) silastic catheter was inserted into the superior vena cava from the internal jugular vein. The tubing was tunneled subcutaneously where it exited from the midscapular region and connected to a flow-through swivel that permitted free movement.

One day after the catheters were placed, the first of two days of lipid infusion was started. The animals received the respective lipid emulsions (safflower oil or fish oil) for two 24-hr periods separated by two days. Prior pilot studies revealed gross lipemia after one day of infusion, which cleared after two days of saline infusion. After the second day of lipid infusion, two more days were allowed to clear the second lipemia. On the morning of the seventh day, the animals received endotoxin intraperitoneally, 0.35 mg/100 g b.w., and then were followed for survival. Survival was noted at 3, 6, 9, 12, 15, 21, 24, 48, 72 and 96 hr after endotoxin injection. There were 11 animals in each group.

Emulsions. The emulsions used were each 10% emulsions. The fish oil emulsion was obtained from Baxter Healthcare Corp. (Deerfield, IL), and the safflower oil emulsion was from Abbott Laboratories (North Chicago, IL). Liposyn, the original formulation made solely from safflower oil and containing no soybean oil, was used. Table 1 depicts the fatty acid composition of the emulsions.

Endotoxin. Endotoxin was obtained from Difco Laboratories (Detroit, MI). The lipopolysaccharide was derived from *Escherichia coli* (026:B6, Lot #3920-10-9, Control #718687). Using the method of Reed and Muench (10), an LD_{50} of 0.35 mg/100 g b.w. was obtained for this lot of

TABLE 2

Lipid Intake

Parameter	Fish oil	Safflower oil
Body weight (b.w.)	500.8 ± 21.0	485.9 ± 24.3
Lipid infused (g/animal)	12.6 ± 0.3	13.0 ± 0.5
Lipid infused (g/kg b.w.)	25.4 ± 1.5	27.5 ± 2.5
Lipid infused (g/kg b.w./dose)	12.7 ± 0.1	13.7 ± 1.2
Lipid infused (g/kg b.w./hr)	0.53 ± 0.3	0.57 ± 0.05
EPA infused (gm/kg b.w.)	5.3 ± 0.3	0

Except for EPA, no weight or lipid differences by Student's t-test. N = 7 for each group. Data expressed as $\bar{x}$ ± SEM.

endotoxin in normal guinea pigs using the intraperitoneal route. The endotoxin was diluted in sterile saline to a maximum volume of 1 ml and injected intraperitoneally.

Anesthesia. A mixture of ketamine (44 mg/ml), acepromazine (0.2 mg/ml) and atropine (40 mcg/ml) was used for anesthesia at a dose of 1 ml/kg body weight, intramuscularly. Lidocaine as a 5% solution was used locally for any dissection.

Statistics. Survival was tested by Kaplan-Meier survival analysis using Surv-Pak-PC, software developed by the Johns Hopkins Oncology Center (Baltimore, MD).

RESULTS

Lipid intake. Table 2 shows the lipid intake for the two groups of animals. Each group received comparable amounts of fat, when analyzed by total amount over the two doses, amount per dose, per kilogram b.w. or rate of infusion. The total amount of EPA the fish oil-fed animals received over the six-day study was 5.3 ± .3 g/kg b.w.

Survival. Figure 1 shows the mortality among the two groups. As shown by Kaplan-Meier analysis, the two curves differ, $p < .006$. By nine hr after endotoxin administration, all nine safflower oil-fed animals that were to die had succumbed. In contrast, two of the four fish oil-fed animals that were to die lived for more than 21 hr.

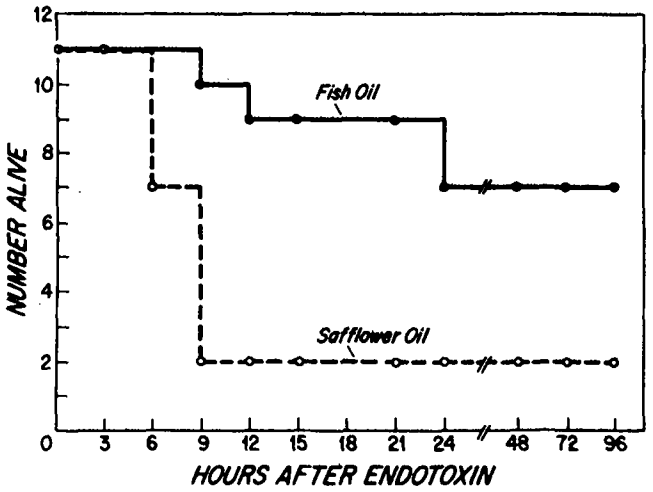

FIG. 1. Survival curves of the two dietary groups. Curves differ by Kaplan-Meier analysis, $p < 0.006$.

DISCUSSION

The beneficial impact of the fish oil may have been mediated through alteration in the metabolism of the prostanoids, thromboxane A_2 and prostacyclin I_2 from their respective tissues of origin, platelets and endothelium, or through leukotriene B_4 from leukocytes. The ability of EPA to antagonize the production of the more vasoconstrictor thromboxane A_2 or to diminish the generation of leukotriene B_4, thereby lessening leukocyte migration and endothelial adherence, could be its primary role. Alternatively, the presence of EPA-derived thromboxane A_3 and prostacyclin I_3 or leukotriene B_5 may have been involved. Because these compounds were not measured in this study, the temporal associations are not known. Further support for this explanation is data recently generated in guinea pigs fed a fish oil-based diet for six wk and then challenged with endotoxin (11). The metabolic acidosis that developed was much less pronounced as compared with those animals fed safflower oil.

Less linoleic acid and therefore less arachidonic acid as a substrate for eicosanoid formation may be another mechanism. This would view the fish oil as merely replacing an oil high in linoleic acid, i.e. safflower oil, leading to less arachidonic acid as substrate. Support for this comes from a recent study in which coconut oil-fed animals, as opposed to corn oil-fed animals, had better survival to endotoxin (12). Determining fatty acid profiles in plasma, platelets and leukocytes could resolve this question.

Identification of N-ε-(2-propenal)lysine as a Major Urinary Metabolite of Malondialdehyde

H.H. Draper*, M. Hadley, L. Lissemore, N.M. Laing and P.D. Cole
Department of Nutritional Sciences, College of Biological Science, University of Guelph, Guelph, Ontario, Canada N1G 2W1

N-ε-(2-propenal)lysine (ε-PL) was identified as one of two major metabolites of malondialdehyde (MDA) excreted in rat and human urine. This compound is derived mainly but not exclusively from the diet, where it arises from a reaction between free MDA generated in the oxidative decomposition of polyunsaturated fatty acids and the ε-amino of the lysine residues of food proteins. It is released during protein digestion and represents the main form in which MDA is absorbed. It is excreted partially in unchanged form and partially as the acetylated derivative N-α-acetyl-N-ε-(2-propenal)lysine. Its administration to rats did not result in an increase in the excretion of free MDA in the urine. The findings that MDA in foods is absorbed mainly as ε-PL, and that this compound is not metabolized to free MDA in vivo, mitigate concern over the possible mutagenicity and carcinogenicity of MDA in the diet.
Lipids 23, 626–628 (1988).

Work in this laboratory has revealed the presence of several malondialdehyde (MDA) derivatives in rat and human urine (1–3). Figure 1 illustrates an elution profile of MDA compounds obtained by anion exchange column chromatography of rat urine. One of two major metabolites (Fig. 1F) has been identified as N-α-acetyl-N-ε-(2-propenal)lysine (1) and two minor metabolites as MDA adducts with the phospholipid bases ethanolamine (Fig. 1B) and serine (Fig. 1E) (2,3). Free MDA (Fig. 1G) was detected in some urine samples. This paper describes the identification of the second major urinary metabolite of MDA (Fig. 1A) as the unacetylated lysine-MDA adduct N-ε-(2-propenal)lysine.

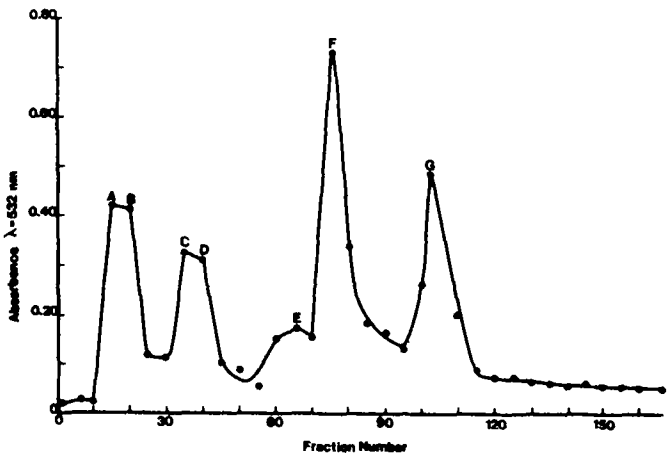

FIG. 1. Elution profile of MDA derivatives obtained by anion exchange chromatography of urine from rats fed a vitamin E deficient diet containing cod liver oil (2). A, N-ε-(2-propenal)lysine; B, N-(2-propenal) ethanolamine; E, N-(2-propenal)serine; F, N-α-acetyl-N-ε-(2-propenal)lysine; G, free MDA. C and D, unidentified. MDA was determined spectrophotometrically as the thiobarbituric acid derivative (9). Reproduced with permission (2).

METHODS

The procedure used for the isolation of urinary metabolites of MDA has been described in detail elsewhere (1). Briefly, it includes anion exchange, cation exchange and size exclusion column chromatography, followed by high performance liquid chromatography (HPLC) on preparative and analytical reverse phase columns.

The occurrence of an acetylated lysine-MDA adduct in urine (1) suggested the co-existence of the unacetylated adduct N-ε-(2-propenal)lysine. This compound (ε-PL) therefore was synthesized by a modification (1) of the procedure of Nair et al. (4). This procedure yields a mixture of N-α and N-ε adducts (α-PL and ε-PL) (Fig. 2). Synthetic ε-PL was subjected to the chromatographic procedures used for the isolation of urinary metabolites, and its elution pattern was compared with those of the remaining unidentified compounds (Fig. 1).

RESULTS

When subjected to anion exchange column chromatography, synthetic ε-PL eluted in the same fractions as a major urinary metabolite of MDA (Fig. 1A). However,

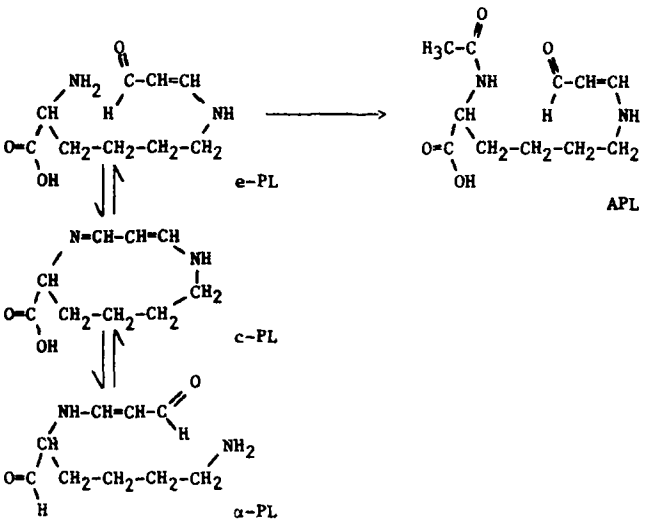

FIG. 2. Interconversions of lysine-MDA adducts. APL is a major form of MDA found only in urine (1). ε-PL is the main form of MDA absorbed from the diet (8) and is also a major form in urine. c-PL and α-PL are formed from ε-PL as isolation artifacts.

Abbreviations: α-PL, N-α-acetyl-N-ε-(2-propenal)lysine; c-PL, cyclized product; ε-PL, N-ε-(2-propenal)lysine; MDA, malondialdehyde; HPLC, high pressure liquid chromatography.

when subjected to analytical reverse phase HPLC, authentic ε-PL and the purified metabolite failed to co-elute.

Coincidentally, storage of pure synthetic ε-PL in aqueous solution at 4 C was observed to result in its partial conversion to two additional compounds (Fig. 3). One of these compounds was found to co-elute with pure, synthetic α-PL when chromatographed on a reverse phase HPLC column. The other co-chromatographed with the MDA derivative isolated from urine (Fig. 4). Under similar storage conditions, α-PL was partially converted to ε-PL and the unidentified product of ε-PL conversion. It was apparent from these observations that the unidentified compound was an intermediate in the interconversion of α-PL and ε-PL.

Characterization of the intermediate by NMR and IR was confounded by its retroconversion to α-PL and ε-PL. Its UV_{max} at 280 nm and its fluorescence spectrum indicated that the Schiff's base bonds present in α-PL and ε-PL were intact. In aqueous solution, it exhibited fluorescence (Ex_{max} 370 nm, Em_{max} 467 nm) consistent with the presence of the general structure R—NH—CH=CH—CH=N—R (5). Cation exchange chromatography showed that it was less positively charged than α-PL and ε-PL. On the basis of these observations, it was concluded that the compound was a cyclized product (c-PL) of intramolecular reactions between the free aldehyde and amino groups of α-PL and ε-PL (Fig. 2).

Anion exchange chromatography of pure, synthetic ε-PL resulted in its almost complete conversion to the cyclized form (Fig. 5), indicating that the c-PL recovered from urine was formed from ε-PL as an isolation artifact. No evidence was obtained for the natural occurrence of either c-PL or α-PL in urine, although their presence in small amounts cannot be excluded.

DISCUSSION

N-ε-(2-propenal)lysine and its N-α-acetylated derivative are the main forms in which MDA is excreted in rat and human urine. Under normal conditions, both compounds are mainly of dietary origin. ε-PL appears to be formed by a reaction between free MDA generated in the oxidative decomposition of polyunsaturated fatty acids in the diet and the ε-NH_2 groups of lysine residues of food proteins, from which it is released during protein digestion.

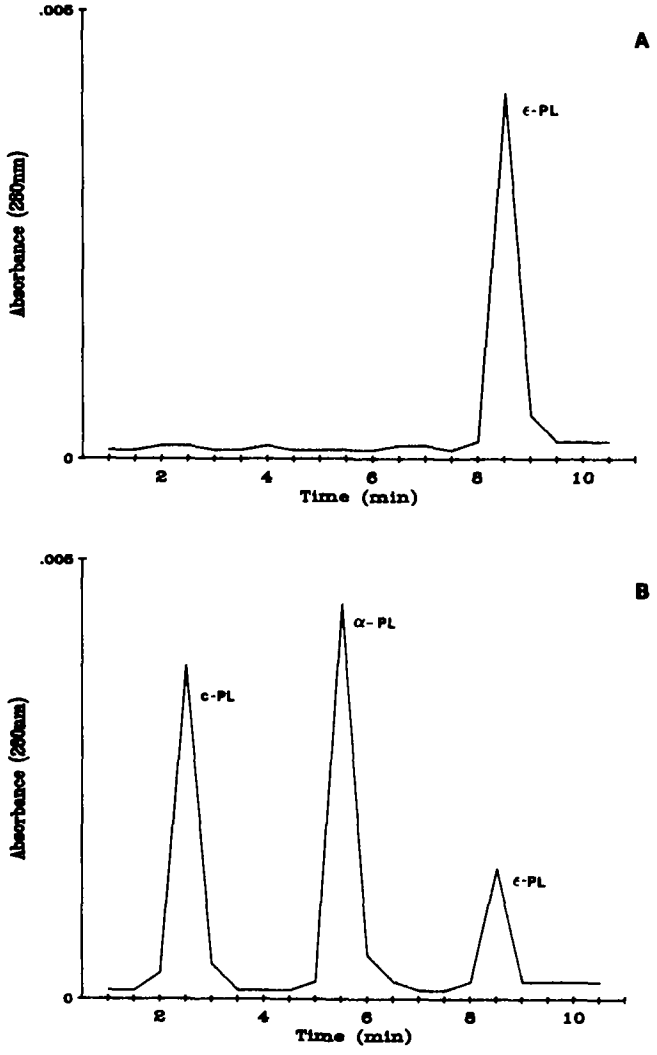

FIG. 3. Reverse phase HPLC elution profile of synthetic ε-PL before (A) and after (B) storage in aqueous solution at 4 C for several weeks.

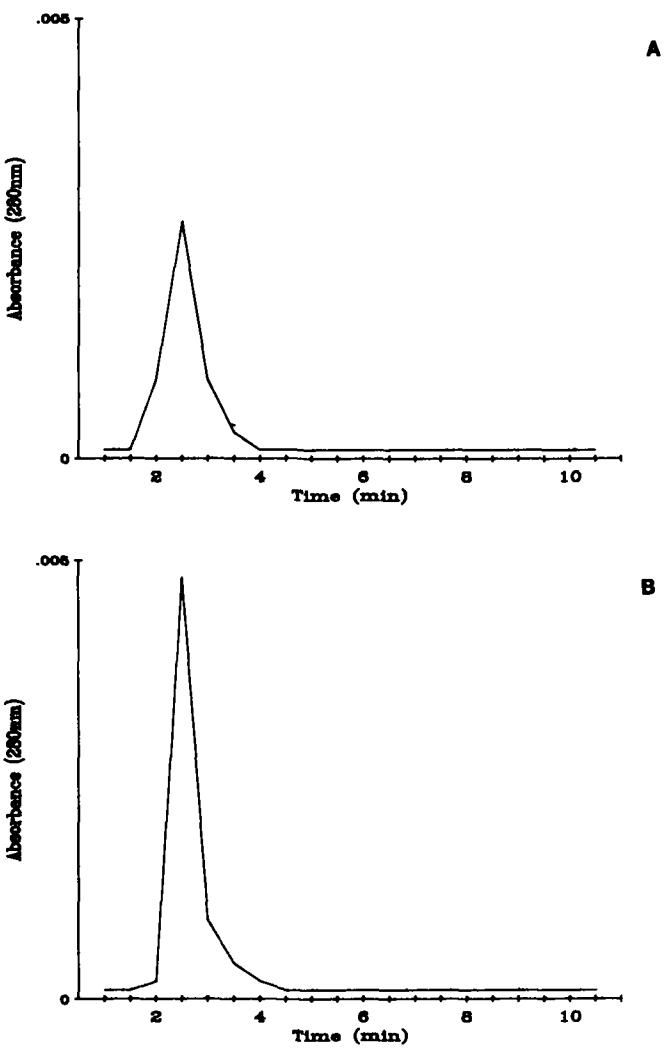

FIG. 4. Reverse phase HPLC elution profile of urinary MDA isolate obtained before (A) and after (B) spiking with synthetic c-PL.

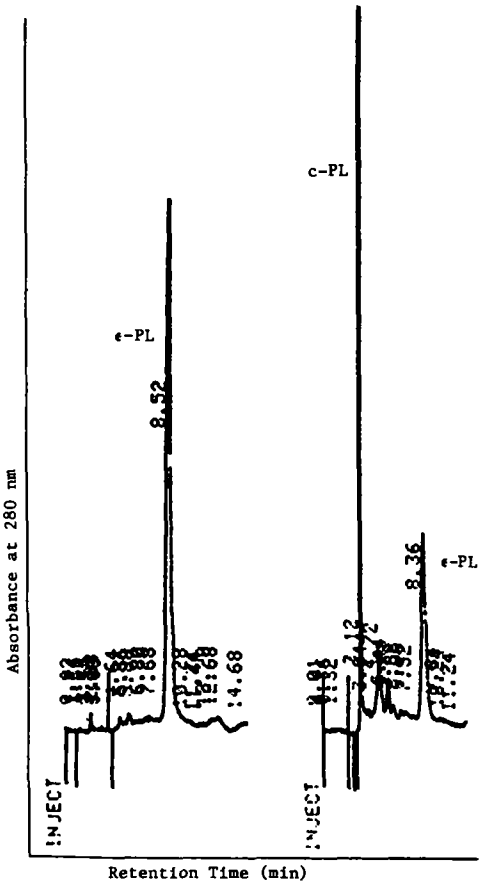

FIG. 5. Reverse phase HPLC elution profile of ε-PL before (A) and after (B) chromatography on anion exchange resin.

Chromatographic fractionation of the in vitro digestion products of several foods showed that ε-PL was the predominant form of MDA present (6). It is excreted partially in the acetylated form. The liver is the main site of N-acetylation reactions.

Intraperitoneal administration to rats of 60 μg of MDA as ε-PL produced no increase in the excretion of free MDA in the urine. Because the excretion of free MDA is responsive to smaller doses of MDA as the sodium enol salt (1), it appears that ε-PL is not a source of free MDA in vivo. The findings that ε-PL is the main form of MDA absorbed from the diet (6) and that this compound is not metabolized to free MDA in the body mitigate concern over the possible mutagenicity (7) and carcinogenicity (8) of dietary MDA.

Although the excretion of lysine-MDA adducts by the rat is markedly decreased by fasting or feeding a diet containing only saturated fat (hydrogenated coconut oil), these compounds are nevertheless detectable in urine, indicating that they are formed in the tissues as well as in the diet. They also are present in human urine collected 12–36 hr after the beginning of a fast, and collected while consuming a protein-free diet. Hence, they appear to reflect reactions of MDA with cellular as well as dietary proteins.

Evidence for Loss of Tritium from 3β-Tritiated Deoxycholic Acid during Enterohepatic Cycling in Man

S.N. Marcus[a,*] and **K.W. Heaton**[b]

[a]Division of Gastroenterology, Department of Medicine, T-013, University of California, San Diego, La Jolla, CA 92093, and [b]University Department of Medicine, Bristol Royal Infirmary, Bristol BS2 8HW, England

A double-label single-intubation isotope technique was assessed for studying deoxycholic acid metabolism by simultaneous IV administration of [3β-^{3}H]deoxycholic acid and [24-^{14}C]deoxycholic acid to five healthy subjects. The ^{3}H/^{14}C ratio in duodenal bile fell progressively in all subjects, the mean reduction on day four being 48.8%. When the same labeled bile acids were administered to three ileostomy subjects, again the ratio fell with a mean reduction of 44.4% on day four. This fall more likely was due to hepatic exchange of tritium for hydrogen, rather than to colonic bacterial oxidation. [3β-^{3}H]Deoxycholic acid should not be used to study the kinetics and metabolism of deoxycholic acid.
Lipids 23, 629–630 (1988).

Vantrappen et al. (1) recently described an isotopic technique for determining the turnover rate of cholic acid from a single sample of bile, which they compared with four- or five-day samples as required by the classical Lindstedt method (2). This new technique requires administration of ^{3}H-labeled as well as of ^{14}C-labeled cholic acid. We intended to study deoxycholic acid pool size and kinetics in relation to colonic transit (3,4) and, attracted by the simplicity of the Vantrappen technique, decided to investigate its feasibility with deoxycholic acid. Because tritiated deoxycholic acid is not commercially available, Amersham International PLC was commissioned to synthesize it for us, the ^{3}H-label being inserted in the 3β-position on the bile acid nucleus. It is recognized that some tritiated bile acids are unsuitable as markers because ^{3}H is exchanged for hydrogen in body water (5–7). Recently, it has been suggested that oxido-reduction of the hydroxyl group at the 3- and 12-position of deoxycholic acid by the intestinal microflora can occur (8). Thus, both mechanisms could result in a fall in specific radioactivity not due to turnover of the bile acid. At the time of study, bile acids tritiated in the 3β position had not been assessed for stability. To examine this, we measured the ratio of ^{3}H/^{14}C radioactivity in biliary deoxycholic acid during enterohepatic circulation after the deoxycholic acid pool had been labeled simultaneously with tracer amounts of [3β-^{3}H]deoxycholic acid and [24-^{14}C]deoxycholic acid. If [3β-^{3}H]deoxycholic acid is stable during enterohepatic circulation, then the ^{3}H/^{14}C ratio should remain constant.

MATERIALS AND METHODS

[3β-^{3}H]Deoxycholic acid was prepared by the selective oxidation of the 3-position of methyl deoxycholate with silver carbonate on celite. The methyl-3-oxo-12α-hydroxy-5β-cholan-24-oate oxidation product was purified by column chromatography and then reduced by sodium boro-[^{3}H]-hydride to the 3α-hydroxyl epimer, which subsequently was purified by thin layer chromatography (TLC). The methyl ester was saponified with sodium hydroxide. Radiochemical purity by TLC was 98%, and the specific activity was 21.2 C/mmol.

Approximately 10 μC of [24-^{14}C]deoxycholic acid and 30 μC of [3β-^{3}H]deoxycholic acid were injected intravenously into four healthy female and one healthy male volunteer, mean age 49 years (range 42–64), three hr after their last meal of the day. The ^{3}H and ^{14}C radioactivities were measured in small aliquots of thoroughly mixed duodenal bile samples collected after cholecystokinin injection on the next four mornings, according to the Lindstedt method (2). In view of the results obtained in these five subjects, the procedure was repeated in three more subjects (two females and one male, mean age 43 years; range 36–51), who had undergone total colectomy and ileostomy for ulcerative collitis at least five years before. In these subjects, bile samples were collected only on the first and fourth morning after their injection. All volunteers gave their informed consent for the study, which was approved by the hospital ethical committee.

After precipitation of bile proteins by boiling methanol, the bile acids were deconjugated with cholylglycine hydrolase (9), extracted in ether and separated by TLC using as development solvent 2,2,4-trimethylpentane/ethyl acetate/glacial acetic acid (5:5:1, v/v/v) (10). The dihydroxy bile acids were eluted and assayed for ^{3}H and ^{14}C radioactivity in a dual-channel liquid-scintillation counter with quench correction by external standardization and the ratio of ^{3}H/^{14}C was calculated.

RESULTS AND DISCUSSION

In the five normal subjects, the ^{3}H/^{14}C ratio fell progressively, with a mean reduction of 48.8% by the fourth day (range 41.5–57.1%) (Fig. 1). In the three ileostomy subjects, the ^{3}H/^{14}C ratio fell by a mean of 44.4% by the fourth day (71.3, 31.5 and 26.9%).

The results in the five healthy volunteers indicate that [3β-^{3}H]deoxycholic acid loses radioactivity during enterohepatic cycling. After this study was performed, Björkhem et al. (8) published similar findings for healthy subjects. We considered two causes for our results: exchange of tritium for hydrogen within the liver (11) and loss of tritium as a result of 3-oxidation by the colonic bacterial flora followed by reduction either in the colon or liver with incorporation of a nonradioactive hydrogen atom and circulation of the now unlabeled bile acid.

Subjects with ileostomies have no or very small amounts of deoxycholic acid in the bile (12,13) because of the relative paucity of anaerobic bacteria able to dehydroxylate cholic acid (14). If bacterial oxidation and reduction of [3β-^{3}H]deoxycholic acid had contributed to the fall of the ^{3}H/^{14}C ratio in the normal subjects, then in the ileostomy patients the ratio should have remained constant or fallen much less, which was not the case. Our

Abbreviation: TLC, thin layer chromatography.

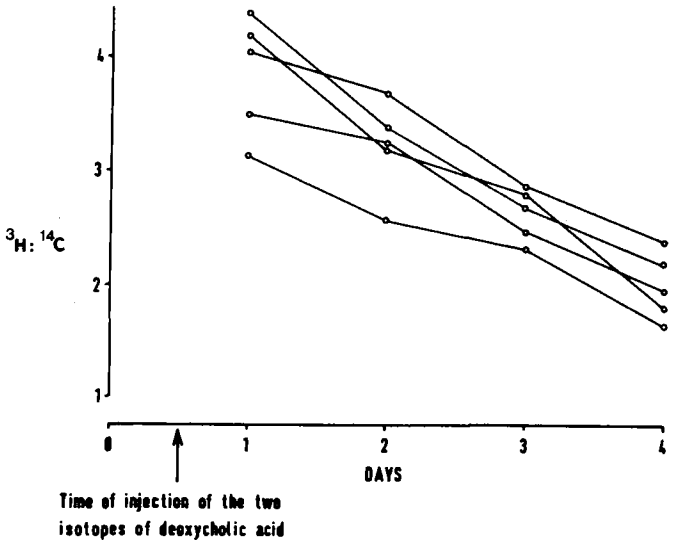

FIG. 1. Ratio of $^3H/^{14}C$ in duodenal bile samples collected on four consecutive mornings from five healthy volunteers following the simultaneous IV administration of tracer amounts of [3β-^{3}H]deoxycholic acid and [24-^{14}C]deoxycholic acid.

results in ileostomy subjects contrast with those of Björkhem et al. (8). But their finding of a slower decline in the $^3H/^{14}C$ ratio in two ileostomy subjects than in seven healthy controls was made after the administration of [12β-^{3}H]deoxycholic acid and not [3β-^{3}H]deoxycholic acid. This indicates that the loss of label in the 12β-position is due mainly to bacterial oxidation. However, our results suggest the same mechanism cannot be assumed to apply to [3β-^{3}H]deoxycholic acid.

We conclude that bacterial oxido-reduction of deoxycholic acid at the 3-position is unlikely to occur to any great extent during its enterohepatic cycling in man, and that loss of the label is more likely due to hepatic exchange of tritium with hydrogen (11). Studies in subjects whose bile flow has been diverted away from the colon, such as in post-cholecystectomy T-tube patients, would help confirm these findings.

When considering the use of tritiated bile acids, recommendations of Panveliwalla et al. (7) should be remembered. The data from our study confirm that [3β-^{3}H]deoxycholic acid loses tritium during enterohepatic cycling, and that it should not be used to measure deoxycholic acid pool size or kinetics. If [2-4-^{3}H]deoxycholic acid (analogous to [2-4-^{3}H]cholic acid used in the original Vantrappen technique) had been chosen instead, the results would probably have been similar, because it also loses label (7). Instead, [22,23-^{3}H]deoxycholic acid could be tried; however, it is not commercially available and would need to be specially synthesized and then tested for its suitability as a label.

Comparison of Fatty Acid and Triacylglycerol Metabolism of Macrophages and Smooth Muscle Cells

Lynn M. Bergstraesser[a] and **Sandra R. Bates**[b,*]

[a]Department of Pathology and the Specialized Center of Research in Atherosclerosis, University of Chicago, Chicago, IL 60637, and [b]Department of Physiology, University of Pennsylvania, G-4 37th and Hamilton Walk, Philadelphia, PA 19104

The response of macrophages and smooth muscle cells to culture in free fatty acid has been compared. Because oleate and linoleate promoted triacylglycerol enrichment of smooth muscle cells, whereas palmitate had little effect, oleate was used for these studies. The kinetics of the accumulation of triacylglycerol produced by oleate was comparable between smooth muscle cells and macrophages. When grown in increasing concentrations of oleic acid at various fatty acid to albumin molar ratios, the extent of triacylglycerol accumulation in both cell types was dependent on the concentration of oleate, the concentration of albumin, and the oleate to albumin molar ratio. However, macrophages contained 2.6-fold more triacylglycerol than smooth muscle cells in the presence of oleate at 0.36 mM or greater and at levels of albumin higher than 0.15 mM. The cellular triacylglycerol content of macrophages was linearly related to the oleate to albumin molar ratio at both a constant albumin concentration and a constant oleate concentration, whereas the accumulation of triacylglycerol in smooth muscle cells showed a curvilinear relationship. When cells were preloaded with triacylglycerol, smooth muscle cells showed a greater loss of lipid when exposed to albumin than macrophages did. Over a two-hr time period, macrophages incorporated twice as much labeled fatty acid as smooth muscle cells. Thus, while smooth muscle cells and macrophages showed similar responses to exogenous fatty acid and albumin, there were also significant quantitative distinctions.

Lipids 23, 641–646 (1988).

One of the principal sources of lipid for cells grown in tissue culture is fatty acids derived from the serum in the medium (1). Most of the plasma fatty acids are esterified in the form of triacylglycerol, phospholipids and cholesteryl esters, with a small portion found as free fatty acid bound to albumin. Due to their high turnover rate, free fatty acids provide a significant portion of the lipid requirements of tissues (2,3). Cells in culture readily take up free fatty acids from the medium via an energy-independent process. Once the fatty acids are incorporated into the cell, they are either oxidized or esterified (4). Free fatty acid transport within the cell probably is mediated by the long chain fatty acid-binding "Z" protein (5,6).

The two primary sources of fatty acids for the arterial wall cells include the free fatty acids present as such in the plasma and the free fatty acids that result from the hydrolysis of chylomicrons and very low density lipoproteins (VLDL) through the action of lipoprotein lipase either on the luminal face of the blood vessel or from resident macrophages. Several past and recent observations provide suggestive evidence that these may be elevated or altered in atherosclerosis. A) Numerous investigations have demonstrated either an elevation in plasma fatty acid concentration or an increase in the plasma free fatty acid to albumin molar ratio in patients who have coronary heart disease or who demonstrate several of the risk factors associated with the disease such as diabetes mellitus, smoking, aging and stress (7–11). B) The endothelium of the diseased vessel wall is more permeable to albumin, the carrier of fatty acids (12,13). C) Atherosclerotic aortas demonstrate an increase in lipoprotein lipase activity that would increase the arterial free fatty acid content (14). Macrophages, found in greater numbers in plaques (15, 16), also may contribute to the fatty acid pool of the vessel wall because they have been shown to secrete lipoprotein lipase (17). D) Finally, in our previous studies we found that the metabolism of normal triacylglycerol-rich VLDL by macrophages, in the presence of albumin, resulted in an enrichment of the medium with free fatty acids (18). We have shown that these fatty acids produced triacylglycerol accumulation in smooth muscle cells (19), indicating that the interaction of these two cell types in the diseased blood vessel wall may be a significant determinant in local lipid accumulation. Because smooth muscle cells and macrophages are the principal cell types of the atherosclerotic lesion, their response to exogenous free fatty acids and the resultant triglyceride accumulation may prove important in the disease process, particularly in view of the report of Adelman et al. (20) that the triglyceride content of cells influences their ability to clear intracellular cholesteryl esters.

Smooth muscle cells and macrophages differ greatly in their metabolism of lipids. Smooth muscle cells obtain cholesterol from low density lipoproteins (LDL). LDL uptake is mediated by cell surface receptors that also will bind VLDL (21–23). In contrast, macrophages probably have few LDL receptors, but contain receptors for triacylglycerol-rich VLDL and cholesteryl ester-rich, beta-migrating VLDL (β-VLDL). Although smooth muscle cells will accumulate some cholesteryl esters when grown with LDL isolated from hyperlipemic animals, these levels are not comparable with the massive levels of cholesteryl esters found in macrophages exposed to β-VLDL from animals on a high-fat, high-cholesterol diet (24). In addition, macrophages store large amounts of triacylglycerol when incubated with normal triacylglycerol-rich VLDL, whereas smooth muscle cells show only slight changes in triacylglycerol content (18). Thus, it was expected that the two cell types would show differences in their metabolism of fatty acids. This study examines the response of these two cell types to exogenous free fatty acid and reports on the differences in their capacity for triacylglycerol production, accumulation and turnover.

Abbreviations: BME, Basal Medium of Eagle; BSA, bovine serum albumin; B-VLDL, beta-migrating very low density lipoprotein; CE, cholesteryl ester; DMEM, Dulbecco's Modified Eagle's Medium; FA, fatty acid; FFA, free fatty acid; J774, macrophages; LDL, low density lipoproteins; PBS, phosphate-buffered saline; PL, phospholipid; SMC, smooth muscle cells; TG, triacylglycerol; VLDL, very low density lipoproteins.

MATERIALS AND METHODS

Tissue culture. Arterial medial smooth muscle cells were obtained from outgrowths of explants from the thoracic aorta of Macaca mulatta monkeys (rhesus) as described (25,26), grown in Basal Medium of Eagle (BME) with 5% bovine calf serum (K.C. Biological, Lenaxa, KS), and used between the third and sixth passages (0.2–1.0 mg protein/flask). Experiments were carried out in 25 cm^2 flasks (Falcon) in a volume of two ml per flask.

The macrophage-like cell line J774 A.1 (J774) (27) was purchased from the American-Type Culture Collection and was maintained in Dulbecco's Modified Eagle's Medium (DMEM, GIBCO, Grand Island, NY) containing 10% heat-inactivated fetal bovine serum (K.C. Biological). Experiments were performed in Multiwell tissue culture plates (12 wells/plate, 0.2–0.6 mg protein/well) at a volume of 1 ml per well. J774 cells were chosen as a model for macrophages because their lipid metabolism has been shown to resemble that of several types of macrophages. For example, mouse peritoneal macrophages and J774 cells secrete lipoprotein lipase (18,28), show similar rates of cholesterol esterification upon exposure to β-VLDL (29), accumulate comparable amounts of triacylglycerol upon exposure to normal VLDL (18) or oleate (30), and demonstrate the same rate of release of labeled free fatty acid (30). Unlike mouse peritoneal macrophages, J774 cells have LDL receptors and, in this regard, they resemble monocyte macrophages (31).

At the start of an experiment, cells were washed twice with sterile phosphate-buffered saline (PBS). One or 2 ml of test medium consisting of DMEM or BME plus additions was added, and the cells were incubated for the appropriate time periods in a 5% CO_2 atmosphere at 37 C. To terminate an experiment, cells were washed three times with PBS and removed from the well by exposure to 0.1 N NaOH for 20 min at room temperature. This brief treatment with NaOH does not hydrolyze intracellular triglycerides or cholesteryl esters. Those dissolved cells sampled for extraction were immediately neutralized with concentrated acetic acid.

Fatty acids and radiolabeled compounds. Fatty acid-free fraction V bovine serum albumin (BSA) was purchased from Miles Labs (Elkhart, IN). Lipids were procured as follows: oleic acid (18:1) and palmitic acid (16:0) from Sigma Chemical Co. (St. Louis, MO), linoleic acid (18:2) from Supelco (Bellefont, PA), [1-C^{14}] oleic acid (57 Ci/mol) from Amersham/Searle (Arlington Heights, IL), [4-^{14}C]cholesterol (54 Ci/mol) and [1,2 − ^{3}H (N)] cholesterol (54.8 Ci/mol) from New England Nuclear (Boston, MA).

Fatty acids were complexed to BSA according to the procedure of St. Clair et al. (32). Fatty acids dissolved in 95% ethanol and dried down under N_2, were bound to 17% BSA in phosphate-buffered saline at 37 C at various molar ratios and concentrations. These solutions were sterilized by filtration through a 0.45 μm Miller-HA filter (Millipore). The experiments were performed using 25, 50, 100, 200 and 300 μg/ml oleate or 0.09, 0.18, 0.36, 0.71 and 1.07 mM oleate.

Analysis. Cells and media were extracted using the method of Bligh and Dyer (33). The triacylglycerol and free fatty acid content of the cells and media were quantitated using the method of Marsh and Weinstein (34) as modified by Kritchevsky et al. (35). Briefly, the extracted lipids were separated on Silica Gel G glass thin layer chromatography plates (Fisher Scientific, Pittsburgh, PA), developed with petroleum ether/ethyl ether/acetic acid (75:25:1, v/v/v), scraped, charred with sulfuric acid, and analyzed spectrophotometrically. [4-^{14}C]Cholesterol added during the extraction served as an internal standard, and results were corrected for recovery (mean recovery = 80%).

[4-^{14}C]Oleate incorporation into cholesteryl esters, triacylglycerol, fatty acids and phospholipids were measured by separating the lipids on silica gel IB2 plastic thin layer chromatography sheets (Baker, Phillipsburgh, NJ). The sheets were then cut and counted. [1,2 − ^{3}H (N)] cholesterol served as an internal standard (26). Protein was determined by the method of Lowry et al. (36), and triacylglycerol content of cells is expressed as n mol/mg cell protein based on the molecular weight of glycerol trioleate (mw. 886).

RESULTS

In recent studies, we have shown that free fatty acids will promote triacylglycerol accumulation in macrophages and smooth muscle cells (18,19) as had been demonstrated in other cell types (37,38). To determine whether different fatty acids would cause variations in intracellular triacylglycerol levels, the ability of oleic acid (18:1) to affect the triacylglycerol content of smooth muscle cells was compared with that of linoleate (18:2) and the saturated fatty acid palmitate (16:0) at two different fatty acid to albumin molar ratios. As seen in Figure 1, both oleate and linoleate promoted triacylglycerol enrichment of the smooth muscle cells, although oleate was more effective. In contrast, palmitate had little effect on the triacylglycerol content of the smooth muscle cells at either fatty acid to albumin molar ratio. Thus, oleate was used for subsequent experiments.

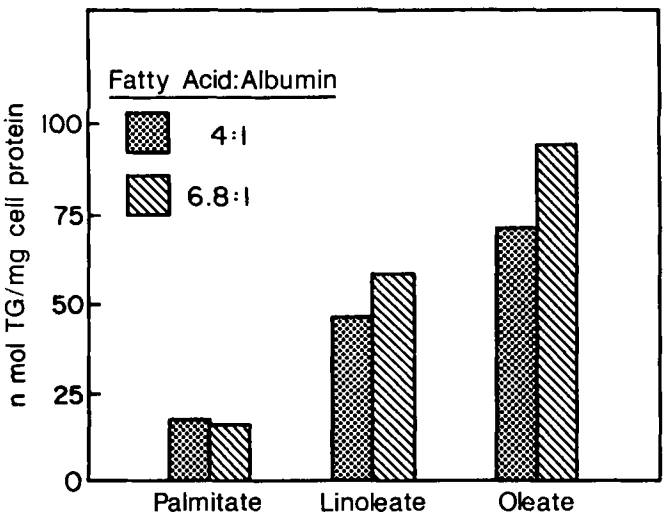

FIG. 1. The influence of various fatty acids on the triacylglycerol content of smooth muscle cells. Smooth muscle cells were incubated for 24 hr with 200 μg/ml of palmitate (0.78 mM), linoleate (0.71 mM) or oleate (0.71 mM), at two different fatty acid to albumin molar ratios. Data are the average of duplicate determinations. TG, triacylglycerol.

A comparison of the increment in cellular triacylglycerol content of monkey arterial smooth muscle cells and J774 macrophages exposed to 0.71 mM oleate for 24 hr at a fatty acid to albumin molar ratio of 4:1 is illustrated in Figure 2. Incubation in oleate stimulated the formation of oil red 0 positive droplets in both cell types (data not shown). Under these conditions, the final intracellular triacylglycerol levels were greater in the J774 macrophages. However, when the two cell types were exposed to the same oleate concentration (0.71 mM oleate) but at a higher oleate to albumin molar ratio (6.8:1, oleate/albumin), the extent of triacylglycerol accumulation after 24 hr was similar in the smooth muscle cells and macrophages. To summarize several experiments performed under these latter conditions, smooth muscle cells contained 166 ± 41 n mol triacylglycerol/mg cell protein (x ± S.D., n = 14) after 24 hr incubation with oleate (6.8:1, oleate/albumin) and macrophages contained 194 ± 28 n mol triacylglycerol/mg cell protein (x ± S.D., n = 8).

Figure 3 illustrates that the kinetics of enrichment in triacylglycerol mass was similar between smooth muscle cells and macrophages. There was an initial lag period of two to four hr for the smooth muscle cells or a slow accumulation in macrophages, followed by a rapid increase in triacylglycerol levels in both cell types up to 8 to 10 hr; this was followed by a slower but continuous rise in lipid up to 24 hr of incubation.

To characterize the difference in the oleate-stimulated enrichment of cellular triacylglycerol between macrophages and smooth muscle cells in greater detail, the two cell types were grown in increasing concentrations of oleic acid at various fatty acid to albumin molar ratios. As shown in Figures 4 and 5, the extent of triacylglycerol accumulation in both cells was dependent on the concentration of albumin and the oleate to albumin molar ratio.

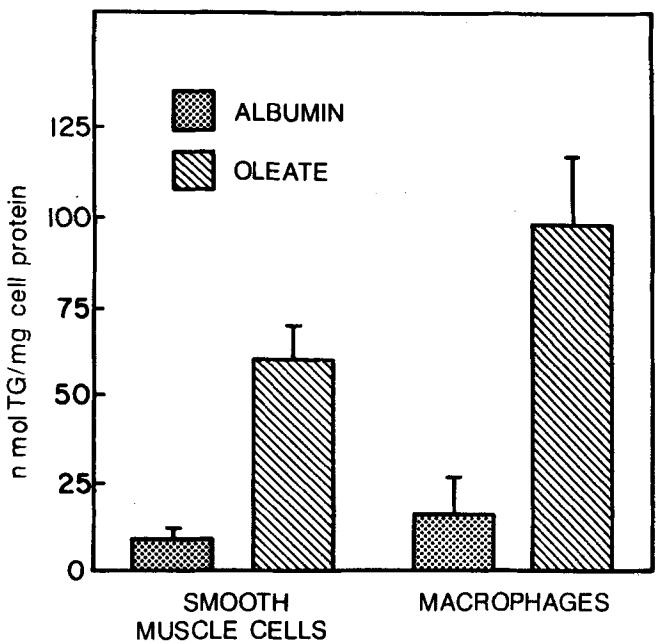

FIG. 2. Stimulation of intracellular triacylglycerol accumulation by oleate. Smooth muscle cells and J774 macrophages were incubated for 24 hr with oleate/albumin at a molar ratio of 4:1 and a concentration of 0.71 mM oleate or with albumin (0.15 mM). x ± S.D. (n = 6); TG, triacylglycerol.

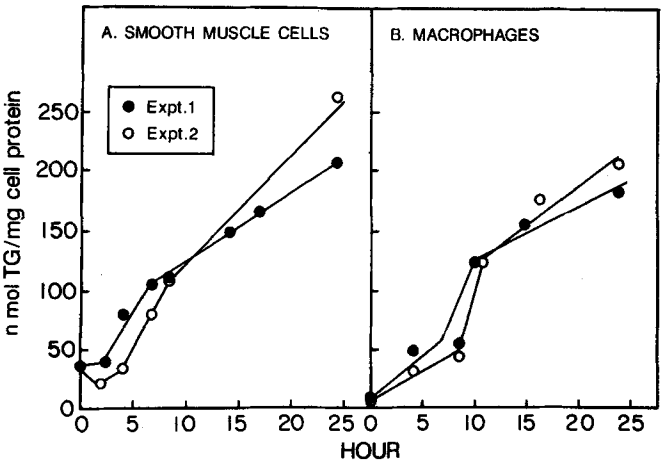

FIG. 3. Comparison of time course of triacylglycerol enrichment between smooth muscle cells and macrophages. Smooth muscle cells or J774 macrophages were incubated with 0.71 mM oleate at an oleate/albumin ratio of 6.8 to 1 for the indicated time period. The values are the average of duplicate determinations. Because the triacylglycerol content differed between experiments in the same cell type, the data in Expt. 1 and 2 were adjusted to the 8 or 10 hr time points, respectively, to compare the rates of triacylglycerol accumulation (factor for J774 = 0.4, smooth muscle cells = 2.5).

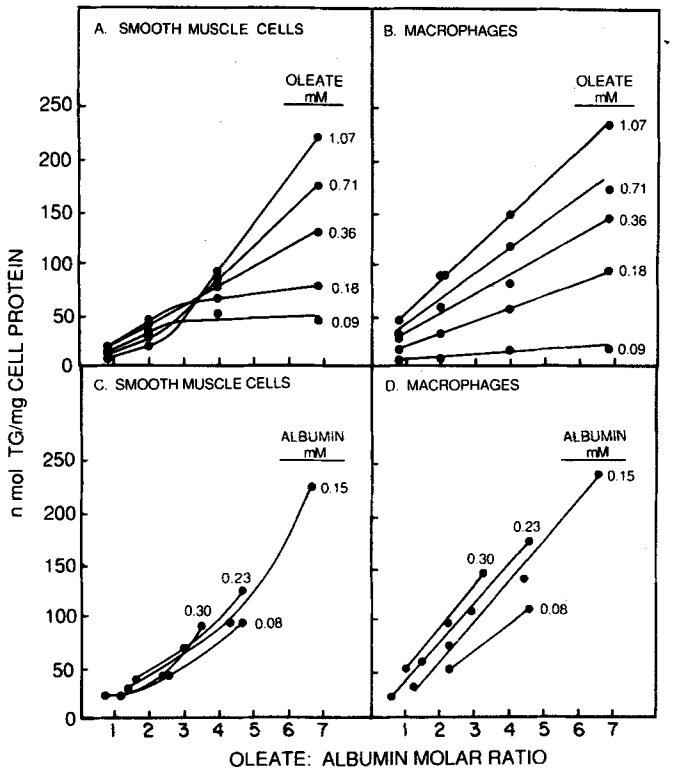

FIG. 4. Effect of oleate and albumin concentration at various oleate to albumin molar ratios on intracellular triacylglycerol content. Smooth muscle cells (A and C) and J774 macrophages (B and D) were incubated for 24 hr with the indicated concentration of oleate complexed to albumin at several molar ratios. Average of six experiments, each performed in duplicate. FA, fatty acid (oleate); BSA, bovine serum albumin; TG, triacylglycerol. The data from the same experiments are plotted in terms of the oleate (A and B) or albumin (C and D) concentration in the media.

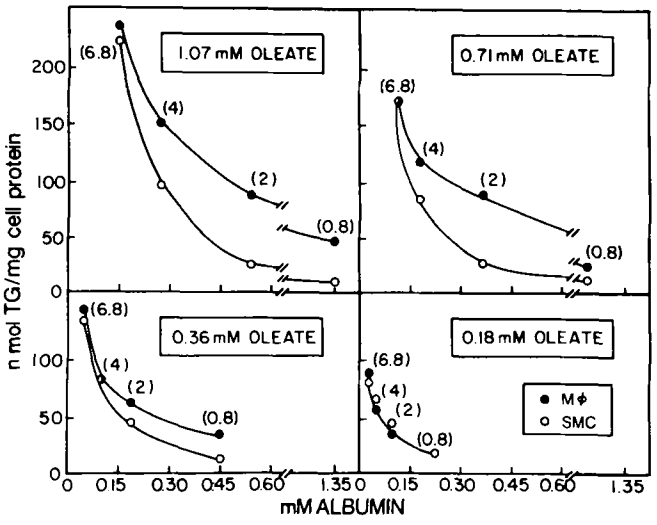

FIG. 5. The effect of increasing media albumin concentrations at a constant oleate concentration on the extent of triacylglycerol accumulation in macrophages and smooth muscle cells. The data are replotted from Figure 4. The molar ratio of oleate to albumin is in parentheses.

The relationship of the exogenous oleic acid concentration to the extent of intracellular triacylglycerol accumulation was complex. At a ratio of 6.8 mol of oleic acid per mole of albumin, smooth muscle cell triacylglycerol content (Fig. 4A) was linearly related to the exogenous oleate concentration up to 0.36 mM oleate. Greater amounts of oleate in the medium continued to promote higher levels of intracellular triacylglycerol, although to a lesser extent, with no indication of saturation. A similar result was shown in macrophages (Fig. 4B, oleate/albumin, 6.8:1).

At oleate to albumin ratios less than 6.8 to 1, the pattern of triacylglycerol accumulation showed three important differences between the two cell types. First, at the two lowest fatty acid to albumin molar ratios, 0.8:1 and 2:1, the smooth muscle cells contained more triacylglycerol at 0.18 mM oleate than at a six-fold higher concentration of oleate, 1.07 mM oleate (Fig. 4A). With macrophages (Fig. 4B), on the other hand, as the medium concentration of oleate increased, the triacylglycerol content of the macrophages rose accordingly, regardless of the oleate to albumin molar ratio. Second, it has been shown that more fatty acid is loosely bound to albumin at a 6.8:1 molar ratio of fatty acid to albumin than at a 2:1 molar ratio (39). By replotting the data holding the concentration of albumin constant, it became clear that the accumulation of smooth muscle cell triacylglycerol (Fig. C) was parallel to the expected amount of fatty acid loosely bound to albumin and thus available for uptake by the cells. This was not the case for macrophages (Fig. D). Finally, Figure 5 directly compares the triacylglycerol enrichment of smooth muscle cells and macrophages at equivalent levels of oleate and albumin. It was apparent that the response of the two cell types to the presence of exogenous albumin also differed. At constant oleate concentrations in the media of 1.07, 0.71 or 0.36 mM (Fig. 5), as the level of albumin is raised, the amount of triacylglycerol in both cells decreased. However, at concentrations of oleate of 0.36 mM or greater and at levels of albumin higher than 0.15 mM, macrophages contained 2.6-fold more triacylglycerol than smooth muscle cells (range = 1.4–5.0).

From the results in Figure 5, it appeared that one of the factors making a contribution to the regulation of intracellular triacylglycerol levels in the two cell types was a difference in their response to albumin in the medium. To examine this question directly, the two cell types initially were exposed to oleate to load the cells with triacylglycerol. When subsequently exposed to 0.15 mM albumin for 24 hr, smooth muscle cells preloaded with triacylglycerol demonstrated a greater loss of lipid (80%) than did similarly treated macrophages (10%), as shown in Table 1.

Differences in the triacylglycerol metabolism between the two cell types also could be attributed to a variation in their uptake of fatty acid. Thus, smooth muscle cells and macrophages were incubated with labeled oleate at a high oleate to albumin molar ratio (6.8 to 1) to reduce the effect of albumin. Early time points were chosen to minimize alterations in specific activity due to the hydrolysis of lipids. The results in Table 2 indicate that the labeled fatty acid was rapidly incorporated into phospholipid and triacylglycerol by both cells. However, in the first two hr, twice as much oleate was taken up by the J774 macrophages as compared with the smooth muscle cells, with the differences between the two cells reflected in the greater incorporation of oleate into triacylglycerol and phospholipid in macrophages.

DISCUSSION

This study has demonstrated that the metabolism of fatty acids by macrophages and smooth muscle cells have some common characteristics although there are significant quantitative differences. Exposure of both cell types to oleic acid at 0.18 mM (50 μg/ml) or greater and at a 2:1 oleate to albumin molar ratio or greater produced substantial intracellular triacylglycerol accumulation. Such a response to elevated media fatty acid concentrations has been found in a number of studies using other cell types (37,38). The pattern of triacylglycerol accumulation over time for macrophages and smooth muscle cells also was similar. Both cell types became enriched in

TABLE 1

Loss of Cellular Triacylglycerol Due to Incubation with Albumin

	n mol TG/mg cell protein			
		24 hr with:		% Loss of TG due to albumin
Cell	0 hr	DMEM (a)	Albumin (b)	(b)−(a) / (a)
J774	121 ± 5	91 ± 8	82 ± 12	10%
SMC	98 ± 7	115 ± 10	23 ± 19	80%

J774 and smooth muscle cells were loaded with triacylglycerol by incubation with 0.71 mM oleate (oleate:BSA molar ratio of 4:1, 0.18 mM BSA) for 24 hr = 0 hr. These media were removed, and the cells were incubated for an additional 24 hr in 0.15 mM BSA. The results represent the mean ± SD of two experiments performed in duplicate or triplicate. TG, triacylglycerol.

TABLE 2

Uptake of Labeled Free Fatty Acid by Smooth Muscle Cells and Macrophages

Hour	Cell	cpm × 10^{-3} in lipid/mg cell protein				
		TG	PL	FFA	CE	Total
1	SMC	18.0 ± 1.6	6.6 ± 0.6	3.2 ± 0.3	0.1 ± 0.0	27.9 ± 2.5
	J774	39.3 ± 4.4	12.5 ± 0.6	3.4 ± 0.6	1.8 ± 0.2	57.0 ± 5.4
2	SMC	26.7 ± 5.6	11.2 ± 0.8	2.0 ± 0.3	0.1 ± 0.0	40.0 ± 6.6
	J774	56.0 ± 7.1	18.1 ± 2.5	3.1 ± 0.2	3.2 ± 0.2	80.4 ± 8.8

Smooth muscle cells (SMC) and macrophages (J774) were incubated for the indicated time period with 0.71 mM ^{14}C-oleate (oleate:albumin molar ratio of 6.8:1). TG, triacylglycerol; PL, phospholipid; FFA, free fatty acid; CE, cholesteryl ester; total, sum of the ^{14}C-oleate cpm incorporated into the lipids. The data are the mean ± SD of triplicate determinations and are representative of the four experiments performed.

triacylglycerol in three phases, an initial slow rise, followed by a rapid increase and a plateau.

Other aspects of fatty acid metabolism by the two cell types were quite different. The extent of triacylglycerol enrichment was more pronounced in the J774 macrophages than in monkey smooth muscle cells under conditions in which the albumin concentration in the medium was greater than 0.15 mM and the oleate concentration was greater than 0.18 mM (Fig. 5). Differences in the degree of triacylglycerol accumulation between different cell types also was noted in a comparative study of human fibroblasts and guinea pig smooth muscle cells where fibroblasts were less reactive than the smooth muscle cells (38).

The extent of triacylglycerol accumulation in cells exposed to free fatty acid bound to albumin is controlled by several factors that govern the uptake of free fatty acid, the activity of the triacylglycerol synthetase and the mobilization of intracellular triacylglycerol. The dissociation of fatty acid from albumin currently is felt to be the rate-limiting step for the uptake of fatty acids by cells (40). Serum albumin binds fatty acid via six binding sites involving three primary and three secondary sites (39). At a constant free fatty acid concentration, a greater proportion of free fatty acid would be associated with albumin via lower affinity sites at a 6.8 to 1 molar ratio of fatty acid to albumin than would be the case at a 2:1 molar ratio. The uptake of fatty acids by cells was shown to be related to the concentration of loosely bound fatty acid in a study examining the one-min uptake of a fatty acid analogue, 3,3,12,12-tetramethylmyristic acid (41). The uptake of the analogue was shown to have a curvilinear relationship to the medium fatty acid to albumin molar ratio at either a constant albumin or a constant fatty acid medium concentration and was greater at the higher fatty acid to albumin molar ratios (41). The accumulation of triacylglycerol in smooth muscle cells at fixed albumin concentrations up to 0.3 mM showed the same curvilinear relationship with increasing oleate: albumin molar ratios (Fig. 4C). Such data might indicate that the accumulation of triacylglycerol in the smooth muscle cells was related to the availability of loosely bound free fatty acid in the media. However, only at the higher fixed oleate concentrations (0.71 and 1.07 mM) was the oleate/albumin molar ratio related in curvilinear fashion to the triglyceride accumulation (Fig. 4A). At the lower oleate concentrations, the exogenous levels of oleate were not sufficient to promote further triacylglycerol accumulation even when the amount of unbound fatty acid was elevated by increasing the fatty acid to albumin molar ratio.

Macrophages responded quite differently to these challenges than smooth muscle cells. Macrophage triacylglycerol content was linearly related to the oleate to albumin molar ratio at both a constant albumin concentration (Fig. 4D) and a constant oleate concentration (Fig. 4B). These data suggest that the accumulation of triacylglycerol in macrophages was related to the total amount of free fatty acid in the media, regardless of its binding affinity to albumin. One possible explanation for these observations is that unlike the smooth muscle cell, the macrophage takes up the albumin and fatty acid complex intact and that the fatty acid only leaves the complex once the latter is inside the cell.

The hydrolysis of cellular triacylglycerol and its mobilization from the cell is felt to be regulated by the concentration of exogenous albumin, which functions as a carrier for the released free fatty acid. At a constant oleate concentration, both cells contained less triacylglycerol as the levels of albumin in the media increased (Fig. 5), but this effect was more pronounced in smooth muscle cells. The ability of albumin to mobilize more triacylglycerol from smooth muscle cells than from macrophages may have contributed to the differences in intracellular triacylglycerol levels observed in these two cell types. The mechanism for the mobilization of triacylglycerol from cytoplasmic droplets is not clear. Most cells contain an acid acylhydrolase in lysosomes. In addition, macrophages have been shown to contain an active neutral triglyceride lipase in the cytosol (42). Loss of intracellular triacylglycerol with a concomitant appearance of free fatty acid in the media in the presence of exogenous albumin has been demonstrated in both J774 and mouse peritoneal macrophages (19,30). Whether smooth muscle cells also contain a neutral lipase and the relative sensitivity of both enzymes to the presence of exogenous albumin in the two cell types remains to be determined.

In summary, in comparison with smooth muscle cells, macrophages were shown to incorporate more free fatty acid over a short time period, accumulate more triacylglycerol under certain conditions and, upon exposure to

albumin, retain more triacylglycerol. In addition, macrophage triacylglycerol accumulation was linearly related to the oleate:albumin molar ratio, whereas smooth muscle cell triacylglycerol accumulation showed a curvilinear relationship. The mechanism for such differences between the two cell types remains to be elucidated. Although differences in the activity of intracellular lipases are a possibility, another interesting alternative involves the fatty acid-binding "Z" protein (5,6). The results are consistent with the hypothesis that the macrophage "Z" protein has a higher affinity for fatty acids than does the smooth muscle cell protein or that there is more "Z" protein in macrophages. Over a two-hr time period at a high oleate concentration to rapidly saturate the "Z" protein, macrophages incorporated twice as much labeled fatty acid as smooth muscle cells. Smooth muscle cells, which readily lost their intracellular triglyceride as fatty acid to albumin, did not appear to take up the fatty acid bound with high affinity to albumin. Finally, macrophages, which did not readily give up intracellular fatty acid to albumin from triacylglycerol hydrolysis, also were able to take up fatty acid from albumin in the media regardless of the molar ratio of fatty acid to albumin.

It was of interest that saturated fatty acids (palmitate, 16:0) supported a much lower level of triacylglycerol accumulation in smooth muscle cells than did unsaturated fatty acids (oleate, 18:1 and linoleate, 18:2). Palmitate binds more tightly to albumin than oleate or linoleate (39), making it less available to the cell for triacylglycerol synthesis. Other studies also have shown that the degree of saturation of fatty acids will influence the degree of triacylglycerol synthesis and accumulation (37,38,43).

Evidence that changes in fatty acids occur with atherosclerosis is accumulating (7-17). Whether the presence of free fatty acids in the arterial wall or their ability to promote the accumulation of intracellular triglycerides contributes to the atherogenic process remains to be determined. We have found that the presence of oleate is associated with a further increase in the cholesteryl ester content of smooth muscle cells exposed to hyperlipemic LDL (data not shown). Recently, an increased triacylglycerol content has been shown to influence the rate of clearance of cholesteryl esters from rat hepatomas (20) and the rate of transport of albumin across endothelial cells (44).

[Received November 3, 1987; Revision accepted March 8, 1988]

Influence of Dietary Soybean and Egg Lecithins on Lipid Responses in Cholesterol-fed Guinea Pigs[1]

Barbara C. O'Brien* and **Sheila M. Corrigan**
Department of Biochemistry and Biophysics, Texas Agricultural Experiment Station, Texas A&M University System, College Station, TX 77843

The comparative influence on plasma and tissue lipids of dietary soybean and egg lecithins, which have contrasting fatty acid compositions, was studied in the hypercholesterolemic guinea pig. The polyunsaturated to saturated fatty acid (P/S) ratios of the soybean and egg lecithins were 3.4 and 0.38, respectively. Hypercholesterolemia was induced by feeding guinea pigs a purified diet that contained 15% lard enriched with 0.5% cholesterol. Subsequently, guinea pigs were fed for six wk the same diet supplemented with either soybean or egg lecithin as 7.5% of the diet. A control group continued to be fed the lecithin-free diet. Parameters measured included body weight and relative liver weight; in plasma, total cholesterol, high density lipoprotein cholesterol (HDLC), phospholipid, and nonesterified cholesterol; in liver, total fat, cholesterol, and the specific activity of the catabolic enzyme cholesterol 7α-hydroxylase; (EC 1.14.13.17); and in the aorta, cholesterol. Among the most noteworthy observations were the 49% decrease in total plasma cholesterol of the soybean lecithin group without decreasing HDLC and the 177% increase in HDLC of the egg lecithin group without a significant increase in total cholesterol compared with those values in the control group. These data suggest that dietary lecithin is particularly effective in increasing the HDLC/total cholesterol ratio in plasma. However, the absolute concentrations of those plasma lipids seem to depend upon the fatty acid composition of the lecithin.
Lipids 23, 647–650 (1988).

Lecithin, primarily from soybeans, is widely used as a hypocholesterolemic diet supplement, although experimental evidence to support that use is inconsistent (1–3). More recent observations suggest that soybean lecithin has greater effectiveness in increasing high density lipoprotein (HDL) cholesterol than in lowering total plasma cholesterol (4–6). This is somewhat surprising because soybean lecithin contains a high level (60–70%) of polyunsaturated fatty acids (PUFA), and dietary PUFA incorporated into triglycerides tend to lower HDL cholesterol (7). However, Childs et al. (5) have presented data that suggest dietary soybean lecithin elicits some plasma lipid responses that are independent of its fatty acid composition.

Eggs are a rich source of dietary lecithin, which is approximately 6.8% (w/w) of a chicken egg yolk (8). The fatty acid composition of egg lecithin is in sharp contrast to that of soybean lecithin as revealed by the polyunsaturated to saturated fatty acid (P/S) ratios of these two sources of dietary lecithin: soybean, 3.4; egg, 0.38.

This investigation was designed to compare the influence of soybean and egg lecithins on plasma lipids and lipoproteins and on the cholesterol contents of liver and aorta in hypercholesterolemic guinea pigs. The guinea pig was chosen as experimental animal because of its normally low HDL, which is similar in composition to human HDL (9).

MATERIALS AND METHODS

Animals. Female English shorthair guinea pigs (Hilltop Laboratory Animals, Scottdale, PA) weighing 400–500 g were housed in polycarbonate cages in an environmentally controlled room that was illuminated from 0600 to 1800 hr.

Frequently, guinea pigs will starve rather than eat purified diets. The mature guinea pigs used in this study were trained to accept a purified diet (20–25 g/day) by gradually changing their food from stock guinea pig diet (Harlan/Sprague Dawley Co., Inc., Madison, WI) to purified diet. During the two-wk period before the experiment began, the guinea pigs were fed, sequentially, ground mixtures of stock/purified (w/w) that were 3:1, 1:1, 1:3, and finally the unadulterated purified diet. All the guinea pigs followed the same training time schedule. They maintained their body weights during the training period.

Diets. The diets were prepared commercially (Dyets, Inc., Bethlehem, PA) according to the formulations shown in Table 1. The cholesterol-free diet (BAS) was used in training the guinea pigs to accept a purified diet. The cholesterol-supplemented diet of purified ingredients without lecithin (NL) was used to induce hypercholesterolemia in the guinea pigs. Other investigators, who used 1% or 1.6% dietary cholesterol, observed aberrant serum lipoprotein responses in the guinea pig (10–12). The level of dietary cholesterol in this study, 0.5%, was judged to be sufficient to produce hypercholesterolemia and to be consistent with the level used by Wong et al. (4) in studying the effect of dietary soybean lecithin on plasma lipids of hyperlipemic rhesus monkeys.

For the two lecithin-containing diets, lecithin replaced 4% of the lard and 3.5% of the sucrose compared to the NL diet. The dietary lecithins were from soybeans (SL diet) and from eggs (EL diet) and were provided by the American Lecithin Company (Atlanta, GA) and the Asahi Chemical Industry Company (Tokyo), respectively. The phospholipid and fatty acid compositions of the soybean and egg lecithins are given in Table 2.

Because phospholipids are highly susceptible to oxidation (15), the diets were stored at −20 C. The diets were assayed weekly for malondialdehyde (MDA), a peroxidation product, using thiobarbituric acid. In preliminary testing, the lecithin-containing diets were assayed for MDA content following exposure to ambient conditions for 24 and 48 hr. MDA was present in measurable quantities only after 48 hr.

[a]Analyses according to Rouser et al. (13).

[b]Determined by gas liquid chromatography (14).

Experimental design and methods. Guinea pigs that had been trained to accept a purified diet were fed the NL diet for six wk to induce hypercholesterolemia. The animals then were randomly assigned to one of three diet groups (eight guinea pigs/group): SL, EL or NL (control group) and fed the assigned diet for six wk. Fresh food was provided daily. Body weights were recorded weekly.

The guinea pigs were anesthetized with carbon dioxide and killed by decapitation. Blood was collected from the neck wound into chilled centrifuge tubes containing 1 mg/ml ethylenediamine tetraacetic acid disodium salt (EDTA) as anticoagulant. Livers were rapidly excised and placed in ice-cold beakers. Aortas were removed intact from the heart to approximately 1 cm below the point of bifurcation and placed in 0.15 M NaCl. Plasma was isolated by centrifugation (2,000 × g) at 5 C for 30 minutes. The HDL fraction was separated from 1-ml aliquots of plasma following manganese-heparin precipitation of very low density (VLDL) and low density lipoproteins (LDL) (16). Total lipids were extracted from 1 ml of plasma according to Kates for the determination of nonesterified cholesterol (FC) and phospholipids (PL) (17). Plasma FC was separated as the digitonide (18). Total plasma cholesterol (TC), FC and HDL cholesterol (HDLC) were determined spectrophotometrically as described (19). Plasma PL were determined spectrophotometrically according to Rouser et al. (13).

For the isolation of microsomes, a six-gram portion of liver was homogenized with 5 volumes of ice-cold 0.1 M potassium phosphate buffer (pH 7.4) containing 20 mM nicotinamide and 1.0 mM EDTA with a Potter-Elvehjem homogenizer equipped with a teflon pestle. Microsomes were prepared from this liver homogenate as described by Mitropoulos and Balasubramaniam (20); the microsomal enzyme cholesterol 7α-hydroxylase (EC 1.14.13.17) was assayed according to Hassan et al. (21). The remainder of the liver tissue was frozen at −20 C to be used later for the determination of total fat and cholesterol.

The liver fat was extracted by the method of Folch (22) and determined gravimetrically. Cholesterol was determined in the lipid extract (1%, w/v, chloroform solution) by the method cited above for plasma.

Aortas were carefully stripped of adventitial fat and other adherent tissue. Aortas from half of the animals in each treatment group were preserved and stained with a lipophilic stain (23). Cholesterol also was determined after the weighed aortas were digested in refluxing 12% (w/w) ethanolic KOH for one hr. Cholesterol was determined in the hexane extract of the nonsaponifiable fraction (16).

Student's t-test was used to evaluate the significance of differences between the SL and NL treatments and between the EL and NL treatments (24).

RESULTS AND DISCUSSION

The final body weights and relative liver weights (as % body weight) for the NL, SL and EL treatment groups are given in Table 3. Although whole body weight did not appear to depend on diet composition, liver weights were significantly higher in animals consuming the EL diet.

Average plasma lipid concentrations are presented in Table 3. Guinea pigs that were fed only the NL diet for the entire treatment period (12 wk) had an average TC of 265 ± 39 mg/dL, a three-fold increase assuming an initial TC of 81 mg/dL, the value reported for stock-fed guinea pigs (10). The SL diet, but not the EL diet, attenuated that increase: SL, 131 ± 19 mg/dL and EL,

291 ± 35 mg/dL. The EL diet had a dramatic effect on HDLC. Guinea pigs fed only on the NL diet had an average HDLC level of 47 ± 6 mg/dL. Hypercholesterolemic guinea pigs fed the SL diet for six wk had HDLC of 58 ± 13 mg/dL, which is a change of marginal significance. However the EL diet elicited a 2.8-fold increase in HDLC to 130 ± 20 mg/dL. It is interesting to note that the ratio of HDLC/TC in plasma is 0.44 and 0.45 for the SL and EL groups, respectively, whereas that ratio is 0.18 for the NL group.

The TC response in guinea pigs fed the SL diet and the HDLC response in guinea pigs fed the EL diet were qualitatively consistent with the expected responses to polyunsaturated and saturated diet fats, respectively. That is, polyunsaturated diet fat tends to lower TC, and saturated diet fat tends to increase HDLC (25). However, the magnitude of the effect of the SL diet on TC exceeded what one would expect from the relatively small contribution of polyunsaturated fat (5.2%) to the diet from soybean lecithin. Likewise, the 3.6% saturated fatty acid esters in the diet from in the egg lecithin probably would not result in the enormous increase in HDLC if that quantity were added as dietary triglycerides. Other investigators have supported that prediction. Childs et al. (5) could not account for the effects of ingested soybean lecithin on TC and HDLC in normolipidemic humans by replacing the dietary lecithin with triglycerides of equivalent fatty acid composition. Other workers have reported nonequivalent hypocholesterolemic responses when rats ingested soybean lecithin compared with the effect of either soybean triglycerides (26) or corn oil (27).

Dietary lecithin (phosphatidylcholine) is not metabolized like dietary triglycerides. In other words, a mole of lecithin is not equivalent to two-thirds of a mole of triglycerides. Dietary lecithin is hydrolyzed to lysolecithin and fatty acids by phospholipase A_2 in the intestines before absorption (28). Diagne et al. (29) have shown that much of the absorbed lysolecithin is reacylated to the corresponding lecithin in guinea pigs. When Beil and Grundy (27) studied the effects of ingested lecithin on lipoproteins in humans, they found that lecithin, in contrast with dietary triglycerides, promotes VLDL formation, and VLDL is a source of phospholipids and apoprotein for HDL (30). Thus, one might predict an increase in HDLC in response to dietary lecithin, but one would not predict the high level of HDLC in the EL group. As with the hypocholesterolemic response when guinea pigs were fed the SL diet, fatty acids incorporated into lecithins seemed to have an exaggerated effect compared with their effect when ingested as triglycerides.

Included in Table 3 are average plasma concentrations of FC and PL. Because the plasma lipid level was very low for SL-fed animals, the lipid extract from the plasma that was available was insufficient to determine both FC and PL. Therefore, the values of FC and PL shown for the SL group were each the average of four different

guinea pigs. The proportion of esterified plasma cholesterol was not altered by these diet modifications. These data suggest an increase in the PL/FC ratio. Of course, that conclusion is particularly questionable because the components of the ratio were determined from different animals in the diet group. When Wong et al. (4) fed soybean lecithin (92% phosphatidylcholine) to hyperlipemic rhesus monkeys, they observed a reduction in total plasma lipids, especially in LDL cholesterol, but a marginal increase in HDLC and a possible increase in the PL/FC ratio. The results of this investigation using hyperlipemic guinea pigs fed soybean lecithin were qualitatively consistent with those results. In both investigations, highly variable individual responses to lecithin were observed.

The specific activities of cholesterol 7α-hydroxylase (hydroxylase) for groups NL, SL and EL also are included in Table 3. Neither treatment group SL nor EL were significantly different from the control, NL. The inhibition of cholesterol absorption by dietary lecithin has been reported in humans (31) and in rats (32). Although the effect of dietary lecithin on cholesterol absorption could be reflected in a coordinate change in hydroxylase activity (19), these hydroxylase activities (Table 3) suggest no such correlation.

Total liver lipid and liver cholesterol levels in these diet groups are summarized in Table 3. Cholesterol ingested as part of a purified diet tends to exacerbate liver fat and cholesterol accumulations in guinea pigs (22) and in rats (11), compared with the effect of stock diets. Egg lecithin induced a further highly significant increase in liver size that could not be attributed to increased fat accumulation. The total fat content of the EL livers was only marginally higher than that of the NL group. Liver cholesterol, however, was significantly increased in the EL group as compared with the NL group.

When aortas from treatment groups NL, SL and EL were exposed to a lipophilic dye, Sudan IV, no fatty deposits were apparent. Compared with guinea pigs fed the NL diet, dietary SL tended to lower aortic cholesterol, while dietary EL had no effect (Table 3). Aortic cholesterol levels tended to reflect plasma cholesterol levels, which could be the result of passive diffusion. However, the accumulation of cholesterol in the liver appeared to be a concerted process in guinea pigs fed cholesterol-supplemented diets, a process that was exacerbated by dietary EL. Although dietary SL elicited a significant decrease in plasma TC, there was no decrease in liver cholesterol in SL-fed guinea pigs, compared with the NL group.

The results of this investigation provide considerable evidence that dietary phospholipids play a significant role in HDL metabolism; a role that is different from that of dietary triglycerides. At the same time, the "dietary phospholipid effect" is modulated by the fatty acid composition of the dietary phospholipid. Further investigations of the mechanism of these interactions are required.

Malondialdehyde-containing Proteins and Their Relationship to Vitamin E[1]

John D. Manwaring and **A. Saari Csallany***
University of Minnesota, Department of Food Science and Nutrition, 1334 Eckles Ave., St. Paul, MN 55108

A high molecular weight (Sephadex G-15 void volume), water-soluble, fluorescent material that was found to increase significantly in the mouse liver in response to vitamin E deficiency was separated into six proteins by high performance liquid chromatography (HPLC) using a TSK G2000 SW column. One of these proteins increased significantly in concentration due to vitamin E deficiency and had a molecular weight of 20,000 daltons. This protein was found to contain malondialdehyde, an end product of lipid peroxidation, attached to it presumably in a Schiff-base type structure with amino groups. This appears to be the first report in the literature of direct evidence that malondialdehyde is attached to protein in vivo. *Lipids 23,* 651–655 (1988).

The accumulation of fluorescent pigments in tissues of nearly all types of animals under stressful conditions such as vitamin E deficiency and aging is widely accepted (1–9). These compounds have been termed "lipofuscin" or "age" pigments and are believed to be metabolic end products of lipid peroxidation in living systems that may be undergoing steady decomposition or turnover (1, 10–13). They have been postulated as Schiff-base products formed by the condensation of primary amino groups of proteins, nucleic acids or amino acids and malondialdehyde (MDA), a by-product of lipid peroxidation in vitro and in biological systems (14). Due to their lipid origin and staining properties, initial separation and purification of these fluorescent pigments was attempted only from the organic solvent-soluble extract (10,15). The amount of fluorescent material extracted, however, did not totally account for the lipofuscin pigment concentration reported in some tissues (3). Recently, four vitamin E-related fluorescent compounds were reported to occur in the water-soluble portion of mouse tissues (16). The purpose of this study was to elucidate the characteristics and possible identity of one of these compounds, a large molecular weight material, especially as it relates to vitamin E in the diet and to in vivo lipid peroxidation.

MATERIALS AND METHODS

Animals, diets and extraction. Female weanling mice (Strain C57BL/6J, The Jackson Laboratories, Bar Harbor, ME) were fed a vitamin E-deficient or a vitamin E-supplemented diet (30 mg RRR-α-tocopheryl acetate/kg diet) as described (16). After 14 months, the mice were killed by decapitation. The livers were removed, washed with cold saline-phosphate solution, blotted with cheesecloth and frozen at −70 C until they were homogenized and extracted with chloroform/methanol (2:1) and water (16). Water-soluble fluorescent compounds were separated chromatographically using Sephadex G-15 or G-25 (Pharmacia Fine Chemicals, Piscataway, NJ), and initial fluorescence measurements were performed using an Aminco-Bowman Ratio Spectrophotofluorometer (American Instrument Co., Silver Spring, MD) standardized as described (16).

HPLC equipment. Instrumentation for HPLC consisted of a Model 210 injection valve (Beckman Instruments, Inc., Berkeley, CA), a Beckman Model 110A solvent metering pump, a Perkin-Elmer Model 650-10S fluorescence spectrophotometer (Norwalk, CT) equipped with a horizontal, flat, 20 μl capacity, quartz flow cell, a Model SP 8400 variable wavelength ultraviolet/visible detector (Spectra Physics, Arlington, IL) equipped with a 10 μl quartz flow cell and a Model SP4100 computing integrator (Spectra Physics). The analytical columns used were a 0.75 × 30 cm Micropak TSK G2000 SW column (Varian Associates, Inc., Walnut Creek, CA) and a Spherogel TSK G1000 PW column (0.75 × 30 cm, Altex Scientific, Inc., Berkeley, CA). Samples were injected with a 100 or a 200 μl blunt needle Hamilton syringe (Rainin Instrument Co., Inc., Woburn, MA).

Molecular weight determination. The TSK G2000 SW column was calibrated for molecular weight determinations by injecting the following protein standards: catalase (250,000 m.w.), bovine serum albumin (65,000 m.w.), β-lactoglobulin (35,000 m.w.), α-chymotrypsinogen-A (23,200 m.w.), and lysozyme (14,100 m.w.). All standards were eluted at 1 ml/min in 0.066 M phosphate, 0.3 M sodium chloride, 0.02% sodium azide (pH 7.0), and detected at 275 nm/350 nm using the Perkin-Elmer fluorometer. The void volume material (ca. 6 ml) from Sephadex G-15 column chromatography of liver extracts was collected, and 100 μl aliquots were injected onto the TSK G2000 SW column under these same conditions. Using a least squares fit equation to the linear portion of the graph for the standard proteins (log m.w. − 0.17811 × elution volume + 6.13513), the molecular weights of each of the six compounds separating on the TSK column from the Sephadex G-15 void volume peak were determined. All these proteins had excitation/emission maxima at 275 nm/350 nm and were quantified by peak height measurement for both vitamin E–sufficient and deficient groups of mice and compared using Student's two-tailed t-test (17).

Hydrolysis for release of MDA. Portions of liver tissue (0.3–0.4 g) were extracted as described (16). The filtered lyophilized water extracts were dissolved in 150 μl water, and 100 μl aliquots were directly injected onto the TSK G2000 SW column. The same protein materials that were observed above were separated and collected (0.4–0.5 ml each). The collected protein peaks from the water-soluble liver extracts were hydrolyzed as follows. Volumes of 400–1000 μl were removed, and the pH was adjusted to greater than 12.5 with concentrated NaOH. The samples were enclosed and placed in the dark at room temperature

[1]Published as Paper No. 13,587 of the Scientific Journal Series of the Minnesota Agricultural Experiment Station.

Abbreviations: MDA, malondialdehyde; HPLC, high performance liquid chromatography.

overnight. The samples were neutralized with concentrated HCl, and 200 μl samples were injected onto a TSK G1000 PW column and eluted at 0.6 ml/min in 0.1 M trisodium phosphate buffer (pH 8.0) for analysis of MDA as described by Csallany et al. (18). Detection of released MDA was accomplished by using the Beckman variable wavelength detector at 267 nm and was compared with the nonhydrolyzed samples for quantitation purposes (18). This detector allowed the simultaneous reading of absorbance at two wavelengths (267 nm and 250 nm) and the scanning (220 nm to 300 nm in 5-nm increments) of eluting peaks without stopping the flow of the mobile phase. Compensation is automatically made in the resulting spectrum for the change in concentration of the peak material.

MDA co-chromatography and derivatization. The MDA peak from TSK G1000 PW chromatography was collected and co-chromatographed with standard MDA on this same column. Preparation of standard MDA is described by Csallany et al. (18). The absorbance ratio at 267 nm: 250 nm was monitored, and scans for 200 nm to 300 nm were measured during the run using the Beckman Model 165 detector. Derivatization of collected MDA peaks with 4,4′-sulfonyldianiline was accomplished as described by Csallany et al. (18). The relative fluorescence of all samples was determined at 470 nm/540 nm, and appropriate fluorescence spectra were done.

Protein determination. Two spectral methods were used to determine protein content of the nonhydrolyzed samples. The Warburg and Christian method (19) utilizes the absorbance at 260 nm and at 280 nm (mg protein/ml = $1.55 \times A_{280} - 0.775 \times A_{260}$). The Murphy and Kies method (20) uses the absorbance difference between 215 and 225 nm (mg protein/ml = $0.154 \times [A_{215} - A_{225}]$). All absorbance readings were obtained using the Beckman DU-8 Spectrophotometer (Beckman Instruments, Inc.).

RESULTS

The vitamin E-related, high molecular weight material from the Sephadex G-15 void volume was further separated on an HPLC size exclusion TSK G2000 SW column. Six proteins were observed, each having the same fluorescence characteristics (275 nm/350 nm) as the original void volume material. Attempts to separate this large protein on Sephadex G-50, G-100 and G-200 columns were unsatisfactory, although they did show the presence of more than one fluorescent compound in the G-15 column void volume material.

The water-soluble portion of the chloroform/methanol (2:1) extracts from livers of six vitamin E-deficient, and six vitamin E-supplemented (30 ppm) mice were injected onto the TSK G2000 column. One of the six proteins discussed above increased significantly due to vitamin E deficiency (Fig. 1). It had the smallest molecular weight of the six proteins, determined to be 20,000 daltons, and eluted at 10.33 ± 0.0125 ml.

These proteins were analyzed for the presence of MDA. Water extracts of mouse liver tissue were injected onto the TSK G2000 SW column, and the major peaks were collected including the 20,000 m.w. compound. Protein determinations were made, and the collected fractions were subjected to hydrolysis. Both the nonhydrolyzed and hydrolyzed fractions were chromatographed on the TSK

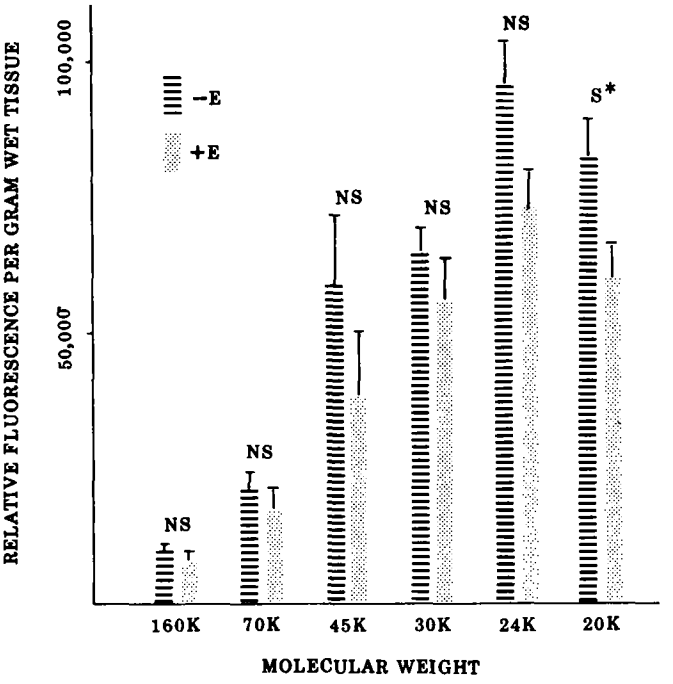

FIG. 1. Summary of the significant differences due to vitamin E seen in the protein materials separated from the Sephadex G-15 void volume peak. NS, not significant (Student's t-test); S*, significant ($P < .05$).

G1000 PW column for MDA analysis. Figure 2 shows a typical elution profile of these chromatographed fractions with the MDA peak eluting at 47.7 min. No MDA was found in any of the nonhydrolyzed fractions. The hydrolyzed 24,000 and 20,000 m.w. samples had the largest MDA peaks, which were 10- to 30-fold greater than those from other hydrolyzed samples. The absorbance ratio of 250 nm:267 nm was the same for all MDA peaks and equalled that obtained during a chromatographic run of standard MDA (0.37 ± .01). Scans from 220 nm to 300 nm were run during elution of each MDA peak. The same shape and maximum absorbance at 265 nm was observed for standard MDA and for each hydrolyzed fraction with a major MDA peak.

A six- to seven-month-old vitamin E-deficient mouse liver was found to contain about 900 ng of MDA per gram wet liver tissue before hydrolysis and 4000 ng of MDA per gram after hydrolysis.

The MDA peak from standard MDA and hydrolyzed samples was collected from the TSK G1000 PW column. An equally absorbant (267 nm) mixture of standard MDA and sample MDA was reapplied to the TSK G1000 PW column. The mixture eluted identically to the MDA standard (Fig. 3).

Derivatized sample MDA exhibited the same fluorescence as that seen for derivatized standard MDA (Fig. 4). The excitation maximum was 470 nm, and the emission maximum was 540 nm. The quantity of MDA present was determined by comparison of the fluorescence of the sample derivative at 470 nm/540 nm with that of the derivative of standard MDA and comparison of the MDA peak height to that of a standard curve of pure MDA chromatographed on the TSK G1000 PW column. These two quantities were almost equal.

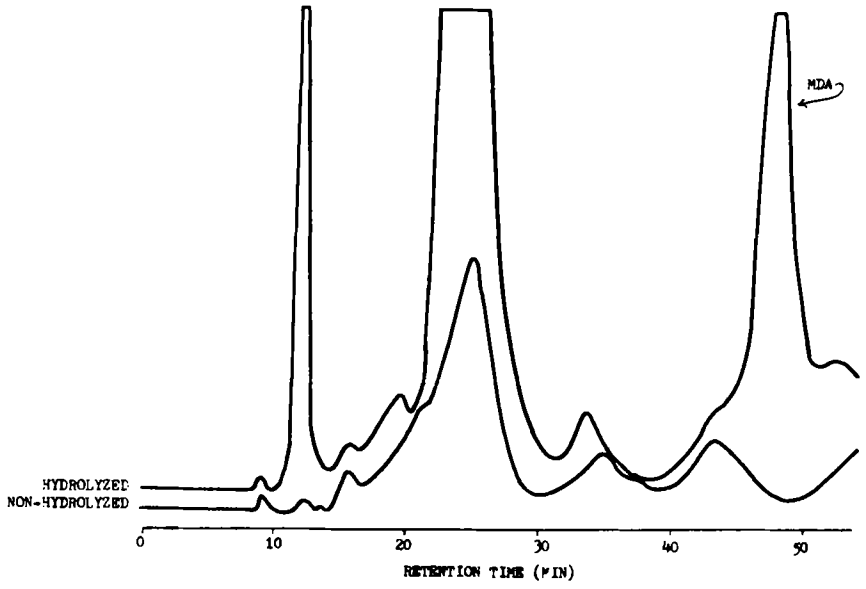

FIG. 2. Elution profile of hydrolyzed and nonhydrolyzed proteins (from G-15 void volume) chromatographed on a TSK-Gel 1000 PW column in 0.1 M phosphate buffer, pH 8.0, 0.6 ml/min.

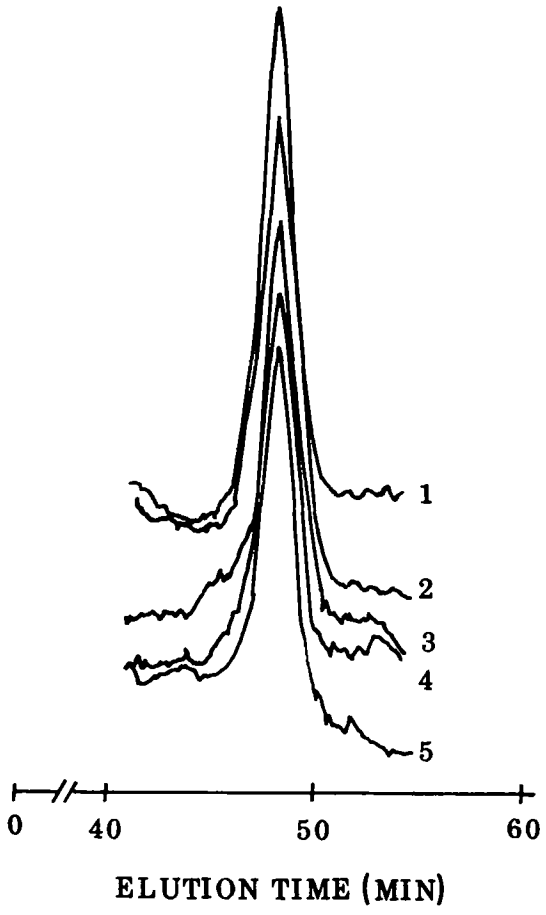

FIG. 3. Co-chromatography of collected MDA peak from hydrolyzed proteins (separated from Sephadex G-15 void volume) with standard MDA on a TSK-Gel 1000 PW column: (1) mixture of MDA + hydrolyzed (HD) 24,000 m.w. material (MDA + HD − 24,000), (2) HD − 24,000, (3) MDA + HD − 20,000, (4) HD − 20,000, and (5) MDA standard.

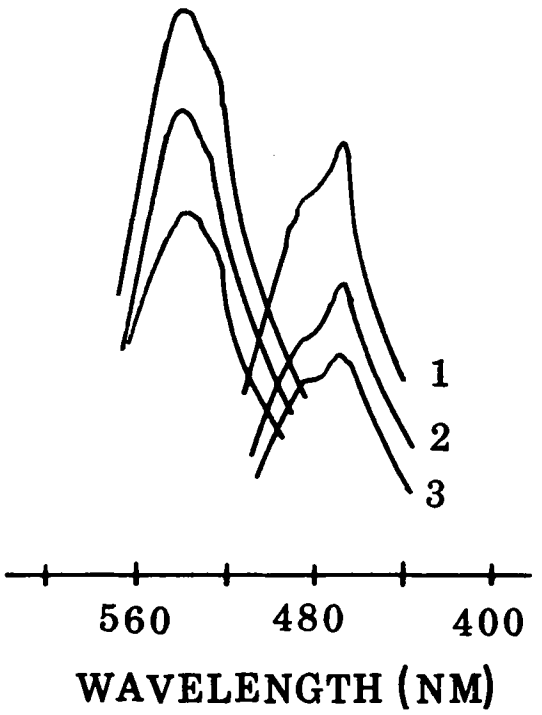

FIG. 4. Excitation and emission spectra of the fluorescent derivatives of the following: (1) malondialdehyde standard, and malondialdehyde released from: (2) 24,000 m.w. protein-like material, and (3) 20,000 m.w. protein.

A comparison of the concentration of MDA with respect to protein content is found in Table 1. Proteins less than 75,000 daltons all contained some MDA. The 20,000 and 24,000 m.w. proteins contained the largest amounts.

DISCUSSION

The water-soluble portion of chloroform/methanol (2:1) extracts was examined for the presence of fluorescent

TABLE 1

Malondialdehyde Content of Fluorescent Proteins in Water Extract of Mouse Liver

Material (m.w.)	μg MDA/ mg protein	Molecules MDA/ protein molecules
75,000	0[a]	0
45,000	3[b]	2
30,000	3[b]	1
24,000	11[b]	4
20,000	9[b]	3

[a]Average of two liver tissues.

[b]Average of three liver tissues.

compounds, as the magnitude of fluorescence from the organic solvent-soluble lipofuscin pigments does not account for the large amount of fluorescence observed microscopically in the liver. There is approximately 100 times more fluorescence in the water extract than in the organic solvent extract. This generally does not account for all of the fluorescence in the intact tissue. Any additional fluorescent materials is present in the insoluble interphase material removed during the extraction process.

Each of the materials separated by TSK G2000 SW chromatography of the Sephadex G-15 column void volume material had a molecular weight greater than 15,000 daltons and fluoresced near 350 nm when excited at 275 nm. From the above findings, it is apparent that each of these compounds are proteins. It generally is observed that in neutral solutions of tissue extracts, there are few materials other than proteins that fluoresce in the 340 nm–350 nm region when excited near 280 nm (21). Under these conditions, nucleic acids, purines and pyrimidines fail to show any fluorescence (21). MDA itself has no sizeable fluorescence, but Chio and Tappel (22) have reported that the formation of Schiff bases by the condensation of the carbonyl groups of MDA and the amine structure of amino acids form 1-amino-3-iminopropene (R-NH-CH = CH -CH = NR) products and have fluorescence in the 450 nm region when excited at 350 nm–360 nm. If this fluorescence was present in the protein materials studied above, it was at such a low level that it could not be detected.

Due to the low concentration of these protein materials within the cell and the necessary dilutions arising from the separation techniques, great difficulty was encountered in their separation. The TSK G2000 PW column was the largest size exclusion column available but still was limited in its ability to completely separate any concentrated samples. A large enough sample had to be used to allow detection and identification of released MDA, but concurrently the sample had to be small enough to allow adequate separation on the column. A compromise that allowed an approximation of the MDA content of these materials to be determined for the primary purpose of comparison between the separated peaks was made.

An approximation of the relative rate for the formation of the condensation product of a primary amino containing compound with carbonyl compounds is shown (Fig. 5)

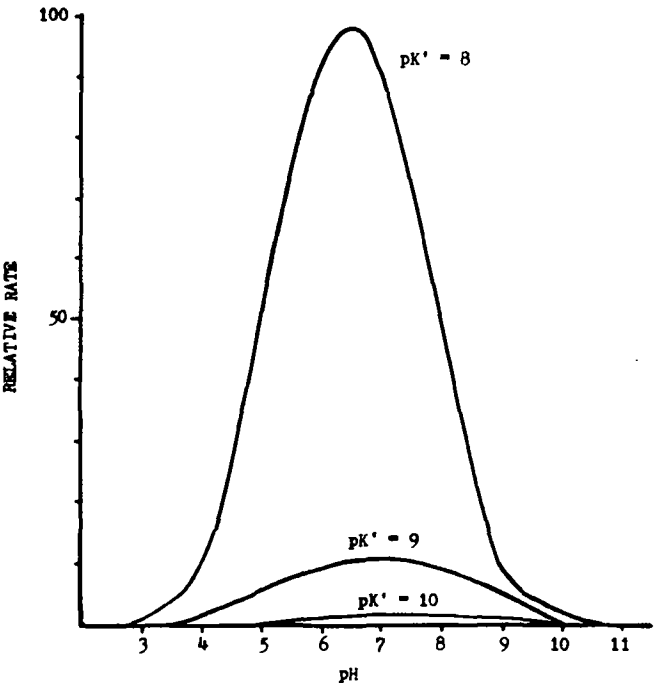

FIG. 5. Relative reaction rate for the formation of the Schiff base vs pH when the pK′ of the amine group is 8, 9 or 10.

vs pH when the pK′ of the amine group is either 8, 9 or 10. The reaction is dependent on the pH of the medium keeping both the carbonyl group protonated and the primary amino group deprotonated (neutral). This will occur at a pH midway between the pK′ for the carbonyl group and that for the amino group. The reversibility of this reaction was the basis for the hydrolysis procedure used to liberate MDA from the protein compounds separated on the TSK G2000 SW column. A high pH was chosen to guard from the possible production of new MDA by acid treatment (23).

Only one of the proteins was found to be significantly related to dietary vitamin E. All proteins that were smaller than 75,000 daltons were found to contain bound MDA with the smallest proteins containing the most MDA. It would be expected that vitamin E deficiency would lead to an increase in MDA levels in the cell and thus to an increase in protein-bound MDA. The 24,000 m.w. material, although not significantly increased ($p < 0.75$), tended to be elevated due to vitamin E deficiency. A larger number of samples might have shown the difference to be significant. It also is possible that within localized regions of the cell such as membranes, specific proteins that readily react with MDA may be present. If these proteins were present only in these areas and if MDA formation was nearly as great as that of the protein, it would not be expected to increase significantly due to vitamin E deficiency unless an increased production of the protein accompanied it.

Effect of Diethyl Ether on Phosphatidylcholine Biosynthesis in Hamster Organs

Karmin O, Grant M. Hatch and **Patrick C. Choy***
Department of Biochemistry, Faculty of Medicine, University of Manitoba, 770 Bannatyne Ave., Winnipeg, Manitoba, Canada R3E OW3

The effect of diethyl ether anesthesia on phosphatidylcholine biosynthesis in hamster organs was investigated. Ether administration did not affect the incorporation of radioactive choline into phosphatidylcholine in the liver, heart, lung, brain and spleen. A significant (29%) decrease in the labeling of phosphatidylcholine was detected in the kidney of ether-treated hamsters. Reduction in phosphatidylcholine labeling was not due to a diminished radioactive choline uptake but a decrease in the conversion of phosphocholine to CDP-choline. The accumulation of labeled phosphocholine was caused by the translocation of CTP:phosphocholine cytidylyltransferase from microsomal (more-active) form to cytosolic (less-active) form. Ether administration appears to modulate the cytidylyltransferase in hamster kidney differently than that in other hamster organs.
Lipids 23, 656–659 (1988).

Phosphatidylcholine is the principal phospholipid in mammalian tissues (1). The majority of phosphatidylcholine is synthesized via the CDP-choline pathway (2,3), and the remainder is formed either from the progressive methylation of phosphatidylethanolamine or from the exchange of the base group of an existing phospholipid with choline (3). In the CDP-choline pathway, choline initially is phosphorylated to phosphocholine by choline kinase (2,3). Phosphocholine is converted to CDP-choline by CTP: phosphocholine cytidylyltransferase (2,3). The CDP-choline formed is rapidly condensed with 1,2-diacylglycerol for the formation of phosphatidylcholine. The conversion of phosphocholine to CDP-choline is regarded as the rate-limiting step of this pathway (2–4).

The effect of aromatic anesthetics on phosphatidylcholine biosynthesis is well-documented (5,6). Administration of polychlorinated biphenyls reduced the incorporation of the labeled phosphate into the choline-containing phospholipids in rat liver, whereas phenobarbital enhanced such incorporation (5). In a subsequent study (6), these investigators demonstrated that the administration of phenobarbital resulted in substantial decreases of choline kinase and microsomal phosphocholine cytidylyltransferase activities. Choline phosphotransferase and cytosolic CTP:phosphocholine cytidylyltransferase activities were not significantly affected by such treatment.

Diethyl ether is a commonly administered anesthetic for small laboratory animals. Previously, we demonstrated that the labeling of phosphatidylethanolamine from ethanolamine was reduced in the kidney of the diethyl ether-anesthetized hamsters (7). In this study, the effect of diethyl ether on phosphatidylcholine biosynthesis in hamster organs was examined.

MATERIALS AND METHODS

Choline iodide, phosphorylcholine chloride and CDP-choline were obtained from Sigma Chemical Co. (St. Louis, MO). [Methyl-^{3}H]choline and CDP-[methyl-^{14}C]-choline were purchased from NEN division, DuPont Co. (Dorval, Quebec). Thin layer chromatographic plates (sil-G25) were the product of Brinkmann (Rexdale, Ontario). Phospho-[methyl-^{3}H]choline was synthesized enzymatically from [methyl-^{3}H]choline by the action of yeast choline kinase as described (8). All other chemicals were of reagent grade and were obtained through Fisher Scientific Co. (Winnipeg).

Male Syrian golden hamsters, 120 ± 10 g, were maintained on Purina hamster chow and tap water, ad libitum, in a light- and temperature-controlled room.

Diethyl ether was administered to the hamster by inhalation as described (7). The animal was placed in a 2-l sealed container, and a cotton ball containing 2 ml of diethyl ether was introduced into the container. Subsequent to the loss of the righting reflex (3–4 min), the animal was removed from the container and labeled choline (0.5 ml of a 20 mM choline chloride solution) containing 20 μCi was injected intraperitoneally. Light anesthesia was administered by the inhalation of a ether/air mixture for the next 60 min. A minimum respiratory rate of 40/min was maintained throughout the experiment. Identical doses of labeled choline were injected into the non-anesthetized animals, and these animals were used as controls. At the prescribed time interval, the control and the anesthetized animals were killed by decapitation, and the organs were rapidly removed and placed in ice-cooled saline (0.9% NaCl). The organs were weighed and homogenized in $CHCl_3/CH_3OH$ (2:1, v/v) to yield a 10% (w/v) homogenate. The homogenate was centrifuged, and the pellet was re-extracted twice with $CHCl_3/CH_3OH$ (2:1, v/v). The extracts were pooled, and an aliquot was taken for the determination of total uptake of radioactivity. Phase separation of the pooled extract was achieved by adding water to the extract until a $CHCl_3/CH_3OH/H_2O$ rato of 4:2:3 (v/v/v) was obtained. Radioactivity in the organic phase was determined, and phosphatidylcholine in this phase was analyzed by thin layer chromatography with a solvent containing $CHCl_3/CH_3OH/CH_3COOH/H_2O$ (70:30:2:4, v/v/v/v) (4). Choline-containing metabolites in aqueous phase was analyzed by thin layer chromatography with a solvent containing CH_3OH/0.6% NaCl/NH_4OH (50:50:5, v/v/v) (4). Because a substantial amount of choline was oxidized into betaine in the liver (2), the labeling of betaine also was determined. Betaine was separated from CDP-choline after thin layer chromatography by a Norit A charcocal column (0.5 × 3 cm) equilibrated with 2% ethanol. Betaine was eluted from the column by 20 ml 2% ethanol, whereas CDP-choline was eluted by subsequent addition of 10 ml 40% ethanol containing 1% NH_4OH.

Subcellular fractions of the hamster organs were prepared by differential centrifugation as described (4). Choline kinase in the cytosolic fraction was assayed with labeled choline (9). CTP:phosphocholine cytidylyltransferases in the cytosolic and microsomal fractions were assayed with labeled phosphocholine at exactly four hr

*To whom correspondence should be addressed.

after the tissues were homogenized (10). In addition, cytosolic CTP:phosphocholine cytidylyltransferase activity was determined in the presence of total liver phospholipid extract (2 mg/ml) and 0.1 mM oleate. Maximal stimulation of the cytosolic cytidylyltransferase was obtained with these lipids (11). Microsomal CDP-choline: 1,2-diacylglycerol choline phosphotransferase was assayed with labeled CDP-choline in the presence of Tween-20 and exogenous diacylglycerol (12). Protein was determined by the procedure of Lowry et al. (13), and lipid phosphorus content was analyzed by the method of Bartlett (14).

Radioactivity was determined by liquid scintillation counting using channels' ratio calibration method. Student's t-test was used for statistical analysis of the results. The level of significance was $P < 0.05$.

RESULTS

The effect of diethyl ether on the labeling of phosphatidylcholine in hamster organs was investigated in a time-course study. Ether-anesthetized hamsters were injected intraperitoneally with labeled choline. Unanesthetized hamsters were used as controls. The animals were killed at the prescribed time intervals, and the phosphatidylcholine content and labeling in the organs were determined. Ether anesthesia did not affect the amount of phosphatidylcholine (estimated by μmol of lipid-P/g tissue wet wt.) in all hamster organs at 30 and 60 min of treatment. However, at 30 min of anesthetic treatment, a 12% decrease ($0.05 < P < 0.1$) in phosphatidylcholine labeling was observed in the kidney. At 60 min, this decrease was more prominent (29%). No significant change in labeling of phosphatidylcholine was detected in other organs (Table 1). One factor that might cause the reduction of phosphatidylcholine labeling in the kidney was a decrease in the uptake of labeled choline. Hence, total labeled choline uptake in hamster organs at 60 min of treatment was determined (Table 2). The total ratioactivity taken up by the kidney was similar between the control and anesthetized hamsters. Although the total choline uptake in the liver might be slightly increased during anesthesia, such differences were not statistically significant.

TABLE 1

Incorporation of Radioactivity into Phosphatidylcholine in Hamster Organs During Diethyl Ether Anesthesia[a]

Tissue	Control dpm/g wet wt. ($\times 10^{-5}$)	Diethyl ether-treated dpm/g wet wt. ($\times 10^{-5}$)
Heart	1.25 ± 0.45 (8)	0.95 ± 0.37 (8)
Liver	8.27 ± 1.36 (10)	9.58 ± 1.80 (10)
Kidney	8.19 ± 2.20 (8)	5.84 ± 1.36* (8)
Lung	7.58 ± 1.74 (5)	6.22 ± 0.50 (5)
Brain	0.31 ± 0.04 (5)	0.32 ± 0.04 (5)
Spleen	2.77 ± 0.44 (4)	2.37 ± 0.65 (3)

*$P < 0.05$.

[a][Methyl-^{3}H]choline was injected intraperitoneally into control and diethyl ether anesthetized hamsters as described in Methods. After 60 min, hamsters were decapitated, and the organs were removed and homogenized in chloroform/methanol (2:1, v/v). The homogenates were separated into aqueous and organic phases by the addition of chloroform and water. Phosphatidylcholine in the organic phase was isolated by thin layer chromatography. The results are depicted as mean ± standard deviation (number of experiments).

TABLE 2

Total Uptake of [Methyl-^{3}H]Choline by Hamster Organs[a]

Tissue	Control dpm/g wet wt. ($\times 10^{-5}$)	Diethyl ether-treated dpm/g wet wt. ($\times 10^{-5}$)
Heart	4.64 ± 1.71 (8)	4.14 ± 1.01 (8)
Liver	24.34 ± 4.17 (10)	27.64 ± 2.92 (10)
Kidney	18.75 ± 4.64 (8)	18.56 ± 4.52 (8)
Lung	11.68 ± 2.47 (5)	12.01 ± 4.30 (5)
Brain	1.87 ± 0.55 (5)	1.40 ± 0.15 (5)
Spleen	9.07 ± 2.53 (4)	8.58 ± 1.14 (4)

[a][Methyl-^{3}H]choline was injected intraperitoneally into control and diethyl ether anesthetized hamsters as described in Methods. After 60 min, hamsters were decapitated, and the organs were removed and homogenized in chloroform/methanol (2:1, v/v). An aliquot was taken for radioactivity determination. The results are depicted as mean ± standard deviation (number of experiments).

The labeling of the choline-containing metabolites in the CDP-choline pathway in the kidney at 60 min of treatment also was determined. As depicted in Table 3, labeling of phosphocholine was substantially increased (41%). Such increase suggests that the ability to convert phosphocholine into CDP-choline was impaired in the kidney during ether anesthesia. Because the uptake of labeled choline in the liver also might be perturbed by ether anesthesia (Table 2), the labeling of the hepatic choline-containing metabolies also was determined. No significant difference was detected between the two animal groups (Table 3). In addition, labeling of betaine was similar between the control and experimental animals (data not shown). These results confirm that total choline uptake in the liver was not changed between the control and ether-treated animals.

The accumulation of radioactivity in the phosphocholine fraction in the kidney of the anesthetized hamster might be caused by a change in the activity of the enzymes in the CDP-choline pathway. Thus, the activities of these enzymes in the hamster organs were determined after 60 min of ether administration. In the kidney, no change in either choline kinase or choline phosphotransferase activities was detected between the two animal groups (Table 4). Interestingly, CTP:phosphocholine cytidylyltransferase activity in the microsomal fraction was substantially reduced in the anesthetized animal, whereas the enzyme activity in the cytosol was not changed. However, in the presence of lipid activators a significant increase in cytosolic enzyme activity was observed in the anesthetized kidney (Table 4). Total cytidylyltransferase activity (μmol/min/g tissue wet wt.) was calculated from the sum of the microsomal and cytosolic enzyme activities. The total enzyme activity was reduced in the kidney of the anesthetized animal in the absence of exogenous lipid activators in the cytosol. When the cytosolic enzyme was fully activated, there was no difference in total enzyme activity. As an additional control, the enzymes of the CDP-choline pathway also were assayed in the other organs. No significant differences in any of the enzyme activities were detected between the control and anesthetized animals (data not shown).

TABLE 3

Radioactivity Incorporated into Choline-containing Metabolites in Hamster Organs[a]

*$P < 0.05$.

[a]Kidneys were obtained from control and diethyl ether-anesthetized hamsters. Subcellular fractions from various organs were prepared as described in Methods. These fractions were assayed for phosphatidylcholine-synthesizing enzyme activities. The results are depicted as mean ± standard deviation (number of experiments).

DISCUSSION

In this study, the effect of diethyl ether anesthesia on phosphatidylcholine biosynthesis via the CDP-choline pathway in hamster organs was investigated. Our results clearly demonstrated that such treatment did not produce any effect on phosphatidylcholine biosynthesis in hamster organs other than the kidney. The reduction in phosphatidylcholine biosynthesis in hamster kidney under ether anesthesia (29%) was quantitatively similar to that reported for phosphatidylethanolamine biosynthesis (30% reduction) (7). The reduced labeling of phosphatidylcholine was not caused by a decrease in labeled choline uptake but probably resulted from a reduction in the conversion of phosphocholine to CDP-choline. Such conversion, which was catalyzed by CTP:phosphocholine cytidylyltransferase, has been regarded as the rate limiting step in the CDP-choline pathway (2–4). Cytidylyltransferase activity is located in both the microsomal and cytosolic fractions (3). The enzyme in the cytosolic fraction is enhanced upon storage at 4 C or at room temperature (10). To obtain valid comparisons, all cytidylyltransferase assays in the cytosol were performed exactly four hr after tissue homogenization (4). Because the cytosolic enzyme has a lipid requirement (2,10,11), lipids were added to the assay mixture to obtain maximum enzyme activation.

Current evidence suggests that the microsomal form of the enzyme is the active form responsible for the conversion of phosphocholine to CDP-choline in vivo (2, 15–17) and the translocation of the cytidylyltransferase from one subcellular fraction to another is an important mechanism for the overall regulation of phosphatidylcholine biosynthesis (2,18). Because the total activity in microsomal form was reduced with a corresponding increase in the cytosolic form (when fully activated), together with the fact that the combined activities in these two forms were not changed, we postulate that ether treatment promotes the translocation of the kidney cytidylyltransferase from the microsomal form to the cytosolic form. Such translocation would cause a reduction in the conversion of phosphocholine to CDP-choline. This was confirmed by the analysis of choline-containing metabolites, and also by the observation that the total cytosolic enzyme activity was not increased without the presence of exogenous lipids. Indeed, the combined

enzyme activity in the two forms when assayed without exogenous lipid was significantly decreased in the anesthetized kidney. The transfer of the microsomal cytidylyltransferase to the cytosolic fraction during ether anesthesia would provide the kidney with a facile mechanism to attenuate the rate of phosphatidylcholine biosynthesis.

One intriguing aspect of this study is the differential effect of diethyl ether on the translocation of the cytidylyltransferase in the kidney, but not in other hamster organs. Presently, only the cytidylyltransferase from the liver has been purified and studied in detail (19). Our results suggest that the enzyme in hamster kidney may be modulated differently than those found in other hamster tissues.

Regulation of the Metabolism of Linoleic Acid to Arachidonic Acid in Rat Hepatocytes

Anne C. Voss and **Howard Sprecher***
Department of Physiological Chemistry, Ohio State University, 5148 Graves Hall, 333 W. 10th Ave., Columbus, OH 43210

When 5×10^6 hepatocytes were incubated for 40 min with from 0.15 to 0.60 mM [1-^{14}C]linoleic acid, [1-^{14}C]6,9,12-octadecatrienoic acid, or [1-^{14}C]8,11,14-eicosatrienoic acid, there was a concentration-dependent acylation of radioactive metabolites into both triglycerides and phospholipids. When the concentration of either [1-^{14}C]linoleic acid or [1-^{14}C]8,11,14-eicosatrienoic acid exceeded 0.3 mM, there was no further increase in the metabolism of either fatty acid to other (n-6) metabolites. When the concentration of [1-^{14}C]6,9,12-octadecatrienoic acid exceeded 0.15 mM, there was an apparent substrate-induced inhibition in its metabolism to 8,11,14-eicosatrienoic acid. With all three substrates (0.3 mM), there was time-dependent metabolism to other (n-6) acids. Cells then were incubated simultaneously with 0.3 mM [1-^{14}C]linoleic acid along with 0.15 to 0.45 mM 6,9,12-octadecatrienoic acid or 8,11,14-eicosatrienoic acid. These exogenous nonradioactive (n-6) acids suppressed but did not abolish the conversion of [1-^{14}C]linoleate to radioactive arachidonate. These findings suggest that some linoleate is converted to arachidonate without intracellular mixing of 6,8,12-octadecatrienoic or 8,11,14-eicosatrienoic acids. This hypothesis is supported by the finding that exogenous linoleate did not markedly affect the metabolism of [1-^{14}C]6,9,12-octadecatrienoic or [1-^{14}C]8,11,14-eicosatrienoic acid by microsomal chain elongating or desaturating enzymes.
***Lipids 23,* 660–665 (1988).**

It is well-established that dietary linoleate is converted to arachidonate in the liver only by an alternating series of position-specific desaturases and malonyl-CoA-dependent chain elongation steps as follows: 18:2 → 18:3 → 20:3 → 20:4 (1). Liver lipids contain large amounts of linoleate and arachidonate but only low levels of 6,9,12-18:3 and 8,11,14-20:3, even though they are both obligatory intermediates in the synthesis of arachidonate. Several studies with liver microsomes (2–4) as well as with hepatocytes (5) have shown that desaturation of linoleate, by the 6-desaturase, is rate-limiting in this metabolic pathway. Although rate studies with microsomes define how rapidly various acids are metabolized, they have not been very informative in explaining why 6,9,12-18:3 and 8,11,14-20:3 are not found in significant amounts in liver lipids. When the CoA derivatives of 6,9,12-18:3 or 8,11,14-20:3 were incubated with lysophospholipids and liver microsomes, both substrates were readily acylated (6). Clearly, rate studies by themselves fail to explain the types of fatty acids found in liver phospholipids.

Recent studies by Christophersen and his colleagues (5,7,8) have shown that hepatocytes can be used effectively to study integrated aspects of polyunsaturated fatty acid desaturation and chain elongation along with the simultaneous acylation of metabolites into lipids. Thus, we carried out studies with hepatocytes from chow-fed rats to define if some linoleate was converted to arachidonate without intracellular mixing of the two obligatory intermediates required for converting dietary linoleate to arachidonate (9).

MATERIALS AND METHODS

Chemicals. [1-^{14}C]Linoleic acid (52 Ci/mol) and [1-^{14}C]-8,11,14-eicosatrienoic acid (55 Ci/mol) were purchased from New England Nuclear (Boston, MA). [1-^{14}C]6,9,12-Octadecatrienoic acid (43 Ci/mol) was made by total synthesis as described (10). Other unsaturated fatty acids were obtained from Nu-Chek Prep. (Elysian, MN).

All solvents were either reagent or high performance liquid chromatography (HPLC) grade. Collagenase was purchased from Boehringer Mannheim GmbH (Indianapolis, IN).

Hepatocyte isolation. Male Sprague-Dawley rats (200–300 g) were maintained on a chow diet for at least one wk. Hepatocytes were isolated according to the general method of Seglen (11) as described (12). The cells were suspended at 5×10^6/ml in a buffer containing 113 mM NaCl, 4.5 mM KCl, 30 mM HEPES, 10 mM glucose, 1.1 mM $CaCl_2$, 1.3 mM KH_2PO_4, 26 mM $NaHCO_3$, 1.5 mM $MgCl_2$ and 1% fatty acid-free bovine serum albumin. Cell viability was routinely greater than 90% as determined by trypan blue exclusion.

Incubations. Hepatocytes, 5×10^6 in 2 ml of suspension buffer containing 10 mM lactic acid, were incubated at 37 C in a Dubnoff metabolic shaker under 95% oxygen – 5% carbon dioxide at a flow of 6 l/min. Incubations were initiated by adding the sodium salt of the fatty acid. The fatty acid concentrations are in the legends to the figures and tables.

Lipid isolation and analysis. Incubations were stopped by addition of 0.2 ml of 2 M formic acid and 2 ml of $CHCl_3$/MeOH (2:1, v/v). The contents of the vials were transferred to screw cap tubes, and the incubation vessels were washed twice with 4 ml of $CHCl_3$/MeOH (2:1, v/v), which then was combined with the original extract. The tubes were vortexed and centrifuged to obtain phase separation. A 50-μl aliquot of the upper aqueous layer was removed and counted in Formula-963 (New England Nuclear, Boston, MA) to quantitate the metabolism of fatty acids into water-soluble products. The bottom organic phase was taken to dryness under a stream of N_2. The lipids were dissolved in $CHCl_3$ and applied to a column of Unisil (Clarkson Chemical Co., Williamsport, PA) in a Pasteur pipette. Neutral lipids were recovered by eluting with 10 ml of $CHCl_3$, while phospholipids were recovered by eluting with 10 ml of methanol. The solvents were removed under N_2, and each lipid fraction was dissolved in 1 ml of $CHCl_3$/MeOH (2:1, v/v). Aliquots of 10 μl were removed from the phospholipid fraction to determine the total nmol of fatty acids incorporated into polar lipids. The remaining phospholipids were saponified by stirring overnight with 1 N KOH in ethanol/H_2O (9:1, v/v).

Aliquots of 50 μl were removed from the neutral lipid fraction and applied to one lane of a preabsorbant zone of a Whatman LK6D plate (Whatman, Clifton, NJ), while another 200 μl was applied to the preabsorbant zone of two other lanes. Thin layer chromatography was carried out using hexane/diethyl ether/acetic acid (80:20:2, v/v/v). The plates were scanned with a Packard Model 7220 radiochromatogram scanner. The free fatty acids and triacylglycerols from the single lane were scraped into scintillation vials and counted. The triacylglycerols from the other two zones were scraped into screw cap vials, and the lipids were saponified.

After saponification, the fatty acids were dissolved in 70 μl of acetonitrile. They were separated by reverse-phase HPLC using a Beckman HPLC consisting of two 112 pumps, a 420 controller and a model 1305 Bio-Rad variable wavelength detector set at 205 nm. Chromatography was carried out at room temperature using a 0.46 × 25 cm Zorbax ODS column (DuPont, Wilmington, DE). The solvent system was acetonitrile/water (80:20, v/v), in which the water was adjusted to pH 2.5 with phosphoric acid. The flow rate was 1 ml/min. Radioactivity was quantitated with a flow-through detector (Radiomatic Instruments and Chemical Co., Tampa, FL). The flow rate of ScintiVerse (Fisher Scientific Co., Cincinnati, OH) was 3 ml/min.

RESULTS

Figure 1 (bottom) shows that when increasing concentrations of [1-^{14}C]linoleate were incubated for 40 min with hepatocytes, there was an almost linear increase in the acylation of radioactive metabolites into phospholipids and triglycerides as well as metabolism into water soluble products. The triglycerides (TG) and phospholipids (PL) then were saponified and the fatty acids were analyzed by reverse-phase HPLC to define the composition of the radioactive (n-6) fatty acids. As shown in the upper panels of Figure 1, small amounts of linoleate were metabolized to other (n-6) acids and incorporated into both PL and TG. Although substrate saturation had not been achieved relative to overall acylation (Fig. 1, bottom), the results in the upper two panels show that maximum metabolism of the linoleate to other (n-6) acids occurred when the substrate concentration was about 0.3 mM. Hepatocytes were then incubated for various periods of time with 0.3 mM [1-^{14}C]linoleate. The results in Figure 2 (bottom) show that there is time-dependent

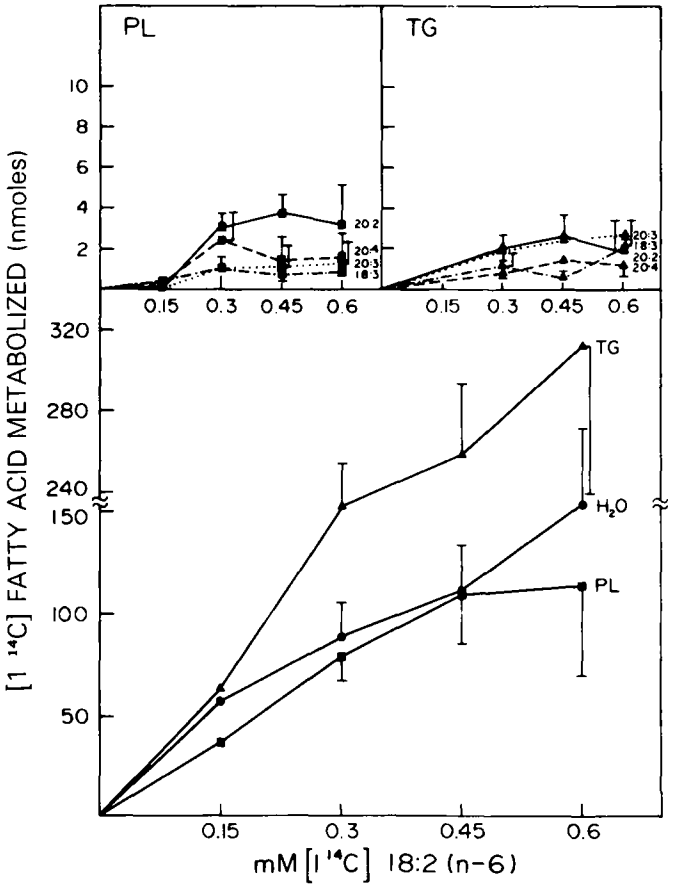

Fig. 1. Substrate-dependent metabolism of [1-^{14}C]linoleate (5 Ci/mol). Hepatocytes (5 × 10^6/2 ml) were incubated for 40 min. The total nmol of fatty acids esterified into phospholipids (PL), triglycerides (TG) or oxidized into water-soluble products (H_2O) are shown in the bottom panel. The upper panels show the nmol of (n-6) acids produced from [1-^{14}C]linoleate that are incorporated into PL and TG. Results are the averages ± the standard deviation of at least six experiments.

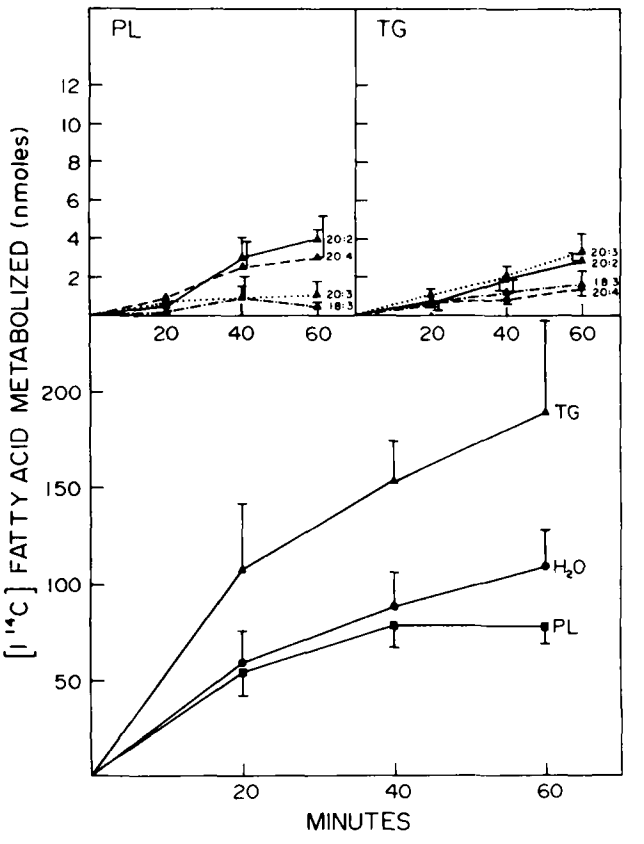

FIG. 2. Time-dependent metabolism of 0.3 mM [1-^{14}C]linoleate. The incubation conditions are as described in Figure 1. The total nmol of fatty acids esterified into water-soluble products (H_2O) are shown in the bottom panel. The upper panels show the nmol of (n-6) acids produced from [1-^{14}C]linoleate that are incorporated into PL and TG. Results are the averages ± the standard deviations of at least six experiments.

acylation of metabolites into both TG and PL as well as metabolism into water-soluble metabolites. The upper two panels of Figure 2 show that there is also time-dependent metabolism of linoleate to other (n-6) acids followed by their incorporation into both PL and TG.

Figures 3 and 4 show the results when an identical series of experiments were carried out using [1-^{14}C]-6,9,12-18:3 as substrate. The results (Fig. 3, bottom) show that there is substrate-dependent acylation of radioactive metabolites into PL and TG as well as metabolism into water-soluble products. However, when the distribution of radioactive (n-6) acids was measured in PL and TG, there was an apparent substrate-induced inhibition in the metabolism of 6,9,12-18:3 to 20-carbon (n-6) acids (Figure 3, top panels). When hepatocytes were incubated with 0.3 mM [1-^{14}C]6,9,12-18:3, there was time-dependent incorporation of metabolites into lipids (Fig. 4, bottom) as well as metabolism to other (n-6) acids. It is apparent that the metabolism of [1-^{14}C]6,9,12-18:3 to 20-carbon (n-6) acids followed by their acylation into phospholipids (Figure 4, top panel) increased in a nonlinear manner with time. These findings suggest that when the intracellular concentration of 6,9,12-18:3 is high, the substrate is an inhibitor of its own chain elongation to 8,11,14-20:3. Over time, there was rapid removal of substrate. The nmol of 6,9,12-18:3 remaining at 20, 40 and 60 min were, respectively 149 ± 29, 29 ± 22 and 25 ± 27. These results suggest that the inhibition of 6,9,12-18:3 chain elongation is a reversible process and that it is regulated by the intracellular concentration of 6,9,12-18:3 or its CoA derivative. This interpretation is consistent with the finding (Fig. 4, top) that the apparent rate of metabolism to 8,11,14-20:3 and to 5,8,11,14-20:4 increased in a nonlinear manner with time.

Figures 5 and 6 show how [1-^{14}C]8,11,14-20:3 was metabolized under identical conditions used for [1-^{14}C]-linoleate and [1-^{14}C]6,9,12-18:3. It is apparent from these results as well as of those of Hagve and Christophersen (8) that 8,11,14-20:3 is a much better substrate for desaturation than is linoleate.

The preceding studies compare how individual exogenous (n-6) acids were metabolized by hepatocytes. Subsequent studies thus were carried out to define if linoleate in part was metabolized directly to 5,8,11,14-20:4 in such a way that some of the radioactive 6,9,12-18:3 and 8,11,14-20:3 produced from [1-^{14}C]linoleate was not available for acylation into hepatocyte lipids. The results in Table 1 compare the metabolism of 0.3 mM [1-^{14}C]linoleate when the incubations also contained increasing amounts of nonradioactive 6,9,12-18:3 and 8,11,14-20:3. These results show that the addition of the two exogenous nonradioactive (n-6) acids did not markedly influence the incorporation of radioactive metabolites into either TG or PL. Under these conditions, the 6,9,12-18:3 and 8,11,14-20:3 were themselves readily incorporated into both TG and PL (subsequent results). These findings simply show

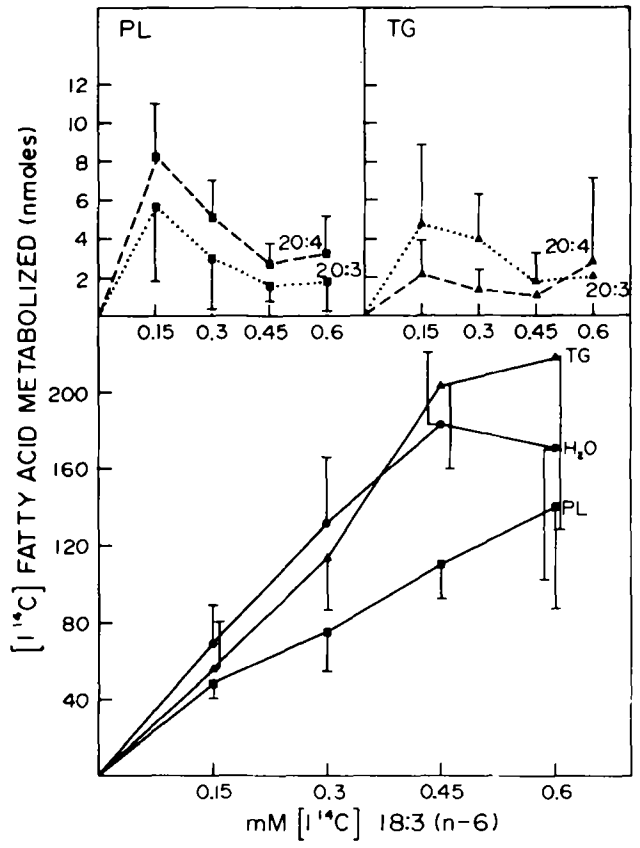

FIG. 3. Substrate-dependent metabolism of 0.3 mM [1-^{14}C]6,9,12-octadecatrienoic acid (2 Ci/mol). The conditions are as described in Figure 1. Results are the average ± the standard deviations of four experiments.

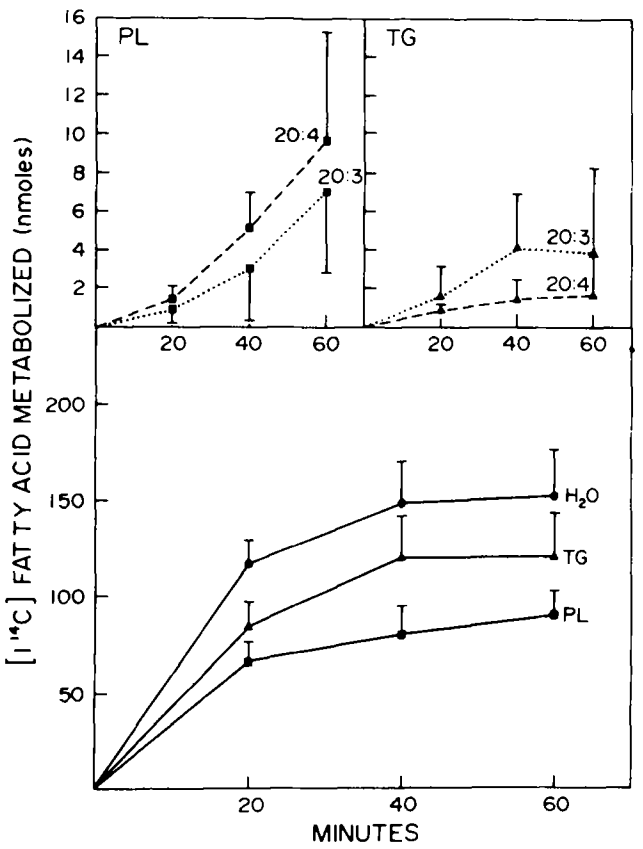

FIG. 4. Time-dependent metabolism of [1-^{14}C]6,9,12-octadecatrienoic acid (2 Ci/mol). The conditions are as described in Figure 2. Results are the average ± the range of two experiments.

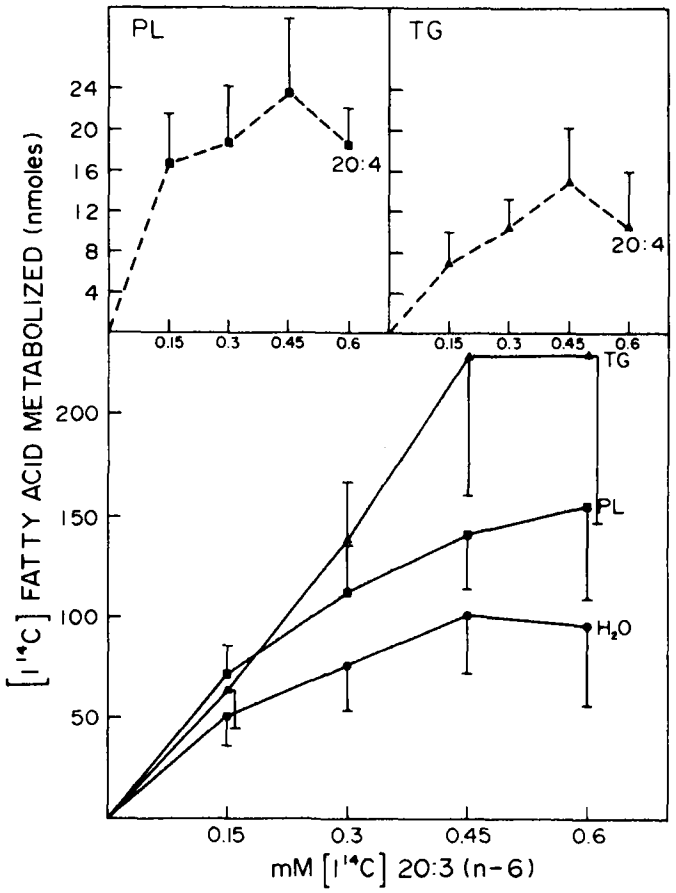

FIG. 5. Substrate-dependent metabolism of [1-^{14}C]8,11,14-eicosatrienoic acid (2, Ci/mol). The conditions are as described in Figure 2. Results are the average ± the standard deviation of five experiments.

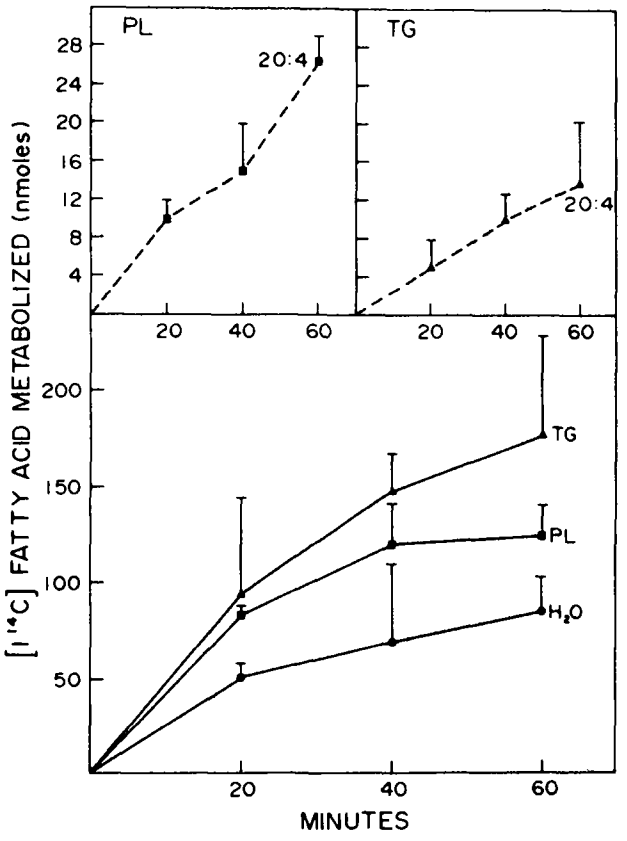

FIG. 6. Time-dependent metabolism of 0.3 mM [1-^{14}C]8,11,14-eicosatrienoic acid (2 Ci/mol). The conditions are as described in Figure 2. Results are the mean ± the standard deviation of four experiments.

Results are shown as nmol of (n-6) acids in triglyceride (TG) or phospholipids (PL) after a 40-min incubation.

[a]Values are average ± the range of two separate experiments.

[b]Values are means ± the standard deviations of six experiments.

that these cells have an enormous capacity to incorporate exogenous acids into lipids. If the small amount of radioactive 6,9,12-18:3 made from [1-^{14}C]linoleate totally mixes with exogenous 6,9,12-18:3, the specific activity of the total intracellular pool of 6,9,12-18:3 should be very low. Under these conditions, it would be virtually impossible to detect the synthesis of radioactive arachidonate. The results in Table 1 show that exogenous 6,9,12-18:3 almost totally blocked the chain elongation of [1-^{14}C]-linoleate to radioactive 11,14-20:2. These results are consistent with studies showing that a common malonyl-CoA condensing enzyme may act on unsaturated primers (13,14). In addition, 6,9,12-18:3 is a better substrate for chain elongation than is 9,12-18:2 (15). Exogenous 6,9,12-18:3 did not markedly depress the synthesis of radioactive 6,9,12-18:3 from [1-^{14}C]linoleate. Conversely, exogenous 6,9,12-18:3 inhibited, but did not totally block, the synthesis of radioactive 8,11,14-20:3 and arachidonate. These findings suggest that some linoleate may be channeled directly to arachidonate without total intracellular mixing of 6,9,12-18:3 and 8,11,14-20:3.

This conclusion is substantiated by the crossover inhibition studies shown in Table 2. These results compare how [1-^{14}C]6,9,12-18:3 was metabolized when incubations were carried out in the presence of increasing amounts of linoleate. Although there was considerable variation between different preparations of hepatocytes, these results show that concentrations of exogenous linoleate below 0.45 mM did not markedly influence [1-^{14}C]-6,9,12-18:3 metabolism. It is equally important to note that there was unreacted [1-^{14}C]6,9,12-18:3 in these incubations. When incubations contained 0, 0.15, 0.30 and 0.45 mM 18:2(n-6), there were 32, 79, 103 and 104 nmol of unreacted [1-^{14}C]6,9,12-18:3. Because these are direct crossover studies of those described in Table 1, the results document that when cells were incubated with [1-^{14}C]-linoleic acid and 6,9,12-18:3, some of the latter substrate still was available to compete with the [1-^{14}C]6,9,12-18:3 that was produced by desaturation of [1-^{14}C]9,12-18:2.

The results in Table 3 show that linoleate did not depress the conversion of radioactive [1-^{14}C]8,11,14-20:3 to arachidonate. The crossover inhibitor studies in Table 1 show that small amounts of linoleate were metabolized to arachidonate in the presence of 8,11,14-20:3. Presumably, small amounts of linoleate also are metabolized to arachidonate in the studies described in Table 3. However, the low levels of 8,11,14-20:3 made from linoleate would not significantly alter the intracellular pool of 8,11,14-20:3 because there still were 238 nmol of unreacted [1-^{14}C]-8,11,14-20:3 remaining when the incubations contained 0.45 mM linoleate.

DISCUSSION

The studies of Christophersen et al. (5), as well as those reported here, show that when hepatocytes are incubated

TABLE 2

Metabolism of 0.3 mM [1-^{14}C]6,9,12-Octadecatrienic Acid in the Presence of Linoleic Acid

	mM Linoleic acid			
Fatty acid	0	0.15	0.30	0.45
TG 18:3	99 ± 27	109 ± 43	107 ± 8	158 ± 30

with [1-^{14}C]linoleate, their lipids contain radioactive 6,9,12-18:3, 8,11,14-20:3, and arachidonate. Conversely, compositional analysis of liver phospholipids usually fail to detect any 6,9,12-18:3 and only low levels of 8,11,14-20:3. Because desaturation of linoleate to 6,9,12-18:3 is rate-limiting in the production of arachidonate, the intracellular concentration of 6,9,12-18:3 must be very low. The intracellular fate of 6,9,12-18:3 then must be defined by K_m-values for the enzymes that incorporate it into phospholipids vs that for the malonyl-CoA condensing enzyme, which in turn is the rate-limiting step for microsomal chain elongation of fatty acids (13). According to this hypothesis, the K_m for the malonyl-CoA-dependent condensing enzyme should be lower than for the enzymes that acylate 6,9,12-18:3 into lipids. However, this hypothesis is not consistent with hepatocyte studies that show 6,9,12-18:3 is, in part, incorporated into lipids when these cells are incubated with linoleate. We reported that when hepatocytes were incubated with [1-^{14}C]-6,9,12-18:3 or [1-^{14}C]6,9,12,15-18:4, both of these substrates were initially rapidly incorporated into lipids (12). Over time, the amounts of 6,9,12-18:3 and 6,9,12,15-18:4 in lipids declined, but this decline was accompanied by an increase in long-chain radioactive (n-6) and (n-3) acids. These findings are at least partially consistent with rate studies. Lands et al. (6) reported that the rate of acylation of 6,9,12-18:3CoA by 1-acyl-GPC-transferase was 28 nmol/min/mg/rat liver microsomal protein. Bernert and Sprecher (4) reported that 4.4 nmol of 6,9,12-18:3 were chain-elongated to 8,11,14-20:3 per min/mg of rat liver microsomal protein. Collectively, these rate studies show that substantial amounts of 6,9,12-18:3 should be incorporated into phospholipids. However, the observed rapid release of 6,9,12-18:3 from hepatocyte lipids suggests that it enters a very small labile phospholipid pool and that it is rapidly released for subsequent metabolism to arachidonate (12).

The above results may, in part, explain why 6,9,12-18:3 is not detected when the fatty acid composition of liver lipids is measured. However, these findings alone probably cannot totally explain the type of labeling pattern that was observed when hepatocytes were incubated with [1-^{14}C]linoleate. Even at relatively short incubation times, it was possible to detect radioactive arachidonate in both triglycerides and phospholipids. This observation suggests that some linoleate may be channeled directly to arachidonate without total intracellular mixing of 6,9,12-18:3 or 8,11,14-20:3. This conclusion is supported by the finding that exogenous 6,9,12-18:3 inhibited but did not totally block the conversion of radioactive linoleate to arachidonate. Collectively, these studies as well as other hepatocyte studies (5,7,8,12) clearly show that measuring individual reaction rates for either phospholipid or fatty acid biosynthesis cannot in themselves be used to explain the types of polyunsaturated fatty acids found in liver lipids.

[Received November 16, 1987; Revision accepted March 9, 1988]

Effects of Dietary Corn Oil and Salmon Oil on Lipids and Prostaglandin E_2 in Rat Gastric Mucosa

Renée Grataroli[a], Jeannie Léonardi[a], Monique Charbonnier[a], Raymond Lafont[b], Huguette Lafont[a] and Gilles Nalbone[a,*]

[a]INSERM Unité 130, 18 avenue Mozart, 13009 Marseille, France, and [b]Laboratoire de Géologie du Quaternaire, CNRS, 13275 Marseille Cedex, France

Three groups of male rats were fed either a corn oil-enriched diet (17%, w/w), a salmon oil-enriched diet (12.5%) supplemented with corn oil (4.5%) or a low-fat diet (4.4%) for eight wk to investigate the possible relationships between dietary fatty acids and lipid composition, and prostaglandin E_2 level and phospholipase A_2 activity in the rat gastric mucosa.

High-fat diets induced no important variation in total protein, phospholipid and cholesterol contents of gastric mucosa.

Compared with a low-fat diet, corn oil produced a higher n-6/n-3 ratio in mucosal lipids, whereas this ratio was markedly lowered by a fish oil diet.

In comparison with the low-fat diet, the production of prostaglandin E_2(PGE_2) in gastric mucosa of rats fed salmon oil was significantly decreased by a factor of 2.8. In the corn oil group, PGE_2 production tended to decrease, but not significantly.

In comparison with the low-fat diet, both specific and total gastric mucosal phospholipase A_2 activities were increased (+ 18 and 23%, respectively) in the salmon oil group; they were unchanged in the corn oil group.

It is suggested that the decrease of gastric PGE_2 in rats fed fish oil is not provoked by a decrease in phospholipase A_2 activity but may be the result of the substitution of arachidonic acid by n-3 PUFA or activation of PGE_2 catabolism.

***Lipids* 23, 666–670 (1988).**

It now is well accepted that prostaglandins can protect the gastric mucosa from becoming injured by various irritants and that this effect is mediated by two distinct mechanisms: inhibition of gastric acid secretion (1,2) and cytoprotection (3,4). It recently has become evident that exogenous and endogenous prostaglandins, mostly of the E-series (PGE_2), exert cytoprotective properties (3) and are effective in the treatment of peptic ulcer disease (5).

Synthesis of prostaglandins is initiated by the release of arachidonic acid through the action of phospholipase A_2 on the 2-position of membrane phospholipids. Such an activity has been described in rat gastric mucosa (6–8), and we recently have shown that this enzyme is mostly associated with microsomal and plasma membranes (8).

Prostaglandin synthesis can be affected by ingestion of fish oils. Fish oils are rich in n-3 polyunsaturated fatty acid (PUFA), which were demonstrated to be efficient in lowering plasma cholesterol and preventing atherosclerosis (9–14). Another beneficial effect of fish oils is to lower platelet aggregability through modifications of prostaglandin I_2 and thromboxane A_2 production (9,15). However, modification of the prostaglandin level in various tissues may lead to nonbeneficial effects. For example, Lokesh et al. (16) have recently reported that menhaden oil fed to mice altered the spleen prostaglandin production, which in turn may affect the immune function of this organ. In the same way, ingestion of cod liver oil by rats resulted in a reduction in kidney PGE_2 generation, which may influence blood pressure regulation (17).

In regard to the importance of prostaglandins in gastric cytoprotection and to the marked effect of the dietary n-3 PUFA on prostaglandin level in various tissues, we investigated the effect of n-3 PUFA (salmon oil) in comparison with n-6 PUFA (corn oil) on gastric prostaglandin production in rat. Possible relationships between dietary fatty acids and lipid composition of gastric mucosa, gastric phospholipase A_2 activity and prostaglandin production were studied.

MATERIAL AND METHODS

Animals and feeding procedures. Three groups of male Wistar rats (IFFA-Credo, L'Arbresle, France) weighing 190–210 g were used. Each group was divided into cages of two rats. One group (10 rats) was fed a low-fat diet containing (4.4%, w/w) of fat consisting of a lard and corn oil mixture giving a P/S ratio of 1.2. A second group (10 rats) received a corn oil-enriched diet (17%, w/w) with a P/S ratio of 5. The third group was fed a salmon oil-enriched diet (12.5%, w/w) supplemented with 4.5% of corn oil, with a P/S ratio of 2.0. The composition of the diets and their fatty acid compositions are given in Tables 1 and 2, respectively.

Corn oil, as supplied, contained 45 mg/100 g of α-tocopherol and salmon oil was supplemented with 100 mg/100 g of α-tocopherol as antioxidant. So, the total amounts supplied by the control diet, corn oil diet and salmon oil diet were 171 mg, 246 mg and 315 mg/kg of diet, respectively. The low-fat and corn oil diets were prepared to last one month and stored at −20 C in plastic bags, and the salmon oil diet was prepared every two wk and stored at −20 C in sealed containers flushed with nitrogen.

The rats were fed ad libitum, and uneaten food was discarded in the morning. They had free access to water, and the feeding period was for eight wk.

Procedures for stomach. The animals were fasted overnight, weighed and guillotined. Their stomachs were removed, opened and extensively washed at 4 C with the homogenization buffer (5 mM Tris HCl, pH 7.4, 0.25 M sucrose). The upper portion of the stomach, the forestomach, was discarded, and the glandular part (antrum plus fundus) was gently scraped on an ice-cold glass plate, the mucosa was weighed and suspended in the same homogenization buffer (10%, w/v) and homogenized by

using a polytron tissue processor (Kinematica PT-10, Luzern, Switzerland) for 10 sec at the rheostat setting of 6.0.

Fractions for the prostaglandin E_2 assay were diluted with a same volume (v/v) of a Tris HCl 0.1 M, pH 7.4, buffer to obtain a final concentration of 50 mM Tris HCl, pH 7.4, 0.125 M sucrose. Then they were stored at −60 C until use, and undiluted fractions were stored at −20 C pending biochemical analysis.

Protein assay. Proteins were measured by the dye-binding method of Bradford (18) using rabbit γ-globulin as standard (protein assay kit, Bio-Rad, Richmond, CA).

Phospholipase A_2 assay. Gastric phospholipase A_2 was assayed as recently described (8). Incubation mixtures contained 0.2 mM 1-palmitoyl-2[1-^{14}C]oleoylphosphatidylcholine (Amersham, France) with a specific radioactivity of 59.2 KBq/μmol and 50 mM sodium cacodylate at pH 7.0 in a final volume of 0.2 ml. Radioactivity was counted by liquid scintillation spectrometry (Beckman LS 9000, Palo Alto, CA) in 10 ml of Readysolve MP (Beckman) scintillation fluid. The results were corrected for a control incubated without protein. All the assays were done in duplicate.

Prostaglandin E_2 assay. Prostaglandin E_2 was extracted with ethylacetate from gastric mucosa homogenates (5 mg protein) according to the method of Lokesh et al. (16). Prostaglandin E_2 was quantified by radioimmunoassay (RIA), using a [^{125}I]prostaglandin E_2 RIA kit (NEK-020) purchased from NEN (Paris, France).

Appropriate blanks for nonspecific binding and tubes for total binding determinations were included. All the assays were done in duplicate (two extractions). All the measurements were in the linear portion of the standard curve.

Lipid analysis. Lipids were extracted from the gastric mucosa homogenate by the method of Folch et al. (19).

A fraction of this extract was used for lipidic phosphorus determination (20). Another part of this extract was used to determine total lipid fatty acid composition. Fatty acid methyl esters (FAME) of total lipids were prepared according to a rapid and convenient method used for vegetable oils (21). FAME recovered in hexane were stored under nitrogen at −20 C pending gas liquid chromatography (GLC) analysis. Separation of FAME was performed as described (22), using a gas liquid chromatograph (Girdel 3000, Paris, France) equipped with a peak integrator (Delsi, Enica 10, Suresne, France) and a 50 m capillary column (Spirawax FS, 1493, Spiral, Dijon, France).

The cholesterol content of gastric mucosa was determined with the cholesterol esterase-cholesterol oxidase kit (Boehringer Mannheim, Mannheim, FRG) using a two-point kinetic method. Measurements were made with an automatic Multistat III (Instrumentation Laboratory, Lexington, MA) at 30 C.

Statistical analysis. Results presented in the tables are mean ±SD. Statistical significance of mean differences between dietary groups was investigated by analysis of variance (ANOVA) and by the multiple comparison of Scheffé at $p < 0.05$ or $p < 0.01$.

RESULTS

Over the eight-wk feeding period, there was no significant difference ($p > 0.05$) in body weight gains. They were (in

g): 180.5 ± 19.3, 203.1 ± 35.0 and 218.0 ± 25.0 for rats fed low-fat, corn oil and salmon oil diets, respectively. Also, gastric mucosa weights were not significantly different among the three groups of rats: they weighed (in g) 0.37 ± 0.03, 0.33 ± 0.06 and 0.37 ± 0.06 in rats fed low fat, corn oil and salmon oil, respectively. No visible gastric ulceration was observed among the three groups of rats.

The content of proteins, total phospholipids and total cholesterol of gastric mucosa is shown in Table 3. In comparison with a low-fat diet, only corn oil induced a moderate increase of 15% in proteins and a slight decrease of 14% in total phospholipids. Total cholesterol was unchanged among the three dietary groups.

To estimate the respective contribution of fatty acid originated from phospholipids and triglycerides, we gravimetrically determined the total amount of gastric mucosa lipids obtained from the Folch extraction. The quantification of lipidic phosphorus and cholesterol in this extract allowed us to estimate the amount of neutral lipids. It showed that the phospholipids represented about 75% (w/w) of the lipids esterified by fatty acids.

The fatty acid composition of total lipids is shown on Table 4. It can be observed that in comparison with the low fat diet, both corn oil and salmo • oil induced profound modifications in the fatty acid composition of gastric lipids. Corn oil diet provoked a significant decrease in both saturated (−40%) and monounsaturated (−20%) fatty acids, whereas PUFA increased two-fold. This rise was due mostly to a three-fold increase in linoleic acid. However, arachidonic acid was significantly decreased by a factor of 1.4. All of these modifications led to a 1.7-fold increase in the n-6/n-3 ratio. Salmon oil–enriched diet provoked a less-pronounced decrease in saturated and monounsaturated fatty acids than corn oil did. In comparison with a low-fat diet, PUFA were 45% higher. In the PUFA, the most pronounced effect of salmon oil was a 2.4-fold decrease in arachidonic acid, whereas n-3 PUFA were drastically increased, particularly the 20:5n-3 and 22:6n-3. Consequently, in comparison with the two other dietary groups, a drastic reduction in the n-6/n-3 ratio and in the 20:4n-6/20:5n-3 ratio was obtained in this dietary group, whereas the unsaturation index was augmented by about 38%.

The activity of gastric phospholipase A_2 and the PGE_2 production under the various dietary conditions were investigated. Results presented in Table 5 show that in comparison with the low-fat diet, only the salmon oil–enriched diet induced a slightly significant increase (+18%) in the specific activity of phospholipase A_2. In the same way, the total phospholipase A_2 activity (μmol/hr/g mucosa) also was slightly increased (+23%) in the salmon oil group. In this last group, compared with the low-fat group, PGE_2 production was considerably lowered by a factor of 2.8. Although the PGE_2 level tended to decrease in the corn oil group, the difference was not significant ($p > 0.05$) compared with the low-fat diet group. However, this PGE_2 level still was significantly ($p < 0.01$) higher (2.1 times) than that of the salmon oil group.

DISCUSSION

Throughout the feeding period, all the diets were well-accepted by the rats as judged by their growth rates. The diets induced no visible ulceration of the gastric mucosa. Protein and lipid composition of mucosa showed no important variation under the different dietary conditions.

Significant modifications were seen in the fatty acid composition of total lipids. Generally speaking, the modifications observed seem to reflect the fatty acid composition of the diet. For the corn oil diet, the decrease in saturated fatty acids was associated with a high increase in linoleic acid. This may be the result of a high affinity of acyl-CoA:lysophosphatidylcholine-acyltransferase for the linoleoyl-CoA during reconstitution of membrane phospholipids initially hydrolyzed by the active gastric phospholipase A_2 (8). Curiously, this increase in linoleic acid was not correlated with a higher conversion into arachidonic acid, the final level of which even decreased. This phenomenon also has been observed in various tissues like kidney (17), heart (22) and platelets (23,24) of animals fed linoleic-rich vegetable oils. This could indicate that, at some point, a balance is reached between the increased availability of linoleic acid and its conversion into arachidonic acid. The results obtained with salmon oil–enriched diet show that n-3 PUFA of the diet are easily incorporated in gastric mucosa lipids, drastically reducing

TABLE 3

Effects of Dietary Corn Oil and Salmon Oil on Protein, Lipidic Phosphorus and Total Cholesterol Content of Rat Gastric Mucosa

UI, unsaturation index: addition of (percent of each fatty acid × double bond/fatty acid).

TABLE 5

Effects of Dietary Corn Oil and Salmon Oil on Phospholipase A_2 Activity and PGE_2 Production of Rat Gastric Mucosa

	Low fat	Corn oil	Salmon oil
Phospholipase A_2 Specific activity nmol/hr/mg protein	628.4 ± 44.0^{a,**}	568.5 ± 57.4^{a,**}	741.7 ± 35.0^{b,**}
Phospholipase A_2 Total activity μmol/hr/g mucosa	123.3 ± 18.8^{a,**}	126.5 ± 17.6^{a,*}	151.7 ± 19.4^{b,**}
PGE_2 ng/g mucosa	327.3 ± 75.4^{a,**}	250.8 ± 82.4^{a,**}	116.5 ± 40.9^{b,**}

Values without a common superscript are statistically different at $^{*}p < 0.05$; $^{**}p < 0.01$. If no superscript appears, values are not different ($p > 0.05$). Values are mean ± SD. For phospholipase A_2, n = 10 for low-fat and corn oil diets; n = 12 for salmon oil diet. For PGE_2 values: n = 9 for low-fat diet; n = 8 for corn oil diet; n = 12 for salmon oil diet.

both the n-6/n-3 and the 20:4n-6/20:5n-3 ratios. The marked reduction of arachidonic acid could not be attributed to the lack of the 18:2n-6 substrate in the precursor pool because an adequate amount of this fatty acid was added to the diet by supplementing with corn oil. Such a competitive incorporation of dietary n-3 PUFA also has been observed in various tissue phospholipids in rat (15–17,25,26). This enhanced incorporation of n-3 PUFA may be the result of several factors, including a better esterification of n-3 PUFA into membrane phospholipids by acyltransferase, or a competition between n-3 PUFA and 18:2n-6 at desaturation step (27) or a direct inhibition of the Δ6-desaturase by the 22:6n-3 (28).

Arachidonic acid is the precursor of the prostaglandins of the 2-series, whereas eicosapentaenoic acid is the precursor of the 3-series. The salmon oil–enriched diet sharply decreased the ratio 20:4n-6/20:5n-3 in gastric phospholipids, which may have important consequences on the gastric prostaglandin level. Among the gastric mucosal prostaglandins, PGE_2 was demonstrated to be more efficient in protecting (3,29) and in treating peptic ulcer diseases (5), therefore we focused our study on this prostaglandin. Clearly, fish oil induced a significant and sharp decrease in gastric PGE_2 production. Reduction of PGE_2 level also was observed in spleen (16) and kidney (17) of animals fed fish oils. The PGE_2 decrease is certainly not the result of a reduction in the release of the precursor 20:4n-6 from membrane phospholipids by the gastric phospholipase A_2, because its specific activity was slightly increased in this dietary group. This PGE_2 decrease can result from the drop in the arachidonic acid pool. Although not significant, this phenomenon also was observed in the corn oil group in which the drop in arachidonic acid might explain that PGE_2 tended to decrease. Reduction in PGE_2 levels also has been noted in other studies in which animals were fed linoleic acid-enriched oils (17,23,30) or in which endothelial cells were cultured with linoleic acid (31,32).

In addition to the diminution of the arachidonic pool, the presence in fish oil diet of n-3 PUFA may exert a direct inhibitory action on the cyclooxygenase (33,34). Combination of these effects may explain the drastic drop in gastric PGE_2 level production in rats fed salmon oil. Lastly, a PUFA-induced enhanced prostaglandin peroxisomal degradation also may lead to a lower PGE_2 level as judged by results in progress that show an increase in the activity of some peroxisomal enzymes in gastric mucosa of animals fed fish oil.

In conclusion, this study brings an additional and original demonstration of the inhibitory effect of high doses of n-3 PUFA on prostaglandin generation in organs. In the case of gastric mucosa, this diminution could impair the cytoprotective properties of PGE_2. This, in turn, may hamper the resistance of the stomach to various injuries like stress, lysolecithins or bile salts after a duodenal reflux.

ACKNOWLEDGMENTS

The authors thank Patrick Garzino for assistance in caring for the animals during the feeding period and Michelle Bonneil for typing the manuscript.

[Received October 6, 1987; Revision accepted March 18, 1988]

Perfluorodecanoic Acid and Lipid Metabolism in the Rat

Marc J. Van Rafelghem, John P. Vanden Heuvel, Lawrence A. Menahan, and Richard E. Peterson*
School of Pharmacy, University of Wisconsin, 425 N. Charter St., Madison, WI 53706

Alterations in lipid metabolism were examined in adult male Sprague-Dawley rats seven days after a single intraperitoneal injection of perfluorodecanoic acid (PFDA; 20, 40 or 80 mg/kg). Because PFDA treatment caused a dose-related reduction in feed intake, the response of vehicle-treated rats pair-fed to those receiving PFDA was monitored to distinguish direct effects of the perfluorinated fatty acid from those secondary to hypophagia. Carcass content of lipid phosphorus and free cholesterol decreased in dose-dependent fashion in both PFDA-treated and pair-fed rats. Carcass triacylglycerols diminished in a similar manner, yet PFDA-treated rats at each dose had a higher concentration of neutral acylglycerols than their vehicle-treated, pair-fed counterparts. In vehicle-treated, pair-fed rats at the 80 mg/kg dose level, lipid phosphorus and free cholesterol as a proportion of carcass fat increased, whereas the share of the triacylglycerols declined. Because of the higher concentration of triacylglycerols in the carcass of rats treated with 80 mg/kg PFDA, enrichment of lipid phosphorus and free cholesterol in carcass fat was less than in their pair-fed partners. The amount of lipid phosphorus and free cholesterol per hepatocyte was similar in both PFDA-treated rats and their pair-fed partners. Liver triacylglycerols were markedly increased in PFDA-treated rats. A similar but less extensive augmentary effect of PFDA on hepatic esterified cholesterol was found. Concentration of triacylglycerols in plasma was not elevated in PFDA-treated rats, in spite of hepatic accumulation of esterified compounds. Also, the plasma level of free fatty acids and 3-hydroxybutyrate was similar in all treatment groups, including those receiving PFDA. Thus, the administration of PFDA appears to divert fatty acids from oxidation toward esterification in the liver.
***Lipids 23,* 671–678 (1988).**

Derivatives of perfluorosulfonic and perfluorocarboxylic acids have been used in a number of industrial applications as lubricants, plasticizers, wetting agents and corrosion inhibitors (1). Aqueous film-forming foams, used as fire extinguishants, contain mixtures of hydrocarbon and fluorocarbon surfactants (derivatized fatty acids) due to their superior surface-active properties (2).

Perfluorodecanoic acid (PFDA), representative of these perfluorinated fatty acids, resulted in a progressive reduction in feed intake, body weight loss, along with an increase in liver mass and changes in hepatic lipid composition in the rat (3,4). These effects followed treatment with a single intraperitoneal dose of PFDA. Recently, PFDA-treated rats were found to either gain less or lose more weight (depending on the dose administered) than vehicle-treated rats with the same caloric intake (5). Despite their lower body weight, PFDA-treated rats had a greater carcass fat content than their pair-fed counterparts (5).

Abbreviations: PFDA, perfluorodecanoic acid; ANOVA, analysis of variance; SAS, statistical analysis system.

Lipid metabolism in the PFDA-treated adult male Sprague-Dawley rat has been examined in this study. By quantifying and comparing values for carcass, liver and plasma lipids in PFDA-treated and pair-fed animals, direct effects of PFDA on lipid metabolism were distinguished from those secondary to hypophagia.

MATERIALS AND METHODS

Chemicals. PFDA (also nonadecafluorodecanoic acid) was purchased from Aldrich Chemical Co. (Milwaukee, WI) and determined to have a purity of 87.4% by gas chromatography (6). All enzymes and cofactors were obtained from Boehringer Mannheim Corp. (Indianapolis, IN), with the exception of cholesterol oxidase and o-dianisidine, which were purchased from Sigma Chemical Co. (St. Louis, MO). Coomassie blue G-250 was obtained from Pierce Chemical Co. (Rockford, IL).

Animals. Male Sprague-Dawley rats (275–300 g), obtained from Harlan Sprague-Dawley (Indianapolis, IN), were individually housed in suspended stainless-steel cages in a temperature-controlled room (ca. 21 C) with a 12-hr light/dark cycle (lighted, 0500-1700 hr). A schedule was maintained so that ground feed (Purina Rat Chow, #5012, Ralston Purina Co., St. Louis, MO) was available from 1700 to 0830 hr and tap water was available ad libitum. An acclimation period of at least one wk was allowed before the initiation of an experiment. Rats then were paired on the basis of similar body weight. PFDA-treated rats received a single intraperitoneal injection of PFDA with dosing at 20, 40 or 80 mg/kg. At 24 hr after the PFDA-treated rat was dosed, its partner with a similar weight was given an equivalent volume of vehicle (propylene glycol/water, 50:50, v/v; 1 ml/kg). This vehicle-treated animal then received the same amount of feed its PFDA-treated partner had consumed during the previous 15–16 hr feeding period (pair-feeding). An additional group of vehicle-treated rats, with unlimited access to ground chow during the feeding period (15–16 hr), was included. Body weight and feed intake were measured daily for seven days following injection of PFDA or vehicle.

Experimental protocols. Two series of protocols were conducted. In the first set, carcass lipid was determined in rats killed by cervical dislocation seven days post-treatment between 1600 and 1700 hr. The gastrointestinal tract was removed, emptied of all contents and returned to the body cavity. Carcasses were weighed, placed in plastic bags, and frozen at −20 C. Each frozen carcass was ground to a homogeneous mixture with a Wiley laboratory mill cooled with liquid nitrogen. The ground carcasses were stored in individually sealed bags (Ziploc) at −20 C for later body composition analysis (5).

Liver and plasma lipid analyses were performed on tissue from rats exsanguinated by decapitation seven days post-treatment between 1300 and 1600 hr in the second series of protocols. Trunk blood was collected in a 50 ml disposable beaker containing 100 μl of 15% (w/v) potassium-ethylenediamine tetraacetic acid. Plasma was separated and stored at −70 C. A portion of liver was

frozen by freeze-stop technique (7) at the temperature of liquid nitrogen, weighed, and ground to a fine powder in a pre-cooled mortar and pestle. The frozen liver powder was stored in cryogenic vials under liquid nitrogen until the time of assay. The remaining liver tissue was excised and weighed. Total liver mass represents the combined weight of these two portions.

Analytical methods. Carcass, liver and plasma lipids were extracted with chloroform/methanol by a micro-adaptation of the procedure described originally by Folch et al. (8). Liver and carcass tissue powders, as well as plasma samples, were homogenized by mechanical disruption (2 × 15 sec with a 30-sec pause) in chloroform/methanol (2:1, v/v) in the proportion of 19 volumes of solvent to 1 volume of sample using a Tissumizer homogenizer with a micro probe (Tekmar Co., Cincinnati, OH). The crude extract was washed with 50 mM NaCl. Aliquots of the washed lipid extract were taken to dryness and analyzed for neutral glycerols (9). For lipid phosphorus determinations (10), digestion of lipid in a dried crude extract was accomplished by gentle refluxing with 70% perchloric acid in the presence of pure carborundum chips (133-A, Hengar and Co., Philadelphia, PA) on a micro-Kjeldahl digestion rack (11). Dipalmitoyl-dl-α-phosphatidylcholine, dipalmitoyl-dl-α-phosphatidylethanolamine, and sodium tribasic phosphate yielded equivalent standard curves. Determination of carcass fat (ether-extractable at 50 C) has been described (5).

Total cholesterol determination followed chemical hydrolysis of the cholesteryl esters to free cholesterol (12). Cholesterol then was oxidized enzymatically to cholest-4-en-3-one and hydrogen peroxide with cholesterol oxidase. The hydrogen peroxide generated was reacted with horseradish peroxidase in the presence of o-dianisidine to form a stable chromophore (13). Determination of free cholesterol was performed with the enzymatic reaction for cholesterol in the absence of chemical hydrolysis. Esterified cholesterol then was calculated as the difference between the values for total and free cholesterol. Enzymatic determination of 3-hydroxybutyrate was made on neutralized, perchloric acid extracts of plasma (14) as described by Williamson and Mellanby (15). The concentration of free fatty acids in plasma was quantitated by a sensitive micro method (16).

For DNA and protein analysis, liver homogenates in water (10%, w/v) were prepared by mechanical disruption (2 × 15 sec; Tissumizer) with a 30-sec pause between bursts with cooling in an ice-water mixture. After extraction of interfering lipids (17), DNA content was estimated by a micro-adaptation of the procedure described by Richards (18) using calf thymus DNA as standard. Total hepatic protein was determined by the dye-binding method of Bradford (19) with crystalline bovine serum albumin as standard.

Statistical analysis. The main effects of treatment (PFDA vs pair-fed) and dosing (20, 40 or 80 mg/kg) were analyzed by two-way analysis of variance (ANOVA) through the use of unweighted cell means (20). Significance of difference between PFDA-treated rats and their pair-fed counterparts at a given dose was detected by pair-wise comparison (20). Effect of dosing between treatment groups, PFDA or pair-fed, including comparison with the vehicle-treated group of rats with unlimited access to feed, was tested by one-way ANOVA and significance of differences between doses was analyzed using Scheffé's multiple comparison method (20). Linear function among doses was evaluated by testing for trends using orthogonal coefficients if effect of dosing in the one-way ANOVA was significant (21). The computations were performed with a VAX-750 computer using SAS (22). In all cases, significance was set at $p < 0.05$.

RESULTS

Body weight and feed intake. Cumulative feed intake of rats during the seven days following PFDA treatment was diminished in a dose-related manner with a remarkable decrease occurring at the 80 mg/kg dose (Fig. 1). Body weight of both PFDA-treated rats and their vehicle-treated, pair-fed counterparts at seven days post-treatment also was reduced in a dose-dependent fashion. Even though the cumulative feed intake of PFDA-treated rats and pair-fed counterparts was comparable at each dose level, the mean body weight of those receiving PFDA was lower at seven days after treatment (Fig. 1). When the change in body weight (calculated as the difference between the initial and final body weight) was analyzed by two-way ANOVA, the difference between PFDA-treated rats and their respective vehicle-treated, pair-fed partners was significant by pair-wise comparison at the 40 and 80 mg/kg dose levels.

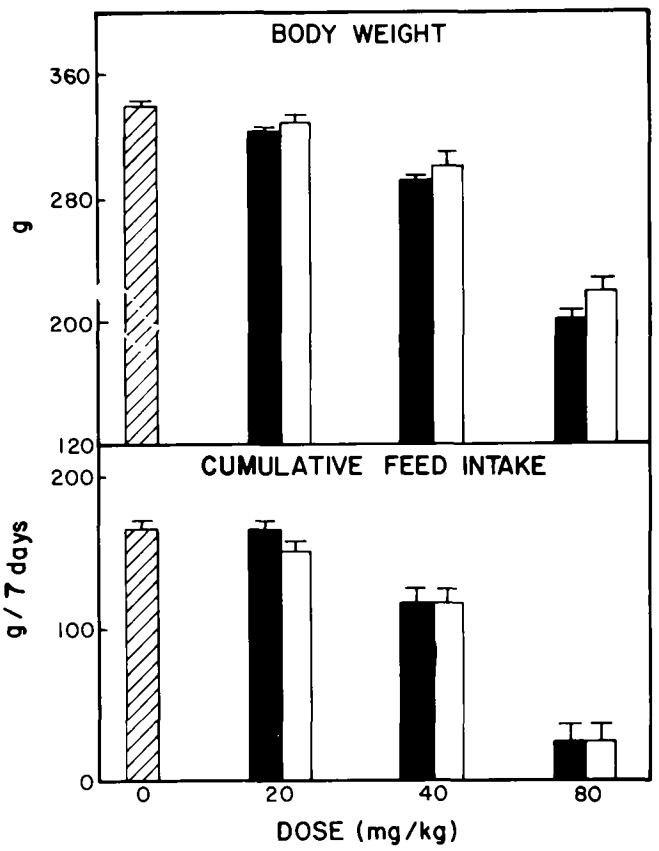

FIG. 1. Body weight and cumulative feed intake in PFDA- (20, 40 or 80 mg/kg) and vehicle-treated rats seven days after treatment. Vehicle-treated rats were either allowed unlimited access to feed (hatched bar) or were pair-fed (open bar) to PFDA-treated rats (closed bar). Each bar and its associated vertical line represent the mean and one S.E.M. (n = 4 for each treatment group).

Carcass. Content of triacylglycerols, whether expressed per g wet wt, carcass, or g fat, was significantly reduced in both PFDA-treated rats and their vehicle-treated, pair-fed counterparts at the 80 mg/kg dose level (Fig. 2). However, PFDA-treated rats at each dose had a higher concentration of triacylglycerols per g wet wt carcass than their pair-fed partners. A reduction in lipid phosphorus per carcass was found in the PFDA-treated rats as well as their vehicle-treated, pair-fed counterparts with increasing dose (Table 1). As a proportion of carcass fat, lipid phosphorus was enriched in the vehicle-treated, pair-fed rats at the 80 mg/kg dose level when compared with either the vehicle-treated group with unlimited access to feed or PFDA-treated rats at the same dose (Table 1). Lipid phosphorus per g fat was reduced in PFDA-treated rats at the 20 and 40 mg/kg dose levels but elevated at 80 mg/kg, in comparison with vehicle-treated rats with unlimited access to feed. With a dose of 40 mg/kg, the concentration of lipid phosphorus in carcass fat of rats receiving PFDA was less than their vehicle-treated, pair-fed partners and this difference was significant (Table 1). The concentration and content of free cholesterol in the carcass did not differ significantly between any of the treatment groups (Table 1). When expressed as a proportion of the carcass fat, free cholesterol was significantly higher in the vehicle-treated rats pair-fed to their PFDA-partners at the 80 mg/kg dose than in other vehicle-treated groups. A similar but less extensive increase was seen in the PFDA-treated rats at the 80 mg/kg dose, and the difference from their vehicle-treated, pair-fed partners was significant (Table 1). An augmentary effect of PFDA on esterified cholesterol concentration and content in the carcass was demonstrated by a significant treatment effect in the two-way ANOVA; however, the difference between PFDA-treated rats and their vehicle-treated, pair-fed partners at each dose level was not significant by pairwise comparison (Table 1).

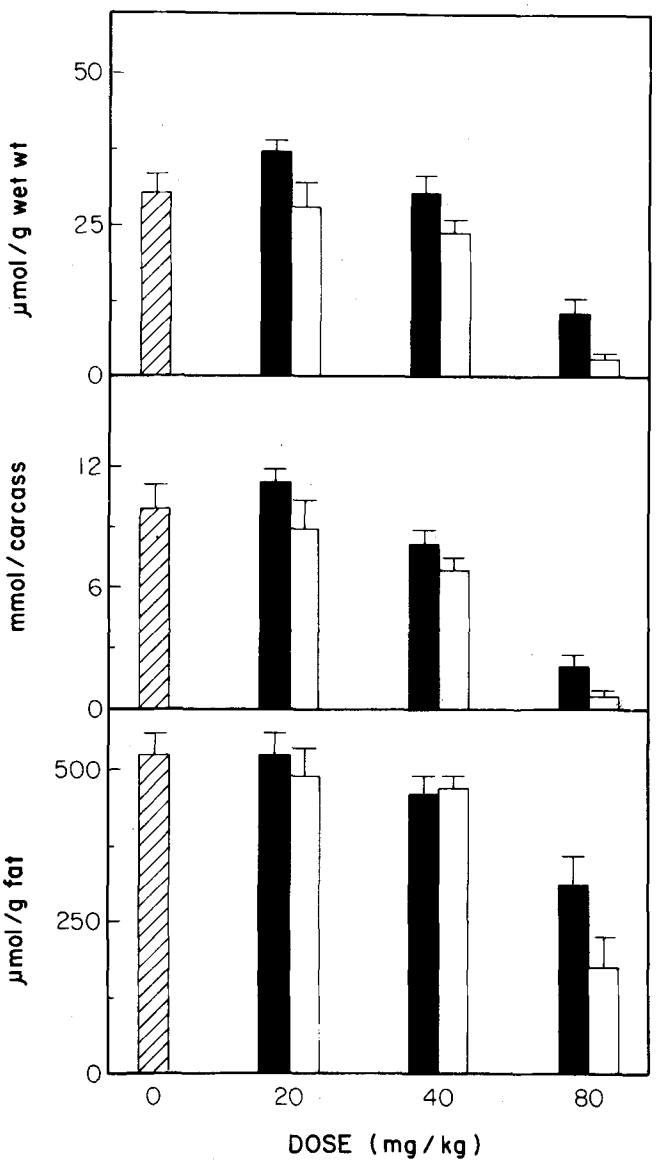

FIG. 2. Effect of PFDA treatment on carcass triacylglycerols in the rat. Vehicle-treated rats were either allowed unlimited access to feed (hatched bar) or were pair-fed (open bar) to PFDA-treated rats (closed bar). Each bar and its associated vertical line represent the mean and one S.E.M. (n = 4 for each treatment group).

Liver. Absolute and relative weight in PFDA-treated animals was significantly greater than in their vehicle-treated, pair-fed partners at all doses examined. When compared with the treatment groups receiving 20 and 40 mg/kg, the absolute increase in liver mass was significantly less, but relative liver weight was maintained in PFDA-treated rats at the 80 mg/kg dose level (Table 2). At the 80 mg/kg dose level, liver mass expressed on an absolute and relative basis, was reduced in vehicle-treated animals pair-fed to PFDA-treated rats (Table 2).

Hepatic DNA concentration was significantly higher in vehicle-treated rats pair-fed to those receiving 80 mg/kg PFDA when compared to the other vehicle-treated groups (Table 2). The concentration of DNA in the livers of PFDA-treated rats was lower than in their vehicle-treated pair-fed counterparts, and this difference was significant at the 20 and 80 mg/kg dose levels (Table 2). The DNA content per liver was reduced in a dose-related fashion in vehicle-treated rats, whereas it was maintained in the animals receiving PFDA at all doses. The difference in total DNA per liver between PFDA-treated rats and their vehicle-treated, pair-fed partners at the 40 and 80 mg/kg dose levels was significant (Table 2). Hepatic protein concentration was higher in vehicle-treated, pair-fed groups than in their PFDA-treated partners, and this difference was significant at the 80 mg/kg dose level (Table 2). At the 80 mg/kg dose level, total protein per liver was reduced significantly in rats receiving PFDA as well as their vehicle-treated, pair-fed partners. When hepatic protein was expressed per mg DNA, no statistically significant differences were detected between any of the treatment groups (Table 2).

Hepatic concentration of lipid phosphorus and free cholesterol was similar in all treatment groups (Table 3). When expressed per liver, a significant reduction in the content of lipid phosphorus and free cholesterol was found in vehicle-treated, pair-fed rats at the 80 mg/kg dose level, when compared with either the other vehicle-treated groups or those receiving PFDA. On a cellular basis (per mg DNA), lipid phosphorus but not free cholesterol was influenced significantly by dose with a decline at the 80 mg/kg dose level (Table 3).

[a]Values are reported as the mean and S.E.M. for three to four rats and are expressed as μmol/ml plasma.

Mean values in a column not followed by the same superscript (b, c, d) are significantly different from other dose levels within the PFDA treatment group using Scheffé's multiple comparison method ($p < 0.05$). The unlimited-fed group serves as the zero-dose level.

Mean values in a column not followed by the same superscript (e, f, g) are significantly different from other dose levels within the pair-fed treatment group using Scheffé's multiple comparison method ($p < 0.05$). The unlimited-fed group serves as the zero-dose level.

*Difference from the respective pair-fed group is significant ($p < 0.05$).

PFDA treatment resulted in a dose-related increase in liver triacylglycerols (Fig. 3). When expressed per g wet wt or mg DNA, the increment of hepatic triacylglycerols between PFDA-treated rats and their vehicle-treated, pair-fed counterparts at the 40 and 80 mg/kg dose levels was significant (Fig. 3). The content of triacylglycerols per liver was significantly greater in PFDA-treated rats than their vehicle-treated, pair-fed partners at all doses examined. However, liver triacylglycerols expressed per g wet wt, liver or mg DNA, were diminished in the vehicle-treated rats pair-fed to those receiving 80 mg/kg PFDA when compared with the other vehicle-treated groups (Fig. 3).

The response of hepatic esterified cholesterol to PFDA treatment was similar but less pronounced than that of liver triacylglycerols. A dose-related increase in liver esterified cholesterol was found in PFDA-treated rats (Fig. 4). The difference in hepatic esterified cholesterol between rats receiving PFDA and their pair-fed partners was significant at the 80 mg/kg dose level, whether expressed per g wet wt, liver or mg DNA. Hepatic esterified cholesterol also was elevated in PFDA-treated rats at the 40 mg/kg dose, but the difference from their vehicle-treated, pair-fed partners was statistically significant only when expressed per liver.

Plasma. The plasma level of free fatty acids and 3-hydroxybutyrate was similar in all treatment groups (Table 4). The concentration of triacylglycerols and lipid phosphorus in plasma decreased in a dose-related fashion in both PFDA-treated and pair-fed groups, but a significant difference between treatments was not detected by two-way ANOVA (Table 4). With a dose of 20 mg/kg, the plasma concentration of free cholesterol was lower in rats receiving PFDA than in their vehicle-treated, pair-fed partners (Table 4). At the 80 mg/kg dose level, the concentration of free cholesterol was higher in the plasma of PFDA-treated rats than their pair-fed counterparts, and the difference was significant. This dissimilarity resulted from a decrease in the plasma level of free cholesterol in the vehicle-treated, pair-fed group (Table 4). Also, the vehicle-treated rats pair-fed to their partners receiving 80 mg/kg PFDA had a concentration of

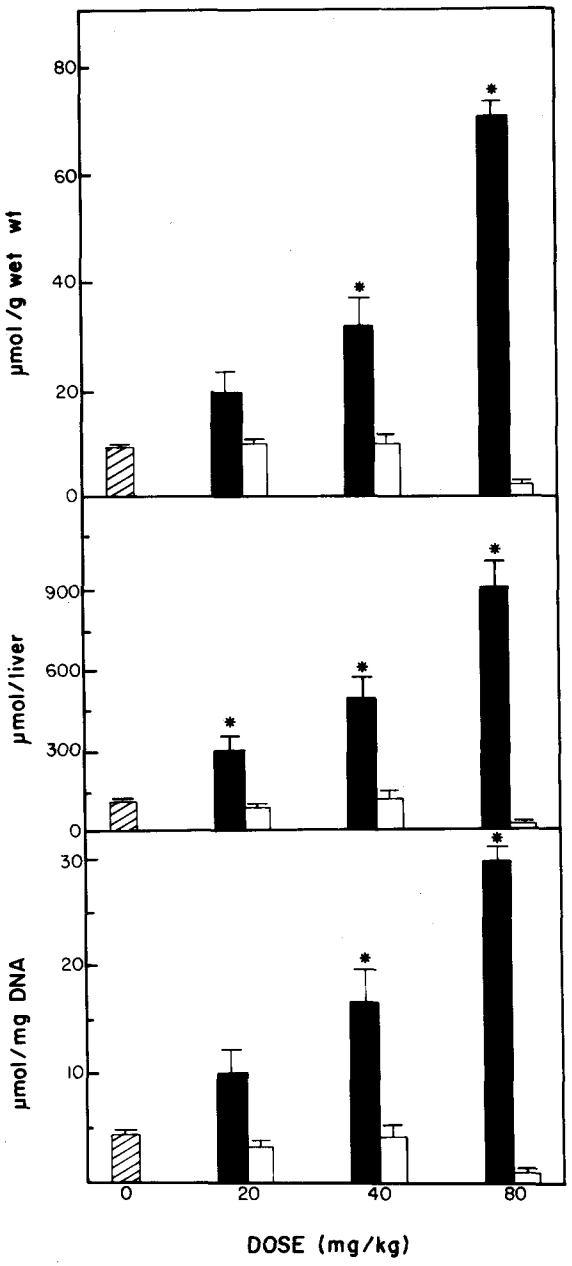

FIG. 3. Liver triacylglycerols in rats seven days after PFDA treatment. Vehicle-treated rats were either allowed unlimited access to feed (hatched bar) or were pair-fed (open bar) to PFDA-treated rats (closed bar). Each bar and its associated vertical line represent the mean and one S.E.M. (n = 4 for each treatment group). *Difference from the respective pair-fed group is significant ($p < 0.05$).

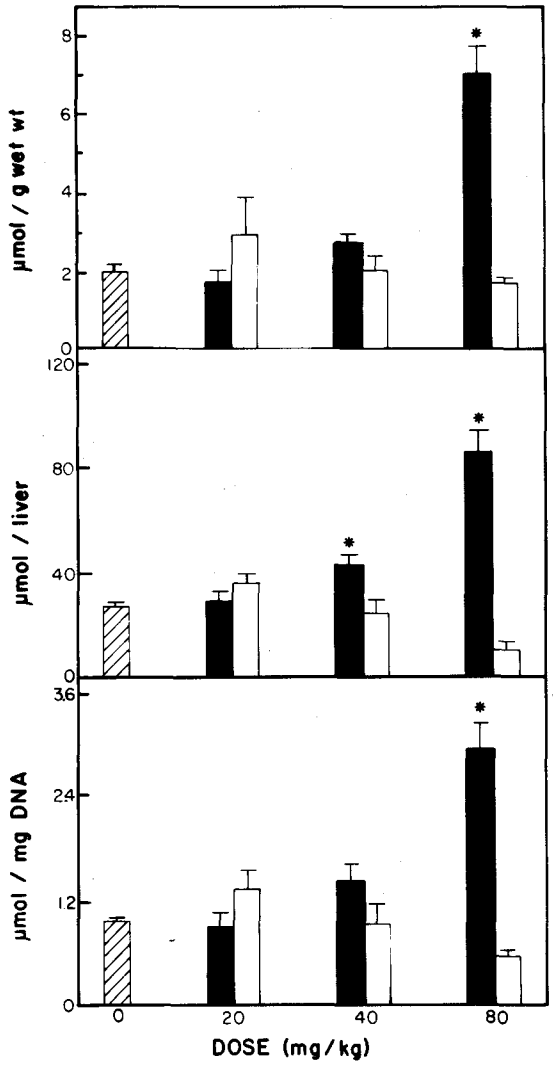

FIG. 4. Liver esterified cholesterol in rats seven days after PFDA treatment. Vehicle-treated rats were either allowed unlimited access to feed (hatched bar) or were pair-fed (open bar) to PFDA-treated rats (closed bar). Each bar and its associated vertical line represent the mean and one S.E.M. (n = 4 for each treatment group). *Difference from the respective pair-fed group is significant ($p < 0.05$).

esterified cholesterol in plasma that was lower than the other vehicle-treated groups, whether pair-fed or with unlimited access to feed (Table 4). In PFDA-treated rats, regardless of dose, the plasma level of esterified cholesterol was lower than that of the vehicle-treated group with unlimited access to feed (Table 4). At the 20 and 40 mg/kg dose levels, the concentration of esterified cholesterol in plasma also was significantly lower in PFDA-treated rats than their vehicle-treated, pair-fed partners.

DISCUSSION

Following a single intraperitoneal injection of PFDA, alterations in lipid metabolism of the adult male Sprague-Dawley rat were investigated seven days after dosing. Because the administration of PFDA causes a dose-dependent reduction in feed (caloric) intake (3–5), it was important to take this into account in the interpretation of the data through the use of a vehicle-treated rat, pair-fed to each one receiving PFDA. Thus, the primary effects of PFDA on lipid metabolism could be distinguished both qualitatively and quantitatively from those secondary to hypophagia.

A dose-related decrease in both body and carcass weight, associated with a diminution in caloric intake, was seen in rats receiving PFDA as well as their vehicle-treated, pair-fed counterparts. Reduction in the carcass content of lipid phosphorus (phospholipid) and free

cholesterol in rats treated with PFDA would seem to be consequent to hypophagia and resulting weight loss, as the appropriate vehicle-treated, pair-fed animals exhibited the same attenuation. Carcass triacylglycerols decreased in a dose-related fashion in both PFDA-treated rats and their pair-fed partners, due to the negative caloric balance, i.e., feed intake. Yet, at every dose level examined (20–80 mg/kg), PFDA-treated rats were found to have a concentration of triacylglycerols in their carcass greater than that of their vehicle-treated, pair-fed counterparts. A similar increment in carcass ether-extractable fat also was detected between PFDA- and vehicle-treated rats (5). Differences in carcass lipid composition between the various treatment groups also were compared by expressing each lipid class as a proportion of ether-extractable fat. At the highest dose (80 mg/kg) examined, the loss of ether-extractable fat in the vehicle-treated rats pair-fed to their partners receiving PFDA was accompanied by an elevation in the proportion of lipid phosphorus and free cholesterol with a concomitant reduction in triacylglycerols. In rats treated with 80 mg/kg PFDA, a similar pattern but less extensive shift in the composition of the ether-extractable fat was found. This was the result of the higher concentration of triacylglycerols found in the carcasses of PFDA-treated rats than their pair-fed partners.

Major shifts in the relative percentages of fatty acids (3) and an increase in the activity of peroxisomal fatty acyl-CoA oxidase (25,26) in the rat liver, following the administration of PFDA would suggest that the perfluorinated fatty acid probably interacts with hepatic lipid metabolism. So that the changes in the concentrations of the various lipids could be compared, differences in hepatic cellularity between the different treatment groups had to be considered. In PFDA-treated rats, liver mass (absolute and relative) increased when compared with that of appropriate vehicle-treated, pair-fed animals. At each dose examined (20–80 mg/kg), an increase in DNA concentration (indicative of a smaller hepatocyte) in vehicle-treated, pair-fed rats was detected when contrasted with their partners receiving PFDA. Reduction in the DNA content per liver (indicating a loss of cells) also was detected in vehicle-treated, pair-fed rats at the 40 and 80 mg/kg dose levels, seven days post-treatment. Content of phospholipid and free cholesterol per total liver was reduced in the vehicle-treated rats pair-fed to those receiving 80 mg/kg PFDA. Corresponding decreases were reported in feed-restricted animals (27–29). A similar decrease in liver content of phospholipids and free cholesterol was not found in the PFDA-treated rats. In spite of this apparent difference between the PFDA-treated animals and their vehicle-treated, pair-fed counterparts, phospholipid and free cholesterol per cell was not different among the various treatment groups when changes in cellularity were taken into account.

Even though there was no effect of PFDA on the amount of phospholipid and free cholesterol per cell, a marked increase in the content of triacylglycerols per liver was detected. The accumulation of hepatic triacylglycerols can occur for a number of reasons, including increased fatty acid load (endogenous and exogenous), decreased fatty acid oxidation, increased synthesis and/or reduced breakdown of triacylglycerols, and a decreased export as very low density lipoproteins (30). Regulation of triacylglycerol synthesis is complex and not fully understood. However, the availability of fatty acids plays a major role in the esterification pathway (31). Free fatty acids in the circulation are taken up by the liver in a concentration-dependent manner (32,33). The level of free fatty acids in the plasma of PFDA-treated rats was similar to those receiving vehicle, whether pair-fed or with unlimited access to feed. However, this determination was an indication of the concentration of free fatty acids at a single time point, seven days after dosing. The increase in the relative percentage of oleic acid in the lipids of livers from PFDA-treated rats (3,4) would suggest that the peripheral fat stores (34) were the source of long chain fatty acyl-CoA's for the synthesis of triacylglycerols. Augmentation in the hepatic content of triacylglycerols already was detected at the lowest dose (20 mg/kg) of PFDA examined. It is possible that PFDA, similar to other carboxylic acids such as 2-bromooctanoic acid and 4-pentenoic acid (35–38), does inhibit fatty acid oxidation, thereby diverting fatty acids from oxidation toward esterification. As with triacylglycerols, a similar but less pronounced augmentation in the content of esterified cholesterol was detected in the PFDA-treated rats. While cholesterol ester synthesis appears to depend on the supply of unesterified cholesterol, moderate increases in long chain fatty acyl-CoA's also can stimulate this esterification pathway (39). Thus, it is conceivable that in PFDA-treated rats this pathway becomes available for the removal of excess long chain fatty acyl-CoA's in addition to esterification as triacylglycerols. However, synthesis of triacylglycerols would appear to be much more sensitive to increases in the concentration of long chain fatty acyl-CoA's. The hepatic capacity for formation of triacylglycerols would seem to be much greater than cholesterol esters.

PFDA has been found to be very persistent and can be detected in the liver of male Fischer-344 rats 30 days after a single intraperitoneal dose of 50 mg/kg (40). If PFDA and/or its activated derivatives (CoA or carnitine esters) were able to partially inhibit hepatic oxidation of fatty acids (35–38), one would expect triacylglycerols to increase. Thus, the impairment of fatty acid oxidation by PFDA could then result in a diminished NADH supply for ATP generation. This has been found in the presence of bromooctanoate, a known inhibitor of fatty acid oxidation (41). The resultant lowering of hepatic ATP concentration could in turn lead to a decrease in protein synthesis including that of apolipoproteins, e.g., apo-B needed for export of triacylglycerols from the liver (30,42). Even though hepatic DNA, phospholipid and free cholesterol content were maintained in PFDA-treated rats at 80 mg/kg, the amount of protein per hepatocyte was decreased. The increase in the activities of hepatic malic enzyme and L-glycerol-6-phosphate dehydrogenase found at lower doses of PFDA (20 and 40 mg/kg) was reduced or obliterated, respectively, in rats receiving 80 mg/kg (43). Thus, a potential decreased hepatic synthesis of apolipoproteins limiting very low density lipoprotein synthesis could contribute to the accumulation of triacylglycerols found in PFDA-treated rats at the highest dose examined (80 mg/kg). Furthermore, plasma triacylglycerols were not elevated in PFDA-treated rats, despite the hepatic augmentation of esterified compounds. The increase in hepatic content of triacylglycerols and esterified

cholesterol would suggest diversion of long chain fatty acyl-CoA's from oxidation toward esterification in livers of PFDA-treated rats.

[Received September 21, 1987; Revision accepted March 23, 1988]

Substituted Fatty Acids in the Leaves of Some Higher Plants

Zi-Ling Hu[1], Yery A. Mendoza, Armand Buchs* and Fazil O. Gülaçar
Laboratoire de Spectrometrie de Masse, University of Geneva 16, Boulevard d'Yvoy, 1211 Geneva 4, Switzerland

Substituted (hydroxy-, epoxy- and dicarboxy) fatty acids have been analyzed in the needles of two gymnosperms *(Pinus sylvestris* and *Juniperus communis)* and the leaves of four angiosperms *(Betula verrucosa, Populus nigra, Quercus petraea* and *Corylus avellana)* growing in the Lake Léman basin. The differences in the distributions of the acids that have been analyzed are greater between the various species than between the spring and autumn samples of a given species. Moreover, the isomeric composition of the 8,16-, 9,16- and 10,16-dihydroxypalmitic acid mixture is specific for each species. *Lipids 23,* 679–681 (1988).

Studies on plant fatty acids have long been restricted mainly to the lipids of the storage organs such as seeds and tubers. The fatty acids of epicuticular waxes, which play an important role in preserving a correct water balance for the plants (1,2), also have been studied for a long time, as well as the fatty acids present in cutin and suberin, because of their protective action against pathogenic fungi and microbes (3). During the last decade, the rapid development of organic geochemistry led to an increased interest in a better knowledge of the composition and distribution of fatty acids in higher plants; although they are more or less easily biodegradable, part of the fatty acids present in plant wax esters and in cutin are incorporated into lacustrine and marine sediments, where they remain unchanged for long periods (4,5). Thus, the composition and the distribution of fatty acids extracted from recent and ancient sediments give information on the sources of the sedimentary organic matter.

In this study, we have analyzed the substituted fatty acids in the whole leaves and needles of *Pinus sylvestris* (pine), *Juniperus communis* (juniper), *Betula verrucosa* (birch), *Populus nigra* (poplar), *Quercus petraea* (oak) and *Corylus avellana* (hazel). The choice of these six species was based on the results of a palynological study of sediments from the Lake Léman basin that showed, since some 14,000 years ago, periods with a predominance of one or several of these species had occurred (6). Our objective was to examine if there existed significant differences between the fatty acid compositions that could be exploited in the geochemical/environmental correlation study that we currently are conducting on the sediments of the Lake Léman Basin (7,8).

EXPERIMENTAL

Immediately after collection, the samples were lyophilized to constant weight. For each plant, between 0.1 and 0.2 g of dried leaves or needles were finely crushed and hydrolyzed during 12 hr by refluxing them in a solution of 10% potassium hydroxide in methanol. Qualitative and quantitative analyses of the hydrolysis products were carried out using the analytical techniques described for sedimentary acids (7,8). Briefly, the hydrolyzate was acidified, and the acidic fraction was isolated by chromatography on a silica gel column (200 × 12 mm, 70-230 mesh, 10% KOH). After methylation with BF_3-MeOH, the acidic fraction was again submitted to chromatography on a silica gel column (300 × 6 mm, same packing as before). The monocarboxylic acid methyl esters were eluted with a mixture of hexane/CH_2Cl_2 (3:1, v/v) and those of the hydroxy- and dicarboxylic acids with a mixture of CH_2Cl_2/EtOAc (7:3, v/v). The recoveries of the hydroxy acids from the columns have been tested through the addition of known quantities of 2-hydroxytetradecanoic and 3-hydroxyheneicosanoic acids and were found to be quantitative.

The hydroxy acid fractions were treated with bis(trimethylsilyl)trifluoroacetamid (BSTFA) to form the trimethylsilyl ethers (TMS). The gas chromatographic (GC) analyses were performed on a 25 m × 0.32 mm OV—73 capillary column using helium as the carrier gas (2.5 ml/min), a splitless injection mode and a flame ionization detector (FID). The column temperature was programmed from 60 to 150 C at 10 C/min and from 150 C to 290 C at 4 C/min. The gas chromatography-mass spectrometry (GC/MS) analyses were carried out on a quadrupole instrument operating at a nominal ionizing potential of 70 eV and an ion source temperature of 250 C. The chromatographic conditions were similar to those used for the GC runs.

The compounds were identified by comparing the GC equivalent chain length values (ECL) and mass spectrometric data with those of authentic samples or data published in the literature (9–11). Quantitative determinations were made by comparing the areas of the GC-FID peaks with that of a known quantity of 2-hydroxytetradecanoic acid used as an internal standard, assuming the same response factors for all the components. The isomeric compositions of the dihydroxyhexadecanoic and hydroxy-1,16-hexadecanedioic acids were determined by measuring the abundances of the characteristic ions arising from the cleavage α to the secondary TMS ether groups (9). 9,10-Epoxy-18-hydroxyoctadecanoic acid was analyzed as a GC coeluting mixture of 9-methoxy-10,18-dihydroxy- and 10-methoxy-9,18-dihydroxyoctadecanoic acids formed during the saponification of the samples (12).

RESULTS AND DISCUSSION

Table 1 shows the amounts and the compositions of the substituted fatty acids extracted from the spring and autumn leaves and needles of the six species that were studied. In all the species, the major acids are the positional isomers of dihydroxypalmitic acid. With the exception of the α-hydroxyacids, all the acids we have found are typical of those present in cutin (3); α-hydroxyacids usually are not found in cutin and have seldom been reported as constituents of the intercellular lipids of higher plants (13). In the samples we have analyzed, they

are absent from the spring needles of the two conifers but represent as much as 12.8% in the spring leaves of *P. nigra*.

It is only in *Q. petraea* and *C. avellana* that the composition of the fatty acids shows a significant evolution between spring and autumn. The proportions of the dihydroxypalmitic acid isomers sharply decrease in the leaves of the oak, while those of 9,10-epoxy-18-hydroxyoctadecanoic and 18-hydroxyoctadecenoic acids increase, the importance of the latter having been measured by GC-MS.

The differences between the species are remarkable. The two conifers are characterized by their content in ω-hydroxyacids. They both contain ω-hydroxypalmitic acid in higher proportion than the other species and also the $C_{12:0}$ and $C_{14:0}$ homologues, which are totally missing in the four angiosperms. ω-Hydroxyoctadecadienoic acid is found only in *C. avellana* and the 9,10-epoxy-18-hydroxyoctadecanoic acid, which belongs to the major components of *Q. petraea* and *P. sylvestris*, is present in only traces, or even absent, in the other species.

The acids extracted from *B. verrucosa* and *P. nigra* show very similar gas chromatograms, but they differ in the proportions of the 8,16-, 9,16- and 10,16-dihydroxyhexadecanoic acids they contain. These positional isomers, and also the two isomers of the midchain hydroxy-α,ω-hexadecandioic acids listed in Table 2, can indeed not be separated by GC, but the isomeric composition of mixtures of them can be determined using GC-MS (9). Table 2 shows that *P. sylvestris* contains almost exclusively the 9,16-dihydroxy isomer and *J. communis* primarily the 10,16-dihydroxy isomer. The two gymnosperms also completely differ with respect to their relative content in the 7-hydroxy and 8-hydroxy isomers of the midchain hydroxy-α,ω-hexadecandioic acids. Our results are in good agreement with those that already have been published for *P. sylvestris* (10) and *B. verrucosa* (9). We also have examined a mixture of barks and stems from *P. sylvestris* and found the same specificity as in the needles. This suggests that for a given species, the isomeric composition is the same in the whole plant.

In addition to the substituted fatty acids, the polar fractions of all the samples contain phenolic acids, mainly p-coumaric and ferulic acids, which also are known to be components of cutin (12). Moreover, the needles of *P. sylvestris* are characterized by a high content of pinifolic acid (14).

TABLE 2

Positional Isomer Composition (%) of Dihydroxyhexadecanoic (M,16-diOH-C16:0) and Hydroxy-α,ω-dicarboxyhexadecanoic (M-OH-α,ω-dic-C16:0) Acids in the Autumn Leaf Lipids

	M,16-di-OH-C16:0			M-OH-α,ω-dic-C16:0	
	8,16-di-OH	9,16-di-OH	10,16-di-OH	7-OH	8-OH
B. verrucosa	4.4	72.9	22.7	15.3	84.7
Q. petraea	—	8.6	91.4	73.8	26.2
C. avellana	—	27.6	72.4	40.6	59.4
P. nigra	—	12.9	87.1	37.5	62.5
J. communis	—	1.0	99.0	93.4	6.6
P. sylvestris	—	98.2	1.8	1.0	99.0

In conclusion, our results show that using the composition of the hydroxy mono- and dicarboxylic fatty acids for chemical taxonomy is quite feasible with the six species we have analyzed. Each one of them can be unambiguously characterized by the composition of the substituted acids present in its leaves or needles. When present in sediments, these acids thus can give information on the vegetation that existed at the time of their deposition, information that can be correlated with palynological data.

The Phospholipid Fatty Acids of the Marine Sponge *Xestospongia muta*

Néstor M. Carballeira* and **Lilliam Maldonado**
Department of Chemistry, University of Puerto Rico, Rio Piedras, Puerto Rico 00931

The rare phospholipid fatty acids 3,7,11-trimethyldodecanoic (*1*), 5,9-hexadecadienoic (*2*) and 12-methyl-hexadecanoic (*3*) were identified in the marine sponge *Xestospongia muta*. Branched fatty acids in *X. muta* accounted for 35% of the total fatty acid mixture. It was observed that the occurrence of the 5,9-hexadecadienoic acid (*2*) coincides with the complete absence of the very long chain fatty acid 5,9-hexacosadienoic. The acid 5,9,19-octacosatrienoic seems to be found in most *Xestospongia* species.
***Lipids 23,* 682–684 (1988).**

Xestospongia muta, commonly known as the barrel sponge, is normally the largest species in volume that would be encountered in the Caribbean (1). It can take many forms, but the most common is a barrel shape with the outer end having a cone-like cavity, hence the name "barrel sponge." This form may reach 1.5 m in height with a diameter nearly as great. The sponge consistency is hard, almost stony, and the outer surface texture is extremely rugged, often buttressed (2).

X. muta has been the source of many unusual sterols and fatty acids. One important sterol, mutasterol(24-methylene-25-ethylcholesterol), was first isolated by Li et al. (3) and was the first example of sterol side-chain bioalkylation at position 25. Schmitz and Gopichand (4) have reported the isolation of a novel dibromo acetylenic acid from *X. muta,* namely the 14,16-dibromo-7,13-15-hexadecatrien-5-ynoic acid, which showed a slight degree of cytotoxicity. Litchfield and Marcantonio examined the related *Xestospongia halichondroides* and found that it contained 13% of the unusually long phospholipid fatty acid, 5,9,19-octacosatrienoic, together with other "demospongic" acids such as the characteristic 5,9-hexacosadienoic (5).

In this work, we studied the phospholipid fatty acids from the marine sponge *X. muta,* and these results are reported.

EXPERIMENTAL METHODS

X. muta was collected near La Parguera, Puerto Rico, during March 1986. The sponge was washed in sea water, carefully cleaned of all nonsponge debris, and cut into small pieces. Immediate extraction with chloroform/methanol (1:1, v/v) yielded the total lipids. The neutral lipids, glycolipids and phospholipids were separated by column chromatography on ammonium hydroxide-treated silicic acid (100–200 mesh) using the procedure of Privett et al. (6). The fatty acyl components of the phospholipids were obtained as their methyl esters by reaction of the phospholipids with methanolic hydrogen chloride (7) followed by purification on column chromatography eluting with hexane/ether (9:1, v/v). The resulting methyl esters were analyzed by gas chromatography-mass spectrometry (GC-MS) using a Hewlett-Packard 5995A gas chromatograph-mass spectrometer equipped with a 30 m × 0.32 mm fused silica column coated with SE-54. For the location of double bonds, N-acylpyrrolidide derivatives were prepared by direct treatment of the methyl esters with pyrrolidine/acetic acid (10:1, v/v) in a capped vial (24 hr at 100 C), followed by ethereal extraction from the acidified solution and purification by preparative layer chromatography (PLC). Hydrogenations were carried out in 10 ml of absolute methanol and catalytic amounts of platinum oxide (PtO_2). Mass spectrometry results are available upon request. Mass spectral data of important fatty acids for this discussion are presented below.

3,7,11-Trimethyldodecanoic acid methyl ester. MS m/z (rel. int.) 256 (M^+, 8), 225 (3), 213 (5), 171 (19), 143 (13), 139 (6), 111 (15), 102 (13), 101 (87), 97 (24), 85 (11), 83 (16), 75 (24), 74 (100), 71 (14), 69 (38), 59 (26), 57 (25), 56 (12), 55 (39).

12-Methylhexadecanoic acid methyl ester. MS m/z (rel. int.) 284 (M^+, 17), 255 (2), 241 (9), 227 (2), 199 (7), 185 (25), 171 (6), 157 (14), 143 (47), 130 (18), 129 (17), 101 (15), 97 (20), 87 (69), 83 (23), 75 (27), 74 (100), 57 (47).

12-Methylhexadecanoic acid pyrrolidide. MS m/z (rel. int.) 323 (M^+, 3), 308 (1), 294 (3), 280 (1), 266 (1), 238 (1), 224 (0.5), 210 (0.3), 196 (0.2), 149 (4), 126 (12), 113 (100), 98 (11), 81 (21), 69 (31), 55 (27).

5,9,19-Octacosatrienoic acid methyl ester. MS m/z (rel. int.) 432 (M^+, 1), 207 (3), 193 (4), 181 (5), 180 (8), 167 (4), 163 (5), 150 (10), 149 (11), 140 (22), 136 (13), 135 (15), 123 (11), 121 (14), 110 (21), 109 (42), 108 (12), 99 (20), 95 (26), 94 (24), 93 (11), 85 (12), 81 (100), 74 (15), 67 (56), 55 (80).

RESULTS

The results presented in Table 1 show that *X. muta* contains many branched fatty acids. In fact, branched fatty acids accounted for 35% of the total phospholipid fatty acid mixture. Interesting was the presence of a fatty acid methyl ester with a molecular weight of 256. This fatty acid was inert upon catalytic hydrogenation, thus excluding any possible unsaturation. Moreover, a molecular weight of 256 provides for 15 carbons in the chain but this acid presented an extremely low equivalent chain length (ECL) value of 13.40, indicating multiple branching. In fact, the mass spectrum of the latter compound presented key fragments at m/z = 101 (100%), and at m/z = 171 (15%). These fragments clearly revealed methyl branching at positions 3 and 7. A literature comparison (8) indicated that the isolated compound was the isoprenoid fatty acid 3,7,11-trimethyldodecanoic (1), unprecedented in marine sponges (Scheme 1).

Three different methyl hexadecanoic acids were identified in *X. muta.* Two of these presented ECL values of 16.62 and 16.70, which definitely match the known values for iso and anteiso methyl hexadecanoic acids (9). When

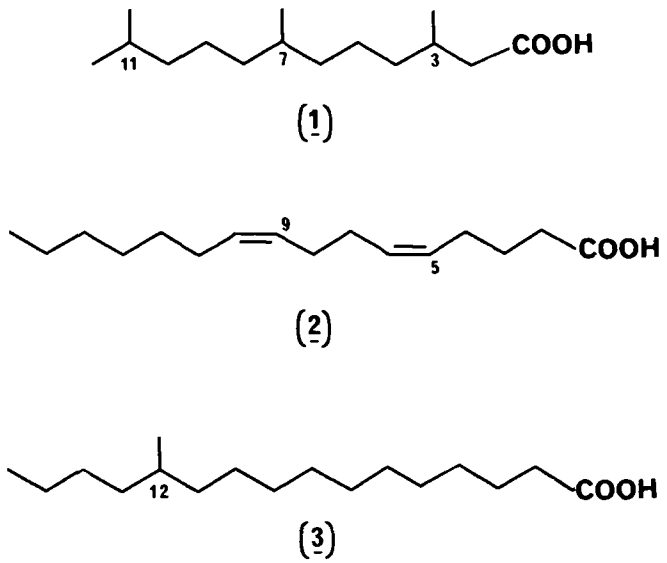
TABLE 1

Identified Phospholipid Fatty Acids From *Xestospongia Muta*

Fatty acids	Abundance (%)
3,7,11-Trimethyldodecanoic (15:0)	3.3
Tetradecanoic (14:0)	2.4
12-Methyltetradecanoic (15:0)	9.4
Pentadecanoic (15:0)	1.4
14-Methylpentadecanoic (16:0)	1.3
5,9-Hexadecadienoic (16:2)	10.5
9-Hexadecenoic (16:1)	11.5
Hexadecanoic (16:0)	10.0
12-Methylhexadecanoic (17:0)	10.2
15-Methylhexadecanoic (17:0)	1.9
14-Methylhexadecanoic (17:0)	1.7
Heptadecanoic (17:0)	1.1
Octadecanoic (18:0)	4.9
16-Methyloctadecanoic (19:0)	7.7
Nonadecanoic (19:0)	1.2
Docosanoic (20:0)	12.5
Behenic (21:0)	1.6
5,9,19-Octacosatrienoic (28:3)	7.4



SCHEME 1

the corresponding pyrrolidies were prepared and their mass spectra taken, these compounds were definitely characterized as the known 15-methyl-hexadecanoic (iso) and 14-methyl-hexadecanoic (anteiso) acids. It is well-established in the mass spectrometry of branched pyrrolidides that if a peak of lower intensity than the analogous peak in a straight chain fatty acid pyrrolidide is observed, then this is indicative of methyl branching at that position (9). The third fatty acid methyl ester in the mixture presented a rather low ECL value of 16.40. This low value is characteristic of fatty acid methyl esters with methyl branching in the middle of the chain (10). Likely positions for the methyl group were 10, 11 and 12, because similar acids have been reported to occur in marine sponges (10). We decided to prepare the corresponding pyrrolidide to determine exactly the methyl group position. The pyrrolidide indicated the absence of a peak at m/z = 252 (carbon 12), while other fragments were present at intervals of 14 amu, that is, peaks at m/z = 224, 238, 266, 280, 294, 308, etc. Therefore, we concluded that the acid in question is 12-methylhexadecanoic (3) (Scheme 1), which has been isolated before from the marine sponge *Parasperella psila* (11).

From Table 1 we can also see that major acids in *Xestospongia muta* were palmitic (16:0), 9-hexadecenoic (16:1) and 5,9-hexadecadienoic (16:2). The latter acids accounted for more than 30% of the total mixture. For the characterization of the 5,9-hexadecadienoic acid (2), capillary GC-MS was used. The base peak in the mass spectrum of 5,9-hexadecadienoic methyl ester was observed at m/z = 81, a typical value for methyl esters with the Δ5,9-unsaturation. Upon catalytic hydrogenation (PtO_2), the hexadecadienoic acid methyl ester was converted to palmitic acid methyl ester, thus excluding the possibility of any branching. The double bonds in the molecule also were located by means of pyrrolidide derivatives. The typical peak at m/z = 180 was observed resulting from allylic cleavage (12). In fact, we isolated this acid some time ago from the sponge *Chondrilla nucula* that was identical to the one in this study (12). Pyrrolidides also provided an answer for locating the double bond in the 9-hexadecenoic acid isolated in this work.

A very long chain fatty acid methyl ester with molecular weight of m/z 432 also was obtained from *X. muta*. Hydrogenation of this methyl ester produced octacosanoic acid (28:0) as characterized by GC-MS. The fatty acid methyl ester of the original compound presented the typical base peak at m/z = 81, indicating Δ5,9 unsaturation. In accordance with previous findings by Litchfield and Marcantonio (5) in *X. halichondroides*, the most likely structure for our compound is that of the 5,9,19-octacosatrienoic acid (28:3). In contrast to Litchfield's results in *X. halichondroides*, we could not detect any 5,9-hexacosadienoic acid (26:2) in *X. muta*.

DISCUSSION

Last year, we carried out a brief survey of isoprenoid fatty acids from marine sponges (8) and concluded that only two isoprenoid fatty acids are found in marine sponges, i.e., the 4,8,12-trimethyltridecanoic acid and the 3,7,11,15-tetramethylhexadecanoic acid (phytanic). We also found that these isoprenoid fatty acids did not occur concomitantly in the same sponge. In this work, we report the isolation of still a third isoprenoid fatty acid not found previously in marine sponges, the 3,7,11-trimethyldodecanoic acid (1). This isprenoid fatty acid has been isolated before from a sediment of Eocene age, the Green River Shale, Colorado (13). Many natural products based on the isoprenoid skeleton could conceivably have given rise to isoprenoid fatty acid (1), but because it is related to phytanic acid, a common biosynthetic route should be operative. It has been established that the phytyl side chain of chlorophyll is the major precursor of phytanic acid (13). Therefore, it is very likely that the 3,7,11-trimethyldodecanoic acid isolated in this sponge could have been the product of oxidative degradation of

phytanic acid. Much work still lies ahead for the elucidation of the origin of these isoprenoid fatty acids in marine sponges.

Another interesting finding in *X. muta* is the isolation of the rare 5,9-hexadecadienoic acid (2), which we also have isolated before from the marine sponge *C. nucula* (12). In both cases, where we have been able to isolate the rare 5,9-hexadecadienoic acid (2), no 5,9-hexacosadienoic acid (26:2) has been found. On the other hand, in the many sponges that the "demospongic" acid 5,9-hexacosadienoic acid (26:2) has been identified, no 5,9-hexadecadienoic acid has ever been detected. This observation immediately brings interesting biosynthetic possibilities. Does the enzymatic system for oxidative desaturation in the sponges that contain the 5,9-hexadecadienoic acid operate at short chain lengths? To answer this question, biosynthetic experiments are in progress.

ACKNOWLEDGMENTS

Thomas R. Tosteson and Vance Vicente from La Parguera, Puerto Rico, did the collection and classification of the sponge. O. Rosario assisted in the mass spectrometry. Financial support was provided by the University of Puerto Rico, FIPI (Grant No. 86-100-12-88.0) and NSF (Grant No. CHE-8715649).

Milk Fat Globules: Fatty Acid Composition, Size and in vivo Regulation of Fat Liquidity

Hermann Timmen* and **Stuart Patton**[1]
Institute for Chemistry and Physics, Federal Dairy Research Center, Kiel, Federal Republic of Germany

Populations of large and small milk fat globules were isolated and analyzed to determine differences in fatty acid composition. Globule samples were obtained by centrifugation from milks of a herd and of individual animals produced under both pasture and barn feeding. Triacylglycerols of total globule lipids were prepared by thin layer chromatography and analyzed for fatty acid composition by gas chromatography. Using content of the acids in large globules as 100%, small globules contained fewer short-chain acids, −5.9%, less stearic acid, −22.7%, and more oleic acids, +4.6%, mean values for five trials. These differences are consistent with alternative use of short-chain acids or oleic acid converted from stearic acid to maintain liquidity at body temperature of milk fat globules and their precursors, intracellular lipid droplets. Stearyl-CoA desaturase (EC 1.14.99.5), which maintains fluidity of cellular endoplasmic reticulum membrane, is suggested to play a key role in regulating globule fat liquidity. Possible origins of differences between individual globules in fatty acid composition of their triacylglycerols are discussed.
Lipids 23, 685–689 (1988).

Whether there are differences in fatty acid composition between individual bovine milk fat globules is a question of both fundamental and practical importance. Such differences could imply heterogeneity in the cellular synthesis-assembly of milk fat globules. At the practical level, compositional variations suggest the possibility of fat globules with assorted properties to meet needs of various dairy products.

Milk fat globules are unique products of the lactating cell. Triacylglycerols synthesized in the rough endoplasmic reticulum (1–3) accumulate into droplets that are secreted from the cell by envelopment in plasma membrane and, to some extent, associated secretory vesicle membrane (4–6). For the bovine, these globules number about 1.5×10^{10} per ml of milk. They range in diameter from <1 μm to 20 μm with a volume surface average diameter of 3.4 μm. Globules <1 μm in diameter, while representing about 75%–80% of the total number, account for only a few percent of the lipid mass (7). On a dry basis, both bovine and human milk fat globules are about 1% protein (7,8) and 99% lipid (by difference). Of the lipid, 96% to 99% is triacylglycerol (7,9). Thus, milk fat globules are relatively pure particles of triacylglycerols.

The principal evidence that there are substantial differences in the fatty acid composition of individual globules of a milking from a single animal is based on refractive index (n^D) measurements by Walstra and Borggreve (10). They found that the spread in n^D among individual globules was 7×10^{-4}. Based on the relationship of n^D to melting properties of milk fat, these authors concluded that in average milk at least a fourth of the fat globules contain a hard fat and another fourth soft fat.

It is not yet possible to determine fatty acid composition of individual globules. However, size distribution curves for milk fat globules (11,12) and morphometric studies of intracellular globule origins (13,14) suggest possible compositional differences between populations of very small and larger globules. These populations can be prepared by centrifugal separation, which segregates the larger ones into cream and the smaller ones with the skim milk (15). We report here an investigation of fatty acid composition in triacylglycerols from such populations of globules under several conditions of feeding and managing lactating cows.

MATERIALS AND METHODS

Milk samples. Milk was obtained from Holstein cows at the Schaedtbek experimental farm of the Federal Dairy Research Center in Kiel, West Germany. Depending on the experiment, aliquots of complete milkings from single animals or of mixed herd milk from the farm bulk tank were used. Samples were obtained under conditions of pasture feeding, barn feeding and underfeeding. Barn feeding was composed of grass or wheat silage, supplemented by grain concentrate according to milk yield. Pasture feeding was supplemented by corn cob silage. Underfeeding was accomplished by giving the cow exclusively 8 kg wheat straw daily for one wk before the milk sample was taken. Samples (1 L) taken in the morning were immediately brought to the laboratory for further processing. Those from individual animals were uncooled; bulk tank samples were cooled to 2–4 C.

Separating large and small fat globules. After warming to 30 C and mixing the milk sample, 400 to 500 ml was centrifuged at $300 \times g$ for 15 min in 20-ml glass tubes plugged at the bottom end with rubber stoppers. Following centrifugation, the tubes were placed in ice water for about 20 min to harden the cream layers, after which the stoppers were removed and the skim milk decanted from the cream plug. The latter was used as the sample of larger globules. To obtain the smaller globules free of other lipid material (membranous vesicles, cell fragments), the skim milk was further centrifuged at $33,000 \times g$ and 4 C for one hr. The very thin cream layer obtained was carefully removed and suspended in water. This served as the sample of smaller globules and, on average, represented 5% of total globule lipid.

Determination of globule diameter. Samples of cream layers from both centrifugations were diluted with warm water and mixed with a 5% solution of gelatin in warm water, final temperature 30 C. An aliquot of this was transferred to the depression in a specially designed glass

Abbreviations: The shorthand convention in the nomenclature for fatty acids of number: number representing carbon chain length and number of double bonds, respectively, is used throughout; br–, branched carbon chain.

microscope slide. A cover glass then was placed over the depression, thereby creating a 0.01-mm thick film containing the globules. The slide was cooled in a refrigerator (5 C) to solidify the gelatin and, after readjustment to room temperature, was viewed with a camera-equipped Leitz Orthomat microscope. Regions of good globule distribution (free of clumps) were photographed. Positive enlargements, total magnification 1790×, were used to measure fat globule diameters. These were determined with the aid of an electronic pencil and tablet to trace 2000 to 3000 globule circumferences per preparation, and a microcomputer to process the data (16). The diameters were calculated as d_n, the number average diameter. This method of assaying globule size, while not adequate in accounting for the huge numbers of very small globules in milk (11), is sufficient to show significant differences in the globule sizes between cream and skim milk.

Preparation and fatty acid analysis of lipids. Whole milk samples and dispersed cream layers were solvent extracted to obtain total lipids by the Röse-Gottlieb procedure (17) as modified by Walstra and de Graaf (18). Polar (membrane) lipids represent a relatively larger component of small as compared with large globules. To obtain compositional data more representative of the globule core, we isolated triacylglycerols of lipid samples by thin layer chromatography. Each sample (30 to 40 mg) was applied the length of one dimension on a precoated 0.25 mm, 20 × 20 cm silica gel thin layer chromatography plate (No. 5721, Merck, Darmstadt, West Germany). Separation of lipids was achieved with petroleum ether/ethyl ether/acetic acid (75:25:1, v/v/v). The band of triacylglycerols (R_f 0.7 to 0.8, detected by covering all but 1 cm at the running edge of the plate and exposing it to iodine vapor, was scraped off with a razor blade and extracted from the silica gel with diethyl ether.

Triacylglycerols were weighed, made to a 5% solution in redistilled heptane and transesterified with sodium methoxide in methanol (19). The resulting methyl esters were analyzed in a Packard-Becker Model 438 gas chromatograph (Delft, Netherlands) with a Spectra Physics 4100 computing integrator under the following conditions: 25 m × 0.23 mm (i.d.) fused silica capillary column coated with SP-1000 (Supelco, Bellefonte, PA); injector, flame ionization detector and oven program temperatures of 220, 260 and 50–235 C, respectively; sample (1 μl) injection with a 1:100 split, column flow of 1 ml/min and additional detector gas flow (auxiliary gas) of 29 ml/min (both N_2). A precisely weighed test mixture of fatty acid methyl esters closely approximating an average milk fat was used to calculate correction factors for peak areas on sample chromatograms. The results were expressed as wt. % of each fatty acid (as acid) in relation to the total fatty acids (as acids). Data in the tables are averages of two gas chromatographic runs for each sample. This methodology for quantitation of fatty acids was developed by scientists of the International Dairy Federation and the European Economic Community for analysis of fats and oils, including milk fat.

RESULTS

Fatty acid composition of total lipid samples from milks of individual animals and of the herd under pasture and barn feeding conditions are presented in Table 1. With

the exception of data from the underfed animal, the principal variations related to elevated 18:0 and 18:1 and lower 16:0 in the pasture feeding as compared with barn feeding trials. This is a characteristic difference that can be attributed to prevalence of 18: acids in pasture lipid (20–22). In general, not only 16:0 was increased under barn feeding, but all the major short and medium chain fatty acids. This effect was least with 4:0. With underfeeding, 4:0 and 16:0 were depressed. This was compensated mainly by increased 18:1. Similar effects of underfeeding have been observed by us and others (22,23). The following fatty acids, occurring rather consistently below 0.1%, have been omitted from the data of Table 1: 5:0, 7:0, 9:0, 11:0, 15:1, 18:0 br, 19:0.

Data illustrating the differences in fatty acid composition of triacylglycerols of whole milk, large globules of cream, and small globules from skim milk are presented in Table 2. For the sake of space, complete data for only herd milk under barn feeding are given as an example. The principal differences are shown by the small globules. Data for whole milk and the cream (larger globules) are virtually identical. This would be expected in that the cream sample accounts for 95% or more of the milk triacylglycerols. The close agreement of data for the whole milk and its cream also reveals the precision of the analytical method. Data variation between larger globules and smaller globules (given in the right hand columns of the table) show slightly less 4:0 to 10:0, slightly more 12:0 and 14:0, virtually no change in 16:0, less 18:0 and greater 18:1 for the small globules. The differences in fatty acid composition of triacylglycerols of larger vs smaller globules for six trials are summarized in Table 3. Mean arithmetic globule diameters for the samples are also included. These data establish that, in all of the normal feeding trials, 1–5, triacylglycerols of the smaller globules were associated with reduced 4:0 to 10:0 and 18:0 and increased 18:1 in comparison with results for the larger globules. Each of the short chain acids was lower in the

smaller globules for all five trials, the mean differences in actual % being: 4:0 −0.21, 6:0 −0.14, 8:0 −0.09, 10:0 −0.20. The other acids in the table, i.e., 12:0, 14:0, 16:0, 18:2 and 18:3, showed no consistent trend. In terms of relative differences, using content of the acids in larger globules as 100%, the mean values were −5.9, −11.7 and +4.6% for short chain, stearic and oleic acids, respectively. Considering the normal fatty acid composition of milk triacylglycerols (Table 1), this reduction in stearic acid, in terms of mass, is rather precisely equivalent to the gain in oleic acid.

Differences in fatty acids for large and small fat globules of the underfed animal (Trial 6, Table 3) bear little or no relationship to data for the other five trials. Because many normal synthetic and secretory pathways within the lactating cell may be perturbed under such stress, it is difficult to rationalize these data at this time. However, in additional trials (not shown) the trends of data for this trial, as well as those in the other five trials, were reproducible.

DISCUSSION

Profound differences in fatty acid composition between large and small fat globules were not found in this study (Table 3). However, the small differences, consistently detected, seem important for a number of reasons. It is notable that the fatty acids involved are crucial to the liquidity of milk fat. It is a liquid at body temperature (24), presumably of necessity for its synthesis and secretion by the lactating cell, as well as for efficient utilization by the offspring. The principal means of assuring this liquidity is the incorporation of oleic acid (18:1, mp 14 C), which is produced from stearic acid (18:0, mp 69 C) in bovine mammary tissue (25-27), and of short chain fatty acids (4:0-10:0, mp −8 to +31 C) into triacylglycerols destined for milk fat globules. Thus, it is reasonable to interpret increases in 18:1 with corresponding decreases in 18:0 as a response to meet liquidity requirements of cytoplasmic fat droplets due to lesser availability of 4:0 to 10:0. Because these small differences are seen as a net effect in a substantial fraction of the total globule population, much larger differences may occur in some individual globules. This is in keeping with the significant differences observed in refractive indices between globules of equal size by Walstra and Borggreve (10). However, in distinction to their interpretation that this means half of the total globules have either relatively solid or liquid fat, this could mean liquidity being maintained by greater incorporation of oleic acid in some globules, thus increasing refractive index, or by greater incorporation of short chain acids in other globules, which would lower the index. Refractive indices (n_D) for the various acids and milk fat are: 4:0, 1.399^{20}; 6:0, 1.416^{20}; 8:0, 1.428^{20}; 10:0, 1.429^{40}; 18:0, 1.430^{80}; 18:1, 1.463^{18} (28); and milk fat (butterfat), $1.4530-1.4555^{40}$ (29).

The conversion of stearic acid to oleic acid in lactating bovine tissue is accomplished by the microsomal enzyme, stearyl-CoA desaturase (EC 1.14.99.5) (25-27). Data reviewed by Thompson (30) show that such desaturases are stimulated by increase in membrane rigidity, a condition that is controlled primarily by membrane lipid composition as well as by temperature. Because newly produced triacylglycerols and their precursor diglycerides would be expected to influence the fluidity-rigidity of membranes accomplishing their synthesis, it is evident that the membrane fluidity-desaturase activity relationship could provide a basic control mechanism for maintaining liquidity of accumulating fat droplets.

As to the origin of compositional differences between large and small globules, one explanation may lie in the mechanism by which intracellular milk lipid droplets grow in size. There is growing evidence that this occurs by a process of small droplet fusion to produce large droplets (13,14,31,32). In detailed studies of the ultrastructure and biochemistry of lipid droplets in the lactating cell (3,31,32), microlipid droplets with diameters <0.5 μm originating in the endoplasmic reticulum were isolated

and characterized. These studies provide evidence that the microlipid droplets may fuse to form larger cytoplasmic droplets or be secreted as such. One interpretation of our findings is that not all of the intracellular microlipid droplets fuse with equal facility; in particular, those containing less short chain fatty acids may be more resistant and tend to be secreted directly or with few fusions. However, observed significant differences in refractive indices of medium-sized milk fat globules (3.5 to 6.5 μm) (10) suggest that there must be differences in fatty acid composition of larger intracellular lipid droplets as well.

Another factor that may cause differences between globules in fatty acid composition is spatial asymmetry in supply and incorporation of the acids. It has been suggested (33) that the basal region of the lactating cell is enriched in long chain fatty acids from the circulation, whereas the mid- to upper-region may be the primary source of short chain acids, these being synthesized de novo within mammary tissue (34). It also is true that if exchange of short chain fatty acids for oleate were occurring at the surface of intracellular lipid droplets, more exchange would take place per unit mass of small droplets because of their larger surface to volume relationship. Other asymmetries may concern varying supply of precursors for milk lipid synthesis at the gland and whole body levels.

In light of observations to date on globule size and composition together with findings on lipid droplets of the lactating cell, it is possible to explain the three (overlapping) size subpopulations of milk fat globules noted by Walstra (11) and Rüegg and Blanc (12). Small globules result from secretion of the microlipid droplets of Deeney et al. (32), which have undergone no or limited fusions, the intermediate-sized globules arise from cytoplasmic droplets resulting from many fusions of microdroplets and, as suggested by Walstra (11), the larger globules, ranging sometimes from 20 μm in diameter, represent post-secretion fusion of globules, because in some cases they tend to exceed dimensions of the cell.

7-Methyl-8-hexadecenoic Acid: A Novel Fatty Acid from the Marine Sponge *Desmapsama anchorata*

Néstor M. Carballeira* and **Maria E. Maldonado**
Department of Chemistry, University of Puerto Rico, Rio Piedras, Puerto Rico 00931

The novel fatty acid 7-methyl-8-hexadecenoic (*1*) was identified in the marine sponge *Desmapsama anchorata*. Other interesting fatty acids identified were 14-methyl-8-hexadecenoic (*2*), better known through its methyl ester as one of the components of the sex attractant of the female dermestid beetle, and the saturated fatty acid 3-methylheptadecanoic (*3*), known to possess larvicidal activity. The main phospholipid fatty acids encountered in *D. anchorata* were palmitic (16:0), behenic (22:0) and 5,9-hexacosadienoic acid (26:2), which together accounted for 50% of the total phospholipid fatty acid mixture.
***Lipids 23,* 690–693 (1988).**

Sponges have been the source of many interesting phospholipid fatty acids possessing unusual unsaturation and methyl branching alternatives not found in terrestrial counterparts (1). The finding by Litchfield et al. of marine phospholipid fatty acids (C26–C30) with an unusual Δ5,9 unsaturation (2) as well as our recent report (3) of the isolation of the rare 5,9-hexadecadienoic acid from the marine sponge *Chondrilla nucula* are interesting. A good example of methyl branching in marine sponges can be found in our recent report of isoprenoid fatty acids from common Caribbean sponges (4) as well as in the original work of Walkup et al. (5). In this paper, however, we would like to report the isolation of several unusual phospholipid fatty acids that combine, in the same structure, unusual unsaturation with odd methyl branching. The phospholipid fatty acids that we report here are the novel 7-methyl-8-hexadecenoic (1), the important 14-methyl-8-hexadecenoic (2), and the rare 3-methylheptadecanoic (3), which were isolated from the Caribbean sponge *Desmapsama anchorata* (Scheme 1). To the best of our knowledge, 7-methyl-8-hexadecenoic is new in nature. The corresponding saturated branched analogue 7-methylhexadecanoic acid has been isolated from sperm whale oil (6) and the linear unsaturated 8-hexadecenoic acid has been detected in several biota, including green and blue-green algae (7). It is important to mention that 14-methyl-8-hexadecenoic acid methyl ester, together with 14-methyl-8-hexadecen-1-ol, have been reported to be the active constituents of the sex attractant of the female dermestid beetle *Trogoderma inclusum* and the khapra beetle *Trogoderma granarium*. These beetles are very serious pests in stored cereal products in hot, dry parts of the world, and they consume a wide variety of products such as grain, cereals and dried milk (8). Here we report the results of our investigation.

EXPERIMENTAL PROCEDURES

D. anchorata was collected January 21, 1987, at the depth of 50 feet near Cayo Enrique, Puerto Rico. The sponge was washed in sea water, carefully cleaned of all non-sponge debris and cut into small pieces. Immediate extraction with chloroform/methanol (1:1, v/v) yielded the total lipids. The neutral lipids, glycolipids and phospholipids were separated by column chromatography on silica gel, grade 62 (60–200 mesh) using the procedure of Privett et al. (9). The fatty acyl components of the phospholipids were obtained as their methyl esters by reaction of the phospholipids with methanolic hydrogen chloride (10) followed by purification on column chromatography eluting with hexane/ether (9:1, v/v). The resulting methyl esters were analyzed by gas chromatography-mass spectrometry (GC-MS) using a Hewlett-Packard 5995 A gas chromatograph-mass spectrometer equipped with a 30 × 0.32 mm fused silica column coated with SE-54. For the location of double bonds, N-acylpyrrolidide derivatives were prepared by direct treatment of the methyl esters with 2 ml pyrrolidine and catalytic amounts of acetic acid in a capped vial (3 days at 100 C) followed by ethereal extraction from the acidified solution and purification by column chromatography on silica gel. Hydrogenations were carried out in 5 ml of absolute methanol and catalytic amounts of platinum oxide (PtO_2). Mass spectral data of key fatty acids for this discussion are presented below.

7-Methyl-8-hexadecenoic acid methyl ester. RESULTS

Our results are presented in Table 1. As can be seen from the table, the main phospholipid fatty acids encountered in *D. anchorata* were palmitic (16:0), behenic (22:0) and 5,9-hexacosadienoic acids (26:2). The latter acids are typical acids from marine sponges and, in this case, they accounted for 50% of the total mixture. It is interesting to point out here that in most of the Caribbean sponges that we have analyzed, behenic (22:0) has been a predominant acid in the mixtures. The 5,9-hexacosadienoic acid (26:2), typical of the Demospongiae, was characterized by means of GC-MS, because fatty acid methyl esters possessing the 5,9-unsaturation reveal a base peak at m/z = 81, and the corresponding pyrrolidide derivatives a key peak at m/z = 180 resulting from allylic cleavage (11). Another interesting fatty acid possessing the 5,9-unsaturation was encountered in *D. anchorata*, namely the 5,9-octacosadienoic acid (28:2), which accounted for 0.9% of the total fatty acid mixture. Its characterization also was performed by means of GC-MS, affording the characteristic fragmentation patterns already discussed above. The phospholipid mixture was analyzed by means of thin layer chromatography (TLC) and shown to consist mainly of phosphatidylcholine (PC) and phosphatidylethanolamine (PE).

Three rather unusual fatty acids for marine sponges were encountered in *D. anchorata*. The most interesting fatty acid methyl ester presented an equivalent chain length (ECL) value of 16.28 and a molecular weight of MW = 282. Upon catalytic hydrogenation, the latter fatty acid methyl ester was converted to a saturated ester (MW = 284) with an ECL value of 16.45 in a SE-54 capillary column. This result confirms the presence of methyl branching, but excludes any of the common iso or anteiso C17 fatty acid methyl esters, because these acids normally present ECL values between 16.60 and 16.69 (12). Moreover, the 16.45 value suggested that the hydrogenated product could be the 7-methylhexadecanoic acid methyl ester, because it has been reported (6) for the latter fatty acid methyl ester an ECL value of 16.4. To confirm what the ECL value was suggesting to us, we carefully looked at the mass spectrum of the hydrogenated product and found a most revealing fragmentation peak at m/z = 157, not significant in the mass spectra of the iso and anteiso C17 series, with a considerable abundance of 27%. The latter fragmentation peak clearly shows methyl branching at C-7, because this fragment corresponds to a favorable fragmentation at the branching between carbons 7 and 8, resulting in the stabilized $C_9H_{17}O_2^+$ cation. Therefore, this mass spectral data confirms C7 methyl substitution but, as definite proof for methyl branching and unsaturation, we prepared the corresponding pyrrolidide derivative of this acid and submitted the product to electron impact mass spectrometry. The results were very revealing, and they are shown in Figure 1, spectrum A. First, double bond unsaturation between carbons 8 and 9 was recognized due to a separation of 12 amu between fragments at m/z = 182 and 194. It is known from the mass spectra of fatty acid pyrrolidides that if an interval of 12 amu, instead of the regular 14, is observed between the most intense peaks of clusters of fragments containing n and n-1 carbon atoms in the acid moiety, a double bond occurred between carbon n and n+1 in the molecule (13). In our case, an interval of 12 amu was encountered between carbons 8 and 7, indicating unsaturation between carbons 8 and 9. Second, a peak of low intensity was observed at exactly m/z = 182, flanked by neighboring peaks higher than usual (Fig. 1), indicating C7 methyl branching. It is well-established in the mass spectrometry of branched pyrrolidides that, if a peak of lower intensity than the

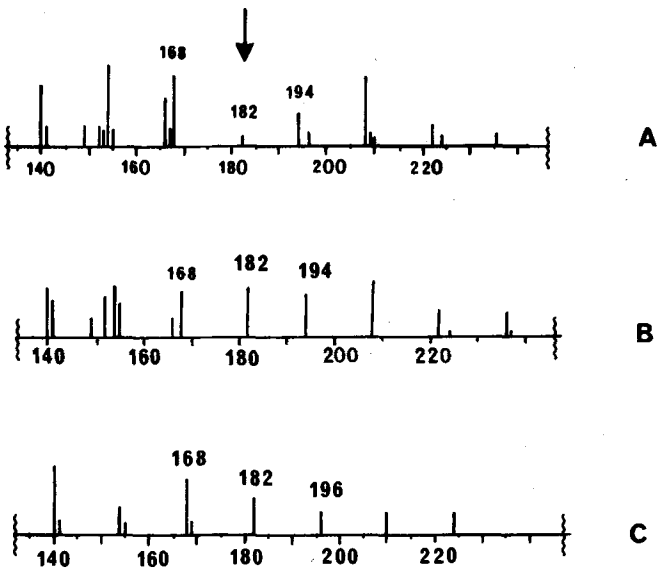

FIG. 1. Partial mass spectra of 7-methyl-8-hexadecenoic acid pyrrolidide (A), 14-methyl-8-hexadecenoic acid pyrrolidide (B) and behenic acid pyrrolidide (C). Spectra are expanded three times.

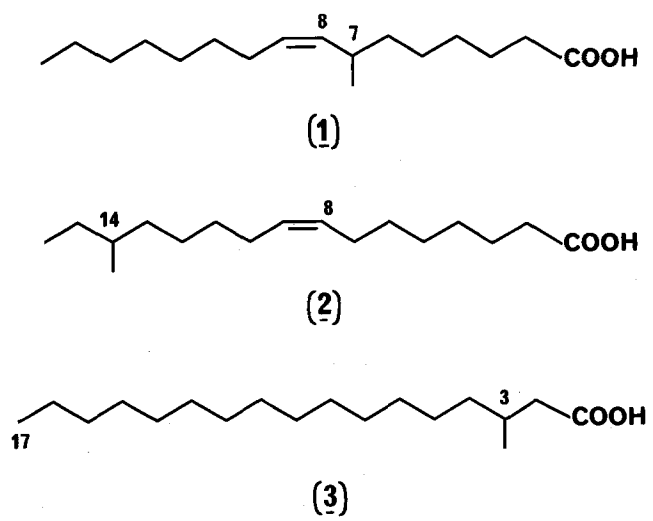
analogous peak in a straight-chain fatty acid pyrrolidide is observed, then this is indicative of a branched methyl at that position. From all of the above experimental data, we concluded that the acid in question is the unprecedented 7-methyl-8-hexadecenoic acid (1), which, to the best of our knowledge, has not been reported to occur in nature (Scheme 1).

Our second interesting fatty acid methyl ester occurred in the mixture at an abundance of 8%. The mass spectrum of this fatty acid methyl ester also presented a molecular peak at m/z = 282. Upon catalytic hydrogenation, this fatty acid methyl ester was converted to its saturated analogue (MW = 284), which presented an ECL value of 16.74, almost the same as that exhibited by an anteiso C17 fatty acid methyl ester. In fact, when coinjected in gas chromatography (GC) with an authentic sample of the anteiso C17 methyl ester obtained from other sponges that we have analyzed in our laboratory, the hydrogenated product proved to be identical. The position of the only double bond in the parent molecule was determined by preparing the corresponding pyrrolidide. The latter clearly presented an interval of 12 amu between m/z = 182 and m/z = 194 (Fig. 1, spectrum B), indicating also unsaturation between carbons 8 and 9. For comparison, we have included in Figure 1, spectrum C, the pyrrolidide derivative of the saturated linear behenic acid, where a difference of 14 amu is clearly seen between m/z = 182 and m/z = 196. From our mass spectral data and GC retention times, we concluded that we have isolated the known 14-methyl-8-hexadecenoic acid (2), most commonly known as its methyl ester as one of the components of the sex attractant of the female dermestid beetle *Trogoderma inclusum!*

Our third unusual fatty acid methyl ester presented an ECL value of 17.55, a rather low value. Mass spectral analysis revealed a molecular weight of 298, suggesting 18 carbons in the molecule and the base peak at m/z = 74 confirmed it to be a fatty acid methyl ester. This compound was inert upon catalytic hydrogenation, confirming branching and no unsaturation. The mass spectrum of the fatty acid methyl ester was very revealing, especially a peak at m/z = 101, not found in iso and anteiso fatty acids, with an impressive abundance of 84%. This clearly indicates methyl branching at carbon 3 due to a favorable cleavage between carbons 3 and 4. Because only one methyl branching can be explained from the observed ECL value, the original compound in question is the rare 3-methylheptadecanoic (3), which was observed in 0.9% abundance (Scheme 1).



SCHEME 1

Because sterols are known to coexist with phospholipids in cell membranes, we decided to take a look at the sterols from *D. anchorata* in detail to see if unusual methyl branching also was to be found in the sterol mixture. With the use of high pressure liquid chromatography (HPLC), 400-MHz ^{1}H-NMR, MS, and comparison with authentic samples, the following sterols were isolated and characterized from *D. anchorata.* Desmosterol (1.8% abundance of the total sterol mixture), cholesterol (41%), sitosterol (13%), stigmasterol (4.7%), 24-methylcholesterol (5.4%), 24(S)-methylcholesta-5,22-dienol (15.1%), 24(R)-methylcholesta-5,22-dienol (4.8%), 24-methylenecholesterol (4.6%), and cholesta-5,22-dienol (9.6%). Therefore, *D. anchorata* presented a common sponge sterol composition (14). However, we should mention in this context that when doing the analyses, we isolated several times reasonable amounts of a compound, which seems to be common in *D. anchorata,* presenting a molecular weight of m/z = 350, which could correspond to a monounsaturated $C_{25}H_{50}$ hydrocarbon or to an aldehyde such as (Z)-17-tetracosenal.

DISCUSSION

As mentioned earlier, this is the first time that the 7-methyl-8-hexadecenoic acid (1) has been isolated. The closest structure reported in the literature has been the isolation of the isomeric 7-methyl-7-hexadecenoic acid from sperm whale oils, which have been a common source of these 7-methyl branched fatty acids (15). In analogy to other similar structures, we probably can speculate at this point that the stereochemistry at the Δ8 double bond could be *cis* but, in any instance, the 7-methyl-8-hexadecenoic acid isolated in this work presents interesting possibilities for stereochemical modifications. For example, the four possible stereoisomers could be synthesized and tested for biological activity, especially pheromone-type interactions. Probably, as is the case of the analogous acid isolated in this work, i.e., the 14-methyl-8-hexadecenoic acid (2), the corresponding alcohol could be expected to provide a more powerful pheromone type of activity (16). As to the biosynthetic origin of this acid, we can only speculate until the necessary biosynthetic experiments are performed. It is very likely that the Δ8 double bond in 7-methyl-8-hexadecenoic acid is introduced after chain elongation and introduction of the 7-methyl group, i.e., the 7-methylhexadecanoic acid is biosynthesized first followed by double bond introduction. Until the latter experiments are performed, we can only speculate about the origin and function of this interesting phospholipid fatty acid.

The corresponding fatty acid methyl ester and alcohol of the 14-methyl-8-hexadecenoic acid (2) have been known for some time to be the active constituents of the sex attractant of both *Trogoderma inclusum* and *Trogoderma granarium* (8), but as to its function in *D. anchorata,* we can only speculate. We should mention here that the

stereochemical features of the natural pheromone are (R)-14-methyl-*cis*-8-hexadecenoate (17). The most likely biosynthetic route for the 14-methylhexadecenoic acid (2) should involve prior biosynthesis of the common 14-methylhexadecanoic acid followed by double bond introduction at Δ8. The origin of terminal 14-methyl branching in short-chain fatty acids has been studied thoroughly (12). The terminal anteiso moiety in fatty acids is generally derived from the branched amino acid isoleucine (12).

The 3-methylheptadecanoic acid is quite rare in nature. In fact, we do not know of any marine source for this acid, and this is the first time that it has been isolated from a marine sponge. However, the latter compound has been shown to be a major component of the overcrowding factors of mosquito larvae, and it possesses larvicidal activity against the southern house mosquito *Culex pipiens quinquefasciatus* (18). The radiolabeled 3-methylheptadecanoic acid also has been useful for heart fatty acid metabolic studies and imaging (18). The [1-^{14}C]β-methylheptadecanoic acid has been used for autoradiographic studies of myocardial infarction while the [1-^{11}C] acid has been useful in positron imaging studies in dog heart (19). Presently, we are synthesizing these fatty acids to test their possible biological activity as a function of stereoisomerism. Work is also in progress trying to elucidate the biosynthetic origin of the isolated acids in this work. We also are studying how the concentration of these acids changes with season.

ACKNOWLEDGMENTS

Thomas R. Tosteson and Vance Vicente from La Parguera, Puerto Rico, did the collection and classification of the sponge. O. Rosario assisted in the mass spectrometry. Financial support was from the University of Puerto Rico, FIPI (Grant No. 86-100-12-88.0) and NSF (Grant No. CHE-8715649).

The Composition of Furan Fatty Acids in the Crayfish

Kazuo Ishii, Haruo Okajima, Tsuyoshi Koyamatsu, Youji Okada and Hiroshi Watanabe*
School of Health Sciences, Kyorin University, Miyashita-cho, Hachioji 192, Japan

Capillary gas chromatography-mass spectrometry (GC-MS) analysis of the sterol ester fatty acid methyl esters of the crayfish hepatopancreas revealed the presence of at least 30 kinds of unusual furan fatty acids (F acids), which accounted for 28.49% of the total sterol ester fatty acids. On the other hand, only small amounts were found in triacylglycerols (0.5%) and phospholipids (0.7%). Among the F acids, 17 acids were the hitherto unknown ones, the major component being 12,15-epoxy-13,14-dimethyleicosa-12,14-dienoic acid (F_6) (41.83% of the total F acids). These novel acids possessed chain lengths of C_{12} to C_{22}, with the largest concentration at C_{20} (45.38%), C_{18} (41.97%) and C_{16} (10.35%). Odd-numbered F acids also were found, though in a very small amount (0.4%). In the living things other than the crayfish, the longest chain F acid (C_{24}) was detected in the sterol ester of the carp hepatopancreas. The bullfrog, an amphibian, and the turtle, a reptilian, were found to have F acids as well in their livers.

Olefinic furan fatty acids, which were detected by GC-MS, were found to have resulted during the analytical process from cyclodehydration of the diketo-ene formed by autoxidation of the F acids.
***Lipids 23,* 694–700 (1988).**

A furan fatty acid (abbreviated to F acid) was found for the first time in the seed oil by Morris et al. (1), and a series of F acids was detected in some fish by Glass et al. (2–4), Gunstone et al. (5,6) and Scrimgeour (7). The latter acids differed on the point of being tri- or tetra-substituted derivatives from the former di-substituted one, and were recognized mainly as the moieties of cholesteryl ester in the liver and triacylglycerol in the testis. One of the tri-substituted acid (14) (F_2, Table 1) was found in the rubber latex as triacylglycerol (8), and a short-chain tetra-substituted F acid (2) (Table 1) was seen in the soft coral (9). Very recently, two types of dibasic-substituted F acids were reported by Spiteller et al., which were extracted from the blood and urine of men and rats and regarded as oxidative products of the F acids at alkyl substituents of the structure in their living bodies (10–18).

Previously, we reported that the crayfish *Procambarus clarkii* had seven F acids (F_0–F_6, Table 1) in the hepatopancreas (19). This paper describes the results of further elaborated studies on the crustacean lipid. The investigations revealed an additional 23 F acids, among which 17 newly found ones were included (Table 1). The subjects of examinations for the F acids were extended to salmon, carp, ayu sweetfish, loach, yamame, lobsters, locusts, bullfrogs and turtles (Table 3).

MATERIALS AND METHODS

Materials. Crayfish, *P. clarkii,* were caught in October 1984 in Inbanuma in Chiba prefecture near Tokyo. The animals (male), 50–70 g, were maintained in tap water at room temperature for at least two wk, and were fed dried sardines. Then, the animals were killed, and the hepatopancreas was removed. Carp (male, 1300 g), *Cyprinus caprio,* were caught in Inbanuma in July 1984, maintained in tap water for two days, and killed. Removed hepatopancreas was not free of some adipose tissue. Salmon (male), *Oncorhynchus keta,* were captured in the Izumida River in Fukushima prefecture in October 1985; ayu sweetfish (male), *Plecoglossus altivelis,* in the Kano River in Shizuoka prefecture in July 1986; and locust (male and female), *Oxya. chinensis,* in Ibaraki prefecture in October 1985. Yamame, *Oncorhynchus masou,* were donated by the Tokyo metropolitan Suisansikenjyo Okutamabunjyo, Ome, in October 1985, and lobster (male), *Panulicus japonicus,* were obtained at a food market in Tokyo in July 1983. Bullfrog, *Rana catesbeiana,* and turtle, *Clemmys japonica,* were obtained from a local supplier in October 1986. These animals were frozen immediately after being killed, and within 24 hr, tissues were removed and extracted.

Lipid extraction, lipid fractionation and preparation of fatty acid methyl esters. The total lipids of tissues of animals were extracted by the method of Folch et al. (20). Fractionation of the total lipids into sterol esters, triacylglycerols and phospholipids was performed by silica gel column chromatography. The sterol esters were eluted with n-hexane/benzene (2:1, v/v), the triacylglycerols with chloroform/benzene (1:1, v/v), and the phospholipids with methanol/chloroform (2:1, v/v). The total lipids were kept in chloroform solution at −40 C until they were used in the experiment. The methyl esters were prepared by transmethylation with 0.5 M sodium methoxide in methanol at 50 C in screw-cap test tubes for 20 min and purified by thin layer chromatography (TLC) (silica gel 60, 0.25 mm thickness, Merck No. 5715) by developing with n-hexane/benzene (1:1, v/v).

Gas chromatography (GC) and gas chromatography-mass spectrometry (GC-MS). GC was carried out with a Hewlett-Packard 5790A with a flame ionization detector (FID), on a Carbowax 20 M fused silica capillary column (25 m × 0.32 mm i.d., Hewlett-Packard), programmed from 150 to 220 C at 4 C/min. The injection and detector were held at 250 and 300 C, respectively. Peak area percentages were obtained with a Hewlett-Packard integrator 3390A. The carrier gas was helium at a flow rate of 1 ml/min. The split ratio was 20:1.

GC-MS was performed with a Hewlett-Packard 5995A, on Carbowax 20 M fused silica capillary column (25 m × 0.32 mm i.d.) with the same temperature programs as used for GC. All mass spectra were obtained at 70 eV ionization electron energy and a source temperature of 180 C.

Mass spectrometry (direct insertion). The mass spectra of the diketo-enes, **36** and **40**, were measured with a JEOL JMS D-300 (inlet temperature 170 C, 70 eV), and of the diketones, **39** and **41**, with a Hewlett-Packard 5995A (inlet temperature 150 C, 70 eV).

High performance liquid chromatography (HPLC) analysis. HPLC was carried out with a Shimadzu LC-6A and a Shimadzu SPD-6A variable wave length UV

*To whom correspondence should be addressed.

Abbreviations: GC, gas chromatography; GC-MS, gas chromatography-mass spectrometry; HPLC, high performance liquid chromatography; TLC, thin layer chromatography.

detector. A Shim-packed CLC-ODS (6 mm × 150 mm, Shimadzu) was used with elution by a 15 min linear gradient of acetonitrile/water (80:20 to 100:0, v/v) at a flow rate of 1.5 ml/min. The effluent was monitored at 234 nm.

Catalytic hydrogenation of fatty acid methyl esters in sterol esters using Lindlar catalyst. Whole fatty acid methyl esters (200 mg) obtained from sterol esters were hydrogenated in n-hexane at an atmospheric pressure over Lindlar catalyst (30 mg) (21). The reaction was followed by measuring the disappearance of the unsaturated fatty acids by GC-MS every 30 min. After three hr, the GC-MS analysis showed that only unsaturated fatty acids were saturated and the furan ring was not hydrogenated under these conditions.

Autoxidation of F_3 methyl ester on the surface of silica gel TLC. A solution of synthetic F_3 methyl ester (50 mg) in n-hexane was applied on the silica gel TLC plate (the same as that used above, Merck No. 5715) that was rinsed with acetone and dried at 100 C for 1.5 hr, developed with n-hexane/benzene (1:1, v/v) up to 3 cm from the upper edge. After the development, the F_3 methyl ester had been spread over about 70 cm^2 of the surface of TLC. Then the plate was left to stand in the air and light (by normal room lamps) at room temperature for one hr. The band, located by spraying with 2′,7′-dichlorofluorescein methanolic solution, was scraped out and extracted with CH_2Cl_2 to give a colorless oil. Fifty-six percent of the starting material (estimated by GC) had disappeared. HPLC analysis of the mixture indicated that the major product was the diketo-ene (**36**), accompanied with a small amount of olefinic F acids (**32**) (**33**). The diketo-ene (**36**) purified by alumina TLC (20 × 20 cm, 0.25 mm thickness, Type E, Merck No. 5713, benzene/ether = 20:1, v/v) produced a colorless oil, 18 mg, which revealed a purity of 80% by HPLC analysis (Fig. 3). On the other hand, purification by silica gel TLC was unsuccessful, owing to its instability on the surface. As described above, this oxidation must be carried out in the light, and in the dark the reaction was slow. When a small amount of F_3 methyl ester (20 mg) was applied on the TLC (spread over about 50 cm^2), 73% of the starting material had reacted. **36**: IR (neat) 1735 ($COOCH_3$), 1685 (C=O), 1605 (C=C) cm^{-1}; UV_{max}(n-hexane) 227 (conjugation) nm; MS (direct insertion, 70 eV) m/z (rel. intensity): 352 (M^+, 48), 334 ($M^+ - H_2O$, 68), 321 ($M^+ - OCH_3$, 28), 305 (21), 303 (12), 295 ($M^+ - (CH_2)_3CH_3$, 55), 291 (47), 281 ($M^+ - (CH_2)_4CH_3$, 4), 277 (13), 263 ($M^+ - (CH_2)_3CH_3 - CH_3OH$, 100), 253 ($M^+ - CO(CH_2)_4CH_3$, 1), 249 ($M^+ - (CH_2)_4CH_3$-$CH_3OH$, 15), 221 ($M^+ - CO(CH_2)_4CH_3$-$CH_3OH$, 3), 205 (28), 195 ($M^+ - (CH_2)_7COOCH_3$, 90), 191 (50), 181 ($M^+ - (CH_2)_8COOCH_3$, 25), 179 (14), 177 (29), 161 (9), 153 ($M^+ - CO(CH_2)_8COOCH_3$, 4), 149 (12), 135 (30), 123 (10), 109 (13).

Synthesis of cyclopentenones (37) (38) from the diketo-ene (36). The diketo-ene (**36**) was converted to cyclopentenones (**37**) (**38**) by the method of Schödel and Spiteller (22), except to use trimethylsilyldiazomethane in place of diazomethane for methylation of carboxylic acid (23) (Scheme 1). Mass spectra of **37** and **38** were identical with those in the literature. **37**: MS m/z (rel. intensity): 352 (M^+, 8), 334 ($M^+ - H_2O$, 4), 321 ($M^+ - OCH_3$, 1), 303 (321 - H_2O, 6), 281 ($M^+ - C_5H_{11}$, 22), 249 (281 - CH_3OH, 22), 196 ($M^+ - CH_2$=$CH(CH_2)_5COOCH_3$, 14), 137 (249 - $(CH_2)_7CO$, 72), 126 (196 - C_5H_{10}, 100). **38**: MS m/z (rel. intensity): 352 (M^+, 13), 334 ($M^+ - H_2O$, 3), 321 ($M^+ - OCH_3$, 5), 303 (321 - H_2O, 4), 296 ($M^+ - C_4H_8$, 2), 278 (296 - H_2O, 4), 181 ($M^+ - (CH_2)_8COOCH_3$, 100), 126 (296 - CH_2=$CH(CH_2)_6COOCH_3$, 65).

Catalytic hydrogenation of the diketo-ene (36). The diketo-ene (**36**) (11 mg) was dissolved in 10 ml ethanol and PtO_2 (3 mg) was added. The mixture was vigorously stirred under hydrogen gas at an atmospheric pressure for 13 hr (Scheme 1). Hydrogenation of **36** was very slow and yielded a complex mixture. Silica gel TLC with n-hexane/ether (3:2, v/v) of the resulting mixture showed the major spots of the dimethyl-1, 4-diketone (**39**) (R_f = 0.4) and F_3 methyl ester (R_f = 0.9). The mass spectrum of **39** isolated by the silica gel TLC (20 × 20 cm, 0.25 mm thickness, n-hexane/ether = 3:2, v/v) was similar to that of the monomethyldiketone, **10**, 13-dioxo-11-methyloctadecanoate (**41**), reported in the literature with an appropriate mass unit shift (24). The compound (**39**) readily converted to F_3 methyl ester with 14% BF_3 in methanol (25). **39**: MS (direct insertion, 70 eV) m/z (rel. intensity): 354 (M^+, 0.5), 336 ($M^+ - H_2O$, 6), 323 ($M^+ - OCH_3$, 9), 251 ($M^+ - (CH_2)_4CH_3$-CH_3OH, 13), 199 ($CO(CH_2)_8COOCH_3$, 13), 198 ($M^+ - CH_2$=CH-$(CH_2)_5COOCH_3$, 6), 183 ($M^+ - (CH_2)_8COOCH_3$, 11), 155 ($M^+ - CO(CH_2)_8COOCH_3$, 29), 139 ($(CH_2)_8COOCH_3 - CH_3OH$, 22), 99 ($CH_3(CH_2)_4CO$, 100).

Conversion of the diketo-ene (36) to olefinic F acid methyl esters (32) (33) during GC analysis. The diketo-ene (**36**), which was confirmed to be free of olefinic F acid methyl esters (**32**) (**33**) by HPLC, was dehydrated to four isomeric olefinic F acid methyl esters during GC analysis under conditions described above (Fig. 4). The retention times and mass spectra of the larger peaks "c" and "d" in Figure 4 were essentially the same as those of **32** and **33**, respectively, in Figure 1B. On the other hand, the mass spectra of the smaller peaks "a" and "b" were basically identical with those of "d" and "c," respectively, suggesting that a pair of two peaks "b" and "c" represent *cis-trans* isomers of the olefinic F acid methyl ester (**32**), and the other pair of "a" and "d," of the olefinic F acid methyl ester (**33**). Peaks "c" and "d" with the longer retention times were *trans* isomers of **32** and **33**, respectively (28).

Oxidation of F_2 methyl ester with m-chloroperbenzoic acid. To a solution of synthetic F_2 methyl ester (114 mg, 0.356 mmol) and $NaHCO_3$ (40 mg) in 15 ml of CH_2Cl_2 at 0 C under N_2 gas was added a solution of m-chloroperbenzoic acid (80 mg, 0.462 mmol, Wako Pure Chemicals, Osaka, Japan, about 70%) in 5 ml of CH_2Cl_2. After being stirred in an ice bath for 10 min, the reaction mixture was washed with 5% $Na_2S_2O_3$, 5% $NaHCO_3$ and brine and dried over anhydrous Na_2SO_4. Removal of solvent gave a yellow oil, which was purified by alumina TLC (20 × 20 cm, 0.25 mm thickness, Merck No. 5713) using benzene-ether (20:1, v/v). Extraction with CH_2Cl_2 gave the diketo-ene derivative of F_2 methyl ester (**40**) (97 mg, 81%), which revealed a purity of 96% by HPLC analysis. **40**: MS (direct insertion, 70 eV) m/z (rel. intensity): 338 (M^+, 9), 320 ($M^+ - H_2O$, 20), 307 ($M^+ - OCH_3$, 22), 291 (3), 289 (10), 281 ($M^+ - (CH_2)_3CH_3$, 3) 277 (10), 249 ($M^+ - (CH_2)_3CH_3$-CH_3OH, 10), 239 ($M^+ - CO(CH_2)_4CH_3$, 29), 235 ($M^+ - (CH_2)_4CH_3$-CH_3OH, 40), 207 ($M^+ - CO(CH_2)_4CH_3$-CH_3OH, 12), 191 (20), 181 ($M^+ - (CH_2)_7COOCH_3$, 42), 177 (7), 167 ($M^+ - (CH_2)_8COOCH_3$, 100), 165 (14), 163 (18), 139 ($M^+ - CO(CH_2)_8COOCH_3$, 23), 123 (31), 121 (30), 111 (60);

IR (neat) 1735 ($COOCH_3$), 1690 (C=O), 1605 (C=C) cm^{-1}; UV_{max}(n-hexane) 226 (conjugation) nm.

The diketo-ene (40) was gradually obtained by autoxidation of F_2 methyl ester on the surface of silica gel TLC as well.

Catalytic hydrogenation of the diketo-ene (40). The diketo-ene (40) (13 mg) in 10 ml ethanol was hydrogenated using PtO_2 (5 mg) under hydrogen gas at an atmospheric pressure for four hr. The resulting mixture was chromatographed on silica gel TLC (20 × 20 cm, 0.25 mm thickness) using n-hexane/ether (3:2, v/v) to give the diketone (41) as a colorless oil, 9 mg. The mass spectrum of 41 was essentially the same as the literature data (24). The compound (41) was cyclodehydrated to F_2 methyl ester with 14% BF_3 in methanol in good yield (88%) (24). 41: MS (direct insertion, 70 eV) m/z (rel. intensity): 340 (M^+, 2), 322 ($M^+ - H_2O$, 4), 309 ($M^+ - OCH_3$, 8), 237 ($M^+ - (CH_2)_4CH_3$-CH_3OH, 12), 199 ($CO(CH_2)_8COOCH_3$, 53), 184 (CH_2=CH-$(CH_2)_5COOCH_3$, 69), 169 ($M^+ - (CH_2)_8COOCH_3$, 46) 141 ($CH_3CHCH_2CO(CH_2)_4CH_3$, 91), 139 ($(CH_2)_8COOCH_3$-CH_3OH, 76), 128 (56), 99 ($CO(CH_2)_4CH_3$, 100).

RESULTS AND DISCUSSION

Capillary GC-MS analysis of the fatty acid methyl esters derived from the sterol ester fraction in the crayfish hepatopancreas revealed several new F acid peaks apart from F_0–F_6 compounds (Fig. 1A) in comparison with the previous packed column data (19). To investigate in detail, the methyl esters were hydrogenated with Lindlar catalyst (21) and followed by urea fractionation (26). The concentrated F acid mixture was analyzed by GC (Fig. 1B) and GC-MS. The spectra showed 30 peaks of F acids (Table 1). Thirteen compounds of them already had been reported, **8, 9, 14, 17, 19, 23, 24** (F_0–F_6) in fish (2–7) and crayfish (19), **7, 15, 25, 29, 30** in fish (3–6 and 12) and a short chain length (2) in the soft coral (9), respectively. But the other 17 acids, **1, 3, 4, 5, 6, 10, 11, 12, 13, 16, 18, 20, 21, 22, 26, 27** and **28**, were newly discovered and identified by GC-MS from the basic data previously reported about F_0–F_6 acids (19). The total content of F acids in the sterol ester was 28.49%. On the other hand, only small amounts were found in triacylglycerols (0.5%) and phospholipids (0.7%).

The other type of F acids **32, 33, 34** and **35** with characteristic mass spectra (Fig. 2) was detected (Fig. 1A, B). These acids were identified by GC-MS as F_3 or F_6 methyl ester with an additional double bond, conjugated with a furan ring (named as olefinic F acids). The former two peaks, **32** and **33**, were derived from F_3, and the latter two, **34** and **35**, from F_6.

Glass et al. (3,27) and Gunstone et al. (6) reported the presence of these olefinic acids in the fish oil but did not

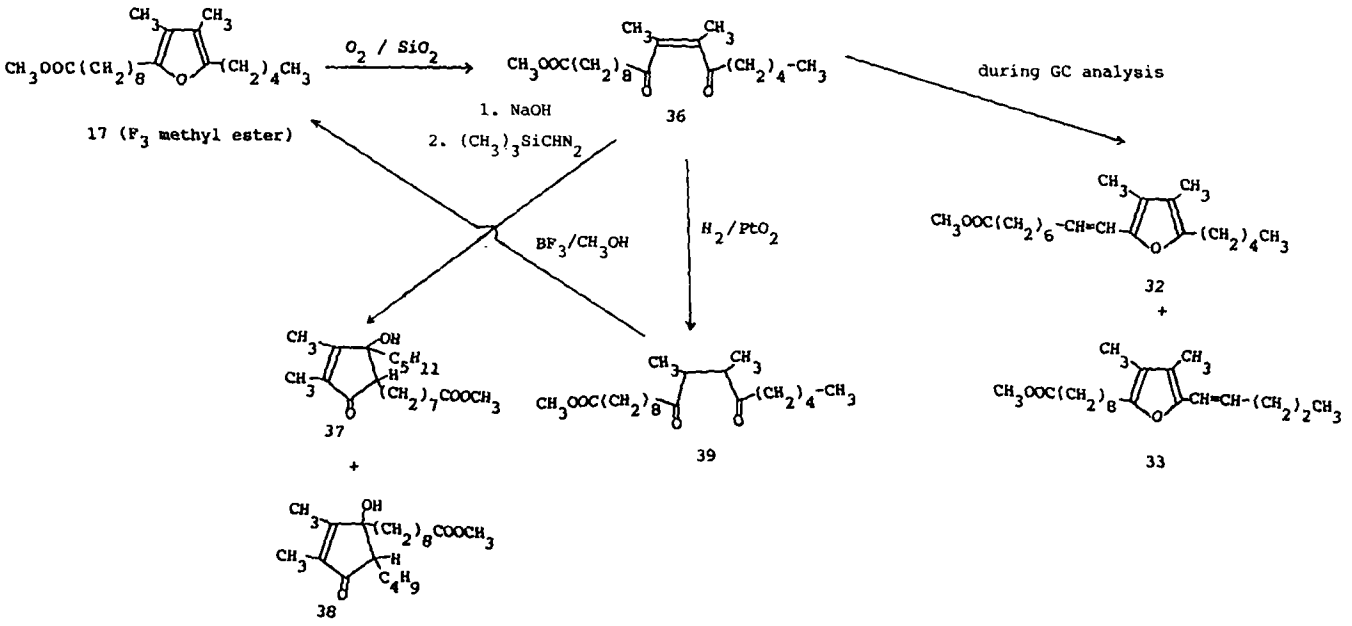

SCHEME 1. Autoxidation of F_3 acid methyl ester to the diketo-ene (36) on the surface of silica gel TLC. The derivatizations of 36 to cyclopentenones (37) (38) and 1,4-diketone (39), and conversion of 36 to olefinic F acids (32) (33) during GC analysis.

refer to detailed points. We found that synthetic F_3 readily underwent autoxidation on the surface of silica gel TLC to afford the diketo-ene (36), though unaffected on the surface of alumina TLC (Scheme 1). The diketo-ene (36) was not stable enough to be isolated in pure state, as pointed out in the literature (22). But the analysis by HPLC showed that the sample purified by alumina TLC had been separated from olefinic F acids (32) (33) and unchanged F_3 (17). The diketo-ene (36) thus obtained was about 80% in purity by HPLC (Fig. 3). The structure of 36 was established on the basis of spectral data (IR, UV and MS) and chemical derivatizations (Scheme 1). The IR spectrum showed bands at 1685 (C=O) and 1605 (C=C) cm^{-1}, and the UV spectrum had only a maximum at 227 (conjugation) nm. The major mass spectrum fragments of 36 were comparable with their counterparts of the more stable monomethyldiketo-ene (40) derived from F_2 methyl ester (14) (Table 2).

The diketo-ene (36) cyclized in aqueous NaOH solution to give cyclopentenones (37) (38), the structure of which were established by Schödel and Spiteller (22) (Scheme 1). In addition, 36 was hydrogenated using PtO_2 in ethanol to yield the 1,4-diketone (39), which was readily converted to F_3 methyl ester with BF_3 in methanol (25) (Scheme 1). In conclusion, these results described above supported that 36 had a diketo-ene structure.

During GC analysis, the diketo-ene (36) was found to be converted to four isomeric olefinic F acids, with small amounts of various unidentified products (Fig. 4). The retention times and mass spectra of the larger peaks "c" and "d" in Figure 4 were fully consistent with those of the peaks 32 and 33, respectively, in Figure 1. These findings suggested that olefinic F acids, shown in Figure 1, were artifacts that during GC analysis, were produced by cyclodehydration of the diketo-enes formed by

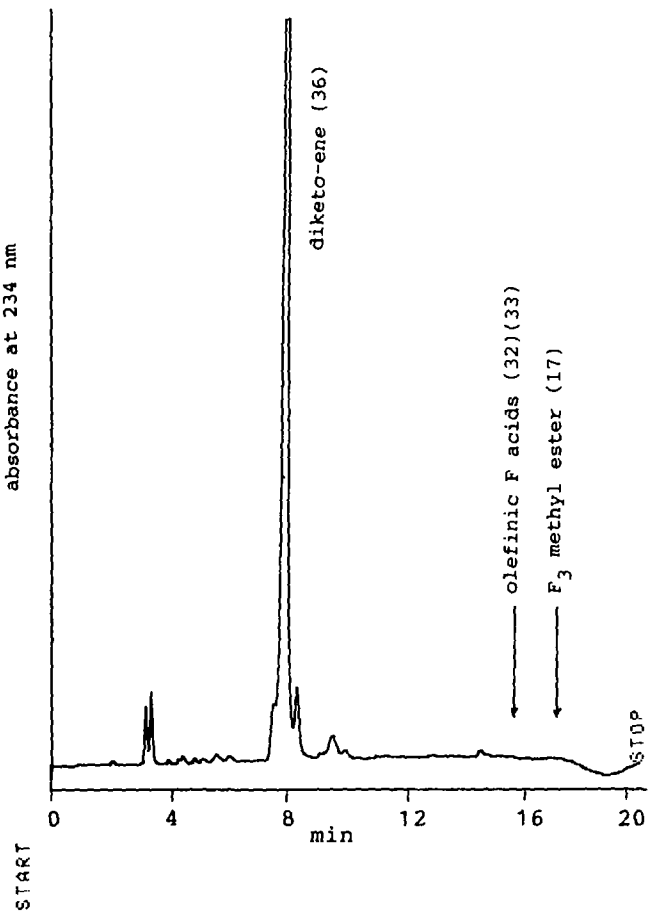

FIG. 3. HPLC of the diketo-ene (36) purified by alumina TLC. The chromatographic conditions are described in the text.

[b]SE, sterol esters; TG, triacylglycerols.

[c]Wt. % of total lipids of individual tissue.

[d]Carbon chain length and equivalent chain length of 31 are 24 and 27.85, respectively. For structure of 31, see Fig. 2A.

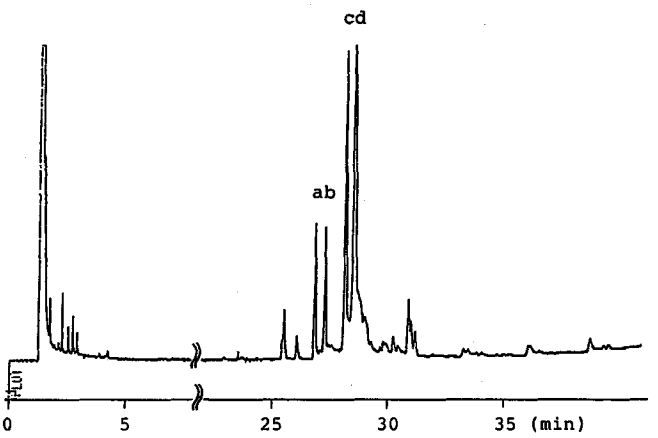

FIG. 4. Conversion of the diketo-ene (36) to olefinic F acids during GC analysis. Peaks "c" and "d" corresponded to 32 and 33, respectively, in Figure 1B. A pair of "a" and "d" was *cis-trans* isomers of 33 and the other pair of "b" and "c," of 32.

autoxidation of F acids under the experimental conditions, mainly on the surface of silica gel TLC.

The carbon chain lengths of the F acids were distributed mainly into 45% of 20 carbon atoms, 42% of 18 carbon atoms followed by 10% of 16 carbon atoms (Table 1). There were also a small amount of odd-numbered acids (10) (11) (12) (13) (18) (20) (21) (22) (26) (27). Their carbon chain lengths ranged from 12 to 22 carbon atoms. The distribution profiles were extremely similar to those of naturally occurring normal fatty acids.

The presence of F acids in the crayfish, one of the crustaceans, prompted us to examine F acids in fish (carp, salmon, ayu sweetfish, loach and yamame), a marine crustacean (lobster), an insect (locust), an amphibian (bullfrog) and a reptilian (turtle) (Table 3). In the carp hepatopancreas and testes, the F acid distribution data were similar to those of fish (4) in order of F_6, F_4 and F_5, but different from those of the crayfish in order of F_6, F_3 and F_5. On the other hand, 31 was a new F acid, having the longest carbon chain of C-24 (Fig. 2). A salmon, which was captured at spawning time, had no detectable F acid (less than 0.01%) in the liver, probably because lipids including F acids had been transported from the liver to the testes at the time. Actually, the testes accumulated F acids as shown in Table 3. Similar facts were reported in brook trout and northern pike by Glass et al. (4). Ayu sweetfish eating mainly river-algae and yamame living in swift streams of inland did not show any special feature of F acids in their organs, and in the lipids of the lobster hepatopancreas (19) and locust (whole body), no F acids were detected. The bullfrog, which belongs to the amphibian family, was found to have F acids in significant amounts in the liver, and its major F acid was F_3, whereas in the fish it always was F_6. Furthermore, the turtle, which belongs to the reptilian family, also contained F acids.

Appreciable quantities of F acids could be observed in animal species besides fish (2-7), including aquatic mollusca (6), and the distribution of the chain lengths presumably parallels that of naturally occurring fatty acids. The functions of such acids in nature are not made clear in spite of active biosynthetic (29), metabolic (12) and physiological studies (18).

ACKNOWLEDGMENTS

The authors thank T. Kinoshita (Analytical and Metabolic Research Laboratories, Sankyo Co., Ltd.) for performing the mass spectral analyses and also K. Takahashi (Tokyo metropolitan suisansikenjyo Okutamabunjyo) for supplying fish.

Rhizomucor miehei Triglyceride Lipase Is Synthesized as a Precursor

Esper Boel*, Birgitte Huge-Jensen, Mogens Christensen, Lars Thim and Niels P. Fiil
Novo Research Institute, Novo Allé, DK-2880 Bagsvaerd-Copenhagen, Denmark

A *Rhizomucor miehei* cDNA library constructed in *Escherichia coli* was screened with synthetic oligonucleotides designed from knowledge of a partial amino acid sequence of the secreted triglyceride lipase (triacylglycerol acylhydrolase EC 3.1.1.3) from this fungus. Lipase-specific recombinants were isolated and their insert sequenced. Unlike characterized bacterial and mammalian triglyceride lipases, the fungal enzyme is synthesized as a precursor, including a 70 amino acid residue propeptide between the 24 amino acid residues of the signal peptide and the 269 residues of the mature enzyme. The precursor processing mechanism, which involves cleavage between a methionine and a serine residue, is unknown. By sequence comparison with other lipases, a serine residue involved in substrate binding was identified in the fungal lipase. The sequence around this residue is well-conserved among characterized lipases. Conservation of an intron in an isolated cDNA recombinant and immunoprecipitation of in vitro synthesized *R. miehei* translation products indicates that the expression of the lipase gene might involve inefficient mRNA splicing.
***Lipids 23,* 701-706 (1988).**

The biosynthesis and activation of extracellular hydrolytic enzymes constitute a problem to secretory cells. Different types of proteases are synthesized as inactive zymogens, presumably to avoid degradation of cell constituents. Among the so far characterized lipases from bacteria and mammals, no zymogen/activated enzyme relationship that could account for a protection mechanism for intracellular or membrane-associated lipids has been described. In the present study, a fungal lipase was chosen as a model for the biosynthesis of lipid-degrading enzymes in lower eukaryotes.

The phycomycete fungus *Rhizomucor miehei* (1) (previously classified as *Mucor miehei* [2]) produces an active extracellular lipase (triacylglycerol acylhydrolase EC 3.1.1.3) that hydrolyzes a broad spectrum of lipids found in animal fat and vegetable oil (3). Recently, we reported the partial purification and characterization of this enzyme (4). The *R. miehei* lipase (RML) was found to be present in fermentation supernatants in a predominant form called RML-A. The RML-A form was converted to the RML-B form during purification involving steps performed at low pH. The two enzyme forms showed a high degree of antigenic identity but differed in a number of characteristics, e.g., in affinity towards concanavalin A. RML-A, with high concanavalin A affinity, required activation at pH 10.5, while the RML-B form, which showed low concanavalin A affinity, did not need this step for maximal lipolytic activity. Therefore, we suggested that RML-B might be activated from RML-A through a partial deglycosylation that could influence the activity toward emulsions (4).

Abbreviations: RML, *Rhizomucor miehei* lipase; SDS, sodium dodecylsulphate; bp, base pair; HIC, hydrophobic interaction chromatography; HPLC, high performance liquid chromatography; kb, kilobase; LU, lipase units.

Multiple forms of extracellular lipases have been described from fungi (5-7), and this phenomenon apparently is due to both postsecretorial modifications like partial proteolysis and deglycosylation and to synthesis of truly different lipases.

We now report on the final purification and characterization of both enzyme forms, and on the molecular cloning of a corresponding cDNA. We present evidence that this triglyceride lipase is synthesized as a precursor with a signal peptide and a substantial propeptide. Maturation of the RML mRNA precursor apparently involved inefficient splicing.

MATERIALS AND METHODS

Purification of RML-A and RML-B. The two initial steps of RML-A purification by anion exchange chromatography on DEAE Sepharose and affinity chromatography on concanavalin A-Sepharose were carried out as described (4). Further purification was performed by hydrophobic interaction chromatography (HIC) on a TSK-Phenyl-5PW column. The ultrafiltration concentrate from the concanavalin A-Sepharose chromatography was made 1.2 M in Na_2SO_4, and applied at a flowrate of 1 ml/min to the TSK-Phenyl-5PW column (7.5 × 75 mm) mounted with a precolumn of TSK Guard gel Phenyl-5PW (6 × 10 mm). The elution was carried out by a linear gradient from 100% buffer A (1.2 M sodium sulfate in buffer B) to 100% buffer B (20 mM sodium phosphate, at pH 7.0) during 15 min. The separation procedure on the TSK-column was repeated several times by the injection of 350 μl aliquots.

The partially purified RML-B (4) was subjected to gel filtration chromatography on TSK G3000 SW. The RML-B preparation was applied at a flow rate of 1 ml/min as a 1% solution in 0.1 M sodium phosphate (pH 7.0) to the TSK G3000 SW column (7.5 × 600 mm) mounted with a precolumn TSK SWP (7.5 × 75 mm). The 1% solution was injected in volumes of 100 μl. Lipase activity (LU) was measured using tributyrine as substrate according to the procedure of Brockman (8) as modified (4). Determinations of protein (9) and sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) (4) were performed as described.

Carbohydrate and amino acid analysis on RML-A and RML-B. Carbohydrate analysis was performed by use of the phenol sulfuric acid method (10) with glucose as a standard. Amino acid analysis was performed on a Beckman Amino Acid Analyzer 121 MB. Half-cystine was determined as the S-β-(4-pyridylethyl)-derivative after reduction with tributylphosphine and coupling with 4-vinylpyridine (11,12). One sample was treated with 4-vinylpyridine without prior reduction for the determination of potential free cysteines.

Partial amino acid sequence determination of RML-A and RML-B. RML-A was digested with *Armillaria mellea* protease (13), with an enzyme to substrate ratio of 1:40 (mol:mol), and the resulting fragments were separated by high performance liquid chromatography (HPLC). To identify suitable fragments for the construction of

oligonucleotide probes, only peptides that showed a high ratio between 280 nm and 214 nm were sequenced because these fragments could contain tryptophan and/or tyrosine. Sequence determination was carried out (14) both on the native enzymes (amino-terminal sequence) and on selected suitable fragments by the use of a Gas Phase Sequencer (Applied Biosystems Model 470 A).

Nucleic acid procedures. A cDNA library that had been used to isolate a cDNA encoding an aspartic proteinase from *R. miehei* (15) was used to isolate RML-specific recombinants. The library was constructed on total cellular mRNA. Oligonucleotides were used in colony screening and primer extension experiments as described (16–18). The methods used for DNA sequencing (19), cell-free translations followed by immunoprecipitations (16) and mRNA blot analysis (15) have been described. Oligonucleotides were synthesized on an Applied Biosystems model 380 A DNA synthesizer.

RESULTS

Purification of RML-A and RML-B and partial amino acid sequence. The purification of RML-A and RML-B are summarized in Table 1. The elution pattern from the HIC of RML-A on the TSK-Phenyl-5PW column showed two main peaks (data not shown). The first peak appeared to contain practically all the lipase activity. Fractions corresponding to this lipase peak were collected from 18 identical runs, and the enzyme was desalted and concentrated (ca. 13 times) by ultrafiltration. The purification of RML-B by gel filtration on the TSK G3000 SW column is shown in Figure 1. The peak corresponding to a volume of elution of 23.43 ml contained the lipase activity. Fractions corresponding to this peak were collected from six identical runs, and the pooled protein material was concentrated (ca. 10 times) by ultrafiltration. The purified RML-A and RML-B were analyzed by SDS-PAGE. Both lipases migrated as a single band with the same apparent molecular weights of ca. 32 kD (Fig. 2). The purified RML-A also was analyzed by gel filtration on a TSK G3000

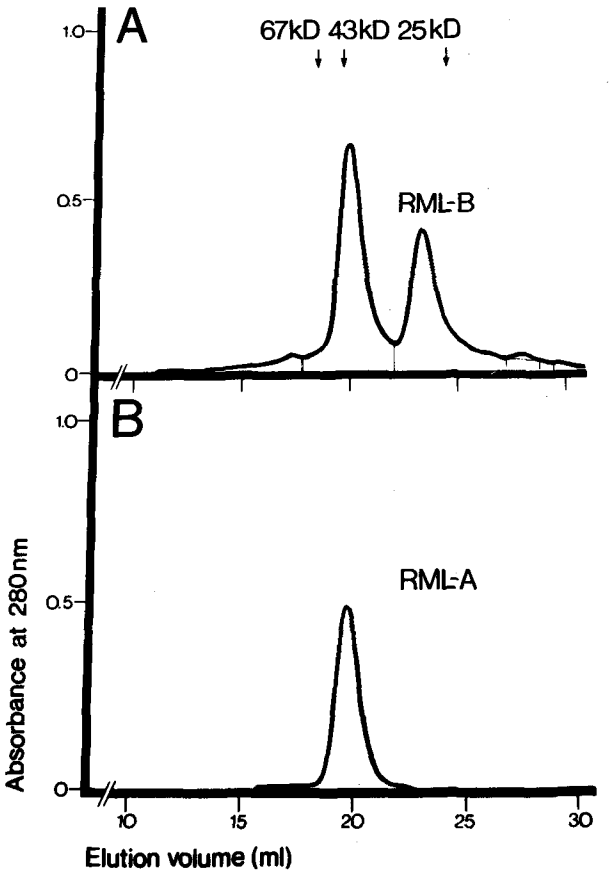

FIG. 1. Gel filtration chromatography of RML-A and RML-B on a TSK G3000 SW column. Panel A: Partially purified RML-B from the Phenyl-Sepharose chromatography. Panel B: Purified RML-A. The arrows indicate the elution positions of the m.w. standards: serum albumin (67 kD), ovalbumin (43 kD) and chymotrypsinogen A (25 kD). The elution positions of the RML-A and RML-B correspond to molecular weights of 42.5 kD and 27.5 kD, respectively. The protein eluting at a position corresponding to a molecular weight of 42.5 kD in panel A is an aspartic proteinase secreted by *R. miehei* (15).

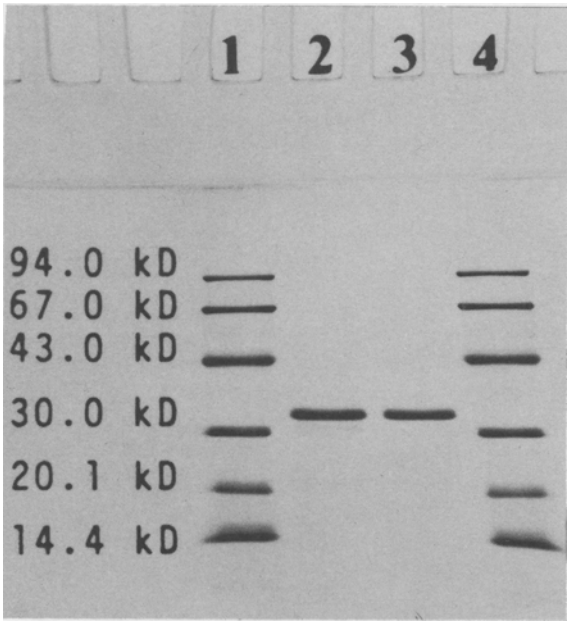

FIG. 2. SDS-PAGE of purified RML-A and RML-B. Lanes 1 and 4: m.w. standards; Lane 2: RML-A (2.7 μg). Lane 3: RML-B (3.4 μg). The gel was stained with Coomassie Brilliant Blue. The apparent molecular weights of both RML-A and RML-B are 32 kD.

SW column (Fig. 1) and eluted as a single peak with an apparent molecular weight of ca. 42.5 kD. RML-B had an apparent molecular weight of ca. 27.5 kD as determined by gel filtration (Fig. 1). The carbohydrate contents of the purified lipases were 11% (w/w) for RML-A and 4% (w/w) for RML-B.

The following N-terminal amino acid sequence was determined on both the A and B form of RML: Ser-Ile-Asp-Gly-Gly-Ile-Arg-Ala-Ala-Thr-Ser-Gln-Glu-Ile-Asn-Glu-Leu-Thr-Tyr-Tyr-Thr-. The following sequence was identified in one of the tryptophan-containing fragments isolated from the proteolytic digest of RML-A: Arg-Thr-Val-Ile-Pro-Gly-Ala-Thr-Trp-Asp. This sequence was used for the design of an RML-specific oligonucleotide mixture.

Molecular cloning and sequence of RML cDNA. An *R. miehei* cDNA library (15) was screened with an RML-specific oligonucleotide mixture, which had the following sequence: 5′ ($\frac{A}{G}$TCCCCANGTNGCNCC)3′. This oligonucleotide mixture is specific for the RML-mRNA in a region encoding the pentapeptide Gly-Ala-Thr-Trp-Asp, corresponding to the described proteolytic fragment of the purified RML-A. Hybridization and initial washing of the filters were done at 43 C. After autoradiography, the filters were washed at 47 C. Colonies that still showed strong hybridization were isolated, and the inserted cDNAs were sequenced. Two such recombinants, p353.7 and p353.16, had inserts of 1.2 kb. The DNA sequence obtained from these two recombinants both started in the middle of a signal peptide (Fig. 3), and extended through to the poly(A) tail. A third recombinant, p566, was found to contain 74 additional nucleotides inserted in the coding region (Fig. 3). Because the isolated recombinants did not include sequence for the 5′ part of a signal peptide with its initiating methionine codon, a synthetic oligonucleotide 5′(CGAGAGGGGATGAGGGGTGG)3′ was synthesized. This oligonucleotide is complementary to the RML

FIG. 3. Sequence of the preproRML cDNA together with the deduced amino acid sequence given by three-letter abbreviations. The horizontal lines show the positions of oligonucleotides used for cDNA-library screening and primer extension. An arrow shows the processing position used in maturation of RML. Nucleotides are numbered from the first base in the initiating Met codon, and amino acids are numbered from the first residue in the mature RML. Two short horizontal arrows indicate the 5′ and 3′ splice sites of the 74 nucleotides long intervening sequence. Amino acid Met-103 is the carboxyterminal residue in a short lipase precursor variant. A pentapeptide around the Ser-residue involved in substrate binding is boxed.

mRNA in a region encoding the amino acid sequence Pro-Pro-Leu-Ile-Pro-Ser-Arg underlined in the propeptide region in Figure 3. After this oligonucleotide had been labeled to a high specific activity with T4 polynucleotide kinase and ^{32}P-γ-ATP, it was used in a primer extension reaction on *R. miehei* mRNA. The primer extension reaction products were electrophoresed on a 10% polyacrylamide/urea gel and two RML-specific cDNA products, one 150 nucleotides long and the other one 160 nucleotides long, were both electroeluted and sequenced.

Structure of the RML precursor. DNA sequence data obtained from cDNA clones p353.7, p353.16 and p566, and from sequencing of the 5′ end of the RML mRNA through specific primer extension as described above, is compiled in Figure 3. Apart from the presence in the cDNA recombinant p566 of 74 extra basepairs, the sequences obtained from the different isolated plasmids and from the primer extension products were in total agreement. From the cDNA sequence data, it can be concluded that RML is synthesized as a part of a 363 amino acids

long precursor with a molecular weight of 39,529. The first 24 amino acid residues constitute a typical hydrophobic signal peptide. According to the predictive rules of von Heijne (20), the signal peptide is cleaved from the subsequent precursor by a cleavage between the alanine and valine residues at positions −71 and −70. Because the amino terminal sequence analysis of purified RML identified Ser-Ile-Asp-Gly-Gly- as the amino-terminus of the active enzyme, the lipase precursor has a 70 amino acid residues-long propeptide. Beginning with the amino-terminal serine residue (number 1 in Fig. 3), the mature lipase extends through 269 residues. The molecular weight of the protein backbone of the mature enzyme is 29,472.

In addition to the described preproRML, a potential variant lipase precursor was identified. A cDNA recombinant, p566, was found to contain 74 additional nucleotides inserted at a position between the codons for Ala-90 and Asp-91 (Fig. 3). This 74-nucleotide insert has the hexanucleotide GTAAGT at its 5′ end and the trinucleotide TAG at its 3′ end. Taking this structure, which is typical for intervening sequences, and the fact that the fragment was present in one cloned cDNA recombinant and absent from two others, this fragment most probably represents the result of differential splicing. A lipase precursor translated from such an intron-containing transcript would be only 197 amino acid residues long due to the presence of an inframe termination codon within the intervening sequence. After posttranslational processing of the signal and propeptides, only 103 residues would be left in this short, mature lipase-related variant. The molecular weight of this precursor and its maturation product would be 21,592 and 11,535, respectively.

After immunoprecipitation by the use of lipase specific antiserum of the primary translation products from *R. miehei* mRNA-supplemented rabbit reticulocyte lysate (Fig. 4), lipase precursors with molecular weights of 40 kD and 22 kD were identified. These two precursors, which corresponded well to the RML precursors suggested by cDNA sequencing, were precipitated in roughly equimolar amounts and therefore indicate that the 74 bp intron is conserved in roughly half of the translatable lipase mRNA.

Structure of RML mRNA. Poly(A)$^+$ mRNA was analyzed after blotting onto nitrocellulose with a ^{32}P-labeled RML-specific cDNA probe. An RML-specific transcript of 1.3 kb (Fig. 5) was identified by this analysis. The size of this mRNA is in good agreement with the length of the sequenced cDNA (Fig. 3). Due to the limitations of gel resolution of polyadenylated mRNA, the hybridizing mRNA may contain both the intron containing (74 nucleotides extra) as well as the spliced variant of RML mRNA. The RML-specific cDNA obtained by primer extension with the propeptide region specific oligonucleotide 5′ (CGAGAGGGGATGAGGGGTGG)3′ were 150 nucleotides and 160 nucleotides long (data not shown). If these cDNA represent full-length reverse transcripts, the cap site of the RML mRNA will be only 20 to 30 nucleotides 5′ to the initiating methionine codon. In the 3′ end of the mRNA, a 104-nucleotides long 3′ untranslated region was found. This region contains no typical polyadenylation signal (AATAAA) as found on most eukaryotic mRNA. At a position 22 nucleotides upstream from the poly(A) tail, a repetitive structure consisting of seven times the dinucleotide TA is localized.

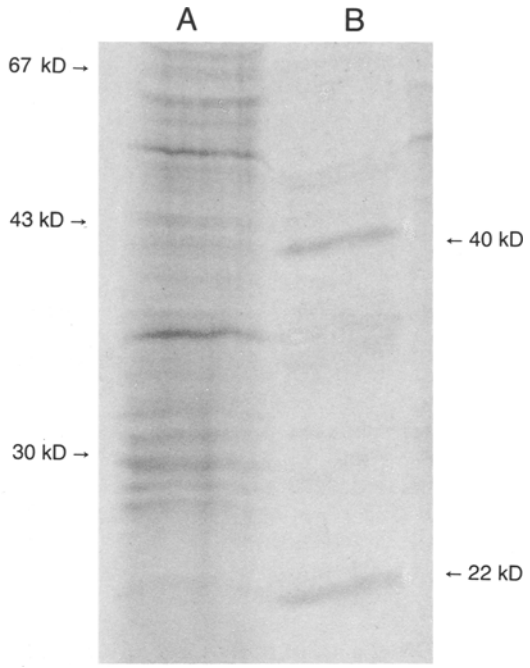

FIG. 4. SDS-polyacrylamide gel electrophoresis, followed by autoradiography of *in vitro* translation products and their immunoprecipitates. Total mRNA extracted from *R. miehei* was translated in a rabbit reticulocyte lysate with L-[^{35}S]methionine (lane A) and immunoprecipitated with rabbit antisera against RML (lane B). Two primary translation products were precipitated. The position of molecular weight standards are shown to the left.

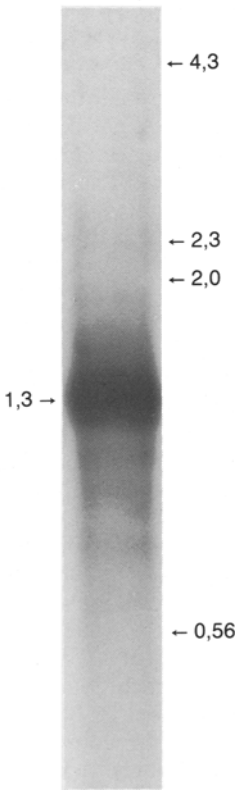

FIG. 5. RNA blot analysis of *R. miehei* poly(A)$^+$ RNA. Five μg of mRNA were separated on a 1.2% agarose gel, blotted to nitrocellulose and hybridized with nick-translated RML cDNA. The nucleotide length of *Hin*dIII digested phage lambda DNA fragments is indicated.

DISCUSSION

The triglyceride lipase from *R. miehei* can be purified as two enzyme forms: RML-A and RML-B. RML-A was isolated when neutral pH was maintained during all purification steps. In contrast, RML-B seems to be generated only when the preparation was exposed to low pH (~4.5) during purification. Both forms show the same apparent molecular weight (32 kD) on SDS gels after reduction. By gel filtration, the A- and B-forms eluted at positions corresponding to molecular weights of 42.5 kD and 27.5 kD, respectively.

The discrepancy between the molecular weights by gel filtration and SDS-PAGE of the A- and B-forms might be due to different apparent molecular size or shape of the enzyme forms in native and denatured conditions. The fact that RML-A and RML-B have identical apparent molecular weights determined by SDS-PAGE, whereas RML-B has a lower apparent molecular weight than RML-A by gel filtration, also could be explained by different molecular size/shape of their native forms. Determination of the total amount of carbohydrate in the purified A- and B-forms indicated a significant difference. Thus, the B-form seems to be less glycosylated than the A-form, which might give rise to the retardation observed by gel filtration (Fig. 1). Consequently, it seems likely that RML-B is generated as a result of low pH-dependent (~4.5) deglycosylation of RML-A. Amino acid composition (Table 2) of the A- and B-forms show that the two enzymes have a similar protein backbone, which, within experimental error, is confirmed by the data obtained through cDNA sequencing.

The possibility of the A- and B-forms being the results of different amino-terminal processing of a common precursor is excluded by the fact that both forms had the same amino-terminal as determined by amino acid sequencing. The fact that three independent cDNA clones all had exactly the same DNA sequence (except for the intron in p566) suggests that both lipase forms are encoded by one gene and therefore have the same primary structure.

Primary structures of triglyceride lipases from bacteria and mammals have been reported. These lipases show a large variation in the length of the protein chain. The shortest lipase has been reported from *Pseudomonas fragi* (21) containing only 135 amino acid residues. Two other bacterial lipases from *Staphylococcus aureus* (22) and *Staphylococcus hyicus* (23) have 690 (including signal peptide) and 603 residues, respectively. Mammalian triglyceride lipases have protein chains with intermediary sizes of 472 (rat hepatic lipase [sequence given in Ref. 27]), 449 (rat lingual lipase [24]), and 377 (porcine pancreatic lipase [25]) residues. The related enzyme, human lecithin-cholesterol acyltransferase (26) has 416 residues. The only regions with significant homology between these lipases and the 269 residues of mature RML are shown in Figure 6, which also includes a region from the human lipoprotein lipase (27). This alignment identifies one serine residue, located in a stretch of hydrophobic amino acid residues, as totally conserved. In porcine pancreatic lipase, this serine residue has been identified as an essential part of a hydrophobic attachment site involved in lipase adsorption to the water-insoluble triglyceride-substrate interfaces (28).

It should be noted that the primary structure of RML deduced from cDNA sequencing has 7 cysteine residues. Analysis by the use of 4-vinylpyridine for determination of potential free cysteines (Table 2) revealed traces of free cysteines in both enzyme forms. In proteins in which all cysteine residues are part of disulfide bridges, this analysis gives a clearly negative result. Therefore, it is likely that RML has a cysteine residue that is not involved in disulfide bridge formation and that is, therefore, free or involved in other as yet unknown bindings.

In none of the so far reported triglyceride lipases (most of them deduced from DNA sequence) has a zymogen been identified. The precursor of RML as deduced from

TABLE 2

Amino Acid Composition of RML-A and RML-B

Amino acid	RML-A	RML-B	Deduced from cDNA

Totals			269

[a]Determined as extrapolated values to 0 or infinite hydrolysis time.

[b]Determined as S-β-(4-pyridylethyl)-cysteine, in parentheses the found amount of potentially free cysteines.

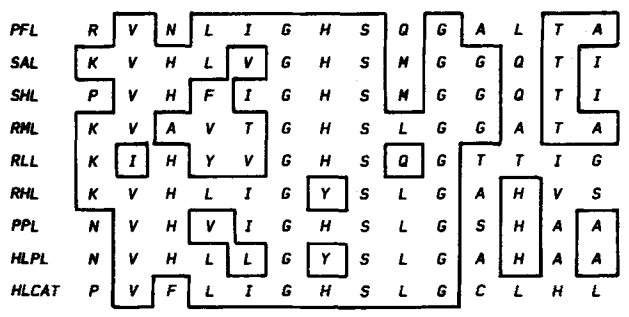

FIG. 6. Homology among substrate binding regions in lipases. Regions from 9 lipases are aligned, and residues are boxed where at least 3 out of 9 possible identities were found. PFL, *Pseudomonas fragi* lipase (21); SAL, *Staphylococcus aureus* lipase (22); SHL, *Staphylococcus hyicus* lipase (23); RML, *R. miehei* lipase; RLL, rat lingual lipase (24); RHL, rat hepatic lipase (sequence from Ref. 27); PPL, porcine pancreatic lipase (25); HLPL, human lipoprotein lipase (27); HLCAT, human lecithin-cholesterol acyltransferase (26). Amino acids are given by their one-letter abbreviations.

the DNA sequence in Figure 3 has a 70 amino acid residues-long propeptide between the typical signal peptide and the amino terminus of the mature enzyme. The maturation involves a proteolytic cleavage between a methionine and a serine residue (Fig. 3). We do not consider it likely that this Met-residue just 5′ to the Ser-residue could be the initiating methionine. If this was the case, the resulting secreted lipase would have no signal peptide, and the length of the identified primary translation products (Fig. 4) could not be accounted for. As the first 24 amino acid residues of the deduced precursor constitutes a typical signal peptide, including two basic residues in its amino terminal end and a long strongly hydrophobic core, we can only conclude that RML is synthesized as a part of a zymogen-like precursor. This observation raises interesting questions as to the temporal events in lipase secretion from a fungal cell. Processing of the 70 amino acid residues-long precursor peptide might involve a step-wise mechanism, because the first five residues end in the typical dibasic target sequence, Lys-Arg (residues −67 and −66 in Fig. 3). Propeptides have been identified in mammalian colipases (see Ref. 29 for an alignment of procolipases from pig and horse), and it is interesting to note that the propeptide in these enzymes are five residues long and read the sequence, Val-Pro-Asp-Pro-Arg. Processing of this colipase propeptide might be an example of proline-directed arginyl cleavage, a processing mechanism that recently has been reviewed (30). The colipase pentapropeptide has three identical residues in homologous positions as compared with the first five residues in the propeptide of RML. Apart from this short region, which may be functionally equivalent in proenzyme processing in proRML and in procolipases, these proteins have no homology.

Out of three isolated RML-specific cDNA recombinants, one (p566) was found to contain a 74 bp intervening sequence. Differential splicing of introns is well-known in higher eukaryotes, and it also has been demonstrated in a few genes from the lower eukaryotes, e.g., the glucoamylase gene of *Aspergillus niger* (16,31). However, no obvious advantages from this extra variation in the mechanism of gene expression can be identified in these two examples from the lower eukaryotes. In the case of RML, we might have observed a phenomenon best characterized as inefficient splicing of a precursor mRNA. The 74 base pair intervening sequence identified in recombinant p566 does not have a sequence showing homology to the internal splicing signal consensus, which is directly involved in lariat formation. A poor fit to this consensus, which in the filamentous fungi reads $\begin{matrix}TG\\AA\end{matrix}CT\begin{matrix}A\\G\end{matrix}AC$, has been suggested as a cause of inefficient mRNA precursor splicing (32) in lower eukaryotes.

It should be stressed that we cannot totally rule out the possibility that the cDNA recombinant p566 might represent a nuclear nonprocessed mRNA species. However, because a substantial fraction of the immunoprecipitable precursors is found as the short variant, we favor a theory of inefficient mRNA splicing, due to a weak internal splicing signal in the intron. We do not believe that the short lipase variant encoded by this intron-containing mRNA could have any lipase activity, simply because the substrate binding site would not be included in the molecule. During purification of the enzyme, we have not at any step observed such a short variant with lipase activity. If it is synthesized by the fungus in vivo, it might be unstable due to as yet unidentified mechanisms that eliminate aberrant protein molecules.

ACKNOWLEDGMENTS

We are grateful to Kjeld Norris and Fanny Norris for the synthesis and purification of oligonucleotides. Excellent technical assistance was provided by Annie Christensen, Karen Randrup, Vibeke Strange Pedersen and Anni Demandt. The manuscript was prepared with expertise by Marit Petersen and Lene Åkesson.

[Received February 25, 1988; Revision accepted April 18, 1988]

Effects of Hyperoxia and Diet on Murine Tissue Levels of Vitamin E and Polyunsaturated Fatty Acids

C.C. Tangney*, K.M. McCloskey and P.L. Aye
Departments of Clinical Nutrition and Internal Medicine, Rush Presbyterian St. Lukes Medical Center, Chicago, IL 60612

One hundred eighty-six adult female mice were studied to examine the effect of manipulating dietary vitamin E and fractional inspired oxygen concentrations (FiO_2) on tissue levels of vitamin E, total polyunsaturated fatty acids (TPUFA) and conjugated dienes (CD) as an index of lipid peroxidation. Animals were fed custom diets containing either 0, 50 or 150 ppm DL-α-tocopheryl acetate. Once plasma vitamin E levels of mice fell below 0.2 mg/dl (at week 19), all mice were placed in chambers containing either room air ($FiO_2 \sim 0.21$) or $FiO_2 > 0.95$ for the next 72 hr. Dietary manipulation had a major impact on the levels of vitamin E in plasma, lung and perirenal adipose tissues ($p < 0.0001$, $p < 0.0001$ and $p < 0.005$, respectively). Dietary vitamin E deprivation was associated with significant reductions in lung glutathione peroxidase (GPX) activities ($p < 0.05$) and in plasma TPUFA levels ($p < 0.05$). No significant effect attributable to either diet or FiO_2 was observed for liver vitamin E, liver TPUFA or lung TPUFA levels, or for those of CD in any tissue examined. Adipose TPUFA levels were depressed in all dietary groups exposed to $FiO_2 > 0.95$, when compared with those of groups exposed to room air. The high FiO_2 exposures also were associated with marked reductions in lung to body weight ratios ($p < 0.01$). These data suggest that dietary vitamin E treatment after long-term feeding can modify vitamin levels in plasma, lung and adipose tissues, and lung GPX activities. Vitamin E levels in liver seemed less responsive to our dietary manipulations in adult female mice, though expressing liver vitamin E levels in terms of TPUFA revealed significant differences between the ratios from 0 and 150 ppm vitamin E groups ($p < 0.05$).
***Lipids* 23, 707-712 (1988).**

Whenever animals are exposed to high fractional inspired oxygen concentrations (FiO_2), acute lung injury ensues. The pathophysiological processes include the recruitment and activation of specific cells to the lung and the generation of toxic oxygen products that are thought to be responsible for the damage of lung vasculature and epithelium. In response to this stress, the lung possesses a number of protective mechanisms against the free-radical peroxidizing compounds. These include vitamin E, ascorbic acid, uric acid, ceruloplasmin and a battery of enzymes, some of which rely on glutathione.

The administration of vitamin E to prevent hyperoxia-associated lung injury has been studied in experimental animals (1-9) with conflicting results. Similarly, reports regarding its benefit for infants with respiratory distress consequent to prolonged oxygen therapy (10,11) are conflicting. Some problems inherent in the interpretation of these findings might be resolved by an investigation of the ability of plasma measures to reflect the distribution or content of vitamin E in those tissues during hyperoxic challenge. Kornbrust and Mavis (12) reported that the degree of peroxidation in microsomes prepared from various rat organs was related to vitamin E content, and that the lung and heart were least susceptible to peroxidation because of the high vitamin E to total polyunsaturated fatty acid (TPUFA) ratios; they did not examine, however, plasma ratios or the impact of hyperoxia. Sevanian and coworkers (13) and Poukka Evarts and Bieri (14) also have reported similar differences in vitamin E to TPUFA ratios among these tissues of young rats.

In the present study, we examined the impact of $FiO_2 \sim 0.21$ (room air) and $FiO_2 > 0.95$ (hyperoxia) along with three dietary levels of vitamin E on tissue vitamin E and TPUFA concentrations of adult female mice. Yam et al. (15) found that adult rats succumbed to hyperoxia, because unlike the newborn animals, they did not exhibit induction of certain lung antioxidant enzymes, glutathione peroxidase (GPX), glutathione reductase, superoxide dismutase and others, in response to hyperoxic challenge. Therefore, we also wished to determine whether adult mice fed insufficient dietary vitamin E and exposed to hyperoxia would manifest alterations in lung GPX activities.

METHODS

Animals. One hundred and eighty-six adult female Swiss Webster mice (Harlan/Sprague-Dawley, Indianapolis, IN) weighing ca. 25 g each were placed in stainless steel cages, three or four per cage. The room was temperature and humidity controlled, having equal periods of light and dark (12 hr). For one wk following delivery, mice were fed ad libitum a custom-prepared diet containing 50 ppm DL-α-tocopheryl acetate (ICN Nutritional Biochemicals, Cleveland, OH) and water. Subsequent to this acclimatization period, animals were randomly assigned by cage to receive purified diets (from the same supplier) containing either 0, 50 or 150 ppm DL-α-tocopheryl acetate. Details of the diet composition and growth data have been reported (16). By week 19, mice that were fed 0 ppm vitamin E exhibited marked weight loss and depressed plasma vitamin E levels (<0.2 mg/dl), which is indicative of vitamin E deficiency. At this time, half the mice in each dietary treatment group were exposed to either $FiO_2 > 0.95$ or room air for the next 72 hr under ambient temperatures (22-26 C). The 72-hr period was selected because research by Poland and colleagues suggested that any period longer than this would be accompanied by considerable mortality (17). Chamber atmospheres were continuously filtered and circulated. Oxygen and CO_2 concentrations were monitored several times each day using a Beckman Medical Gas Analyzer LB-2 (Beckman Instruments, Inc., Fullerton, CA). Chambers were opened daily for several min to provide animals with food and water.

Abbreviations: GPX, glutathione peroxidase; ANOVA, analysis of variance; CD, conjugated dienes; FiO_2, fractional inspired oxygen concentrations; TPUFA, total polyunsaturated fatty acids.

Tissue collections. Following the 72 hr exposures, mice were removed from chambers and anesthesized briefly with methoxyflurane (Pitman-Moore, Inc., Washington Crossing, NJ). No animals died at the end of the 72 hr exposure period, although several mice from the vitamin E deficient group appeared to suffer respiratory distress once they were removed from chambers for killing. Data from seven mice were not included in these analyses because of problems with tissue processing; therefore, 63 mice comprised the 0 ppm group (30 at $FiO_2 > 0.95$), 56 mice were in the 50 ppm group (26 at $FiO_2 > 0.95$) and 63 mice were in the 150 ppm group (33 at $FiO_2 > 0.95$). Blood was obtained following procedures previously described (16). Analyses performed on plasma aliquots represent pooled samples from three to four mice in each cage on the same treatments, specifically, 17 samples for the 0 ppm vitamin E group, 16 samples for the 50 ppm and 18 for the 150 ppm vitamin E group. Whole lungs, livers, perirenal adipose tissues were excised, perfused with saline to remove blood, wrapped in an aluminum foil and frozen at −70 C. Once thawed, all tissues were minced, weighed and homogenized in ice-cold 1% (w/v) EDTA. Adipose tissues from three to four animals in each cage also were pooled before analyses.

Vitamin analyses. Extractions of tissues other than plasma were performed with hexane following saponification as described (18,19). Vitamin E, specifically α- and γ-tocopherols were measured using a Waters model 510 high performance liquid chromatograph (Waters Assoc., Milford, MA) equipped with a Perkin Elmer LC-75 variable UV-visible spectrophotometer (Perkin Elmer, Norwalk, CT). The reversed-phase analytical column was a 3 μm Supelcosil ODS column, 15 cm long × 4.6 mm, i.d. (Supelco, Inc., Bellfonte, PA). The isocratic solvent system consisted of 5% water in absolute methanol (v/v) at a flow rate of 1.2 ml/min. The column effluent was monitored at 292 nm. Calibration curves were established for all compounds of interest from measured peak heights of standards supplied by Bhagavan of Hoffmann La Roche relative to those of the selected internal standard, dl-tocol. Data for α- and γ-tocopherols are given as the sum total of α- and γ-tocopherols (vitamin E), because γ-tocopherol was not detected frequently in any of the tissue samples.

Total polyunsaturated fatty acid (TPUFA) analyses. Aliquots of plasma, lung, liver or adipose homogenates were extracted according to the method of Folch and coworkers (20), redissolved in toluene, and transesterified according to a published procedure (21). Pentadecanoic acid (15:0) was added at the beginning of the extraction to serve as an internal standard. Fatty acids from 14:0 to 22:6ω3 were separated and quantified by gas-liquid chromatography using a Perkin Elmer Sigma 3B chromatograph with a 10 ft long by 2 mm i.d. glass column packed with 3% SP2310 and 2% SP2300 on Chromosorb WAW (Supelco, Inc., Bellefonte, PA). A calibration mixture of fatty acid methyl esters (NuChek, Elysian, MN) and additional standard solutions were injected daily to confirm retention times and to calculate response factors. The instrument was operated with an injection temperature of 210 C, the flame detector at 250 C and the column from 185 to 220 C. Peak heights were electronically calculated by a Hewlett Packard 3390A recording integrator (Avondale, PA). Total PUFA (TPUFA) was defined as the sum of 18:2ω6, 18:3ω3, 20:2ω6, 20:3ω6, 20:4ω6, 20:5ω3, 22:3ω3, 22:4ω6 and 22:6ω3. These definitions were selected to reproduce those originally reported by Poukka Evarts and Bieri (14).

Other measurements. Lung homogenates (in 1% EDTA, w/v) were centrifuged at 105,000 g for one hr so the soluble fraction could be obtained for determination of GPX activity. The activities were measured using H_2O_2 according to the method of Lawrence and Burk (22). Linear regression analyses of log-transformed data were used to calculate activities that were corrected for spontaneous reaction rates. Protein concentration was determined by the method of Lowry et al. (23). DNA content was assessed by the microfluorometric method of Kissane and Robbins (24). GPX activities then were expressed per mg protein and per μg DNA. Analysis of conjugated dienes (CD) as an index of lipid peroxidation was performed in tissue homogenates at 233 nm by the method of Recknagel and Ghoshal (25) as modified by Till and coworkers (26). The amount of dienes was estimated using a molar extinction coefficient of 2.52×10^4 M^{-1} and then expressed in μmoles per mg protein or μmoles per μg DNA. The lung wet weight to body weight ratio was calculated to reflect the extent of lung edema (15) and is referred to as the lung edema index.

Statistical analyses. All data are expressed as mean ±1 SEM. Data were analyzed by two-way analysis of variance (ANOVA) using dietary vitamin E and FiO_2 exposures as factors. Whenever appropriate, one-way ANOVA and Duncan's multiple-range tests available in the statistical package, Statistics for Physical and Social Sciences, $SPSS^X$ (27,28) also were employed. Pearson r correlation and multiple linear regression analyses also were performed using $SPSS^X$.

RESULTS

Dietary treatments had a marked influence upon several components quantified in lung tissue homogenates. After 19 weeks of feeding the 0 ppm vitamin E diet, mice exhibited significantly lower ($p < 0.0001$) lung vitamin E levels than their supplemented counterparts (Table 1). No significant differences were apparent between lungs of mice fed 50 and 150 ppm vitamin E, or between mice on $FiO_2 > 0.95$ and those exposed to room air. Neither diet

	$FiO_2 > 0.95$	$FiO_2 \sim 0.21$	Both FiO_2 groups combined[b]
(ppm)	(μg/g wet weight)		
0	7.94 ± 3.8	11.78 ± 5.5	9.95 ± 3.4[c]
50	133.32 ± 16.9	100.59 ± 14.2	115.78 ± 11.0[d]
150	131.69 ± 18.5	177.83 ± 29.5	153.66 ± 17.2[d]

[a]All values are expressed as mean ± SEM.

[b]Significant differences were observed for dietary treatments only. Values in the same column not sharing the same superscript (c, d) are significantly different from each other: $p < 0.0001$.

nor FiO_2 treatments had any significant effect on lung TPUFA levels (Table 2). Dietary vitamin E deprivation resulted in lower lung GPX activities as compared with those from mice on 150 ppm vitamin E (Table 3). No differences in GPX activities were apparent between animals on hyperoxic and normoxic exposures within each dietary group, but considerable variation was observed in those of the 150 ppm dietary group. When GPX activities were expressed per μg DNA, there were no significant differences observed among dietary or FiO_2 groups (data not shown). Lung cell number was not altered by dietary treatments, but hyperoxia produced a significant ($p < 0.05$) reduction in lung cell number in both 0 and 50 ppm groups (data not shown). In contrast, neither treatment affected lung protein levels.

Data for lung CD levels, lung edema index, liver vitamin E and liver TPUFA levels are shown in Table 4. No significant differences in lung CD levels were obtained for either dietary or FiO_2 treatments. Lung edema indices were significantly greater in all dietary treatment groups exposed to hyperoxia as compared with those on room air ($p < 0.01$). Vitamin E and TPUFA levels in liver homogenates precluded detecting any significant effects attributable to dietary or FiO_2 treatments (data not shown).

As observed in lung homogenates, vitamin E levels of adipose tissue homogenates from animals fed the 0 ppm vitamin E were significantly lower ($p < 0.005$) than those of the 50 and 150 ppm dietary groups (Table 5). However, unlike the lung measures, a consistent dose-response trend can be observed for the 0, 50 and 150 ppm dietary groups in both hyperoxic and normoxic treatments. This trend is apparent despite the large variation in vitamin E levels of mice exposed to $FiO_2 > 0.95$ and receiving either 50 or 150 ppm vitamin E. Mean adipose TPUFA levels (g per g wet tissue) were consistenly lower in groups exposed to hyperoxia as compared with those on room air, respectively: for 0 ppm (20.99 ± 9.2 vs 70.26 ± 29.8), 50 ppm (14.78 ± 6.2 vs 37.42 ± 19.6), and 150 ppm dietary vitamin E (10.84 ± 5.6 vs 38.39 ± 12.8). Considerable variability was apparent in TPUFA levels of normoxic groups, though significant differences between FiO_2 groups were observed ($p < 0.05$). In contrast, no statistically significant differences were observed for CD

TABLE 2

50	233.68 ± 156.8	158.53 ± 30.1	193.60 ± 72.5[d]
150	453.80 ± 175.0	352.16 ± 61.6	408.63 ± 99.2[d]

[a]All values are expressed as mean ± SEM.

[b]Only a significant diet effect was found. Values in the same column not sharing the same superscript (c, d) are significantly different from each other: $p < 0.005$.

levels of adipose tissue among dietary or FiO_2 groups (data not shown).

Plasma vitamin E levels were highly correlated with those of lung tissue, $r = +0.68$, $p < 0.0001$. Significant differences in plasma levels were observed among all three dietary treatment groups ($p < 0.0001$), as shown in Table 6. No differences were apparent between FiO_2 groups. In Table 7, plasma TPUFA levels of both hyperoxic and normoxic 0 ppm vitamin E groups were markedly lower than those on 150 ppm vitamin E ($p < 0.05$). Again, no significant differences in plasma levels of CD among any of the groups were observed (data not shown).

Table 8 shows the vitamin E to TPUFA ratios for all tissues examined in these experiments. As observed with tissue vitamin E levels for plasma and adipose, we observed significant differences largely among dietary treatment groups with one exception: lung vitamin E to TPUFA ratios exhibited a significant interaction effect

150	~0.21	15.27 ± 4.5	15.88 ± 2.6	1.44 ± 0.2	14.63 ± 3.8

[a]Values represent mean ± SEM.

[b]Significant differences were found among all three dietary groups for plasma ratios ($p < 0.0001$).

[c]Lung ratios exhibited a significant interaction effect ($p < 0.05$).

[d]A significant dietary effect was observed for liver ratios, with ratios for the 0 ppm group being significantly lower than those of the 150 ppm group ($p < 0.05$).

[e]Significant differences between ratios for the 50 and 150 ppm supplemented groups with those of 0 ppm group were observed ($p < 0.01$). Adipose ratios have been multiplied by 1000.

between dietary and FiO_2 exposures ($p < 0.05$). Hyperoxic mice fed 50 ppm vitamin E had significantly higher ratios than those found for normoxic mice consuming the same level of dietary vitamin E ($p < 0.05$). In addition, in contrast to the lack of observed significant differences with liver vitamin E and TPUFA levels separately among diet groups, the use of the vitamin E to TPUFA ratio for liver homogenates provided at least an indication of dietary manipulation: the ratios for mice on 0 ppm vitamin E were significantly lower than those for mice on the 150 ppm vitamin E diet ($p < 0.05$).

When examining these ratios across tissues from supplemented mice only, plasma and lung ratios were similar in magnitude. Liver ratios were nearly 10-fold lower and adipose, nearly 300 to 1000 times lower than those of plasma or lung. These relative differences for tissue ratios were not observed in tissues of mice fed 0 ppm vitamin E.

DISCUSSION

Plasma vitamin E levels (not plasma vitamin E to TPUFA ratios) were fairly good predictors of lung vitamin E levels in these experiments. FiO_2 treatments may explain some of the remaining variation, but the results of ANOVA analyses did not support this speculation.

Statistical analyses suggest that plasma, lung and adipose tissues respond to the dietary vitamin E regimens, though not to the same magnitude. Differences in affinity, uptake, depletion and degradation of the vitamin among tissues as well as the concentrations of other antioxidant-like compounds and prooxidants may affect the static tissue levels of vitamin E. For example, by expressing hepatic vitamin E levels in terms of those for TPUFA, we observed differences in tissue ratios among dietary treatments. These differences were not observed when tissue vitamin E levels were contrasted across dietary groups.

Dietary vitamin E also appeared to correlate with lung GPX activities (Table 3). This observation is inconsistent with that reported by Chow and coworkers (29); they found no difference in lung GPX activities of adult rats fed 0 or 45 mg vitamin E per kg diet for eight wk. Our results also suggest that GPX is not induced by short-term hyperoxia as observed in newborn rabbits (6). Others (15) have found that short-term hyperoxia was not accompanied by GPX induction in lungs of adult rats. However, it is important to note that we measured selenium-dependent GPX activity in adult murine lung. Jenkinson and coworkers (30) have found that in young rats, lung glutathione S-transferase activities (a reflection of nonselenium-dependent GPX) were increased by hyperoxic conditions similar to ours.

TPUFA measures are considered important for two reasons. First, several investigators consider the expression of vitamin E to TPUFA a meaningful index of tissue antioxidant status (12,14). Only when expressed in this way did lung tissue reflect some influence of both diet and FiO_2 manipulations. Second, losses in TPUFA are often interpreted as indicators of lipid peroxidation in vitro (31). In these studies, dietary treatment influenced plasma TPUFA levels, and not those of lung or any other tissue. Donovan and Menzel (32) also found that dietary vitamin E treatments (0, 10.5 and 105 ppm vitamin E) had no marked effect on murine lung fatty acids. On the other hand, FiO_2 treatment had little impact on plasma, lung or liver TPUFA levels; only adipose TPUFA levels were diminished by hyperoxic exposures. Caution should be advised in interpreting the data for tissue homogenate TPUFA, because these measures usually are performed on intracellular membrane preparations and not on crude tissue homogenates. The dynamic nature of TPUFA levels must be considered; that is, changes in TPUFA may be masked by systemic effects of hyperoxia and dietary vitamin E as well as changes in TPUFA and vitamin E metabolism.

No differences in tissue CD levels were detected among dietary or FiO_2 treatment groups. We selected the CD assay in lieu of the traditional assay for malonaldehyde, because several reports indicated that CD may reflect a greater representation of total peroxidation in vivo (33,34). One problem with this assay is the possibility that compounds other than products of lipid peroxidation may be detected (35). Second, the increased permeability of the lung (lung edema index) and reduced lung cell number (lung DNA) in some mice on hyperoxia may have caused varying degrees of entrapment of CD within the lung vasculature. Third, although the initial stages of lipid peroxidation are accompanied by an accumulation of lipid peroxides and CD, the instability of these products over time may preclude an accurate assessment of the extent of tissue lipid peroxidation (36). Sevanian and coworkers (37) observed that products formed later—malonaldehyde and lipid epoxides—were increased with vitamin E deficiency and NO_2 exposures in newborn rats. Wispe et al. (38) found that expired pentane, and lung thiobarbituric reactants and lipid peroxides were not significantly altered by hyperoxia in newborn rabbits, though IV administration of α-tocopherol reduced the amounts of expired pentane and lung thiobarbituric reactants. On the other hand, lung lipid peroxides were not changed by vitamin E administration. The selection of an appropriate measure for tissue lipid peroxidation remains equivocal. Perhaps, measurement of CD and lipid epoxides along with TPUFA and vitamin E levels in the microsomal fractions may be more meaningful in future experiments, because assays reflecting both early and later stages of lipid peroxidation would be used.

The role of vitamin E as an antioxidant has been examined in a number of experimental animal models in which the degree of lipid peroxidation was inversely related to the tissue level of vitamin E. When expressed in terms of vitamin E to TPUFA ratios, a relatively consistent relationship for specific organs among different species has been noted by several investigators (12–14). Our data are consistent with previous reports in that plasma and lung have the highest amounts of the vitamin relative to TPUFA content (12,14). That these tissues were less susceptible to lipid peroxidation as assessed as CD was not observed in the present study.

In summary, long-term dietary manipulation effected marked changes in lung, adipose and plasma vitamin E levels along with lung GPX activities. Short-term hyperoxia produced changes in plasma TPUFA, adipose TPUFA, lung DNA and, in concert with dietary vitamin E treatments, a modification of vitamin E to TPUFA ratios in lung tissue homogenates of adult female mice. Finally, under the conditions described, plasma vitamin

E levels may be used to predict those in the lung with reasonable confidence.

ACKNOWLEDGMENTS

The authors thank Dennis Taff for his assistance in animal surgical procedures and T. B. Stibolt for his discussions regarding experimental design. This study was supported in part by a grant from Hoffmann La Roche and one from the University Research Committee for Biomedical Science and Research Grants. Special thanks to H. Bhagavan for his advice and provision of standards for HPLC assays.

Trans Fatty Acids. 1. Growth, Fertility, Organ Weights and Nerve Histology and Conduction Velocity in Sows and Offspring

Johannes Opstvedt[a,*], **Jan Pettersen**[a] and **Sverre J. Mork**[b]

[a]Norwegian Herring Oil and Meal Research Institute, N-5033 Fyllingsdalen, Bergen, Norway, and [b]Gades Institute, Department of Pathology, N-5016 Haukeland Hospital, Bergen, Norway

Effects of dietary *trans* fatty acids on the pre- and postnatal growth and development in pigs were studied with special emphasis on nervous tissue. In experiment 1, female pigs were fed partially hydrogenated fish oil (PHFO) (28% *trans*) or soybean oil (PHSBO) (36% *trans*), in comparison with lard (0% *trans*) from weaning (3 wk) through the first reproduction cycle (up to 2 yr). In experiment 2, female pigs were fed two fish oils (33 and 19% *trans*) in comparison with coconut oil (0% *trans*) in diets with low and high levels of linoleic acid (18:2n-6 *cis,cis*) from gestation until their offspring were three wk old. Compared with the *trans*-free fats, the *trans*-containing fats had no effect on growth and development, feed consumption and utilization or on the weight of the brain, heart, kidneys, liver, lungs or spleen in the adult sows and their offspring. No effects from the experimental fats were found on histology and conduction velocity of the peroneal nerve. An increased number of the sows fed PHFO had fertility problems compared with those fed lard and PHSBO in Expt. 1, but no similar effects were seen in Expt. 2. It is concluded that consumption of *trans* fatty acids with 18–22 carbon atoms from PHFO and with 18 carbon atoms from PHSBO at levels that were 5 to 12 times higher than those normally consumed by humans had no detrimental effects on female pigs or their offspring during pregnancy and lactation.
***Lipids* 23, 713–719 (1988).**

The literature on metabolic effects of *trans* fatty acids and their possible nutritional implications is abundant and includes several extensive reviews over recent years (1–8). General biochemical findings include incorporation of *trans* fatty acids into various tissues and fluids of several animal species (9–15), and changes in contents of n-6 polyunsaturated fatty acids (10,14–16) that in some studies (17,18) have been linked to uncoupled phosphorylation. Under extreme experimental conditions, using essential fatty acid (EFA) deficient diets, high intakes of *trans* fatty acids have been found to affect organ weights and cause histological changes (19–21), but no discernible effects on cell or organ function have been found under experimental conditions resembling those of practical human diets (22–27).

Although the nutritional effects of *trans* fatty acids appear to be well-documented in most fields, there are areas in which the knowledge is limited. Thus, the majority of the studies have been conducted with rats, and consequently, there is a need for studies on species that developmentally and metabolically more resemble humans with regard to lipid metabolism, e.g., the domestic pig. Further, long-chain polyunsaturated n-6 and n-3 fatty acids, present in large amounts in nervous tissue (28,29), appear to have a role in nerve functionality, including synaptosomal activity and transmitter uptake (30). EFA deficiency during the period of brain development has caused changes in brain size, and brain lipid class and fatty acid composition (31,32). Experimental data in this field in relation to *trans* fatty acids are, however, meager. Hence, there is a need to explore further the effect of *trans* fatty acids on the composition and functionality of nervous tissue.

Previous studies on *trans* fatty acids have mainly employed partially hydrogenated vegetable oils (PHVO) and, in particular, partially hydrogenated soybean oil (PHSBO), with few experiments on partially hydrogenated fish oil (PHFO). *Trans* fatty acids in PHVO have chain lengths mainly of 18 carbon atoms or less, while PHFO also contain appreciable amounts of *trans* fatty acids with 20 and 22 carbon atoms (33). Thus, there is a need to further elucidate the effects of *trans* fatty acids with 20 and 22 carbon atoms.

It is commonly accepted that *trans* fatty acids in most instances behave differently metabolically from saturated fatty acids (1–8). However, because data on long chain (e.g., 20 and 22 carbon atoms) fatty acids in this regard is rather meager, it is desirable to include saturated fatty acids when long chain *trans* fatty acids are studied.

The main objective of the present series of experiments was to study the nutritional effects of *trans* fatty acids with 20 and 22 carbon atoms in PHFO in comparison with *trans* fatty acids with 18 carbon atoms in PHSBO, and with saturated fatty acids with 20 and 22 carbon atoms in "fully" hydrogenated fish oil (FHFO). Emphasis was placed on nervous tissue. Accordingly, the feeding period comprised the periods of pregnancy and lactation during which most of the nervous tissues are formed. Pigs were chosen as the experimental animal due to their physiological resemblance to man, in particular with regard to brain growth (34–36) and accretion of long-chain polyenoic fatty acids in nervous tissue (28,29).

The study used diets that resemble those of human diets in industrialized countries with regard to fat content and content of EFA, and with varying levels of *trans* fatty acids. The observations comprised overall growth and organ development from three wk until about two yr of age, reproduction, and fetal and early postnatal development of offspring. Development and functionality of nervous tissues were monitored by brain growth and by histology and conduction velocity of the peroneal nerve. The fatty acid composition of brain lipids will be compared with the composition of other organ lipids in later publications.

MATERIAL AND METHODS

The study comprised two experiments. Both experiments used female Norwegian Landrace Pigs obtained from local

*To whom correspondence should be addressed.

Abbreviations: CF, short chain fatty acids; EFA, essential fatty acids; FHFO, "fully" hydrogenated fish oil/capelin oil; HFO, hydrogenated fish oil; PHFO, partially hydrogenated fish oil; PHSBO, partially hydrogenated soybean oil; PHVO, partially hydrogenated vegetable oil; PUFA, polyunsaturated fatty acids; GLC, gas liquid chromatograph.

breeders. They were offered feed according to practical standards (37) and had free access to water. The pigs were held in environmentally regulated rooms consisting of a grower unit with pens holding five individually fed pigs and a farrowing unit with six individual farrowing crates to which the pigs were moved at day 95 of gestation. The sows were inseminated with stock semen from the same breed. In Expt. 1, 24 three-wk-old piglets were allocated, littermate randomly, to three groups and fed the experimental diets (Table 1). Insemination of the sows was scheduled to achieve equality between groups with regard to age at farrowing and taking into account the capacity of the farrowing unit. Thus, two sows from each group, six sows total, were to be inseminated about every seventh week. Sows that failed to conceive were reinseminated at the next visible oestrus.

In Expt. 2, groups of six six-month-old pigs were allocated randomly to six experimental groups (Table 1) and fed a commercial pig feed until their second oestrus from which time they received the experimental diets. The sows were inseminated at their second visible oestrus.

Sows that did not become pregnant after the first insemination were replaced by a new animal. A total of 37 sows were inseminated to obtain four sows that farrowed on each of the six diets.

Immediately after birth, and without having suckled their mothers, half the males and females in each litter were tested for nerve conduction velocity, and thereafter electrocuted and sampled. The other half were tested for nerve conduction velocity, electrocuted and sampled after three wk of suckling only sow's milk. In Expt. 1, sows were tested for nerve conduction velocity, electrocuted and sampled three wk after parturition. Organs were freed from attached tissues before being weighed.

Diets and experimental fats. The composition of the different diets and the experimental design are shown in Table 1. Thus, Expt. 2 was conducted according to a factorial design with EFA levels as one factor and the experimental fats as the other factor. All diets were isocaloric and isonitrogeneous and contained nutrients to meet the requirements of growing and pregnant pigs (37).

The experimental fats (lard, partially hydrogenated capelin oil = PHFO, melting point 30–32 C, partially hydrogenated soybean oil = PHSBO, melting point 40 C;

[c]Calculated as g protein × 16.75 KJ + g fat × 37.68 KJ + g carbohydrates × 16.75 KJ.

[d]P/F, wt % polyunsaturated fatty acids/wt % saturated fatty acids.

CF, coconut fat; EFA, essential fatty acids, e.g., linoleic acid; FHFO, "fully" hydrogenated fish oil; PHFO, partially hydrogenated fish oil; PHSBO, partially hydrogenated soybean oil.

coconut fat = CF, and "fully" hydrogenated capelin oil = FHFO, melting point 50–52 C) were ordinary human food products of commercial origin. It was intended that the "fully" hydrogenated fish oil should contain only saturated fatty acids. This was only partly achieved. The slight differences in contents of linoleic acids between experimental diets containing similar levels of added sunflower seed oil were due to the content in the experimental fats of linoleic acid or of other fatty acid isomers that overlapped linoleic acid in the gas liquid chromatograph (GLC).

Velocity of nerve conduction. The peroneal nerve, from the hip to the dorsal area, was employed to measure velocity of nerve conduction using an adaption of the method described by Lahoda et al. (38) and an electromyograph model DISA Type 14 A 20 2 Channel with pulses of 50 V strength. The distance between the two electrodes was measured externally and, together with the registered time, used to calculate velocity (m per sec).

Histology of the peroneal nerve. About 5 cm length of the peroneal nerve was dissected out between the hip and the dorsal area and placed in buffered (9.25 g $Na_2PHO_4 \cdot 2H_2O$ + 0.818 $K_2HPO_4 \cdot 2H_2O$ per l) 4% formaldehyde solution. Fixed nerves were cut in longitudinal and transverse sections. After routine embedding in paraffin blocks and sectioning at 5 μ, staining with hematoxylin and eosin and Luxol Fast Blue-cresyl violet (modified Klüver-Banera), microscopic evaluation of nerve, nerve sheet (myelin) and connective tissue was performed. The examinations were carried out without any knowledge of the dietary treatment of the animals.

Chemical methods. Total lipids in the diets were determined as described by Folch et al. (39). An aliquot of the lipids was hydrolyzed in 0.5 N NaOH and methyl esters prepared using BF_3 as a catalyst (40). The fatty acid composition of the lipids was determined by glass capillary GLC (Carlo Erba 2900, on column injector and a Hewlett Packard (3390A) integrator) using a 50-m glass capillary column (CP Sil 88, Chrompack).

Statistical calculations The bulk of the statistical analyses were carried out using simple linear regression programs, plots, and correlation analysis (Minitab statistical package for the micro computer, fundamental version, rd. 82.1). The more complex models (mixed linear models) were analyzed using the PC-ISP statistical package (41). Covariance analyses were applied to separate effects of differences in body wt and ages (sows in Expt. I) from dietary effects on organ weights and nerve conduction velocity.

RESULTS

Expt. 1. Body weights and indices of reproduction in the sows are shown in Table 2. Eight sows were started on

each diet. Of these, seven sows on Diet 1 (lard), four on Diet 2 (PHFO) and four on Diet 3 (PHSBO) gave birth to sufficient numbers of offspring and completed the experiment. Those eliminated from the experiment were one pig in each of diets 2 and 3 who died of heart failure, one pig on diet 3 that had to be slaughtered due to a mechanical injury, two pigs on Diet 3 who were hermaphrodites, one pig on Diet 2 that did not become pregnant, one pig on Diet 2 that aborted three normal fetuses in the ninth wk of gestation, one pig on Diet 1 that gave birth to only one piglet and one pig on Diet 2 that gave birth to two piglets, one of which was stillborn.

The first sow to become pregnant was bred at an age of 280 days. Growth and development were normal in all pigs and with no significant (not significant means $P > 0.05$) differences between diets for the period 21 to 280 days. Neither were there significant differences between diets in total feed consumption or in the amount of feed consumed per kg gain in body weight. Age at the first visible oestrus and number of oestrus periods (e.g., number of inseminations) required before pregnancy was achieved were not significantly different between diets although, on an average, about one more insemination was needed to achieve pregnancy on Diet 2 compared with Diets 1 and 3. This fact, coupled with practical problems in connection with limited capacity in the farrowing unit, resulted in the sows on Diet 2 being about 100 days older at parturition than those fed Diets 1 and 3. There were no significant differences between diets with regards to length of pregnancy, total number of piglets born or number of stillborn piglets as judged by the Chi-square test. None of the stillborn piglets showed abnormalities on macroscopical examination. There were no significant differences between diets with regard to body weight at birth or growth rate between birth and three wk of age of the piglets (Table 2).

Despite the conduction velocity of the peroneal nerve (Table 2) increasing significantly ($P < 0.05$) from newborn to three-wk-old piglets and sows, neither body weight nor age (in sows) contributed significantly to the variation in the conduction velocity within each age group. There were no significant effects of diets on conduction velocity in the sows or their offspring at birth and at three wk of age. No abnormalities were found on histological examinations of the peroneal nerve and no differences between diets were observed in this respect.

Weights of different organs in sows and offspring are shown in Table 3. There were no significant effects of diets on relative (g per 100 g body weight) weights of brain, heart, kidneys, lungs and spleen in sows and offspring, but sows fed on Diet 2 (PHFO) and 3 (PHSBO) had, on an average, somewhat higher relative liver weights than those fed on Diet 1 (lard).

Expt. 2. Indices of reproduction in sows and body weights and nerve conduction velocity of their offspring at birth and at three wk of age are shown in Table 4. Although the number of sows that were excluded because they did not become pregnant after the first insemination varied between the different diets, the data show no systematic trends with regard to level of linoleic acid or source of experimental fat. There were no significant differences between the different diets with regard to length of pregnancy, number of piglets born or number of stillborn piglets as judged by the Chi-square test and none of the stillborn piglets showed abnormalities on macroscopical examination.

[a]From three wk of age and through their first reproduction cycles.
SEM, standard error of treatment means = (error mean square/number of replicates per treatment)$^{1/2}$.

The piglets of sows fed PHFO and FHFO had, on an average, 15% and significantly ($P < 0.005$) lower birth weights compared with those fed CF. This occurred despite the fact that the number of piglets born in these groups was lower than in those fed on CF. There were no significant differences in the birth weight of piglets from sows fed PHFO diets and those on FHFO or between the two levels of dietary linoleic acid. Neither were there significant interactions between levels of linoleic acid and fat source in this respect. Average body weights at three wk are not directly comparable with average birth weights because the latter figures include piglets that were killed after birth. Piglets from sows fed PHFO grew 11% and significantly ($P < 0.05$) faster from birth to three wk than piglets from sows fed CF and FHFO with no significant differences between the latter two groups or between different dietary levels of linoleic acid.

Conduction velocity of the peroneal nerve (Table 4) was significantly ($P < 0.025$) higher in three-wk-old piglets compared with newborn. Within each age group, conduction velocity was significantly ($P < 0.025$) correlated with body weight in newborn ($r = 0.462$), but not in three-wk-old piglets ($P > 0.05$). There were no significant effects of diets on the conduction velocity of the peroneal nerve in newborn piglets. In three-wk-old piglets, offspring from sows fed FHFO had significantly ($P < 0.025$) lower conduction velocity compared with offspring from sows fed CF, while the differences between CF and PHFO, between PHFO and FHFO and between the two levels of dietary

linoleic acid were insignificant. There was significant ($P < 0.025$) interaction between dietary levels of linoleic acid and CF and PHFO, conduction velocity being higher on high levels compared with low levels of linoleic acid with CF, while the opposite constellation was found with PHFO.

Relative (g per 100 g body weight) brain weight at birth was significantly ($P < 0.05$) higher in offspring from sows on diet 1.2 (PHFO at low level of linoleic acid), compared with those from the other diets.

Brain weights at three wk of age were significantly ($P < 0.005$) higher in offspring from sows fed PHFO and FHFO, compared with those from sows fed CF with no significant differences between the two former groups. Dietary levels of linoleic acid did not affect the brain weights of the offspring (Table 5). Newborn piglets from sows fed low levels of linoleic acid had significantly ($P < 0.01$) higher relative lung weights than newborn piglets from sows fed high levels. Furthermore, piglets from sows fed FHFO had significantly ($P < 0.05$) lower relative lung

weights than piglets from sows fed CF and PHFO that were not significantly different in this respect. There was no significant difference between diets in the relative weights of heart, kidneys, liver and spleen in newborn piglets, but there were significant ($P < 0.05$) interactions between fat source and the level of linoleic acid for relative heart weight. There were no significant effects of diets on the relative weights of brain, heart, kidneys, liver, lungs and spleen in three-wk-old piglets, but there was a significant ($P < 0.05$) interaction between fat source and level of linoleic acid for relative spleen weight.

DISCUSSION

This study used diets with high fat contents, i.e., 35 to 41% of the dietary energy. The contents of linoleic acid varied from about 4 to 1 wt% (about 9-2 cal%) and the P/S (polyunsaturated fatty acids/saturated fatty acids) from about 0.1 to 0.8. The contents of *trans* fatty acids in the experimental diets varied from about 15-30% of total fatty acids (about 6-10% of dietary energy), which provided from about 0.5-1.2 g of *trans* fatty acids per kg of body wt per day. Thus, the experimental diets resembled human diets in industrialized western societies with regard to content of fat and linoleic acid (42), but contained 5 to 12 times more *trans* fatty acids than the estimated average consumption (1).

Dietary *trans* fatty acids could influence nervous tissue directly by being incorporated into neuronal membranes or indirectly by reducing the level of long-chain polyunsaturated fatty acids (PUFA) due to their possible inhibitory effects on the Δ6 and Δ5 desaturases (10,14-16). The outcome of such events could be changes in the conformity and functionality of neuron membranes and synapses due to the altered fatty acid composition. Furthermore, lack of long-chain PUFA could lead to reduced growth and development of neuronal tissue (31,32). We used brain weight and peroneal nerve histology to monitor growth and development and conduction velocity to measure functionality of neuronal tissue. In this series of experiments, significant effects of diets were only seen in three-wk-old piglets in Expt. 2 for brain weight and nerve conduction velocity, and the effects were inconsistent. Despite the fact that the consumption of *trans* fatty acids was high, and for some of the diets combined with a marginal supply of linoleic acid, it did not create adverse effects on nerve tissues as judged by the criteria applied, including nerve histology. It thus appears that very high consumption of *trans* fatty acids, even in combination with a limited supply of linoleic acid over a long period of time and including pregnancy and lactation, do not have negative effects on nerve tissue. To our knowledge, the effects of *trans* fatty acids on brain weight, or histology and conduction velocity of nervous tissue have not been studied.

The limited number of animals to some extent limit the interpretation of the data on the effects of *trans* fatty acids on growth, fertility and teratogenecity or the general toxicological data. However, it is of some concern that fewer of the sows fed the partially hydrogenated fats in Expt. 1 completed the experiment compared with those fed lard. However, heart failure is a common disease in Norwegian landrace pigs, and the fact that one pig in each of the groups fed partially hydrogenated fat died from this disease, while none was affected among those fed lard, may have occurred by chance.

The fact that three out of seven sows on PHFO had major infertility problems (not becoming pregnant, suffering abortion and severely reduced number of piglets) compared with one out of eight on lard (severely reduced number of piglets) and none on PHSBO, appears to be a matter of concern. Further, PHFO-fed sows were, in general, more difficult to get pregnant than the sows fed lard and PHSBO in Expt. 1. However, although a possible relationship to the diet cannot be totally excluded, this explanation is unlikely because the remaining four sows on PHFO that completed the study were equal to or better than the lard-fed sows with regard to their reproduction indices after becoming pregnant. It thus appears that the higher number of PHFO-fed sows with infertility problems compared with those fed lard or PHSBO occurred by chance. This conclusion is partly supported by the results from Expt. 2 where the feeding of PHFO from conception to parturition did not show negative affects on fertility. However, in all groups, pregnancy was more difficult to achieve than is commonly experienced under practical conditions. It is likely that the high fat content of the diets contributed to these results.

The general impression is that dietary *trans* fatty acids with chain lengths of 20 and 22 carbon atoms (PHFO) or 18 carbon atoms (PHSBO) had no consistent effects on growth, reproduction or teratogenecity, when compared with the *trans*-free diets with low content of saturated fatty acids (lard) or high content of short chain fatty acids (CF). Neither were there any differences between PHFO with high content of *trans* fatty acids compared with FHFO containing more saturated long chain fatty acids. These results are in agreement with previous studies with PHVO fed to rats (22,23,27), mice (24) or swine (12), and PHFO fed to swine with adequate levels of EFA (26), and to rats in EFA-deficient diets (20). However, using EFA-deficient diets and EFA-depleted (19) or normal (21) rats, PHVO has been found to decrease growth rate.

The increased lung weights in newborn piglets from sows fed high levels of linoleic acid compared with those fed low levels, and the reduced lung weights in newborn piglets from sows fed FHFO compared with CF and PHFO in Expt. 2 in this study, deserve some comments because Yu and Kinsella (21) observed reduced lung weights in rats fed linolelaidate and partially hydrogenated coconut oil in EFA-deficient diets. However, it is unlikely that the reduced lung weights in our newborn piglets were due to the consumption of *trans* fatty acids, because the content of *trans* fatty acids was lower in FHFO than in PHFO. Furthermore, sows fed PHFO and PHSBO in Expt. 1 had higher liver weights than those fed lard (not significant). Similar observations were made by Vles and Gottenbos (24) using HSBO with 56-65% *trans* fatty acids. However, no histological changes in the livers were found in that study.

Based on the overall results, it may be concluded that consumption of *trans* fatty acids with 18, 20 and 22 carbon atoms from PHFO or with 18 carbon atoms from PHSBO at levels which were 5 to 12 times higher than those normally consumed by humans, had no detrimental effects on female pigs or their offspring, when the diets contained high levels of fat and liberal or limited amounts of linoleic acid.

ACKNOWLEDGMENTS

The authors thank Helge Bruland of the division of Neurological Unit, Haukeland Hospital, Bergen, for valuable advise regarding the use of EMG, and J. H. Knutsen, Department of Political Sciences, University of Bergen, for conducting the statistical calculations. Trans Fatty Acids. 2. Fatty Acid Composition of the Brain and Other Organs in the Mature Female Pig

Jan Pettersen and **Johannes Opstvedt***
Norwegian Herring Oil and Meal Research Institute, N-5033 Fyllingsdalen, Bergen, Norway

Female pigs were fed from three wk of age and up to two years a diet containing partially hydrogenated fish oil (PHFO, 28% *trans* monoenoic fatty acids), partially hydrogenated soybean oils (PHSBO, 36% *trans* fatty acids) or lard. No consistent differences were found between PHFO and PHSBO with regard to incorporation of *trans* fatty acids in organ lipids, but *trans* incorporations were highly organ-specific. No *trans* fatty acids were detected in brain phosphatidylethanolamine (PE). The incorporation of monoenoic *trans* isomers, as a percentage of total *cis* + *trans*, in other organs was highest in subcutaneous adipose tissue and liver mitochondria PE, followed by blood lipids with the lowest level in heart PE. The percentage of *trans* isomers compared with that of dietary lipids was consistently lower for 20:1, compared with 18:1 in organs from PHFO-fed pigs. The only effect of dietary *trans* fatty acids on the fatty acid pattern of brain PE was an increased level of 22:5n-6. Heart PE and total serum lipids of pigs fed the hydrogenated fats contained higher levels of 18:2n-6, and these lipids of the PHFO-fed group also contained slightly elevated amounts of 20:3n-6, 18:3n-3 and 20:5n-3. Liver mitochondria PE of the PHFO group also contained higher levels of 20:3n-6 and 22:5n-6. Dietary *trans* fatty acids caused a consistent decrease of saturated fatty acids compensated by increased levels of monoenes. Thus, it may be concluded that dietary long-chain *trans* fatty acids in PHFO behaved similarly metabolically to 18:1-*trans* in PHSBO in pigs, without noticeable influence on brain PE composition and with moderate to slight effects on the fatty acid profile of the other organs.
***Lipids* 23, 720–726 (1988).**

Nutritional effects of *trans* isomeric fatty acids are mainly of concern to people in industrialized countries due to their relatively high consumption of partially hydrogenated fats. Thus, the intake of *trans* isomeric fatty acids in these societies was calculated to be about 3–6% of the total fat consumption or about 5–9 g/day per person (1).

Several reports have shown that *trans* isomeric fatty acids are incorporated into membrane lipids of heart (2–4), liver (2–5), brain (5–8) and the developing fetus in rats (7–11), and in several tissues in humans (12). Furthermore, it has been shown that some *trans* isomers of unsaturated fatty acids may affect the tissue content of long chain polyunsaturated fatty acids (LC-PUFA, e.g., 20:4n-6 all *cis*) by reducing the activity of Δ-6 desaturase (13–17), an enzyme that is important in their biosynthesis. Because it has been shown that LC-PUFA is essential for nerve function (18,19), it is particularly important to establish whether consumption of *trans* fatty acids causes incorporation of *trans* fatty acids or alters the LC-PUFA profile in nerve tissue.

Previous studies of *trans* fatty acids have mainly employed partially hydrogenated vegetable oils (PHVO), and in particular partially hydrogenated soybean oils (PHSBO), with few experiments on partially hydrogenated fish oils (PHFO). Because PHFO contains *trans* fatty acids with 20 and 22 carbon atoms, in addition to those with 18 that are prevalent in PHVO (20), there is a need for further studies on PHFO. Furthermore, because most studies on *trans* fatty acids have been conducted with rats, there is a need for data with other animal species that developmentally and metabolically more resemble humans with regard to lipid metabolism, e.g., the domestic pig (21–23).

This study was conducted with pigs to examine the effect of long-term feeding of PHFO in comparison with PHSBO and lard on the incorporation of *trans* fatty acids and the fatty acid profile of the brain PE in comparison with that of other organs.

We have reported the lack of effects of PHFO and PHSBO on growth, histology and conduction velocity of nervous tissue, and on overall growth, teratogenecity and organ weights, while fertility apparently was somewhat impaired on PHFO, but not on PHSBO compared with lard (24).

EXPERIMENTAL

General procedures. Three-wk-old female Norwegian Landrase piglets were allotted to groups of four and fed the experimental diets until three wk after their first parturition as described (24). The diets were isocaloric and isonitrogeneous and composed to meet the nutritional requirement of pigs. Sunflower seed oil (65% linoleic acid) was added to all diets. From three wk of age until the body weight of 22 kg was achieved, the pigs were fed diets containing 5 wt percent sunflower seed oil and 16 wt percent experimental fat. Thereafter, the dietary composition was changed (24), and the content of sunflower seed oil and experimental fat were 4, respectively, 14 wt percent, which together with lipids present in the other feed ingredients gave an analyzed lipid content of about 22%. The experimental fats were lard (control, Diet I), PHFO (partially hydrogenated capelin oil, mp 30–32 C, Diet II) and PHSBO (mp 40 C, Diet III). Fatty acid composition of the diets is shown in Table 1. Diet I had somewhat higher levels of linoleic acid, which evidently was due to linoleic acid present in the lard (6.6%). The fat of the other feed ingredients contained 31% linoleic acid. Agreements in the different diets between analyzed and calculated content of linoleic acid were good, except for the PHFO-diet, in which the analyzed content showed somewhat higher levels than the calculated content. This deviation may have been due to an overlap of unidentified isomers from PHFO and linoleic acid in the gas liquid chromatography.

[b]Relative amount of PUFA (P) to sum saturated fatty acids (S).

PUFA, polyunsaturated fatty acids.

The pigs were electrocuted about 15 hr after feeding and samples were immediately taken from brain, liver, heart, venous blood (right ventricle) and subcutaneous adipose tissue from the belly.

Chemical methods. Total lipids from samples of blood plasma, heart and adipose tissue were immediately extracted as described by Folch et al. (25). This procedure was modified for the extraction of brain lipids in which the chloroform/methanol ratio was altered from 2:1 to 1:1 (26). Membrane lipids of the liver mitochondria were immediately isolated as described by Hóy and Hólmer (27). All lipid extracts were stored at −25 C, pending further analysis. Lipids of the heart (phosphatidylethanolamines [PE]), the liver mitochondria (PE) and the brain (PE and galactocerebrosides [CB]) were prepared by high performance liquid chromatography (HPLC) from 50 mg samples of the respective lipids, using a Constra Metric III pump with 500 μl loop for injection, and detection by differential refractive index (LDC Mod. 1107). The column (25 × 0.46 cm) material was a cation exchanger (Whatman's Partisil 10 SCX). When isolating CB and PE of the brain, a discontinuous elution (1 ml/min) procedure was used. CB was eluted into two separate fractions, one containing CB of α-hydroxy fatty acids, and the elution times from injection were 2.5 and 3.0 min. CB was eluted by a mixture of 31.3% *n*-propanol, 31.3% chloroform, 31.3% methyl acetate and 6.1% methanol and PE (including PE-plasmalogen) by an eluent composed of 28.1% *n*-propanol, 28.1% chloroform, 28.1% methyl acetate, 11.3% methanol and 4.4% water. Elution time of PE was 2.3 min. When isolating only PE (e.g., heart PE and liver mitochondria PE), the composition of the eluent was 47.0% *n*-propanol, 21.4% chloroform, 21.4% methyl acetate, 6.8% methanol and 3.4% 10 mM acetic acid, and the elution time was 3.5 min. The identity and purity of the isolated lipid classes were verified by thin layer chromatography (TLC) (28) using standard phospholipids (Serdary Research Laboratories Inc., Lond, Ontario, Canada).

The fatty acid composition of the lipids was determined by glass capillary chromatography (GLC) (Carlo Erba 2900, On Column injector and a Hewlett Packard [3390A] integrator) using a 50 m glass capillary column (CP Sil 88 [Chrompack]). Before GLC analysis, the lipids were hydrolyzed by 0.5 N NaOH and methyl esters prepared from methanol using BF_3 as a catalyst (29). *Trans* isomeric double bonds in methyl esters of unsaturated fatty acids were analyzed by IR-spectroscopy (Pye Unicam SP3-200, and 10 μ microcells of sodium chloride). The *trans* content was determined as elaidic acid (18:1n-9 *trans*) equivalents as the percentage of total carbonyl bonds (30).

Statistical methods. The basic principle of the statistical methods used were estimation of the maximum likelihood. The program package chosen was BMDP, program P3V (31).

RESULTS

Brain. The fatty acid composition of the PE in total brain lipids is shown in Table 2. No *trans* fatty acids were detected in any of the dietary groups. Except for 22:5n-6, there were no significant (not significant means $P > 0.05$)

[a]Fed these diets from three wk of age through their first reproduction cycle (up to 2 years).

[b]Pooled std. dev. = pooled standard deviation, (error mean square)$^{1/2}$.

Means that deviate significantly from the corresponding values of the control diet (diet I) are shown by superscript a ($P < 0.05$), b ($P < 0.025$), c ($P < 0.01$) and d ($P < 0.005$). Average of four replicate determinations.

differences in fatty acid composition between the different groups. The relative portion of 22:5n-6 in the respective groups fed PHFO and PHSBO were about 55% ($P < 0.05$) and 45% ($P < 0.05$) higher than that in the lard-fed group.

Heart. Fatty acid composition of the PE in total heart lipids is shown in Table 2. PE from the heart of sows fed PHFO and PHSBO contained appreciable levels of 18:1-*trans*, but only traces of 20:1-*trans*. However, noticeable levels of 18:1-*trans* were detected in heart PE from sows fed lard.

Feeding PHFO caused a significant ($P < 0.01$) increase in the percentage of linoleic acid, and a somewhat less but significant ($P < 0.05$) increase of 20:3n-6, compared with lard feeding. Feeding PHSBO, the same effects as shown for the PHFO-fed group were found, although the variations were insignificant compared with the lard-fed group. Further, feeding of any one of the hydrogenated fats, in particular PHFO, caused a significant increase in the percentages of 18:3n-3 ($P < 0.05$) and 20:5n-3 ($P < 0.01$), with compensatory but smaller, insignificant reductions in the percentages of 22:5n-3 and 22:6n-3. The different dietary fats led to variations in the sum of the different fatty acid classes. Thus, compared with lard, feeding PHFO increased the percentage of PUFA n-6, had no effect on the percentage of PUFA n-3 or monoenoic fatty acids and decreased the percentage of saturated fatty acids. PHSBO-feeding, on the other hand, led to reduced percentages of PUFA n-3 and saturated fatty acids with a compensatory increase in the percentage of PUFA n-6 and monoenoic fatty acids compared with lard feeding.

Liver. The fatty acid composition of the PE in the liver mitochondria is shown in Table 2. As was found in heart PE, *trans* isomers of 18:1 and *cis* and *trans* isomers of 20:1 were present also in liver mitochondria PE and were significantly influenced by the dietary treatment ($P < 0.005$). Feeding PHFO, and in particular PHSBO, the percentages of stearic acid were significantly ($P < 0.005$) reduced compared with lard. Feeding with PHFO, but not with PHSBO, increased the percentages of 20:3n-6 ($P < 0.005$) and 22:5n-6 ($P < 0.05$). The overall effect of feeding PHFO and PHSBO, compared with lard feeding, was an increase in the relative portion of monoenoic fatty acids

[a]Fed these diets from three wk of age through their first reproduction cycle (up to 2 years).

Pooled std. dev. = pooled standard deviation, (error mean square)$^{1/2}$.

Means that deviate significantly from the corresponding values of the control diet (diet I) are shown by superscript a ($P < 0.05$), b ($P < 0.025$), c ($P < 0.01$) and d ($P < 0.005$). Average of four replicates.

and a decrease in saturated fatty acids with negligible effects on the percentages of n-6 and n-3 PUFA.

Blood. The fatty acid composition of venous blood lipids (total) is shown in Table 3. The dietary fats had a profound effect on the fatty acid composition of the blood lipids.

Total plasma lipids from sows fed hydrogenated fats, in particular PHSBO, contained considerable amounts of 18:1-*trans* isomers. Long-chain *trans* isomers (i.e., 20:1-*trans*) were not detected in blood lipids, and the percentages of the *cis* isomeric homologs were low. Due to the low percentages of 22:1 isomers, we were not able to analyze separately for *cis* and *trans* isomers. The dietary level of *trans* 22:1 was about 50% of the total content of 22:1. Considering the dietary composition and the exclusion of 20:1-*trans* from the blood lipids, it seems reasonable to assume that, at most, 50% of 22:1 in blood lipids were *trans* isomers. No long-chain saturated fatty acids (e.g., 20:0, 22:0 and 24:0) were detected. Compared with those of sows fed lard, blood lipids of sows fed PHFO and PHBO contained more linoleic acid and less arachidonic acid, only the first different being significant ($P < 0.025$). Other n-6 fatty acids were not noteworthily different between the groups, except for 20:3n-6, which was increased on PHFO ($P < 0.025$) and PHSBO ($P > 0.05$). Feeding with PHFO caused a significant increase in the percentages of 18:3n-3 ($P < 0.05$) and 20:5n-3 ($P < 0.025$). Sows fed the hydrogenated fats had significantly ($P < 0.005$) lower relative portions of 16:0 and 18:0, compared with the lard-fed group. Sows fed PHFO had significantly higher percentage of 16:1 ($P < 0.01$) and lower percentage of 18:1 *cis* ($P < 0.01$), compared with sows fed PHSBO and lard. In general, feeding with partially hydrogenated fats increased the relative portion of PUFA n-6 and also, to some extent, that of monoenoic fatty acids, and reduced the percentage of saturated fatty acids in the blood lipids, compared with lard feeding.

Adipose tissues. The fatty acid composition of subcutaneous adipose tissue from the belly fat is shown in Table 3. Significant percentages of 18:1-*trans* isomers were found in sows fed PHSBO ($P < 0.005$) and of 18:1-*trans* ($P < 0.05$) and 20:1-*trans* ($P < 0.005$) in sows

fed PHFO. The percentage of 22:1-*trans* isomers could not be determined and was calculated as described for the blood lipids.

Also, appreciable percentages of long-chain monoenoic (20:1 and 22:1) *cis* fatty acids, but not their saturated homologs, were found in sows fed PHFO. The relative portions of linoleic and arachidonic acids were not significantly different between groups. However, PHFO led to significant reduction in the percentage of 22:4n-6 ($P < 0.005$), 22:5n-3 ($P < 0.005$) and 22:6n-3 ($P < 0.025$), and PHSBO, a reduction in the percentage of 22:4n-6 ($P < 0.005$), compared with lard. In general, feeding of partially hydrogenated fats increased the percentages of monoenoic fatty acids and reduced the percentages of saturated fatty acids, but had minor effects on the percentage of PUFA, compared with lard feeding.

DISCUSSION

This study used diets with contents of fat and linoleic acid resembling those of human diets in industrialized countries but containing five times more *trans* fatty acids (i.e., 25% vs 5% of total fatty acids) (1). Further, pigs were used as experimental animals due to their resemblance to humans (20–22), and the study comprised a noticeable part of their life-span period, i.e., about two years. This paper presents data with the aim of exploring if isomeric fatty acids are incorporated into nervous tissue or if the presence of *trans* fatty acids in the diet affects the metabolism of fatty acid in such a way that the overall fatty acid profile and, in particular, the relative portion of PUFA is changed. The emphasis was on nerve tissue (i.e., brain), but it was felt necessary to compare reactions in the brain with those of structural (i.e., heart and liver mitochondria) and non-structural (i.e., blood and adipose tissue) lipids in other organs. Analyzing other organs than the brain also facilitated comparison of results from this study with those of other studies not involving nervous tissue (2–5). Phosphatidylcholine (PC) and PE are, in general, the main structural lipids of the cell membranes. Brain phospholipids of different species contain about 30–38% PC and 30–42% PE (32).

Regretfully, our capacity did not permit us to analyze both PC and PE. Due to the fatty acid composition, i.e., the high content of long-chain polyunsaturated fatty acids (LC PUFA) in PE, compared with that of PC (33), and the assumed structural importance of these LC PUFA, the fatty acid composition of PE was chosen as an indicator for the metabolic effect of *trans* fatty acids. Also, PE was chosen to facilitate the comparison of our results with those of other investigations (5,33,34).

The identification of fatty acid isomers in partially hydrogenated fats is a tedious and difficult task. In particular, this is the case for PHFO containing positional and geometrical isomers of the LC PUFA abundant in marine lipids (e.g., 18:4n-3, 20:5n-3 and 22:6n-3) (20). Our inability to identify the numerous fatty acid isomers led us to search for an alternative method to determine *trans* fatty acids, i.e., IR-spectrophotometry. However, *trans* isomerism analyzed by IR-spectrophotometry showed higher values of total *trans* content (1.5–4 times) than the sum of identified *trans* fatty acids determined by GLC. This was found for all lipid extracts analyzed, except for the brain CB, in which only IR-measurements were performed, and was particularly pronounced for organ and dietary lipids related to PHFO. The differences may partly be due to the fact that some *trans* isomers were not identified by the GLC-analysis. Our results are in line with those of Perkins et al. (35), who compared the content of *trans* fatty acids determined by GLC (packed columns) analysis with total content of *trans* isomerism analyzed by IR-spectrophotometry in margarine. However, the deviation between GLC and IR-analysis in our experiment was greater than would be expected from their results. The molar IR-absorption of fatty acid *trans* isomers might depend on the chain lengths, the position of the *trans* double bond in the chain, the degree of unsaturation (i.e., monoenoic vs polyenoic fatty acids) and the plurality of *trans* double bonds in the chain (36).

In our analysis, the total *trans* content was calculated as percent methyl elaidate (18:1n-9 *trans*) equivalents, i.e., the IR absorption of the fatty acid methyl esters of the samples compared with that of the methyl elaidate. This may have led to incorrect estimates of the total *trans* contents. Admitting that there may be sources of error in both GLC and IR determinations of *trans* isomerism, we decided to use the GLC analysis as the most accurate one.

Ohlrogge et al. (12), studying the distribution of *trans* fatty acids in human organ lipids, also detected *trans* fatty acids in brain lipids. Brain lipids of rats fed *trans* fatty acids also were reported to contain *trans* fatty acids (5–8). In this study, no *trans* fatty acids were detected in brain PE. Similar results were obtained by analyzing the total lipids extracted from brain (not reported) and from the IR-spectrophotometric analysis of brain CB (results not reported). This was in contrast with other structural lipids such as heart and liver mitochondria PE, in which significant amounts of *trans* 18:1 and 20:1 were found. It should be noted that lipids of liver mitochondria and, in particular, of heart from lard-fed pigs also contained 18:1 *trans*. These results are in line with that reported by Wood (33), who examined various tissues from rats maintained on a chow diet, and by Royce et al. (37), who found that the total heart lipids of weanling pigs fed lard for six months contained about 0.6% 18:1-*trans*. Although our control diet did contain low levels of *trans* 18:1, this cannot explain the presence of *trans* fatty acids found in the PE of heart and liver mitochondria, particular since *trans* fatty acids were not detected in blood lipids and adipose tissue. The source of the *trans* fatty acids in PE of heart and liver mitochondria, therefore, are obscure.

The difference between different organs and the effect of fatty acid chain length of the monoenes (i.e., 18 and 20 carbon atoms) and fat sources (PHFO and PHSBO) with regard to incorporation of *trans* fatty acids may be judged from the discrimination factor (e.g., the relation of the percentage *trans* isomers of the total monoene content in the organ lipids to that of the respective dietary lipids) as shown in Table 4. Thus, there was apparently little discrimination against 18:1-*trans* fatty acid incorporation into the liver mitochondria PE, while the level of *trans* fatty acids in heart PE and blood was somewhat reduced, compared with the diet. There was no consistent difference in the incorporation of 18:1-*trans* from PHFO and PHSBO. The incorporation of 20:1-*trans* was consistently lower than that of 18:1-*trans*. It is of interest that the content of 20:1-*trans* in the organ lipids, relative the content

TABLE 4

Ratio of the Percentage *trans* Isomers of the Total Monoene Content of Organ Lipids to That of the Respective Dietary Fats

	Tissues				
	Brain	Heart	Liver	Blood	Adipose
18:1-*trans* PHFO	0	0.45	0.94	0.63	1.33
PHSBO	0	0.32	1.22	0.51	0.58
20:1-*trans* PHFO	0	0.15	0.41	0	0.87

of the dietary lipids, showed a similar picture as that for 20:1-*cis* and 22:1 *cis* plus *trans*, i.e., a significant discrimination against the dietary long-chain monoenoic acids irrespective of the geometry of the double bond. The analysis of total *trans* isomerism determined by IR-spectrophotometry (results not shown) support the conclusion on the organ specific incorporation of *trans* fatty acids revealed by the GLC analysis, i.e., no *trans* isomerism due to dietary treatment was detected in brain PE and brain CB.

Previous studies have shown somewhat elevated levels of linoleic acid and reduced levels of arachidonic acid in tissue lipids of animals consuming *trans* fatty acids (38). These findings have been explained by that *trans* fatty acids may interfere with the biosynthesis of arachidonic acid (20:4n-6) from linoleic acid (18:2n-6). One explanation postulated is that 18:1-*trans* fatty acids exert a competitive inhibition on the activity of the enzyme Δ-6 desaturase (13,39,40), while *trans* isomers of 20:1 and 22:1 fatty acids have been found to inhibit both Δ-6 and Δ-5 desaturases (16,17). In our study, the feeding of *trans* fatty acids and, in particular, PHFO increased the relative portion of linoleic acid in total plasma lipids and heart PE.

However, despite the fact that the percentages of arachidonic acid and of the other long-chain n-6 fatty acids were slightly reduced in those organ lipids, the reduction did not compensate for the increased percentages of linoleic acid. It is worth noting that the percentages of total PUFA n-6 in blood and heart lipids were higher in the groups fed hydrogenated fats, compared with that of the lard-fed group. Furthermore, liver mitochondria PE, heart PE and the lipids of venous blood of pigs fed PHFO, but not PHSBO, contained significantly higher levels of 20:3n-6, compared to that of the lard-fed groups. These results may support the hypothesis on inhibition of the enzymatic activity of Δ-5 desaturase by *trans* isomers of 20:1 and 22:1 fatty acids in PHFO (16,17).

The only effect of dietary *trans* fatty acids on brain PE in our study was an increased level of 22:5n-6 in PHFO-fed pigs. A similar observation was made by Sanders et al. (34) in the brain PE of rats fed margarine. Because the brain did not contain detectable amounts of *trans* fatty acids in our study, it is possible that the increased percentage of 22:5n-6 was a consequence of the fatty acid metabolism in organs outside the brain (e.g., the liver). Increased percentage of 22:5n-6 was, except for the brain, only found in PE of the liver mitochondria of the PHFO-fed pigs. This coordinated effect of dietary PHFO on the fatty acid pattern of liver mitochondria-PE and brain-PE may be explained by the appearance of long-chain *trans* isomeric fatty acids and the biochemical activity in these organs, i.e., the capability to synthesize LC PUFA (41).

It thus may be hypothesized that dietary *trans* fatty acids in the liver partly inhibited Δ-6 desaturases and Δ-5 desaturases and, consequently, elevated levels of 18:2n-6 and 20:3n-6 were transported to the brain. Due to the elongation/desaturation capacity of the brain (41), those substrates (e.g., 18:2n-6 and 20:3n-6) were metabolically transformed to 22:5n-6.

Feeding PHFO led to increased levels of linolenic acid (18:3n-3) and 20:5n-3 in heart PE and the blood lipids. This may be explained by a relative inhibition of the desaturation/elongation of n-6 fatty acids by the LC *trans* fatty acids that favored the biosynthesis of 20:5n-3.

Because it has been discussed (42) whether *trans* monoenoic fatty acids resemble *cis* monoenoic or saturated fatty acids in their metabolism, a closer examination of the effect of PHFO and PHSBO on the percentage of the different fatty acid classes (i.e., PUFA, *cis*, respectively, *trans* monoenoic and saturated fatty acids) in the respective organs may be relevant. Whenever the feeding of partially hydrogenated fats affected the level of fatty acid classes in an organ, there was a striking similarity in the effect of PHFO and PHSBO. In all organs studied, the total levels monoenoic fatty acids were changed in the same direction and opposite to that seen for saturated fatty acids. This influence increased as the percentage of *trans* fatty acids in the organ lipids increased and was most striking for PHSBO-fed animals. It might be possible to conclude from these observations that the *trans* monoenoic fatty acids simply replaced the saturated fatty acids in the lipid molecules. An equally justified explanation would be that *trans* and *cis* monoenes follow the same metabolic pathway.

Based on the combined results, it may be concluded that PHFO and PHSBO show similar metabolic effects on fatty acid composition in the organs of pigs after long feeding. None of them affect the fatty acid profile of the brain-PE to a significant degree, while small amounts of *trans* fatty acids are incorporated into other organs and slight changes in the fatty acid profile may be observed. These results confirm and extend previously reported lack of adverse effect from *trans* fatty acids on nerve conduction velocity and general biological performance (24).

ACKNOWLEDGMENTS

The authors thank J. H. Knutsen, Department of Political Sciences, University of Bergen, for conducting the statistical calculations. This work was supported by the Royal Norwegian Council for Scientific and Industrial Research, and the Research Fund of Norwegian Dietary Fat Producers.

[Received May 22, 1987; Revision accepted March 21, 1988]

Lipids from the Paracloacal Glands of the American Alligator *(Alligator mississippiensis)*

P.J. Weldon[a,*], A. Shafagati[b] and J.W. Wheeler[b]
[a]Department of Biology, Texas A&M University, College Station, TX 77843, and [b]Department of Chemistry, Howard University, DC 20052

Lipids from the paracloacal glands of adult and of immature American alligators *(Alligator mississippiensis)* were analyzed by gas chromatography-mass spectrometry. Acetate esters (C_{12}–C_{18}) were indicated in the adults' secretions. Immature alligators contain C_{10}–C_{18} acetates, C_{12}–C_{18} dodecanoates, tetradecanoates and other high molecular weight esters, and C_{10}–C_{16} 3-methylbutanoates. Cholesterol, C_{16} and C_{18} free fatty acids, and α-tocopherol (vitamin E) were detected in some samples. The results are compared with those published for South American caiman species.
***Lipids 23,* 727-729 (1988).**

All extant crocodilians possess paired exocrine organs known as paracloacal glands that discharge secretions through duct openings in the lateral walls of the cloaca. A histological study of the American alligator *(Alligator mississippiensis)* indicated that each gland is a single secretory sac with a single duct (1). Parenchymal cells containing lipid droplets migrate toward and accumulate in a cylindrical conglomerate that partially occludes a lumen in the center of the gland. Secretions from degenerating cells of the central conglomerate collect near the secretory duct. A histochemical test indicated lipids in the glandular exudate.

Fester and Bertuzzi (2) analyzed chemicals from the paracloacal glands of two caimans, *Alligator sclerops* (= *Caiman crocodilus*) and *A. latirostris* (= *C. latirostris*), where secretions apparently were pooled from both species. Fatty acids, nitrogenous bases, glycerol, cholesterol and traces of phosphorus-containing compounds were reported among the constituents. A nine-carbon alcohol dubbed "yacarol" also was indicated. The melting point, refractive index and other physical properties of this constituent were taken to indicate *d*-citronellol (3). This compound remained unchanged following years of storage in an inert atmosphere (4).

We report here on the identification of lipids present in the paracloacal glands of adult and of immature *A. mississippiensis.* This is the first detailed description of paracloacal gland chemicals from this species.

METHODS

Secretions were obtained from 80 immature (total lengths = 45–118 cm) and five adult (1.5–3.0 m) alligators from Port Arthur, TX (Murphree Wildlife Refuge) and 15 adults (1.6–3.3 m) from Grand Chenier, LA (Rockefeller Wildlife Center) during September 1985. Secretions from immature (unsexed) and adult alligators were kept separate. Materials were pooled according to sex for eight males and seven females from Louisiana. The adult alligators were sampled within one hr after their death. Samples from living, immature alligators were collected after they had been hand-captured and confined with 15 or more individuals for several hours.

Paracloacal gland secretions were collected by manually everting the glands and squeezing their contents into glass vials containing methylene chloride (CH_2Cl_2). The vials were wrapped individually in paper towels and shipped on dry ice. They were kept frozen (−4 C) before extraction with CH_2Cl_2 and before analysis of CH_2Cl_2-soluble material.

The CH_2Cl_2 extracts were drawn off with pipettes and analyzed by capillary gas chromatography-mass spectrometry (GC-MS) using either a 30 m × 0.32 mm SE-54 column (0.25 μm) or a 30 m × 0.32 mm SPB-5 column (0.25 μm) connected to a Finnigan 4500B mass spectrometer. Spectra and retention times were compared with those of authentic compounds, obtained commercially, or in the case of esters, prepared from the appropriate acid chloride and alcohol. The mass spectra of the 3-methylbutanoates and the isomeric pentanoates differed significantly from one another.

RESULTS AND DISCUSSION

Hexadecyl acetate (Fig. 1) was a major constituent in most samples of alligator paracloacal gland secretions (Table 1). In addition, two other C_{16} acetates were detected; one contained one double bond, the other, two double bonds (positions unknown). Tetradecyl acetate, dodecyl acetate, and relatively small quantities of octadecenyl and octadecadienyl acetates (double bond positions unknown) also were present in many adult samples.

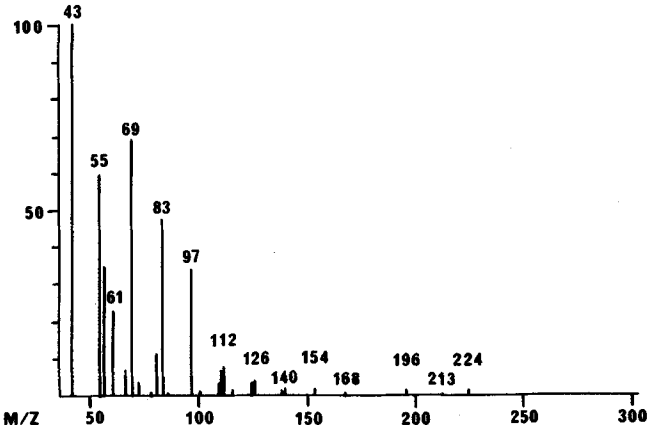

FIG. 1. Mass spectrum of hexadecyl acetate. m/z 43 (CH_3CO^+), 61 ($CH_3CO_2H_2^+$), 224 ($C_{16}H_{32}^+$).

Two of the three extracts of the pooled secretions from adult females contained trace amounts of pentadecyl acetate, which was not indicated in samples containing secretions from only adult males.

Identification of the acetates was facilitated by the appearance of CH_3CO^+ and $CH_3CO_2H_2^+$ peaks in their mass spectra at m/z 43 and 61, respectively. The chain length of the alcohol portion was indicated by a peak at $[R-H]^+$ corresponding to: m/z 140 = C_{10}, 168 = C_{12}, 196 = C_{14}, 224 = C_{16}, 252 = C_{18}.

The samples from immature alligators showed none of the unsaturated C_{16} acetates but contained traces of tetradecyl acetate, dodecyl acetate and decyl acetate; the latter was not indicated in the adults' secretions. Immature individuals also included C_{12} and C_{14} 3-methylbutanoates (Figs. 2 and 3) and traces of the C_{10} 3-methylbutanoate; the C_{12} compound was a major component in three of the four pooled samples.

Hexadecyl acetate was indicated as the major component in one sample of immature alligators (28 individuals). This as well as the other three samples from immature alligators contained small amounts of higher molecular weight esters corresponding to mixtures of dodecyl dodecanoate and decyl tetradecanoate (m.w. 368), dodecyl tetradecanoate and tetradecyl dodecanoate (m.w. 396), dodecyl hexadecanoate and tetradecyl tetradecanoate (m.w. 424), and dodecyl octadecanoate, tetradecyl hexadecanoate and hexadecyl tetradecanoate (m.w. 452). These compounds were not detected in the adults.

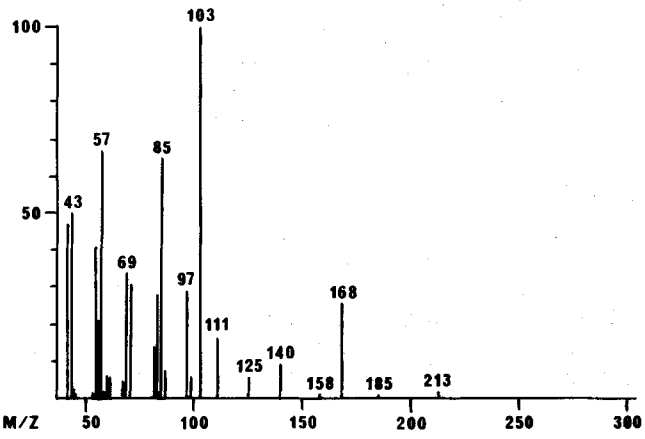

FIG. 2. Mass spectrum of dodecyl 3-methylbutanoate. m/z 85 $[(CH_3)_2CHCH_2CO^+]$, 103 $[(CH_3)_2CHCH_2CO_2H^{2+}]$, 168 $(C_{12}H_{24}^+)$.

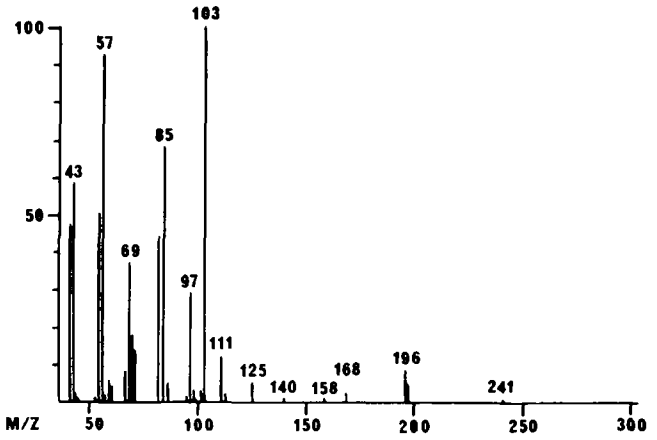

FIG. 3. Mass spectrum of tetradecyl 3-methylbutanoate. m/z 85 [$(CH_3)_2CHCH_2CO^+$], 103 [$(CH_3)_2CHCH_2CO_2H_2^+$], 196 ($C_{14}H_{28}^+$).

Fester and Bertuzzi (2) found that saturated and unsaturated fatty acids were 45% and 35%, respectively, of the water-insoluble saponification products of *Caiman* spp. paracloacal gland secretions. Palmitic (C_{16}), myristic (C_{14}), and isovaleric (C_5) acids were among those detected. Free and esterified constituents, however, were not distinguished. Hexadecanoic acid was detected as a major free fatty acid in a sample of adult male Louisiana *A. mississippiensis* and as a trace component in two pooled samples of immature individuals from Texas. Octadecanoic and octadecenoic acid are trace or minor components in two samples of immature alligators and in one sample of adult males from Louisiana.

Sterols are indicated in a number of analyses of reptile shed skin extracts and integumental gland secretions (5–9). The specific compounds present have not been determined in most of these studies, for which thin layer chromatography or nuclear magnetic resonance of gross secretions are the analytical methods used. Cholesterol occurs in most samples of the paracloacal gland secretions we examined by GC–MS. Steryl esters were indicated by Fester et al. in *Caiman* spp. paracloacal gland secretions (3), but it is as yet unclear whether similar compounds occur in the secretions of other crocodilians.

The fatty alcohols reported in caiman paracloacal gland secretions by Fester and colleagues (2,3) include cetyl alcohol and "yacarol." The latter compound was initially thought to be 2,6-dimethyl-2-hepten-7-ol, but, on the basis of a variety of physical tests, was identified as *d*-citronellol. We did not detect free alcohols in the paracloacal gland secretions of *A. mississippiensis*. The possibility that these compounds occur in alligators or other crocodilians needs to be explored further.

Two dominant peaks in the mass spectrum of one elutant (m/z 430 and 165) indicate α-tocopherol (vitamin E) as a trace component of the secretions of several adult males. The chromatographic retention time and mass spectrum of an authentic sample of α-tocopherol (Aldrich, Milwaukee, WI) confirmed the identity of this vitamin. No other tocols or tocotrienols were detected.

α-Tocopherol, which is produced by higher plants and algae (10), has been detected in the plasma of farm-reared *A. mississippiensis* (11). This compound could be transported to the paracloacal glands via a circulatory or (perhaps from interstitial fluids) a lymphatic route, because elements of both systems have been observed in crocodilian paracloacal glands (1,12–15). The significance of α-tocopherol in alligator paracloacal gland secretions is open to speculation. This substance is known to inhibit lipid oxidation (16,17) and therefore may prevent the degradation of other paracloacal gland compounds.

ACKNOWLEDGMENTS

Louise Hayes, Kirby Brown and Perry Smith permitted access to alligators in Texas, and Ted Joanen and Larry McNease allowed us to obtain samples from Louisiana alligators. This study was conducted while P.J. Weldon was supported by grants from Texas A&M University and the Whitehall Foundation.

Distal Small Bowel Resection Does Not Modify the Intestinal 3-Hydroxy-3-methylglutaryl CoA Reductase Activity

M.T. Molina and C.M. Vazquez*
Departamento de Fisiologia Animal, Facultad de Farmacia, Universidad de Sevilla, 41012 Sevilla, Spain

The activity of 3-hydroxy-3-methylglutaryl coenzyme-A reductase (HMG-CoA red.) has been evaluated in rat jejunal, caecal and colonic mucosa adapting to 50% or 75% distal small bowel resection (SBR). Six wk after surgery, the total activity and the activity state (active form) of the enzyme were determined. The results show that HMG-CoA red. activity was stimulated per organ but not per unit mass in the mucosa adapting to SBR. As a side result, we noted regional differences in the active/total reductase ratio (RA/RT) for HMG-CoA red. that was lower in small intestine compared with that of the large intestine.
Lipids 23, 730-732 (1988).

The interruption of the entero-hepatic circulation produces a decrease in the input of bile acids into the liver, leading to an increase in hepatic synthesis of bile acids from cholesterol and hepatic synthesis of cholesterol (1).

Intestinal mucosa commonly is considered to play a secondary role as a source of endogenously synthesized cholesterol. Thus, in the rat, the intestinal mucosa accounts for about 24% of whole-body sterol synthesis, compared with 50% for the liver (2). It has been suggested that under circumstances in which cholesterol needs increase (as in intestinal resection), many extrahepatic tissues may synthesize in situ much of the cholesterol that they require for cholesterol turnover (3). In the liver and intestine, the rate-limiting step for cholesterol biosynthesis is catalyzed by the enzyme 3-hydroxy-3-methylglutaryl coenzyme-A reductase (HMG-CoA red., EC 1.1.1.34) (4,5). In the liver and intestine, the activity of this enzyme could be altered by changes in rates of enzyme synthesis or degradation, or by changes in the activity state of preformed enzyme, as might occur through a phosphorylation-dephosphorylation reaction (6-8). It has been reported that more rapid changes in cholesterol synthesis were linked to the state of enzyme phosphorylation (9).

We have reported that distal small bowel resection (SBR) increases the activity of this enzyme in rat liver (10). This study was designed to evaluate the intestinal cholesterol synthesis determining the total activity of HMG-CoA red., and its active form, in the mucosa of remnant jejunum, caecum and colon in rats after either 50% or 75% distal SBR.

MATERIAL AND METHODS

Animals. Male Wistar rats weighing about 300 g that were maintained on a standard pellet diet with free access to tap water were used. The rats were randomly assigned to one of three groups: sham-operated, 50% and 75% distal SBR. The rats were anaesthetized with intraperitoneal sodium pentobarbitone (4.5 mg/100 g body wt.) after a 24-hr fast period. Laparotomy was performed, and rats assigned for SBR underwent either 50% or 75% SBR, as described by Murillo et al. (11). In another group, sham operation was performed, and the intestine was cut and re-anastomosed without resection. In each instance, continuity of the gut was restored by end-to-end anastomosis. After the surgical operation, the rats were housed in a temperature-controlled laboratory with a strict 4 a.m.-4 p.m./4 p.m.-4 a.m. dark/light cycle. Six wk after SBR, the rats were fasted for 20-24 hr and, between 9 and 10 a.m., to concide with peak nocturnal activity of intestinal HMG-CoA red., were killed by a blow at the base of the skull (4). Both control and experimental groups were treated in the same manner to prevent effects that could mask differences between groups.

Sample preparation procedures. After the animals were killed, the abdomen was opened, and the jejunum, caecum and colon were excised, rinsed free of intestinal contents with ice-cold saline solution and their lengths and weights recorded. The mucosa from each segment was scraped off with a glass slide, weighed and immediately frozen in liquid N_2 and stored at −70 C until the assay of the enzyme. The storage time did not result in significant loss of enzyme activity (unpublished data).

Assay of intestinal enzyme activity. All subsequent operations were carried out at 4 C. The mucosa was homogenized in a Potter-Elvehjem homogenizer with ice-cold homogenization medium containing 0.25 M NaCl, 50 mM imidazole (pH 7.4), 20 mM ethylenediamine tetraacetic acid (EDTA), 5 mM dithiothreitol (DTT) and either 50 mM NaCl (for total reductase activity) or 50 mM NaF (for the active reductase form). In the presence of NaF (an inhibitor of the dephosphorylation), the measured activity of the enzyme reflects the activity that was present initially in the tissue (active form).

Reductase activity was measured essentially as described by Shapiro et al. (12) with light modifications. This method measures the formation of radioactive mevalonate from labeled HMG-CoA. One hundred µl preincubation medium containing 0.2-0.4 mg mucosal protein, in addition to the components present in the homogenization medium, was incubated at 37 C for 15 min. Then, 50 µl of solution containing 0.25 M NaCl, 50 mM imidazole (pH 7.4), 20 mM ethylenediamine tetraacetic acid (EDTA), 5 mM DTT, 110 mM glucose-6-phosphate, 13 mM NADP, 1 unit of glucose-6-phosphate dehydrogenase and 1 mM DL-3-^{14}C-HMG-CoA (specific activity 4000-8000 dpm/nmol), was added to the preincubation mixture and incubated for 30 min at 37 C. The reaction was stopped by adding 25 µl of 5 N HCl. The ^{14}C-mevalonate formed was converted into the labeled lactone, isolated by thin layer chromatography and counted by liquid scintillation using an internal standard of ^{3}H-mevalonate to correct for incomplete recovery.

Protein assay. Mucosal protein was determined by the method of Lowry et al. (13), with bovine serum albumin as the standard.

Abbreviations: DTT, dithiothreitol; EDTA, ethylenediamine tetraacetic acid; RA/RT, active/total reductase ratio; SBR, small bowel resection.

Materials. All radiochemicals for the assay of HMG-CoA red. activity were obtained from Amersham (UK). All other chemicals were from Sigma Chemical Co. (St. Louis, MO).

Statistical analysis. The two-tailed Student's t-test was used to evaluate the statistical significance of the differences in the values obtained.

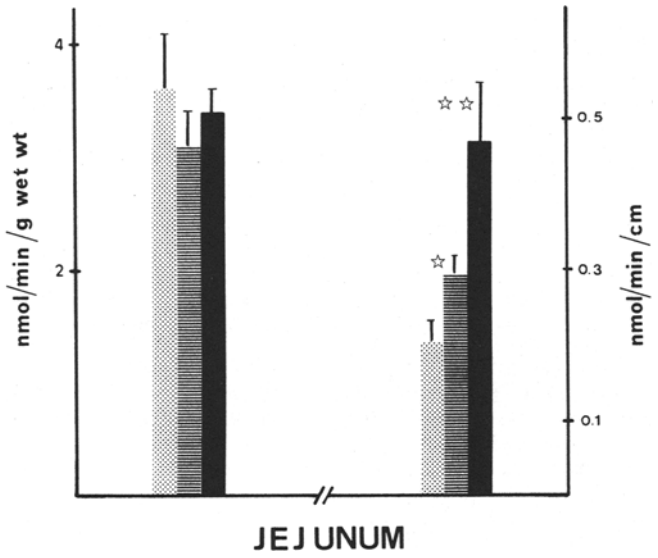

FIG. 1. HMG-CoA reductase activity in jejunal mucosa after 50% (stripes) and 75% (solid) distal SBR, compared with sham rats (dots). Results are given as means ± S.E. of 10 animals. ☆, $p < 0.025$; ☆☆, $p < 0.01$.

RESULTS AND DISCUSSION

We have shown (10) that in rats, both total hepatic activity of HMG-CoA red. and the ratio of active to total reductase (RA/RT) were significantly increased after 50% and 75% SBR. The present data shows that SBR increased both jejunal (Fig. 1) and colonic (Fig. 2) total activity of the enzyme, expressed as nmol/min/cm. However, when the data was referred to unit tissue mass (nmol/min/g wet tissue), the differences between groups were abolished (Fig. 1 and Fig. 2). Therefore, the increased activity was due entirely to intestinal tissue growth induced by the surgical operation (14). In the caecum, HMG-CoA red. total activity expressed per organ was significantly increased after the surgical operation (Fig. 3). This increase again was due to the larger mucosal mass (14), because reference to unit mass (nmol/min/g wet tissue) abolished the differences between groups (Fig. 3). As indicated in Methods, these results were obtained in the fasting state. The response in animals on an ad libitum intake is not known.

Although no change in the total activity of the enzyme was observed in any of the intestinal segments tested, a change in the activity state could have occurred. Therefore, we considered it of interest to investigate whether the state of enzyme phosphorylation was modified by SBR. In the jejunum of sham animals, we found a RA/RT ratio of 0.16, which was not significantly modified by SBR (Table 1), but was significantly lower than that observed in isolated rat enterocytes (8) or in intestinal microsomes (15). These differences could be due to the different preparations used. In caecum and colon of sham rats, this ratio was higher than in jejunum, i.e., 0.56 and 0.57, respectively. Again, this ratio was not changed by SBR (Table 1).

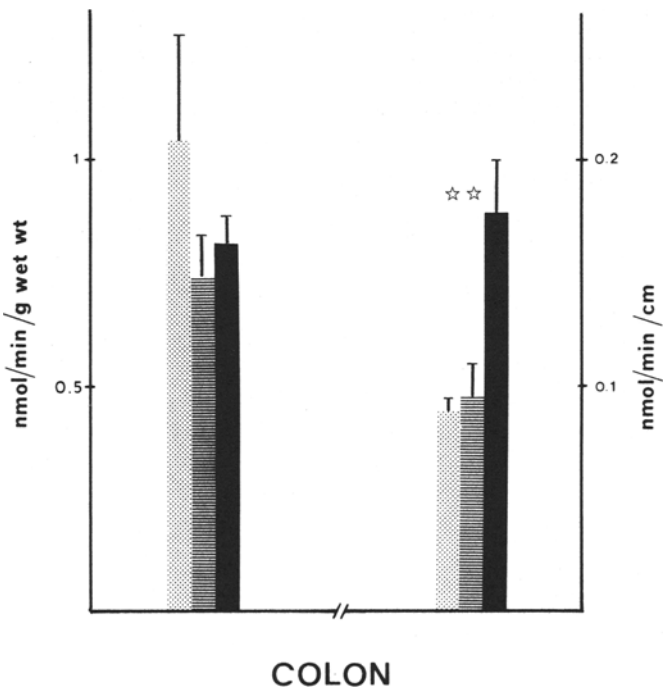

FIG. 2. HMG-CoA reductase activity in colonic mucosa. Results are given as means ± S.E. of 10 animals. Other details as in Figure 1. ☆☆, $p < 0.01$.

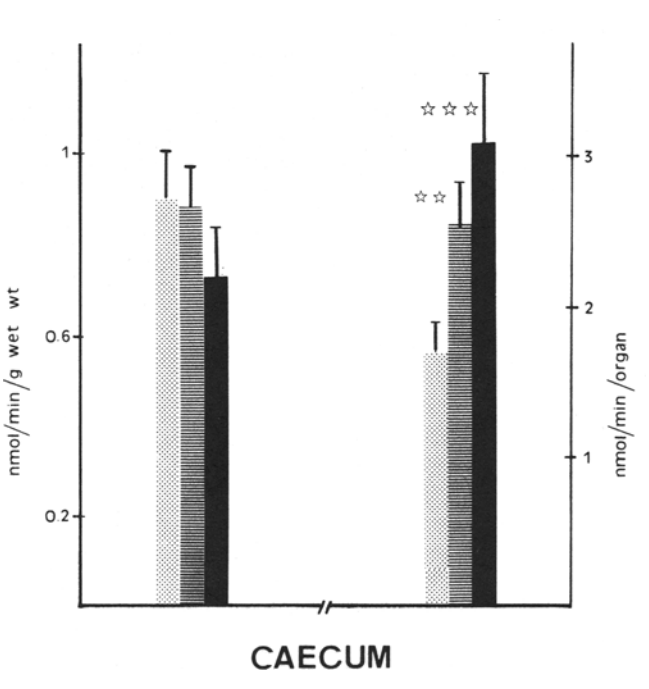

FIG. 3. HMG-CoA reductase activity in caecal mucosa. Results are given as means ± S.E. of 10 animals. Other details as in Figure 1. ☆☆☆, $p < 0.005$.

TABLE 1

Active/Total Reductase (RA/RT) in Jejunal, Caecal and Colonic Mucosa[a]

	Jejunum	Caecum	Colon
Sham	0.16 ± 0.02	0.56 ± 0.03	0.57 ± 0.01
50%	0.15 ± 0.01	0.53 ± 0.02	0.55 ± 0.02
75%	0.14 ± 0.02	0.50 ± 0.03	0.58 ± 0.02

[a]Results are given as means ± S.E. of 10 animals.

Taken together, these results show that SBR altered neither the total activity nor the activity state of the enzyme. An increase in the activity of the intestinal reductase has been observed when the entero-hepatic circulation has been interrupted by either administration of the bile acid-binding resin, as cholestyramine (16) or by external diversion of the bile (17). This discrepancy could be due to differences in the experimental procedures. Thus, in the latter studies bile acid recirculation is interrupted before uptake by the mucosa, while in the current experiments the area of intestinal uptake is reduced as are the sites for bile acid and cholesterol absorption.

We have reported that SBR increases hepatic HMG-CoA red. activity (10). This observation, together with the present findings, might suggest that hepatic activity may be sufficient to supply the majority of cellular needs for cholesterol in resected animals. Other possible causes could contribute to explain the current observations after intestinal resection, such as increased intestinal absorption of cholesterol, increased cellular lipoprotein uptake in intestinal epithelium, etc. However, the possibility that the utilization of newly synthesized cholesterol for chylomicron formation may be the major usage of the intestinal cholesterol cannot be ruled out. These possible causes are under investigation in our laboratory.

In conclusion, this study demonstrates that intestinal HMG-CoA red. does not change in rat jejunal, caecal and colonic mucosa adapting to SBR. As a side result, we noted regional differences in the RA/RT ratio for HMG-CoA red. that was lower in mucosa scraped off the small intestine compared with that of the large intestine.

Cell Membrane Localization of Long Chain C_{24}-C_{30} Fatty Acids in Two Marine Demosponges[1]

Mishelle P. Lawson, Janice E. Thompson and **Carl Djerassi***
Department of Chemistry, Stanford University, Stanford, CA 94305

Subcellular fractionation by differential centrifugation was performed on two previously unstudied marine sponges (*Reniera* sp. and *Pseudaxinyssa* sp.) that represent both major subclasses of the Demospongiae. Long chain fatty acids (LCFA) with 24-30 carbon units were found as major constituents of cell membrane isolates of both sponges. Most LCFA were polyunsaturated and were constituents of the phospholipids, which are typical membrane lipids, and in particular the amino-phospholipids. The LCFA composition of phospholipids from whole sponge tissue was shown to provide a reliable indication of the LCFA composition of cell membrane phospholipids in the sponges studied. An unusual triply branched C_{16} isoprenoid fatty acid, 4,8,12-trimethyltridecanoic acid, also was identified as a cell membrane acid in the sponge *Pseudaxinyssa* sp.
***Lipids* 23, 741-749 (1988).**

Long chain fatty acids (LCFA) with molecular chains of 24-30 carbon units have been identified as major components of cellular membranes in one marine sponge (1). In the aforementioned study, 51% of the fatty acids in a mixed membrane isolate from the intertidal species *Halichondria moorei* were LCFA with chain lengths in excess of the 14-22 carbon units which usually occur in the membranes of eucaryotic cells (2). Sponges are renowned for their content of LCFA, which can comprise up to 85% of the total fatty acids present in their tissue (3-10); in the few sponge species that have been studied, most LCFA were found localized in phospholipids (1,5,11-15).

No studies, however, yet have unambiguously established the presence of LCFA in sponge cells; all studies have employed sponge tissue or membrane preparations potentially contaminated by microorganism symbionts (e.g., bacteria and unicellular algae) that typically inhabit the matrix region of sponge tissue (16-18). While bacteria typically contain fatty acids with chain lengths up to 22 carbons (2,19-23), there are rare instances in which bacterial species contain high molecular weight fatty acids (e.g., mycobacteria produce β-hydroxy fatty acids with between 60 and 83 carbons [24]). Moreover, there is little information on the identities of other microorganism sponge symbionts or on their fatty acid contents.

Sponges also are unique in the diversity and often novelty of their sterols (25-31). While there are sponge species that solely contain conventional cholesterol-type sterols, which are typical of eucaryotes (32), many sponges substitute unusual sterols (e.g., unusual patterns of alkylation and unsaturation in the C_{17} side chain). Because sterols are major components of cellular membranes in almost all eucaryotic organisms, it is expected (28) that such unconventional sterols assume important structural positions in sponge membranes, but it is unknown whether these unusual sterols co-occur with LCFA in sponge membranes.

Therefore, the purpose of this study was to determine unambiguously whether LCFA are components of sponge membranes, while the companion study (33) seeks to establish whether unconventional sterols also are sponge membrane components. Here the subcellular fractionation study of Lawson et al. (1) is extended to include two additional species that together represent both major subclasses of the Demospongiae, with one species that lacks discernible matrix symbionts and contains conventional sterols, and another species that is noted for its high matrix symbiont content and unconventional sterols.

The California ceractinomorph sponge *Reniera* sp. is seasonally abundant (April-July) in the San Francisco Bay. Specimens of this sponge that are devoid of microorganism symbionts can be obtained during early rapid stages of growth April-May (Fig. 1a). *Reniera* sp. contains LCFA that often have Δ5,9 unsaturation (described herein) and conventional sterols (33).

The Great Barrier Reef tetractinomorph sponge, *Pseudaxinyssa* sp., is a long-lived animal that contains considerable bacterial populations, especially phototropic cyanobacteria (= blue-green algae), in the illuminated surface (<1 mm) tissues (18, unpublished data, this laboratory). *Pseudaxinyssa* sp. contains LCFA that often have Δ5,9 unsaturation patterns (unpublished data, this laboratory) and unconventional sterols with an isopropyl branch at C-24 of the side chain (27,33-39).

EXPERIMENTAL

Sponge samples. Reniera sp. (Order Haplosclerida, California Academy of Sciences Museum specimen #063176) was collected by hand from San Francisco Bay, CA (3 m) in April 1985. *Pseudaxinyssa* sp. (Order Axinellida, Australian Museum specimen #Z4988) was collected by hand from the John Brewer Reef, Australian Great Barrier Reef (18 m) in June 1985 (for biological and chemical studies) and July 1986 (for further electron microscopy [EM] studies).

Chemicals and materials. Electron microscopy reagents were EM grade from either Electron Microscopy Sciences (Fort Washington, PA), Ted Palla Inc. (Tustin, CA) or Ernest F. Fullam Inc. (Latham, NY). Phospholipid reference compounds included phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, phosphatidyl-

Abbreviations: BHT, butylated hydroxytoluene; EDTA, ethylenediamine tetraacetic acid; FAME, fatty acid methyl ester; LCFA, long chain fatty acid; LCPUFA, long chain polyunsaturated fatty acid; LCUFA, long chain unsaturated fatty acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; TMTD, 4,8,12-trimethyltridecanoic acid; UFA, unsaturated fatty acid; A, archaeocytes; CC, choanocyte chambers; ECL, equivalent chain length; EM, electron microscopy; F, flagella; FSW, filtered seawater; GC, gas chromatography; GC-MS, gas chromatography-mass spectrometry; MV, microvilli.

glycerol, diphosphatidylglycerol, phosphatidic acid, phosphatidylinositol, lysophosphatidylcholine, phosphatidylethanolamine plasmalogen, and sphingomyelin, and were from Sigma Chemical Co. (St. Louis, MO). Other reference lipids were cholesterol (Aldrich-Milwaukee, WI), cholesteryl myristate (Sigma Chemical Co.), and tripalmitin (Sigma Chemical Co.). General laboratory reagents were purchased from May & Baker Pty. Ltd, Sigma and Aldrich Chemical Companies. All solvents were analytical grade and were distilled before use.

Thin layer chromatography (TLC) plates (silica coated aluminium, Kieselgel 60 F254, 0.2 mm, Merck Chemical Co., Darmstadt, Germany) were prewashed in diethylether before use. Fatty acid methyl esters (FAME) were purified on Davisil 62 silica gel.

Subcellular fractionation. Subcellular fractionation of sponge tissue was modified after Lawson et al. (1). Filtered seawater (FSW, 10 C, 0.4μ nucleopore filter) was used throughout the procedure. *Reniera* sp. (300 g, 20 specimens) and *Pseudaxinyssa* sp. (200 g portion of 1 individual) were chopped into pieces (1 cm^3) and placed in cold homogenizing medium (50 mM Tris, 250 mM sucrose, 5 mM ethylenediamine tetraacetic acid [EDTA]/FSW, 10 C, pH 7.4, 0.5 ml/g tissue). Sponge tissue was homogenized in a Galaxie Osterizer dual-range 14 kitchen blender at high speed for 40 sec for *Reniera* sp. and in a Sorvall Omni-mixer (model 17220) at 16,000 rpm (high speed) for 80 sec for *Pseudaxinyssa* sp; homogenization conditions were restricted to minimize disruption of intracellular organelles. *Pseudaxinyssa* tissue did not completely homogenize, as did *Reniera* tissue, due to its resilient siliceous and collagenous skeleton. Homogenates were filtered through nylon mesh (200μ). Residual *Pseudaxinyssa* sp. tissue, which remained after filtration, was found to have a lipid content similar to that of whole sponge. Filtrates were diluted in homogenizing medium (1:1, v/v) and were successively centrifuged at 600 × g/15 min/10 C, 15,000 × g/15 min/10 C (Sorvall RC 5 centrifuge, GSA rotor for *Reniera* sp; Beckman J-21B centrifuge, JA14 rotor for *Pseudaxinyssa* sp.) and 100,000 × g/1 hr/4 C (Beckman L8-70M ultracentrifuge, 70.1 Ti rotor for *Reniera* sp; ICE/B-60 ultracentrifuge, A21 rotor for *Pseudaxinyssa* sp.). For each sponge, the three successive tissue pellets that are referred to according to convention as P1, P2 and P3, respectively, and a final supernatant resulted from these respective centrifugations. P1 was washed once in homogenizing medium, and P2 was washed twice. All fractions were held on ice throughout the procedure.

Electron microscopy. Fresh tissue samples from whole sponge and pelleted subcellular fractions were fixed in 2.5% glutaraldehyde/0.4 M sodium cacodylate buffer/10 C, post-fixed in 1% osmium tetroxide in the same buffer, and embedded in epoxy resin (40). Silver sections were stained with 1% uranyl acetate and lead citrate and were examined at 2,250, 7,500, 30,000, and 138,000 × magnification with a Philips 410 electron microscope (80 kv). The resulting micrographs allowed description of cellular and subcellular components in each sample to be made, although those for *Pseudaxinyssa* sp. were of poor contrast and consequently are not reprinted here.

Lipid analysis. Tissue was frozen and stored at −20 C and, in the case of *Pseudaxinyssa* sp., was lyophilized before workup. Total lipids were extracted (3 times) with chloroform/methanol (2:1) containing 0.002% butylated hydroxytoluene (BHT) (41). Supernatants were extracted in chloroform/methanol (4:1, v/v) at 5 C to facilitate partitioning of aqueous and organic phases. Before analysis, lipids were stored in chloroform/methanol (1:1, v/v) containing 0.002% BHT under argon at −20 C.

A portion of the total lipid extract from *Reniera* sp. whole tissue was separated by column chromatography (SIL-R 100-300 mesh silicic acid, Sigma Chemical Co.) into fractions that conventionally contain triacylglycerols and sterol esters (fraction 1), diacylglycerols and free sterols (fraction 2), monoacylglycerols (fraction 3), glycolipids (fraction 4), and phospholipids (fraction 5), after the methods of Privett et al. (42) and Walkup et al. (11). Fractions 1-3 were eluted with chloroform, fraction 4 with acetone, and fraction 5 with methanol. The composition of eluates was monitored by TLC that utilized codeveloped reference compounds and spray reagents (iodine vapor, rhodamine 6G, ceric sulfate, and molybdenum blue [43]) to identify classes of lipids.

Phospholipids were further separated according to head groups by one- and two-dimensional TLC of a small phospholipid sample. For single-dimension chromatography, the solvent system was chloroform/acetone/methanol/ammonium hydroxide (28% aq.)/water (65:35:4:4:0.2, v/v/v/vv/) (11). For two-dimensional chromatography, tetrahydrofuran/acetone/methanol/water (50:20:40:6, v/v/v/v) was employed in development in the first dimension, and chloroform/acetone/methanol/acetic acid/water (50:20:10:15:5, v/v/v/v/v) in the second dimension (44). Phospholipid head groups were identified from TLC R_f-values and by response to specific spray reagents (ninhydrin, Dragendorff, periodate-Schiff, and 2,4-dinitrophenylhydrazine [45]).

The fatty acyl components of total lipid extracts from whole sponges, P3 membrane, and other subcellular isolates of *Reniera* sp. and *Pseudaxinyssa* sp., and of lipid class fractions from whole sponge extracts of *Reniera* sp., were converted to methyl esters (1.25 N hydrochloric acid/methanol [46]). The resulting FAME were purified by silica gel column chromatography with elution by hexane/ether (15:1, v/v). Portions of FAME samples were hydrogenated (methanol, platinum IV oxide catalyst [47]).

Phospholipids from the P3 membrane isolate of *Reniera* sp. were separated according to head groups and isolated by preparative TLC. The major phospholipid head groups were analyzed for fatty acid composition by transesterification on silica with methanolic boron trifluoride (48). The resulting FAME were purified as above.

FAME were analyzed by temperature-programmed gas chromatography (GC) (cooled column injection system, flame ionization detector) on either a Carlo Erba series 4160 Fractovap chromatograph (25 m × 0.32 mm i.d. SE-54 coated fused silica column; program 130-290 C, 5 C/min; detector temp. 290 C, Omniscribe Series D-5000 recorder) or a Hewlett-Packard 5898A series gas chromatograph (25 m × 0.3 mm i.d. SE-54 coated fused silica column; program 170-320 C, 5 C/min; injector temp. 250 C; detector temp. 320 C), with automatic injection system (automatic sampler Model 7672A), integrator (Model 3392A), sampler/event control module (Model 19405A) and computer fatty acid library (software s/n: 2614R100027, vers. 1.2). For Carlo Erba GC, the non-integrated traces were enlarged (1.5 times) and peak areas

were measured by triangulation for calculation of relative proportions of fatty acid components.

Individual FAME were identified by mass spectrometry of their N-acylpyrrolidide derivatives (treatment of FAME with pyrrolidine/acetic acid [10:1, v/v]) (49). Capillary gas chromatography-mass spectrometry (GC-MS) analyses were performed with a Ribermag R10-10 quadrupole mass spectrometer connected to a Carlo Erba series 4160 Fractovap chromatograph (30 m × 0.32 mm i.d. SE-54 fused silica column), and a Hewlett-Packard 5970 series mass selective detector connected to a 5890A gas chromatograph (12 m × 0.2 mm i.d. SE-30 fused silica column).

RESULTS

Subcellular fractionation. Substantial P1 and P2 isolates were produced from both sponges as numerous subcellular organelles remained intact and sedimented at the P1 and P2 centrifugation steps. For both sponges, P1 consisted of partially disrupted cells and large organelles (>2.8 μ diam.) (Fig. 1b), and P2 consisted of smaller organelles (≤2.8 μ diam.) (Fig. 1c). Large numbers of cyanobacteria also were present in the P2 fraction of *Pseudaxinyssa* sp.

P3 membrane isolates for both sponges contained membrane vesicles (mean diam. 0.42 μ), and nonlipidic ribosomes that should not have interfered with lipid analyses (Fig. 1d and 1e). For *Reniera* sp., the P3 membrane isolate would have been essentially free from microorganism membranes because the experimental specimens used were free of matrix microorganism symbionts and contained only a few bacteria in archaeocyte cell digestive vacuoles (Fig. 1a). For *Pseudaxinyssa* sp., the P3 membrane isolate, however, cannot be assumed free of microorganisms because extracellular cyanobacteria characterized by distinctive thylakoids were observed in abundance in the surface tissues (<1 mm) of the sponge. However, such microorganism membrane contamination would be expected to be minor because many intact cyanobacteria were observed in the P1 and P2 isolates, while few thylakoid fragments were observed in any isolate fraction. The sponge membranes present almost certainly included a mixture of plasma and organelle membranes from the many sponge cell types present, although plasma membranes and endoplasmic reticulum from the abundant archaeocyte cells should have dominated due to the great numbers of intact organelles observed in the denser P1 and P2 isolates.

Lipid analysis. Sponge lipid extracts from whole tissue, P1 and P2 isolates, consisted mainly of pigments, sterol esters, triacylglycerols, sterols and phospholipids, while P3 membrane isolates of both sponges were free of pigments and consisted of sterols, phospholipids and lesser amounts of sterol esters. P1 and, especially, P2 fractions from *Pseudaxinyssa* sp. were enriched in chlorophylls that probably originated in the symbiotic cyanobacteria that sedimented in these isolates. A non-esterifiable yellow compound that gave an orange product upon reacting with the ceric sulfate spray reagent (R_f = 0.16 in hexane/ether [1:1, v/v]) was concentrated in the P2 fraction from *Reniera* sp. An unidentified compound (R_f = 0.57 in hexane/ether [1:1, v/v]) was detected in the P3 membrane isolate from *Pseudaxinyssa* sp. Final supernatant isolates from each sponge contained lipidic and water-soluble pigments and sterol esters.

Whole sponges contained LCFA to 28 carbon units in *Reniera* sp. and to 30 carbon units in *Pseudaxinyssa* sp., including many Δ5,9 unsaturated acids (Tables 1 and 2) largely contained in phospholipids (76% and 42%, respectively). The major fatty acids of *Reniera* sp. were $C_{26:2}$ (23%), $C_{23:3}$ (12%), and $C_{28:3}$ (11%), and those of *Pseudaxinyssa* sp. were $C_{16:0}$ (10%), $C_{28:1}$ (9%), and $C_{18:1}$ (7%) (Fig. 2). High levels of typical bacterial acids ($C_{16:0}$ and $C_{18:1}$) in *Pseudaxinyssa* sp. may reflect the large populations of bacterial symbionts present in this sponge, although these acids also commonly occur in eucaryotic cells (2). For *Pseudaxinyssa* sp. but not *Reniera* sp. LCFA content of whole tissues was almost identical for phospholipid and total lipid extracts (Fig. 2).

P3 membrane isolates of both sponges contained a high proportion of LCFA, largely present in phospholipids (Fig. 2). For the *Reniera* sp., P3 membrane-isolate LCFA composed 62% of the total lipid fatty acids and 79% of the phospholipid fatty acids. In contrast, for the *Pseudaxinyssa* sp., P3 membrane isolate LCFA equaled 63% of the total lipid fatty acids but only 37% of the phospholipid fatty acids (Fig. 2), suggesting that LCFA also were abundant in other membrane-associated lipid classes in this sponge. For both sponges, P1 and P2 isolates contained a lower proportion of LCFA. Less than 10% of fatty acids in supernatant isolates from *Reniera* sp. and less than 5% of fatty acids in supernatant isolates from *Pseudaxinyssa* sp. were LCFA.

The presence of LCFA in other lipid classes was demonstrated for whole tissues in *Reniera* sp. in lesser amounts than were detected in phospholipids (Fig. 3). Lipids with chromatographic patterns (42) similar to sterol esters and triacylglycerols (Fraction 1), diacylglycerols (Fraction 2) and monoacylglycerols (Fraction 3) contained 55%, 62% and 7% LCFA, respectively. A predominance of mid-range fatty acids between C_{22} and C_{24} chain lengths (67%) characterized lipids with chromatographic patterns like glycolipids (Fraction 4). Insufficient sponge tissue was available to conduct similar analyses for *Pseudaxinyssa* sp., but it is known from earlier studies on this sponge that LCFA also are concentrated in the phospholipids (unpublished data, this laboratory).

It was notable that for *Reniera* sp. the proportions of LCFA from both phospholipid and total lipid extracts of the P3 membrane isolates were virtually identical (i.e., within 2%) to the respective proportions of LCFA in phospholipid and total lipid extracts from the whole animal (Fig. 2). Such a trend has been noted before in the intertidal sponge *Halichondria moorei* (1) but was not observed in *Pseudaxinyssa* sp. where the P3 membrane isolate contained appreciably more LCFA in the total lipid extract (63%) than did whole sponge tissue (41%), likely due to the substantial numbers of microorganism symbionts present in the whole sponge. Thus, in sponges where symbionts are absent or present in relatively small populations, as in *Halichondria moorei* and *Reniera* sp., the fatty acid composition of whole sponge phospholipids may provide a useful approximation to the LCFA composition of sponge cell membrane phospholipids, while the total lipid composition also may reflect that of the membrane isolate, assuming the sponge does not store significant concentrations of fatty acids in intracellular organelles.

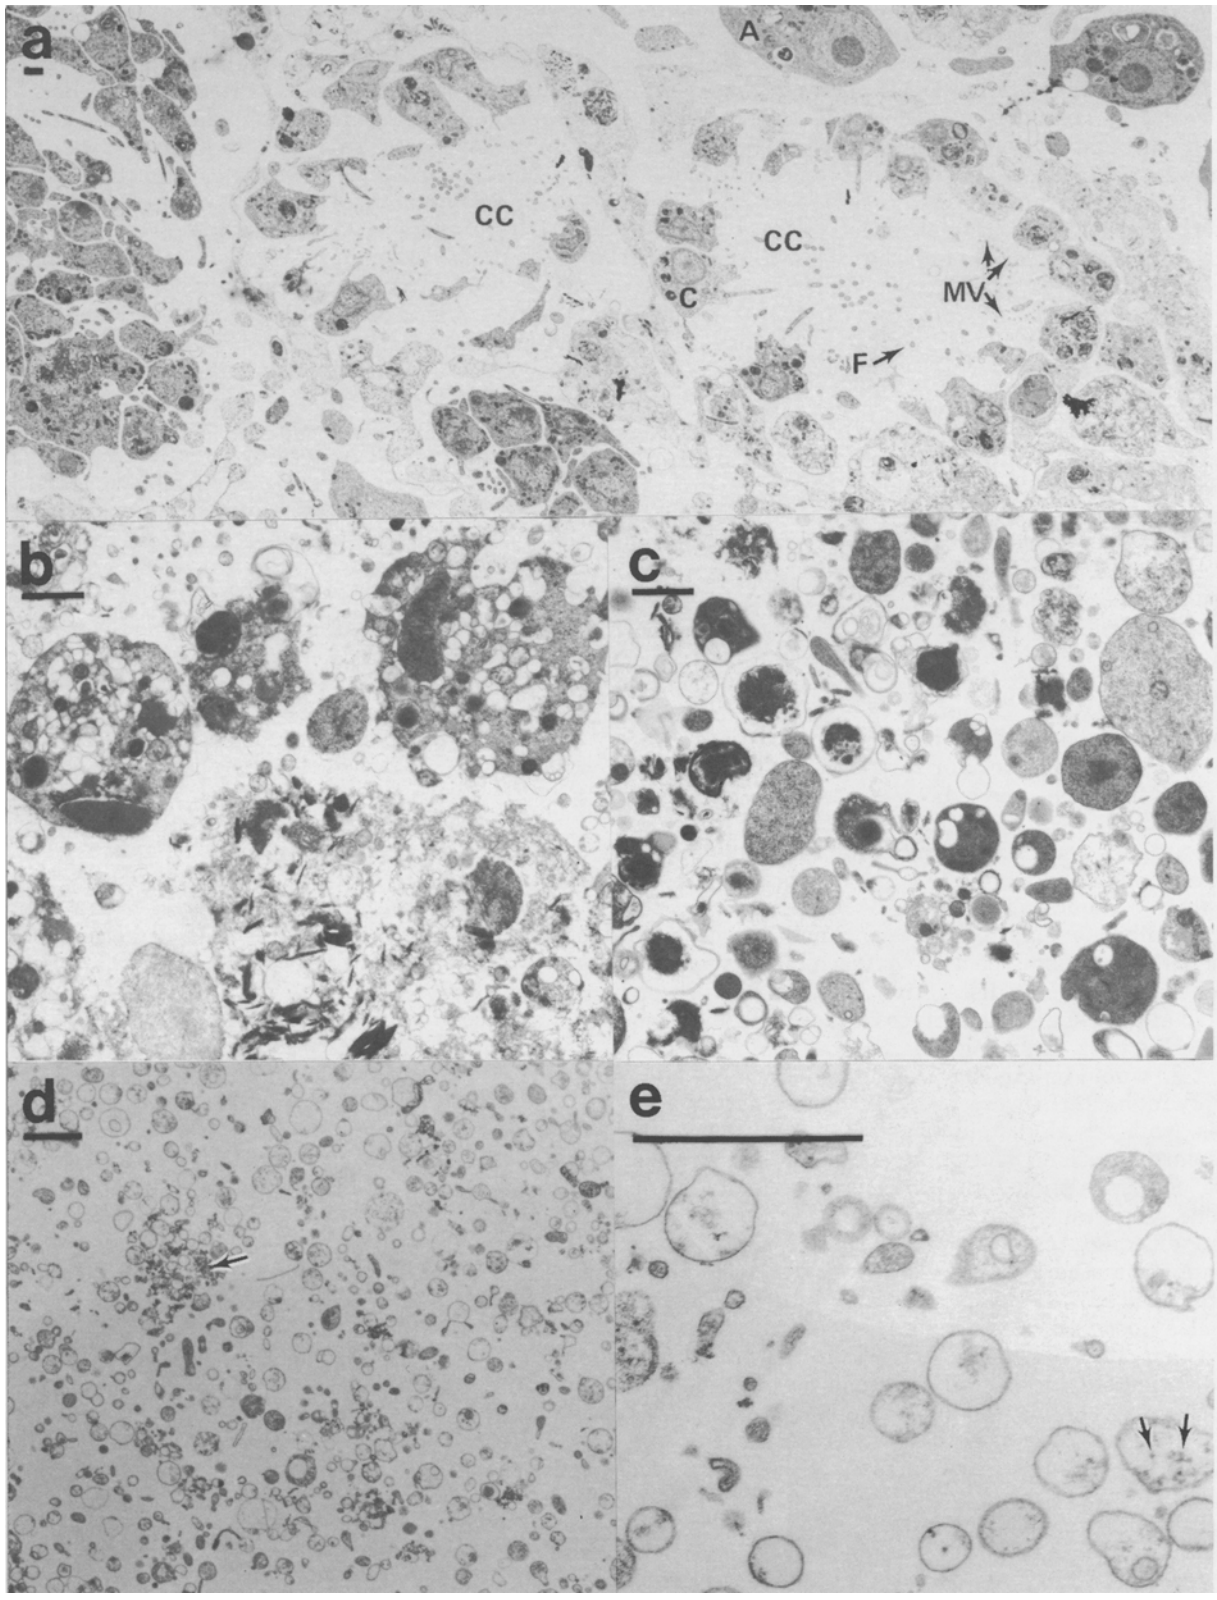

FIG. 1. Electron micrographs of whole sponge and subcellular tissue from *Reniera* sp. (a) Whole sponge tissue contained numerous choanocyte chambers (CC) with component choanocytes (C) of which flagella (F), and microvilli (MV) are obvious. Heavily vacuolated archaeocytes (A) were present in the mesohyl matrix. Mean archaeocyte plasma membrane width 5.3 nm. (b) The P1 subcellular fraction contained partially disrupted cells, and large organelles (>2.8 μ diam.). (c) The P2 fraction contained smaller organelles (≤2.8 μ diam.). (d,e) The P3 fraction contained membrane vesicles (mean vesicle diam. 0.42 μ; mean membrane thickness 5.3 nm) and ribosomal contaminants (arrows). Each bar equals 1 μ.

TMTD, 4,8,12-trimethyltridecanoic acid.

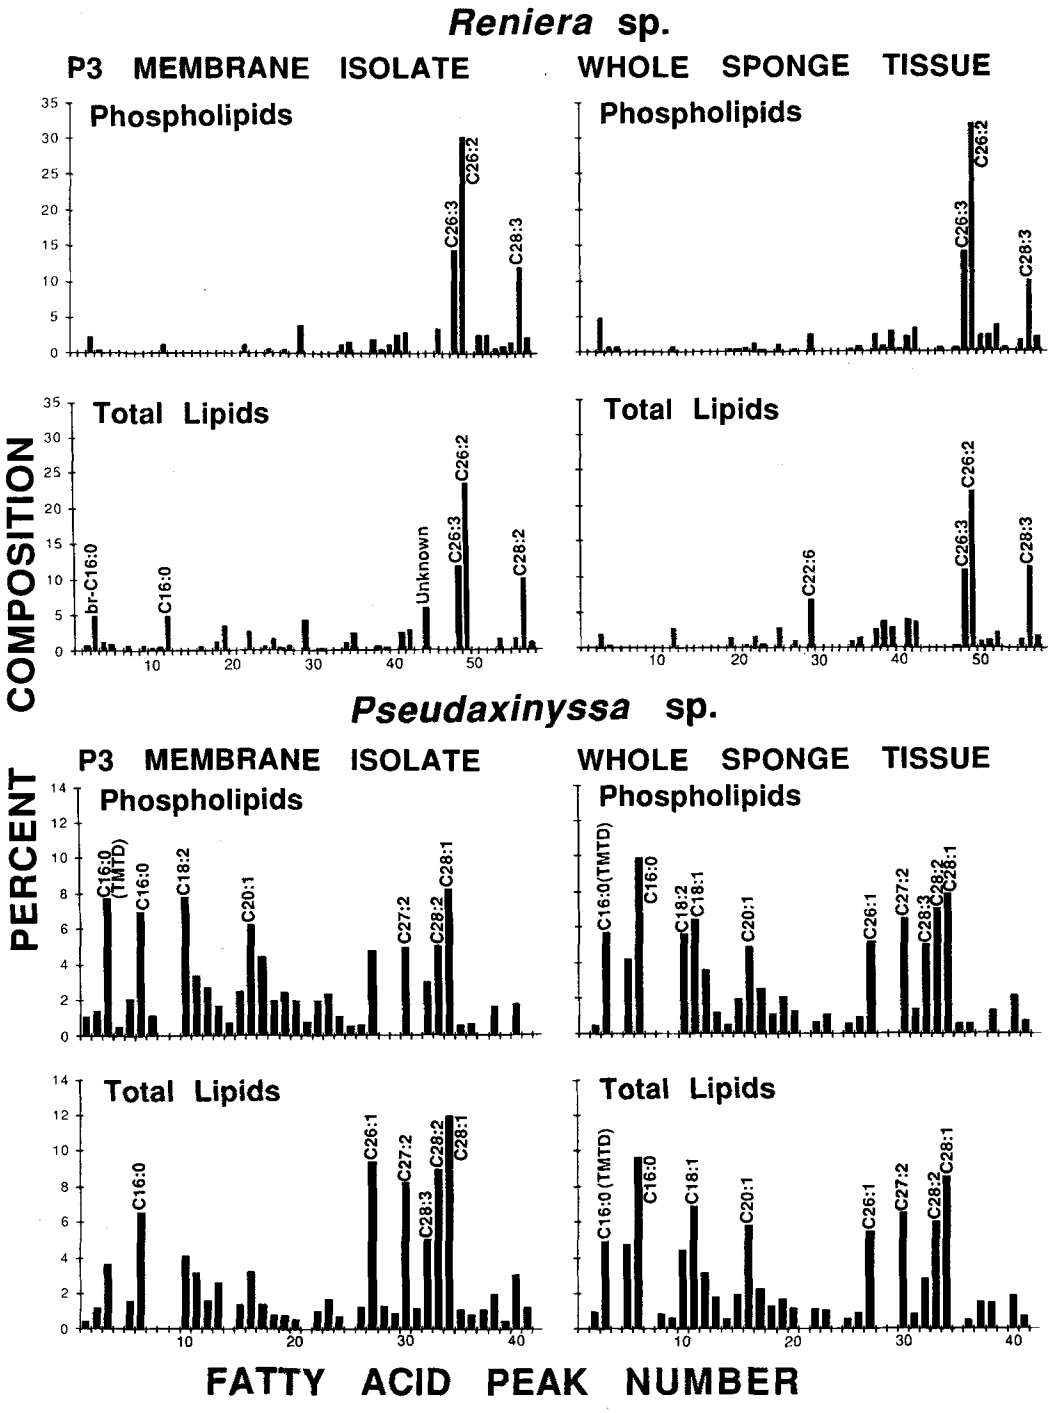

FIG. 2. The proportional distributions of fatty acids in phospholipid and total lipid extracts from P3 membrane isolates and whole sponge tissues of *Reniera* sp. and *Pseudaxinyssa* sp. Fatty acids are described for *Reniera* sp. in Table 1 and for *Pseudaxinyssa* sp. in Table 2. Fatty acids that compose ≥5% of the total fatty acids are labeled.

The LCFA encountered in all tissue samples were predominantly unsaturated, mainly polyunsaturated, while shorter chain fatty acids tended to be saturated (Fig. 4). Such features of unsaturation and polyunsaturation in LCFA are commonly observed in sponges (4,9,10), but it should be noted that the content of LCFA and the degree of unsaturation in individual species of sponge can vary with seasonal temperature (5,50) and with geography (51).

For *Pseudaxinyssa* sp., the unusual isoprenoid fatty acid 4,8,12-trimethyltridecanoic acid (TMTD) was more abundant in the phospholipids of the P3 membrane isolate (7.8%) than in the whole sponge (5.8%) (Fig. 2). This result is in agreement with our unpublished data that documents lesser concentrations of TMTD in the cyanobacteria-rich outer tissues of the sponge.

The principal phospholipids in *Reniera* sp. and *Pseudaxinyssa* sp. whole sponge and P3 membrane isolates were phosphatidylserine (PS), phosphatidylethanolamine (PE), and phosphatidylcholine (PC) as is typical of those sponges that have been studied for phospholipid content

(5,11,12,52). In all *Reniera* sp. lipid samples, PS appeared as two almost distinct spots on TLC and this may indicate that there are sufficient differences in chain lengths and unsaturation of the fatty acid substituents of PS to result in separation by TLC. In addition to PS, PE and PC, *Pseudaxinyssa* sp. whole sponge tissue and the P1 and P2 isolates contained phosphatidylglycerol, diphosphatidylglycerol and phosphatidylinositol, the former two phospholipids being typical bacterial phospholipids (2).

For the *Reniera* sp., P3 membrane isolate LCFA predominated in amino-phospholipids where PE contained 78% LCFA, and PS contained 58% LCFA (Fig. 5). Almost 40% of the fatty acids in PE consisted of $C_{26:2}$ with $C_{26:3}$ and $C_{28:3}$ accounting for 14 and 13% of the total, respectively. In PS, $C_{26:2}$ was present as 33% of the total and $C_{22:0}$ at 22%. Short chain fatty acids characterized PC with $C_{16:0}$ (37%), $C_{18:0}$ (28%), and $C_{22:6}$ (16%) as the major acids. Insufficient sample was available to perform similar analyses for *Pseudaxinyssa* sp.

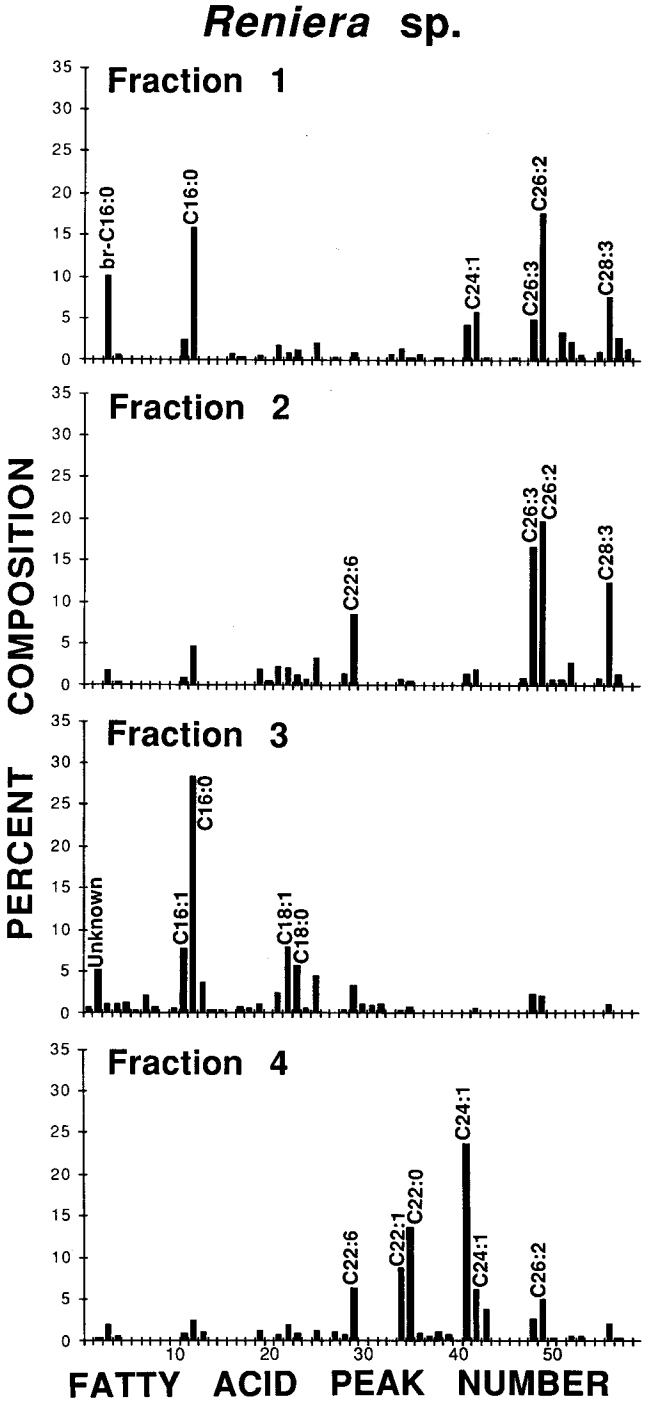

FIG. 3. The proportional distributions of fatty acids in lipid fractions from whole sponge extracts of *Reniera* sp., according to standard column chromatography methods that typically yield fractions of the following compositions: Fraction 1 = triacylglycerols and sterol esters; Fraction 2 = diacylglycerols and free sterols; Fraction 3 = monoacylglycerols; Fraction 4 = glycolipids. Fatty acids are described in Table 1. Fatty acids that compose ≥5% of the total fatty acids are labeled.

DISCUSSION

There now can be no doubt that fatty acids with chain lengths of 24-30 carbons are components of sponge cellular membranes, principally in phospholipids, in addition to appreciable amounts of shorter chain fatty acids. Including this study, three geographically and environmentally distinct sponge species now have been found to contain long chain fatty acids (LCFA) in their cell membranes (1). Moreover, the presence, quantity and nature of mesohyl matrix symbionts do not appear to influence whether a sponge contains LCFA in its cell membranes: *Halichondria moorei* (1) and *Reniera* sp. contained few or no bacterial symbionts, while *Pseudaxinyssa* sp. contained large populations of both phototrophic and nonphototrophic bacterial symbionts; all of these sponges contained LCFA in their cell membranes.

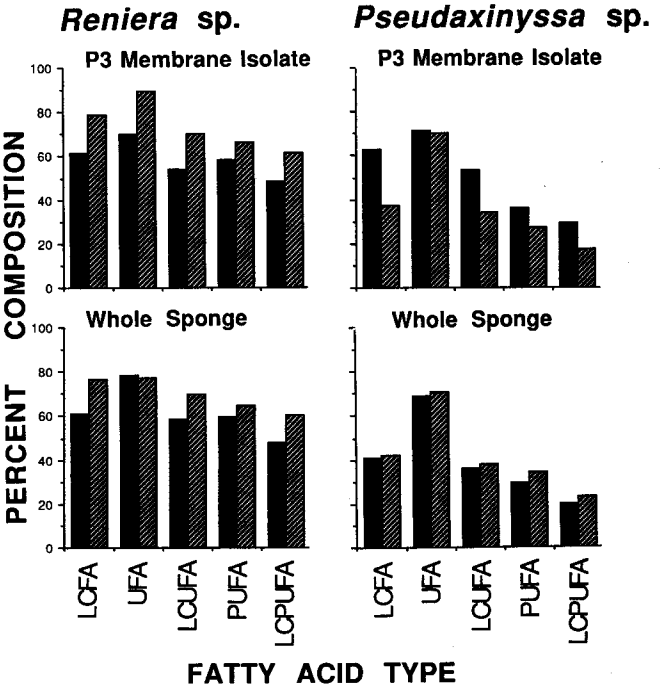

FIG. 4. A comparison of the distribution of long chain and unsaturated fatty acids in total lipids (solid) and phospholipids (hatched) from P3 membrane isolates and whole sponge tissue of *Reniera* sp. and *Pseudaxinyssa* sp. LCFA, long chain fatty acids; UFA, unsaturated fatty acids; LCUFA, long chain unsaturated fatty acids; PUFA, polyunsaturated fatty acids; LCPUFA, long chain polyunsaturated fatty acids.

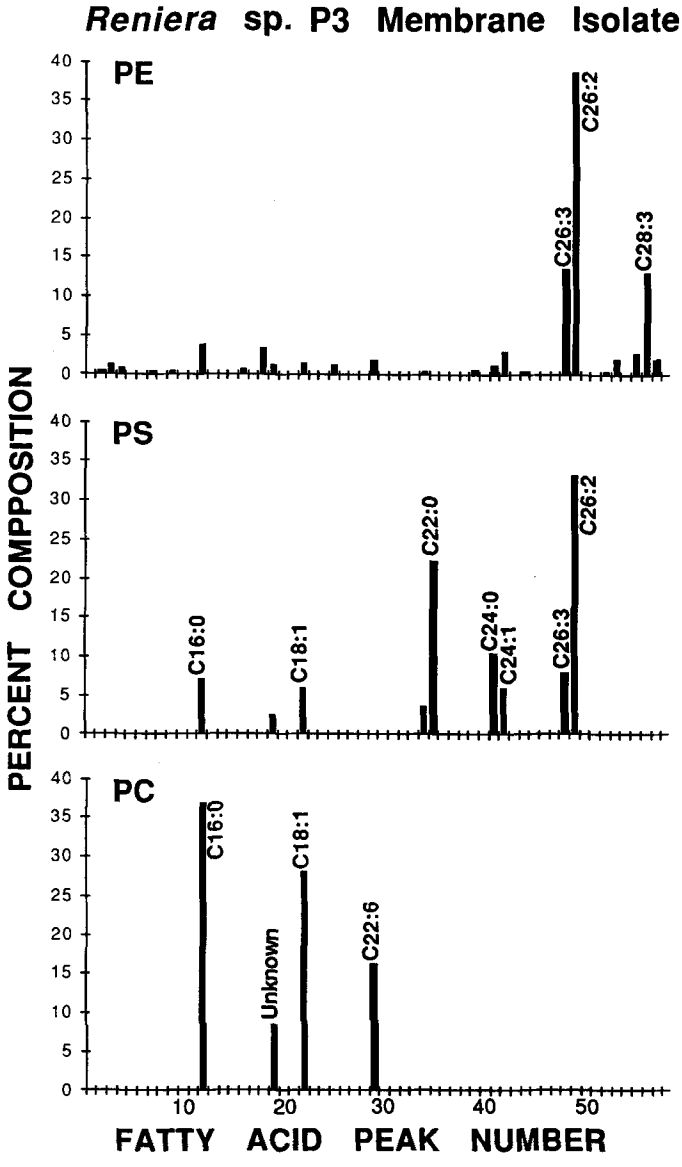

FIG. 5. The proportional distributions of fatty acids in the major phospholipid head groups in a P3 membrane isolate of *Reniera* sp.: phosphatidylethanolamine (PE); phosphatidylserine (PS); phosphatidylcholine (PC). Fatty acids are described in Table 1. Fatty acids that compose ≥5% of the total fatty acids are labeled.

Because we now have examined sponges of both major subclasses of the most prolific sponge class, the Demospongiae, we feel justified in concluding that the occurrence of LCFA in sponge cell membranes is at least characteristic of demosponges, if not all sponges, that contain LCFA. However, the origin of LCFA in sponges has yet to be ascertained because it is not known whether sponges independently synthesize their own short chain fatty acids (i.e., <24 carbon units), whether they incorporate and utilize dietary short chain acids, or whether there is a transfer of short chain acids from symbionts to sponge to be used as such in the sponge or to be further elongated by the sponge as has been demonstrated in our laboratory for two branched LCFA (53,54). Appropriate biosynthetic experiments are underway in our laboratory to answer these outstanding questions.

The presence of LCFA in sponge membranes is incompatible with biomembrane structure and function as it presently is understood (5,11,28,32). The cellular membranes of most living organisms contain phospholipid fatty acids drawn from a very limited pool of structural types. These fatty acids are usually even carbon-numbered, straight chain acids with between 12 and 22 carbon units. Fatty acid chain lengths over 24 carbon units prompt questions about their structural accommodation and molecular interactions within the membrane bilayer.

The accommodation of LCFA within the sponge membrane would be expected to impact membrane structure and organization (e.g., membrane thickness, fatty acid stereochemical orientation, and lipid-lipid and lipid-protein molecular interactions [5]), although there is no information regarding how sponge lipids are organized on a molecular level within membranes or whether they are directly involved in defining membrane functions. There is, however, no superficial morphological distinction between sponge cell membranes and those of other organisms: sponge membranes display typical trilaminate bilayer structure, membrane width, and response to freeze-fracture procedures (1,55, unpublished data from this study).

Questions regarding the structural and physiological implications of siting unusual lipid molecules in sponge cell membranes, the origin of these molecules, and possible reasons why sponges contain these lipids are addressed in the following companion paper to this study (33) where the first direct evidence is provided for the occurrence of unconventional-type sterols in sponge cell membranes.

ACKNOWLEDGMENTS

We thank Fran Thomas for preparation of electron micrographs, Ivan Stoilov for collection of *Reniera* sp. and advice on lipid analysis, Eser Ayanoglu and Mary Zimmerman for helpful discussions and guidance, Robert Simoni for guidance with biochemical methodology and for provision of research facilities, Annemarie Wegmann-Szente for some GC-MS analyses, and the Australian Institute of Marine Science for provision of facilities. Support for this study was provided by the National Institutes of Health (Grants No. GM06840 and GM28052), the National Science Foundation (Grant No. DMB8606249) and Hewlett-Packard Inc. (equipment grant).

[Received November 30, 1987; Revision accepted March 16, 1988]

Cell Membrane Localization of Sterols with Conventional and Unusual Side Chains in Two Marine Demosponges[1]

Mishelle P. Lawson, Ivan L. Stoilov, Janice E. Thompson and **Carl Djerassi***
Department of Chemistry, Stanford University, Stanford, CA 94305

Subcellular fractionation by differential centrifugation was performed on two previously unstudied marine sponges that predominantly contain either conventional (*Reniera* sp.) or unconventional (*Pseudaxinyssa* sp.) sterols. Direct evidence for the presence of unconventional sterols with C_{24} alkylated side chains in the cellular membranes of *Pseudaxinyssa* sp. is provided, but the presence of unconventional sterols in sponge membranes is shown not to be a universal feature of the Porifera. Possible structural and functional roles of unconventional lipid molecules in sponge cell membranes are discussed. *Lipids 23,* 750–754 (1988).

Marine sponges are distinctive because they commonly contain sterols with unusual patterns of ring unsaturation, methylation and side-chain branching (1–7), although this is not a universal feature of the Porifera because many species contain only conventional, cholesterol-type sterols (4). Indeed, sponges contain the greatest variety of sterols in the animal kingdom (3). The subcellular localization of such unconventional sterols within sponges has not been established, although it has been suggested that such sterols are present in the sponge cell membranes because sterols, notably cholesterol, are principal constituents of cellular membranes in other animals (5–8). Furthermore, it has been proposed that such unconventional sterols may act as stereochemical complements to the long and sometimes multiply branched fatty acids in sponges (5,9,10).

Therefore, the purpose of this study was to establish whether such unconventional sterols, where abundant, can be present in sponge cell membranes in substantial amounts and whether conventional sterols occupy typical membrane positions in the absence of unconventional sterols. The preceding companion study of Lawson et al. (10) is extended here to include the evaluation of cell membrane sterol content for two demosponges with widely divergent sterol compositions.

Pseudaxinyssa sp. presented an excellent example for study because more than 99% of the sterols in this sponge consist of two sterols of unconventional structures (11), each with a multi-branched side chain that results from a complex triple bioalkylation at C_{24} by the sponge (12, 13). These are 24-isopropylcholesterol (2) and its unsaturated counterpart 22-dehydro-24-isopropylcholesterol (1) (Fig. 1A). Furthermore, the minor sterols of this sponge also have novel structures that include cyclopropane (14), tert-butyl and 24-dialkylated sterols (15), and sterols with side chains that exhibit triple and quadruple methylations (16).

Reniera sp. provided an excellent example for comparison as preliminary studies (to be described here) established the sole presence of conventional-type sterols (Fig. 1B). Further, specimens of this sponge that are devoid of microorganism symbionts, as is described in the companion study (10), can be obtained.

EXPERIMENTAL

Sponge samples. Samples of *Reniera* sp. (order Haplosclerida, California Academy of Sciences Museum specimen #063176) and *Pseudaxinyssa* sp. (order Axinellida, Australian Museum specimen #Z4988) were those described in the companion paper (10).

Chemicals and materials. Cholesterol (Sigma Chemical Co., St. Louis, MO) was used for reference in high performance liquid chromatography (HPLC), gas chromatography (GC) and thin layer chromatography (TLC) analyses. TLC plates (silica coated aluminium, Kieselgel 60 F254, 0.2 mm, Merck Chemical Co., Darmstadt, Germany) were washed in diethylether before use. General laboratory reagents were purchased from Sigma or Aldrich (Milwaukee, WI) Chemical Companies, or May and Baker Pty. Ltd. Analytical grade solvents for lipid analysis were distilled before use.

Subcellular fractionation. Whole sponge tissue and tissue isolates were identical to those of the companion study (10) and were generated from the differential centrifugation subcellular fractionation of whole sponge homogenates at 600, 15,000 and 100,000 × g. The subcellular isolates included the pellets P1, P2 and P3 from these respective centrifugations. The cellular and subcellular contents of these pellets were determined by electron microscopy in the companion study (10).

Lipid analysis. Total lipid extracts were subsamples of extracts produced for the companion study (10). Sterols were isolated by column chromatography (Davisil 62 silica gel, elution with hexane/ether [2:1, v/v]). Individual sterols were isolated by reversed-phase HPLC (2 Altex Ultrasphere ODS columns [5 μ, 25 cm × 10 mm i.d.] connected in series; eluent = abs. methanol). Sterols were identified on the basis of relative retention times from GC (Hewlett-Packard model 5790 gas chromatograph; column 2 m × 0.5 mm i.d. OV-17/3% chromasorb; 260 C isothermal), mass spectra (Hewlett Packard 5970 series mass selective detector connected to a 5890A gas chromatograph; 12 m × 0.2 mm i.d. SE-30 fused silica column), and proton nuclear magnetic resonance spectroscopy (^{1}HNMR; 360 MHz Bruker HXS-360). Stereochemical assignments were made from interpretation of ^{1}HNMR spectra and comparison with spectra from earlier studies (17). Relative proportions of sterols were calculated from electronic integration (Hewlett Packard model 3392A integrator) of GC traces.

RESULTS

Pseudsaxinyssa sp. and *Reniera* sp. were found to contrast in the nature and quantity of sterols. As previously

[1]Part 59 of "Sterols in Marine Invertebrates." For Part 58 in this series, see Cho, J.-H., and Djerassi, C. (1987) *J. Org. Chem. 52,* 4517–4521.

*To whom correspondence should be addressed.

Abbreviations: GC, gas chromatography; HPLC, high performance liquid chromatography; LCFA, long chain fatty acids; TLC, thin layer chromatography.

reported (11), *Pseudaxinyssa* sp. contains two major sterols, 24-isopropylcholesterol (2) and its unsaturated counterpart 22-dehydro,24-isopropylcholesterol (1) (Fig. 1A), that account for more than 99% of the total sterols. In contrast, *Reniera* sp. contains 13 major (>0.5% total) sterols that apparently result from biosynthetically simple methylations at C_{24} and double bond introductions around C_{24} and C_{22} in the side chain of the parent animal sterol cholesterol (5) (Fig. 1B). Stigmasterol (12) and sitosterol (13), which are characteristic sterols of photosynthetic organisms (18), constitute 8.7% of the sterols in *Reniera* sp. (Fig. 1B); such sterols, however, may not be produced de novo by the sponge, but rather may be assimilated from a dietary source such as micro-algae.

The subcellular fractionation method employed produced fractions with the following compositions: P1, partially disrupted cells, collagen, nuclei and other large organelles (>2.8 μ diam.); P2, smaller organelles, and in the case of *Pseudaxinyssa* sp., large numbers of intact cyanobacteria; and P3, membrane vesicles and nonmembrane-bound protein and ribonucleic acid ribosomes (10).

The P3 membrane isolates must be regarded as multimembrane mixtures that could have contained both plasma and organelle membranes from the many cell types present, although the P3 isolates were likely enriched in archaeocyte plasma membrane and endoplasmic reticulum as discussed in the preceding paper (10). The P3 isolates were highly pure in the sense that they were devoid of lipidic, nonmembranous contaminants. Furthermore, there appeared to be little contamination of the P3 membrane isolates by symbiotic microorganisms:

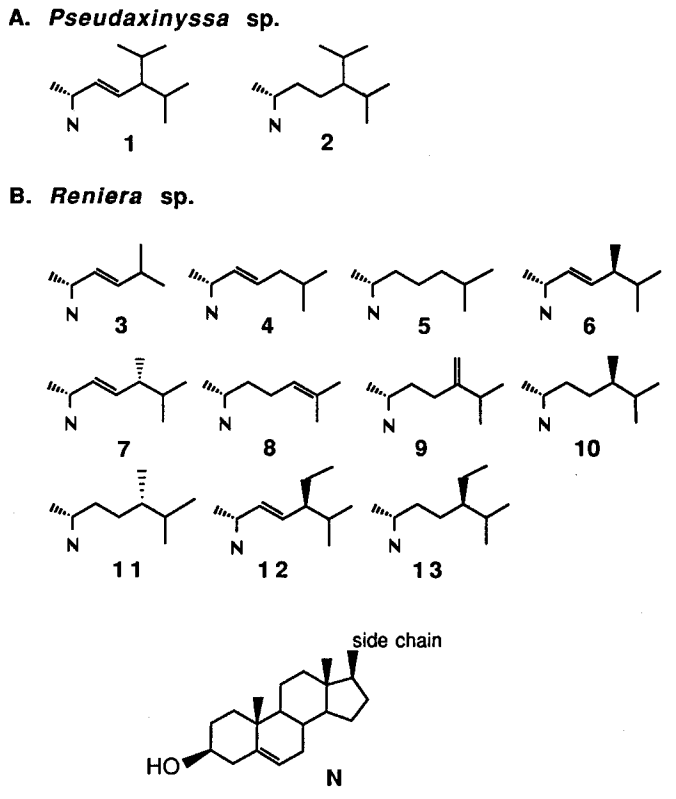

FIG. 1. Major sterols (>0.5%) of: A) *Pseudaxinyssa* sp. and B) *Reniera* sp.

whole *Reniera* sp. specimens contained essentially no microbial symbionts that could have contaminated the P3 isolates, while the cyanobacterial symbionts present in *Pseudaxinyssa* sp. appeared to remain intact during homogenization of the tissue and were largely isolated in the P2 fraction (10). Moreover, it is unlikely that bacteria, including cyanobacteria, would have interfered with sterol analyses as these microorganisms are not known to contain sterols within their plasma membrane (19–22).

The sterol compositions of both *Pseudaxinyssa* sp. and *Reniera* sp. P3 membrane isolates were virtually identical to those sterol compositions observed for whole sponges (Figs. 2 and 3), indicating that any extramembranous, stored sterols were either minor or present in similar proportions to that of the cell membranes. Thus, as has been noted with fatty acid content (10,23), the sterol content of whole sponges provides a valid indication of the sterol content of sponge cell membranes.

The compositions of the P1 and P2 isolates, like the P3 membrane isolate, also reflected the sterol composition of the respective whole sponges, although the mixed natures of these isolates allows no cellular or subcellular conclusions.

DISCUSSION

This study presents the first direct evidence of unconventional sterols occurring in sponge cell membranes, although we also have demonstrated that this is not a universal feature of the Porifera. It is rare for animals to contain sterols other than cholesterol (5) in their cellular membranes (24,25), while plants typically contain sterols with more than eight carbon atoms in the side chain (phytosterols including stigmasterol [12] and sitosterol [13] in higher plants and mycosterols including ergosterol in lower plants) (18).

However, there are a few eucaryotic organisms that substitute the conventional-type sterols of animals and plants with stereochemically similar molecules in their cell membranes (8,20,24,26,27). For example, the freshwater protozoan *Tetrahymena pyriformis* is devoid of membrane sterols and instead contains a sterol-like triterpenoid (tetrahymanol) (28) and in the mycoplasma *Acholeplasma laidlawii,* a low level of cholesterol in the membrane is compensated by a high content of carotenoids (29). In this study, we also see that the unusual membrane sterols 1 and 2 in *Pseudaxinyssa* sp. are stereochemically similar to cholesterol (5), possessing an identical nuclear ring system, a 3β-hydroxy group and a C_{17}-β-side chain alkylation.

Sponge membranes already are known to be unusual in other aspects of their lipid content. More than half of the fatty acids in cell membranes from three demosponges, including the species of *Pseudaxinyssa* and *Reniera* that are the subject of this investigation, consist of long chain C_{24}-C_{30} fatty acids (LCFA), that often exhibit distinctive Δ5,9 unsaturation (10,23), whereas conventional animal cell membranes usually contain fatty acids with chain lengths between C_{14} and C_{22} units (30).

However, there are no clear patterns of lipid content in sponges because unconventional sponge sterols do not always co-occur with LCFA (e.g., *Reniera* sp., this study), and different sponge species produce a heterogeneous and diverse array of fatty acid, sterol and sterol-like

molecules. Still, the most unusual structural features of sponge membrane lipids appear to reside deep within the lipophilic region of the phospholipid bilayer. However, there is indirect evidence that suggests that sponge membrane differences also extend to the hydrophilic regions of the phospholipid bilayer as an unusually high proportion of the amino group-containing phospholipids (phosphatidylethanolamine and phosphatidylserine) are present in sponges (31–33), in contrast with phosphatidylcholine in most animals (30). Further, in dictyoceratid and dendroceratid sponges, which either lack or contain minute amounts of sterols, a membrane role has been suggested for terpenoid sterol analogs (e.g., tetracyclic sesterterpenes) that are present in abundance (23).

The accepted general model for cellular membrane structure envisions a complementary system of sterol

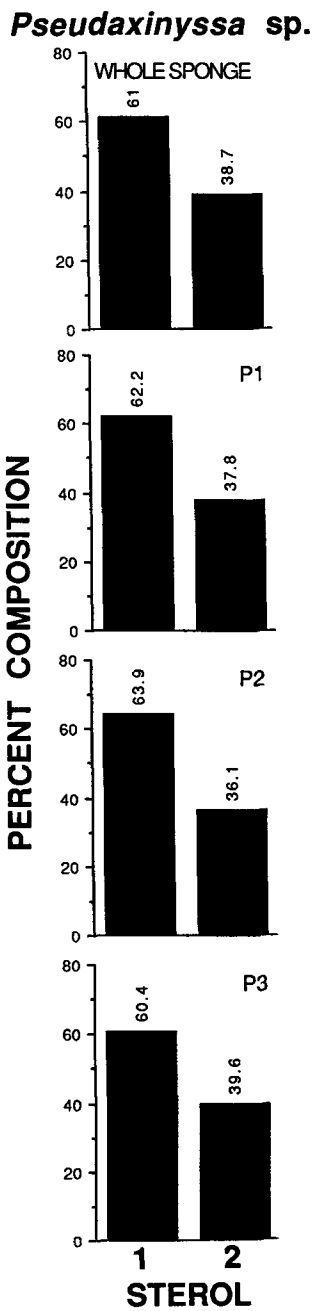

FIG. 2. Percent composition of total sterols present in whole sponge tissue and subcellular tissue isolates from *Pseudaxinyssa* sp. Subcellular fractions were P1, P2 and P3 (membrane isolate), which resulted from differential centrifugation at 600, 15,000 and 100,000 × g, respectively. Sterols are 22-dehydro-24-isopropylcholesterol (*1*) and 24-isopropylcholesterol (*2*) (Fig. 1).

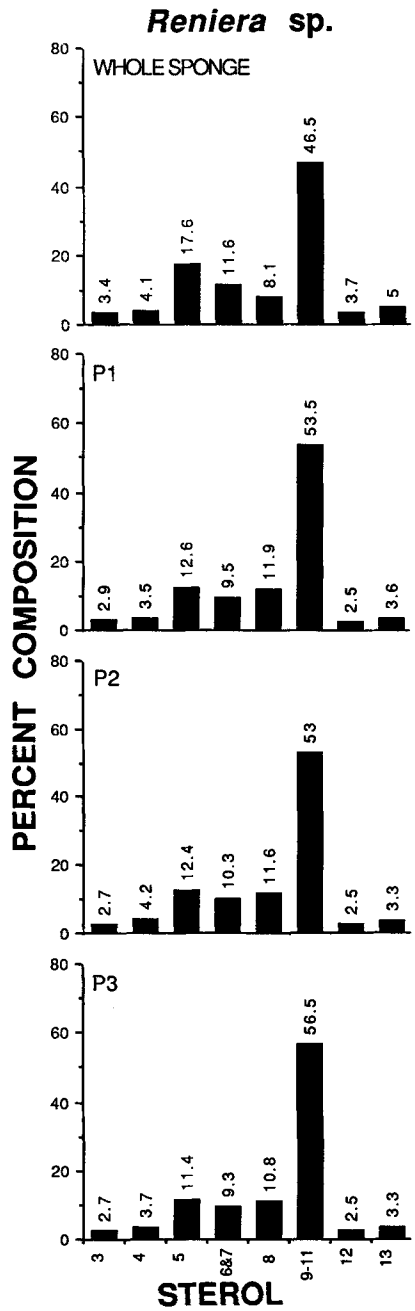

FIG. 3. Percent composition of total sterols present in whole sponge tissue and subcellular fractions of *Reniera* sp. Subcellular fractions, P1, P2 and P3 (membrane isolate), were obtained by differential centrifugation at 600, 15,000 and 100,000 × g, respectively. Sterols are 22-dehydro-24-norcholesterol (*3*), 22-dehydrocholesterol (*4*), cholesterol (*5*), crinosterol (*6*), brassicasterol (*7*), desmosterol (*8*), 24-methylenecholesterol (*9*), campesterol (*10*), dihydrobrassicasterol (*11*), stigmasterol (*12*), and sitosterol (*13*) (Fig. 1).

molecules intercalated between the fatty acyl chains of a phospholipid bilayer (34). In the same manner, our laboratory (5,9) has proposed that some unique structural features of sterols and fatty acids in sponges structurally complement each other in the cell membranes, although such interaction has yet to be demonstrated. For example, Walkup et al. (9) hypothesized that aplysterol, a C_{24} and C_{26} side chain alkylated sterol, might preferentially pair with monomethyl-branched or $\omega 7$ unsaturated fatty acid chains in the sponge *Aplysina fistularis;* however, more recent model membrane studies in our laboratory (35) with this sponge do not support such a hypothesis. It is likely that sponge membrane proteins contribute in an essential manner and the nature of these macromolecules is now under examination in our laboratory.

In addition to structural roles, membrane sterols also may modulate a variety of physiological regulatory processes (25,36), although it is unknown whether unconventional sponge sterols serve any such roles. It is tempting to speculate that the presence of unconventional sterols in sponges is related to some biological or ecological situation unique to sponges. For example, sponges are characterized by a unique cell-cell recognition system dependent on membrane-bound, proteinaceous aggregation factors (37). In addition, many sponges also contain large quantities of species-specific bacterial symbionts (38). Furthermore, as a group, sponges are capable of occupying virtually any aquatic environment, possibly varying membrane LCFA content within species-specific ranges according to environmental temperature (39).

Although sponges can be regarded as a very successful group by evolutionary terms, as they have been present at least since the mid-Cambrian, and there are over 5,000 extant species (37), the production of so-called primitive lipid molecules by sponges (e.g., the anaerobically formed terpenes and β-face demethylated sterols), together with the failure of the Porifera to give rise to evolutionarily more advanced lines, has resulted in sponges being regarded as a dead end branch of the phylogenetic tree (8). Still, the question remains unanswered why the Porifera evolved methods to produce, or assimilate from dietary sources, and perpetrate this range of complex molecules when more advanced animals rely on cholesterol and a narrower array of simpler fatty acids with chain lengths between C_{14} and C_{22} in their cell membranes.

The production of such unusual lipids by sponges may either be due to chance mutations in biosynthetic routes that did not affect species fitness or due to selection for particular cell membrane or physiological molecules (8). The first explanation might apply if the bulk structures of the lipid molecules fulfill a purely structural role in the cell membrane. The latter explanation might, however, apply if: 1) minor differences in the parent molecule's structure allowed improved structural (e.g., conformational alignment of membrane molecules) or functional membrane organization and/or 2) if modified sterols could serve some important nonmembrane functional role.

Of equal interest is whether sponges synthesize unusual membrane sterols and other lipids de novo. In some sponges, it has been observed that sterols cannot originate from de novo biosynthesis, but arise by modification of dietary sterols (40-43). This supports Bloch's (25) suggestion that marine invertebrates, regardless of whether they are sterol auxotrophs, appear to discriminate much less against dietary sterols with the result that their tissue sterol compositions show varying degrees of complexity. Goad (44) and Djerassi (6) have remarked that unusual sterols in sponges may be a result of sponge interaction with symbionts.

None of these questions can be answered, however, until sponge cellular and subcellular membrane lipid compositions are more carefully characterized as 1) sterol content is expected to vary widely from species to species and from one cell or intracellular membrane system to another based on studies of mammalian cells (45), and 2) different sponge cells and their subcellular membrane systems fulfill different functions (37). Studies that seek to characterize the sterol distributions of particular sponge cell types and their subcellular membrane systems are underway in our laboratory. In addition, we have undertaken studies with synthetic vesicles consisting of pure long chain fatty acid phospholipids to describe more fully the limits to structural and functional interactions and to determine the physical properties of unusual lipids in sponge membranes (35).

ACKNOWLEDGMENTS

We thank Fran Thomas for the preparation of electron micrographs, Robert Simoni for advice, Eser Ayanoglu and Mary Zimmerman for helpful discussions and guidance, and the Australian Institute of Marine Science for provision of facilities. This study was supported by the National Institutes of Health (Grants No. GM06840 and GM28352) and Hewlett-Packard Inc. (equipment grant).

[Received November 30, 1987; Revision accepted March 16, 1988]

Effects of 2-(2,4-Dimethylphenyl)indan-1,3-dione on Serum Lipoprotein and Lipid Metabolism of Rodents

Iris H. Hall*, Akula R.K. Murthy, Patricia A. Day and John Clavin
Division of Medicinal Chemistry and Natural Products, School of Pharmacy, University of North Carolina at Chapel Hill, NC 27599

2-(2,4-Dimethylphenyl)indan-1,3-dione was shown to be a potent hypolipidemic agent in rodents, lowering significantly both serum cholesterol and triglyceride levels at 20 mg/kg/day. The agent in vivo inhibited the enzymatic activities of ATP-dependent citrate lyase, acetyl-CoA synthetase, cholesterol-7-α-hydroxylase, acyl-CoA cholesterol acyl transferase, *sn*-glycerol-3-phosphate acyl transferase and phosphatidylate phosphohydrolase. Tissue lipid levels of liver and small intestine also were reduced by the agent. The rat serum lipoprotein lipid content was modulated by the drug, which should be favorable for the removable of cholesterol from peripheral tissue for conduction to the liver for clearance from the body. Low density lipoprotein (LDL) cholesterol levels were reduced after treatment, which suggests that the agent potentially reduces deposition of cholesterol in plaques. If chemotherapy for atherosclerosis is to be successful, then the high density lipoprotein (HDL) cholesterol level needs to be elevated more than 16% to 25%, the level produced by current hypolipidemic agents. 2-(2,4-Dimethylphenyl)-indan-1,3-dione offers a 75% increase in HDL cholesterol levels and a 30% reduction of LDL cholesterol levels with a suppression of de novo synthesis of lipids and a reduction of tissue cholesterol deposition.
***Lipids* 23, 755–760 (1988).**

The hypolipidemic activity of a series of N-substituted cyclic imides (1–4), i.e., phthalimide, 1,8-naphthalimide, diphenimide, glutarimide and saccharin, has been well-established in rodents. Further structure activity studies have demonstrated that 2-substituted indan-1,3-dione possesses potent hypolipidemic activity in mice (5). Of this series, the 2-(2,4-dimethyl-phenyl)indan-1,3-dione derivatives proved to be one of the more potent compounds of the series lowering serum cholesterol levels by 46% and serum triglyceride levels by 42% after 16 days dosing at 20 mg/kg/day i.p. to mice. The N-substituted cyclic imides were not HMG-CoA reductase inhibitors, rather they inhibited the enzymatic step in the early synthesis of cholesterol. Triglyceride synthesis was inhibited at the rate-limiting enzyme of the de novo synthetic pathway, i.e., *sn*-glycerol-3-phosphate acyl transferase and phosphatidylate phosphohydrolase (5). At this time, a more in-depth study was undertaken to examine the effects of this agent on lipid metabolism in rodents to establish if the agent is feasible for clinical use as a hypolipidemic agent against hyperlipidemic disease states and atherosclerosis. Specifically, the purpose of the investigation was to determine if 2-(2,4-dimethylphenyl)-indan-1,3-dione raised high density lipoprotein (HDL) cholesterol levels and lowered low density lipoprotein (LDL) cholesterol levels, a ratio that supposedly protects man against myocardial infarctions (6). Previous studies have shown that N-substituted cyclic imides did not modulate this ratio rapidly enough (1) to be effective in a clinical situation to treat atherosclerotic patients.

Abbreviations: HMG-CoA, 3-hydroxy-3-methyl-glutaryl-CoA; HDL, high density lipoprotein; LDL, low density lipoprotein; VLDL, very low density lipoprotein.

MATERIALS AND METHODS

Sources of compounds. 2-(2,4-Methylphenyl)indan-1,3-dione was synthesized by the procedure previously outlined (5), and the physical and chemical characteristics were consistent with those reported. Isotopes were purchased from New England Nuclear (Boston, MA). Substrates and cofactors were obtained from Sigma Chemical Co. (St. Louis, MO). Clofibrate was obtained from Ayerst Laboratories (New York, NY).

Antihyperlipidemic screens in normal rodents. Compounds were suspended in 1% carboxy methyl cellulose-water, homogenized and administered to CF_1 male mice (~25 g) intraperitoneally for 16 days. On days 9 and 16, blood was obtained by tail vein bleeding and the serum separated by centrifugation for three min. Sprague-Dawley rats (~300 g) were administered compounds at 20 mg/kg/day orally by intubation needle for 14 days. Blood samples were collected by tail vein bleeding on days 9 and 14. Control animals were administered 0.2 ml of 1% carboxy methyl cellulose as the vehicle and bled on the same days. All blood samples were collected between 8–9 a.m. Nonhemolyzed samples were used for the assays. The serum cholesterol levels were determined by a modification of the Liebermann-Burchard reaction (7). The triglyceride content was determined using the Bio Dynamic/bmc Triglyceride Kit, Boehringer Mannheim (Indianapolis, IN). Serum was also collected on day 16 for mice and on day 14 for rats.

Testing in hyperlipidemic mice. CF_1 male mice (~25 g) were placed on a commercial diet (U.S. Biochemical Corporation Basal Atherogenic diet) that contained butterfat (400 g), celufil (cellulose) (60 g), cholesterol (53 g), choline dihydrogen citrate (4 g), Wesson oil (40 g), sodium cholate (20 g), sucrose (223 g), vitamin-free casein (200 g) and total vitamin supplement for 10 days. After the cholesterol and triglyceride levels were assayed and observed to be elevated, the mice were administered test drugs at 20 mg/kg/day intraperitoneally for an additional 14-day period. Serum cholesterol and triglyceride levels were measured after 14 days of administration of the drugs.

Enzymatic studies. In vitro enzymatic studies were determined using 10% homogenates in 0.25 M sucrose + 1 mM EDTA, pH 7.2 of CF_1 mouse liver with 50–200 μM of test drug. In vivo enzymatic studies were determined using 10% homogenates of liver from CF_1 male mice obtained after administering the agents for 16 days at a dose of 20 mg/kg/day intraperitoneally. Acetyl-CoA synthetase (8) and adenosine triphosphate-dependent citrate lyase (9) activities were determined spectrophotometrically at 540 nm as the hydroxamate of acetyl-CoA formed after 30 min at 37 C. Mitochondrial citrate exchange was determined by the procedure of Robinson et al. (10,11) using

^{14}C-sodium bicarbonate (41 mCi/mmol) incorporated into mitochondria. ^{14}C-citrate was determined after incubating the mitochondrial fraction, which was loaded with labeled citrate and test drugs for 10 min. Then the radioactivity was measured in the mitochondrial and supernatant fractions of Fisher Scintiverse fluid using a Packard Scintillation counter and expressed as a percentage of the total counts. Cholesterol 7α-hydroxylase activity was determined by the method of Shefer et al. (12) using [1,2-^{3}H(N)]-cholesterol (54.8 mCi/mmol). Acyl cholesterol acyl transferase activity was determined using ^{14}C-oleic acid (50 mCi/mmol). Oleic acid was separated from cholesteryl esters on thin layer chromatography (TLC) silica gel eluted with ether (13). 3-Hydroxy-3-methyl-glutaryl-CoA reductase (HMG-CoA reductase) activity was measured using [1-^{14}C]acetyl-CoA (56 mCi/mmol) and a post-mitochondrial supernatant (9000 g $\times$ 20 min) incubated for 60 min at 37 C (14). The digitonide derivative of cholesterol was isolated and counted (15). Acetyl-CoA carboxylase activity was measured by the method of Greenspan and Lowenstein (16). Initially, the enzyme had to be polymerized for 30 min at 37 C, and then the assay mixture containing sodium ^{14}C-bicarbonate (41.0 mCi/mmol) was added and incubated for 30 min at 37 C with test drugs. *sn*-Glycerol-3-phosphate acyl transferase activity was determined with glycerol-3-phosphate [L-2-^{3}H(N)] (7.1 Ci/mmol) and the microsomal fraction of the liver (17). The reaction was terminated after 20 min, and the lipids were extracted with chloroform/methanol (2:1) containing 1% conc. HCl and counted. Phosphatidylate phosphohydrolase activity was measured as the inorganic phosphate released after 30 min from phosphatidic acid by the method of Mavis et al. (18). The released inorganic phosphate after development with ascorbic acid and ammonium molybdate was determined at 820 nm. Hepatic heparin-induced lipoprotein lipase activity was determined using the method of Chait et al. (19).

Liver lipid extraction. In CF_1 male mice that had been administered test drugs for 16 days, the livers were removed, and in Sprague-Dawley rats treated orally with the test drug 14 days, the liver, small intestine and 24-hr fecal samples were collected. A 10% homogenate in 0.25 M sucrose + 1 mM (ethylenedinitrilo)tetraacetic acid was prepared for each tissue. An aliquot (2 ml) of the homogenate was extracted by the methods of Folch et al. (20) and Bligh and Dyer (21), and the number of mg of lipid weighed. The lipid was taken up in methylene chloride and the cholesterol level (7), triglyceride levels (Bio-Dynamics/bmc Triglyceride Kit), neutral lipid content (22) and phospholipid content (23) were determined. Protein was determined by the method of Lowry et al. (24).

^{3}H-cholesterol distribution in rats. Sprague-Dawley male rats (~350 g) were administered the test compound for 14 days orally at 20 mg/kg/day. On day 13, 10 μCi of ^{3}H-cholesterol was administered orally to rats, and feces were collected over the next 24 hr. Twenty-four hr after cholesterol administration, the major organs were excised and samples of blood, chyme and urine were obtained. Homogenates (10%) were prepared of the tissues that were combusted (Packard Tissue Oxidizer) and counted (25). Some tissue samples were plated on filter paper (Whatman #1) dried and digested for 24 hr in 30% KOH at 40 C and counted. Results were expressed as dpm per total organ.

Plasma lipoprotein fractions. Sprague-Dawley male rats (~350 g) were administered the test compound at 20 mg/kg/day orally for 14 days. On day 14, blood was collected from the abdominal vein. Serum was separated from whole blood by centrifugation at 3500 rpm. Aliquots (9 ml) were separated by ultracentrifugation, according to the methods of Havel et al. (26) and Hatch and Lees (27) as modified for normal rats (28), into the chylomicrons, very low density lipoproteins (VLDL), HDL and LDL. Each of the fractions was analyzed for cholesterol, triglyceride, neutral lipids, phospholipids and protein levels.

Acute toxicity. The LD_{50} values were determined in CF_1 mice (~25 g) by administering test drug intraperitoneally from 100 mg/kg to 1 g/kg as a single dose. The number of deaths were recorded over a seven-day period for each group.

Animal weights and food intake. Periodic animal weights were obtained during the experiment and expressed as a percentage of the rat's weight on day 0. After dosing for 14 days with the test drug at 20 mg/kg/day, selected organs were excised, trimmed of fat and weighed. The food consumption was determined daily and expressed as gm/day/rat.

RESULTS

2-(2,4-Methylphenyl)indan-1,3-dione was shown to be a potent hypolipidemic agent in rodents. A dose response study in mice from 5 to 40 mg/kg/day i.p. demonstrated that the maximum lowering of serum cholesterol levels of 46% and the maximum lowering of serum triglyceride levels of 42% was achieved at 20 mg/kg/day i.p. for 16 days. At this same dose administered orally to rats, serum cholesterol levels were reduced 40% and serum triglyceride levels were reduced 48% after 14 days (Table 1). The agent was also found to be effective in diet-induced hyperlipidemic states in mice, where the serum cholesterol level was reduced 40% and serum triglyceride levels were reduced 25% at 20 mg/kg/day for 14 days (Table 1).

2-(2,4-Dimethylphenyl)indan-1,3-dione was shown to inhibit in vitro mitochondrial citrate exchange and ATP-dependent citrate lyase greater than 25% (Table 2). Acetyl-CoA synthetase activity was inhibited greater than 50% at all three concentrations of drug. HMG-CoA reductase, acetyl-CoA, carboxylase and heparin-induced lipoprotein lipase activities were not affected by the presence of the drug. Cholesterol-7α-hydroxylase and acyl cholesterol acyl transferase activities were inhibited in a concentration-dependent manner, with the latter enzyme being inhibited 81% at 200 μM. *sn*-Glycerol-3-phosphate acyl transferase and phosphatidylate phosphohydrolase activities were inhibited in a concentration-dependent manner with 200 μM, resulting in greater than 50% inhibition.

The in vivo effects of the agent on the identical enzyme activities demonstrated that the agent was a potent inhibitor of acetyl-CoA synthetase activity, i.e., greater than 50%, and ATP-dependent citrate lyase activity, i.e., greater than 60% (Table 3). HMG-CoA reductase activity was elevated for all four doses of the drug. Cholesterol-7α-hydroxylase activity was suppressed 44% at 40 mg/kg/day. Acetyl-CoA cholesterol acyl transferase activity

*P < 0.001.

was reduced 92% at 20 mg/kg/day. Acetyl-CoA carboxylase activity was also elevated by the drug from 10 to 40 mg/kg/day. *sn*-Glycerol-3-phosphate acyl transferase activity was reduced greater than 65% at 5 and 10 mg/kg of drug, but elevated 130% at 40 mg/kg/day. Phosphatidylate phosphohydrolase activity was suppressed by the drug in a dose-dependent manner with 65% inhibition at 40 mg/kg/day. Heparin-induced hepatic lipoprotein lipase activity was reduced 32% at 5 mg/kg and 25% at 20 mg/kg/day of drug.

When the lipid content in tissues was evaluated, mice dosed for 16 days showed a reduction in lipid content at all four doses employed (Table 4). Cholesterol and triglyceride contents were reduced at all doses. Neutral lipids demonstrated essentially no change after drug administration and phospholipid content was unchanged at all doses in mice (Table 4). Similar studies in rats treated with the agent at 20 mg/kg/day orally showed that lipid content was reduced in the liver and small intestine (Table 5). Cholesterol content was reduced 18% in the liver and 29% in the small intestine. Triglyceride content was reduced 49% in the liver and 28% in the small intestine of treated rats. Neutral lipids were suppressed 15% in the small intestine but not in the liver. Phospholipids were lowered in the small intestine by 28%. Protein content of the liver was reduced 13%. Fecal samples from treated rats demonstrated an 18% increase in cholesterol content.

Serum lipoproteins lipid content also was examined after treating rats for 14 days at 20 mg/kg/day. Cholesterol content was reduced 30% in the LDL fraction, whereas cholesterol content was elevated 75% in the HDL fraction and 114% in the chylomicron fraction. Triglyceride content was reduced 44% in the HDL fraction. Neutral lipid content was elevated 127% in the LDL and reduced 26% in the HDL fraction. Phospholipid content

was reduced 43% in the VLDL and 37% in the LDL fraction. The protein content of the LDL fraction was reduced 39% (Table 5).

^{3}H-Cholesterol distribution studies showed that after drug administration for 14 days to rats at 20 mg/kg/day orally, the tissue in tested animals demonstrated a slight increase in radioactivity content. The lungs, liver, reproductive organs, stomach, spleen and kidney demonstrated reductions in radioactive content after 14 days of drug administration. Elevations in radioactive content were observed in the small intestine (67%), large intestine (21%), feces (33%) and chyme (4%) (Table 6).

The organ weights of the treated animals demonstrated small reductions for most of the organs, compared with the control animals' weights. The adrenal weights were reduced in the treated animals, indicating no hypertrophy due to stimulated steroidiogensis or estrogen activity of the compound. The body weights of the rats after 14 days treatment did not differ significantly from the control rats. The food consumption was reduced 6% in the treated rats. The LD_{50} of 2-(2,4-dimethylphenyl)indan-1,3-dione was greater than 500 mg/kg/day i.p. in mice as a single dose.

DISCUSSION

The 2-(2,4-dimethylphenyl)indan-1,3-dione derivative demonstrated hypolipidemic activity at the low dose of 20 mg/kg/day. The compound was more effective than clofibrate, which lowers serum cholesterol levels 15% and serum triglyceride levels 25% at 150 mg/kg/day in rats (25). The indan-1,3-dione derivative was equally effective pharmacologically by both oral and intraperitoneal administration, lowering both cholesterol and triglyceride

levels greater than 40%. In this respect, the agent demonstrated a profile that has been shown to be fairly standard for N-substituted cyclic imides in rodents.

The 2-(2,4-dimethylphenyl)indan-1,3-dione derivative suppressed the activity of enzyme involved in the early cytoplasmic synthesis of cholesterol and fatty acids, i.e., acetyl-CoA synthetase and ATP-dependent citrate lyase. Liver HMG-CoA reductase activity was not inhibited, which also has been observed for other cyclic imides (1-5). The 2-(2,4-dimethylphenyl)indan-1,3-dione derivative was a potent inhibitor of acyl-CoA acyl transferase activity at 20 mg/kg/day, which is the enzyme responsible for the synthesis and deposition of cholesteryl esters in tissues. Suppression of this enzyme would effectively reduce cholesterol storage in tissues. The rate-limiting enzymes of the de novo synthesis of triglycerides also were inhibited. In particular, phosphatidylate phosphohydrolase activity was suppressed by 2-(2,4-dimethylphenyl)indan-1,3-dione in a dose-dependent manner.

Lipids removed from the blood compartment in treated animals were not deposited in the organs of the body. The lipid reduction was demonstrated by the ^{3}H-cholesterol distribution study as well as the chemical analysis of lipids in the liver and small intestine where cholesterol and triglyceride levels were significantly reduced by drug treatment. The studies also suggested that the drug may cause excretion of cholesterol via the bile into the feces, thus clearing blood cholesterol from the body by this mechanism.

Serum lipoprotein lipid analysis showed that LDL-cholesterol levels were reduced significantly and HDL-cholesterol levels were significantly elevated after two wk of drug administration. Triglyceride and neutral lipids were reduced in HDL fractions. The modulation of the HDL/LDL cholesterol to this favorable ratio allows lipid clearance from peripheral tissue, e.g., aorta plaques and reduction of tissue cholesterol deposition from LDL. Nevertheless, other cyclic imides, e.g., phthalimide and saccharin, did not achieve this desired ratio within the two-wk administration of the drug. This ratio is better than that achieved by clofibrate, niacin, cholestyramine, oxandrolase or probucol in human treatment in which HDL cholesterol content was maximally raised only 4% to 16%. Supposedly, high cholesterol content of HDL and low cholesterol content of LDL protects man against myocardial infarction (6). Thus, the 2-(2,4-dimethylphenyl)indan-1,3-dione may have promise as a potential agent to use in atherosclerosis for therapeutic use, because the lipoprotein cholesterol content is modulated to a more favorable content for lipid clearance from the body.

[Received December 7, 1987; Revision accepted April 18, 1988]

Reaction of Cholesterol 5,6-Epoxides with Simulated Gastric Juice

Gerhard Maerker*, Edwin H. Nungesser and Frank J. Bunick[1]
U.S. Department of Agriculture, Eastern Regional Research Center, 600 East Mermaid Lane, Philadelphia, PA 19118

Cholesterol 5α,6α-epoxide (α-epoxide) and cholesterol 5β,6β-epoxide (β-epoxide) were individually suspended in simulated gastric juice (pH 1.2) at 37 C, and their reaction was followed by gradient high performance liquid chromatography (HPLC) with flame ionization (FID) detection. Both epoxides reacted rapidly in the aqueous acid medium. The α-epoxide formed 6β-chlorocholestane-3β,5α-diol (α-chlorohydrin) and 5α-cholestane-3β,5,6β-triol (triol), while the β-epoxide formed 5α-chlorocholestane-3β,6β-diol (β-chlorohydrin) and triol. The isomeric chlorohydrins reacted further to form the triol. In mildly alkaline aqueous medium, each chlorohydrin reverted to the epoxide from which it was formed. The data suggest that both epoxides, which have been reported to have adverse health effects in animals, would be largely hydrolyzed in the stomach and to the triol, which also has been reported to have biological activity. The data further suggest that residual chlorohydrins surviving stomach residence can be expected to revert to epoxide in the more alkaline intestinal environment.
***Lipids 23,* 761-765 (1988).**

It is well-recognized that the exposure of cholesterol to oxidizing conditions gives rise to oxidation products (1), and many of these have been identified and now can be measured with some precision (2). A few of the major products of cholesterol oxidation have been reported to have adverse biological effects (3-12), and their implication in cardiovascular disease has been of concern. The possible adverse health effects of cholesterol oxidation products are highly relevant to food safety, because many cholesterol-containing foods are subjected to oxidizing conditions during various stages of processing, storage and/or preparation. Indeed, the problem may extend to foods that contain plant sterols, compounds that are closely related chemically to cholesterol and can be expected to give similar oxidation products, but this aspect has been studied only superficially.

The cholesterol oxidation products that have greatest relevance to food safety are the 5α,6α-epoxide, which has been reported to be carcinogenic and mutagenic (11) and the 3β,5α,6β-triol, which has been cited as being cytotoxic (6,9,10). The 5β,6β-epoxide also has recently been reported to be toxic (13), and because it is hydrated to form the triol at a faster rate than the 5α,6α-epoxide (14), its presence also must be considered pertinent to the food safety perspective.

The presence of cholesterol oxidation products in animal-derived foods has been reported with increasing frequency in recent years. Products that were reported to contain these cholesterol derivatives include heated tallow (15,16), dried egg preparations (17-21), butter and other dairy products (17,20,22-24), and other foods (17, 20,25,26). The documented existence of the 5,6-epoxides and of the triol in a large variety of foods raises the question of their fate upon ingestion.

Cholesterol 5α,6α-epoxide (α-epoxide) reacts with hydrochloric acid to give 6β-chlorocholestane-3β,5α-diol (α-chlorohydrin) (27,28). Similarly, cholesterol 5β,6β-epoxide (β-epoxide), on reaction with hydrochloric acid, yields 5α-chlorocholestane-3β,6β-diol (β-chlorohydrin) (28-31). Both chlorohydrins might be formed when mixtures of the isomeric cholesterol 5,6-epoxides are ingested. This paper reports a study of the reaction of the cholesterol epoxides with simulated gastric juice (pH 1.2) at 37 C.

EXPERIMENTAL

Materials and reagents. Cholesterol, 99+%, and α-epoxide were purchased from Sigma Chemical Co. (St. Louis, MO) and 5-cholestene-3β,25-diol was purchased from Research Plus, Inc. (Bayonne, NJ). β-Epoxide was prepared from cholesterol via 5α-cholestane-3β,5,6β-triol (triol) (32) and the corresponding triacetate (33) by the method of Chicoye et al. (34). Dulbecco's Modified Eagle Medium (high glucose) was purchased from Flow Laboratories (McLean, VA).

All solvents used were "distilled in glass grade" and for high performance liquid chromatography (HPLC) were degassed by vacuum filtration through a 0.2 μm filter. Water was double-deionized, glass distilled. Thin layer chromatography (TLC) plates, Silica Gel G and GHL (250 μ), were purchased from Analtech (Newark, DE).

Simulated gastric juice was prepared by diluting a solution of conc. HCl (0.82 ml, 12 M) and 0.411 g NaCl in distilled, deionized water to a total volume of 100 ml. The solution had a pH of 1.22. Phosphate buffer (pH 7.44) was a solution of monobasic potassium phosphate (KH_2PO_4, 0.5905 g) and dibasic sodium phosphate (Na_2HPO_4, 2.130 g) in 500 ml water.

PROCEDURES

Preparation of chlorohydrins: 6β-chlorocholestane-3β,5α-diol (3) (α-chlorohydrin). α-Epoxide (1) (501 mg) in a glass stoppered 500 ml Erlenmeyer flask was dissolved in ether (230 ml), and conc. HCl (125 ml) was added with cooling. The stoppered flask was allowed to stand at room temperature for 18 hr with magnetic stirring. After addition of 50 ml water and 50 ml ethyl acetate, the mixture was neutralized with 50% aqueous NaOH with cooling in ice to a pink phenolphthalein endpoint. The ether layer was separated, and the aqueous phase was extracted with 2 × 100 ml ethyl acetate. The combined organic phases were dried over anhydrous Na_2SO_4 and distilled on a rotary evaporator under aspirator vacuum to a dry residue (590 mg). The product was purified by semi-preparative HPLC using hexane/2-propanol (100:3, v/v).

Abbreviations: α-Chlorohydrin, 6β-chlorocholestane-3β,5α-diol; α-epoxide, cholesterol 5α,6α-epoxide; β-chlorohydrin, 5α-chlorocholestane-3β,6β-diol; β-epoxide, cholesterol 5β,6β-epoxide; triol, 5α-cholestane-3β,5,6β-triol; FID, flame ionization detector; GC, gas chromatography; HPLC, high performance liquid chromatography; TLC, thin layer chromatography.

5α-Chlorocholestane-3β,6β-diol (4) (β-chlorohydrin). The method used to prepare the β-chlorohydrin from the β-epoxide (2) was identical to that used for the α-chlorohydrin.

Reaction of epoxides with simulated gastric juice: cholesterol 5α,6α-epoxide (1). To a 100 ml three-neck flask, equipped with magnetic stirring bar and a thermometer to which a thermoregulator was attached, 75.0 ml of simulated gastric juice was added. The flask was set on a stirring hot plate, and the temperature of the solution was regulated at 37.0 ± 0.5 C with vigorous agitation. α-Epoxide (21.03 mg) dissolved in 2-propanol (1000 μL) was injected slowly (3 min) below the surface of the stirred aqueous solution by means of a 500 μL syringe, resulting in a cloudy suspension. Aliquots (5 ml) were withdrawn from the reaction mixture immediately after the injection was completed and at periodic intervals thereafter by use of a volumetric pipette. Each aliquot was placed in a 20 ml screw-top vial containing 5 ml of ethyl acetate and 1 ml of a solution of internal standard (568 μg 5-cholesten-3β, 25 diol in 1 ml ethyl acetate). Vigorous shaking of the aliquot mixture was followed by phase separation and additional extractions (3 × 5 ml ethyl acetate) of the aqueous layer. Combined extracts were dried over anhydrous Na_2SO_4 and evaporated to dryness under a stream of N_2. The dry residue was dissolved in 30 μL 2-propanol, and the resulting solution was diluted with 1000 μL hexane in preparation for HPLC analysis.

Cholesterol 5β,6β-epoxide (2). The procedure used was the same as that used for the α-epoxide.

Reaction of chlorohydrins with simulated gastric juice: 6β-chlorocholestane-3β,5α-diol (3) (α) (α-chlorohydrin). The α-chlorohydrin was somewhat less soluble in 2-propanol than the α-epoxide, and 1500 μL 2-propanol were required to dissolve 24 mg of the α-chlorohydrin. Otherwise, the procedure described for the reaction of α-epoxide with simulated gastric juice was followed in detail.

5α-Chlorocholestane-3β,6β-diol (4) (β-chlorohydrin). The procedure used was identical to that described for the reaction of the α-epoxide, except that 24 mg of β-chlorohydrin was dissolved in 600 μL 2-propanol for injection in the reaction flask. The β-chlorohydrin appeared to be much less soluble in the aqueous phase than either of the epoxides or the α-chlorohydrin and formed large particles in the water layer and deposits on the outside of the injection needle.

Measurement of stability of the α-chlorohydrin (3) and the β-chlorohydrin (4) in Dulbecco's Modified Eagle Medium (high glucose), pH 7.35. The procedure described for the reaction of the α-epoxide with simulated gastric juice at 37 C was followed in detail, except that the aqueous medium was Dulbecco's Modified Eagle Medium (high glucose) rather than simulated gastric juice. Each chlorohydrin (~24 mg) was injected into the medium in a separate experiment, and product analysis was performed as described.

Measurement of the stability of α-chlorohydrin (3) in phosphate buffer, pH 7.44. α-Chlorohydrin (21.1 mg) in 2-propanol (1500 μL) was injected into 75 ml of phosphate buffer at 36 C, and product isolation and measurement were carried out as described above for the reaction of α-epoxide in simulated gastric juice.

Gas chromatography (GC). Analyses were performed as described (14).

Liquid chromatography (HPLC). The instrumentation used, including a flame ionization HPLC detector, has been described (35). Normal phase separations were performed on a 3.9 mm × 30 cm, 10 μm μ-Porasil column (Waters Associate, Framingham, MA) at ambient temperature. Separations of the four compounds of interest were achieved with a gradient solvent system at a total flow rate of 1.5 mL/min. The mobile phase consisted of solvent A, which was hexane/2-propanol (100:3, v/v), and solvent B, which was 2-propanol. At injection and for 10 min thereafter, the mobile phase was 100% A. The solvent composition then was changed linearly over a period of 10 min to 50% A and 50% B, stayed at that composition for five min and then changed linearly over a period of five min to 100% A to reach the starting point for the next analysis.

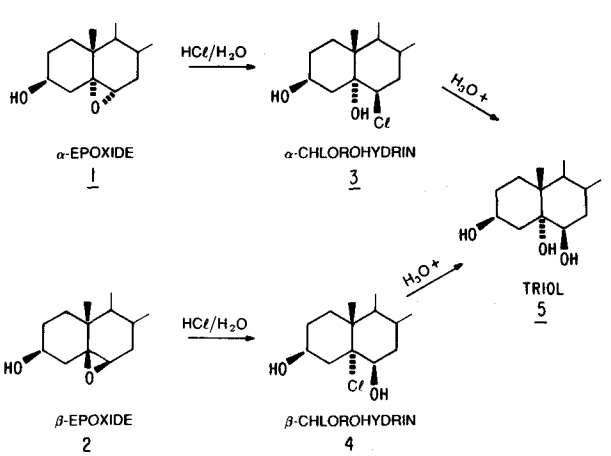
Thin layer chromatography. Before use, plates were washed by development with chloroform:methanol (2:1, v/v) and activated overnight in an air oven at 110 C. Spotted samples were developed with benzene:ethyl acetate:acetic acid (60:40:1, v/v/v). Air-dried plates were sprayed lightly with 50% sulfuric acid, placed on an unheated hot plate and gradually warmed to produce maximum color display of the cholesterol oxidation products, followed by complete charring at 220 C.

RESULTS AND DISCUSSION

Addition of hydrogen chloride to α-epoxide (1) and to β-epoxide (2) gave α-chlorohydrin (3) and β-chlorohydrin (4), respectively (Scheme 1).

Observation of the progress of the reaction in simulated gastric juice required analytical means to distinquish between the three expected components of these mixtures and to measure their concentrations. The components of interest were the epoxide and its corresponding chlorohydrin as well as triol (5).

The α-epoxide and its chlorohydrin were not resolvable by TLC with any of the several developing solvents tried. They gave single peaks by isocratic, normal phase HPLC and by capillary GC with or without prior silylation. Gradient, normal-phase HPLC gave excellent resolution of the three compounds of interest and the internal standard, 25-hydroxycholesterol (Fig. 1), with the use of a



SCHEME 1

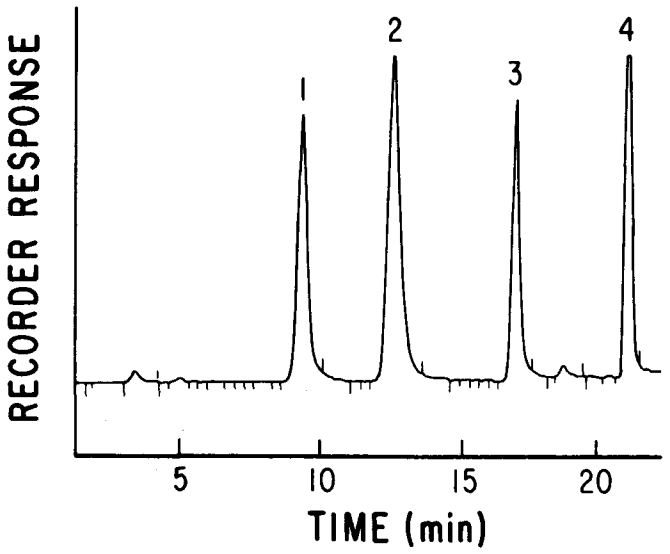


FIG. 1. Gradient HPLC of a four component mixture with FID detection (see Experimental). Peaks: (1) 5-cholestene-3β, 25 diol, (2) cholesterol 5α,6α-epoxide, (3) 6β-chlorocholestane-3β, 5α-diol, (4) 5α-cholestane-3β,5,6α-triol.

FID. The initial mobile phase was hexane/2-propanol (100:3, v/v) the polarity of which was increased linearly with 2-propanol. Response factors and linearity of response over a concentration range of 100 μg-0.39 μg per 100 μL were determined as reported (35) and permitted measurement of the relative concentrations of the components in the mixture from their area counts.

The β-epoxide and its chlorohydrin were readily resolved by TLC but not by GC. The gradient, normal-phase HPLC procedure developed for the α-epoxide and derived compounds was used without change to analyze mixtures of β-epoxide, β-chlorohydrin and triol, again with 25-hydroxycholesterol as internal standard.

Human gastric juice contains a variety of organic and inorganic constituents. The current study was confined to a simulated gastric juice consisting of an aqueous solution of hydrochloric acid and sodium chloride that approximates the concentration of these components in stimulated human gastric juice (36). A comparison of the cited composition and that of the present study is shown in Table 1.

Injection of the substrates (either of the two epoxides or either of the two chlorohydrins) into the vigorously stirred simulated gastric juice at 37 C was carried out slowly to minimize particle size of the resulting suspensions. Nevertheless, individual suspended particles were clearly visible and did not appear to change during the course of the reaction. Concentrations of the substrate in 75 ml reaction medium were chosen so that injection of 100 μL of an extract of each 5 ml aliquot produced a sizable signal on the HPLC-FID detector.

In early experiments, each 5 ml aliquot removed from the reaction mixture was immediately neutralized with concentrated sodium hydroxide to a phenolphthalein endpoint before the mixture was extracted with ethyl acetate. It was discovered, however, that this led to erroneous product compositions. Because the chlorohydrins are highly sensitive to base that converts them to epoxides, fleeting

local concentrations of base during the neutralization procedure gave unrealistically high concentrations of epoxides and low concentrations of chlorohydrins in these aliquots of the reaction mixture. The same sensitivity to base accounts for the presence of low concentrations of α-epoxide in the synthesized α-chlorohydrin where a neutralization step also is involved (see Experimental). The β-chlorohydrin is somewhat less sensitive to base-catalyzed dehydrohalogenation, so the synthesized β-chlorohydrin could be obtained free of contaminating β-epoxide. In the experiments reported here, neutralization with base before extraction was avoided (see Experimental).

The course of the reaction of the α-epoxide in simulated gastric juice is shown in Figure 2.

During the first two hr, the α-epoxide concentration decreased to less than 15%, and after four hr its concentration was less than 4%. Most foods are considered to have a residence time of two to four hr in the stomach (37). While the α-epoxide concentration decreased, the α-chlorohydrin concentration reached a maximum after about one hr and then decreased. Meanwhile the triol concentration increased steadily. The simultaneous decrease of the α-epoxide and the α-chlorohydrin accompanied by a steady increase in triol led to the expectation that a substantial portion of the α-chlorohydrin reacted further in the acid, aqueous medium to form triol. To test this

[a]The same triol is formed from both chlorohydrins.

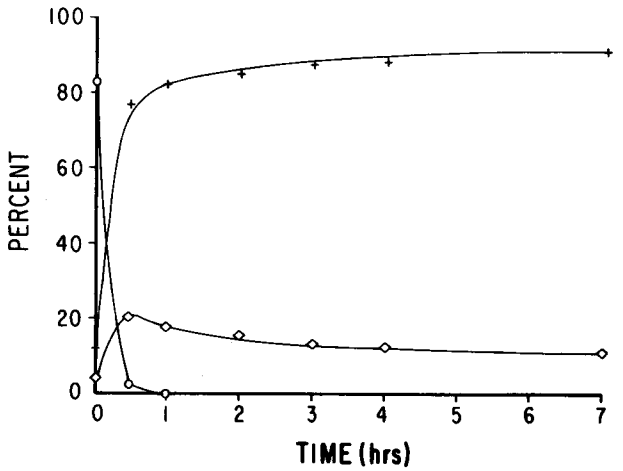

FIG. 3. Reaction of cholesterol 5β,6β-epoxide (β-epoxide) in simulated gastric juice 37 C. (○) β-epoxide, (□) β-chlorohydrin, (+) triol.

hypothesis, α-chlorohydrin was suspended in simulated gastric juice at 37 C. Results are shown in Table 2. It is apparent from these data that the α-chlorohydrin was indeed converted rather rapidly to triol. The small amount of α-epoxide that was present in the starting material as an impurity, was also mostly converted to triol. This latter conversion probably occurs via the α-chlorohydrin and directly, as well.

Exposure of the β-epoxide to the action of simulated gastric juice at 37 C caused a very rapid disappearance of epoxide from the mixture, as shown in Figure 3. The β-chlorohydrin peaked at only 1/2 hr into the experiment after it had reached the 20% level and then tapered off gradually, while the triol concentration rose steeply during the first hour. These data seem to indicate that much of the β-epoxide is converted directly to triol without the intermediacy of the β-chlorohydrin. The rapid hydration of the β-epoxide at pH 5.5 had been observed and measured earlier (14). Exposure of the β-chlorohydrin to simulated gastric juice at 37 C (Table 2) confirmed that the hydrolysis of the β-chlorohydrin was much slower than that of the α-chlorohydrin.

TABLE 3

Stability of Chlorohydrins in Growth Medium (pH 7.35)[a] at 37 C

24.0	46.8	47.3	50.3	49.8	2.9	2.9

Stability of the isomeric chlorohydrins to mildly alkaline aqueous media is of concern, if their physiological activity is to be measured. Each of the chlorohydrins separately was placed into Dulbecco's Modified Eagle Medium (high glucose), which had a measured pH of 7.35. Results are shown in Table 3. It is clear that both chlorohydrins were converted to their respective epoxides at a very significant rate in this mildly alkaline medium. The conversion rate of the α-chlorohydrin appeared to be somewhat more rapid than that of the β-chlorohydrin, and surprisingly, a small amount of the latter was hydrolyzed to triol. Because this growth medium is a complex mixture of organic and inorganic ingredients, it was desirable to test the question whether dehydrohalogenation of the chlorohydrins was due to pH or possibly due to one or more of the components of the medium. Some of the α-chlorohydrin was suspended in phosphate buffer (pH 7.44) at 37 C, and the composition of the mixture was analyzed. The results are shown in Table 4 where the data at pH 7.35 (growth medium) and pH 7.44 (phosphate buffer) are compared. The similarity of the data in the two media confirms that the effect is due to pH rather than an ingredient of the growth medium. The comparison also serves as an indication of the reproducibility of the analytical procedure used in these experiments.

Dietary Manipulation of Macrophage Phospholipid Classes: Selective Increase of Dihomogammalinolenic Acid

Robert S. Chapkin*, Scott D. Somers and Kent L. Erickson
Department of Human Anatomy, School of Medicine, University of California, Davis, CA 95616

Because alterations in the dietary content of fatty acids are an important method for modulating macrophage eicosanoid production, we have quantitated the levels of n-6 and n-3 polyunsaturated fatty acids in peritoneal macrophage individual phospholipids from mice fed diets (3 wk) with either safflower oil (SAF), predominantly containing 18:2n-6, borage (BOR) containing 18:2n-6 and 18:3n-6, fish (MFO) containing 20:5n-3 and 22:6n-3, and borage/fish mixture (MIX) containing 18:2n-6, 18:3n-6, 20:5n-3 and 22:6n-3. Dietary n-3 fatty acids were readily incorporated into macrophage phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS) and phosphatidylinositol (PI). The increase in n-3 fatty acid levels was accompanied by a decrease in the absolute levels of 18:2n-6, 20:4n-6 and 22:4n-6 in PC, PE and PS. Interestingly, PI 20:4n-6 levels were not significantly lowered ($P > 0.05$) in MIX and MFO macrophages relative to SAF and BOR. These data demonstrate the unique ability of this phospholipid to selectively maintain its 20:4n-6 levels. In BOR and MIX animals, 20:3n-6 levels were significantly increased ($P < 0.05$) in all phospholipids relative to SAF and MFO. The combination of borage and fish oils (MIX diet) produced the highest 20:3n-6/20:4n-6 ratio in all phospholipids. These data show that the macrophage eicosanoid precursor levels of 20:3n-6, 20:4n-6 and n-3 acids can be selectively manipulated through the use of specific dietary regimens. This is noteworthy because an increase in phospholipid levels of 20:3n-6 and 20:5n-3, while concomitantly reducing 20:4n-6, may have therapeutic potential in treating inflammatory disorders. *Lipids 23,* **766–770 (1988).**

Macrophages are a highly diverse population of cells capable of executing or modifying a number of important biological functions. Because of their abundance, distribution and versatility, macrophages can influence almost every aspect of the immune and inflammatory responses (1). Because macrophages contain high levels of arachidonic acid (20:4n-6) in their phospholipids, it is likely that macrophage-derived eicosanoids are involved in inflammation and cellular regulation (2). In addition, the eicosanoids also may play an important role in the autoregulation of several macrophage functions (3–6).

It is well-established that alterations in the dietary content of fatty acids are an important method for modulating eicosanoid production because, in general, eicosanoid biosynthesis is dependent upon the size of the fatty acid precursor pool(s) (7,8). In earlier studies (9), we have demonstrated that fish oil feeding qualitatively increases murine peritoneal macrophage total phospholipid levels of eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), while borage oil, containing linoleic acid (18:2n-6) and γ-linolenic acid (18:3n-6), increases the macrophage dihomo-γ-linolenic acid (20:3n-6) to 20:4n-6 ratio. This is noteworthy because the manipulation of eicosanoid precursor levels of 20:3n-6, 20:4n-6 and 20:5n-3 could potentially attenuate the phlogistic response (10–12).

Previous studies have proposed different classes of phospholipids as sources of eicosanoid fatty acid precursors (13,14). Therefore, the distribution of n-3 and n-6 fatty acids among individual phospholipids in macrophages may be important in determining the quantitative release of these potential eicosanoid antecedents (14). As yet, no attempt has been made to quantitate macrophage individual phospholipid fatty acid levels following borage or borage/fish oil feeding. The purpose of the present work was to quantitate the levels of n-6 and n-3 polyunsaturated fatty acids in peritoneal macrophage individual phospholipids from mice fed either safflower oil (SAF) predominantly containing 18:3n-6, borage oil (BOR) containing 18:2n-6 and 18:3n-6, menhaden fish oil (MFO) containing 20:5n-3 and 22:6n-3, and borage/fish oil mixture (MIX) containing 18:2n-6, 18:3n-6, 20:5n-3 and 22:6n-3.

MATERIALS AND METHODS

Materials. Fatty acid methyl ester standards were from NuChek Prep. (Elysian, MN). Diheptadecanoyl-L-alpha-phosphatidylcholine was from Sigma Chemical Co. (St. Louis, MO). Silica gel 60 plates were from E. Merck (Darmstadt, FRG). The dietary oils were from: safflower, California Oils (Richmond, CA); borage, Traco Labs (Champaign, IL); and menhaden fish oil, Zapata-Haynie (Reedville, VA). ACS-grade organic solvents were from Fisher Scientific (Chicago, IL).

Animals and dietary treatments. Pathogen-free female C57BL/6NCR mice (Charles River, Wilmington, MA), weighing 15–20 g were used. All mice had been fed a commercial pelleted mouse diet (Ralston-Purina, St. Louis, MO) and were housed (6–8 animals per cage) in autoclaved cages with laminar flow hoods to minimize spontaneous macrophage activation (15). On day zero of the experiment, the mice were randomly assigned to one of four purified diets for three wk. The diet varied only in the type of oil fed, i.e., either safflower, borage, fish or borage/fish mixture in a 2.5/7.5 ratio at 10% of the diet by weight. All dietary components were purchased from ICN Nutritional Biochemicals (Cleveland, OH), except where noted. The basic compositions of the purified diet by weight was casein, 20%; DL-methionine, 0.3%; corn starch, 15%; sucrose, 44%; cellulose, 5%; mineral mix, 3.5% (16); vitamin mix, 2.0% (16); choline chloride, 0.2%; and the appropriate dietary oil, 10%. The fatty acid composition of the different dietary oils are shown in Table 1. The diets were adequate in all nutrients, except MFO, which was deficient in 18:2n-6 (17). A diurnal light cycle of 12 hr was maintained, and food and autoclaved water were available ad libitum. The powered diets were mixed and stored under nitrogen at −20 C. Fresh diet was provided daily to each group to minimize auto-oxidation. Diets were

22:6n-3	tr	tr	6.2	7.8

Results are expressed as mg/100 mg total fatty acids present. Only the major fatty acids are presented. tr, Trace amounts, less than 0.1%.

periodically checked by determination of the fatty acid composition. The profiles did not vary significantly in the diets over the three-wk feeding period. Body weights were recorded weekly, and the food intakes of the diets were diurnally monitored and not found to be significantly ($P > 0.05$) different (data not shown).

Macrophage cultures. Mice were injected intraperitoneally with 2 ml of thioglycollate broth (Difco, Detroit, MI) prepared to manufacturer's specification, three days before killing. Primary cultures of peritoneal macrophages were established from responsive cells as described (18).

Lipid analysis. Macrophage monolayers were scraped from the culture dish in 3 ml of chilled methanol and extracted by the method of Folch (19). All solvents contained 0.01% butylated hydroxytoluene to prevent oxidative breakdown. The individual phospholipids were separated by thin layer chromatography (TLC) on silica gel 60 plates using chloroform/methanol/acetic acid/water (50:37.5:3.5:2, v/v/v/v) (20). The purified phospholipids so obtained represented 90.3 ± 1.4% (mean ± SEM, n = 13) of the phospholipid present in the original total lipid extract as judged by recovery of radioactivity from endogenously labeled phospholipid from mouse peritoneal macrophages. Bands were detected under ultraviolet light after spraying with 0.2% 2′,7′-dichlorofluorescein in ethanol. A known concentration of diheptadecanoyl-L-alpha-phosphatidylcholine as an internal standard was added to the isolated phospholipids before transmethylation (21,22). The resultant fatty acid methyl esters (FAME) were further purified on silica gel 60 plates run in a benzene solvent system and detected by dichlorofluorescein. The corresponding FAME bands were scraped and extracted using 2 ml methanol, 2 ml petroleum ether and 1 ml water. The concentration and fatty acid composition of the isolated phospholipids were determined after gas chromatographic analysis of the derived FAME as described (21,22). Replicate cell monolayers were solubilized in 0.1 M sodium hydroxide for protein determination using a modified Lowry method (23) with bovine serum albumin as the standard. Data were subjected to one-way analysis of variance using multiple comparisons, with the upper level of significance chosen at $P < 0.05$.

RESULTS

The data in Table 1 show that the four diets differed dramatically in the relative percentage of n-6 fatty acids (18:2n-6 and 18:3n-6) and n-3 fatty acids (20:5n-3 and 22:6n-3). BOR contained 26% by weight 18:3n-6, while this fatty acid represented less than 1% of the total acids present in either SAF or MFO diets. MFO was characterized by its content of 20:5n-3 (15%) and 22:6n-3 (8%). As expected, the MIX diet contained a blend of 18:2n-6 (11%), 18:3n-6 (7%), 20:5n-3 (12%) and 22:6n-3 (6.2%) as the major polyunsaturated fatty acids. No differences ($P > 0.05$) between the diets were noted with respect to the numbers or relative proportions of resultant peritoneal exudate populations after thioglycollate injection (data not shown). The effects of SAF, BOR, MIX and MFO supplementation on macrophage individual phospholipid fatty acid composition are shown in Tables 2–5. BOR and MIX feeding consistently increased 20:3n-6 levels ($P < 0.05$) relative to SAF and MFO in phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS) and phosphatidylinositol (PI). PC and PE contained the highest absolute levels of 20:3n-6. Although the macrophage PI 20:3n-6 concentration was significantly increased after feeding 18:3n-6 rich diets, the relative increment was smallest among the phospholipids examined (Table 5). Interestingly, 18:3n-6 was not detected in PC, PE, PS and PI from mice fed BOR and MIX. These results are consistent with our earlier findings (9), in which 18:3n-6 was not detected in macrophage total phospholipids in mice fed BOR. Levels of 20:5n-3, 22:5n-3, and 22:6n-3 were significantly higher ($P < 0.05$) in PC, PE, PS and PI in MFO and MIX macrophages. The increase in the n-3 fatty acid levels was accompanied by a decrease in the absolute levels of 18:2n-6, 20:4n-6 and 22:4n-6 in PC, PE and PS. In contrast, PI 20:4n-6 was not significantly lowered ($P > 0.05$) in MIX and MFO diets relative to SAF and BOR. The present study also demonstrates that 22:4n-6 is a major polyenoic acid in SAF and BOR PC, PE and PS. Only trace amounts of 22:4n-6 were observed in PI.

Figure 1 shows the 20:3n-6/20:4n-6 ratios in macrophage individual phospholipids. BOR and MIX diets,

each containing 18:3n-6, significantly increased ($P < 0.05$) PC, PE, PS and PI 20:3n-6/20:4n-6 ratios relative to SAF and MFO. Interestingly, the combination of BOR and MFO oils, i.e. MIX diet, produced the highest ratios of 20:3n-6/20:4n-6. The MIX ratios in decreasing order were PS, 1.62 ± 0.12; PC, 0.56 ± 0.04; PE, 0.23 ± 0.02; and PI, 0.21 ± 0.05. Although MIX PC, PE and PS 20:3n-6 levels were lower than BOR, 20:4n-6 levels were competitively reduced through substitution by n-3 fatty acids.

DISCUSSION

We have demonstrated that the total phospholipid fatty acid profile of mouse peritoneal macrophages can be dramatically manipulated by BOR and MFO feeding (9). The data suggested that 20:3n-6 and 20:5n-3, normally found in much smaller amounts than 20:4n-6 in cellular phospholipids and therefore not considered to be major precursors for eicosanoid formation in the macrophage, could following dietary manipulation serve as important substrates for the cyclooxygenase and lipoxygenase enzymes (10,11,24). However, to date, detailed studies documenting the ability of BOR or borage/fish (MIX) dietary manipulation to change macrophage individual phospholipid fatty acid concentrations (μg/mg protein) are lacking. The present study includes such an examination, focusing on the nebulous relationship of BOR and MIX feeding on quantitative fatty acid changes in mouse peritoneal macrophages.

The data presented demonstrate that dietary n-3 fatty acids were readily incorporated into macrophage PC, PE, PS and PI. The increases in 20:5n-3 and 22:6n-3 were associated with a concomitant reduction in PC, PE and PS 20:4n-6 levels. These results are consistent with previous macrophage n-3 feeding studies (25,26). Interestingly, PI 20:4n-6 levels were not significantly lowered in MIX and MFO macrophages relative to SAF and BOR. Unfortunately, there are no analogous quantitative data on macrophage PI with which to compare the present results. The inability of BOR, MIX or MFO to influence 20:4n-6 levels in PI demonstrate the unique ability of this phospholipid to selectively maintain its polyunsaturated fatty acid composition. The retention of 20:4n-6 in macrophage PI is of interest because it is a major eicosanoid precursor (27). In addition, the accumulation of n-3 fatty acids in PC, PE, PS and PI is noteworthy because n-3 fatty acid-enriched macrophages secrete reduced amounts of 20:4n-6-derived eicosanoids (25,26).

Comparison of the fatty acid composition of macrophage phospholipids in mice fed 18:3n-6 rich diets (BOR, MIX), showed that 20:3n-6 levels were significantly increased in PC, PE, PS and PI, relative to SAF and MFO. The fatty acid profile changes following BOR and MIX feeding, specifically the absence of 18:3n-6 and the elevated 20:3n-6/20:4n-6 ratios, support our earlier in vitro observations in which the presence of an active long chain elongase and modest Δ5 desaturase activities in the peritoneal macrophage were documented (18,24). The selective accumulation of 20:3n-6 is of particular interest because this fatty acid can serve as a precursor for the biosynthesis of the 1-series prostaglandins (8) that possess antiphlogistic properties (11,28).

The combination of 18:2n-6, 18:3n-6, 20:5n-3 and 22:6n-3 (MIX diet), produced the highest 20:3n-6/20:4n-6 ratio in all phospholipids, relative to SAF, MFO and BOR diets. These data are consistent with earlier studies (29,30), in which n-3 fatty acids were shown to inhibit the Δ5 desaturation of 20:3n-6 to 20:4n-6. In addition, the reduction in the absolute levels of 18:2n-6, 20:4n-6, and 22:4n-6 in MIX and MFO PC, PE and PS, also demonstrates the ability of n-3 fatty acids to competitively reduce n-6 fatty acid levels through substitution. Although only a single MIX treatment of borage and fish oil was examined, the results suggest that the 20:3n-6/20:4n-6 levels can be significantly manipulated through combined oil feeding. Therefore, it is possible to markedly increase the macrophage phospholipid levels of 20:3n-6, an eicosanoid precursor with antiphlogistic potential, while concomitantly reducing 20:4n-6, whose oxidative metabolism via the cyclooxygenase and lipoxygenase pathways plays a role in inflammation.

In summary, data from this study demonstrate that the peritoneal macrophage eicosanoid precursor levels of

20:3n-6, 20:4n-6, and n-3 acids can be selectively manipulated through the use of specific dietary regimens. This possibility underscores the need for further experimentation in elucidating the potential of these alterations to attenuate the phlogistic response.

[Received February 18, 1988; Revision accepted April 11, 1988]

Lipid Abnormalities in Pancreatic Tissue of Streptozotocin-induced Diabetic Rats

Emile Levy, Claude C. Roy, Guy Lepage and Moise Bendayan*
Departments of Nutrition, Anatomy and Gastroenterology, University of Montreal and Research Center, Ste-Justine Hospital, Montreal, Quebec, Canada

Pancreatic lipid and fatty acid composition was determined in streptozotocin-induced diabetic rats and compared to control and insulin-treated diabetic rats. A pronounced decrease of total fatty acids was recorded and mainly accounted for by a drop of fatty acids in glycerides. Cholesterol, on the other hand, was significantly increased two- to three-fold, leading to an elevated cholesterol/phospholipid ratio. Morpho-cytochemical studies confirmed these findings because the multiple lipid droplets present in acinar cells of diabetic animals were found to be of cholesterol nature. The major alterations in phospholipid-fatty acid composition were characterized by an increase of linoleate coupled to a decrease of monounsaturates and arachidonate, suggesting defective metabolism of saturates and of linoleate. This was further supported by fatty acid ratios that suggested low Δ5 and Δ9 desaturation. Daily administration of insulin for 10 days restored and overcorrected the various lipid alterations. This study suggests that there are alterations in lipid composition and metabolism in the exocrine pancreas of chronic streptozotocin-induced diabetic rats. Their possible role in the mechanism regulating pancreatic function and secretion remains to be elucidated. ***Lipids 23,*** **771-778 (1988).**

Modifications in the secretory activity of the exocrine pancreas have been reported in diabetic humans (1-3), as well as in experimental diabetic animals (4-9). In addition, frequent lesions such as generalized fatty degeneration of the acini are pancreatic histologic changes characteristic of both latent and overt diabetes (10-12). Earlier studies suggested that these alterations, and the impairment of amylase secretion in particular, result from the disturbance of the high insulin supply to the acinar cells by the islet-acini portal system (9,13-15).

Diabetes is commonly associated with increased levels of all plasma lipids (16,17). This hyperlipidaemia reflects more of an increase of the saturated and monounsaturated than of the polyunsaturated fatty acids (18). Recently, attention has been drawn to similar lipid abnormalities in different tissues such as heart, liver, testes and intestine of diabetic animals (19-21). The decrease in the relative proportion of the polyunsaturated fatty acids, mainly arachidonic acid, was determined in these tissues and was found to result from an impairment of desaturation activity. The changes in lipid composition might affect the morphological and functional integrity of the pancreas in diabetes (20,22), an observation that has been established for testes and seminal vesicles (20).

The present studies were designed to investigate the effect of streptozotocin-induced diabetes on the lipid and fatty acid profile of the pancreas of diabetic rats. By means of fatty acid ratios, the capacity of the tissue to elongate and desaturate fatty acids was evaluated. Furthermore, pancreatic tissue was studied by a morphological-cytochemical approach. Finally, the ability of insulin to normalize the biochemical and morphological changes was examined.

MATERIALS AND METHODS

Animals. The experiments were performed on male Sprague-Dawley rats weighing 100 g at the beginning of the experiment. Diabetes in 12 rats was induced by i.v. injection of 50 mg/kg body wt of streptozotocin (Boehringer Mannheim, Quebec, Canada) freshly dissolved in 10 mmol/l sodium citrate (pH 4.5). Six control rats were given the vehicle alone. The animals had been maintained on a standard laboratory chow and tap water ad libitum for three months. A group of six streptozotocin-injected animals demonstrating both hyperglycemia and glucosuria were treated with a daily injection of insulin (NPH, Connaught Laboratories, Ontario, Canada; 8 U/day per animal) for 10 days. With this treatment, normal homeostasis was reestablished. These animals received their 10th injection two hr before killing. At the time of decapitation, the different groups of rats were fasted overnight. Blood was collected on ethylenediamine tetraacetic acid (EDTA) and separated into plasma for various biochemical determinations.

Tissue lipid extraction. Immediately after the rats had been exsanguinated, the pancreas were excised. The tissues were minced, extensively washed in 0.15 mol/l cold NaCl solution, blotted, weighed and extracted in chloroform/methanol (2:1, v/v) (23). To ensure that total lipids were extracted, the samples were subjected to an additional extraction with chloroform/methanol.

Thin layer chromatographic separation and gas liquid chromatography analysis. The chloroform phase was evaporated under a gentle stream of nitrogen at 24 C. The lipid components were either directly methylated for analysis of fatty acid distribution in total lipids or first separated on thin layer chromatography plates (Silica Gel G) with a solvent system containing hexane/diethyl ether/glacial acetic acid (80:20:3, v/v/v). The different spots were identified with the help of standards that comigrated on the plate. The cholesteryl ester (CE), triglyceride (TG), free fatty acid (FFA), diglyceride (DG), monoglyceride (MG) and phospholipid (PL) fractions were scraped into small glass tubes and transesterified as described (24). Supernatant aliquots, including internal standard, were injected into a 60 m fused silica column with an internal diameter of 0.32 mm and coated with

*To whom correspondence should be addressed at the Department of Anatomy, Faculty of Medicine, University of Montreal, P.O. Box 6128, Station A, Montreal, Quebec, H3C 3J7 Canada.

Abbreviations: CE, cholesterol ester; DG, diglyceride; EDTA, ethylenediamine tetraacetic acid; FA, fatty acid; FC, free cholesterol; HDL, high density lipoprotein; MG, monoglyceride; LDL, low density lipoprotein; PL, phospholipid; TC, total cholesterol; TG, triglyceride.

0.20 mm of SP-2331. Analyses were performed on a Hewlett-Packard No. 5880 gas chromatograph equipped with a flame ionization detector. Standard mixtures of fatty acids (Sigma Chemical Co., St. Louis, MO) were used to determine the retention times and the calculation of correction factors. The area under the chromatogram peaks was calculated with the aid of integrator, calibrated with the standard methylated fatty acid mixtures.

Calculation of desaturation activities. The activity of desaturase enzymes was not measured directly but inferred from calculation of immediate product to substrate ratios of fatty acids. The following fatty acid ratios were selected because in all chromatograms they were present and reliably quantitated; the index of Δ5 desaturase activity was 20:4ω6/20:3ω6, and that of Δ9 was 18:1ω9/18:0. In the calculation of Δ4 and Δ6 desaturase activities, one elongase for each was included. We were forced to use 22:6ω3/20:5ω3 and 20:3ω6/18:2ω6 for the Δ4 and for the Δ6 desaturates because the substrates 22:5ω3 and 18:3ω6 were not always present on each chromatogram.

Other analytical methods. Plasma triglycerides, total cholesterol and free cholesterol determinations were carried out by enzymatic kits from Boehringer (Mannheim, Quebec, Canada). Glucose levels were determined by the glucose oxidase method and insulin by radioimmunoassay.

Morphological studies. For studies at the electron microscope level, small fragments of pancreatic tissue were sampled from the dorsal and ventral parts of the pancreas of the different groups of animals and fixed by immersion in 0.1 M phosphate-buffered 1% glutaraldehyde for two hr at room temperature. The tissue fragments then were post-fixed with 1% osmium tetroxide and embedded in Epon 812 according to standard procedures. Thin sections were cut, stained with uranyl acetate and lead citrate and examined with the electron microscope. The cytochemical staining of cholesterol was performed using modifications of the technique proposed by Frühling et al. (25). In short, after fixation with glutaraldehyde and osmium tetroxide, the tissue fragments were dehydrated in ethanol 30% and 70% (15 and 30 min, respectively), infiltrated in ethanol 70%/Epon (l/l) twice 30 min and finally embedded in Epon and polymerized at 60 C. The thin sections were lightly stained with uranyl acetate and examined. For the light microscopy immunocytochemical investigation of endocrine cells in the islets of Langerhans, the pancreatic tissues were fixed with Bouin's fluid and embedded in paraffin according to standard techniques. Sections (5 μm thick) were stained, applying the indirect immunofluorescence technique, for the demonstration of insulin, glucagon and somatostatin containing cells as described (13). Specific antibodies directed towards these pancreatic hormones were used (13).

Statistical analysis. Analysis of variance and the multiple comparison procedure of Scheffe (26) were used to test for differences between means. If F was significant at the 0.05 level, the difference between means was evaluated by the method of least significant differences.

RESULTS

At the time of killing, three months after the streptozotocin injection, the diabetic rats had significantly higher plasma glucose as well as TG and TC concentrations than control and insulin-treated rats (Table 1). On the other hand, their insulin levels were significantly depressed to about 32% of normal values, while those of insulin-treated diabetic animals showed a marked increase above control values.

The composition of plasma fatty acids is reported in Table 2. The proportion of linoleic acid (18:2ω6) was higher, while that of α-linolenic acid (18:3ω3) was lower in diabetic rats. No significant difference could be demonstrated in the monounsaturates and the arachidonate (20:4ω6), although a decrease was noted for both. Table 2 also demonstrates that streptozotocin diabetes produced changes in fatty acid levels consistent with a 55% inhibition of Δ5 desaturation. However, the 18:1ω9/18:2ω6 ratio, an index of essential fatty acid deficiency, was found to be similar to that of controls, while the 18:2ω6/20:4ω6 ratio indicative of fatty acid elongation and both Δ5 and Δ6 desaturation was higher, although not significantly. In contrast, the percentages of comparable fatty acids were corrected in diabetic rats treated with insulin, except for 18:3ω3. Insulin therapy altered the relative content of some fatty acids such as 15:0, 16:1ω7 and 20:3ω9 and corrected the Δ4 and Δ5 desaturations indices to normal values.

Lipid fatty acid concentration in pancreatic tissue. Table 3 presents the concentrations of fatty acids in the various lipid classes found in the pancreas. There was a significant decrease in the total fatty acid content in the diabetic state. This change was largely accounted for by a marked decrease of TG (~35-fold). The only significant ($P < 0.05$) increment in pancreatic fat content was in the

TABLE 1

Biochemical Plasma Parameters in Control, Diabetic and Insulin-treated Hyperglycemic Rats

Rats	Glucose (mg/dl)	TG (mg/dl)	TC (mg/dl)	Insulin (U/ml)
Controls	159 ± 9	65 ± 9	72 ± 6	36.6 ± 2.2
Diabetics	535 ± 42[a]	384 ± 70[a]	112 ± 9[a]	24.8 ± 3.0[a]

Insulin-treated + diabetics	7513.3 ± 1207.1	5344.1 ± 1413.7	81.8 ± 16.8	141.1 ± 41.7	60 ± 12	37.3 ± 4.3[b]	985.5 ± 99.1

Values are means ± SEM for four animals in each group, expressed in μg/g tissue. TG, triglyceride; DG, diglyceride; MG, monoglyceride; FFA, free fatty acid; CE, cholesteryl ester; PL, phospholipid.

[a]Significant difference between the control and diabetic tissue.

[b]Significant difference between the diabetic and diabetic insulin treated.

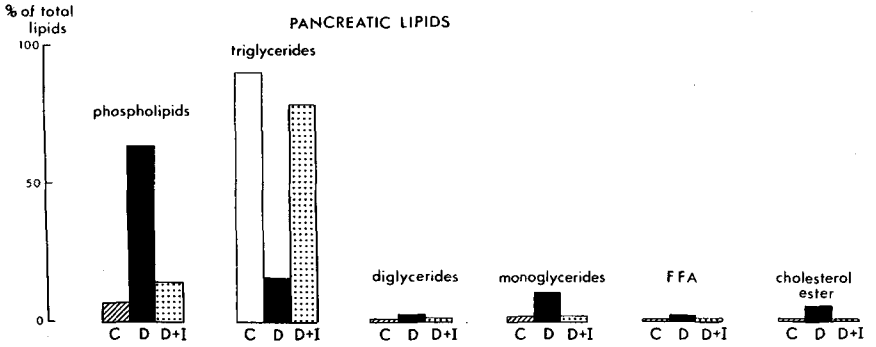

FIG. 1. Percent distribution of lipid classes in pancreatic tissue. The different lipid classes were extracted by chloroform/methanol (2:1, v/v), separated by thin layer chromatography, transesterified, and injected to GLC as described in Materials and Methods.

CE fraction (~3-fold increase). Treatment of rats with insulin led to a restoration of normal lipid concentrations. This suggests that the changes noted in the diabetic condition are the result of insulin deficiency.

Distribution of lipid components in pancreatic tissue. When values of the various lipid components were expressed as percentages of total amount of fat recovered from the pancreatic tissue, an abnormal pattern was obtained in the diabetic state (Fig. 1). As expected from Table 3, a substantial decrease of TG is noted and is associated with a relative increase of the other lipid classes, the phospholipid fraction being predominantly affected. On the other hand, insulin-treated diabetic animals demonstrated the same profile as controls.

Nonesterified cholesterol concentration in pancreatic tissue. Besides the cholesterol increment recorded in Table 3, a significant increase of nonesterified cholesterol was found in pancreatic tissues of diabetic animals (Fig. 2). When the ratio of cholesterol/phospholipid was calculated, it was found to be significantly higher in diabetic (5-fold) than in control rats. Again, treatment with insulin abolished the large difference between the normal and the diabetic state.

Fatty acid distribution in total lipids of pancreatic tissue. The fatty acid profile of the total lipids extracted from the pancreas is recorded in Table 4. The pattern observed in diabetics differs markedly from that of controls. The major essential fatty acids (18:2ω6, 20:4ω6) together with other polyunsaturates (20:3ω6, 20:5ω3) were higher, while most saturates (except 18:0) and monounsaturates were lower. The decreased oleic acid could be the result of the diminished Δ9 desaturation, while Δ5 desaturation was found to be significantly decreased as inferred from fatty acid changes in the diabetic animals. Insulin administration partly corrected these abnormalities.

Fatty acid profile of phospholipids. Fatty acid analysis of PL of pancreatic tissue was performed. Table 5 shows that linoleic acid and 20:3ω6 were increased and arachidonic acid was decreased, indicating an impaired utilization of linoleic and 20:3ω6 acid in diabetic animals. This led to a three-fold increase of the 18:2ω6/20:4ω6 ratio and a decrease of the ω3 fatty acid family, which together could be secondary to the apparent decrease of Δ5 desaturation. In addition to the diminished proportions of 14:0, 15:0 and 16:0, altered percentages of monounsaturates

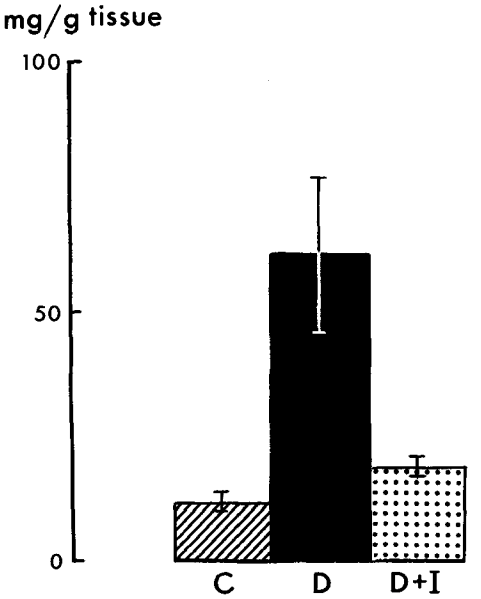

FIG. 2. Free cholesterol concentration in pancreatic tissue.

(16:1ω7 and 18:1ω9) were noticed, which is the likely result of a diminished Δ9-desaturation responsible for the conversion of saturated fatty acids to monounsaturates. Treatment of the diabetic animals with insulin corrected or even overcorrected the abnormal fatty acid pattern of the PL fraction without changing the decreased Δ5 fatty acid desaturation.

Morphological studies. Immunofluorescence studies performed on the endocrine portion of the pancreas demonstrated a drastic decrease in the number of insulin-containing cells in the islets of Langerhans of the streptozotocin-induced diabetic animals when compared with the controls (results not illustrated). By electron microscopy, the acinar cells in control animals appeared pyramidal in shape, with the nucleus in basal position surrounded by a well-developed rough endoplasmic reticulum arranged in parallel rows (Fig. 3). The Golgi apparatus and numerous secretory zymogen granules were present in a supra-nuclear position, close to the apical plasma membrane. Lipid droplets, in particular, were small in size and very few in number. When present, they were located

at the basal part of the cell (Fig. 3). In contrast, the acinar cells of the diabetic animals appeared infiltrated with large amounts of lipid droplets (Fig. 4). These were quite variable in size, some of them reaching 2000 nm in diameter. Because of these large aggregates of lipid droplets, the morphology of the cells was somewhat altered, in particular the arrangement of the rough endoplasmic reticulum at the basal part of the cell (Fig. 4). The Golgi apparatus and the secretory granules remained located towards the apical region of the cell. The

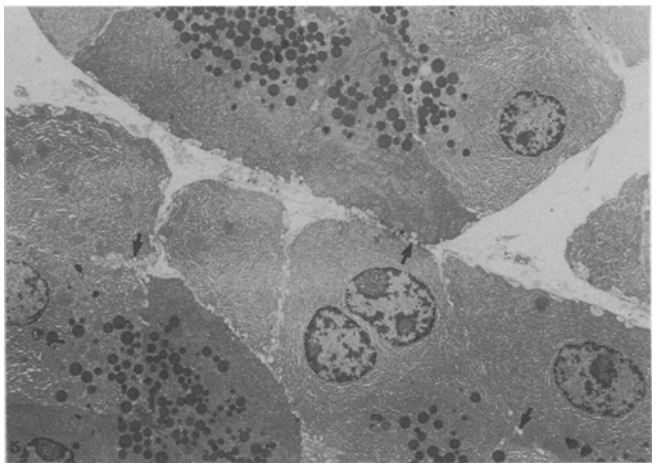

FIG. 5. Pancreatic tissue from an insulin-treated diabetic animal. Small lipid droplets (arrows) are present in the acinar cells. ×1500.

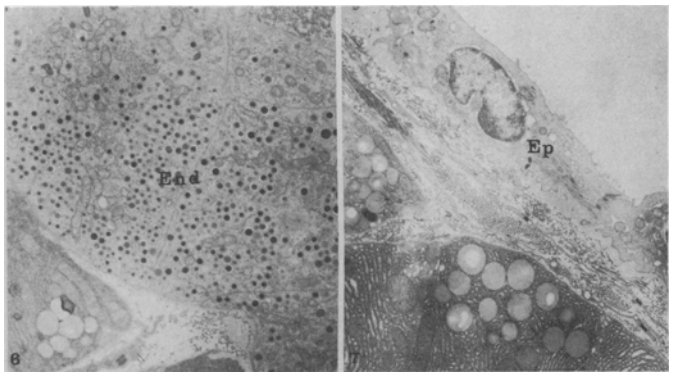
accumulation of lipid droplets in the acinar cells was found in both the ventral and dorsal parts of the pancreas. The acinar cells of insulin-treated diabetic animals resembled those of the normal ones (Fig. 5); the large accumulation of lipid drops was almost completely reversed with only some small droplets remaining at the basal part of the cells (Fig. 5). In contrast to the large accumulation of lipid droplets found in acinar cells of diabetic animals, the endocrine cells remaining in the islets of Langerhans of these animals (mainly glucagon, somatostatin and pancreatic polypeptide cells) (Fig. 6), as well as the epithelial cells of the exocrine ducts (Fig. 7) were devoid of lipid accumulation. These results suggest that only the acinar parenchyma is affected by the lipid changes described above.

The electron microscopy results corroborated the biochemical findings. Indeed, the cytochemical study demonstrated that the lipid droplets, present in acinar cells of diabetic animals, are of cholesterol nature, because the selective technique used yielded a positive staining (Fig. 8).

DISCUSSION

The use of animal models displaying diabetes has contributed greatly to our understanding of the disease in humans. In this study, the characteristic metabolic changes occurring in the diabetic state were noted, i.e., hyperglycemia, hyperlipidemia and hypoinsulinemia. Our



FIGS. 6 and 7. Pancreatic tissue from a diabetic animal. The endocrine cells (End) of the islet of Langerhans (Fig. 6) as well as the epithelial cells (Ep) of the secretory duct (Fig. 7) are devoid of lipid droplets. In contrast, the neighboring acinar cells display lipid accumulation. Fig. 6 ×4200. Fig. 7 ×3500.

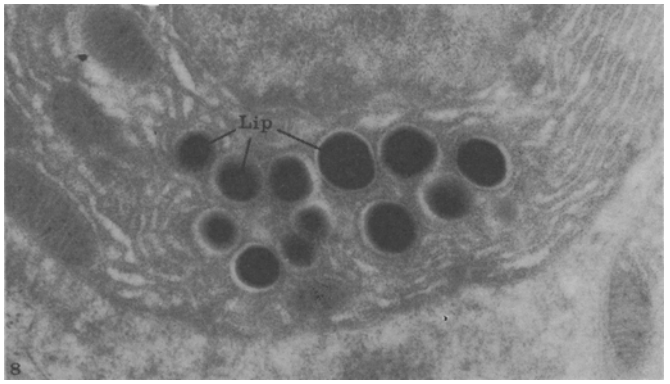


FIG. 8. Pancreatic tissue from a diabetic animal. The tissue was prepared for the demonstration of cholesterol. The lipid droplets (Lip) present in the acinar cells display a positive cytochemical reaction since they appear electron dense. ×13000.

results conclusively demonstrated that diabetes in the rat led to several changes in the concentration as well as in the composition of fatty acids and lipid components in the pancreas. The lipid classes responsible for the large diminution of total fat included TG, DG, MG and FFA. By contrast, esterified- and free-cholesterol were surprisingly high. This finding involved only acinar cells because the remaining endocrine cells as well as the epithelial cells did not show any accumulation of lipid droplets. Another crucial observation was that the phospholipids of the pancreas of experimental diabetic rats disclosed increased linoleic acid (18:2ω6) and diminished palmitoleic, oleic and arachidonic acid. Daily insulin replacement for 10 days normalized or overcorrected the abnormal lipid profile of the pancreas of diabetic rats in conjunction with restoration of the plasma changes.

At this time, the precise mechanism for the accumulation of cholesterol in the diabetic state is not known because cholesterol levels in all cells represent a balance between cellular uptake, de novo synthesis and catabolism (27). Some investigators have recently documented enhanced cholesterol synthesis in the small intestine of streptozotocin-treated rats (28,29). However, we must be careful not to extrapolate these findings to the pancreas because the activity of the key synthetic enzyme, HMG-CoA reductase, is reportedly depressed in the liver of streptozotocin-diabetic rats (30). Additional studies are required to explore the possibility of an increased uptake of cholesterol by the pancreas from circulating lipoproteins. It is evident from many studies that the major way by which numerous peripheral tissues in man may acquire cholesterol to supplement endogenous synthesis is by means of cholesterol uptake from low density lipoproteins (LDL) (31). But in animal species, such as the rat where plasma LDL levels are excessively low, HDL may fulfill this role (32). This process could be active in diabetic rats because cholesterol metabolism is altered and leads to a marked increase in plasma.

As stated before, the extensive lipid alterations found in diabetes appear to be focused only on the exocrine parenchyma. Previous studies described alterations in the secretion of amylase (4–9,13), a reduction of the exocrine mass and diminished pancreatic reserve (33,34). Others not only observed insulinitis but also severe atrophy of the acinar cells surrounding the islets of Langerhans (35). Furthermore, the pancreas of diabetic animals showed lymphatic infiltration and acinar cell damage around the islets (8). In our diabetic model, a drastic decrease in insulin secreting cells has been found in agreement with previous results (13,36). The remaining islets of Langerhans consisted mainly of glucagon- and somatostatin-secreting cells. On the other hand, the acinar parenchyma does not appear to be altered apart from changes in the secretory activity of the cells (9,13) and the presently described lipid deposition. Esters of some saturates, monounsaturates and of arachidonic acid were decreased more than esters of linoleic acid. Because of these variable individual changes, the relative composition of the total and PL fractions differed from that of controls. Benjamin and Gellhorn (37), studying adipose tissue, Brenner et al. (38), working with adipose tissue and testis, and Holman et al. (19), examining heart, liver, kidney and aorta described the same trend in the fatty acid profiles. Therefore, it seems that almost all organs are affected by the metabolic derangements of diabetes.

In view of the percent increase of linoleic acid in the pancreas of diabetic rats coupled with the substantial decrease of arachidonic acid, it is reasonable to suggest that the metabolism of linoleate is impaired. Similarly, although the relative proportion of α-linolenic acid (18:3ω3) was unchanged, the metabolite, 20:5ω3, was significantly decreased. The enzyme is responsible for the desaturation of 20:3ω6 to 20:4ω6 as well of 20:4ω3 to 20:5ω3, and of 20:2ω9 to 20:3ω9. Given that the content of the 20:3ω6 substrate for Δ5-desaturation, was found to be increased by 84% above the control value, and that arachidonic acid was suppressed by 91.9%, the activity of the n3 Δ5-desaturation enzyme must be impaired in diabetes. We have paid particular attention to the PL fraction because assessment of EFA status through PL analysis is thought to be more reliable (39). The rats in our investigation had been diabetic for more than 90 days and demonstrated a decrease total ω3 acids from 1.72 ± 0.18 in controls to 0.52 ± 0.08. Although Holman et al. (19) proposed that the magnitude and direction of the effect of diabetes on the proportions of ω3 acids is mediated

by diet, this does not seem to be the case in the present study because the diet remained identical.

Previous studies in diabetic animals reported altered physical properties and fluidity of membranes in tissues other than the pancreas (22). Our results relative to TC/PL ratios referred to the whole cell content. Therefore, additional studies are required to determine the membrane lipid composition and fluidity, and to assess their implication in the various alterations observed in diabetic pancreas.

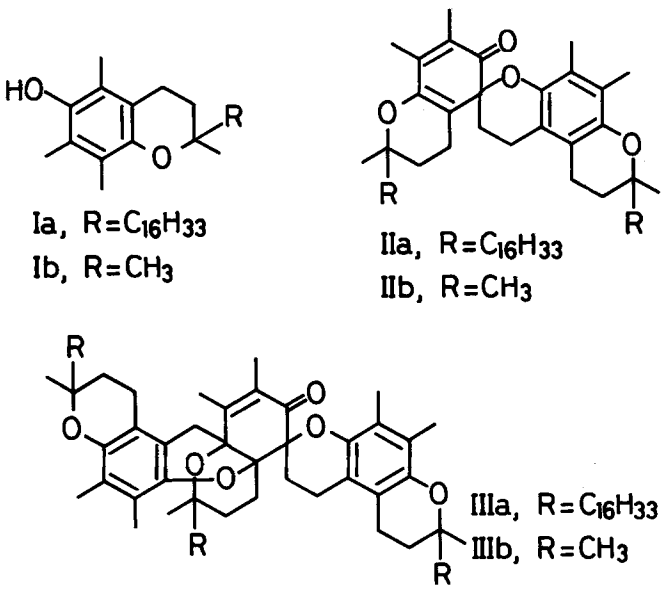
Formation of Trimers of α-Tocopherol and Its Model Compound, 2,2,5,7,8-Pentamethylchroman-6-ol, in Autoxidizing Methyl Linoleate

Ryo Yamauchi*, Koji Kato and Yoshimitsu Ueno
Department of Agricultural Chemistry, Gifu University, 1-1, Yanagido, Gifu City, Gifu 501-11, Japan

The reaction products of α-tocopherol and its model compound, 2,2,5,7,8-pentamethylchroman-6-ol, during the autoxidation of methyl linoleate at 37 C were investigated. Two isomeric trimers were obtained as the major reaction products of α-tocopherol, and a trimer was obtained as that of its model chroman. The structure of each trimer has been characterized by IR, UV, ^1H and ^{13}C NMR, and mass spectroscopy. The ^{13}C NMR spectra showed the presence of a quaternary carbon atom and a carbon atom bearing two oxy substituents in the molecule. On methanolysis of each trimer, equimolar amounts of the 5-methoxymethyl compound and the dihydroxy dimer were formed, indicating the presence of a ketal group in the molecule. From these results, new trimeric structures are proposed. The reaction products of α-tocopherol could be well-separated by reverse-phase high performance liquid chromatography. When methyl linoleate was autoxidized in the presence of 1 mol% α-tocopherol, spirodiene dimer was the initial reaction product of α-tocopherol, and trimers were formed with the decrease of α-tocopherol.
Lipids 23, 779–783 (1988).



SCHEME 1

Tocopherols are generally present in seed oils and are viewed as natural antioxidants. The role of α-tocopherol, the major constituent of vitamin E, in foods or living cells is believed to be as a free radical scavenger. Its oxidation in these systems is most likely a result of its reaction with lipid peroxy radicals (1,2). Csallany et al. (3) have shown that the major reaction products of α-tocopherol formed during autoxidation of methyl linoleate at 60 C are identical to compounds produced by mild oxidation of α-tocopherol with alkaline $K_3Fe(CN)_6$. The major products of these oxidations are the spirodiene dimer (IIa) and trimer (IIIa) of α-tocopherol (Ia) (Scheme 1). It has been well-established that free radical oxidation of α-tocopherol leading to characteristic products takes place via the tocopheroxy radical intermediate (4,5). If a suitable free-radical is not present, dimer and trimer would be expected to be major products of these reactions.

We have studied the reaction products of α-tocopherol and its model compound, 2,2,5,7,8-pentamethylchroman-6-ol (PMC), during the autoxidation of methyl linoleate in bulk phase at 37 C.

MATERIALS AND METHODS

Materials. 2*R*,4′*R*,8′*R*-α-Tocopherol (Type V) was purchased from Sigma Chemical Co. (St. Louis, MO), and 2*R*,4′*R*,8′*R*-γ-tocopherol was prepared from mixed isomers of tocopherol (Eisai Co., Tokyo, Japan). Tocopherols were purified by Sephadex LH-20 column chromatography (6).

An α-tocopherol model compound, PMC, was prepared by the method of Nilsson et al. (7), and obtained as colorless needles: mp 96–97 C; MS *m/z* 220 (M^+, 100%); IR (KBr) ν 3250 cm^{-1}; UV (hexane) λ 295 nm (ε 3420). α-Tocopheryl quinone was produced from α-tocopherol by oxidation with $FeCl_3$ in ethanol (4), while α-tocopherol spirodiene dimer was synthesized following the procedure of Nelan and Robeson (8). Methyl linoleate purchased from Tokyo Kasei Kogyo (Tokyo, Japan) was purified by silica gel column chromatography to be peroxide-free (9). All other chemicals were obtained from common laboratory suppliers. All solvents were distilled in an all-glass still before use.

High performance liquid chromatography (HPLC). HPLC was performed with a Jasco Trirotar V pump equipped with a Model GP-A40 gradient programmer and with a Model 875 UV detector. Reverse-phase HPLC was done with a Wakosil 5C18 column (4.6 × 250 mm, Wako Pure Chemical Ind., Osaka, Japan) developed with a 15 min linear gradient of methanol to methanol/isopropyl ether (1:1, v/v) at a flow rate of 1.5 ml/min. Normal-phase HPLC was done with a μBondasphere 5μ Si-100Å column (3.9 × 150 mm, Nihon Waters Ltd., Tokyo, Japan) developed with hexane/isopropyl ether (97:3, v/v) at a flow rate of 1.5 ml/min.

Oxidation procedure. For the structural analysis, methyl linoleate (3.0 g) with α-tocopherol (1.0 g) or PMC (0.60 g) was placed in a glass shalet (7 cm in diameter). To assure that the methyl linoleate and the tocopherol were well mixed, they were dissolved in ethyl ether and then dried under nitrogen and allowed to autoxidize at 37 C for 30 days in the dark. The reaction products of α-tocopherol or PMC were analyzed by thin layer chromatography (TLC) on a Merck pre-coated silica gel 60 plate

Abbreviations: PMC, 2,2,5,7,8-pentamethylchroman-6-ol; HPLC, high performance liquid chromatography; IR, infrared; NMR, nuclear magnetic resonance; TLC, thin layer chromatography.

(Darmstadt, West Germany) using hexane/ethyl ether/acetic acid (80:30:1, v/v/v) as the solvent system. The products were separated by silica gel column chromatography. The column was developed with increasing proportions of ethyl ether in hexane. For the time-course experiment, methyl linoleate (1 mmol), either with or without 1 mol% of α-tocopherol, was placed in a glass vial (1.5 cm in diameter) and autoxidized at 37 C in the dark. At regular intervals, aliquots of the sample were withdrawn, dissolved in isopropanol and injected into the HPLC. The amounts of α-tocopherol and its reaction products were calculated from the peak area by monitoring the elutions at 285 nm. γ-Tocopherol was used as the internal standard (10). The peroxide values were measured by the iodometric method (9).

Methanolysis of the reaction products. Each solution of the products in benzene (10 ml) and 5% HCl in methanol (5 ml) was heated at 100 C for three hr in a sealed tube. After cooling, each product was extracted with ethyl ether, washed with distilled water and dried in vacuo. The extracts were analyzed by TLC with hexane/ethyl ether/acetic acid (90:10:0.5, v/v/v) as the solvent system. The methanolized products were separated by silica gel column chromatography developed with increasing proportions of ethyl ether in hexane.

Apparatus. All melting points were determined with a Yanagimoto microapparatus and are uncorrected. Proton (^{1}H) and carbon-13 (^{13}C) nuclear magnetic resonance (NMR) spectra were recorded on a JEOL JNM-GX-270 FT NMR spectrometer with $CDCl_3$ as the solvent and with tetramethylsilane as the internal standard. NMR spectra are taken at ca. 27 C; ^{13}C NMR at 67.8 MHz with proton decoupling, and ^{1}H NMR at 270.05 MHz. Mass (MS) spectra were obtained with a Hitachi RMU-6 mass spectrometer at ionizing energy of 70 eV. Infrared (IR) spectra of samples in KBr tablets or liquid film were taken on a Jasco A-302 IR spectrometer. Ultraviolet (UV) spectra were measured with a Hitachi Model 200-10 spectrophotometer.

RESULTS

Characterization of reaction products. The reaction products of α-tocopherol in the autoxidized methyl linoleate were analyzed by TLC. Spots corresponding to two reaction products of α-tocopherol (IVa: R_f 0.96 and IVb: R_f 0.91), methyl linoleate (R_f 0.76), α-tocopherol (R_f 0.55) and methyl linoleate monohydroperoxide (the autoxidation product of methyl linoleate (11): R_f 0.26) were observed on the TLC plate. The reaction products, IVa and IVb, were separated by silica gel column chromatography and obtained as pale-yellow waxes (the yields of IVa and IVb were 106 mg and 94 mg, respectively).

The autoxidation of methyl linoleate in the presence of PMC gave methyl linoleate (R_f 0.76), a reaction product of PMC (V: R_f 0.69), PMC (R_f 0.44) and methyl linoleate monohydroperoxide (R_f 0.26) on the TLC plate. The reaction product, V, was separated by silica gel column chromatography, crystallized from ethanol/ethyl ether/water and obtained as white powder (yield 62.6 mg, mp 223–226 C).

The compounds IVa, IVb and V agreed spectrometrically with trimers of α-tocopherol and PMC (12,13). IVa: MS *m/z* 858 ([M-428]$^+$, 0.4%); IR (film) ν 1695 cm^{-1}; UV (hexane) λ 293 nm (ε 6100). IVb: MS *m/z* 858 ([M-428]$^+$, 0.1%); IR (film) ν 1690 cm^{-1}; UV (hexane) λ 293 nm (ε 6200). V: MS *m/z* 654 (M$^+$, 2%); IR (KBr) ν 1690 cm^{-1}; UV (hexane) λ 292 nm (ε 6400).

The ^{1}H NMR spectra of IVa, IVb and V were consistent with that expected for trimers of α-tocopherol and PMC (Table 1). In particular, the geometric relationship between IVa and IVb could be established by interpretation of the spectra (14,15). When the third α-tocopherol residue is *trans* to the 2′a-methyl group (IVa), the 2′a-methyl group (1.22 ppm) is localized in a shielding environment above the plane of the enone system. When the third α-tocopherol residue is *cis* to the 2′a-methyl group (IVb), deshielding of the 2′a-methyl group (1.44 ppm) is observed and may be due to 1,3-diaxial interaction of this group with the third α-tocopherol.

The ^{13}C NMR spectra of IVa, IVb and V show, in addition to other peaks that are consistent with the assigned structure as shown in Table 2, a single carbonyl (IVa: 198.9 ppm, IVb: 198.7 ppm, V: 198.7 ppm), a quaternary carbon (IVa: 42.8 ppm, IVb: 41.6 ppm, V: 41.7 ppm), four tertiary ethers (IVa: 85.6, 77.2, 74.7, and 74.3 ppm; IVb: 85.5, 76.2, 74.7, and 74.5 ppm; V: 85.5, 74.5, 72.7, and 72.4 ppm), and a carbon atom bearing the two oxy substituents (IVa: 100.3 ppm, IVb: 99.5 ppm, V: 99.7 ppm).

The trimers (IVa, IVb and V) were hydrolyzed by HCl according to the conditions of Skinner and Parkhurst (13).

Each hydrolyzed sample examined by TLC showed only one spot identical to that of each original trimer.

The trimers (IVa: 50.4 mg, IVb: 34.2 mg, and V: 23.0 mg, respectively) in benzene solutions were methanolized with 5% HCl in methanol. IVa and IVb gave the same two products, VIa (R_f 0.29) and VIIa (R_f 0.22), in addition to the unreacted trimer (IVa: R_f 0.76 and IVb: R_f 0.51) on the TLC plate. V (R_f 0.33) also gave two products, VIb (R_f 0.16) and VIIb (R_f 0.12) on the plate. The products were separated by silica gel column chromatography. Both VIa and VIIa were obtained as pale yellow oils (the yields of VIa and VIIa were 6.8 mg and 13.7 mg from IVa, and 4.9 mg and 10.7 mg from IVb, respectively). VIb was crystallized from hexane and obtained as white needles (yield 3.2 mg, mp 53–54 C), and VIIb from ethanol/water gave white plates (yield 7.9 mg, mp 187–188 C).

The structures of VIa, VIIa, VIb and VIIb were confirmed from their spectral data and identified as follows: VIa, 5-methoxymethyl-7,8-dimethyltocol: MS *m/z* 460 (M^+, 3%); IR (film) ν 3420 cm^{-1} (OH); UV (hexane) λ 298 nm (ε 3800); ^{1}H NMR ($CDCl_3$) δ 4.64 ppm (*s*, H), 3.42 (*s*, 3H), 2.59 (*t*, 2H, J = 6.8 Hz), 2.10 (*s*, 3H), 1.75 (*q*, 2H, J = 10.6 Hz), 1.52 (*t*, 2H, J = 6.6 Hz), 1.21 (*s*, 3H), 0.88 (*s*, 6H), 0.85 (*s*, 6H); ^{13}C NMR ($CDCl_3$) δ 147.4 ppm, 144.7, 125.8, 123.1, 115.9, 115.4, 74.4, 69.8, 58.1, 39.8, 39.4, 37.5, 37.4 (2 atoms), 37.3, 32.8, 32.7, 31.5, 28.0, 24.8, 24.5, 23.7, 22.7, 22.6 (2 atoms), 21.0, 19.9, 19.7, 11.9, 11.7. VIIa, dihydroxy dimer of α-tocopherol. The spectral data were essentially identical with the literature values (8,12): MS *m/z* 858 (M^+, 22%); IR (film) ν 3450 cm^{-1}; UV (hexane) λ 297 nm (ε 7500); ^{1}H NMR ($CDCl_3$) δ 5.68 ppm (*s*, 2H), 2.72 (broad, 4H), 2.14 (*s*, 6H), 2.11 (*s*, 6H), 1.80 (*q*, 4H, J = 6.6 Hz), 1.23 (*s*, 6H), 0.88 (*s*, 12H), 0.85 (*s*, 12H); ^{13}C NMR ($CDCl_3$) δ 145.7 ppm, 144.9, 123.4, 123.0, 121.2, 116.3, 74.6, 40.1, 39.4, 37.5, 32.8, 31.7, 28.0, 26.1, 24.8, 24.5, 23.9, 22.8, 21.7, 19.8, 12.2, 11.9. VIb, 5-methoxymethyl-2,2,7,8-tetramethylchroman-6-ol: MS *m/z* 250 (M^+, 76%); IR (KBr) ν 3320 cm^{-1} (OH); UV (hexane) λ 293 nm (ε 3700); ^{1}H NMR ($CDCl_3$) δ 4.62 ppm (*s*, H), 3.46 (*s*, 3H), 2.58 (*t*, 2H, J = 7.0 Hz), 2.13 (*s*, 3H), 2.10 (*s*, 3H), 2.09 (broad, 2H), 1.73 (*t*, 2H, J = 7.0 Hz), 1.26 (*s*, 6H); ^{13}C NMR ($CDCl_3$) δ 147.3 ppm, 144.8, 125.6, 123.0, 116.0, 115.1, 72.3, 69.6, 57.9, 32.8, 26.6, 26.5, 20.1, 11.8, 11.7. VIIb, dihydroxy dimer of PMC. The spectral data were identical with the literature values (12): MS *m/z* 438 (M_+, 74%);

IR (KBr) ν 3420 cm^{-1}; UV (hexane) λ 293 nm (ε 6600); ^1H NMR ($CDCl_3$) δ 5.61 ppm (broad *s*, 2H), 2.75 (*t*, 4H, J = 6.6 Hz), 2.73 (*s*, 4H), 2.15 (*s*, 6H), 2.11 (*s*, 6H), 1.81 (*t*, 4H, J = 6.9 Hz), 1.30 (*s*, 12H); ^{13}C NMR ($CDCl_3$) δ 145.8 ppm, 144.9, 123.3, 122.9, 121.6, 116.1, 72.6, 33.1, 26.8, 26.7, 26.0, 20.4, 12.2, 12.1, 11.9.

From above results, we propose new trimeric structures, IVa, IVb and V (Scheme 2).

Reaction products of α-tocopherol in autoxidizing methyl linoleate. Methyl linoleate was autoxidized at 37 C in the presence of 1 mol% α-tocopherol. The reaction products of α-tocopherol were analyzed by reverse-phase HPLC (Fig. 1A). Peaks corresponding to γ-tocopherol (an internal standard), α-tocopherol and the products, spirodiene dimer, an unknown peak (could not be identified) and trimer, appeared on the chromatogram. The peak corresponding to trimer was fractionated and analyzed by the normal-phase HPLC. Equal amounts of geometric isomers, IVa and IVb, appeared on the chromatogram (Fig. 1B).

Figure 2 shows the results of autoxidation of methyl linoleate with or without 1 mol% of α-tocopherol in a period of 34 days. Methyl linoleate containing 1 mol% α-tocopherol showed a linear increase in peroxides with incubation time, and α-tocopherol in methyl linoleate decreased. No decrease was observed in the level of α-tocopherol when it was mixed with methyl myristate. A small amount of spirodiene dimer formed initially, and then trimer accumulated with the decrease of α-tocopherol. No α-tocopheryl quinone, which was considered to be as the reaction product of α-tocopherol with

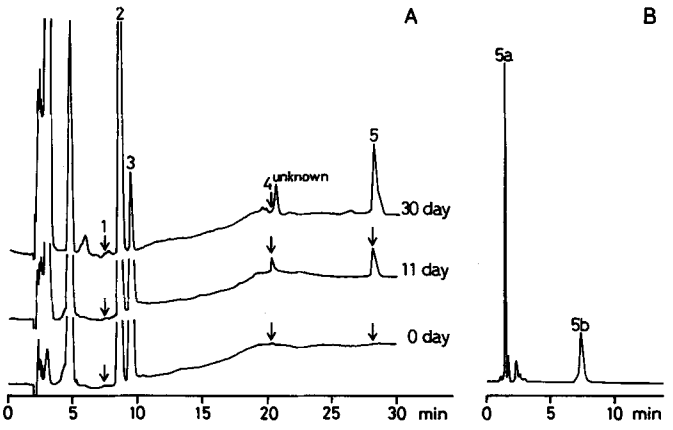

FIG. 1. Reverse-phase HPLC of the reaction products of α-tocopherol during the autoxidation of methyl linoleate for 0, 11 and 30 days (A). Arrows indicate as follows: 1, α-tocopheryl quinone; 2, γ-tocopherol (internal standard); 3, α-tocopherol; 4, spirodiene dimer; 5, trimer. Peak 5 was separated by normal-phase HPLC (B). 5a, trimer IVa; 5b, trimer IVb. The chromatographic conditions are described in the text. The eluent was monitored by an absorbance at 285 nm.

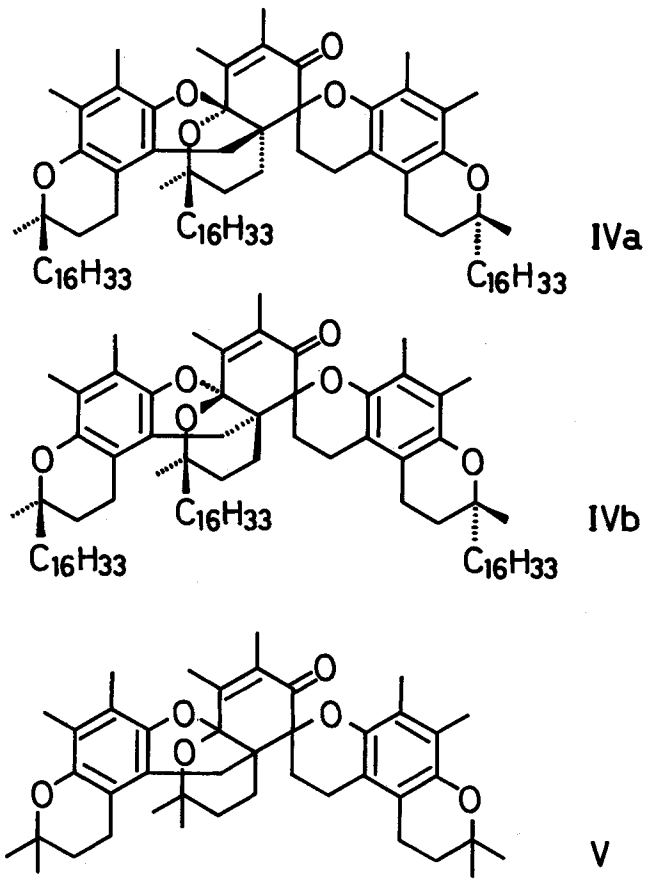

SCHEME 2

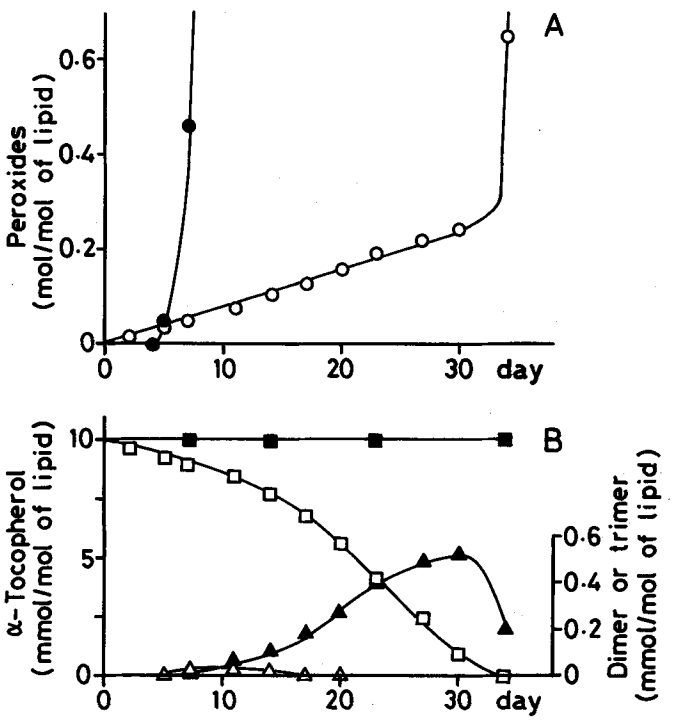

FIG. 2. Reaction of α-tocopherol during the autoxidation of methyl linoleate at 37 C. (A) Formation of total peroxides; (B) changes in amounts of α-tocopherol and its reaction products. Methyl linoleate (1 mmol) was autoxidized with 1 mol% α-tocopherol (○) and without α-tocopherol (●). Methyl myristate (1 mmol) containing 1 mol% α-tocopherol was incubated under the same conditions. Residual amounts of α-tocopherol in methyl linoleate (□) and in methyl myristate (■), and the reaction products, spirodiene dimer (△) and trimer (▲), in methyl linoleate are shown.

free radicals (16), could be detected during the reaction process.

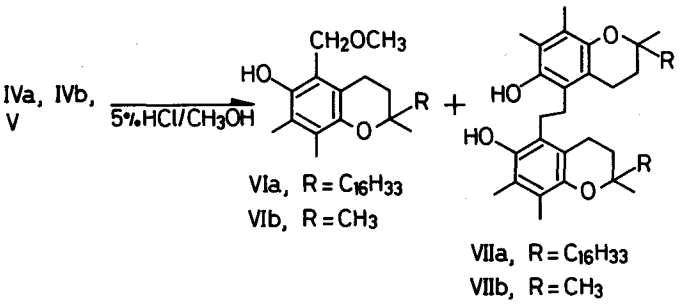
DISCUSSION

Two major products (IVa and IVb) were isolated as the reaction products of α-tocopherol formed during the autoxidation of methyl linoleate, and a major product (V) was obtained as the product of PMC oxidation. It appears that an *ortho*-quinone methide was formed from the monomer (α-tocopherol or PMC) upon oxidation by alkaline $K_3Fe(CN)_6$ (17). The *ortho*-quinone methide then added to the dimer to form the trimer. Two modes of addition of the *ortho*-quinone methide to the dimer are possible, wherein an α,β-unsaturated ketone is left in the adduct. One of those structures (III) would be acid-resistant and the others (IV and V) would be acid-labile, owing to the presence of a ketal group. Skinner and Parkhurst (13) reported the structure of trimer as III from its resistance to acid hydrolysis. The trimers reported here also were found to be acid resistant according to their experimental conditions. However, the trimers could be methanolyzed at 100 C to form equimolar quantities of the 5-methoxymethyl compound (VI) and the dihydroxy dimer (VII) (Scheme 3). Because the conditions reported by Skinner and Parkhurst were too mild for the acid hydrolysis (the sample solutions were maintained at temperature below 45 C), the trimers might be resistant toward acid. Their ^{13}C NMR spectra showed the presence of one quaternary carbon atom and one carbon atom bearing the two oxy substituents in the molecule. These results indicate that the structure of each trimer is a ketal type (Scheme 2).

The ^1H NMR spectra indicated that trimers IVa and IVb were geometric isomers. Although Skinner and Alaupovic (12) isolated two trimers of α-tocopherol (named compounds A and B and their spectral data were almost the same), they could not identify the structure of compound B. Their compounds A and B correspond to trimers IVa and IVb, respectively.

α-Tocopherol and its reaction products in the autoxidized methyl linoleate could be well separated by the reverse-phase HPLC. When methyl linoleate was autoxidized in the presence of 1 mol% α-tocopherol, the spirodiene dimer formed initially, and then the trimer accumulated. The reaction of α-tocopherol did not proceed in the saturated fatty acid methyl ester. These observations agree with those of Csallany et al. (3), who reported dimer and trimer were the major products of the autoxidation of α-tocopherol with methyl linoleate. Fujimaki et al. (4) also reported that trimer was the major product of the autoxidation of PMC after 40 days in oxygen-saturated heptane at 90 C.

α-Tocopherol at a high concentration induces the formation of lipid hydroperoxides during the autoxidation of polyunsaturated lipids (18–20). α-Tocopherol can terminate a chain reaction by donating hydrogen atoms to lipid peroxy radicals, and the resulting α-tocopheroxy



SCHEME 3

radicals participate in the prooxidant effect of α-tocopherol (20). In addition, our results indicate that the resulting α-tocopheroxy radicals react with each other and form the spirodiene dimer and trimer. The reaction products of α-tocopherol during the autoxidation of unsaturated lipids containing low levels of α-tocopherol are still unknown.

Essential Fatty Acid Pattern of Glycerolipids in Rat Hepatocytes in Primary Culture and in Coculture With Rat Liver Epithelial Cells

D. Pepin[a], J. Chambaz[a,*], M.Y. Rissel[b], A. Guillouzo[b] and G. Bereziat[a]

[a]U.A. 524, C.N.R.S., CHU Saint Antoine, 27 rue Chaligny -75571 Paris Cedex 12, and [b]U.A. 49, INSERM, CHU PONCHAILLOU - 35011 RENNES Cedex, France

The linoleic acid content of phosphatidylethanolamine (PE), phosphatidylcholine (PC) and triglyceride (TG) rapidly fell in rat hepatocytes in primary culture up to four days and in coculture with liver epithelial cells up to eight days. At the same time, the level of polyunsaturated fatty acids (PUFA), especially arachidonic acid, remained constant in PE, slightly decreased in PC and dropped in TG. There was no variation of the nonessential PUFA, 20:3n-9.

Linoleic acid supplementation of cultures 24 hr before the harvest induced a rise in the linoleic acid level of the three lipid classes. Arachidonic acid remained constant in TG and only slightly decreased in PE and PC at day 4 of primary culture and day 8 of coculture. The level of 20:3n-9 increased in PE and PC and much more in TG. This net increase in the arachidonic acid and 20:3n-9 levels in TG could not be explained only by a transfer from the phospholipid pools of PUFA because the phospholipid content of hepatocytes and PUFA levels of phospholipids did not vary under linoleic supplementation. The low percentage of arachidonic acid in epithelial cells rules out any participation of these cells in the increase of arachidonic acid in supplemented cocultures.

Triglycerides may act as a storage pool for plasma PUFA up to four days of primary culture and eight days of coculture. Besides, coculture seems more potent than primary culture to maintain the phospholipid level, to spare the essential PUFA in PE and to increase the TG synthesis in response to linoleic acid supplementation. *Lipids 23,* **784-790 (1988).**

The liver is essential to maintain homeostasis of polyunsaturated fatty acids (PUFA). In man, a decrease in the linoleic and arachidonic acid content of lipoproteins and of platelet and erythrocyte phospholipids has been shown to occur during different hepatic diseases in which hepatic function and/or biliary secretion are altered (1-4). During essential fatty acid (EFA) deprivation in the rat, Lefkowith et al. (5) observed a decrease in the linoleic acid content of all lipid classes of the liver, whereas the level of arachidonic acid decreased only in phosphatidylcholine (PC), phosphatidylinositol (PI) and neutral lipids but not in phosphatidylethanolamine (PE) or in phosphatidylserine (PS) (5).

Several authors have reported mechanisms of arachidonic acid transfer between phospholipids in thymocytes (6), macrophages (7,8) and platelets (9,10). This might explain the sparing of arachidonic acid and its accumulation in PE as shown by Aeberhard et al. in cultured skin fibroblasts (11).

We have studied the uptake of PUFA of the n-6 series by adult rat hepatocytes in primary culture (12). We have shown that PUFA were as effective as other fatty acids for triglyceride (TG) synthesis in hepatocytes. On the contrary, the incorporation into phospholipids was not related to an increase in the phospholipid content of hepatocytes and therefore must occur by the deacylation-reacylation cycle (12). From these results, the question arose of whether liver triglycerides as well as phospholipids act as a storage pool for plasma arachidonic acid.

The behavior of hepatocytes in long-term culture needed to be studied with respect to their fatty acid pattern. To maintain the phenotypic expression of hepatocytes in culture for long periods of time, Guguen-Guillouzo et al. have perfected a system in which hepatocytes are cocultured with a liver epithelial cell line (13).

In the present paper, we compared the fatty acid composition of PE, PC and TG of rat hepatocytes in primary culture up to four days with those of hepatocytes cocultured up to eight days. In addition, we studied the effect of a linoleic acid supplementation of the culture medium.

MATERIAL AND METHODS

Materials. Linoleic acid and fatty acid-free bovine serum albumin (Grade V) were obtained from Sigma Chemical Co. (St. Louis, MO). Minimum essential medium (MEM) and 199 medium were purchased from Boehringer (Mannheim, FRG).

Hepatocyte culture preparation. Hepatocytes were isolated by collagenase perfusion (14) from male adult Sprague-Dawley rats weighing 200-250 g and fed a standard chow comprised of 4% fat (w/w) with 60 mol% linoleic acid (U.A.R., France). Hepatocytes were seeded at a density of 8×10^6 cells per 75 cm^2 flask in 10 ml of the nutrient medium composed of a mixture of MEM and medium 199 (75:25, v/v) containing 80 IU/ml insulin and 10% fetal calf serum (v/v). The medium was renewed four hr after cell seeding. At that time, a part of the cultures was set up as cocultures by adding an equivalent number of rat liver epithelial cells (RLEC) (13).

RLEC were prepared from young rat livers and subcultivated in Williams medium supplemented with 10% fetal calf serum, as described elsewhere (15). For both pure culture and coculture, the medium supplemented with 7×10^{-5} M hemisuccinate hydrocortisone was renewed every day thereafter.

Pure RLEC cultures used as controls were maintained in Williams medium supplemented with serum until confluency was reached, then washed with phosphate-buffered saline and shifted to the medium used for hepatocyte cultures.

Incubation procedure. Primary cultures were carried out for one, two or four days, cocultures for four or eight

days and epithelial cells for three days in a medium MEM/199 3:1 (v/v) containing insulin and hydrocortisone as indicated above and 0.15 mM fatty acid free bovine albumin prepared as described (16).

The medium was changed every day. Half of the flasks were supplemented the last 24 hr with 0.3 mM linoleic acid bound to fatty free albumin at a ratio linoleic acid/albumin = 2. At the end of the incubation, the medium was removed, the plated cells were washed, collected and disrupted as described (12). Cell samples were collected for protein assay according to Lowry et al. (17) and extracted as described by Bligh and Dyer (18).

Lipid analysis. TG, PC and PE, were separated by preparative thin layer chromatography using a two-step migration in the same direction as described (12). Samples spots were scrapped off by comparison to standards, revealed by iodine vapor. Enzymatic assay of triglycerides was directly performed on the silica gel extract (18). Lipid phosphorus was assayed as described by Chen (19). For gas liquid chromatography analysis, hydrolysis and methylation (20) were performed directly on silica gel. Fatty acid separation was achieved on a 25 m capillary column filled with 20 M Carbowax operating between 200 C and 220 C at 1 C per min. Detection was by flame ionization.

RESULTS

The triglyceride content of hepatocytes remained constant in primary culture up to four days but slightly increased in coculture after eight days (Table 1). The phospholipid content of hepatocytes decreased as a function of time in primary cultures as well as in cocultures. The addition of linoleic acid 24 hr before the harvest did not modify the phospholipid content but increased the triglyceride content of hepatocytes in all the cases (Table 1).

To assess the respective lipid content of hepatocytes and epithelial cells in coculture, we also assayed lipids in epithelial cells just before confluency (3 days of culture). The triglyceride level of epithelial cells was lower than in hepatocytes in primary culture, whereas their phospholipid content was in the same range. Because epithelial cells accounted for half the cocultured cells, and the protein weights of epithelial cells and hepatocytes were, respectively, around 0.3 and 1 mg per 10^6 cells, we could estimate that epithelial cell proteins represented 25% of

coculture proteins. The triglyceride contents of hepatocytes and epithelial cells in coculture were respectively, 24.5 and 3.5 μg per mg of coculture proteins in the flasks incubated without linoleic acid and 45.7 and 6.3 μg in the flasks supplemented with linoleic acid. We could, therefore, estimate the proper triglyceride contents of hepatocytes after four days of coculture: 33 and 61 μg/mg of hepatocyte proteins in cells incubated, respectively, without and with linoleic acid.

The fatty acid composition of PE varied slightly during either primary culture or coculture (Fig. 1). We observed only an increase in monounsaturated fatty acids and a concomitant decrease in fatty acids of the n-6 and n-3 series after four days of primary culture and after eight days of coculture (Fig. 1). More precisely, linoleic acid fell from 14.8% at day 0 to 8.9% after four days of primary culture and to 4.3% after eight days of coculture, while arachidonic acid did not change. The nonessential PUFA (20:3n-9) did not vary even after eight days of coculture.

The fatty acid variations were larger in PC (Fig. 2) than in PE. The monounsaturated fatty acid level rose with the incubation time of both primary culture and coculture. At the same time, fatty acids of the n-6 and n-3 series decreased, and in contrast with PE, this decrease affected both linoleic and arachidonic acids. These fatty acids fell, respectively, from 17.1% (linoleic acid) and 28.3% (arachidonic acid) at day 0 to 7.1% and 23.2% after four days of primary culture and to 4.4% and 20.2% after eight days

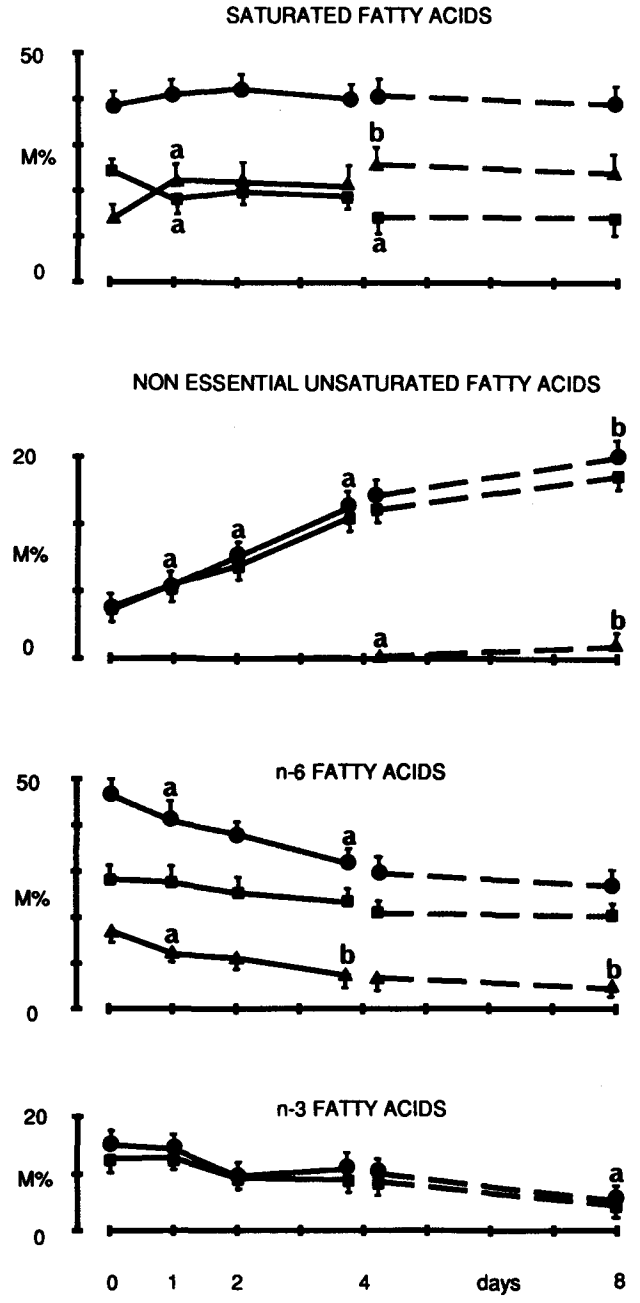

FIG. 2. Fatty acid distribution in phosphatidylcholine of rat hepatocytes. For legend, see Figure 1.

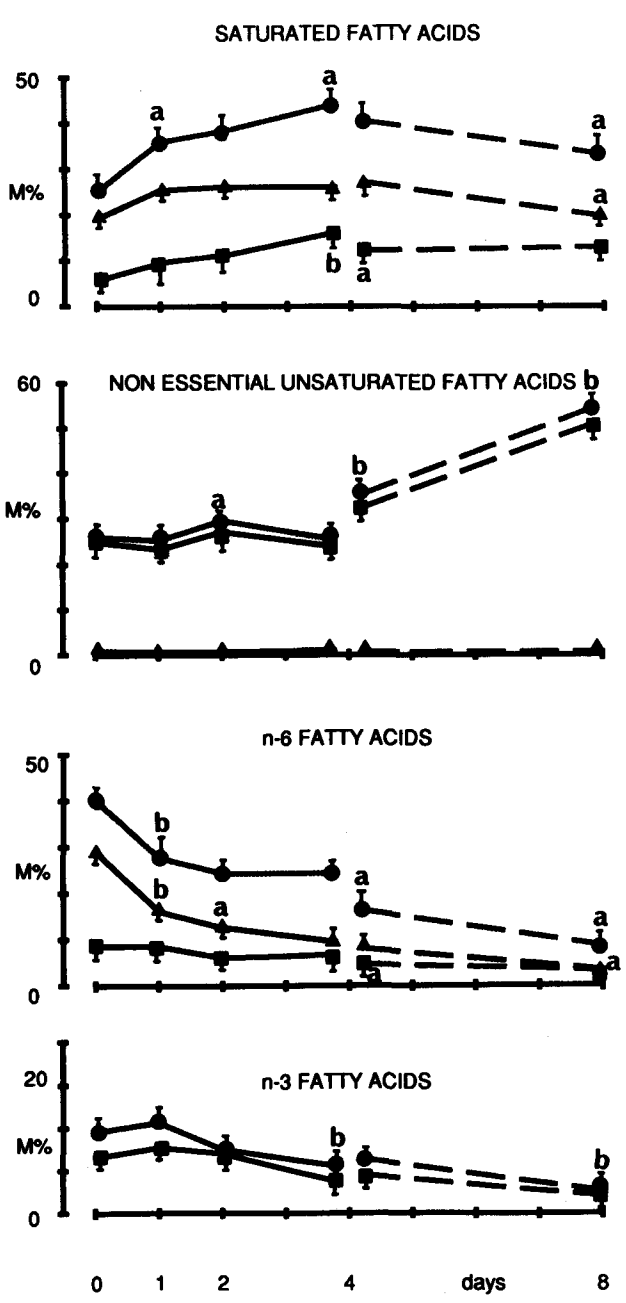

FIG. 3. Fatty acid distribution in triglycerides of rat hepatocytes. For legend, see Figure 1.

of coculture (Fig. 2). The nonessential PUFA (20:3n-9) increased only after eight days of coculture.

Figure 3 shows the dramatic loss of essential fatty acids in triglycerides. When the linoleic and arachidonic acid contents of the triglyceride fraction were respectively, 29.1% and 8.6% at day 0, it fell to 9.3% and 6.8% after four days of primary culture and to 3.3% and 2.6% after eight days of coculture (Fig. 3). The n-3 fatty acids decreased from 9.5% to 2.6% after eight days of coculture. This decrease in EFA was counterbalanced by an increase in saturated fatty acids in primary culture and by an increase in monounsaturated fatty acids in coculture. As in PC and PE, the nonessential PUFA (20:3n-9) remained low (Fig. 3).

Linoleic acid supplementation of primary culture and coculture medium 24 hr before the harvest induced a significant increase in the linoleic acid content of PE (Table 2), PC (Table 3) and TG (Table 4). The increase in linoleic acid in PE and PC was greater in primary culture than in coculture: for example, whereas linoleic acid level was in the same range in deprived primary culture and coculture at day 4, under supplementation it reached 25.2 ± 1.3 and 23.8 ± 0.1 in primary culture vs 17.2 ± 1.1 and 17.0 ± 4.0 in coculture respectively in PE and PC, whereas we observed no difference in TG. The level reached in PE, PC, and TG was nearly the same after two and four days of primary culture but higher than the level reached after 24 hr. In PE, this increase was compensated by a decrease in saturated fatty acids. The level of arachidonic acid and of n-3 fatty acids in PE remained nearly the same, except after four days of primary culture (Table 2).

In PC, the increase of linoleic acid was associated with a decrease in monounsaturated fatty acids and fatty acids of the n-3 series. The arachidonic acid content did not vary after one and two days of primary culture and four days of coculture but fell after four days of primary culture and eight days of coculture (Table 3). In both culture systems, the increase in linoleic acid in TG was paralleled by a decrease in monounsaturated and saturated fatty acids and, to a lesser extent the fatty acids of the n-3 series (Table 4). The arachidonic acid percentage in TG did not vary in primary culture but slightly increase in coculture.

Unexpectedly, we observed an increase in the nonessential PUFA (20:3n-9) level in all lipid classes of hepatocytes in primary culture and in coculture supplemented with linoleic acid. The level reached by 20.3n-9 was higher in TG (Table 4) than in PE (Table 2) and PC (Table 3), i.e., 4.0 ± 0.3, 0.75 ± 0.15 and 1.1 ± 0.1, respectively, at day 4 of primary culture.

To assess the part taken by epithelial cells in the changes that we observed with cocultures, we have performed the same experiments on epithelial cells cultured alone during three days. Table 5 displays the fatty acid composition of epithelial cells supplemented with or without linoleic acid the last 24 hr. The essential fatty acid content of PE, PC and TG was very low in cells incubated without linoleic acid, as compared with hepatocytes in primary culture. Linoleic acid supplementation induced a large enrichment in linoleic acid, which was mainly compensated in PE and PC by a decrease in monounsaturated fatty acids and in TG by a decrease in saturated fatty acids.

Arachidonic acid was not modified, whereas docosahexaenoic acid decreased slightly in PE and PC but increased in TG. We also observed in epithelial cells a surprising increase in the 20:3n-9 level in the three lipid classes.

DISCUSSION

Our results displayed a rapid fall in the linoleic acid content of rat hepatocytes in primary culture and in coculture with rat liver epithelial cells. After four days of primary culture, the linoleic acid content in PE, PC and TG was, respectively, 60, 65 and 32% of the level at day 0. It fell

to 26%, 25% and 11%, respectively, after eight days of coculture. These results confirm those obtained by Lefkowith et al. with suckling mice deprived of essential fatty acids (5). These authors observed that the linoleic acid depletion was higher in the liver than in other tissues. They showed that it was paralleled by a progressive fall in the arachidonic acid content in rat liver PC, PI and neutral lipids but not in PE and PS.

We observed a similar evolution after four days of primary culture and eight days of coculture: arachidonic acid did not decrease in PE, decreased slightly in PC but broke down in TG. At the same time, the end-product of the n-3 series, docosahexaenoic acid, exhibited a moderate decrease in PE but a larger one in PC and TG. These data evidenced the tenacity by which the organism can conserve arachidonic acid when the diet is deprived in EFA,

TABLE 5

Fatty Acid Composition of Epithelial Cell Line Lipids after Three Days of Culture

a tenacity that was underestimated before Lefkowith's report. We further demonstrated that this tenacity involves a mechanism that is conserved up to four days of primary culture and up to eight days of coculture of rat hepatocytes.

We found that PE was more stable than PC when cultured hepatocytes were deprived of EFA, in accordance with Lefkowith et al. (5). Furthermore, after four days, cocultured hepatocytes exhibited a greater stability of PE composition than cells in primary culture. This effect could not be explained by an arachidonic acid transfer from epithelial cells to hepatocytes because epithelial cells were largely depleted in arachidonic acid (Table 5).

The fatty acyl composition of PE remained stable when hepatocytes in primary culture or in coculture were supplied with linoleic acid. This agrees with Weiner and Sprecher, who observed that feeding rats with linoleate did not significantly modify the arachidonic acid level in liver and platelet phospholipids (21). Furthermore, PC and PE exhibited a clear difference in the fate of their fatty acids when linoleic acid was added to the culture medium 24 hr before the harvest. The linoleic acid increase was balanced by a decrease of saturated fatty acid in PE (Table 2) and by a decrease in monoenoic fatty acids in PC (Table 3). These differences might be explained by a different potency of the deacylation-reacylation cycle towards PE and PC and/or by the existence of sparing mechanisms for arachidonyl molecular species of PE such as those evidenced by Aeberhard et al. in cultured skin fibroblasts (11).

The nonessential PUFA 20:3n-9 did not increase in PE or in PC during primary culture and only slightly increased in cocultures. This confirms a previous observation that, during a more severe EFA deprivation (8 wk), 20:3n-9 moderately accumulated in liver, whereas its accumulation in other tissues was much greater (5). Similarly, 20:3n-9 accumulated into 3T3 cells in culture with 10% fetal bovine serum (22).

As we have reported (12), linoleic acid addition to the medium induced an increase in the TG level but no change in the PL level of hepatocytes in primary culture as well as in coculture (Table 1). Whereas TG were highly enriched in linoleic acid, the arachidonic acid level remained rather stable, and the 20:3n-9 level increased. Taking into account the increase in the TG mass of hepatocytes in primary culture incubated with linoleic acid, we can evidence a net increase in both arachidonic acid and 20:3n-9 levels in TG: 2- to 3-fold and 7- to 17-fold, respectively (Table 6). This net increase might have been explained by a fatty acid transfer from phospholipid stores of polyunsaturated fatty acids because we have observed a phospholipid loss as a function of time. However, (1) medium was changed every day, (2) the PL content of hepatocytes remained constant under linoleic acid supplementation, and (3) arachidonic acid and 20:3n-9 levels remained constant in PL at least during two days of primary culture and four days of coculture (Tables 2 and 3).

TABLE 6

Net Increase of Arachidonic Acid or Mead Acid in Hepatocyte Triglycerides after Linoleic Acid Supplementation

	Primary culture		Coculture	
	Day 2	Day 4	Day 4	Day 8
Arachidonic	1.95 (×2.6)	1.58 (×1.8)	1.94 (×2.5)	2.24 (×3.0)
(20:3n-9)	1.81 (×17)	1.87 (×8.5)	1.50 (×9.9)	1.86 (×7.0)

Results are expressed in μg/mg of proteins. Values in parentheses are the ratio between these data and the mass of triglyceride arachidonic acid in cultures nonsupplemented with linoleic acid. This mass was calculated from the triglyceride level (Table 1) and the fatty acid composition of triglycerides (Table 4) at the indicated times of incubation.

The low percentage of arachidonic acid observed in epithelial cells cultured in presence or in absence of linoleic acid, rules out any participation of these cells in the increase of the arachidonic acid in TG of cocultures. The large increase of 20:3n-9 in TG of epithelial cells when they were supplemented with linoleic acid did not allow us to assess the respective role of hepatocytes and epithelial cells in the rise of this fatty acid in coculture. Additional experiments remain to be made to measure a putative Δ5 or Δ6 desaturase induction or stimulation under such circumstances.

Nevertheless, TG appear to act as a storage pool for plasma PUFA up to four days in primary culture and to eight days in cocultures. Besides a coculture seems more potent than primary culture to maintain the phospholipid level, to spare the essential PUFA in PE and to increase the TG synthesis in response to linoleic acid supplementation.

Absorption and Transport of Deuterium-Substituted 2*R*,4′*R*,8′*R*-α-Tocopherol in Human Lipoproteins

Maret G. Traber[a,*], Keith U. Ingold[b], Graham W. Burton[b] and Herbert J. Kayden[a]

[a]Department of Medicine, New York University School of Medicine, New York, NY 10016, and [b]Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada K1A OR6

Oral administration of a single dose of tri- or hexadeuterium substituted 2*R*,4′*R*,8′*R*-α-tocopheryl acetate (d_3- or d_6-α-T-Ac) to humans was used to follow the absorption and transport of vitamin E in plasma lipoproteins. Three hr after oral administration of d_3-α-T-Ac (15 mg) to 2 subjects, plasma levels of d_3-α-T were detectable; these increased up to 10 hr, reached a plateau at 24 hr, then decreased. Following administration of d_6-α-T-Ac (15–16 mg) to 2 subjects, the percentage of deuterated tocopherol relative to the total tocopherol in chylomicrons increased more rapidly than the corresponding percentage in whole plasma. Chylomicrons and plasma lipoproteins were isolated from 2 additional subjects following administration of d_3-α-T-Ac (140 or 60 mg). The percentage of deuterated tocopherol relative to the total tocopherol increased most rapidly in chylomicrons, then in very low density lipoproteins (VLDL), followed by essentially identical increases in low and high density lipoproteins (LDL and HDL, respectively) and lastly, in the red blood cells. This pattern of appearance of deuterated tocopherol is consistent with the concept that newly absorbed vitamin E is secreted by the intestine into chylomicrons; subsequently, chylomicron remnants are taken up by the liver from which the vitamin E is secreted in VLDL. The metabolism of VLDL in the circulation results in the simultaneous delivery of vitamin E into LDL and HDL. ***Lipids 23,*** **791–797 (1988).**

Vitamin E is a fat-soluble vitamin which is transported in human plasma entirely within lipoproteins; no other transport proteins in plasma have been demonstrated (1,2). We have suggested that the transport of vitamin E and its delivery to tissues appears to be related to lipid and lipoprotein metabolism (3). Previously, two mechanisms which deliver lipids to tissues also have been recognized as delivering tocopherol to tissues. Lipoprotein lipase, which hydrolyzes triglycerides contained in lipid-rich lipoproteins (chylomicrons and very low density lipoproteins [VLDL]), also delivers tocopherol to cells, as has been demonstrated in vitro (4). The low density lipoprotein (LDL) receptor, which delivers cholesterol-rich LDL to cells, also delivers tocopherol to cells (5). Although the mechanisms for delivery of tocopherol can be studied in vitro, the question of how and where tocopherol is incorporated into lipoproteins previously was not resolvable due to the lack of an adequate metabolic tracer that could be used in vivo in humans.

Abbreviations: d_0-α-T, nondeuterated α-tocopherol; d_3-α-T, 2*R*,4′*R*,8′*R*-α-(5-C^2H_3)tocopherol; d_6-α-T, 2*R*,4′*R*,8′*R*-α-(5,7-$[C^2H_3]_2$)-tocopherol; d_9-α-T, ambo-α-(5,7,8-$[C^2H_3]_3$)tocopherol; d_3-α-T-Ac, d_3-α-T acetate; d_6-α-T-Ac, d_6-α-T acetate; EDTA, ethylenediaminetetraacetic acid; GC-MS, gas chromatography-mass spectrometry; HDL, high density lipoprotein; IDL, intermediate density lipoprotein; LDL, low density lipoprotein; RBC, red blood cells; VLDL, very low density lipoprotein.

Recently, we have developed a protocol for the synthesis of 2*R*,4′*R*,8′*R*-α-tocopherol (the "natural" stereoisomer) substituted with a precise amount of deuterium and have used deuterated tocopherol to measure the in vivo accumulation of vitamin E in a variety of rat tissues (6). Because deuterium is a stable isotope of hydrogen and presents no hazard to health, deuterium-substituted vitamin E can be safely administered to humans. While many studies have been carried out on vitamin E absorption using single doses of vitamin E (natural and synthetic) or of radioactively labeled vitamin E, the use of deuterium-substituted vitamin E is new and has certain advantages. These include: lack of radioactive toxicity, excellent quantitation at low doses and long-term stability after preparation.

This report describes the use of deuterated α-tocopherol in humans for the study of the absorption of vitamin E and its transport in plasma lipoproteins.

METHODS

Deuterated tocopherol. The procedure for the synthesis of deuterated tocopherol has been described previously (6,7). 2*R*,4′*R*,8′*R*-α-Tocopheryl acetate substituted with either three deuterium atoms (2*R*,4′*R*,8′*R*-α-(5-C^2H_3)tocopheryl acetate; d_3-α-T-Ac) or six deuterium atoms (2*R*,4′*R*,8′*R*-α-(5,7-$[C^2H_3]_2$)tocopheryl acetate; d_6-α-T-Ac) was administered to subjects. The α-tocopherol content of these compounds was shown to be >99% both by thin layer chromatography (TLC) and by gas chromatography-mass spectrometry (GC-MS). The degree of incorporation of the nominal amount of deuterium into each compound was determined precisely by GC-MS and was found to be greater than 85%. All data were adjusted to reflect the true level of the deuterium-substituted tocopherol in the blood samples. The deuterated tocopheryl acetate was taken as a single dose of a weighed quantity of the pure material in a hard gelatin slip-joint capsule.

Subjects. The subjects studied were normal human volunteers without metabolic abnormalities of lipid metabolism and were of normal weight. The subjects gave informed consent and the study was carried out within the guidelines established by the Institutional Review Board of New York University School of Medicine. Following an overnight fast (12 hr), blood was drawn for a pretreatment sample. The subject then swallowed a capsule containing a known weight of deuterated α-tocopheryl acetate, as indicated in the text, consumed a usual breakfast immediately afterwards and followed the usual pattern of daily activities and meals. Blood was drawn into vacutainer tubes containing 0.05 ml 15% ethylenediaminetetraacetic acid (EDTA) (Becton Dickinson, Rutherford, NJ) at the indicated time intervals following the capsule administration. Plasma was immediately separated (within 5 min of blood drawing) from red cells by centrifugation at 20 C. The red cells were washed as previously described (8,9), by repeated resuspension in

phosphate buffered saline and centrifugation at 20 C. Aliquots of known hematocrit were stored at −70 C until shipment on dry ice to Ottawa, Canada, for analysis.

Isolation of lipoproteins by ultracentrifugation. Chylomicrons and lipoproteins were isolated using the newly available TL100 ultracentrifuge (Beckman Instruments, Inc., Palo Alto, CA). Chylomicrons were isolated by a modification of the technique described by Weintraub et al. (10). Plasma (1 ml) was overlayered with 1 ml dialysis buffer (0.15 M NaCl, 0.3 mM EDTA, pH 7.4) in polyallomer centrifuge tubes (11 × 34 mm) and centrifuged with a TLS55 rotor for 8 min at 40,000 rpm in the TL100 ultracentrifuge at 20 C using acceleration and deceleration factors of 3. The chylomicrons were recovered from the top of the tube by tube slicing with a Centritube Slicer (Beckman Instruments, Inc.). The bottom fraction then was aliquoted (1 ml) in duplicate into polycarbonate tubes (11 × 34 mm; Beckman Instruments, Inc.) for isolation of plasma lipoproteins as described (11). The VLDL fraction ($d < 1.006$) was isolated by centrifuging the samples in a TLA-100.2 fixed angle rotor (Beckman Instruments, Inc.) at 435,680 × g for 2 hr at 8 C. The upper 0.25 ml was collected by slicing the tubes. The bottom fraction was collected and the density adjusted to 1.063 g/ml with solid KBr. The samples were then centrifuged at 435,680 × g for 2 hr at 8 C and the top ($1.006 < d < 1.063$, LDL) and bottom ($d > 1.063$, HDL) fractions were recovered as described above. Upon isolation, the lipoprotein fractions were frozen and stored at −70 C until overnight shipment to Ottawa, Canada, on dry ice. The KBr was not removed from the samples prior to analysis.

Analysis of deuterated tocopherol. The relative amounts of deuterated α-tocopherol were determined as previously described (6). In addition, ambo-α-(5,7,8-$[C^2H]_3$)tocopherol (d_9-α-T) was synthesized and was used as an internal standard in order to quantitate the absolute amounts of nondeuterated and d_3- or d_6-substituted α-substituted α-tocopherols. The d_9-α-T, dissolved in *n*-decane, was added to the samples prior to extraction. The d_3-α-T measurements were corrected for the contribution of natural abundance isotopes present in the nondeuterated α-tocopherol. This correction is negligible for d_6-α-T, which permits more precise measurements of very low levels of deuterated tocopherol. This would make d_6-α-T the compound of choice in these experiments. However, d_6-α-T is more expensive to prepare than d_3-α-T and furthermore, pure δ-tocopherol, the d_6-precursor, is more difficult to obtain than pure γ-tocopherol, the d_3-precursor.

RESULTS

Following the oral administration of d_3-α-T-Ac (15 mg) to two male subjects, the percentage of d_3-α-tocopherol (d_3-α-T) relative to the total α-tocopherol present in plasma and red cells was determined. As shown in Table 1, the percentage of d_3-α-T increased during the first 24 hr, reaching nearly 8% of the total tocopherol present in the plasma of subject 2. As would be expected from the known rapid exchange of α-tocopherol between plasma and red cells (8,12,13), the red cells also contained d_3-α-T, with the fractional increase in the deuterated α-tocopherol following a pattern similar to that of the plasma (Table 1).

	50	5.1	5.8

[a]Percentage of d_3-α-T relative to the total α-tocopherol, $100 \times [d_3\text{-}\alpha\text{-T}/(d_3\text{-}\alpha\text{-T} + d_0\text{-}\alpha\text{-T})]$.

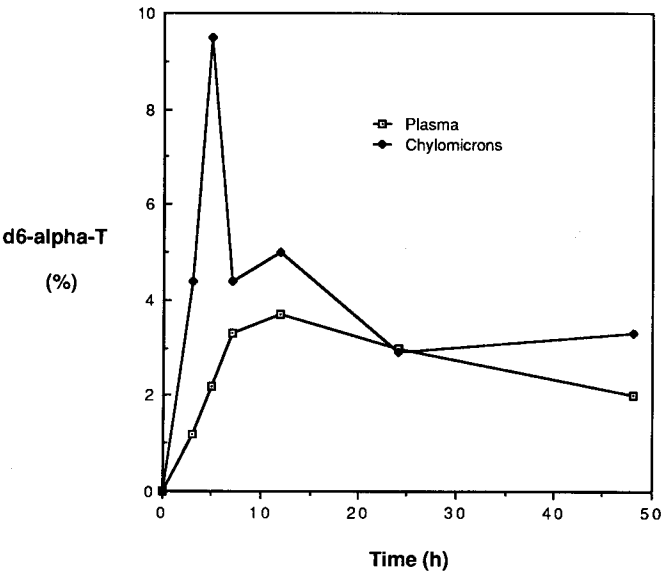

FIG. 1. Percentages of d_6-α-T of the total tocopherol present in the chylomicron fraction and in the plasma of subject 3 (female) at the indicated intervals following oral administration of d_6-α-T-Ac (16 mg).

To assess the mechanism of vitamin E transport from the intestine, two subjects (one male, one female) were given d_6-α-T-Ac (15–16 mg) and plasma was collected at intervals for 48 hr. The percentage of d_6-α-T relative to the total α-tocopherol content of both the chylomicron fraction and whole plasma were determined. As shown in Figure 1, the d_6-α-T in the chylomicron fraction of the plasma of the female subject (subject 3) had increased after 5 hr to nearly 10% of the total α-tocopherol in this lipoprotein fraction. This increase in the percentage of d_6-α-T occurred more rapidly in the chylomicron fraction than the corresponding increase in the plasma, and the maximum percentage was greater in the chylomicrons than in the plasma. A second peak in the chylomicron fraction was observed at 12 hr. Qualitatively similar data were obtained for the male subject (subject 4, data not shown).

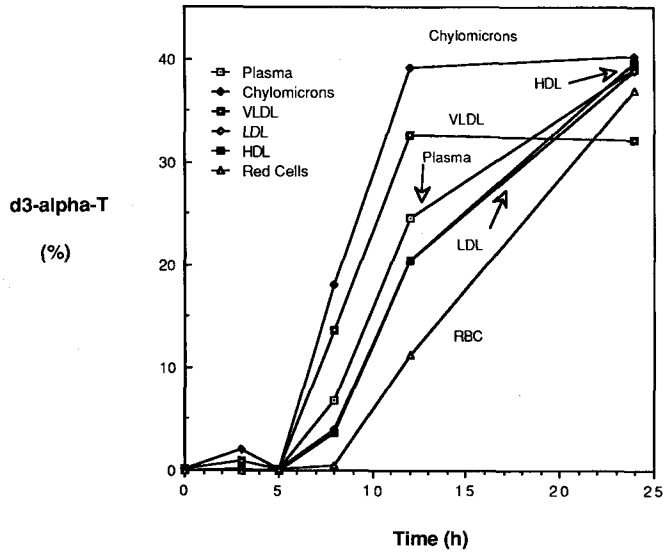

FIG. 2. Percentages of d_3-α-T in chylomicrons, VLDL, LDL, HDL, plasma and RBC relative to the total α-T in each fraction of subject 5 at the indicated intervals following oral administration of d_3-α-T-AC (140 mg).

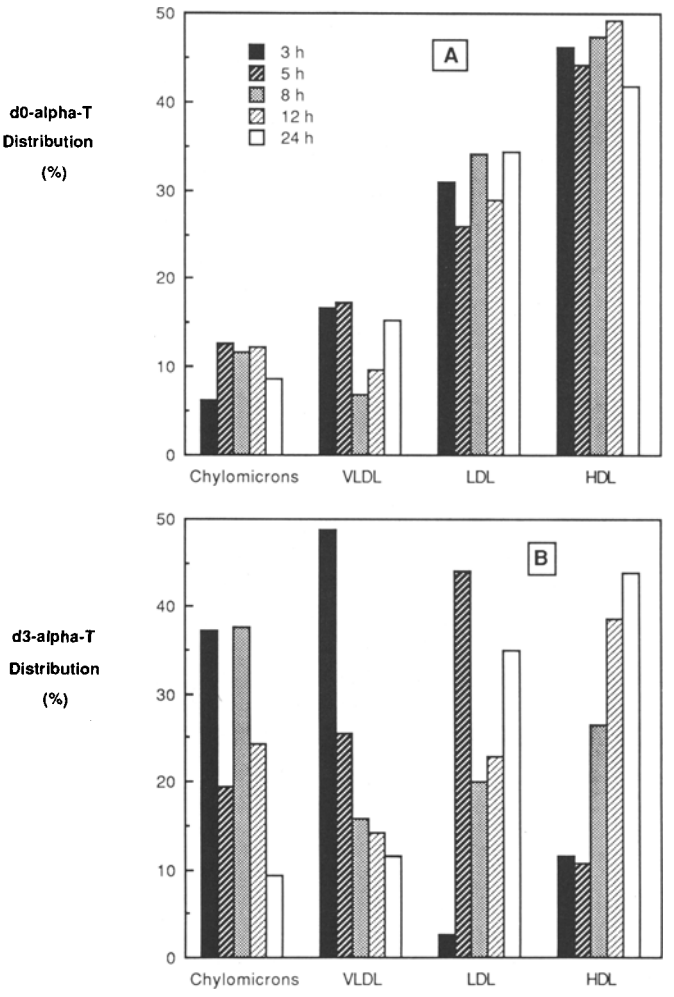

FIG. 3. Distribution (%) of nondeuterated (d_0-α-T, A) and deuterated (d_3-α-T, B) tocopherol between chylomicrons, VLDL, LDL and HDL isolated from the plasma of subject 5 at each of the time points following oral administration of d_3-α-T-Ac (140 mg).

The purpose of this study was to follow the incorporation of vitamin E into all of the plasma lipoproteins. Therefore, a larger dose (140 mg) of d_3-α-T-Ac was administered to subject 5 and the distribution of d_3-α-T in the major lipoprotein fractions was assessed after various intervals of time. As shown in Figure 2, the chylomicron fraction contained the largest percentage of d_3-α-T at all of the time points measured. Unlike the data shown in Figure 1, the deuterated tocopherol reached a maximum in the chylomicron fraction at 12 hr rather than at 5 hr. The lipoprotein fraction that showed the second fastest increase in the percentage content of d_3-α-T was the VLDL fraction, a result which is consistent with uptake of chylomicron remnants by the liver and secretion of the newly absorbed lipids in VLDL particles. The percentages of d_3-α-T in the LDL and HDL fractions were virtually identical at all times, with the highest percentage of d_3-α-T observed at 24 hr.

The absolute quantities of nondeuterated α-tocopherol (d_0-α-T) and of d_3-α-T measured in the plasma, in the four lipoprotein fractions (chylomicrons, VLDL, LDL and HDL), and in the red blood cells of subject 5 are given for each time point in Table 2. The sums of the quantities of d_0-α-T and of d_3-α-T recovered from all of the lipoprotein fraction were between 80–110% of the values in whole plasma. Figure 3 shows the percentages of d_0-α-T and of d_3-α-T in each lipoprotein fraction based on the sum of the quantities of each of these materials recovered at the corresponding time point. From the distribution of d_0-α-T in each lipoprotein fraction (Fig. 3A), it is apparent that most (40–50%) of the tocopherol is present in the HDL fraction of this subject, while the chylomicron and VLDL fractions each contain less than 17%. In marked contrast, Figure 3B shows that at 3 hr the chylomicron fraction contained nearly 40% of the d_3-α-T present in the plasma, with the VLDL fraction containing almost 50%. At 5 hr the d_3-α-T in the chylomicron fraction decreased to 19% with a corresponding increase to 44% in LDL. The remaining time points (8–24 hr) show the stepwise decrease in the d_3-α-T present in the triglyceride-rich particles with the concomitant increases in d_3-α-T in the LDL and HDL particles, finally resulting by 24 hr in the similar distribution of d_3-α-T and d_0-α-T.

Subject 6 was given a smaller amount (60 mg) of d_3-α-T-Ac than subject 5 because the 140-mg dose given to subject 5 produced a plateau in the d_3-α-T/d_0-α-T ratio in the chylomicron fraction, suggesting that the intestine continued to secrete chylomicrons containing d_3-α-T for as long as 24 hr after administration of the dose. As can be seen from Figure 4, a similar pattern of increases in the percentage of d_3-α-T in the lipoprotein fractions was observed in subject 6 as in subject 5 (Fig. 2). However, in subject 6, the percentage of d_3-α-T in the VLDL fraction increased at 8 hr and remained above that seen in the chylomicron fraction. The absolute quantities of d_0-α-T and of d_3-α-T in the plasma, lipoprotein fractions and red blood cells of subject 6 are given in Table 3 for each time point. Table 3 also includes the total quantities of

n.d., not determined.

α-tocopherol and the percentages of d_0-α-T and d_3-α-T in each lipoprotein fraction (based on the sum of d_0-α-T and d_3-α-T, respectively, in these four fractions). The sums of the d_0-α-T recovered from each lipoprotein fraction were 49–108% of the corresponding quantities measured in whole plasma.

As shown in Figure 5A, the distribution of d_0-α-T in the plasma of subject 6 was equally divided into LDL and HDL, with little in the triglyceride-rich lipoproteins. At times 3.5 and 5 hr, the percentage of d_0-α-T in the chylomicron fraction decreased in response to the absorption of d_3-α-T, although only 8% and 10% of the total d_3-α-T was present in chylomicrons (Figure 5B). It is likely that this subject had a peak in chylomicron d_3-α-T prior to the 3.5 hr time point, as the HDL fraction by this time contained 55% of the plasma d_3-α-T. This subject appears to rapidly catabolize triglyceride-rich particles and by 8 hr, d_3-α-T is distributed identically to d_0-α-T.

DISCUSSION

Deuterium-substituted α-tocopherol was used in this study to follow vitamin E transport in human plasma. The technique allows the α-tocopherol derived from newly-ingested α-tocopheryl acetate to be distinguished from existing, nondeuterated α-tocopherol present in the individual. We have demonstrated that a dose of 15 mg of deuterated α-tocopheryl acetate gives measurable

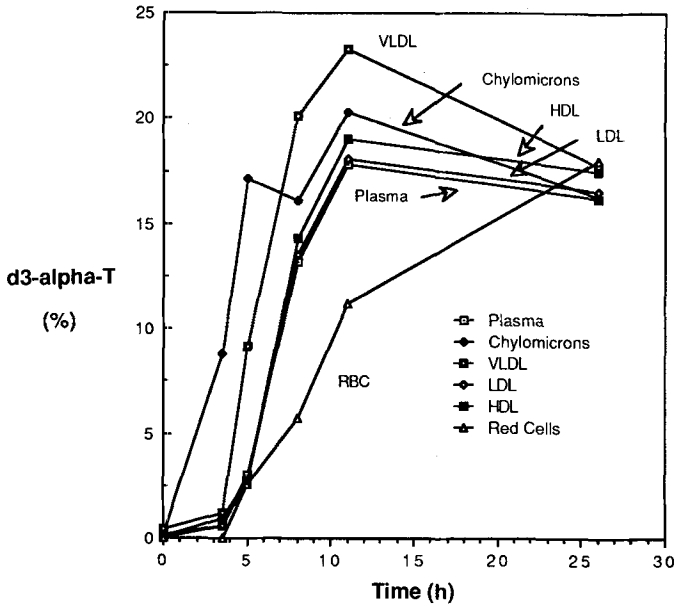

FIG. 4. Percentages of d_3-α-T in each of the lipoprotein fractions, plasma and RBC relative to the total α-T in each fraction of subject 6 at the indicated intervals following oral administration of d_3-α-T-Ac (60 mg).

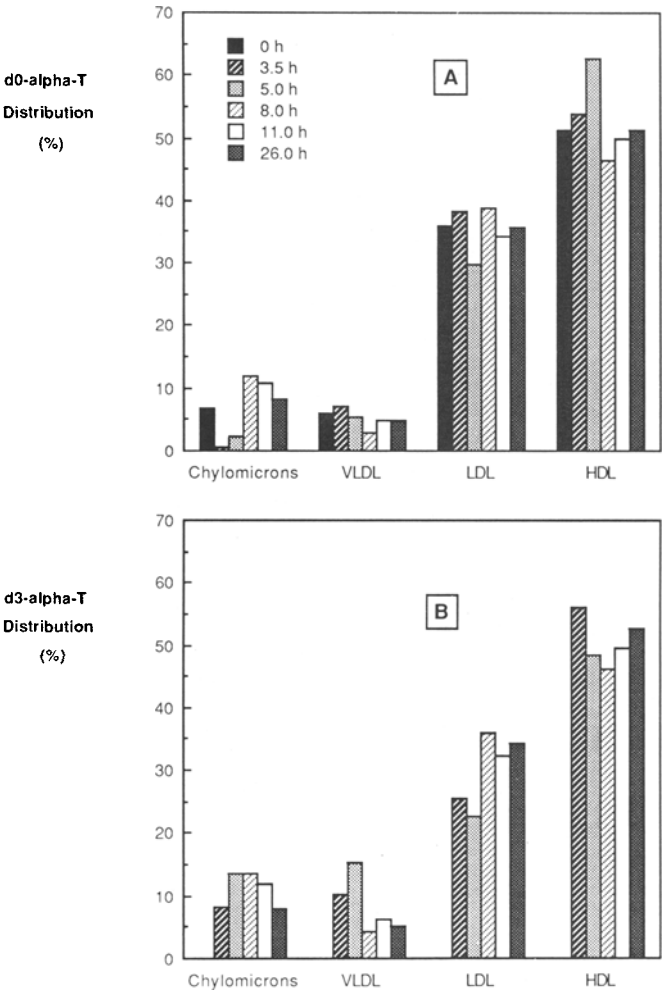

FIG. 5. Distribution (%) of nondeuterated (d_0-α-T, A) and deuterated (d_3-α-T, B) tocopherol within each of the lipoprotein fractions isolated from the plasma of subject 6 at the indicated intervals following the oral administration of d_3-α-T-Ac (60 mg).

quantities of deuterated α-tocopherol in the plasma and is sufficient to document its incorporation into chylomicrons. The time course of the transport of α-tocopherol in lipoproteins was studied using 140-mg and 60-mg doses of d_3-α-T-Ac. It can be seen from the data in Tables 2 and 3, that the effect of these fairly large doses of d_3-α-T is to produce rather small but clearly discernible increases in the total quantity of vitamin E (i.e., d_0-α-T + d_3-α-T) in the plasma of subjects 5 and 6, in most of the lipoprotein fractions of subject 5 and in the red blood cells.

α-Tocopherol from orally-administered deuterated α-tocopheryl acetate appeared first in the chylomicron fraction of the plasma. The percentage of deuterated tocopherol increased in this fraction before increasing in the whole plasma and before the increase in any of the other lipoprotein fractions (Figs. 2 and 4). The VLDL fraction was the next to become labeled. This result is consistent with the secretion of chylomicrons by the intestine, uptake of chylomicron remnants by the liver and secretion by the liver of α-tocopherol in newly synthesized VLDL. Both chylomicrons and VLDL are substrates for lipoprotein lipase, which hydrolyzes the triglycerides present in these lipid-rich particles, producing chylomicron remnants and intermediate density lipoproteins (IDL), respectively. Traber et al. (4) have shown in vitro that lipoprotein lipase transfers tocopherol to cells during the hydrolysis of triglyceride-rich particles. Thus, the newly absorbed vitamin E is first incorporated into chylomicrons, then, during the production of chylomicron remnants by lipoprotein lipase (14), some α-tocopherol is transferred to tissues, but much of the vitamin E remains in the remnants which are subsequently taken up by the liver. The liver then secretes the newly absorbed tocopherol in VLDL particles, which also are subject to catabolism by lipoprotein lipase. During the latter process, some IDL particles are converted to LDL, while some are taken up by the liver (14).

From the pattern of deuterated tocopherol present in the LDL and HDL fractions (Figs. 2 and 4), it is clear that the increase in the percentage of d_3-α-T in these two fractions occurs after the increase of deuterated tocopherol in VLDL. The striking finding shown in Figures 3 and 5 is the demonstration of the differences in tocopherol transport in the two subjects, despite the apparent similarities of Figures 2 and 4. In subject 5 (Fig. 3), the d_3-α-T was predominantly in the triglyceride-rich lipoproteins at early time points, with little d_3-α-T in the HDL fraction until the 12- and 24-hr time points. By contrast, in subject 6, 56% of the d_3-α-T tocopherol present in the plasma at 3.5 hr was in the HDL fraction—the chylomicron fraction never contained a major portion of the plasma d_3-α-T. The differences in the two subjects are probably a result of the larger dose of d_3-α-T-Ac given to subject 5, and to differences in the lipoprotein metabolism in the two subjects. The results do not unequivocally demonstrate whether the majority of tocopherol in the plasma arises from the catabolism of VLDL to LDL, as the data in Figure 3B suggest, or whether the majority

of plasma tocopherol arises from the transfer of tocopherol with surface components to HDL (14) during the hydrolysis of triglyceride-rich particles, as Figure 5B suggests. The ability of tocopherol to exchange between LDL and HDL (12) quickly results in the equilibration of the newly ingested tocopherol in these two fractions, such that the percentages of d_3-α-T of the total tocopherol are similar in LDL and HDL. It appears that differences in lipid metabolism and in lipoprotein synthesis and turnover between individuals are most important in determining the distribution of tocopherol between the individual lipoproteins.

In conclusion, the data presented in this study using deuterium-labeled α-tocopherol demonstrate that vitamin E is incorporated and transported in the lipoproteins in a manner consistent with the known mechanisms of lipid and lipoprotein transport and catabolism. The use of deuterium-substituted α-tocopherol will be invaluable for assessing the bioavailability of different stereoisomers of α-tocopherol, for measuring the absorption and transport of vitamin E in patients at risk from vitamin E deficiency due to abetalipoproteinemia, cholestatic liver disease, cystic fibrosis and other related diseases.

[Received January 11, 1988; Revision accepted May 2, 1988]

Effect of Previous Nutritional Status on the Formation of Cholesterol Gallstones in the Prairie Dog

Bertram I. Cohen*, Erwin H. Mosbach and Charles K. McSherry
Beth Israel Medical Center and Mount Sinai School of Medicine of the City University of New York, New York, NY 10003

In the prairie dog model of cholesterol cholelithiasis, a high incidence of gallstones is achieved by feeding a semipurified lithogenic diet containing 0.4% cholesterol for 2 mo. On occasion, we noted a decrease in the percentage of animals with gallstones from 90–100% to 50–55%. To explain this phenomenon, we studied the effect of dietary history on gallstone formation. After weaning, animals were fed either rodent chow or alfalfa plus corn (mo 0–3) followed by a cross-over experiment at mo 4–6. Gallstone formation then was studied by feeding the lithogenic diet from mo 7 to 8. At sacrifice, the incidences of gallstones, biliary lipids and tissue cholesterol levels were correlated with dietary history. The incidence of gallstones was 100% only in animals fed the alfalfa-corn diet from weaning to 3 mo. In addition, the feeding of the alfalfa-corn diet at mo 4–6 increased gallstone incidence from 65% to 86%. The lithogenic index of all groups was highest when the animals received only alfalfa-corn prior to the lithogenic stimulus. The activity of hepatic HMG-CoA reductase was elevated in animals fed alfalfa-corn from weaning to 8 mo, suggesting that this diet stimulates hepatic cholesterol synthesis, leading to increased biliary cholesterol secretion. It is concluded that previous nutritional conditioning affects the incidence of gallstones. The prairie dog is a useful model of cholesterol cholelithiasis, but the dietary history of the animals plays an important role in lithogenesis.
Lipids 23, 798–803 (1988).

The formation and prevention of cholesterol gallstones have been studied in a number of animal models, most frequently in the mouse (1), hamster (2–6) and prairie dog (7–12). Studies in man have been concerned largely with dissolution of stones (13), but the prevention of stone recurrence following dissolution by chenodeoxycholic acid, ursodeoxycholic acid, methyl tertiary butyl ether or physical means has recently become of considerable interest (14). Dissolution of cholesterol gallstones in man following the oral administration of chenodeoxycholic acid (750 mg per day) was the objective of extensive clinical trials in the United States (13) and Canada (15), but the results were disappointing, apparently because the dose of the drug per unit of body wt was too low. Recently, considerably higher dissolution rates were obtained by European investigators using dosages of 12–16 mg/kg/day (16). Nevertheless, there exists still the need for developing a second generation of cholelitholytic drugs that possess greater efficacy than chenodeoxycholic acid and ursodeoxycholic acid and do not give rise to the potentially hepatoxic lithocholic acid via bacterial 7-dehydroxylation.

Our laboratory has been moderately successful in studying the prevention of gallstones by hydrophobic and hydrophilic bile acids in the prairie dog (10,11). For this purpose, gallstones were induced routinely in 90–100% of the animals by the administration of a semipurified diet containing 0.4% cholesterol. Occasionally, for reasons not entirely clear to us, the incidence of gallstones in animals fed the lithogenic diet for the standard period of 8 wk decreased to less than 50%. We decided to investigate this undesirable phenomenon, because a low incidence of gallstones in the control groups would make the evaluation of gallstone-preventing or dissolving agents very difficult.

This manuscript describes the effect of the dietary history of the prairie dogs on the subsequent incidence of gallstones after animals are placed on the semipurified, lithogenic diet. The data strongly suggest that the dietary history of the prairie dogs plays a role in cholesterol metabolism and gallstone formation.

MATERIALS AND METHODS

Animals and diets. Male prairie dogs *(Cynomys ludovicianus)* were bred in captivity by R-Zoo, Neshboro, WI. The animals were maintained at the R-Zoo facility from weaning to 5.5 mo. They were received at the Beth Israel Medical Center Animal Facility and maintained from 5.5 mo to age 8 mo, when the experiment was completed. The animals were fed either Purina rodent chow or alfalfa and whole grain corn (50:50, w/w), ad libitum, from weaning to 6 mo of age as summarized in Table 1. For periods 1 and 2, these diets were fed at R-Zoo (0–5.5 mo) or Beth Israel (5.5–6 mo). The animals were quarantined for the last 2 wk of mo 6. At the start of period 3 (mo 7), the animals were weighed and then fed the following: (a) semipurified diet plus 0.4% cholesterol (lithogenic diet—fed to groups 2, 3, 5 and 6), (b) chow (group 1) or (c) alfalfa-corn (group 4). The lithogenic diet was prepared by Teklad (Madison, WI) and consisted of sucrose, 51.9%; corn starch, 13.9%; soy protein, 21.0%; corn oil, 1.6%; cellulose, 2.6%; vitamin mix, 1.0% (Teklad 40860); and mineral mix, 4.0% (Teklad 40060). Cholesterol (0.4%) was incorporated as egg yolk powder (4%). Period 3 lasted 8 wk; food intake was limited to 40 g/day with water supplied ad libitum. The animals were kept on an alternating 12-hr light–12-hr dark cycle. Food was removed during the 24 hr prior to sacrifice of the animals (mo 8) to insure adequate quantities of bile in the gallbladder for biliary lipid analyses. The animals were anesthetized with 100 mg of ketamine hydrochloride (Bristol Labs, Syracuse, NY) and 20 mg of xylazine (Haver Lockhart, Shawnee, KA). They were killed by exsanguination and blood was collected for determination of serum cholesterol. The gallbladder was removed and bile was aspirated with a Hamilton syringe. The fresh bile was immediately examined by polarized light microscopy (Olympus MCHAP microscope, Olympus Corp., Lake Success, NY) to determine the presence of cholesterol crystals, liquid crystals and cholesterol

gallstones (17). The liver was excised and weighed and aliquots removed for cholesterol determination and preparation of microsomes.

Biliary lipid composition. Gallbladder bile obtained at sacrifice was immediately centrifuged at 2000 × *g* for 10 min. Aliquots (50 μl) were prepared and used for determination of the three biliary lipids (10,11). The lithogenic indices were calculated using the methods of Carey (18) and Kuroki et al. (19).

Enzyme assays. Liver microsomes were prepared from samples of fresh liver. HMG-CoA reductase and cholesterol 7α-hydroxylase were measured using methods described earlier (10,11).

Gas liquid chromatography and gas liquid chromatography-mass spectrometry. Gas liquid chromatography (GLC) of cholesterol in liver, plasma and bile was carried out as described earlier (10,11). Biliary bile acids were separated and quantitated as their methyl ester acetates on a Hewlett-Packard 5831A gas chromatograph equipped with a capillary column (SPB-5, 25 m, Supelco Inc., Bellefonte, PA). The conditions for the GLC analysis were: injector temp, 270 C; detector temp, 270 C; auxiliary temp, 270 C; temp 1, 200 C for 2 min; temp 2, 270 C for 25 min (rate 10 C/min). In every group, the identity of the bile acids was confirmed by gas liquid chromatography-mass spectrometry (GLC-MS) using a Hewlett-Packard 5992B mass spectrometer. The conditions used were: 4 ft glass column, 2 mm ID, 4 mm OD, packed with 3% SP 2250 on 100/120 mesh Supelcoport; column temp, 260 C; injector temp, 265 C; source pressure, 1.5×10^{-6} torr; source temp, 140 C.

Reference compounds. 5α-Cholestane (Applied Science) was used as an internal standard for quantitation of cholesterol. 3α,7α-Dihydroxy-12-keto-5β-cholanoic acid (Steraloids, Wilton, NH) was used as a recovery standard for biliary bile acids.

Statistical calculations. All data are reported as mean ± SEM. Analysis of variance was used to determine the F statistic. Students' t-test was used for the values where the F statistic was significant (20). Chi square was used to determine the statistical significance of gallstone incidence between groups (20).

RESULTS

All prairie dogs were bred in captivity and fed the various diets after weaning to the end of the experiment (Table 1). The average initial and final weights of the animals in all groups were similar and did not differ statistically. Food intake and fecal outputs, monitored during period 3 for the six groups, also were similar.

At sacrifice, the incidence of cholesterol gallstones, cholesterol crystals, biliary lipids, activities of the rate-limiting enzymes of cholesterol and bile acid synthesis and tissue-cholesterol levels were correlated with dietary history. Incidences of gallstones and cholesterol crystals are summarized in Table 2. Animals given the chow diet during periods 1 and 2 had a lower incidence of both stones and crystals, regardless of the diet given in period 3 (groups 1 and 2 vs 4 and 5). Stone incidence was found to be greater for groups fed alfalfa-corn in period 1 (groups 4-6 vs 1-3). The highest stone incidence was found in animals fed alfalfa-corn for periods 1 and 2 followed by the lithogenic diet in period 3 (group 5 vs group 2).

The data summarized in Table 3 show levels of cholesterol in liver, plasma and bile and the activities of the rate-limiting enzymes of cholesterol and bile acid synthesis, HMG-CoA reductase and cholesterol 7α-hydroxylase. Liver cholesterol levels were elevated in animals fed the lithogenic (0.4% cholesterol) diet during period 3. Feeding either chow or alfalfa-corn during periods 1 and/or 2 did not affect liver cholesterol. However, plasma cholesterol levels, which also were elevated by feeding the lithogenic diet, were highest for animals fed only the alfalfa-corn during periods 1 and 2. Animals given only chow or alfalfa-corn during all three feeding periods had normal liver and plasma cholesterol levels. Bile cholesterol levels were generally higher with administration of the lithogenic diet (groups 2, 3, 5 and 6). The activity of HMG-CoA reductase showed several interesting differences. First, animals fed alfalfa-corn (group 4) had an enzyme activity more than 2 times that of animals fed only chow (group 1). As expected, feeding the high cholesterol lithogenic diet (groups 2, 3, 5 and 6) led to a decrease in enzyme activity (10,21). Cholesterol 7α-hydroxylase activity averaged from 8 to 17 pmoles/mg protein/min for the experimental groups.

The data summarized in Table 4 illustrate the effect of the various dietary regimens on biliary lipid composition and lithogenic index of the bile. All groups fed the lithogenic diet had increased levels of cholesterol in the bile. This was coupled with an increased level of biliary phospholipid. The total lipid concentration for all groups ranged from 7.1 to 9.2 g/dl. Animals fed the lithogenic

TABLE 1

Experimental Design of Eight-Month Feeding Experiment[a]

[c]Differs significantly from groups 5 and 6 by chi square; $p < 0.01$.

diet had lithogenic indices which approached or exceeded 1.0. The highest lithogenic index was present in animals fed alfalfa-corn for periods 1 and 2 followed by the lithogenic diet in period 3 (lithogenic index, 1.58). Even though the lithogenic index for the group given only alfalfa-corn (group 4) averaged 0.81, the one animal in this group that had cholesterol gallstones was found to have a lithogenic index of 1.01.

Biliary bile acid composition was analyzed at sacrifice (Table 5). The amount of chenodeoxycholic acid in the chow-fed animals (group 1) was twice that for animals fed only alfalfa-corn (group 4). As expected from previous studies, feeding diets high in cholesterol led to an increase in the amount of chenodeoxycholic acid and a decrease in cholic acid. These changes were similar for groups 2, 3, 5 and 6. The amounts of lithocholic acid and deoxycholic acid were small (ranging from 0.3% to 0.8% and 0.7% to 2.6%, respectively).

DISCUSSION

The prairie dog has been employed as a model of cholesterol cholelithiasis (8,22,23). In this species, it is relatively easy to induce cholesterol gallstones by administering a diet containing 0.4-1.2% cholesterol for a period of a few wk to several mo. Many investigators have reported a gallstone incidence of close to 100% when a semipurified basal diet was employed, to which cholesterol was added in the form of dried egg yolk powder and as crystalline cholesterol monohydrate (8,24). For unknown reasons, the combination of the semipurified diet plus cholesterol is not an ideal lithogenic diet in this model because it induces significant hepatotoxicity, characterized by bile duct proliferation, inflammatory reaction and portal fibrotic changes (10). When chow was substituted for the semipurified diet, liver damage was no longer observed, but the rate of stone formation was significantly decreased (24).

In our hands, gallstone formation in the prairie dog was not as consistent and reproducible as reported by others (8,22,23). We attributed this phenomenon to the fact that initially the animals used by most investigators including our group had been trapped in the wild and were quite heterogeneous. However, the present experiments demonstrate that even animals bred in captivity and in much better physical condition than trapped specimens exhibited a phenomenon not observed previously in prairie dogs: the response of the animals to the semipurified, high-cholesterol lithogenic diet depended on the dietary history of the animals or, more specifically, on the dietary regimen fed to the animals after weaning. The effect of prefeeding the prairie dogs different diets before administering the lithogenic diet became apparent when, in successive experiments of identical design, the incidence of cholesterol gallstones dropped from nearly 100% to 40-50%. In both studies, the lithogenic diet was identical (semipurified diet plus 0.4% cholesterol, for 8 wk), a diet previously shown to produce a high incidence of gallstones (8,10,23). Further investigation showed that the supplier of our animals had, for reasons of convenience, changed the diets of the prairie dogs during the six-month period after weaning. The diet given previously was an alfalfa-corn mixture that produced an adequate, high incidence of cholesterol gallstones when the lithogenic diet was administered. The diet fed subsequently was Purina rodent chow; after receiving this diet for six mo, followed by the lithogenic diet, the incidence of cholesterol stones was reduced to only 40-50%. We designed the present experiment to elucidate whether the incidence of gallstones was indeed affected by the dietary history, i.e., whether prefeeding the animals with either chow or alfalfa-corn would affect the incidence of gallstones when the animals were subsequently placed on the lithogenic diet.

The experimental protocol, a modified Latin square design, is shown in Table 1. The experiment was designed to show whether maintaining prairie dogs with an alfalfa-corn regimen, immediately after weaning (period 1) or after an intervening period on rodent chow or alfalfa-corn (period 2), affects gallstone formation and cholesterol metabolism after administration of the semipurified, cholesterol-containing lithogenic diet (period 3).

The data on the incidence of gallstones and biliary cholesterol crystals listed in Table 2 clearly demonstrate the difference between the chow diet and the alfalfa-corn regimen. As expected, the control animals fed chow throughout the three experimental periods had neither gallstones nor biliary cholesterol crystals. In contrast, administration of the alfalfa-corn diet during the entire eight-mo experimental period induced biliary cholesterol crystals in three out of four animals and gallstones in one animal. This result was unexpected, because this group (group 4) had not been exposed to any cholesterol in the diet. To confirm this effect of the alfalfa-corn diet, we maintained eight animals on a pelleted diet containing equal amounts of alfalfa and corn by weight. At the end of two mo, four of the animals had cholesterol gallstones and exhibited numerous cholesterol crystals in bile. Thus, it seems probable that this cholesterol-free diet is lithogenic in the prairie dog.

In general, the results listed in Table 2 confirm our previous observation that the incidence of cholesterol gallstones was reduced in animals raised and maintained

on chow before being exposed to the lithogenic diet (group 2) (24). In contrast, animals given alfalfa-corn, either before or after a period on chow, had an incidence of gallstones ranging from 86% (group 3) to 100% (groups 5 and 6). The animals in all three groups exhibited a 100% incidence of biliary cholesterol crystals. These data lead to the conclusion that the alfalfa-corn diet has both a long-term and a direct effect on one or several factors affecting gallstone formation.

We examined a number of parameters of cholesterol metabolism in an attempt to explain our data. On the cholesterol-free diets (groups 1 and 4), liver and serum cholesterol levels were within normal limits (Table 3) and the lithogenic indices were well below 1.0. However, the single animal of group 4 with gallstones had a lithogenic index of 1.01. The presence of cholesterol crystals in the gallbladder bile at sacrifice (group 4) suggests that during the experiment these biles must have been supersaturated and that nucleating agent(s) may have been present. It is known that cholesterol-containing lithogenic diets produce, in the prairie dog, increased secretion of mucus and this may serve as the nucleating factor (25). It also is noteworthy that feeding the cholesterol-free alfalfa-corn diet was associated with a very significant elevation of hepatic microsomal HMG-CoA reductase activity (269 units for group 4; 121 units for group 1 [chow]). It has been observed previously that this enzyme activity was elevated in human gallstone patients, and it has been suggested that increased hepatic HMG-CoA reductase activity is associated with an increased secretion of cholesterol into the bile (26,27). In rats, we determined that HMG-CoA reductase activity reflected hepatic cholesterol synthesis (28). At present, we have no mechanistic explanation for the stimulation of HMG-CoA reductase activity by the alfalfa-corn diet, but it seems likely that the very high fiber content inhibits cholesterol absorption. However, it also must be stated that, on the average, the alfalfa-corn group had the lowest cholesterol level in gallbladder bile of all the groups studied. Obviously, more detailed studies on the influence of these diets on hepatic cholesterol secretion are needed.

The effects of the cholesterol-containing lithogenic diet in animals previously maintained with alfalfa-corn again demonstrates the effect of dietary history on the development of cholesterol cholelithiasis. Only those prairie dogs receiving alfalfa-corn immediately after weaning (period 1) subsequently exhibited a 100% incidence of gallstones and cholesterol crystals (groups 5 and 6). It is of interest that animals maintained with chow immediately after weaning, followed by alfalfa-corn in period 2, also had a very high incidence of gallstones (group 3, 86%) in comparison with animals given only chow during periods 1 and 2 (group 2, 59%). Measurement of tissue-cholesterol concentration and hepatic HMG-CoA reductase activity again suggested a strong effect of the alfalfa-corn diet on cholesterol metabolism. The highest plasma cholesterol levels and HMG-CoA reductase activity were found in group 5 (alfalfa-corn fed during periods 1 and 2). The data in Table 3 further demonstrate that animals fed chow before being given the lithogenic diet had lower HMG-CoA reductase activities than those receiving alfalfa-corn (groups 2 vs 3 and 5 vs 6). The activities of hepatic cholesterol 7α-hydroxylase in these groups were low, as is usually the case in the prairie dog, but nevertheless it can be seen that the activity of this rate-determining enzyme of bile acid synthesis varied in the opposite direction of that shown by HMG-CoA reductase.

These studies demonstrate a phenomenon not previously reported in the prairie dog or other species, namely, that the nature of the diet fed early in life affects the susceptibility to a lithogenic diet at a later time. Other investigators have had variable success in attempting to condition a hypercholesterolemic response by feeding different diets early during the life cycle. In the rat, high-fat or high-carbohydrate diets did not appear to modify the subsequent response to a high-cholesterol diet (29). In contrast, in the guinea pig, the administration of cholestyramine (a bile acid sequestrant) to neonatal animals caused a dramatic increase in plasma cholesterol and cholesterol degradation in adult life (30). The latter experiment suggested the possibility that dietary changes in early life can affect the subsequent response to a cholesterolemic stimulus.

The specific role of alfalfa-corn in the present studies, of course, is not yet known. On the basis of earlier work, it seems likely that nonnutritive dietary fiber may be responsible for the "memory" effect on cholesterol (and/or biliary lipid) metabolism. For example, in rats given a single dose of [4-^{14}C]cholesterol, the highest fecal excretion of radioisotope was observed when the animals were maintained with a diet containing alfalfa and corn oil (31). This suggests that in those and the present experiments alfalfa might have a bile acid binding effect similar to that of cholestyramine (32). Indeed, when Kritchevsky and Story studied the binding of taurocholate by semipurified diets supplemented with different dietary fiber, they found that alfalfa bound about one-fifth as much bile salt as cholestyramine and one-third as much as colestipol. (The latter drug, like cholestyramine, is used clinically to bind bile acids and reduce serum cholesterol concentrations [32,33].) In vitro studies likewise have shown that alfalfa can bind significant amounts of taurocholate (34). Kritchevsky and Story have presented an excellent, concise summary of the effect of dietary fiber on cholesterol/bile acid binding, absorption and metabolism (32). In the present experiments, taurocholate is the major bile salt of the prairie dog, but is partially replaced by taurochenodeoxycholate in the presence of dietary cholesterol.

Thus, our data suggest that, in the prairie dog, early exposure to the high-fiber, alfalfa-corn diet increases bile cholesterol biosynthesis. This increased rate of synthesis presumably persists even after this diet has been replaced by a diet of reduced fiber content (chow). It is known from studies in man that increased hepatic cholesterol synthesis is associated with, although not necessarily the cause of, cholesterol cholelithiasis. Obviously, the exact mechanism operative in animals given high-fiber diets remains to be established and, in particular, its effect on biliary lipids and nucleating/antinucleating agents.

METHODS

Location of Methyl Branchings in Fatty Acids: Fatty Acids in Uropygial Secretion of Shanghai Duck by GC-MS of 4,4-Dimethyloxazoline Derivatives[1]

Q.T. Yu, B.N. Liu, J.Y. Zhang and Z.H. Huang*
Laboratory of Mass Spectrometry, Shanghai Institute of Materia Medica, Chinese Academy of Sciences, 319 Yue-yang Rd., Shanghai 200031, China

2-Substituted 4,4-dimethyloxazolines (DMOX) have been found to be a useful alternative to the commonly used methyl esters for the localization of unsaturated bonds and other substituents in the fatty chain by mass spectrometry. The powerful directed fragmentation coupled with good gas chromatographic ability enables the structure elucidation of modified fatty acids in complex mixtures. Continuing our previous study, 76 out of a total of 86 fatty acids obtained from the preen gland wax of Shanghai duck now have been identified by gas chromatography-mass spectrometry (GC-MS) of their oxazoline derivatives. The identification was based on the interpretation of the mass spectra and comparison with the spectra and equivalent chain lengths (ECL) of the corresponding methyl esters. Main components of this lipid mixture are straight chain fatty acids (8.22%), and 2-, 4- or 6-monomethyl branched acids (53.69%), amounting to 61.91% of the total acid fraction. In addition, a large number of dimethyl-substituted fatty acids (31.4%) also have been found. Typical mass spectra, which are easily recognizable and highly specific for fatty acids substituted at various positions, are presented and classified according to the structural feature of the chain.
***Lipids 23,* 804–810 (1988).**

Wax produced by the uropygial gland of birds has been the subject of intensive investigations. It is generally accepted that this wax, mainly composed of monoesters of fatty acids and alcohols, protects the plumage against wet. However, some additional functions can be assumed from the very complex structure of the lipids, which are known to be highly species-dependent. The uniqueness of this waxy material manifests itself in the number and kind of carbon skeletal types, in the wide range of chain lengths, and in the unusual patterns of substitution. Although much has still to be explained, from these variations a new taxonomy of birds has evolved (1,2). By studying the structure of relevant components, one may gain clues to the understanding of the functions of these externally secreted lipids.

Since the pioneering contributions of Stenhagen and collaborators, the structure of these fatty acids has been established with the aid of mass spectrometry (3,4). The mass spectra of branched fatty acid methyl esters have been studied most thoroughly (5–8). Because most identifications depend upon rather subtle differences in mass spectral peak intensities, an independent means of vertification is adopted in the concept of equivalent chain length (ECL), which has been fully expounded by Nicolaides et al. (9,10).

A newer, more attractive approach involves the use of other fragmentation-directing derivatives. Of particular interest is the achievement of N-acyl pyrrolidine derivatives by Andersson (11), and pyridylmethyl esters by Harvey (12,13). The latter has led to the structure elucidation of a very complex mixture of branched (iso- and anteiso-) fatty acids obtained from the meibomian gland secretion of rats (14).

In our efforts to develop newer methods that would lead to a clear-cut demonstration of chain feature in mass spectra, a search for derivatives with even better fragmentation-directing ability was initiated. Our strategy was to incorporate the carboxylic acid group into a nitrogen-containing heterocycle followed by examining the 70 eV EI mass spectra of the resulting "hidden" carboxylic acids (15). 2-Substituted benzoxazoles (16) and 2-substituted 4,4-dimethyloxazolines (DMOX) (17) were finally chosen for further investigation. The latter represent a class of interesting structure with a basic nitrogen atom. They are readily prepared and purified, markedly stable towards most reagents, and capable of hydrolytic decomposition on heating in acidic medium to regenerate the starting material. By virtue of these properties, they have been recommended by Meyers (18,19) as a means for the protection of -COOH group. Long chain fatty acid derivatives of this type were first prepared by Gronowitz and coworkers (20,21), and the mass spectral fragmentation were briefly discussed therein. Detailed study in our laboratory has shown that while possessing promising mass spectrometric as well as gas chromatographic characteristics, DMOX are useful derivatives for exploring chain structure in complex mixtures, for example, double bond (17), cyclopropane ring (22), triple bond, cyclopentene ring, and oxygenated groups (Zhang, J.Y., Yu, Q.T., and Huang, Z.H., unpublished data).

This paper describes an extension of the oxazoline method to the structure determination of branched acids derived from the wax of the uropygial gland of the Shanghai white duck, which is common in this area and belongs to the common species of *Anas platyrhynchos.*

MATERIALS AND METHODS

Materials. All standard fatty acids were purchased from the Sigma Chemical Co. (St. Louis, MO) with a purity

[1]Chemical Modification in Mass Spectrometry 6. For preceding paper in this series, see Ref. 17.

*To whom correspondence should be addressed.

Abbreviations: AMP, 2-amino-2-methyl-propanol; DCC, dicyclohexylcarbodiimide; DMF-DMA, N,N-dimethyl formamide dimethyl acetal; DMOX, 4,4-dimethyloxazolines; ECL, equivalent chain lengths; GC-MS, gas chromatography-mass spectrometry.

greater than 99%. 2-Amino-2-methyl-propanol (AMP) was a product of Aldrich Chemical Co. (Milwaukee, WI) with a purity of 99%.

Preparation of the mixed fatty acids. After washing with cold ether to remove the contaminating triglycerides from surrounding tissues, four preen glands (9.0 g), excised from freshly killed (in April) Shanghai ducks, were homogenized and extracted with chloroform/methanol (1:1, v/v) at room temperature. The organic layer, after diluting with an equal volume of water, was separated, dried and evaporated. The residue was taken up in petroleum ether (b.p. 60–90 C) and evaporated to afford 0.6 g of waxy material. The latter was finally saponified (1 part of KOH in 1 part of water and 4 parts of methanol, 80 C, 2 hr) and worked up by usual means. Yield of the mixed fatty acid was 70 mg.

Preparation of n-nonadecanoic acid-3d₂. The preparation of this new labeled acid was carried out according to literature (23). A mixture of 1.5 g of sodium salt of stearic acid and 3 ml of D_2O containing 12 mg of NaOD was heated in sealed tube at 200 C for 96 hr. After cooling, the mixture was acidified with dilute HCl and extracted with 3 × 5 ml of diethyl ether. The ether solution was evaporated. The residue was recrystallized from acetone and gave 1.4 g (92%) of 18:0-2d₂. Deuterium incorporation was 88.4%, based on MS.

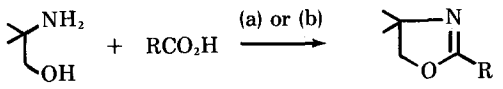
1.2 g of stearic acid-2d₂ was converted into its methyl ester by refluxing with 30 ml of 5% $BF_3 \cdot Et_2O/CH_3OH$ (v/v) solution for 0.5 hr. The methyl ester was separated by usual ways, dried, evaporated and dissolved in 30 ml of anhydrous diethyl ether. To this solution, 1.5 g of lithium aluminum hydride was added, the mixture then was refluxed for five hr. The excess hydride was decomposed by adding water, then the solution was acidified with 10% sulfuric acid and extracted with 3 × 10 ml of ether. The ether layer was washed with aqueous $NaHCO_3$ and water, dried and evaporated to leave 830 mg (73%) of stearyl alcohol-2d₂.

One g of methane sulfonyl chloride was added dropwise to a cooled (0 C) solution of 500 mg of stearyl alcohol-2d₂ in 7 ml of dry pyridine. The mixture was stirred five hr at room temperature. The residue was taken up in 10 ml of methylene chloride, washed with water and dried. Recrystallization from petroleum ether gave 590 mg (92%) of stearyl-2d₂-mesylate.

Four hundred mg of potassium cyanide was added to a solution of 590 mg of above mesylate in 10 ml of dimethyl sulfoxide. The mixture was heated at 120 C with stirring for two hr, then cooled and dissolved in 2 ml of methylene chloride. After washing with water and drying, evaporation gave 430 mg of n-nonadecanoyl nitril-3d₂ (91%).

A solution of 400 mg of above nitrile in a mixture of 2 ml of 90% potassium hydroxide and 2 ml of ethanol was refluxed for 48 hr. Acidification with hydrochloric acid and extraction with chloroform after removal of the solvent and recrystallization from acetone gave 300 mg (70%) of n-nonadecanoic acid-3d₂. Deuterium incorporation 86.6% based on MS.

Derivatization. The procedure described in our previous paper (17,22) was modified as follows. (a) Ten mg of AMP was added to 5 mg of the fatty acid mixture in a microreaction flask equipped with an air-condenser and a magnetic bar. The mixture was heated at 180 ± 5 C under



nitrogen for one to two hr. The cooled mixture was triturated with 1 N aq KOH and extracted with light petroleum ether (10 ml). The extract was allowed to pass through a small column packed with ca. 500 mg of silica gel, which was covered with 20 mg of anhydrous sodium sulfate, and eluted with 20 ml of the same solvent. The eluate was collected and evaporated to dryness in a rotary evaporator to furnish a pale-yellow oily substance. Yields were nearly quantitative. (b) Another preparation was based on a modification of Ref. 24. Five mg of dicyclohexylcarbodiimide (DCC) was added to a solution of 5 mg of fatty acid sample in 1 ml of dichloromethane. After stirring for 10 min, 5 mg of AMP was added. The mixture was allowed to react under stirring at room temperature for four hr. After filtration, the mixture was evaporated to dryness. The oily intermediate was dissolved in 1 ml of dry diethyl ether and treated with 500 μl of freshly distilled thionyl chloride (0 C, 0.5 hr; then room temperature, 0.5 hr), washed with ice-cold sodium carbonate solution, and worked up as described in (a).

Methyl esters and ECL measurement. Methyl esters were prepared by a "on-column" esterification procedure by dissolving about 1 mg of sample in 100 μl of N,N-dimethyl formamide dimethyl acetal (DMF-DMA) and directly injecting the mixture (ca. 0.5 μl) onto injector port of gas chromatograph for GC-MS analysis. ECL for component acids were calculated by Nicolaides' method (8).

Instruments. GC-MS analysis was carried out on a MAT 44S gas chromatograph-mass spectrometer equipped with a 29 m × 0.28 mm glass capillary column coated with SE-54 (cross-linked and bonded). Carrier gas flow was 1 ml He/min, split ratio 1:10. Both separator and ion source were maintained at 250 C, column temperature 240 C. Other parameters were: electron energy 70 eV, emission current 0.6 mA.

RESULTS AND DISCUSSION

By using this derivatization technique, 76 out of 86 individual components have been identified. These acids, either normal or branched, have chain lengths from C_6 to C_{18}. The gas chromatogram and results of analysis are presented in Figure 1 and Table 1, respectively.

High-quality mass spectra were produced from the resulting DMOX in GC-MS analysis. Interestingly, the mass spectra of these derivatives are closely similar to those of the corresponding N-acyl pyrrolidines in the region above *m/z* 100. They both exhibit rather simple fragmentation patterns that are highly characteristic with respect to the carbon skeleton of the chain. A marked difference is that oxazolines suffer less from interference and appear to show more prominent diagnostic peaks, thus rendering the latter, in particular those occurring at the high-mass end of the spectrum, more easily recognizable.

All normal chain fatty acid DMOX derivatives (Table 1) have been checked by comparing their mass spectra and retention times with those obtained from authentic samples. For illustration, the spectrum of the palmitic acid [16:0] derivative is presented in Figure 2a. Generally,

*"Local minimum" in the general profile of the spectra.

[a]All saturated fatty acids show identical diagnostic peaks as in the corresponding standards.

[b]Components with amount less than 0.1% (9:1[3], 8:0, 2,4,x-Me_3-7:0, 6-Me-8:0, 10:1[3], 9:0, 12:1[6], 8-Me-10:0, 2,4-Me_2-10:0, 2,8-Me_2-11:0, 13:0, 2,8-Me_2-13:0, 2,10-Me_2-13:0, 15:0, 2,8-Me_2-15:0, 6,x-Me_2-15:0 and two unidentified peaks) are not given in the table.

[c]Peaks 19, 20; 24, 25; 29–31; 41, 42 of methyl esters emerged in different orders as the corresponding DMOX.

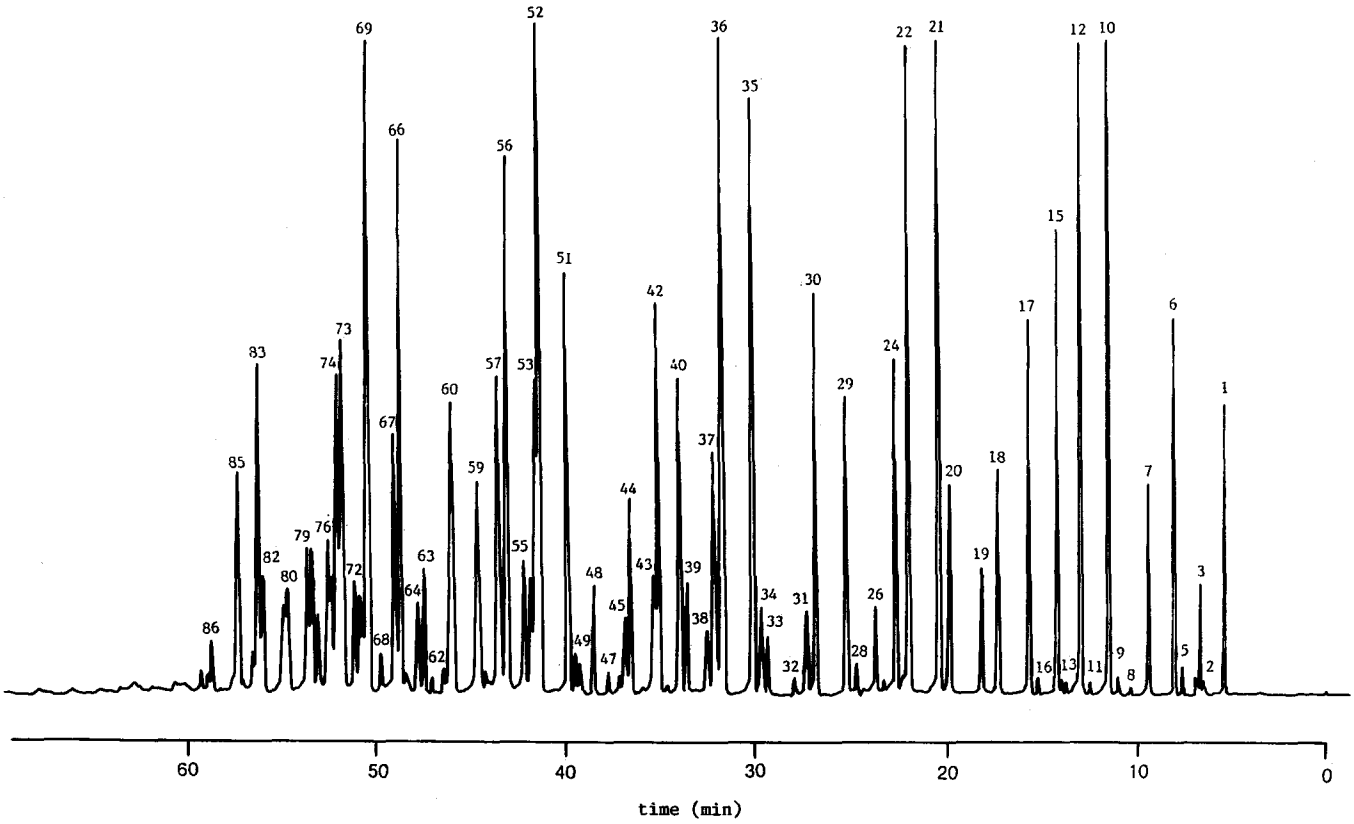

FIG. 1. Gas chromatogram of DMOX of fatty acid mixture obtained from the preen gland secretion of Shanghai white duck *(A. platyrhynchos)*.

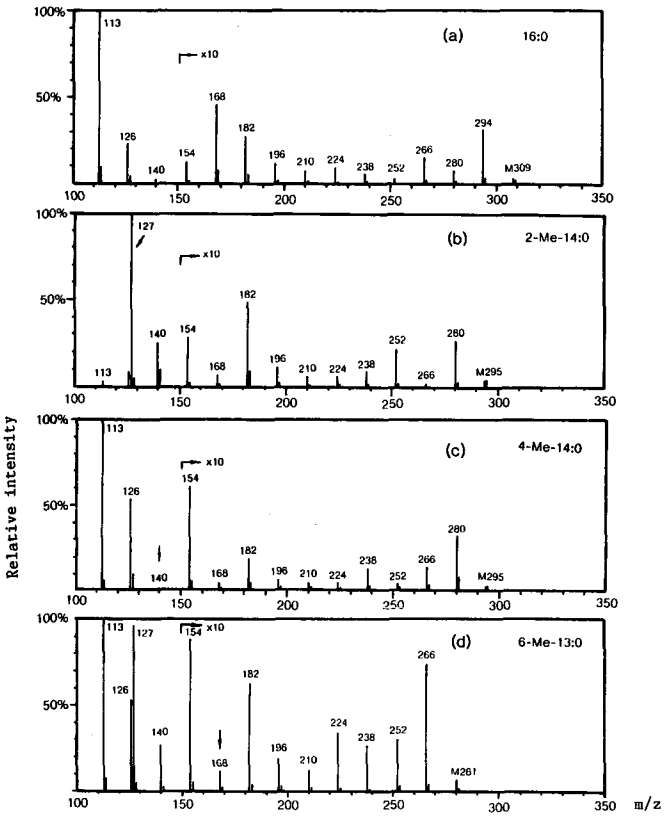

FIG. 2. (a–d) Typical mass spectra of DMOX of branched chain fatty acids.

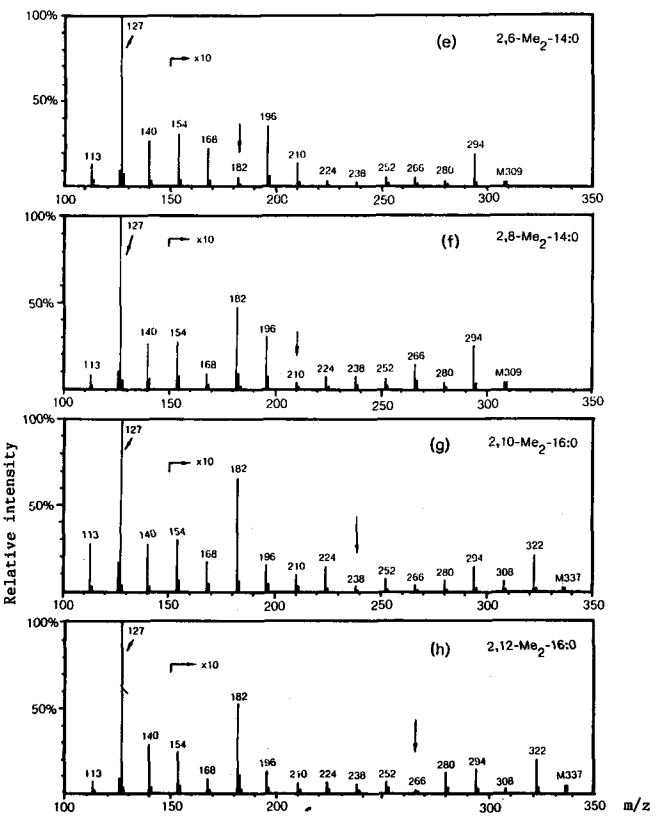

FIG. 2. (e–h) Typical mass spectra of DMOX of branched chain fatty acids.

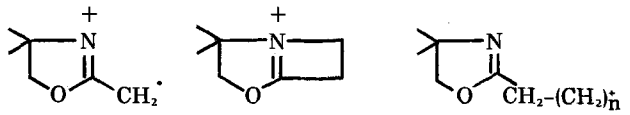
two types of fragment ion peaks are displayed in the spectra of DMOX of saturated fatty acids: (i) an intense peak at *m/z* 113 (normally as base peak) is obtained as a result of the McLafferty rearrangement of 2-unsubstituted acids; and (ii) an even-mass homologous ion series at *m/z* 126 + 14n (n = 1, 2, 3, . . .) is formed by simple cleavage of the chain. This series, generally with a "local minimum" at C_5 (*m/z* 154) in straight chain homologs, distributes continuously up to the molecular ion region. The initial member, *m/z* 126, generated via cyclization-displacement reaction, frequently appears to be the most abundant ion within this series.



From the above statement, one can infer any variation in the peak profile may serve as a sign of chain-substitution. For example, the presence of a methyl branch is indicated by the existence of a newly created "local minimum" between two flanking ion clusters, whereupon the highest peaks of them are spaced by an interval of 28 mass units. Therefore, 2-methyl-substituted acid derivatives (see, for example, Fig. 2b) exhibit a base peak at *m/z* 127 (= 113 + 14) and a "local minimum" at *m/z* 168 in their spectra. Here a mass shift of 14 a.m.u. occurs as compared with the normal chain compound (Fig. 2a). Other substituted acids behave in like manner. This peak profile analysis is easy to handle and presents little uncertainty in structure assignment of fatty acids having a higher degree of substitution.

Similar to methyl esters, additional information may sometimes be provided by an elimination reaction resulting in the loss of two or three carbon atoms from within the chain (3,4). DMOX of a deuterated fatty acid, 19:0-3d_2, shows extrusion of carbon 2 and 3 of the original fatty acid as indicated by the ion M-31 (and M-45 for a three carbon loss) in the spectrum (Fig. 3).

Consequently, if a methyl branch is attached to either of these C-atoms (e.g., 2-Me, 4-Me, or di-Me substituted acids with the first branch at C-2 or C-4), the ion representing M-29 in case of 2-Me, or M-43 in the case of 4-Me, is seriously weakened, while the mass of the fragment lost from within the chain is correspondingly increased by 14 a.m.u. (compare, for example, M-29 in Fig. 2b, e–h; and M-43 in Fig. 2c, i and j).

The mass spectrometric characteristics of the fatty acids listed in Table 1 are classified according to the substitution pattern (Table 2). Typical mass spectra are presented in Figure 2.

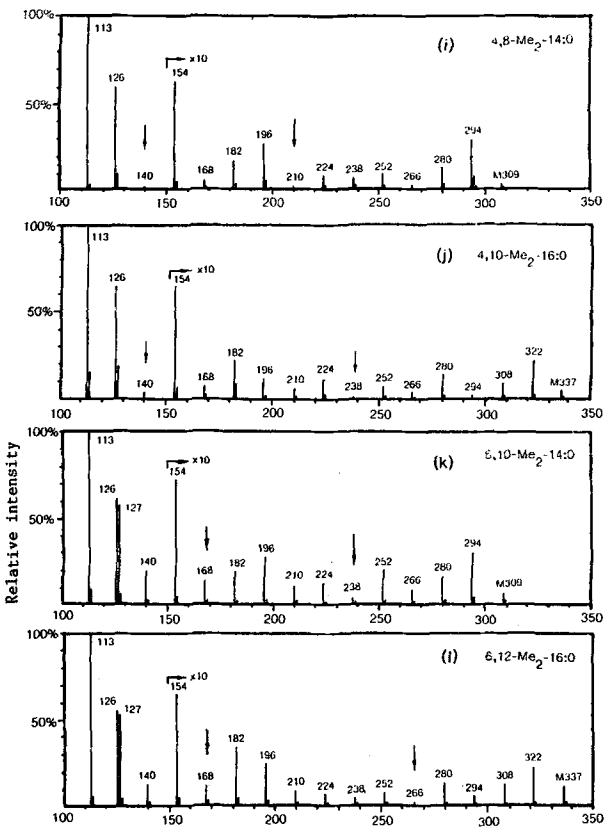


FIG. 2. (i–l) Typical mass spectra of DMOX of branched chain fatty acids.

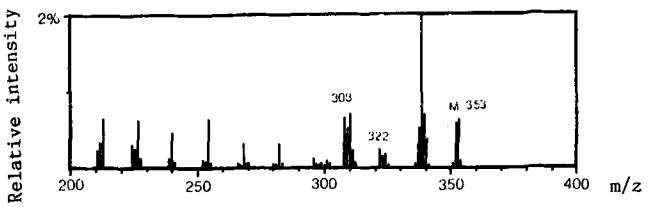

FIG. 3. Spectrum of DMOX from 19:0-3d_2.

TABLE 2

MS Characteristic Peaks of DMOX[a]

[a] *m/z* 126 is accompanied by a strong satellite peak at *m/z* 127 in 6-Me series by an unexplored mechanism. Similar observation of *m/z* 127 occurred with DMOX of 6,7-methyleneoctadecanoic acid (22).
*"Local minimum" in the general profile of the spectra.

The structural assignment was further substantiated by GC-MS of methyl esters obtained from the same origin. Mass spectral data and ECL of individual methyl esters are presented in Table 1. Small, but acceptable differences between measured and calculated ECL values were observed and could be attributed to the change in experimental conditions. Identification by both DMOX and methyl esters agrees quite well except for certain minor components, which were not detected by the ester method. Generally, DMOX are rather volatile and a column temperature of ca. 10 C higher than that for the methyl esters is enough to achieve good separation. In addition, their relatively abundant diagnostic peaks and regular fragmentation make detection easy and the interpretation of spectra straightforward. The advantages of DMOX are obvious in cases of fatty acids having one or more than one branch located remote from the carboxylic acid end, such as 8- or 10-substitution. Under such circumstances, the utility of methyl esters is seriously hampered.

Uropygial gland waxes of the Peking duck, the common European mallard, the Rouen duck and the East Indian duck, all of which originate from *A. platyrhynchos*, were studied by several laboratories. Odham found and identified, from Peking duck wax, 16 normal-chain and monomethyl substituted fatty acids of C_6 to C_{11} (25) and from mallard duck wax, 10 C_6–C_{11} analogs (26). Of these, the waxes are composed mainly of 2-methyl and 4-methylhexanoic acids (about 74% of the total acids). A different picture is related to the waxes of the black East Indian ducks, which were shown by Bertelsen and Nguyen (27) to consist essentially of 4-methyl substituted C_6-, C_8-, C_{15}- and C_{18}-carboxylic acids. Kolattukudy et al. have studied in detail the wax esters of male mallard ducks and revealed dramatic seasonal variation of the components (28). The fatty acid profile (Table 3) of the Shanghai duck appears to be in fairly good agreement with the findings of Kolattukudy. Nevertheless, the presence of fatty acids with 6-methyl substituents was not known until now.

TABLE 3

Distribution Pattern of Fatty Acids from the Preen Gland Wax of Shanghai White Duck

Structure	% of total	Structure	% of total
Normal C_{7-18}	8.22	4,10-Me_2-C_{16}	1.92
2-Me-$C_{6-10,12,14,16}$	21.60	4,10,x-Me_3-C_{16}	0.51
2,4-Me_2-C_{10}	0.04	6-Me-$C_{8,11,13,16,17}$	8.87
2,4,x-Me_3-C_7	0.06	6,8-Me_2-$C_{13,15}$	1.92
2,6-Me_2-C_{8-14}	10.01	6,8,x-Me_3-C_{16}	0.57

Analysis of Free Malondialdehyde in Photoirradiated Corn Oil and Beef Fat Via a Pyrazole Derivative

K. Umano, K.J. Dennis and T. Shibamoto*
Department of Environmental Toxicology, University of California, Davis, CA 95616

Malondialdehyde (MA) formed in linolenic acid, linoleic acid, corn oil and beef fat upon photoirradiation was determined by gas chromatography (GC). The MA produced was reacted with methylhydrazine to give 1-methylpyrazole and was subsequently analyzed on a GC equipped with a nitrogen-phosphorus specific detector and a fused silica capillary column. MA values determined by this method correspond to free or unbound MA levels. Linolenic and linoleic acids produced 867 μg MA/g and 106 μg MA/g, respectively. Oleic and stearic acids did not produce detectable levels of MA upon photoirradiation. Amounts of MA produced after eight hour irradiations of corn oil and beef fat were 56.24 μg/g and 25.01 μg/g, respectively. Some photoreaction products in irradiated corn oil also were identified as methylhydrazine derivatives.
Lipids 23, 811–814 (1988).

Malondialdehyde (MA) is well known as a product of lipid peroxidation and prostaglandin biosynthesis in animal tissues. It has been implicated in aging (1), mutagenesis (2,3,4), carcinogenesis (3,5) and radiation damage (6).

MA, as 2-thiobarbituric acid (TBA) reacting substances, has been found in steam distillates of lipid-rich foods such as roasted meats (7). In most cases, these MA levels were found to increase with cooking (7,8). A major source of MA is from peroxidation of polyunsaturated fatty acids (PUFA) containing more than two double bonds (9). Direct analysis of MA is very difficult because of its extreme reactivity. In addition, MA can be in hydrolyzable forms (i.e., protein or amino acid conjugates [10,11] or cyclic hydroperoxy intermediates [12]), which can complicate analysis of free MA.

Among methods for MA determination, the TBA method has been commonly used to give an indication of MA content in samples. This method is not specific for MA, and there are several examples that demonstrate its overestimation of MA (13–15). Several methods that give more accurate measures of bound MA in samples than the TBA assay have been reported. Some of these involve modification of the TBA assay (13,16). The TBA-MA adduct obtained from an extract of spinach leaves and purified on a Sephadex G-15 column resulted in a TBA value much less than that of the crude sample (13). More recently, the TBA-MA adduct has been measured after its separation by high performance liquid chromatography (HPLC) from other interfering TBA-complexes (16).

Among other methods, MA was reacted with 1-dansylhydrazine under acidic conditions and the resulting product, 1-dansylpyrazole, was determined by HPLC (15). Gas chromatography (GC) of MA as the tetramethyl acetal derivative prepared under acidic conditions also was reported (12). All of the above methods are generally expected to measure total (free plus bound) MA, since conditions in the assays are sufficient to hydrolyze bound MA.

Some methods for determination of free MA that have been reviewed include spectrophotometric, distillation and HPLC methods (16). Free MA in microsomal and urine samples has been directly determined by ion-pairing HPLC, but the structure of the eluate was not confirmed (17). Other HPLC procedures have been described by Esterbauer and coworkers (18) and by Lee and Csallany (19). In contrast to the HPLC methods, capillary GC methods offer greater efficiencies of separation and a variety of selective detectors not available in HPLC. A search of existing literature did not reveal any GC methods capable of free MA measurement.

In the present study, MA formed in lipid or fatty acid samples during photoirradiation was reacted with methylhydrazine. The reaction product, 1-methylpyrazole (1-MP), was analyzed by GC. This reaction occurs readily at neutral pH and at room temperature and can be used to measure free MA levels in the samples. Furthermore, because the reaction product contains nitrogen atoms, the highly sensitive and selective nitrogen-phosphorus detector (NPD) can be used.

MATERIALS AND METHODS

Synthesis of standard 1-MP. Malonaldehyde bis(dimethyl acetal) (10 g) (Aldrich Chemical Co., Milwaukee, WI) was added to 300 ml of 0.1 N HCl and the solution stirred for one hr at 50 C. After the solution was cooled to room temperature, 0.3 g methylhydrazine (Aldrich) in 30 ml water was added dropwise over a 10-min period with constant stirring. The reaction solution was stirred for an additional 30 min and then 22 ml of 2 N NaOH solution was added. The solution was stirred for an additional 10 min. Dichloromethane (40 ml) was added to the solution and the mixture shaken for five min. The dichloromethane layer was separated with a separatory funnel. The aqueous layer was extracted once more with dichloromethane (20 ml) and the extract was added to the original dichloromethane fraction. The combined solvent fractions were washed three times with 10 ml deionized water. After drying over anhydrous sodium sulfate, the extract was concentrated to 7 ml by distillation. The final colorless liquid product (1.86 g) was obtained from the concentrate by fractional distillation under reduced pressure (23 mm Hg) at 39 C. The spectral data of 1-MP are as follows: mass spectrum, *m/z* (relative intensity) 82 (M^+, 100), 54 (65), 53 (47), 41 (35); ^{1}H NMR (CDCl3) δ 3.80 (s, 3H), δ 6.12 (dd, 1H, J = 1.8, 2.2 Hz), δ 7.22 (d, 1H, J = 2.6 Hz), δ 7.38 (m, 1H).

Instrumental. A Hewlett-Packard Model 5880A GC equipped with a NPD and a 50 m × 0.25 mm i.d. bonded phase DB-WAX fused silica capillary column (J & W Scientific) was used for routine quantitative analysis. GC peak areas were calculated with a Hewlett-Packard 5880A

Abbreviations: MA, malondialdehyde; 1-MP, 1-methylpyrazole; NMA, N-methylacetamide;PUFA, polyunsaturated fatty acid; TBA, 2-thiobarbituric acid; GC, gas chromatography; HPLC, high performance liquid chromatography; NPD, nitrogen-phosphorus detector.

series GC terminal. All photoreactions were performed at room temperature within a Rayonet RPR-100 reaction chamber fitted with eight medium-pressure UV lamps (λ = 300 nm). The GC-MS identification of methylhydrazine derivatives was performed with a ZAB-HS high resolution magnetic sector instrument equipped with a Hewlett-Packard Model 5790 GC. The ^{1}H NMR spectra were recorded on a Varian EM-390 NMR spectrometer.

Preparation of calibration curve for 1-MP analysis. A standard stock solution was prepared by adding 1 mg of 1-MP to 1 ml of dichloromethane. Various amounts of this stock solution (10, 20, 30, 40, 50, 60, 80 and 100 μl each) were measured into separate volumetric flasks. One hundred μl of GC internal standard N-methylacetamide (1 mg/ml dichloromethane) was added to each flask and each solution was adjusted to exactly 25 ml with dichloromethane. A 2μl aliquot of each solution was injected onto a GC equipped with an NPD. The GC peak area ratio of 1-MP to N-methylacetamide (NMA) was plotted against concentration of 1-MP. The calibration curve was linear for all of the above solutions.

Sample extracts in dichloromethane were treated exactly as were the standard solutions for the calibration curve. When necessary, samples were concentrated to 20 ml by fractional distillation. One hundred μl of NMA internal standard solution was added, and volumes adjusted to exactly 25 ml with dichloromethane. 1-MP concentrations were determined by comparison of peak area ratios (1-MP/NMA) with the standard calibration curve.

Determination of MA in photoirradiated fatty acids. Linolenic, linoleic, oleic and stearic acids of the highest available quality were purchased from Aldrich Chemical Co. and used without further purification. Each fatty acid (40 mg) was dissolved in 40 ml hexane in separate Pyrex containers. The hexane solutions were irradiated for four hr at 25 C. Separate 40 ml hexane solutions, each containing 40 mg of one of the fatty acids, were also prepared as nonirradiated controls. The photoreaction mixture or nonirradiated control was mixed with 20 μl of methylhydrazine and stirred for 10 min. The solution was twice extracted with 10 ml of 1 N HCl to recover 1-MP from the hexane phase. The combined aqueous extracts were mixed with 12 ml of 2 N NaOH solution. After stirring for 10 min, the 1-MP derivative was extracted into two 7-ml portions of dichloromethane. The combined dichloromethane extracts were further processed and analyzed for 1-MP as described at the end of the section on calibration curve preparation.

The recovery of 1-MP for the above method was performed as follows. Hexane (40 ml) containing 60 μg of 1-MP was extracted exactly as described above for irradiated and control fatty acid solutions beginning with the extraction with 1 N HCl. Amounts of recovered 1-MP were determined as described at the end of the section on calibration curve preparation.

Modified method for recovery of 1-MP from hexane solutions. The modified method was developed after the fatty acid studies in order to maximize recovery of 1-MP. Four hundred μl of 1-MP standard solution (3.18 mg/ml dichloromethane) was added to 100 ml of hexane and stirred for 30 min at room temperature. After addition of 40 ml of 1 N HCl, the solution was stirred for 20 min at room temperature. The hexane layer was separated and extracted once more with 40 ml of 1 N HCl. This HCl extract was added to the previous aqueous fraction and the combined extracts were washed with 15 ml of hexane. The aqueous fraction was mixed with 50 ml of 2 N NaOH (resulting pH was ca. 12) and 120 ml of deionized water, and then extracted with 45 ml of dichloromethane for four hr in a liquid-liquid continuous extractor. This final extract was further processed and analyzed for 1-MP as described at the end of the section on calibration curve preparation.

Recovery of 1-MP from malonaldehyde bis(dimethyl acetal) was performed as described below. Stock solutions containing 30–40 mg of the malondialdehyde precursor in 200 ml 0.1 N HCl were heated at 45–50 C to liberate free MA. Aliquots (0.5 ml) of the stock solution were added to 100 ml hexane. After addition of 50 μl methylhydrazine, the solution was extracted and analyzed for 1-MP as described above.

Quantitative analysis of MA formed from photolysis of corn oil and beef fat. Corn oil (2 g) or purified beef fat (2 g) (20) was dissolved in 250 ml of hexane. Solutions were irradiated in Pyrex containers for various time periods at 25 C. After irradiation, 100 μl of methylhydrazine was added to the solutions, which were then stirred for 30 min at room temperature. Recovery of the 1-MP was performed as described in the modified recovery method. Reaction solutions were mixed with 40 ml of 1 N HCl solution and stirred for 20 min. After separation of the aqueous layer, the remaining hexane layer was mixed with 40 ml of 1 N HCl solution and stirred for 20 min. The aqueous layer was added to the former aqueous fraction and the combined extracts were washed with 15 ml of hexane. The aqueous solution was then mixed with 50 ml of 2 N NaOH solution and stirred for 20 min. This solution was adjusted to 250 ml with distilled water and extracted with 45 ml of dichloromethane for four hr with a liquid-liquid continuous extractor. This final extract was further processed and analyzed for 1-MP as described at the end of the section on calibration curve preparation. The dichloromethane extract from irradiated corn oil was further analyzed for other methylhydrazine derivatives by GC–MS.

RESULTS AND DISCUSSION

In this work, free MA in samples was rapidly derivatized with methyl hydrazine to form 1-MP. Recovery of standard 1-MP from hexane solution by the method described for the determination of MA in photoirradiated fatty acids was 66% ± 8 (mean ± S.D., 3 determinations). To maximize sensitivity of the assay for MA, the extraction procedure used for MA determination in the fatty acid samples was modified. Recovery of standard 1-MP by the modified method was 94.4% ± 2.2 (mean ± S.D., 5 determinations). Recovery of MA (as the 1-MP derivative) prepared by the hydrolysis of malonaldehyde bis(dimethyl acetal) was 79.1% ± 2.1 (mean ± S.D., 4 determinations). The yield of 1-MP from reaction of MA and methyl hydrazine was calculated as 86% from the above recovery results. The reaction yield may be low because MA preparation in the present study may have generated side products (21) or the hydrolysis reaction may have been incomplete.

Photoirradiation of linolenic and linoleic acids for four hr produced 867 μg MA/g and 106 μg MA/g, respectively.

Nonirradiated control samples showed only 57 μg MA/g and 14 μg MA/g for linolenic and linoleic acids, respectively. Stearic and oleic acids did not produce detectable levels of MA upon photoirradiation.

The mechanism for formation of MA from linolenic acid radical via a prostaglandin-like endoperoxide intermediate has been proposed by Pryor and coworkers (9). The mechanism accounts for the observation that linolenic acid (3 double bonds) produced more MA than did linoleic acid (2 double bonds). It is possible that small amounts of MA could be generated from linoleic acid via such a mechanism, however the rate would be relatively slow since the stability of the bicycloendoperoxide intermediate formed from linoleic acid would be considerably less than that formed from linolenic acid (9).

Photosensitized oxidation of methyl linoleate has been reported to produce hydroperoxy cyclic peroxide intermediates that can be decomposed to produce volatile secondary oxidation products (22). These cyclic peroxide intermediates have been reported to form small amounts of MA by acid decomposition in methanol solution (12). It seems reasonable that such intermediates may have formed from linoleic acid in the presence of photosensitizer impurities. It is not known, however, if these intermediates decompose to form free MA under conditions of the present method.

Table 1 shows amounts of free MA determined from corn oil and beef fat irradiated (λ = 300 nm) in hexane solution for various time periods at 25 C. Previously reported fatty acid compositions for beef fat and corn oil also are given (23). Formation of MA from both corn oil and beef fat was linear with irradiation time. MA formation in corn oil was considerably higher than that in beef fat. This may be due to the difference in linoleic acid content based on the results of fatty acid photoirradiation experiments. The concentrations of linoleic acid in corn oil and beef fat have been reported as 57.3% and 3.7%, respectively (23). Among the fatty acids listed in Table 1, linolenic acid with its three double bonds should also produce MA, however its levels are similar in both beef fat and corn oil and may not account for the observed differences in MA production.

TABLE 1

Amounts of MA Determined in Irradiated Corn Oil and Beef Fat

Sample	Irradiation time (hr)	Amount (μg/g)[a]	Fatty acid composition (g/100 g sample)[b]	
Corn oil	2	8.52	Palmitic	10.7 ± 0.8
	4	16.91	Stearic	1.7 ± 0.2
	8	36.01	Palmitoleic	0.1 ± 0.1
	12	56.24	Oleic	24.6 ± 1.7
			Linoleic	57.3 ± 2.5
			Linolenic	0.8 ± 0.3
Beef fat	4	5.99	Palmitic	24.8 ± 3.5
	12	25.01	Stearic	18.7 ± 3.7
			Palmitoleic	4.7 ± 2.4
			Oleic	36.0 ± 4.9
			Linoleic	3.7 ± 2.0
			Linolenic	0.6 ± 0.6

Several methylhydrzine derivatives found in a reaction mixture of methylhydrazine and irradiated corn oil are reported in Table 2. Methylhydrazine reacted with carbonyl compounds and produced different derivatives. Figure 1 illustrates the general reactions of methylhydrazine with different carbonyl compounds. Monocarbonyl compounds such as formaldehyde react with methylhydrazine to form hydrazones. α,β-Unsaturated aldehydes such as acrolein form 1-methyl-2-pyrazolines and β-dicarbonyl compounds such as MA give 1-methylpyrazoles after reaction with methylhydrazine. Acrolein was recently shown to form in heated cooking oils and beef

TABLE 2

Methylhydrazine Derivatives Identified in Corn Oil Irradiated for Four Hr

Derivatives	Original compounds	GC peak area (%)
1-Methyl-2-pyrazoline	Acrolein	0.54
1-Methylpyrazole	Malondialdehyde	3.18
1,3 (or 5)-Dimethyl-2-pyrazoline	Acetylacetaldehyde	*a*
1-Methyl-5-propyl-2-pyrazoline	(E or Z)-2-hexenal	*a*
1,3,5-Trimethylpyrazole	2,4-Pentanedione	*a*

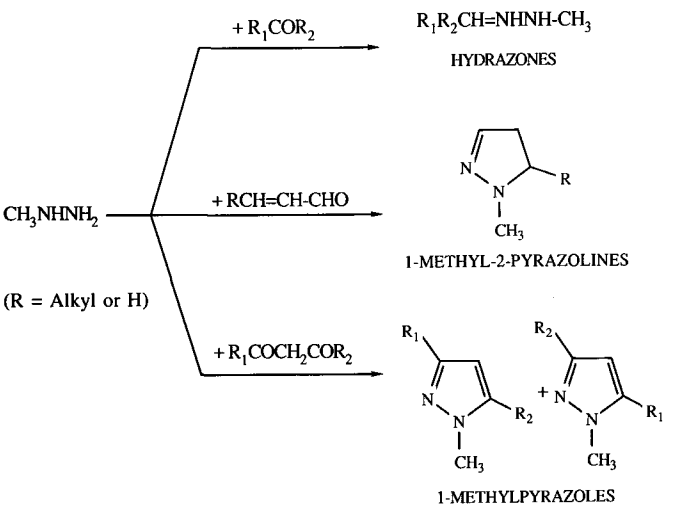

FIG. 1. Reactions of methylhydrazine with different classes of carbonyl compounds.

fat (24). 2,4-Dienoic aldehydes would be expected to produce 4-vinyl-1-methylpyrazoline derivatives, but were not observed in the MS analysis of photoirradiated corn oil. Further study must be done to determine if such compounds rearrange to form 4-alkyl-1-methylpyrazoles. Some compounds in Table 2 were deduced only as partial structures due to lack of authentic standards.

The method described in this work provides a means of measuring levels of free MA in certain samples. In pure lipid samples or other samples lacking amino acids and other compounds that may react with free MA, the method must provide a measure of the total MA. However, in many biological samples, MA may exist largely in a bound form which, under conditions of the present study, would not be released to form the MA derivative, thus underestimating total MA in these samples (10,16, 19). Other methods for MA analysis, such as that of Bird and Draper (16), may be more appropriate for measurement of MA in such samples because MA conjugates are hydrolyzed under conditions of the analysis.

In spite of limitations of the method presented here, there are certain advantages that allow a more specific measure of free MA. As mentioned, the mild conditions required for formation of 1-MP minimize the chance of hydrolysis or decomposition of bound forms of MA. Analysis of the MA derivative by capillary GC offers a higher degree of separation than can be accomplished by HPLC methods, thus minimizing the chance of coelution of interfering materials. Finally, methylhydrazine reacts rapidly with MA to form one major product, whereas other carbonyl compounds will react with methylhydrazine to form other derivatives. Further work is being performed to adapt the method for simultaneous analysis of trace levels of highly volatile or unstable compounds such as formaldehyde, acrolein and MA by capillary GC-NPD.

ACKNOWLEDGMENTS

This research was supported in part by a training grant from NIEHS (5-T32-ES007059). Mass spectrometry was performed at the UC Davis Facility for Advanced Instrumentation on a ZAB-HS, supported in part by NIH Grant No. RR01460-01.

The phospholipid composition and fatty acid profiles of human eosinophils were studied. Extremely high levels of ether phospholipids were found in this type of cell, such as alkylacylglycerophosphocholine (GPC) and alkenylacylglycerophosphoethanolamine (GPE); these two ether phospholipids accounted for about three-fourths of the choline and ethanolamine glycerophospholipids (CGP and EGP), respectively. Fatty acid analyses revealed that very large portions of arachidonic acid (20:4) were esterified to alkylacyl-GPC (92.0% in CGP) and alkenylacyl-GPE (86.6% in EGP), respectively. While high amounts of alkylacyl-GPC and the abundance of 20:4 in this ether phospholipid have been observed in other types of blood cells of various animals, these percentages for human eosinophils are the highest among such cells. These results suggest that alkyl and alkenyl ether phospholipids play essential roles in human eosinophils in various physiological and pathological conditions.
Lipids 23, 815–817 (1988).

It is well known that eosinophilia is an important diagnostic feature of several diseases such as parasitic infections (1–3) and bronchial asthma (4–7). Although the exact functions of eosinophils are not fully understood, it generally has been assumed that they are closely involved in the pathogeneses of such diseases. Eosinophils contain a number of granule cationic proteins that probably are involved in host defense reactions against parasitic infections (3,8) and tissue damage on inflammation (9). In addition, several chemical mediators, including platelet-activating factor (PAF) (10) and eicosanoids (11–13), were shown to be synthesized and released from eosinophils. These chemical mediators could play very important roles in active bronchial asthma (14,15). Despite the increased importance of eosinophils and their lipid mediators in allergic reactions, very little information is available as to the biochemical properties of the eosinophil membrane. For example, there are no data concerning the lipid composition or fatty acid distribution in eosinophils. Therefore, it is very important to investigate these points in detail to get a better understanding of the mechanism and the regulation of the biosynthesis of potent lipid mediators such as PAF (10) and leukotrienes (11–13) in eosinophils.

In this study, the phospholipid composition and fatty acid profiles of human blood eosinophils were investigated, and the highest levels of ether-containing choline glycerophospholipids (CGP) and ethanolamine glycerophospholipids (EGP) were observed as compared with other types of blood cells, whose phospholipid compositions had been analyzed.

MATERIALS AND METHODS

Chemicals. All chemicals were of reagent-grade, and solvents were distilled before use.

Cells. Human eosinophils were separated from peripheral blood of patients with eosinophilia by the Percoll (Pharmacia, Uppsala) discontinuous density gradient method (16). Briefly, leukocytes were isolated from heparinized blood by erythrocyte sedimentation. The cells were washed twice in isotonic buffer (Ca^{2+}, Mg^{2+}-free, pH 7.4) containing 10 mM ethylenediamine tetraacetic acid (EDTA) and 0.03% of human serum albumin, and then suspended in an isotonic Percoll solution (density, 1.070 g/ml). Isotonic Percoll solutions (1.100, 1.090, 1.085 and 1.080 g/ml) were layered in plastic tubes, and then the leukocytes in a Percoll solution were laid on top of the gradients. The tubes were centrifuged at 1600 × g for 20 min. The eosinophil and neutrophil fractions were collected and washed, respectively. The purity of eosinophils was 93%–97% and that of neutrophils >97%, as judged on morphological assessment (toluidine blue and light-green staining). The contaminating cells were mainly neutrophils or eosinophils, respectively.

Extraction and fractionation of lipids. Lipids were extracted by the method of Bligh and Dyer (17). Individual phospholipids were separated by two-dimensional thin layer chromatography (TLC) (18). Lipid spots were detected under ultraviolet light after spraying with primuline. Lipid phosphorus was estimated as described by Rouser et al. (19). CGP and EGP were eluted from the silica gel with chloroform/methanol/water (1:2:0.8, v/v/v) and extracted by the method of Bligh and Dyer (17).

Separation of alkenylacyl, alkylacyl and diacyl phospholipids. Alkenylacyl, alkylacyl and diacyl CGP and EGP were separated as 1,2-diradyl-3-acetylglycerol derivatives as described (18). The amounts of alkenylacyl, alkylacyl and diacyl compounds were estimated from their fatty acyl contents, using methyl heptadecanoate as an internal standard.

Determination of fatty acid compositions. Fatty acids were analyzed as methyl esters by gas liquid chromatography (GLC) as described (18).

Abbreviations: CGP, choline glycerophospholipids; ECF-A, eosinophil chemotactic factor of anaphylaxis; EDTA, ethylenediamine tetraacetic acid; EGP, ethanolamine glycerophospholipids; FMLP, formylmethionylleucylphenylalanine; GPC, glycerophosphocholine; PAF, platelet-activating factor; GLC, gas liquid chromatography; TLC, thin layer chromatography.

TABLE 1

Phospholipid Composition of Human Blood Eosinophils[a]

Phospholipids	% of total phospholipids[b]
Choline glycerophospholipid	34.7 ± 2.5
Ethanolamine glycerophospholipid	27.7 ± 3.8
Sphingomyelin	19.8 ± 2.1
Serine glycerophospholipid	9.2 ± 1.6
Inositol glycerophospholipid	4.7 ± 0.6
Others	4.0 ± 2.0

[a]The mean percentages are for different samples (n = 6).

[b]The values were calculated on the basis of lipid phosphorus.

TABLE 2

Class Compositions of Choline and Ethanolamine Glycerophospholipids of Human Blood Eosinophils and Neutrophils

	Eosinophils[a]		Neutrophils[b]	
Class	CGP	EGP	CGP	EGP
Alkenylacyl	4.1 ± 2.6	72.7 ± 11.0	9.1	70.0
Alkylacyl	75.5 ± 4.4	6.1 ± 3.1	45.0	10.1
Diacyl	20.4 ± 5.9	21.2 ± 8.1	45.9	19.9

[a]The mean percentages are for different samples (n = 4).

[b]The mean percentages are for different samples (n = 2).

The values were calculated from the quantities of acyl moieties in each lipid class.

RESULTS AND DISCUSSION

Phospholipid composition. Table 1 shows the phospholipid composition of human blood eosinophils. The amount of lipid phosphorus was calculated to be 3.46 μg/10^7 cells. The predominant components were CGP and EGP. These results are generally consistent with the results for human neutrophils (20).

Amounts of ether-containing and diacyl phospholipids. Table 2 shows the class compositions of CGP and EGP of eosinophils and neutrophils. The class compositions of neutrophils were essentially the same as that reported by Mueller et al. (20). In eosinophils, an extremely high level of alkylacyl compounds was found in CGP. EGP contained a large amount of alkenylacyl compounds. The amounts of diacyl analogues were rather small in both CGP and EGP. The levels of alkenylacyl compounds in CGP and alkylacyl compounds in EGP were very low. We and some other investigators (18,20,21) have found that several types of white blood cells, such as neutrophils, macrophages and lymphocytes, contain very high amounts of alkylacyl-glycerophosphocholine (GPC) (16%–50% of CGP), which now is considered to be the stored precursor form of a potent lipid mediator, PAF (22). For example, 45 or 50% of CGP was accounted for by alkylacyl compounds in human blood neutrophils (Table 2, 21). Thus, the relative proportion of alkylacyl-GPC in human eosinophils is the highest, as compared with those in other types of white blood cells and other mammalian tissues, as far as we know (21). Although the biological roles of alkylacyl-GPC have not been fully elucidated, the extremely high proportion of alkylacyl-GPC in eosinophils could be favorable for the synthesis and release of PAF from them. In fact, increased acetyltransferase activity has already been observed in eosinophils stimulated with eosinophil chemotactic factor of anaphylaxis (ECF-A), C5a, formylmethionylleucylphenylalanine (FMLP) and Ca^{2+}-ionophore, A23187 (10).

Fatty acid compositions of CGP and EGP. The fatty acid compositions of CGP and EGP of human eosinophils and neutrophils are shown in Table 3. The fatty acid compositions in alkenylacyl-GPC and alkylacyl-glycerophosphoethanolamine (GPE) were not shown because of their very small amounts. The predominant fatty acids at the 2-position of alkylacyl-GPC were 20:4, 18:1 and 16:0, and those in the case of alkenylacyl-GPE 20:4, 22:5, 18:1 and 22:6. On the other hand, the relative proportions of C_{20} and C_{22} polyunsaturated fatty acids in diacyl-GPC and GPE were considerably lower. These fatty acid profiles of human eosinophils are similar to those of human neutrophils (Table 3). However, the percentage of 20:4 in alkylacyl-GPC in human eosinophils is ca. two times higher than that in human neutrophils.

Figure 1 shows the distribution of 20:4 in CGP and EGP in human eosinophils. Very large portions of 20:4 were found in alkylacyl compounds in CGP (92.0%) and alkenylacyl compounds in EGP (86.6%). These results indicate that most of the 20:4 in human eosinophils is stored in ether-containing phospholipids, which suggests the important roles of alkylacyl-GPC and alkenylacyl-GPE in the storage of 20:4.

High amounts of 20:4 in alkylacyl-GPC and alkenylacyl-GPE also have been observed in rabbit alveolar macrophages (18) and human neutrophils (20). We have already suggested that the high accumulation of 20:4 in ether phospholipids is due to the selective mobilization of 20:4 from diacyl-GPC to alkyl and alkenyl ether phospholipids in rabbit alveolar macrophages (23). These ether phospholipids could be one of the main sources of 20:4 in these cells upon stimulation. Several investigators have already demonstrated the release of considerable amounts of 20:4 from alkylacyl-GPC in various types of white blood cells upon stimulation with a variety of agents (24–27). It is very likely that the rapid release of 20:4 from this ether

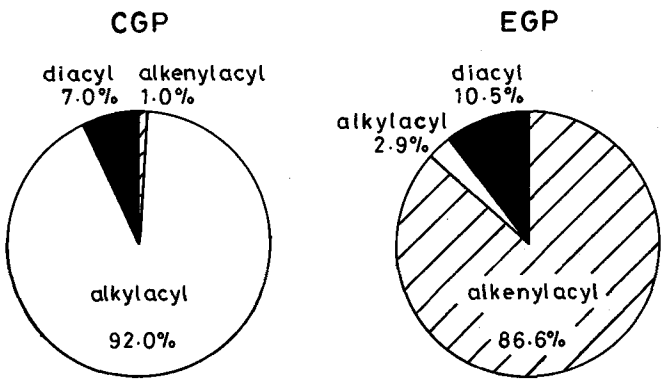

FIG. 1. Distribution of arachidonic acid among the lipid classes of choline and ethanolamine glycerophospholipids in human blood eosinophils. The values were calculated from the quantities of arachidonic acid in each lipid class.

18:1	19.8 ± 3.0	32.6 ± 4.7	14.6 ± 4.5	28.9 ± 2.3	33.3	41.1	36.4	41.0
18:2	10.2 ± 2.8	10.4 ± 2.7	7.2 ± 2.1	3.2 ± 1.2	28.8	11.9	16.7	6.7
18:3 + 20:1	0.3 ± 0.2	0.9 ± 0.9	1.3 ± 1.3	1.3 ± 0.2	n.d.	2.6	0.6	2.1
20:3n-6	2.3 ± 1.5	0.1 ± 0.2	3.1 ± 0.8	n.d.	0.9	0.4	3.8	n.d.
20:4	23.3 ± 1.9	3.4 ± 1.0	36.2 ± 2.4	8.9 ± 0.7	11.7	1.5	26.7	5.9
22:4	5.7 ± 0.7	0.2 ± 0.4	5.1 ± 0.7	0.7 ± 0.5	0.2	n.d.	0.9	n.d.
22:5n-3	11.7 ± 1.5	n.d.	15.3 ± 3.8	5.2 ± 1.0	0.9	0.1	4.9	n.d.
22:6	9.0 ± 0.5	0.4 ± 0.2	12.6 ± 2.0	4.3 ± 2.0	0.9	0.1	5.0	n.d.

[a]The mean percentages are for different samples (n = 4).

[b]The mean percentages are for different samples (n = 2).

Fatty acids were analyzed as methyl esters by GLC. The fatty acid composition of diacyl subclass reflects both the *sn*-1 and *sn*-2 positions, whereas those of ether subclasses represent only the *sn*-2 position. n.d., Not detected.

phospholipid also takes place in eosinophils. Although the hydrolysis and release of 20:4 from stimulated eosinophils have not been studied in detail, it has been established that the generation of 5-lipoxygenase products, especially LTC_4, occurs in stimulated eosinophils (11-13). The results of this study indicate that significant portions of these lipoxygenase products probably originate from 20:4 derived from alkylarachidonoyl-GPC, a common precursor for PAF and eicosanoids. Although the biochemical features of alkylacyl-GPC have been studied in detail in rabbit alveolar macrophages (23,24), there is little information on that in human eosinophils. Further studies will reveal the dynamic and metabolical aspects of alkylacyl-GPC, and their biological significance in human eosinophils.

4th Separation Science and Biotechnology Symposium (August 31–September 3, 1988, Palazzo Feltrinelli, Gargnano del Garda, Italy). Requests for information should be sent to Chairman, Prof. Pier Giorgio Righetti, c/o Euro Business Center, P.O. Box 10552, 1001 EN Amsterdam, The Netherlands.

The 29th International Conference on the Biochemistry of Lipids (September 19–22, 1988, Tokyo, Japan). Sponsored by The Japanese Biochemical Society and the Foundation for Advancement of International Science. For more information, contact Prof. Y. Seyama, Department of Physiological Chemistry and Nutrition, Faculty of Medicine, University of Tokyo, Bunkyo-ku, Tokyo 113, Japan.

Genetic Basis for Obesity and Diabetes (October 30–November 1, 1988, Stouffer Pineisle Resort, Lake Lanier Islands, Georgia). Sponsored by the University of Georgia, Center for Continuing Education and the College of Home Economics. For more information, contact Dr. Carolyn D. Berdanier, Conference Chair, University of Georgia, Department of Foods and Nutrition, Dawson Hall, Athens, GA 30602.

Vitamin E: Biochemistry and Health Implications (October 31–November 3, 1988, The Sheraton Centre, New York, NY). Sponsored by The New York Academy of Sciences. For more information, contact the Conference Department, The New York Academy of Sciences, 2 East 63rd St., New York, NY 10021, (212) 838-0230.

International Symposium on Clinical, Biochemical and Molecular Aspects of Fatty Acid Oxidation (November 6–9, 1988, Penn Tower Hotel, Philadelphia, PA). For more information, contact Paul M. Coates, Ph.D., Division of Genetics, The Children's Hospital of Philadelphia, 34th St. and Civic Center Blvd., Philadelphia, PA 19104.

23rd Annual Hugh Lofland Conference on Arterial Wall Metabolism (May 24–27, 1989, Welches, Oregon). Requests for information should be sent to M. R. Malinow, M.D., Chairman, Hugh Lofland Conference, Oregon Regional Primate Research Center, 505 NW 185th Avenue, Beaverton, OR 97006, (503) 690-5258.

10th Anniversary Meeting of the European Association for Cancer Research (University College, Galway, Ireland, September 11–13, 1989). For further information, contact Dr. S. M. Lavelle, Experimental Medicine, University College, Galway, Ireland; or in North America, contact Dr. J. H. Weisburger, American Health Foundation, Valhalla, New York, NY 10595-1599. The program involves plenary lectures, workshops, symposia and poster sessions.

Dietary Fat Ratios and Liver Plasma Membrane Lipid Composition[1]

Michael W. Hamm*, Anna Sekowski and **Roni Ephrat**
Department of Nutrition, Rutgers University, New Brunswick, NJ 08903

Male Sprague-Dawley weanling rats were fed isocaloric diets consisting of 10% (by wt) fat. The six groups differed in the ratio of corn oil and butter fat present in the diets such that: 10C, 10% corn oil (C); 8C2B, 8% C/2% butter fat (B); 6C4B, 6% C/4% B; 4C6B, 4% C/6% B; 2C8B, 2% C/8% B; and 10B, 10% B. Liver plasma membranes were analyzed for fatty acid composition and cholesterol/phospholipid molar ratio. The 18:2n-6 content was constant in the 10C and 8C2B diets and then decreased linearly through the 2C8B diet. The 20:4n-6 and 18:1n-9 contents were constant except in the 10B diet, in which a significant decrease and increase, respectively, were observed. The cholesterol/phospholipid molar ratio increased between the 10C and 6C4B diets and subsequently (4C6B and 10B diets) remained constant. This data indicates that changes in n-6 fatty acid content in the liver plasma membrane are directly related to dietary intake only for 18:2n-6. Arachidonic acid content in the membrane is maintained at a constant level until the linoleic acid content of the diet is reduced to 0.5% of calories. It also indicates that the cholesterol content of the membrane becomes saturated and does not increase with increasing concentrations of saturated fat in the diet. *Lipids 23,* 829–833 (1988).

It has been proposed in the U.S. that we decrease our total fat consumption from approximately 42% of calories to 30% and alter the ratio of fat intake such that there is an equal distribution of saturated, monounsaturated and polyunsaturated fatty acids (1). However, studies investigating the effects of dietary lipid on membrane lipid structure have generally utilized single-fat sources (2–7) that did not contain an equal ratio of fatty acids. Others have utilized fats that did not contain altered ratios of polyunsaturated to saturated (P/S) fat, but rather monounsaturated/saturated (8) or n-6/n-3 fatty acid alterations (9). In addition, a number of these studies have correlated changes in lipid characteristics with cellular protein function (4,5,7,10,11). These types of dietary fat alterations either demonstrate P/S ratios that differ by several orders of magnitude or monounsaturated/saturated/polyunsaturated (n-6) ratios that are very different from the 1:1:1 recommendations (1). Thus, they are very useful dietary manipulations for determining membrane lipid changes due to extremes of diet. However, the relationship of these single-fat-source diets to a more uniform distribution of classes of fatty acids with respect to membrane lipid composition is not clear.

Investigators have considered the effect of different quantities of individual fatty acids (12,13) or types of fat (14) in the diet on total liver-lipid composition. Those studies were designed to investigate the interrelation of various fats with respect to essential fatty acid deficiency of the whole liver and not a particular membrane's structure or function. Therefore, total liver lipids, as opposed to a particular membrane fraction, were analyzed. We were interested in studying a purified membrane (liver plasma membrane) system that would allow us to examine the changes in membrane lipid composition through a continuum of dietary fatty acid compositions. This allows for a comparison of membrane lipid compositions between the extremes of single-fat-source diets and more intermediate compositions. This will provide a much better understanding of the relationship between the effects of typical experimental diets (single-fat-source) and the recommendations of various national scientific panels regarding dietary fatty acid distribution.

MATERIALS AND METHODS

Forty-eight male Sprague-Dawley weanling rats (Charles River Breeding Labs, Wilmington, MA) were housed individually in wire bottom cages in a temperature-controlled room on a 12-hr light/dark cycle. Animals were divided into six groups and fed an isocaloric diet containing either 10% (w/w) corn oil (10C diet); 8% corn oil/2% butter fat (8C2B diet); 6% corn oil/4% butter fat (6C4B diet); 4% corn oil/6% butter fat (4C6B diet); 2% corn oil/8% butter fat (2C8B diet); or 10% butter fat (10B diet). The compositions of the diets are given in Table 1 and the fatty acid profile in Table 2. The 10B diet contained approximately 220 mg cholesterol/kg diet and the others proportionally less. Diets were formulated by Dr. E. A. Ulman (Research Diets, Inc., New Brunswick, NJ). All diets were fed ad libitum for a period of four wk, at the end of which animals were killed by decapitation. The body wt and liver wt were not different by one-way ANOVA between the groups at the end of the feeding period (data not shown). In several cases, samples were lost so that all animals are not reflected in the final analysis.

Livers were excised and passed through a tissue press. They were then homogenized in three vols of buffer (0.25 M sucrose, 0.5 mM EGTA, 5 mM Hepes, pH 7.4) in a Potter-Elvehjem homogenizer. Plasma membranes were prepared by the Percoll gradient method of Epping and Bygrave (15). Protein was determined by the method of Lowry et al. (16), as modified by Markwell et al. (17). Typical membrane purification with this procedure in our hands is seven- to 20-fold for plasma membrane, 0.5-fold for microsomes and 0.06-fold for mitochondria, as determined by enzyme markers. Plasma membrane protein recovery was 0.3–0.7 mg/gm liver.

Total membrane lipid was extracted with chloroform/methanol (2:1) containing 0.005% BHT, according to the method of Folch et al. (18). Fatty acids were methylated with boron trifluoride according to the procedure of Morrison and Smith (19) and quantitated by gas-liquid capillary chromatography (Hewlett-Packard 5490 gas chromatograph/3392 integrator, SP-2330 30 m capillary column). Individual fatty acids were identified by comparison with known standards. Total membrane cholesterol and phospholipid were determined spectrophotometrically from the Folch extract by the method of Chiamori and Henry (20) and Bartlett (21), respectively.

[a]Data are mean ± SEM for the number of animals indicated below each dietary group. Values in a row with common superscripts are not statistically different than one another. All other values in a row are different at $p < 0.05$.

Data were analyzed for variance and by Duncan's multiple range test, utilizing the SAS Statistics package, or regression analysis where appropriate.

RESULTS

The fatty acid profiles of liver plasma membranes from animals fed the various diets are presented in Table 3. There were no changes observed in the saturated fatty acids between any of the dietary groups, with 16:0 comprising approximately 24% and 18:0, 17–19% of the total fatty acid. There were, however, alterations in the various unsaturated fatty acids. 16:1n-7 remained constant in liver plasma membranes from the 10C- through the 4C6B-fed animals, but then increased significantly in those from the 2C8B- and 10B-fed animals. A similar change was observed with 18:1n-9. It was constant in liver plasma membranes isolated from animals fed the 10C through the 2C8B diets, but increased significantly in the 10B-diet-fed animals. In contrast to these modest changes observed in the monounsaturated fatty acids, there were marked changes in the polyunsaturated fatty acids as the ratio of fat in the diet was altered. This was observed most clearly for 18:2n-6. There was a decline that was not apparent (Table 3) until the 6C4B diet. That is, liver plasma membranes prepared from animals fed the 10C and 8C2B diets were not significantly different than one another, but there was a steady decline in the percentage of 18:2n-6 with the remainder of the groups. This can also be observed in Figure 1 as a linear decline in the [18:2n-6/(16:1n-7 + 18:1n-9)] ratio, as the percentage of corn oil in the diet was decreased ($r = 0.816$, $p < 0.001$).

This linear decrease is not seen in the case of arachidonic acid (20:4n-6). Arachidonic acid in the liver plasma membrane remained at a constant level (approximately 19%) until all of the corn oil had been eliminated from the diet (10B diet). At this point it declined to 12.9%. When the data were replotted as the ratio of 20:4n-6/18:2n-6 (Figure 2), it is evident that the ratio was constant in liver plasma membranes from the 10C- through 6C4B-fed animals (100–60% of fat source as corn oil) and then increased linearly. Furthermore, the total n-6 fatty acids in liver plasma membranes remained constant (diets 10C through 4C6B), up to the point where n-6 fatty acids comprised less than 3% of the calories (2C8B and 10B diets).

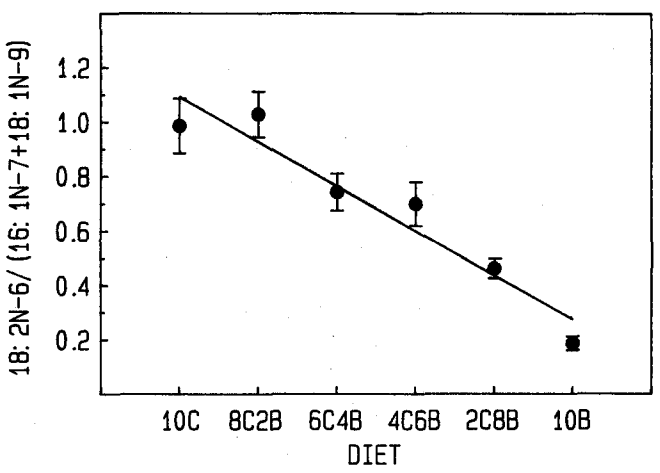

FIG. 1. 18:2n-6/[16n-7 + 18:1n-9] Fatty acid ratio vs diet. All data are X ± SEM. The line was fitted by linear regression to: Y = (−0.816)X + 1.259 with r = 0.816 (p < 0.05). By ANOVA values for diets 10C and 8C2B were significantly greater than all others. Diets 6C4B, 4C6B and 2C8B were significantly different than 10C, 8C2B and 10B, while diet 10B was different than all others. Values were considered significant when p < 0.05.

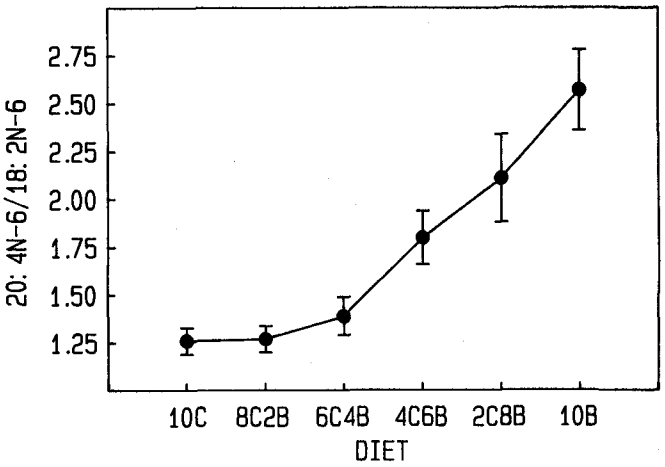

FIG. 2. 20:4n-6/18:2n-6 Fatty acid ratio vs diet. All data are X ± SEM. Statistical differences were as follows. Different letters associated with each diet indicate that values are significantly different. Diet 10C, a; 8C2B, a; 6C4B, a,b; 4C6B, b,c; 2C8B, c; 10B, d. Values were considered significant when p < 0.05.

The liver plasma membrane content of 22:5n-3 decreased, while that of 22:6n-3 increased, as butter fat was added to the diets. The total of n-3 fatty acids in the membrane remained relatively constant.

The cholesterol and phospholipid values of the liver plasma membranes from animals fed the various diets are presented in Table 4. There was an increase (although not statistically significant) in the cholesterol/phospholipid molar ratio of the membranes as the butter fat content of the diet was increased from 10C to 6C4B, which remained relatively constant for diets 4C6B and 10B. The 2C8B diet (0.475 ± 0.057) was anomalous in this regard. The cholesterol/phospholipid molar ratio was significantly lower in liver plasma membranes from the 10C- and 2C8B-fed animals compared with the 4C6B- and 10B-fed animals ($p < 0.05$). The cholesterol and phospholipid levels relative to protein content were not different between any of the groups.

DISCUSSION

There have been a number of investigations through the years that have studied the effects of dietary lipids on membrane structure (2–9,22). However, the vast majority of these have investigated single-fat-source diets as opposed to ratios of the dietary fats. This distorts the dietary lipid composition markedly towards highly saturated, monounsaturated or polyunsaturated fatty acid diets. For example, in the present study, the 10C diet is composed of 62% polyunsaturated, while the 10B diet is composed of 65% saturated fatty acids. This study demonstrates that an approach of utilizing ratios of fats producing intermediate fatty acid compositions may be an important consideration in determining the effect of

TABLE 4

Cholesterol and Phospholipid Composition of Liver Plasma Membranes[a]

Diet	Cholesterol μmol/mg protein	Phospholipid μmol/mg protein	Cholesterol/Phospholipid molar ratio

4C6B (7)	0.126 ± 0.028[a]	0.202 ± 0.047[a]	0.646 ± 0.049[a,b]
2C8B (4)	0.126 ± 0.020[a]	0.284 ± 0.064[a]	0.475 ± 0.057[a]
10B (6)	0.104 ± 0.014[a]	0.155 ± 0.026[a]	0.697 ± 0.057[b]

[a]Data are mean ± SEM for the number of animals indicated for each dietary group. Values in a column with common superscripts are not statistically different than one another at $p < 0.05$.

dietary fat on biochemical and physiological function. The data in the present study illustrate that single sources of dietary fat produce liver plasma membrane changes that are not necessarily representative of those produced by intermediate ratios.

The most useful comparison would relate the 6C4B diets with the 10C and 10B diets. The 6C4B diet had a polyunsaturated/monounsaturated/saturated fatty acid ratio of approximately 1:1:1 (Table 2). This is the fatty acid ratio currently recommended by a variety of organizations (1) relative to optimal human consumption patterns.

Liver plasma membranes from animals fed the 6C4B diet exhibited a cholesterol/phospholipid molar ratio most similar to those from animals fed the 10B diet (Table 4) and a fatty acid profile more similar to those from animals fed the 10C diet. In other studies utilizing single-fat sources, we have found that the major changes observed between butter and corn oil are a shift in the 18:2n6/(18:1n-9 + 16:1n-7) ratio (23). Thus, we have chosen to compare the ratio of these two fatty acids across the diets. The slight decline in 18:2n-6 from animals fed the 6C4B diet, relative to the 10C diet, was not statistically significant (Table 3), but is clearly seen with linear regression when expressed as a ratio with n-9 and n-7 unsaturated fatty acids (Fig. 1) ($p < 0.05$). Furthermore, a slight shift in the ratio (4C6B diet) produces a significant change in the amount of 18:2n-6 (Table 3) and the ratio of 20:4n-6/18:2n-6 (Fig. 2) found in the liver plasma membrane. However, the 18:2n-6/(18:1n-9 + 16:1n-7) ratio was not different between these two groups.

Thus, the use of single-fat-source diets, while being extremely useful in determining the effects of extremes in dietary modifications on changes in cell structure and function, may not be precise enough to predict changes to be expected within the framework of human nutritional modifications.

It is also of interest to compare this data with that of Caster et al. (14), relating the intake of various dietary lipids to total liver lipid composition. They reported no correlation between the saturated fatty acid content of the diet and the saturated fatty acid content of total liver lipid, when studied with an array of common fatty acids in various ratios. This is a generally observed phenomenon, indicating that total organ lipid saturated fatty acids are very refractory to change, and it is consistent with our data. We also observed similar effects in the case of the monounsaturates, primarily 18:1n-9. The animals maintained a fairly constant amount of monounsaturates in the liver plasma membrane (Table 3). This is in relatively good agreement with the work of Caster et al. (7), in which a low correlation between the 18:1n-9 dietary- and tissue-total lipid concentration was reported. We consider these compensatory changes by the organism an attempt to balance the decline seen in the n-6 polyunsaturates as large amounts of saturated fat is added to the diet.

The major change seen in these membranes was in the amount of 18:2n-6. As seen in Table 3, the wt% of 18:2n-6 in liver plasma membranes remained constant with the first two diets, which supplied 100% and 80% of the fat source as corn oil. A linear decline was observed through the rest of the diets, as the percentage of calories from linoleic acid went below 10%. It is interesting to note from Table 2 that the amount of arachidonic acid remained constant in the plasma-membrane total fatty acids as long as the percentage of calories from 18:2n-6 was greater than 0.5% (of calories). This becomes interesting in light of the current recommendations that 1% of our calories be derived from linoleic acid. There is no change in rats, with respect to wt gain or dermal score (2), as the linoleic acid content of the diet is increased above 1% of calories. This may be interpreted as arachidonic acid changes being the primary determinant of n-6 deficiency symptoms, because membrane linoleic acid concentration decreased at dietary concentrations well in excess of reported requirements. It should be noted, however, that we did not observe significant amounts of 20:3n-9, a biochemical marker for essential fatty acid deficiency (25), or any visual signs of deficiency in these animals. This is not entirely surprising, because the animals were only maintained on these diets for four wk.

A recent report by Nasser et al. (9) investigated the effect of various ratios of n-3/n-6 dietary lipids on total liver-phospholipid fatty acid composition. No changes were reported in 18:2n-6 content over a range of evening primrose oil (high 18:2n-6 and 18:3n-6) and polepa (n-3 rich marine fish oil) ratios. Their lowest percent of evening primrose oil was 50% of the total fat content, an amount similar to those amounts in the 6C4B and 4C6B diets in the present study. At this point, however, we observed significant decreases in 18:2n-6, while they observed no

such differences. This difference in the two studies could be due to the different types of oil mixtures or differences in the samples. In the present study, total fatty acid profile of purified liver plasma membranes was analyzed, while in the study of Nasser et al. (9), the total liver-phospholipid fatty acid profile was determined.

The cholesterol/phospholipid molar ratio exhibited an increase commensurate with the quantity of cholesterol and saturated fat in the diet up to a saturation point (6C4B diet). The exception to this was liver plasma membranes from animals fed the 2C8B diet. The marked change at this dietary fat ratio is unclear. It should be noted that this decrease was due primarily to an increase in the phospholipid/mg protein content.

It is clear from this study that single-fat sources do not necessarily give a true indication of the purified membrane lipid composition of mixed fats. This is especially important in studies attempting to relate changes in function of membrane proteins with dietary fat alteration. The range of modification that most individuals will be able to make in their dietary pattern is much more limited than the single-fat-source feeding studies most often performed in rats. This is not meant to imply that such studies are not useful, but rather to point out that, if animal studies are to be used as an aid in determining potential alterations in cell function by dietary lipid in human populations, more work must be addressed at intermediate ratios of these fats. For example, if the 6C4B were taken as approximately a 1:1:1 ratio of polyunsaturated/monounsaturated/saturated fatty acids, the fatty acid composition would be similar to the 10C diet, whereas the cholesterol/phospholipid molar ratio would be most similar to the 10B diet. Both of these components could have an effect on membrane protein function and hence, it is important to investigate the interaction of these changes.

The uptake of α-tocopherol from 2*R*,4′*R*,8′*R*-α-tocopherol and 2*R*,4′*R*,8′*R*-α-tocopheryl acetate has been compared in rats and humans. The two forms of vitamin E were compared simultaneously in each subject (rat and human) by using a combination of deuterium-substitution and gas chromatography–mass spectrometry (GC–MS) to distinguish and measure the competitive uptake of α-tocopherol from an orally ingested mixture of the acetate and the free phenol forms. When rats were dosed in a manner analogous to that used in traditional bioassays, i.e., providing the two forms of vitamin E once daily in tocopherol-stripped corn oil for four successive days immediately prior to sacrifice, the net uptake of α-tocopherol from the free phenol form was only half that from the acetate. This result is consistent with the greater activity of the acetate that had been observed previously in bioassays. However, when the two forms of tocopherol were intubated into rats as a single dose mixed in with an aqueous bolus of standard laboratory diet, the amount of α-tocopherol taken up from the free form after 24 hr was very similar to that derived from the acetate. In five adult humans, competitive uptake studies of the two forms after a single dose taken with a meal showed that the amount of α-tocopherol from the free phenol form was equal to that from the acetate in plasma and red blood cells. These findings illustrate the value and potential of using deuterium-substituted α-tocopherol and GC–MS in evaluating the effectiveness of different forms of vitamin E in human studies. The results also stress the need for caution in using data obtained from animal bioassays when considering comparative human nutritional standards.

Lipids 23, **834–840 (1988).**

α-Tocopheryl acetate (α-T-Ac) is the most common form of vitamin E used for oral supplementation in humans. In the gut, the acetate is hydrolyzed with the aid of pancreatic enzymes and bile to yield free α-tocopherol (α-T-OH) which is then partially absorbed through the intestinal wall into the lymph (1–3). No measurable α-T-Ac is found in blood serum (4). Naturally occurring vitamin E is present in food as the free phenol.

The relative bioavailabilities of α-T-OH and α-T-Ac have been of interest for many years. In 1949, Harris and Ludwig (5) reported the surprising result that *dl*-α-T-OH was only about 0.6 times as active as *dl*-α-T-Ac in the rat fetal resorption assay. (It is almost certain that at the time this study was conducted the *dl*-form was synthesized using natural phytol and was therefore a mixture of equal amounts of the 2*R*,4′*R*,8′*R*- and 2*S*,4′*R*,8′*R*-diastereoisomers [1]. The mixture of these two α-tocopherols is now designated as *ambo*-α-tocopherol.) Harris and Ludwig suggested that the lower activity of the nonesterified form was the result of a diet-mediated oxidative destruction of the compound in the gut. In support of this, they reported that simultaneous feeding of the antioxidant, diamylhydroquinone, with free α-tocopherol significantly increased the effectiveness of the tocopherol in the bioassay (5). Much later, Leth and Sondergaard (6) confirmed the lower activity of the nonesterified form, reporting that, in this case, *all-rac*-α-T-OH (i.e., a mixture of equal amounts of the eight possible diastereoisomers) was less active than *all-rac*-α-T-Ac in both the fetal resorption and red cell hemolysis assays, by factors of 0.79 and 0.85, respectively. (The authors did not indicate whether the relative potencies were calculated on a weight or a molar basis.) They also reported, however, the surprising result that the two forms of vitamin E exhibited identical activities in the liver storage assay. Further confirmation of the lower potency of α-T-OH was recently provided by Wieser and coworkers (7), who reported results obtained using the fetal resorption, plasma pyruvate kinase (myopathy) and liver storage assays. On a molar basis, it was found that *all-rac*-α-T-OH was less active than *all-rac*-α-T-Ac in all three assays by factors of 0.47, 0.57 and 0.62, respectively.

On the basis of the findings from these animal tests, it has been suggested (6) or implied (7) that the biopotencies of *all-rac*-α-T-OH and *RRR*-α-T-OH, expressed relative to *all-rac*-α-T-Ac as the standard, should be lowered from their officially accepted values (8) of 1.10 and 1.49, respectively. (The difference between the accepted biopotencies of the acetate and the corresponding free tocopherol arises solely from the difference in the molecular weights of the two forms. The officially accepted biopotency of *RRR*-α-T-Ac relative to *all-rac*-α-T-Ac is 1.36 [8].)

In humans, studies have been limited to comparing the absolute increases in the level of plasma α-T-OH in individuals administered large, single, oral doses of either the free tocopherol or the acetate. The results of these studies have suggested that, in contrast to rats, the free form is slightly more potent than the acetate.

Thus, in 1952, Week and coworkers (9) reported higher plasma levels of α-T-OH in subjects given *all-rac*-α-T-OH compared with subjects given an equimolar amount of *all-rac*-α-T-Ac. Much later, Baker and coworkers (10) appeared to confirm this finding in subjects given 400–1600 mg of either *all-rac*-α-T-OH or its acetate in both short-term (24 hr) and long-term (21 days) studies. In this investigation, equal weights of the free phenol and of the acetate were compared. It is not evident from the data, however, that the increases in plasma tocopherol levels in the subjects who took the free phenol, compared with the data from those who took the acetate, were significantly greater than the ca. 10% that would have been

Abbreviations: α-T-Ac, α-tocopheryl acetate; α-T-OH, α-tocopherol; EDTA, ethylenediamine tetraacetic acid; d_3-*RRR*-α-T-OH, 2*R*,4′*R*,8′*R*-α-(5-C^2H_3)tocopherol; d_6-*RRR*-α-T-OH, 2*R*,4′*R*,8′*R*-α-(5,7-$(C^2H_3)_2$)tocopherol; d_9-α-T-OH, *ambo*-α-(5,7,8-$(C^2H_3)_3$)tocopherol; SDS, sodium dodecyl sulfate; GC–MS, gas chromatography–mass spectrometry; HPLC, high performance liquid chromatography; RBC, red blood cells.

expected simply from the difference in molecular weight between α-T-OH and α-T-Ac. More recently, Horwitt and coworkers (11) have reported that subjects given 800 IU of *RRR*-α-T-OH showed a mean increase of 71% in their serum levels of α-T-OH after 24 hr, compared with a smaller increase of 61% in subjects given 800 IU of *RRR*-α-T-Ac (The doses were equimolar, in conformity with the existing USP standard.).

Recently, we have used deuterium-substituted α-tocopherols and gas chromatography–mass spectrometry (GC–MS) to probe the biokinetics of the uptake of dietary α-tocopherol into rat tissues (12). In this paper, we report results obtained by applying this technique directly to the question of the relative uptake, in rat and man, of α-T-OH derived from the free tocopherol and acetate forms of vitamin E. In contrast to the experimental methods used earlier by others, we have taken advantage of the fact that, by distinguishing the free tocopherol and acetate with tri- or hexadeutero-substitution (i.e., differential labeling), it is possible to measure the competitive uptake of the two forms, when given as a mixture of known composition to a single subject. This approach has the advantage of eliminating the effects of variations in absolute uptake between individual subjects. Individual variation in net uptake is an important factor confounding the interpretation of the results of studies obtained with conventional techniques using nonlabeled compounds. Only one or the other of the two forms being compared can be tested at one time on each individual, which requires the use of a large number of subjects in order to obtain statistically significant results.

Another advantage of our method is that the deuterated α-tocopherol absorbed from the mixture is easily distinguished from the nondeuterated, background α-tocopherol already present in the subject.

EXPERIMENTAL

Synthesis of deuterated RRR-*α-tocopherols. RRR*-α-(5-C^2H_3)tocopherol (d_3-*RRR*-α-T-OH) and *RRR*-α-(5,7-(C^2H_3)$_2$)tocopherol (d_6-*RRR*-α-T-OH) were synthesized, as described previously (12,13), by deuteriomethylation of *RRR*-γ- and *RRR*-δ-tocopherols, respectively. The γ- and δ-tocopherols were obtained from soybean oil concentrate. The tocopheryl acetates were prepared as described previously (12). While this work was in progress, *ambo*-α-(5,7,8-(C^2H_3)$_3$)tocopherol (d_9-α-T-OH) was prepared and was used as an internal standard for quantitating d_0-, d_3- and d_6-α-T-OH in some of the experiments. The details of the synthesis of this compound will be reported elsewhere.

The degree of incorporation of the nominal amount of deuterium into d_3-*RRR*-α-T, d_6-*RRR*-α-T and d_9-α-T (acetate or free tocopherol) ranged from 75% to 90%, as determined by GC–MS. The remaining material was composed principally of α-tocopherol, containing one less deuterium atom and, to a much lesser extent, two less deuterium atoms. All measurements of deuterated α-tocopherols were corrected accordingly, to reflect the true amount of the particular α-tocopherol present in each sample.

Measurement of α-T-OH by GC–MS. α-T-OH was extracted from plasma by the ethanol/heptane method and from tissues, red blood cells, intestinal and fecal material by the sodium dodecyl sulfate (SDS) method (12,14). The heptane lipid extract was passed through an analytical, high performance liquid chromatography (HPLC) silica gel column and the recovered α-T-OH fraction was trimethylsilylated after removal of the HPLC eluent by evaporation under a stream of nitrogen (12). When it became available, d_9-α-T-OH was added as an internal standard (ca. 6 nmol) in decane solution immediately prior to extraction of the sample.

The tocopheryl trimethylsilyl ethers were injected into a 12 m × 0.2 mm ID Ultra-1 (OV 101 methyl silicone) capillary column in a Hewlett-Packard benchtop model 5995 GC–MS, operating in the single-ion monitoring mode (12). The 502 (d_0-α-T), 505 (d_3-α-T), 508 (d_6-α-T) and 511 (d_9-α-T) parent trimethylsilyl ether molecular ions were monitored continuously and their corresponding peak areas integrated to give the relative abundance of each tocopherol.

GC–MS also was used to confirm the composition of the mixture of deuterated α-tocopherols provided to the animal or human subjects in each experiment. In those experiments in which the starting molar ratio was significantly different from unity, the ratios found in the tissues and blood were corrected accordingly.

Rat studies: Experiment 1. Two pairs of ten-week-old male Sprague-Dawley rats (ca. 300 g) were dosed daily for four days with an equimolar mixture of d_3-*RRR*-α-T-Ac and d_6-*RRR*-α-T-OH (combined dose: 2 mg/kg body wt/day) dissolved in ca. 100 μl of tocopherol-stripped corn oil that had no added antioxidant. One pair of rats was maintained on a vitamin E-free AIN-76A diet (15) and the other on a vitamin E-sufficient AIN-76A diet (50 mg *all-rac*-α-T-Ac/kg diet) from weaning (3 wk) through the duration of the experiment. (The proportion of corn oil in each diet was increased from 5% to 10% with a compensating decrease in the proportion of corn starch.) The food was provided ad libitum. Blood and tissues were obtained on the day after the last dose. The blood was obtained by heart puncture under halothane anesthesia, and the tissues from the anesthetized animals were then dissected. All of the fecal material in the large intestine was collected and care was taken to ensure that the total combined sample from each animal was analyzed. All samples were stored at −80 C prior to analysis.

Experiment 2. Five 13-week-old, nonfasted male Sprague-Dawley rats weighing 425–510 g were intubated with about 5 ml of an aqueous slurry of AIN-76A diet (5% corn oil; 20 g diet slurried in 15 ml water) containing ca. 3.8 g of dry mixture and 4 mg of a mixture of d_3-*RRR*-α-T-Ac and d_6-*RRR*-α-T-OH. The weighed deuterated tocopherols were first dissolved in the correct amount of tocopherol-stripped corn oil (with no added antioxidant) and were then thoroughly mixed with the dry base diet (no corn oil) before adding water to make a slurry. This was done immediately prior to dosing. After dosing, the rats were returned to their cages and permitted uninterrupted access to water and their usual AIN-76A diet. Blood was obtained as described above at four and 24 hr after dosing. Tissues were obtained at 24 hr by the procedure already described for Experiment 1. In addition, the small intestine was divided into three equal-sized segments and each segment, including its contents, was subsequently analyzed for α-tocopherol.

Human studies: Experiment 3. Trials were performed on five healthy adults (three males and two females, ages

36-59 years), who were not taking any form of medication. A neat, equimolar mixture of d_3-*RRR*-α-T-OH and d_6-*RRR*-α-T-Ac was weighed out into gelatin slip-joint capsules (ca. 100 mg total/capsule). The capsules were always taken with an evening meal.

Part A: A total of two capsules, one per day, was taken by each of two males (GB and KI) on successive days. Blood, collected over disodium EDTA, was obtained by venipuncture from both subjects ca. 15 hr after taking each capsule and, for one of the subjects (KI), two days after the last capsule. The ratio of the two deuterated α-T-OH's was determined in the lipid extracts obtained from plasma and red blood cells in the usual way (12).

Part B: Two females (HB and SL) and one male (DF) each took one capsule, only, of 100 mg of the mixture of deuterium-substituted tocopherols. Blood was obtained from the subjects ca. 19 and 43 hr after taking the capsule.

RESULTS

The data for the competitive uptake into rat blood and tissues of α-tocopherol from a mixture of free α-tocopherol and α-tocopheryl acetate are presented as OH/Ac ratios in Tables 1 (Experiment 1) and 2 (Experiment 2).

The combined mean value of the OH/Ac ratio for the four animals dosed daily for four successive days with the corn oil mixture (Experiment 1) was found to be 0.49 ± 0.05 (SEM). Clearly, in this experiment, α-tocopheryl acetate was about twice as effective a source of absorbed α-T-OH. The combined amounts of absorbed deuterated

[a]Rats were fed a single dose of a mixture of d_3-*RRR*-α-T-Ac and d_6-*RRR*-α-T-OH mixed in an aqueous bolus of laboratory diet (Experiment 2). Results corrected for an initial d_6-*RRR*-α-T-OH/d_3-*RRR*-α-T-Ac mole ratio = 1.372.

[b]The small intestine (including contents) was divided into three equal segments starting at the end closest to the stomach. The free α-T-OH was separated from α-T-Ac by HPLC. The data in the table refer only to the free α-T-OH.

[c]100 × (d_3-α-T-OH + d_6-α-T-OH)/(d_0-α-T-OH + d_3-α-T-OH + d_6-α-T-OH).

α-tocopherols, expressed as a percentage of the total α-tocopherol in each of the tissues and blood fractions examined, are compared for the vitamin E-deficient and vitamin E-sufficient animals in Figure 1. The effect of the vitamin E-deficient diet is clearly evident in the larger percentages of deuterated tocopherol in the rats maintained on that diet. However, the data in Table 1 show that the vitamin E status of the animals does not affect the OH/Ac ratios.

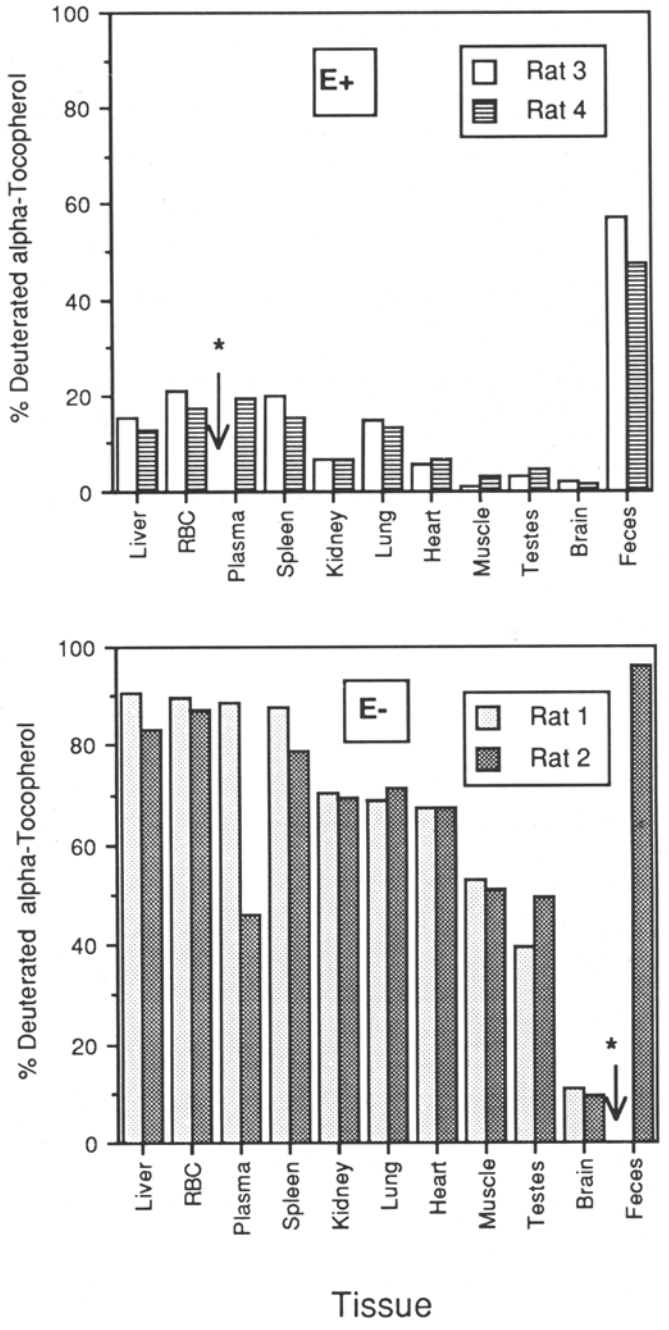

FIG. 1. Percent deuterated α-tocopherol, 100 × [d_3-α-T-OH + d_6-α-T-OH]/[d_0-α-T-OH + d_3-α-T-OH + d_6-α-T-OH], in plasma, RBC, tissues and feces of rats, maintained on vitamin E-deficient (E−) and sufficient (E+) diets, after receiving four daily doses of a mixture of d_6-*RRR*-α-T-OH and d_3-*RRR*-α-T-Ac in tocopherol-stripped corn oil (Experiment 1). An asterisk above or beside a bar denotes a missing value for the tissue indicated.

The data in Table 2 show that free α-tocopherol competed much more effectively with the acetate, when the two compounds were incorporated into an aqueous bolus of laboratory diet (Experiment 2; vitamin E-sufficient rats), than when the two compounds were given in the corn oil. In Experiment 2, the combined mean OH/Ac ratio from the liver, spleen, lung, heart, plasma and RBC at 24 hr was found to be 1.06 ± 0.11 (SEM). Comparison of the OH/Ac values for plasma and RBC at four hr and 24 hr shows that in all but one case the ratio is less at 24 hr than at four hr. This indicates that the proportion of absorbed α-tocopherol derived from the free form declines more rapidly than that derived from the acetate. In the small intestine, the ratios of the original free α-tocopherol (d_6-α-T-OH) to the α-tocopherol (d_3-α-T-OH) derived from the acetate are similar to the OH/Ac ratios in the other tissues, although there is perhaps a slight tendency for this ratio to decrease, from the first segment, closest to the stomach, through to the third, most distant segment. This trend suggests that the hydrolysis of the acetate continues to occur into at least the middle segment of the intestine.

The data for the percent total deuterated α-tocopherol in the plasma and RBC show that although there is little change in the plasma values between four hr and 24 hr, there is a sharp rise in the RBC values over the same period, indicating a time lag in the uptake of tocopherol into RBC. The lag in the uptake into RBC is consistent with the results obtained from two independently conducted in vitro experiments in which it was found that the half-life for the equilibration of α-T-OH between rat plasma and RBC is 2.2 hr at 37 C (16,17).

The mean absolute concentrations of d_0-α-T-OH, d_3-*RRR*-α-T-OH and d_6-*RRR*-α-T-OH measured in the tissues, plasma, RBC, small intestinal segments and feces at 24 hr are presented in Figure 2.

The data obtained from the human study (Experiment 3, Parts A and B) are given in Tables 3 and 4. In the first application of this technology to the measurement of vitamin E uptake in humans (Part A), it is clear from the data in Table 3 that a single dose of 100 mg of deuterated vitamin E is easily detectable in plasma and RBC. The two subjects show that, despite striking differences in the percentages of deuterated α-tocopherol in their plasma and RBCs, the corresponding OH/Ac ratios are remarkably constant over time and between subjects (mean = 1.12 ± 0.04 [SD]), with slightly more absorption of vitamin E occurring from the nonesterified α-tocopherol.

Part B of Experiment 3 illustrates the fact that only one capsule of 100 mg of the mixture of α-tocopherols was required to obtain good data. The results, shown in Table 4, indicate no significant advantage to either form of vitamin E (mean OH/Ac = 0.97 ± 0.04 [SD]). This result agrees well with that obtained in Part A of the experiment. The absolute concentrations of the deuterated and nondeuterated α-tocopherols also are presented in Table 4.

The human data differ markedly from the data obtained with rats dosed according to the traditional bioassay method (Experiment 1), but do agree rather well with the data obtained when the rats were given vitamin E premixed with food (Experiment 2).

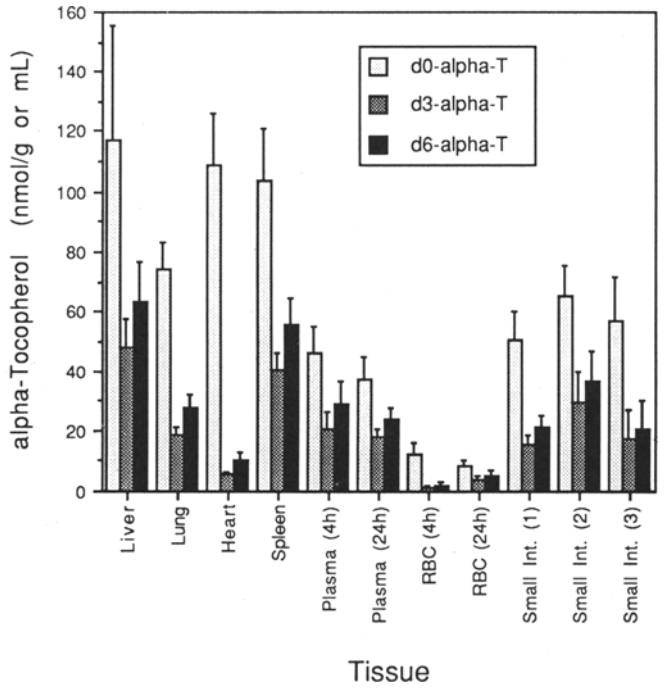

FIG. 2. Mean absolute concentrations of d_0-α-T-OH, d_3-*RRR*-α-T-OH and d_6-*RRR*-α-T-OH in plasma, RBC, tissues and small intestine and contents (divided into thirds) from five rats, four hr (plasma and RBC only) and 24 hr after a single oral dose of d_6-*RRR*-α-T-OH and d_3-*RRR*-α-T-Ac mixed into an aqueous bolus of rat diet (Experiment 2; note: initial d_6/d_3 mole rato = 1.372). Error bars represent one standard deviation. Not shown are the corresponding, substantially larger values for feces which were 176 ± 26, 267 ± 130 and 376 ± 198 nmol/g for the d_0-, d_3- and d_6-α-tocopherols, respectively.

DISCUSSION

The advantage of our experimental approach is that the two forms of vitamin E are compared directly within the same subject (rat and human). This eliminates many of the problems associated with interindividual variations, as is clearly and abundantly evident by the consistency of the data we have obtained.

The results from Experiment 1 confirm that the lower activity of nonesterified α-tocopherol observed in bioassays (5–7) is due to the fact that less of it is absorbed from the gut. This result is not affected by the vitamin E status of the animal. However, the much improved relative absorption of the free phenol in Experiment 2 reveals that there is a striking dependence of absorption on the choice of vehicle for delivery of the vitamin.

It has been pointed out that rat diets contain mineral supplements that can promote the oxidation of free tocopherol and that the low potency of the tocopherol, relative to the acetate in rat bioassays, may reflect partial oxidative destruction of the free tocopherol (11,18). Our results, obtained when the vitamin E was mixed in directly with the food, appear, at first, to argue against this suggestion. Thus, even though in Experiment 1 the tocopherol mixture would inevitably come into contact with the rat diet, because dosing occurred over a four-day period, it would be expected that the greatest loss of free tocopherol would occur in Experiment 2, where the free α-tocopherol is exposed to the diet continuously, right from the moment of dosing. (It should be noted that, in order to prevent oxidative losses before dosing, the mixing of the vitamin E with the base diet was delayed until immediately prior to dosing the animals.)

There is, however, the possibility that intestinal oxidative destruction of tocopherol did occur in the animals in Experiment 2, but that it was masked by the operation of other processes. Thus, if hydrolysis of the acetate were rapid compared to the rate of oxidative destruction of the free tocopherol, the effects of oxidation would not be obvious because both forms would be lost at similar rates. Indeed, a rapid hydrolysis of the acetate does appear to have occurred in Experiment 2. Table 2 and Figure 2 show that even as early as four hr after the dose, the amounts of d_3-*RRR*-α-T-OH and d_6-*RRR*-α-T-OH in the plasma are similar (taking into account the differences in the initial proportions of the 2 tocopherols) and are as large as the corresponding values at 24 hr. (However, the d_6-*RRR*-α-T-OH/d_3-*RRR*-α-T-OH ratio is slightly larger at four hr than at 24 hr, indicating that there is some lag in the hydrolysis of the acetate.) Further evidence for a rapid hydrolysis is provided by the d_6-*RRR*-α-T-OH/d_3-*RRR*-α-T-OH ratio obtained for the first third of the small intestine and included contents. The value is essentially the same as that found for the plasma, RBCs and tissues. Furthermore, there is little change, if any, in this ratio in the remaining two-thirds of the small intestine. It appears, therefore, that most of the hydrolysis of the acetate occurred in the first third of the intestine under the conditions of Experiment 2. Also, Figure 2 shows that the absolute amounts of d_3-*RRR*-α-T-OH and d_6-*RRR*-α-T-OH did not vary much between the three small intestinal segments. Another measure of the completeness of hydrolysis was obtained by comparing the d_6-*RRR*-α-T-OH/d_3-*RRR*-α-T-OH ratios in the three, small intestinal segments and in the combined feces (recovered from the large intestine) before and after alkaline hydrolysis. The data, presented in Table 5, show that there is little of the d_3-*RRR*-α-T-OH, if any, remaining after 24 hr.

TABLE 5

Comparison of d_6-α-T-OH/d_3-α-T-OH Ratios, Before and After Alkaline Hydrolysis[a]

	Rat	Before hydrolysis[b]	After hydrolysis[c]	Before/After[d]
Small intestine Segment 1[e]	1	0.96	1.00	0.96
	2	1.05	1.02	1.04
	3	1.03	1.16	0.89
Small intestine Segment 2[e]	1	0.91	0.98	0.93
	2	0.99	0.97	1.02
	3	0.98	1.06	0.92

	5	1.01	1.00	1.01

[a]In small intestinal segments (three animals) and total fecal material from large intestine (five animals) of rats 24 hr after feeding with a mixture of d_6-*RRR*-α-T-OH and d_3-*RRR*-α-T-Ac in a bolus of food (Experiment 2). Ratios corrected for an initial d_6-*RRR*-α-T-OH/d_3-*RRR*-α-T-Ac mole ratio of 1.372.

[b]These correspond to the OH/Ac ratios in Table 2.

[c]The values will be less than the values before alkaline hydrolysis, if there is d_3-*RRR*-α-T-Ac present. Alkaline hydrolysis was carried out on three equally divided intestinal segments from three of the five rats.

[d]Ratio of the value before hydrolysis to that after hydrolysis. Values which are greater than one indicate the presence of unhydrolyzed d_3-*RRR*-α-T-Ac in the gut 24 hr after receiving the dose.

[e]The small intestine, including contents, was divided into three segments of equal size, beginning with the segment closest to the stomach.

Although a comparable analysis of the small intestine was not conducted in Experiment 1, small but significant amounts of acetate were indeed isolated from fecal material recovered from the large intestine 24 hr after the last dose (Table 1, footnote b). Thus, it is reasonable to infer that hydrolysis of the acetate occurs more slowly when the dose of vitamin E is given in tocopherol-stripped corn oil, leading to a proportionately greater loss of the α-tocopherol originally present as the free phenol.

Oxidative loss, then, still remains the most likely explanation for the poor uptake of free α-tocopherol in Experiment 1. Unfortunately, direct evidence for this phenomenon has, so far, eluded us. Preliminary analyses of fecal material recovered from the large intestine of the rats in Experiment 1 failed to reveal significant amounts of α-tocopheryl quinone, which is, admittedly, only one of several possible oxidation products. Also, this quinone was not detected in the plasma of these animals.

The small variations in the OH/Ac values observed between tissues from the same animal in Experiment 1 may be real, because the proportions of α-tocopherol from the free phenol source and the acetate source passing across

the intestinal wall into the lymph may have varied with time, due to the lag in the hydrolysis of the acetate. Furthermore, it is likely that different tissues absorbed α-tocopherol from plasma at differing rates during the course of the experiment (12).

The competitive uptake of α-T-OH into human blood from a mixture of free α-tocopherol and α-tocopheryl acetate consumed during a regular evening meal shows that the free form, on a mole-for-mole basis, is at least equal to the acetate in bioavailability. This finding, which is in agreement with the earlier studies (9–11), is the most direct and strongest support for maintaining the existing USP standard for the relative biopotencies of α-tocopherol and α-tocopheryl acetate. That is, these two forms should continue to be accorded equal potency on a molar basis.

Although data were obtained from only five human subjects, the results for the relative uptake of the two forms of vitamin E show remarkably little variation, suggesting that dietary status, type of meal, sex and other factors had relatively little influence on the result.

Finally, these experiments illustrate the need for caution in relying on results obtained from laboratory animals as a guide to relative potencies of different forms of tocopherol in human nutrition.

Influence of Dietary Fats on Pancreatic Phospholipids of Chronically Ethanol-treated Rats

Tomas Cronholm[a,b,*], Aldo Neri[b], Fredrik Karpe[b] and Tore Curstedt[c]
Departments of [a]Physiological Chemistry, [b]Experimental Alcohol and Drug Research and [c]Clinical Chemistry at Karolinska Hospital, Karolinska Institutet, S-104 01 Stockholm, Sweden

Male rats were given liquid diets by pair-feeding for 24–30 days, and phosphatidylinositols in pancreas were analyzed as derivatives of diacylglycerols and fatty acids. Addition of arachidonic acid or changing the fat component (35 energy%) in the liquid diet from olive oil/corn oil to oil from *Borago officinalis*, which contains 22% γ-linolenic acid, increased the fraction of arachidonoyl-containing species. This fraction was decreased by more than 50% by substituting ethanol for 36 of the 47 energy% provided by carbohydrate. A smaller difference between ethanol-fed and control rats was seen in the composition of phosphatidylcholines and phosphatidylethanolamines. There was no difference in the composition of phosphatidylinositols when fat, instead of ethanol, was used to substitute the 36 energy% in the diet containing olive oil/corn oil. Substituting ethanol for 28 of 35 energy% provided by fat as corn oil in a liquid diet had no effect on the fraction of arachidonoyl-containing species. The results indicate that the effect of ethanol on phosphatidylinositols in pancreas is not due to a deficiency of arachidonic acid, and that the effect of the ethanol-containing diet is not due to the lowered carbohydrate content. However, high contents of fat or of ethanol appear to be necessary for the effect.
***Lipids* 23, 841–846 (1988).**

Chronic ethanol abuse may cause pancreatitis in man. The pathogenesis is incompletely understood, and this hampers rational treatment and prevention. Studies on chronic effects of ethanol are commonly performed by feeding rats an ethanol-containing liquid diet (1). Using this model, it was found that the arachidonoyl-containing phosphatidylinositols in the pancreas were replaced with other molecular species to a large extent (2,3). Phosphatidylinositols are involved in the mediation of secretion responses upon stimulation (4,5). It was therefore considered that the change in composition could be related to the pathogenesis of secretion disturbances and pancreatitis.

The decrease of arachidonoyl-containing phosphatidylinositols might have been due to deficiency of arachidonic acid, e.g., due to increased production of eicosanoids (6,7). Diets rich in γ-linolenic acid (all-*cis*-6,9,12-octadecatrienoic acid), a precursor of arachidonic acid, might protect against some detrimental effects of ethanol (7–9). Administration of arachidonic acid also has been shown to protect against the ethanol-induced fatty liver (7,8,10,11). Liquid ethanol-containing diets therefore were enriched with these fatty acids in order to study if this protects against the biochemical changes in the pancreas.

Abbreviations: γ-linolenic acid, all-*cis*-6,9,12-octadecatrienoic acid; GLC, gas liquid chromatography.

The liquid-diet model described by DeCarli and Lieber (12) involves administration of much more carbohydrate to the control rats than to the ethanol-fed rats and this might, in fact, be the reason for several of the differences seen between the ethanol-fed and the control rats (13). A control experiment, therefore, was designed to study the effect of isocaloric substitution of the carbohydrate in the control diet with fat. A high-fat content in the diet might be necessary for the chronic effects of ethanol on the digestive enzymes in the pancreas (14,15). The effect of ethanol on the phospholipid composition, therefore, also was studied in an experiment using a low-fat content in the ethanol-containing diet.

MATERIALS AND METHODS

Materials. Male Sprague-Dawley rats were used. The body weights are given in Tables 2 and 6–8. Alcohol and control liquid diets according to DeCarli and Lieber (12) and the same diets without the fat component were obtained from Bioserv, Inc. (Frenchtown, NJ). Oil obtained by hexane-extraction of seeds from *Borago officinalis* was prepared by BioOil Research Ltd. (Crewe, England), analyzed by Dr. Bengt Herslöw, KabiVitrum, Stockholm, Sweden, and found to contain 11.8% palmitic, 3.7% stearic, 16.9% oleic, 38.0% linoleic, 22.1% γ-linolenic, 3.6% eicosanoic, 1.0% docosahexanoic and 2.0% erucic acid by weight. Arachidonic acid (>90% pure) was obtained from NuChek Prep, Inc. (Elysian, MN).

Diets. The composition of the diets is shown in Table 1. The diets used in Experiments 1–3 were based on the alcohol and control diets described by DeCarli and Lieber (12). The diets used in Experiment 4 were based on the low-fat diets described by Thompson and Reitz (16). The energy content was 1.24 kcal/ml, as compared to 1 kcal/ml in the DeCarli-Lieber diet, and the major nutrients were lactalbumin (Sigma, St. Louis, MO), sucrose and corn oil. These diets also contained citric acid, vitamins and salts (16) and Tween-80 (Sigma), 0.1 g/g fat.

Animal experiments. The rats were pair-fed, i.e., the rats eating the smallest volume on one day determined the provision of diet to the other rats in each pair or group on the following day. The diets were given for 24 days (Expts. 1–3) or 30 days (Expt. 4). The mean intake of ethanol in the different groups was 12.3–13.7 $g \times kg^{-1} \times day^{-1}$. To ensure that control rats and rats fed ethanol were equally nourished at the time of sacrifice (09.00), the diets were changed both at 09.00 and 24.00 on the day before sacrifice. The rats were killed by cervical dislocation, and the pancreas and liver were taken out, avoiding visible fat.

Analytical procedures. The contents of triacylglycerols and phospholipids in the liver were determined by extraction and chromatography as previously described (11). The species compositions of glycerophosphatides in pancreas were quantitatively determined by gas liquid chromatography (GLC) of 1,2-diacylglycerol 3-trimethylsilyl

ethers (2,3,17). The major acyl groups in pancreatic phospholipids were determined by GLC of methyl esters obtained by transmethylation in boron trifluoride-methanol (18), using a fused silica capillary column coated with methyl silicone. Student's t-test was used for statistical analysis.

RESULTS

Effects of diets rich in γ-linolenic acid (Expt. 1). The content of hepatic triacylglycerol was markedly and significantly higher in the rats fed the ethanol-containing diets than in the control diets (Table 2). This was true both when the diet contained the olive oil/corn oil mixture (12) and when it contained the *Borago* oil, rich in γ-linolenic acid. The content of hepatic phospholipids was the same in the different groups.

The fatty acyl composition of the pancreatic phospholipids was significantly different in rats fed the *Borago* oil and in rats fed olive oil/corn oil (Tables 3-5). In all three phospholipid classes, the fraction of arachidonoyl groups was higher and the fraction of oleoyl groups lower in the group fed *Borago* oil. The fraction of stearoyl groups in phosphatidylethanolamine and phosphatidylcholine and the fraction of palmitoyl groups in phosphatidylcholine were higher in the rats fed *Borago* oil. The results were in agreement with those obtained by analysis of molecular species. Thus, both the 36:4 and 38 species of phosphatidylcholines and phosphatidylinositols, consisting mainly of the 1-palmitoyl- and 1-stearoyl-2-arachidonoyl species, respectively (2), constituted larger fractions in the rats fed *Borago* oil. The 34:1-2 fractions contain mainly the 1-palmitoyl-2-oleoyl species and the 36:1-2 fraction the 1-stearoyl-2-oleoyl and 1-stearoyl-2-linoleoyl species (3). These fractions were lower in the rats fed the *Borago* oil.

The composition of phosphatidylinositols was markedly and significantly different in the pancreas of rats fed the control diet and the ethanol-containing diet which both contained olive oil/corn oil (12) (Table 3). The fraction of the 36:4 species, consisting mainly of the palmitoyl-arachidonoyl species, was about 80% lower, and the fraction of the 38:3-4 species (mainly the 1-stearoyl-2-arachidonoyl), 50% lower in the ethanol-fed rats. These results are confirmed by the decreased content of arachidonoyl groups in the ethanol-fed rats. Corresponding differences in the opposite direction were seen for the relative content of oleoyl groups and for the 34:0 species (probably palmitoyl-stearoyl) and the 36:1-2 species. Similar differences between ethanol-fed and control rats were seen with the rats fed the *Borago* oil. However, the relative content of oleoyl groups was less markedly elevated in the ethanol-fed rats among the rats given *Borago* oil. Instead, the relative content of linoleoyl groups was markedly elevated. In accordance with this, the 36:2-3 species, which contain linoleoyl groups, constituted a larger fraction in these ethanol-fed rats than in the corresponding controls.

The composition of phosphatidylcholines was significantly different in pancreas from rats fed the control diet and the ethanol diet containing olive oil/corn oil (12) (Table 4). Thus, the 36:1-2 fraction and the content of stearoyl and linoleoyl groups were higher in the ethanol-fed rats. There were no marked differences in the content of arachidonoyl-containing species. However, such differences were seen between the control rats and ethanol-fed rats that had been given the diets containing *Borago* oil. Thus, the 36:4 fraction was much lower in the ethanol-fed rats, which caused the difference between the groups given *Borago* oil and olive oil/corn oil to disappear. The difference also was seen from the acyl group composition. The content of linoleoyl groups was higher, and that of arachidonoyl groups was lower, in the ethanol-fed rats.

The acyl group composition in the phosphatidylethanolamine fraction was significantly different in pancreas from control rats and ethanol-fed rats (Table 5). The differences were essentially the same in the rats fed the diets containing olive oil/corn oil (12) and in the rats fed the diets containing *Borago* oil. The relative content of the saturated acyl groups was lower, and that of the oleoyl and linoleoyl groups higher, in the rats given ethanol. The relative content of arachidonoyl groups was the same in control rats and in ethanol-fed rats.

Effects of diets containing arachidonic acid (Expt. 2). The species composition of phosphatidylinositols in pancreas was analyzed in rats fed the liquid ethanol-containing and control diets (12) supplemented with arachidonic acid or oleic acid (Table 6). The 38:3-4 fraction was

increased in the control rats given the arachidonic acid-supplemented diet. The differences between the compositions seen in control rats and ethanol-fed rats were about the same when the diets were unsupplemented (Table 3) or supplemented with oleic acid or arachidonic acid. The relative content of arachidonoyl-containing species in ethanol-treated rats was higher in experiments with arachidonoyl-containing diets than in experiments with diets supplemented with oleic acid.

Comparison of energy substitution with lipid and with carbohydrate (Expt. 3). Rats were pair-fed the control diet described by DeCarli and Lieber (12), which contains carbohydrate instead of ethanol, and a corresponding control diet with fat instead of ethanol. The species composition of the phosphatidylinositols in pancreas was about the same in these two groups of controls (Table 7).

Effects of ethanol addition to a low-fat diet (Expt. 4). Phosphatidylinositols in pancreas were analyzed both

with respect to species composition and acyl group composition (Table 8). No differences were observed between the two groups in the content of the arachidonoyl group or the arachidonoyl-containing species. The content of linoleoyl groups and linoleoyl-containing species was lower in the ethanol-fed rats, and the linoleoyl group was then replaced by oleoyl and palmitoyl groups.

DISCUSSION

Very pronounced decreases have been observed previously for arachidonoyl-containing phosphatidylinositols in pancreas of rats fed an ethanol-containing liquid diet (2,3). These results were confirmed in the present study (Table 3). This effect of ethanol might have been due to

deficiency of arachidonic acid (6-8). Since prostaglandins might protect against pancreatitis (19), a vicious circle was suggested to explain the effects (17). Thus, the diets were supplemented with arachidonic acid or its precursor γ-linolenic acid. The results indicate that the decrease in arachidonoyl-containing phosphatidylinositols in the pancreas is not due to insufficient supply of arachidonic acid or to reduced activity of the Δ^6-desaturase (7,20).

In a previous study, no significant differences were seen in the composition of phosphatidylcholines and phosphatidylethanolamines in the pancreas of rats fed ethanol-containing and control diets (2). A more detailed analysis revealed significant differences in the compositions, but these were smaller than for the phosphatidylinositols (Tables 3–5). The differences seen between ethanol-fed and control rats were more marked when the diet was based on the γ-linolenic acid-containing *Borago* oil than when it was based on olive oil/corn oil (12).

It is difficult to assess the effect of these changes on the physical properties of the membrane. The changes in the composition of phosphatidylcholines and phosphatidylethanolamines do not appear to be consistent with a decrease in fluidity (21,22). However, it was recently reported that phosphatidylinositols specifically confer membrane tolerance to ethanol when obtained from ethanol-fed rats (23). This is consistent with the pronounced changes in the composition of this phospholipid in ethanol-treated rats.

One aim of the present study was to evaluate if the composition of phosphatidylinositols could be changed by dietary means, since this might protect against the effects of ethanol on pancreas. Diets containing oil from evening primrose *(Oenothera biennis)* have been suggested for prevention of various diseases (24), including those caused by ethanol (8,9), and the active component is considered to be γ-linolenic acid. The methyl ester of this attenuates the ethanol-induced fatty liver when administered intraperitoneally (8,25). Since oil from *Borago officinalis* has more than twice the γ-linolenic acid content of evening primrose oil (9), it was chosen for the present study. However, the dietary, rather than the intraperitoneal, administration of larger amounts of γ-linolenic acid did not attenuate the hepatic accumulation of triacylglycerols in the ethanol-fed rats (Table 2). Possibly, this was due to the difference in mode of administration or in the molecular species composition of the oils.

The rats fed the *Borago* oil had elevated fractions of arachidonoyl-containing phospholipids in pancreas. The changes in the phosphatidylinositols were small and it is not known if they might have had any effect on the function, e.g., in the phosphoinositide cycle (5) or the attachment of acetylcholine esterase (26). Diets containing arachidonic acid and *Borago* oil had about the same effects on the composition, in agreement with efficient conversion of γ-linolenic to arachidonic acid.

The differences between the compositions of the phospholipids in ethanol-fed and control rats were not eliminated by the *Borago* oil. However, the relative content of arachidonoyl-containing phosphatidylcholines was the same, in the control rats fed the olive oil/corn oil diet, as in the rats fed the ethanol-containing diet based on *Borago* oil. Thus, this oil might protect against effects of ethanol which are due to certain membrane changes (21) and to general deficiencies of arachidonic acid (7,9,24).

When rats are pair-fed liquid ethanol-containing diets, the energy provided by ethanol (36%) is usually substituted with carbohydrate in the control diets (12). Feeding two control diets that differed with respect to fat and carbohydrate content indicated that the effect of the ethanol-containing diet was not due solely to the low content of carbohydrate. However, when the diets contained equal and high amounts of carbohydrate (47 energy%), there was no difference in the arachidonoyl-containing fraction of phosphatidylinositols between rats given 35 energy% as fat and rats given a diet providing 28 energy% from ethanol and 7 energy% from fat. Thus, high contents of fat or of ethanol appear to be necessary for the effect on the phosphatidylinositol composition. This is similar to the requirements for effects on the secretory function of the pancreas (14,15) and accumulation of fat in the liver (27–29).

[Received December 21, 1987; Revision accepted May 16, 1988]

Differential Effects of Dietary Linoleic and α-Linolenic Acid on Lipid Metabolism in Rat Tissues

M.L. Garg, E. Sebokova, A. Wierzbicki, A.B.R. Thomson and M.T. Clandinin*
Nutrition and Metabolism Research Group, Departments of Foods & Nutrition and Medicine, 533 Newton Research Building, University of Alberta, Edmonton, Alberta, Canada T6G 2C2

Comparative effects of feeding dietary linoleic (safflower oil) and α-linolenic (linseed oil) acids on the cholesterol content and fatty acid composition of plasma, liver, heart and epididymal fat pads of rats were examined. Animals fed hydrogenated beef tallow were used as isocaloric controls. Plasma cholesterol concentration was lower and the cholesterol level in liver increased in animals fed the safflower oil diet. Feeding the linseed oil diet was more effective in lowering plasma cholesterol content and did not result in cholesterol accumulation in the liver. The cholesterol concentration in heart and the epididymal fat pad was not affected by the type of dietary fatty acid fed. Arachidonic acid content of plasma lipids was significantly elevated in animals fed the safflower oil diet and remained unchanged by feeding the linseed oil diet, when compared with the isocaloric control animals fed hydrogenated beef tallow. Arachidonic acid content of liver and heart lipids was lower in animals fed diets containing safflower oil or linseed oil. Replacement of 50% of the safflower oil in the diet with linseed oil increased α-linolenic, docosapentaenoic and docosahexaenoic acids in plasma, liver, heart and epididymal fat pad lipids. These results suggest that dietary 18:2ω6 shifts cholesterol from plasma to liver pools followed by redistribution of 20:4ω6 from tissue to plasma pools. This redistribution pattern was not apparent when 18:3ω3 was included in the diet. *Lipids 23,* 847–852 (1988).

Attempts to elucidate mechanisms by which dietary polyunsaturated fatty acids (PUFA) lower blood cholesterol level in man (1–2) and animals (3–7) have led to the hypothesis that dietary PUFA cause redistribution of cholesterol from blood to tissue pools. To test this hypothesis, several studies have examined the effect of dietary PUFA on plasma and tissue cholesterol levels (8–12), using vegetable oils rich in linoleic acid (18:2ω6). Marine oils rich in eicosapentaenoic (20:5ω3) and/or docosahexaenoic acid (22:6ω3) have been shown to be more effective against hypercholesterolemia (12–15). However, one study (16) has shown that both the vegetable oil and fish oil cause similar decreases in cholesterol levels. While vegetable oils rich in ω6 fatty acids have proaggregatory effects in thrombosis (17–19), marine oils rich in very long ω3 fatty acids may account for the enhanced bleeding tendency observed (20–22), due to their antiaggregatory effects. Some studies have shown that vegetable oils have antiaggregatory effects (23,24). However, these studies suggest one thing in common, that the number and arrangement of double bonds within a fatty acid molecule is an important factor for cholesterol-lowering and thrombotic activity. Eicosapentaenoic and docosahexaenoic acids present in marine oils are the desaturated-chain elongated products of α-linolenic (18:3ω3) acid (25). The question of whether 18:3ω3 can affect the plasma and/or tissue cholesterol and fatty acid metabolism has not been given much attention. It is conceivable that 18:3ω3 may have an intermediate effect, in terms of its antiaggregatory and hypocholesterolemic effects, between that of ω6 fatty acids of vegetable oils and very long-chain ω3 fatty acids of marine oils.

The present experiment was designed to clarify the effect of feeding 18:3ω3 on tissue cholesterol pools and fatty acid composition. Safflower- and linseed-oil-fed rats were used to identify the specificity of the action of 18:2ω6 and 18:3ω3 on the distribution of tissue cholesterol pools and levels of 20:4ω6, in comparison with animals fed a diet high in hydrogenated beef tallow.

MATERIALS AND METHODS

Animals and diets. Male adult Sprague-Dawley rats weighing 200–250 g were allotted to individual stainless steel cages and provided water and laboratory chow for three days before starting the experimental diet treatment. After three days of feeding chow, rats were weighed and divided into three groups of five rats per group in a manner ensuring that the average body wt was similar in each group. Each group of animals was fed a semisynthetic diet enriched with either saturated or linoleic or α-linolenic acid. Semipurified diets containing 20% (w/w) fat (26) were prepared by mixing either 180 g hydrogenated beef tallow plus 20 g safflower oil or 200 g safflower oil or 100 g linseed oil plus 100 g safflower oil (Table 1) per kg of total diet. The fatty acid composition of these diets is illustrated (Table 1). The fat mixture of the hydrogenated beef tallow diet contained 26% palmitic and 41% stearic acid, the safflower oil diet was high in linoleic acid (71.2%), while the linseed oil diet provided a high content of α-linolenic acid at 24.1% (Table 1). Diets were prepared weekly and stored at −20 C. Food and water were available to the animals ad libitum for a feeding period of 28 days.

Analytical procedures. After feeding the experimental diets for four weeks, animals were killed between 0800 and 1000 hr and liver, heart and epididymal fat pads were removed and placed in ice-cold physiological saline. After decapitation, trunk blood was collected in heparinized tubes and the plasma was separated (1500 × *g* for 10 min). For lipid extraction, plasma, livers, hearts and epididymal fat pads from animals fed the fat-supplemented diets were homogenized in chloroform/methanol (2:1, v/v) (27). Aliquots of the total lipid extracts from these tissues were taken for determination of free cholesterol, esterified cholesterol and total cholesterol (28). Free cholesterol and esterified cholesterol from lipid extracts of the epididymal fat pad were separated by thin-layer chromatography (TLC) on Silica Gel G plates using a solvent system composed of petroleum ether/diethyl

[a]Fatty acids are designated by the chain length, number of double bonds and the position of the first double bond from the methyl end of the molecule.

[b]Only major individual fatty acids are reported.

[c]Fats were added to the basal diet in the following proportions: 180 g hydrogenated beef tallow plus 20 g safflower oil (beef tallow diet); 200 g safflower oil (safflower oil diet); and 100 g linseed oil plus 100 g safflower oil (linseed oil diet) per kg of diet. The basal diet contained the following components (g/kg diet): casein, 270; starch, 200; glucose, 207; nonnutritive cellulose, 50; vitamin mix, 10; mineral mix, 50; choline, 2.75; L-methionine, 6.25; as described elsewhere (23).

ether/acetic acid (80:20:1, v/v/v), extracted and then assayed individually (28).

Lipid extracts were converted to fatty acid methyl esters using BF_3-methanol (14%, w/w) reagent (29). Fatty acid methyl esters were separated and quantified by automated gas-liquid chromatography (GLC) (Varian, Model-6000; 30), using a 20-m fused-silica capillary column (BP-20, S.G.E. Pty. Ltd., Melbourne, Australia). Helium was used as the carrier gas. Injector and detector temperatures were maintained at 250 C. The column temperature was programmed from 130 C to 225 C, at a rate of 20 C/min up to 175 C, and then at a rate of 5 C/min up to 225 C. These chromatographic conditions separated all major positional and geometric isomers for fatty acids from 12 to 24 carbons in chain length. Fatty acid methyl ester peaks were identified by injecting authentic standard mixtures of fatty acid methyl esters.

STATISTICAL ANALYSIS

All data are presented as the mean ± standard deviation. The effect of dietary fat supplements was analyzed using analysis of variance procedures and the effect of individual diets was compared for statistical significance ($p < 0.05$) using a Duncan's multiple range test (31).

RESULTS

The average body wt, liver wt, liver wt to body wt percentages, heart wt and amount of food consumed per day for the animals fed the fat-supplemented diets for a four wk period are presented (Table 2). Rats fed the linseed oil diet had significantly higher body wt compared with those fed the hydrogenated beef tallow diet. Animals consumed similar amounts of food per day irrespective of the fat supplement. The wet wt of the livers, liver wt to body wt ratios and heart wt were also unaffected by the dietary fatty acid composition (Table 2).

Feeding the safflower oil diet for 28 days reduced plasma cholesterol content compared with control animals fed beef tallow (Table 3). This reduction was detected in the esterified-cholesterol content while the unesterified-cholesterol content was increased in the plasma of rats fed the safflower oil diet. Feeding the linseed oil diet was more effective in lowering the plasma cholesterol level (Table 3). Total cholesterol content of liver tissue was significantly increased following feeding of the safflower oil diet. This increase was due to accumulation of both free and esterified cholesterol in the liver. Replacement of 50% of the safflower oil by linseed oil reduced accumulation of cholesterol in liver tissue. Cholesterol levels in heart and epididymal fat pads were unchanged by dietary treatments. Neither the free- nor the esterified-cholesterol content of heart or the epididymal fat pad was affected by changes in the dietary fat composition (Table 3).

Essential fatty acid (18:2ω6 and 20:4ω6) content of plasma was elevated by feeding the safflower oil diet, with an accompanied decrease in 16:0, 18:0 and 18:1 content when compared with animals fed diets containing beef tallow (Table 4, Fig. 1). Feeding the linseed oil diet resulted in accumulation of 18:3ω3, 22:5ω3 and 22:6ω3 in the plasma lipids, but failed to alter the 20:4ω6 content. In liver tissue, both the safflower oil and the linseed oil diets lowered the 20:4ω6 content (Table 4, Fig. 1) to the

[c]Monounsaturated fatty acid.

same extent (ca. 28% compared with the group fed beef tallow). Consumption of the safflower oil diet increased deposition of 18:2ω6, 20:2ω6 and 22:4ω6 and depletion of 22:5ω3 and 22:6ω3 in the liver lipids. On the other hand, 18:3ω3, 22:5ω3 and 22:6ω3 in the liver tissue increased following the feeding of the linseed oil diet (Table 4).

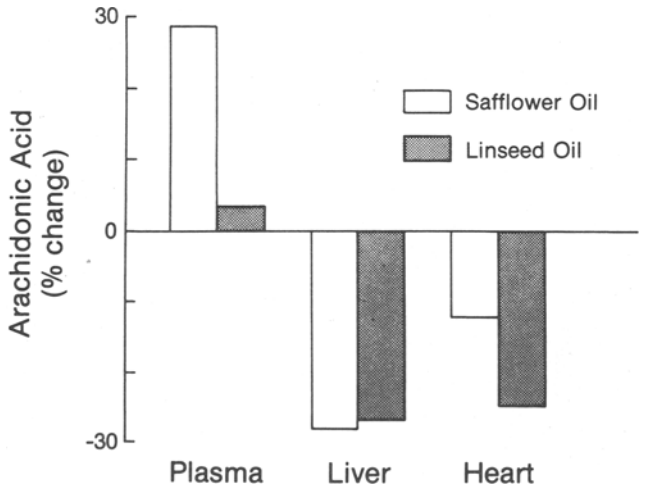

FIG. 1. Percentage change in the arachidonic acid content of plasma, liver and heart lipids compared with the hydrogenated beef tallow group.

Ingestion of the safflower oil diet increased 18:2ω6 and 22:5ω6 content in cardiac lipids and was accompanied by decreased 20:4ω6 and 22:6ω3 content (Table 5). Feeding the linseed oil diet decreased the 20:4ω6 levels in the heart more effectively than observed for the safflower oil diet (12.2% vs 24.9%, respectively; Fig. 1). The linseed oil diet also increased 18:3ω3, 22:5ω3 and 22:6ω3 in heart lipids (Table 5). The fatty acid composition of the epididymal fat pad resembled that of the dietary fat treatment, e.g., the safflower oil diet increased 18:2ω6 content, whereas the linseed oil diet elevated 18:2ω6 and 18:3ω3 content at the expense of saturated (14:0, 16:0 and 18:0) and monounsaturated (16:1 and 18:1) fatty acids (Table 5).

DISCUSSION

The results suggest that dietary 18:2ω6 and 18:3ω3 act differentially to alter lipid metabolism of rat tissues. Animals fed the diet containing linseed oil grew faster than those fed the beef tallow diet (Table 2). The amount of food consumed per day, although not statistically different ($p > 0.05$), was somewhat higher in the linseed diet fed group. Therefore, it is conceivable that the increase in body wt after linseed oil consumption may be due to increased food intake. Liver wt, heart wt, and liver wt to body wt ratios, however, remained unchanged by the dietary fat treatments (Table 2). Therefore, the changes observed in cholesterol content and fatty acid composition of tissues apparently are a result of dietary fat treatment and do not stem from differences in growth rate.

[c]Monounsaturated fatty acid.

The reduction in plasma cholesterol level following consumption of the safflower oil diet accompanied by increased liver cholesterol content is in agreement with previous observations (8–12) that suggest PUFA of the ω6 family increase cholesterol accumulation in liver relative to feeding diets high in saturated fatty acids. Both free- and cholesterol-ester content increased following feeding of the safflower oil diet, but this increase was more pronounced in the cholesteryl-ester fraction. This observation is consistent with the fact that diets rich in linoleic acid (18:2ω6) accelerate esterification of cholesterol by acyl coenzyme A:cholesterol acyltransferase (EC 2.3.1.26) activity in the rat liver microsomes (32). This increased esterification of cholesterol following feeding of the safflower oil diet, in turn, may increase the capacity of hepatic cells to take up more free cholesterol from circulating levels in the plasma (33). Replacement of 50% of safflower oil with linseed oil restricted deposition of cholesteryl esters in the liver and concomitantly lowered the plasma cholesterol level to an even greater extent than the safflower oil diet. In the light of these results, the hypothesis that dietary PUFA shift plasma cholesterol to tissue cholesterol pools cannot be generalized for all types of PUFA and may be restricted to ω6 fatty acids only. The cholesterol levels in heart and adipose tissue of rats, however, remained unaltered by the composition of the fat fed.

Consumption of the safflower oil diet resulted in a significant increase in plasma 20:4ω6 level, while in liver and heart lipid, the concentration of 20:4ω6 was significantly decreased in comparison with animals fed the diet high in beef tallow (Tables 4 and 5, Fig. 1). Increase in plasma 20:4ω6 content may be due to increased synthesis in the liver microsomes via desaturation and chain elongation of 18:2ω6 (34). However, this seems unlikely as the 20:4ω6 level in the liver decreased when rats were fed the safflower oil diet. Increased 20:4ω6 content in plasma lipids with concomitant depletion of 20:4ω6 in liver and heart tissue for animals fed the safflower oil diet treatment may be taken as evidence for shift of tissue 20:4ω6 to plasma pools. Some studies have reported either no change (35), or even a decrease (36), in liver microsomal Δ^6-desaturase activity, a rate-limiting enzyme in the 20:4ω6 biosynthetic pathway, following feeding of a diet rich in linoleic acid. Previous evidence indicates transfer of cholesterol from plasma to the liver pools with participation of liver phosphatidylcholine containing 20:4ω6 in the SN-2 position (37). The present paper demonstrates that this process of transfer of plasma cholesterol to liver pools and liver 20:4ω6 transport to plasma pools occurs at a faster rate when rats are fed an 18:2ω6 enriched diet. Inclusion of 18:3ω3 in the diet appears to slow this cycle by depleting the liver 20:4ω6 pool via inhibition of 20:4ω6 biosynthesis. In this context, the diet rich in 18:3ω3 did not change the 20:4ω6 content of plasma, depleted the 20:4ω6 level in the liver to the same extent as observed for animals fed the safflower oil diet, and depleted the 20:4ω6 level to an even greater extent in heart lipids. α-Linolenic present in the linseed oil diet competes with 18:2ω6 for Δ^6-desaturation, thus limiting synthesis of 20:4ω6 from 18:2ω6 (38). It is also conceivable that some of the tissue 20:4ω6 may shift to plasma pools for maintenance of circulating levels of 20:4ω6. These observations are further supported by the observation that an increase in the desaturated-chain elongated products of 18:3ω3 metabolism, i.e., 22:5ω3 and 22:6ω3, occurs in plasma, liver and heart lipids of rats fed the linseed oil diet. Interestingly, 20:5ω3 did not accumulate in any of the tissues examined even after feeding a high dietary load of 18:3ω3. In an earlier study, we noticed an increase in plasma and tissue 20:5 levels (39) following the feeding of 18:3ω3 rich diets. This contradiction may be due to the fact that the linseed oil diet in the present study contained a high level of 18:2ω6 in addition to a high 18:3ω3 content, whereas in the previous study, 18:3ω3 was fed to the rats along with saturated and monounsaturated fatty acids (39). In this regard, the balance between ω6 and ω3 fatty acids recently has been shown to be an important factor for modification of desaturase enzymes responsible for synthesis of 20:5ω3 and 22:6ω3 from 18:3ω3 (40). The decrease in monounsaturated fatty acids (16:1ω7 and/or 18:1ω9) in rat tissues by the diets containing high levels of 18:2ω6 and/or 18:3ω3 is consistent with the fact that PUFA inhibit Δ^9-desaturase activity (34,35).

The present study demonstrates that dietary 18:3ω3 is more potent than 18:2ω6 in lowering plasma cholesterol level and does not result in accumulation of cholesterol in liver tissue. However, 18:3ω3 appears to be relatively less effective for reducing cholesterol level than 20:5ω3 and/or 22:6ω3 present in fish oils (12–15). Feeding diets high in linseed oil for 28 days did not lower plasma 20:4ω6 level, but depleted tissue levels. Longer-term use of 18:3ω3 supplements may lower plasma 20:4ω6 level and, thus, may show antiaggregatory effects (19). Consumption of fish oils rich in 20:5ω3 and/or 22:6ω3 lowers plasma, platelet and tissue 20:4ω6 content more effectively even after a short-term feeding (41,42), which may account for the enhanced bleeding time observed after such diet treatments. Therefore, 18:3ω3 appears to have an effective intermediate in reducing cholesterol levels and, perhaps, platelet aggregation between that of 18:2ω6 and 20:5ω3. As ω6 PUFA shift cholesterol from blood to the liver pools, but do not lower total body cholesterol, they may not be as beneficial against cardiovascular diseases as they currently are thought to be. However, α-linolenic acid from linseed oil appears to lower plasma cholesterol without accumulation of cholesterol in the liver tissue. Dietary PUFA have also been shown to have different lipid-lowering effects in animals and humans (43,44), e.g., fish oil lowers the circulating cholesterol level in the rat (43), but not in the human (44). Therefore, the effect of α-linolenic acid should be examined in human subjects with appropriate controls, before any further conclusion can be drawn.

[Received January 22, 1988; Revision accepted May 18, 1988]

Effects of Estrogen-induced Hyperlipidemia on the Erythrocyte Membrane in Chicks

B.H. Simon Cho*, Terrance L. Smith, Jeong R. Park and Fred A. Kummerow
Harlan E. Moore Heart Research Foundation, 503 South Sixth Street, Champaign, IL 61820; and Department of Food Science, University of Illinois, 1208 West Pennsylvania Avenue, Urbana, IL 61801

The effects of estrogen-induced hyperlipidemia on plasma lipid peroxidation, fatty acid composition and osmotic fragility of erythrocytes in chickens were studied. Young male chickens implanted with estrogen for three wk developed a marked hyperlipidemia. Plasma levels of triglyceride, cholesterol and phospholipid were elevated 68-, four- and 24-fold, respectively, over controls. There was also a two-fold increase in plasma lipid peroxidation measured by the thiobarbituric acid test. Vitamin E supplement (1,000 IU/kg diet) reduced the plasma lipid peroxidation to the control level, but had no effect on the plasma lipid content. Estrogen-induced hyperlipidemia resulted in changes in the fatty acid composition of membrane lipids of erythrocytes. The major changes were an increase in oleic acid from 10.0% to 14.2% and a decrease in linoleic acid from 31.3% to 26.0%. The erythrocytes with an altered membrane fatty acid composition were found to have an increased osmotic fragility. It was apparent that there was a direct correlation between the oleic acid content and the osmotic fragility of erythrocytes.
Lipids 23, 853–856 (1988).

It is well-established that the physical state of membrane lipids and, thus, indirectly their composition, are important in the functioning of membranes (1). Alterations in membrane lipid composition induced by diet affect glucagon-stimulated adenylate cyclase activity in liver membranes (2) and Ca^{2+}-ATPase activity in rat erythrocytes (3). Changes in the erythrocyte fatty acid composition also result in an increased osmotic fragility (4). Erythrocyte aging is also accompanied by increased osmotic fragility, increased density, accumulation of fluorescent chromolipids and the formation of high molecular-wt proteins (5). These changes can be induced in vitro by the addition of the secondary peroxidation product, malondialdehyde (5–7). Peroxidation products are found in the blood of restricted ovulator chickens (8). These chickens have a greatly elevated blood lipid level (9) and develop atherosclerosis at an early age (10).

It was our purpose here to investigate the effect of hyperlipidemia on the erythrocyte membrane. To do this, we used an alternative model to the restricted ovulator chicken. The genetic defect in restricted ovulator chickens causes a rise in estrogen levels and this, in turn, seems to be responsible for the alteration in lipid metabolism (11). Studies in our laboratory have shown that implantation of estrogen in young male chickens resulted in a hyperlipidemia similar to that seen in restricted ovulator chickens. The advantages of this model are that the use of male chickens eliminates the cycling of blood lipid levels seen in laying hens, and it is not necessary to wait for pubescence to begin an experiment.

Abbreviation: TBARS, thiobarbituric acid reacting substance.

MATERIALS AND METHODS

Animals. Male chickens (New Hampshire male × Columbian female), seven weeks old, were used in these experiments. The birds were housed individually in wire cages under a constant lighting program (09:00–21:00 hour). Chicks were fed ad libitum a pullet starter-grain diet (Table 1). In the vitamin E-supplemented group, vitamin E was added to the feed at the level of 1,000 IU/kg of diet.

Preparation of estrogen implants. Estrogen tubes were prepared by the method of Smith et al. (12). Briefly, polymethylsiloxan tubing (1.5 mm i.d. × 3.13 mm o.d.) was cut into 6-cm lengths, filled with approximately 50 mg of β-estradiol dipropionate (Sigma Chemical Co., St. Louis, MO), and both ends of tubes were sealed with Medical Adhesive Silicon Type A. Prior to implantation, the tubes were incubated in 0.01 M phosphate buffered saline (pH 7.4) for 48 hr at 37 C. Under light ether anesthesia, the necks of the chickens were incised (0.5–1.0 cm) with a surgical knife and tubes were inserted through the incisions. Incisions were closed with an Auto Suture skin stapler.

Analysis of blood lipids. At the end of the three-week treatment period and after an overnight fast, blood was drawn from the wing vein into heparinized tubes and centrifuged at 1,000 × *g* for 20 min at 4 C. The plasma was removed and the level of plasma total cholesterol was measured enzymatically (13), using A-Gent cholesterol reagent (Abbott Laboratories, N. Chicago, IL). The level of plasma triglycerides was measured by a colorimetric

Vitamin mix[b]	0.25
Calculated composition:	
Metabolizable energy (Kcal/kg)	2.882.0
Crude protein (%)	20.2

[a]Trace mineral mix provided (per kg diet): 75 mg manganese, 75 mg iron, 75 mg zinc, 5 mg copper, 0.75 mg iodine and 0.1 mg selenium.
[b]Vitamin mix provided (per kg diet): 4400 USPU vitamin A, 1000 USPU vitamin D_3, 11 IU vitamin E, 4.4 mg riboflavin, 10 mg d-pantothenic acid, 22 mg niacin, 11 μg vitamin B_{12} and 2.3 mg menadion sodium bisulfate.

Hantzsch condensation method of Foster and Dunn (14). The phospholipid content was determined by measuring the phosphorus content of plasma total lipid extract after perchloric acid digestion (15), and multiplying by 25.5.

Determination of thiobarbituric acid reacting substances (TBARS). TBARS were determined using the flourometric assay of Yagi (16). Twenty μl of plasma were diluted with 4.0 ml of 0.08 N H_2SO_4, followed by addition of 0.5 ml of 10% phosphotungstic acid. After sitting at room temperature for 5 min, the samples were centrifuged at 1,000 × *g* for 10 min. The supernate was removed and the pellet was resuspended with the above solution and centrifuged again. The washed pellet was then suspended in 4.0 ml of distilled water and 1.0 ml of TBA reagent (thiobarbituric acid/glacial acetic acid, 1:1, v/v). After incubation for 1 hr at 95 C, the tubes were cooled under tap water and 5.0 ml of n-butanol added. The tubes were shaken and centrifuged at 1,000 × *g* for 15 min. The butanol layer was taken for fluorometric measurement at 553 nm with excitation at 515 nm. Standards of 0.5 nmol tetramethoxypropane in 4.0 ml of distilled water were incubated with 1.0 ml of TBA reagent, extracted and read at the same time as the samples. The amount of TBARS was determined by the equation (Iu/Is) × 25 = nmol malondialdehyde/ml of plasma, where Iu = fluorescence intensity of the sample, and Is = fluorescence intensity of the standard.

Preparation of erythrocyte membrane. After removal of plasma, the sedimented erythrocytes were resuspended with isotonic Tris buffer (310 imOsM), pH 7.6, by gentle mixing and centrifuged at 1,000 × *g* for 20 min. The supernate was removed by careful suction and the washing procedure was repeated twice more. The washed erythrocytes were resuspended in the same isotonic Tris buffer to an approximate hematocrit of 50%, and the erythrocyte membranes were then prepared by osmotic lysis with 20 imOsM Tris buffer, according to the method of Hanahan and Ekholm (17).

Analysis of fatty acid composition. Total lipids were extracted from the erythrocyte membrane with 20 volumes of chloroform/methanol (2:1, v/v), according to the method of Folch et al. (18). Butylated hydroxy toluene was added as antioxidant to the lipid-extracting solvent (0.001%). The fatty acid methyl esters of total lipid extracts were prepared with 14% borontrifluoride in methanol at 90 C for 2 hr, by the method of Morrison and Smith (19). A Hewlett-Packard Model 5790 gas chromatograph with dual flame ionization detectors and split capillary injector was used for analysis of fatty acid methyl esters. The capillary column was a highly polar fused silica SP-2330 column (30 m × 0.25 mm i.d., 0.20 μm film thickness). The oven temperature was programmed from 190–210 C at 2 C/min. The split ratio at 190 C was 1:80 with hydrogen carrier at a flow rate of 1.2 ml/min and injector and detector temperatures were 250 C, respectively. The identification of the fatty acid methyl esters was based on retention times relative to methyl stearate and comparison of authentic standard methyl ester mixtures (NuChek Prep., Elysian, MN).

Osmotic fragility test. Buffered saline, pH 7.4 (154 mM NaCl, 85 mM Na_2HPO_4 and 16 mM NaH_2PO_4 $2H_2O$) was prepared and diluted into a series of different concentrations of saline, and the osmotic fragility test was carried out, as described by Dacie and Lewis (20). Briefly, to each test tube containing 5 ml of buffer, 50 μl of whole heparinized blood was added and mixed immediately. After standing for 30 min at room temperature, the samples were centrifuged at 500 × *g* for 5 min, and the supernate was read in a spectrophotometer at 545 nm. The degree of hemolysis is expressed in percentage, where 100% represents full hemolysis.

Data were analyzed by the difference between means, and statistical significance was based on Duncan's new multiple-range test (21).

RESULTS AND DISCUSSION

Chickens with estrogen implants for three wk developed a marked hyperlipidemia as shown in Table 2. The levels of plasma lipids increased 68-fold in triglyceride (60 vs 4,060 mg/dl), four-fold in cholesterol (135 vs 550 mg/dl) and 24-fold in phospholipid (73 vs 1,770 mg/dl), respectively, over the corresponding values of control chickens. The development of endogenous hyperlipidemia appears to be consistent in both humans (22) and avian species (23), as a consequence of estrogen treatment. Compared with controls, the level of plasma lipid peroxidation also increased significantly ($p < 0.05$) in hyperlipidemic chickens with estrogen implants (9.3 vs 20.4 nmol/ml). An increase in plasma lipid peroxidation in the presence of hyperlipidemia has previously been reported in restricted ovulator chickens (8). Vitamin E supplementation (1,000 IU/kg diet) resulted in a two-fold reduction of plasma lipid peroxidation to a level that was statistically no different than that of the controls (10.4 vs 9.3 nmol/ml), but did not alter hyperlipidemia. This finding seems to indicate that an increased amount of vitamin E is required to prevent lipid peroxidation in hyperlipidemic individuals.

The fatty acid composition of erythrocyte membrane lipids in chickens with estrogen implants is shown in Table 3. In control chickens, linoleic acid was the major fatty acid (31.3%), followed by palmitic (18.5%), stearic (18.1%), oleic (10.0%) and arachidonic acid (9.8%). Low levels of docosatetraenoic (2.3%) and docosahexaenoic acids (2.2%) were also present. Estrogen treatment induced an alteration in the fatty acid composition of erythrocyte membrane lipids with major changes in the 18-carbon unsaturated fatty acids. Compared with controls, the estrogen-implanted chickens exhibited an increase in oleic acid (10.0% to 14.2%), with a decrease in linoleic acid (31.3% to 26.0%). There was also a small increase in

TABLE 2

Levels of Plasma Lipids and Lipid Peroxidation in Chickens Implanted With Estrogen for Three Weeks[a]

	Control	Estrogen	Estrogen + vit E
Cholesterol (mg/dl)	135 ± 18[a]	550 ± 150[b]	518 ± 190[b]

[b]Thiobarbituric acid reactive substances (TBARS).

palmitic acid (18.5% to 20.7%), but little change occurred in the 20-carbon polyunsaturated fatty acids in chickens with estrogen implants. Estrogen-treated and vitamin E-supplemented chickens had the same fatty acid profile as estrogen-treated chickens, except for stearic acid which was further decreased and oleic acid which was further increased. The enrichment of oleic acid in erythrocyte membrane lipids follows a similar pattern to that seen in the fatty acids of plasma lipids of estrogen-induced hyperlipidemic chickens (24) and of restricted ovulator hens (9). Although the mechanism of changes in the fatty acid composition of avian erythrocytes with hyperlipidemia is not known, the decrease in the amount of linoleic acid relative to oleic and palmitic acids in erythrocyte membrane of the estrogen-treated birds is explainable in terms of the marked stimulation of lipogenesis under estrogenic influence (24). Because the amount of linoleic acid available for incorporation into membrane lipids is constrained by the amount available from the diet, whereas the amounts of oleic and palmitic acid available are markedly increased by endogenous synthesis, these latter fatty acids are more competitive for the acylation of lysophosphatides in the erythrocyte membrane (25).

The osmotic fragilities of erythrocytes from chickens are shown in Figure 1. Compared with controls, the osmotic sensitivity to hypotonic NaCl solutions was increased in estrogen-treated chickens with or without vitamin E supplement. The NaCl concentrations for 50% hemolysis for the estrogen-treated (66.4 mM) and estrogen-treated-plus-vitamin-E-supplemented chickens (68.7 mM) were significantly ($p < 0.05$) higher than that of the control (63.5 mM). However, there was no significant difference between the NaCl concentrations for the estrogen and vitamin E groups. As shown in Figure 2, a strong relationship was noted between the osmotic fragility and the amount of oleic acid present in the erythrocyte membrane. An increased level of oleic acid corresponded to an increased osmotic fragility. Workers in this laboratory previously have noted such an association between the octadecenoate content of rat erythrocytes and their osmotic fragility (4). Phillips et al. have also shown an increase in oleic acid in the fatty acids of aging human erythrocyte (26). Because the low level of linoleic acid present in the erythrocytes should reduce the oxidation potential of the membrane lipids, the inverse relationship between the linoleic acid content of the membrane and osmotic fragility seems paradoxical. One possible explanation might be that the rigidity of the membrane is enhanced by replacement of linoleic acid with oleic acid. An increased osmotic sensitivity to hypotonic treatment has been reported in erythrocytes from essential fatty acid-deficient rats, in which the level of linoleic acid is reduced to nearly half that of the control values (27).

With age, erythrocytes increase in density, accumulate high molecular-wt protein and become less deformable (5). Loss of deformability is a factor involving membrane fluidity and is thought to be a trigger for erythrocyte removal by the spleen. Aging of erythrocytes can be accelerated by genetic factors or drug administration (28). There is mounting evidence that lipid peroxidation plays a crucial role in erythrocyte aging (28,29). The initiation of peroxidation in suspensions of erythrocytes results in all the changes typical of naturally aged erythrocytes (29).

*Mean ± standard deviation for five birds. Values on the same line bearing different superscripts are significantly different ($p < 0.05$).

Therefore, the presence of an increased level of peroxidation found in hyperlipidemia (8) may have a detrimental effect on membrane stability and aging of erythrocytes. Vitamin E deficiency also increases the rate of erythrocyte aging (28), and it seems reasonable that under certain conditions additional vitamin E might reduce the aging rate. As expected, there was an increase in erythrocyte fragility in the estrogen-implanted group, as there was an increase in plasma lipid peroxidation (Table 2). However, the addition of vitamin E to the diet, while it brought the plasma peroxidation levels down to normal, failed to reduce the erythrocyte fragility (Fig. 2). Studies by Mino et al. (30) on hyperlipidemic rats have shown that vitamin E is partitioned away from the erythrocytes and into the hyperlipidemic plasma. It is possible that, while the dietary level of supplemented vitamin E was sufficient to reduce the plasma lipid peroxidation, the partitioning effect seen by Mino et al. may have prevented the same degree of protection being given the erythrocytes.

Our present findings of increased plasma peroxidation and the occurrence of fatty acid compositional alterations in erythrocyte membranes under hyperlipidemic condition, accompanied by greater osmotic fragility, are of clinical significance, because an increased osmotic fragility of erythrocytes is noted in several blood diseases including hemolytic anemia (31). The association between hyperlipidemia and coronary heart disease has received great attention. However, little is known about the possible effects of hyperlipidemia on membrane function and aging of erythrocytes, which are questions that deserve further investigation.

Biosynthesis of Membrane Cholesterol During Peripheral Nerve Development, Degeneration and Regeneration[1]

Jeffrey K. Yao*
Veterans Administration Medical Center, Highland Drive, and Western Psychiatric Institute & Clinic, University of Pittsburgh, Pittsburgh, PA 15206

Biosynthesis of peripheral nerve cholesterol was investigated by the in vivo and in vitro incorporation of [1-^{14}C]-acetate into sciatic endoneurium of normal rats during development, degeneration and regeneration. Labeled sterols were rapidly formed (<10 min) within the endoneurial portion of sciatic nerve after [1-^{14}C]acetate administration by intraneural injection. The majority of labeled sterols were initially found in lanosterol and desmosterol. After six hr, the ^{14}C-labeling in both precursors was decreased to minimum, whereas cholesterol became the major labeled product of sterol. As myelination proceeded, the incorporation of [1-^{14}C]acetate into endoneurial cholesterol decreased rapidly and reached a minimum after six mo. In mature adult nerve, an increased proportion of biosynthesis of lanosterol and desmosterol also was demonstrated. The in vitro incorporation of [1-^{14}C]acetate into cholesterol was inhibited during Wallerian degeneration. Instead, cholesteryl esters were labeled as the major sterol product. Such inhibition, however, was not observed in the adult Trembler nerve (*Brain Res. 325,* 21–27, 1985), which is presumed to be due to a primary metabolic disorder of Schwann cells. The cholesterol biosynthesis was gradually resumed in degenerated nerve by either regeneration of crush-injured nerve or reattachment of the transected nerve. These results suggest that cholesterol biosynthesis in peripheral nerve relies on the axon to provide necessary substrates. De novo synthesis appears to be one of the major sources of endoneurial cholesterol that forms and maintains peripheral nerve myelin.
Lipids 23, 857–862 (1988).

Cholesterol is a major structural component of mammalian cell membranes. However, its functional role in neural tissue still is not completely understood. It may be important in the regulation and maintenance of various properties such as membrane fluidity and rigidity, numerous membrane bond enzymatic activities and cellular proliferation (1,2). Volpe and Obert (3) have suggested that a critical level of membrane cholesterol is essential for the expression of oligodendroglial differentiation and, perhaps, myelination. In peripheral nerve, the rate of lipogenesis does not change to the same extent for each lipid subclass during development, degeneration and regeneration. Cholesterol biosynthesis appears to be the most sensitive to aging (4) and to nerve fiber degeneration (4,5). It has been shown that substantial amounts of [1,2-^{3}H]cholesterol, incorporated into normal nerve during myelination, do not leave the nerve during Wallerian degeneration, but are retained and reutilized during nerve regeneration (6,7). An inhibition of cholesterol biosynthesis by *trans*-1,4-bis(2-chlorobenzylaminomethyl) cyclohexane dihydrochloride (AY-9944) leads to a decrease in peripheral nerve myelination (8). Therefore, cholesterol plays a vital role in the myelinogenesis of peripheral nerve.

Spady and Dietschy (9) have demonstrated that liver is quantitatively far less important as a site for sterol synthesis than previously indicated and most sterol utilized by extra hepatic tissues is largely synthesized locally within those tissues. Considerable interests have been focused on the cholesterol biosynthesis and its regulation in various extra hepatic tissues (10–12). However, when $^{3}H_2O$ was used as a precursor, no incorporation was found in either brain (10) or sciatic nerve (4). The superiority of $^{3}H_2O$ over [^{14}C]acetate in studying cholesterol synthesis is, thus, limited to the nonneural tissues. Previously, we (4) have demonstrated that incorporation of [1-^{14}C]acetate without stimulation by any specific cofactors, provides a sensitive, convenient and reproducible method for studying in vitro lipid biosynthesis in peripheral nerve. Alternatively, endoneurial lipids in peripheral nerve can be labeled exclusively by endoneurial microinjection of radiolabeled precursor (13). The present studies were undertaken, utilizing both in vivo and in vitro incorporation of [1-^{14}C]acetate, to elucidate the metabolic significance of cholesterol biosynthesis during nerve development, degeneration and regeneration.

MATERIALS AND METHODS

Materials. [1-^{14}C]Acetate (sodium salt, 54–60 mCi/mmol) was purchased from Amersham (Arlington Heights, IL). Lipid standards were purchased from NuChek (Elysian, MN) and Supelco (Bellefonte, PA). Silica Gel G_1 uniplates (250 μm) were purchased from Analtech (Newark, DE), and high-performance thin-layer plates (4.5 μm silica gel) with preadsorbent area were purchased from Whatman (Clifton, NJ). All solvents were high purity (HPLC grade) from Burdick and Jackson (Muskegon, MI).

In vivo incorporation of [1-^{14}C]acetate. The procedure used for endoneurial injection of [1-^{14}C]acetate was essentially the same as described by Yao (13). A nanoliter pump, consisting of controller, drive unit and pump chamber (model 1400 EC; W-P Instruments, Inc., New Haven, CT) was used for endoneurial microinjection. A glass capillary (1.0 ± 0.1 mm o.d., 4-inch length) was pulled, using a vertical pipette puller (model 700C; Kopf Instruments, Tunjunga, CA), to produce a needle tip of

[1]A preliminary report of this work was presented at the 17th Annual Meeting of the American Society for Neurochemistry held in Montreal, Quebec, Canada, on March 20, 1985. Part of this work was conducted while the author was associated with Mayo Clinic.

Abbreviations: C, cholesterol; Ca, ceramide; CE, cholesteryl ester; Cs, coprostanol; Ds, desmosterol; 1,2-DG, 1,2-diacylglycerol; 1,3-DG, 1,3-diacylglycerol; FAME, fatty acid methyl ester; FFA, free fatty acid; GL, glycolipids; Ls, lanosterol; MG, monoacylglycerol; PL, phospholipids; TG, triacylglycerol; HPTLC, high-performance thin-layer chromatography; O, origin; S, std, standards; SF, solvent front; TLC, thin-layer chromatography.

5–15 μm o.d.. The barrel of this micropipette was placed inside the pump chamber, and both were filled with mineral oil just before the pipette tip was filled with delivery fluid. Care was taken to exclude air bubbles. [1-^{14}C]-Acetate was diluted in Evans blue solution (0.5 mg/ml) to yield a concentration of 1.1×10^7 dpm/μl. Under the dissecting microscope, the micropipette tip was placed inside the sciatic endoneurium (only one side was used for injection), after which 0.4 μl of [1-^{14}C]acetate solution was injected at a rate of 0.1 μl/min.

Tissue preparation. Unless otherwise indicated, one-mo-old male Sprague-Dawley rats were used throughout this study. Approximately 1 cm of sciatic nerve segment, including the injection site (blue dye served as marker), was removed at various times after injection. Each group consisted of four or more nerve samples. Immediately after removal, the sciatic nerve was desheathed on a cold plate (surface temperature 10 C) under a dissecting microscope. The desheathed portion (endoneurial tissue or a myelin-enriched portion) was blotted dry with filter paper before the wet wt was taken. The endoneurium was then lyophilized overnight to obtain the dry wt before lipid extraction.

Surgical procedure. Wallerian degeneration and regeneration were produced in rat sciatic nerve by either crush injury or transection, according to the methods described previously (14). Reattachment of transected nerve was according to the procedure of nerve xenograft described by Dyck et al. (15).

In vitro incorporation of [1-^{14}C]acetate. The procedure used for the in vitro incubation of sciatic endoneurium with [1-^{14}C]acetate was essentially the same as that described by Yao and Cannon (4). Immediately after removal, the proximal 3 cm of the sciatic nerve was desheathed on a cold plate under a dissecting microscope. The desheathed portions (endoneurial tissue) were placed in 1 ml of modified Kreb's glucose medium (16), pH 7.4. They were preincubated in a Dubnoff metabolic shaking incubator (ca. 50 strokes/min) at 37 C under a mixture of 95% O_2 and 5% CO_2. After 30 min, 200 μl of modified Kreb's glucose solution containing 2.5 μCi of [1-^{14}C]-acetate was added to the medium, and the incubation was continued for another 2 hr under the same conditions. At the end of this time, the nerve segments were removed and washed four times with ice-cold unlabeled medium before the procedure of lipid extraction was started.

Lipid extraction and separation. The lipids were extracted from sciatic endoneurium according to the method described previously (4,14). An aliquot was counted by a Beckman liquid scintillation counting system to obtain the total incorporation of labeled precursor into endoneurial lipids. Lipid profiles of sciatic endoneurium were analyzed by high-performance thin-layer chromatography (HPTLC), using method I of nonplar lipid separation described by Yao and Rastetter (17). The plate was first developed in solvent system I, consisting of benzene/diethyl ether/ethanol/acetic acid (60:40:1:0.05, v/v/v/v). The solvent front (SF) was allowed to migrate to 5.5 cm above the origin (O). After complete removal of acetic acid by hot air, the plate was developed in solvent system II, consisting of hexane/diethyl ether (94:6, v/v) to a groove scraped 7 cm above the preadsorbent layer (full length). After it was dried, the plate was finally developed to full length again in hexane alone. Sterols were identified by their comigration with standards on HPTLC using the solvent systems described above. Isolation of nonpolar lipids from total lipid extracts was achieved by column separations on Sep-Pak silica cartridge (17). Fatty acid methyl esters (FAME) were prepared by transesterification of lipid extracts, according to the method of Morrison and Smith (18). Distribution of radioactivity among lipid subclasses and methyl esters was determined by scraping lipid zones from thin-layer chromatography (TLC) plates into counting vials containing 1 ml of distilled water, to which was added 10 ml of Ready-Solv MP (Beckman, Irvine, CA) scintillation fluid. The amount of [1-^{14}C]acetate incorporated into nerve lipids was calculated using the specific activities of [1-^{14}C]acetate present in the incubation medium and was expressed as either the pmol of acetate or the total ^{14}C radioactivity (dpm) incorporated into nerve lipids per mg of wet tissue per hr.

Identification and distribution of radiolabeled lipids by fluorography. After HPTLC separation, the plate was sprayed with EN^{3}HANCE three times and covered with Glad Wrap (Union Carbide Corp., Danbury, CT). The plate then was exposed at −70 C for various times to Kodak X-Omat S or AR X-ray film in a Kodak X-Omatic cassettes with Du Pont Cronex Lightening-Plus intensifying screens (13,17). Quantification of fluorograms was carried out by LKB Ultrascan Laser Densitometer and Apple IIe computer.

RESULTS

In vivo cholesterol biosynthesis was investigated in rat sciatic nerve at various intervals after intraneurial microinjection of [1-^{14}C]acetate. Following removal of phospholipids (PL) and glycolipids (GL) by Sep-Pak silica cartridges, the distribution of ^{14}C-labeled nonpolar lipids in rat sciatic endoneurium was revealed by fluorography of high-performance thin-layer chromatograms (Fig. 1). Endoneurial triacylglycerol (TG), 1,3-diacylglycerol (1,3-DG), 1,2-diacylglycerol (1,2-DG), free fatty acid (FFA), ceramide (Ca) and sterols were rapidly labeled from

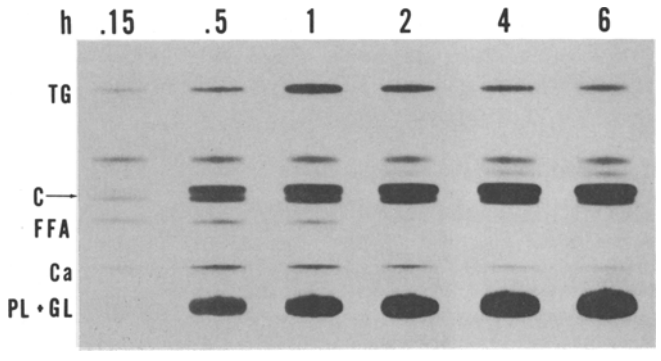

FIG. 1. Fluorograms of HPTLC of total ^{14}C-labeled lipids following microinjection of [1-^{14}C]acetate into rat sciatic endoneurium for various times (hr). Each sample represents total ^{14}C-labeled lipids extracted from 0.05 mg dry wt of endoneurium, except 0.15 hr (sample was extracted from 0.15 mg). After TLC development, the plate was exposed to Kodak X-Omat S film at −70 C for 4 days. Abbreviations: TG, triacylglycerol; C, cholesterol; FFA, free fatty acid; Ca, ceramide; PL, phospholipids; and GL, glycolipids.

[1-^{14}C]acetate following endoneurial injection. Most of labeled nonpolar lipids, except sterols, were all metabolized after 12 hr. Approximately one-fourth of total ^{14}C-labeled lipids were found to be endoneurial cholesterol.

To avoid possible contamination of radioactivity between sterols and acylglycerols, all acylated lipids were converted into FAME by transesterification before thin-layer separation. Figure 2 indicates that, in addition to cholesterol, lanosterol (Ls) and desmosterol (Ds) also were labeled from [1-^{14}C]acetate. A similar result also was obtained under in vitro conditions (data not shown). Those labeling in precursors of cholesterol were decreased gradually with time. Twelve hr after injection, over 80% of labeled sterols from [^{14}C]acetate were found to be cholesterol. The results concerning the incorporation of [1-^{14}C]acetate into fatty acids and PL have been published elsewhere (13).

To localize the site of cholesterol biosynthesis, [1-^{14}C]-acetate was incorporated in vitro into endoneurial tissue, as well as epi- and perineurial tissues. Figure 3 demonstrates that cholesterol biosynthesis in rat sciatic nerve was found mainly in myelin-enriched endoneurium. In addition to cholesterol, Ls and Ds, one of the cholesterol metabolites—coprostanol (Cs)—also was labeled in endoneurium. This was not revealed in previous fluorograms (Fig. 2), due to a shorter exposure time to X-ray film. On the other hand, the majority of ^{14}C-labels in the epi- and perineurial lipids were acylglycerols, i.e., TG, 60% and 1,2-DG, 30%.

Peripheral nerve cholesterol biosynthesis decreased rapidly with increasing age (Fig. 4). After one month, the decrease continued, but at a much lower rate. The in vitro rate of [^{14}C]acetate into endoneurial sterols was >13 times higher in 10-day-old rats ($9.91 \pm 0.48 \times 10^{-4}$ dpm/mg wet wt/hr) than in four-mo-old rats ($0.73 \pm 0.11 \times 10^{-4}$ dpm/mg wet wt/hr). In mature adult nerve, there was an increased proportion of ^{14}C-label in Ls and Ds (Fig. 5).

To test whether the inhibited cholesterol biosynthesis in injured nerve can be induced by surgical correction, the in vitro incorporation of [1-^{14}C]acetate into endoneurial cholesterol was investigated in rat sciatic nerve with and without reattachment after 14 days transection (Table 1). Rat sciatic nerves were transected for 14 days to ensure that cholesterol biosynthesis was minimized before surgical reattachment. In control experiments, the transected nerves were allowed to degenerate for another 14 days and 30 days. The total incorporation of [1-^{14}C]acetate into endoneurial lipids was substantially lower than that of contralateral intact nerves. The majority of labeled cholesterols were in the form of cholesteryl esters. (CE).

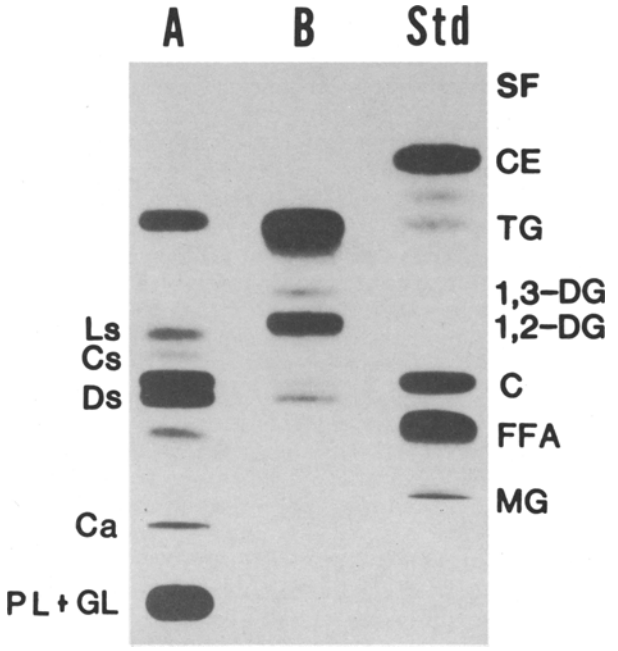

FIG. 3. Fluorograms of HPTLC of total ^{14}C-labeled lipids following 2 hr in vitro incorporation of [1-^{14}C]acetate into endoneurium (A) and epineurium and perineurium (B) of rat sciatic nerve. Ca. 5,000 cpm/sample were applied to a thin-layer plate which was exposed to Kodak X-Omat S film at −70 C for 7 days. Abbreviations: Std, standards; SF, solvent front; CE, cholesteryl ester; TG, triacylglycerol; 1,3-DG, 1,3-diacylglycerol; 1,2-DG, 1,2-diacylglycerol; Ls, lanosterol; Cs, coprostanol; C, cholesterol; Ds, desmosterol; FFA, free fatty acids; MG, monoacylglycerol; Ca, ceramide; PL, phospholipids; and GL, glycolipids.

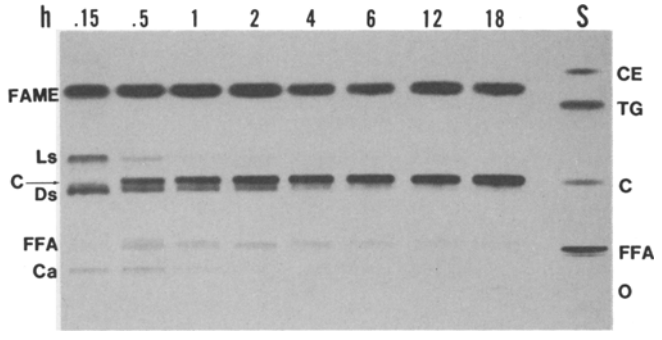

FIG. 2. Separation of ^{14}C-labeled sterols on HPTLC after methanolysis of total ^{14}C-labeled lipids at various times following endoneurial microinjection of [1-^{14}C]acetate. Ca. 7,000 cpm/sample were applied to a thin-layer plate which was exposed to Kodak X-Omat S film at −70 C for 2 days. Abbreviations: S, standards; CE, cholesteryl ester; FAME, fatty acid methyl ester; TG, triacylglycerol; Ls, lanosterol; C, cholesterol; Ds, desmosterol; FFA, free fatty acid; Ca, ceramide; and O, origin.

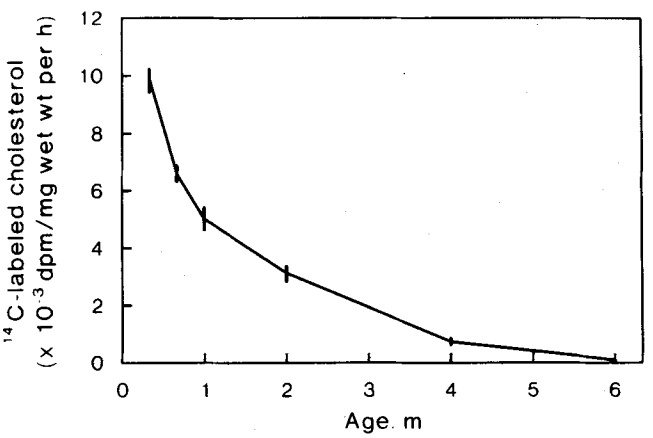

FIG. 4. Effect of age on cholesterol biosynthesis following 2 hr in vitro incorporation of [1-^{14}C]acetate into endoneurial lipids of rat sciatic nerve.

On the other hand, there was a marked increase of [1-^{14}C]acetate incorporation into total endoneurial lipids of transected nerve which was surgically reattached for 30 days. Concomitantly, the level of cholesterol biosynthesis was resumed, and the proportion of labeled CE also was substantially reduced. The induction of cholesterol biosynthesis was further confirmed by fluorography following HPTLC separation (Fig. 6A). In addition, marked decrease of endoneurial CE in reattached nerve also was revealed by charred HPTLC (Fig. 6B).

To test whether cholesterol biosynthesis is affected by Schwann cell disorder, in vitro [1-^{14}C]acetate incorporation into endoneurial cholesterol was compared between Trembler mutant and Wallerian degeneration models (Table 2). Incorporation of [1-^{14}C]acetate into endoneurial cholesterol reached its minimum level in adult rat sciatic nerve seven days after crush injury or 60 days after transection. By contrast, cholesterol biosynthesis in adult Trembler nerve was not significantly different than that of normal controls (19). On the other hand, the level of CE formation was elevated more significantly in both models than in normal controls.

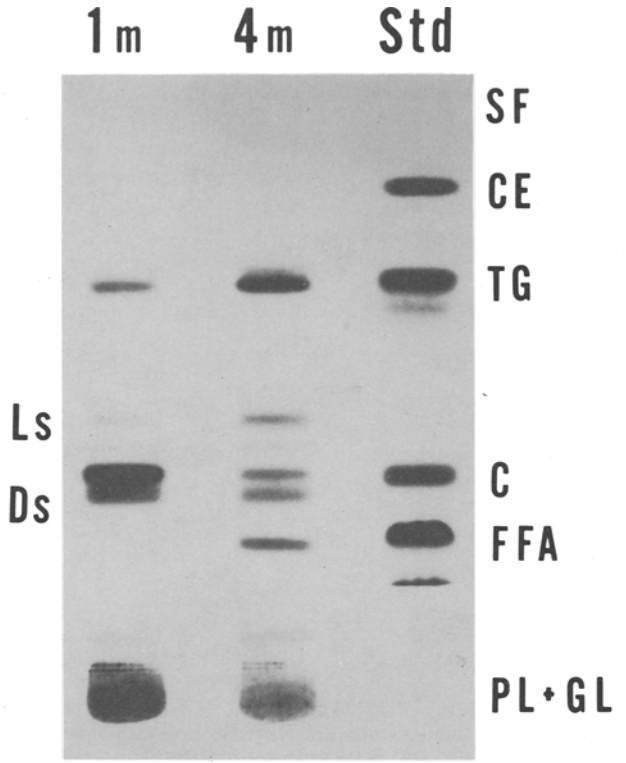

FIG. 5. Fluorograms of HPTLC of total ^{14}C-labeled lipids following 2 hr in vivo incorporation of [1-^{14}C]acetate into endoneurial lipids of young (1-month-old) and mature (4-month-old) adult rat sciatic nerves. Each sample represents total labeled lipid extracts from 0.25 mg wet wt of endoneurium. After TLC development, the plate was exposed to Kodak X-Omat S film at −70 C for 3 days. Abbreviations: SF, solvent front; CE, cholesteryl ester; TG, triacylglycerol; Ls, lanosterol; C, cholesterol; Ds, desmosterol; FFA, free fatty acid; PL, phospholipids; and GL, glycolipids.

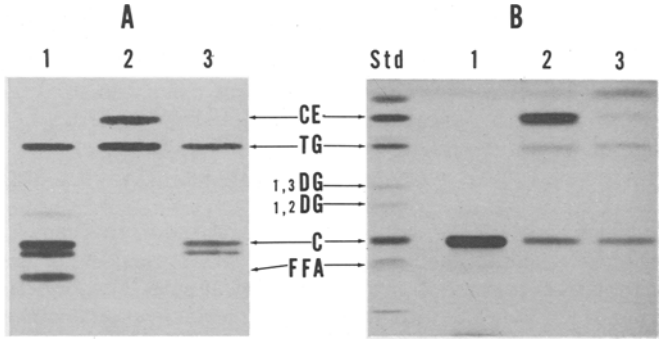

FIG. 6. HPTLC of nonpolar lipids separation by fluorography (A) and by charring (B) following 2 hr in vitro incorporation of [1-^{14}C]acetate into endoneurial lipids of control nerve-contralateral uninjured (1), injured nerve-30 days after transection (2), and regenerated nerve—30 days after reattachment of transected nerve (3). Ca. 5,000 cpm/sample were applied to thin layer plates. After development, one plate was sprayed with 10% (wt/vol) curpic sulfate in 8% (wt/vol) phosphoric acid and charred at 180 C for 10 min. The other plate was exposed to Kodak X-Omat S film at −70 C for 4 days. Abbreviations: CE, cholesteryl ester; TG, triacylglycerol; 1,3-DG, 1,3-diacylglycerol; 1,2-DG, 1,2-diacylglycerol; C, cholesterol; and FFA, free fatty acid.

DISCUSSION

Previously, our laboratory has shown that exclusive labeling of endoneurial lipids in peripheral nerve by endoneurial microinjection of radiolabeled precursor provides a unique model for studying metabolic turnover of fatty acids and acylglycerols in rat sciatic nerve (13). The present paper is an extension of our previous studies, demonstrating that peripheral nerve is capable of de novo biosynthesis of cholesterol. A temporal association between decreased ^{14}C-label in Ls and Ds, and increased ^{14}C-label in cholesterol (Fig. 2), suggests that the overall pathway of cholesterol biosynthesis in peripheral nerve appears to be the same as that in liver (20). This result is in accordance with the recent findings by Bourre et al. (21), demonstrating that both 7-dehydrodesmosterol and Ds are present in developing rat sciatic nerve and nearly absent in mature adult nerve.

Labeled glucose (22) and leucine (23,24) also have been utilized to synthesize cholesterol in peripheral nerve, because a common intermediate-acetyl CoA can be generated by both precursors. In brain, ketone bodies serve as important precursors of myelin cholesterol (25-27). It is not clear, however, whether a direct metabolic path from ketone bodies via acetoacetyl CoA toward formation of cholesterol exists in peripheral nerve. Squalene, which was not normally found in the [1-^{14}C]acetate metabolites, became a major product in the presence of excessive NADP$^+$ (28), which suggests that epoxidation of squalene may be a key step in the regulation of cholesterol biosynthesis in the peripheral nervous system.

The level of cholesterol biosynthesis is highest in the developing peripheral nerve and decreases rapidly as myelination proceeds (Fig. 4). Furthermore, there is an increased proportion of biosynthesis of cholesterol precursors (Fig. 5) with increasing age. This incomplete biosynthesis of endoneurial cholesterol may imply a decreased activity in certain specific enzymes, e.g., Ds reductase, in adult peripheral nerve. Although the mature adult nerve maintains a minimum activity of cholesterol biosynthesis, the ability to synthesize sterols continually even after myelination (Fig. 5) suggests that adult peripheral nerve myelin is not a stable metabolic entity. In the absence of myelin assembly, cholesterol biosynthesis is completely abolished. The inhibited biosynthesis, however, can be resumed by regeneration of injured nerve (Fig. 7) or by surgical reattachment of transected nerves (Fig. 6). On the other hand, the adult Trembler nerve, which is presumed to be due to a metabolic disorder of Schwann cells (29,30), do not exhibit a defect in cholesterol biosynthesis (19). These data indicate that cholesterol biosynthesis may be dependent on the axon as the major source of substrate and the level of membrane cholesterol is essential for expression of myelinogenesis.

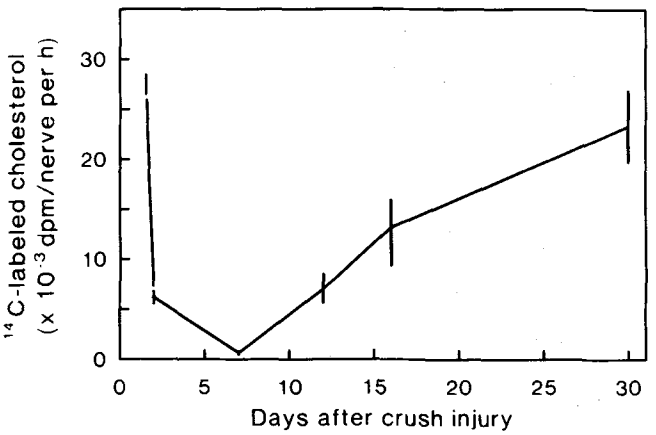

FIG. 7. In vitro cholesterol biosynthesis in rat sciatic endoneurium during Wallerian degeneration and regeneration. Data were calculated from previously published data (4).

One of the major biochemical events associated with demyelination is the temporal changes in membrane cholesterol with histological observations. In general, nerve fiber degeneration is accompanied by a decrease in free cholesterol and an increase in CE that return to normal levels on regeneration (14,31). The altered levels of endoneurial cholesterol are associated temporally with the rate of [1-^{14}C]acetate incorporation into endoneurial cholesterol (4). On the other hand, an increase in cholesterol esterifying activity, which is temporally associated with axonal degeneration (32), is primarily responsible for

cholesterol esterification in degenerated nerve. During remyelination, CE hydrolysis, which is active in normal nerve (33), appears to overshadow cholesterol esterification. Thus, it is possible that, to detoxify the increased FFA during demyelination (31), cholesterol is stored as CE and then is reutilized in remyelination after hydrolysis (14,34). In summary, de novo synthesis of cholesterol from acetate and hydrolysis of CE formed during degeneration appear to be the two major sources of endoneurial cholesterol that are used to form new myelin. Alternatively, cholesterol incorporated from blood stream by the Schwann cells (6,35), already present in nerve before degeneration (6,7) and transported via axoplasmic flow (36–38), also may be utilized to form new myelin.

[Received March 18, 1988; Revision accepted May 31, 1988]

Dexamethasone-induced Alterations in the Glycosphingolipids of Rat Kidney

Rajvir Dahiya and **Thomas A. Brasitus***
Departments of Medicine, The University of Chicago and Michael Reese Hospitals; Pritzker School of Medicine, University of Chicago, Chicago, IL 60637

To determine whether glucocorticoids would influence the glycosphingolipid composition of the rat kidney, male albino rats of the Sherman strain were subcutaneously administered dexamethasone (100 μg/100 g body wt/day) or diluent for four days. The compositions of ceramide and of acidic and neutral glycosphingolipids of the kidneys of these animals were then examined and compared. The results demonstrated that dexamethasone administration: 1) increased the content of ceramide and of acidic and neutral glycosphingolipids in kidney; 2) increased the relative percentage of globotriaosyl- and globotetraosylceramide, but decreased the relative percentages of glucosylceramide; 3) decreased the relative percentages of G_{M3} and increased other gangliosides; 4) increased the relative percentages of *N*-glycolylneuraminic acid in G_{M3}; 5) did not appear to influence significantly the long-chain bases of the major glycosphingolipids; and 6) altered the relative percentages and chain length of the hydroxy and nonhydroxy fatty acids of the major acidic and neutral glycosphingolipids in this tissue. The data show that dexamethasone administration induces quantitative and qualitative changes in the glycosphingolipids of the rat kidney.
Lipids 23, 863-868 (1988).

Previously, the mammalian kidney has been shown to be rich in glycosphingolipids (1-5). While their functional significance remains to be elucidated, prior studies from a number of laboratories (6-9) have suggested that these lipids may play a role in many important cellular processes in various tissues, including the kidney. For example, Spiegel et al. (10) have recently implicated glycosphingolipids as modulators of sodium channels in the apical membranes of A_6 cells, a cultured kidney epithelial cell line. In the rat kidney, earlier studies (1) have suggested that alterations in the glycosphingolipids may be associated with the aging process.

Relatively few studies have been undertaken with the aim to modulate the glycosphingolipid composition of mammalian kidney. In this regard, sex hormones have been shown to influence the glycosphingolipids of the rat and mouse kidney (1-5). Recent studies by our laboratory (11) and others (12) also have shown that glucocorticoid hormones may influence the glycosphingolipid composition of various tissues, including the rat small intestine (11). To date, however, data concerning the influence of these latter hormones on the glycolipids of the rat kidney are lacking. The present experiments were undertaken to characterize the effects of the synthetic glucocorticoid, dexamethasone, on the acidic and neutral glycosphingolipid composition of the rat kidney. The results of these investigations, a comparison of the effects of this hormone on the glycolipids of rat kidney with those previously noted in rat small intestine (11), and a discussion of their potential physiological significance are presented.

Abbreviations: GLC, gas-liquid chromatograph(y); HPTLC, high-performance thin-layer chromatography; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Materials. Dexamethasone was purchased from Sigma Chemical Co. (St. Louis, MO). Sphingosine standards, 3% OV-1 on Anakron ABS and ceramide were purchased from Analabs (North Haven, CT). Phytosphingosine was obtained from Calbiochem (La Jolla, CA). Florisil (60-100 mesh) and fluorescamine (Fluram-Roche) were obtained from Fisher Scientific (Fairlawn, NJ). Mixtures of nonhydroxy and hydroxy fatty acid standards and EGSS-X 10% on Gas Chrom P and Power-Sil-Prep were obtained from Alltech/Applied Science Lab. Inc. (State College, PA). The ganglioside standards G_{M1}, G_{D1a}, G_{T1a}, and G_{T1b} were purchased from Supelco (Bellefonte, PA). G_{M2}, isolated from Tay-Sachs brain, was a gift from Dr. G. Dawson. G_{M3} was isolated from rat small intestine and purified by the method of Glickman and Bouhours (13). Glucosyl-, lactosyl-, globotriaosyl-, and globotetraosylceramide, purified from human erythrocytes, were gifts from Dr. S. K. Kundu (14). All other chemicals were purchased from Fisher Scientific or Sigma Chemical Co., unless otherwise indicated.

Lipid extraction. Two groups of 16 male albino rats of the Sherman strain, weighing 200-250 g, were injected subcutaneously with vehicle (0.9% saline) or dexamethasone (100 μg/day100 g body wt) for four days. The last injection was administered two hr before the animals were killed (11). With water ad libitum, the animals were fasted overnight, killed rapidly by cervical dislocation and their kidneys were excised. The kidneys were decapsulated and papillae removed, then sliced and washed with saline to remove blood clots. The glycosphingolipids of the kidneys of each group were extracted as previously described (11,15). Briefly, the samples were homogenized with methanol in a Waring Blender, and the glycolipids extracted overnight with 20 vol of chloroform/methanol (2:1, v/v) (15). The protein residue was collected by filtration and reextracted with chloroform/methanol (1:2, v/v). The filtrates were combined, dried in a rotary evaporator and redissolved in chloroform/methanol (2:1, v/v) for further analysis.

Glycosphingolipid, ceramide purification and identification by high-performance thin-layer chromatography (HPTLC). Total lipid extracts were partitioned with water and the lower phase washed five times with Folch upper phase (chloroform/methanol/water, 3:48:47, v/v/v) to insure complete extraction of gangliosides into the upper phase (15). The upper-phase gangliosides were then purified by passage through Sep-pak cartridges as described previously (16).

The neutral glycolipids and ceramide were purified by chromatography of the acetylated neutral lipids on a Florisil column (17). The gangliosides, ceramide and the deacetylated neutral lipids were analyzed by HPTLC on Silica Gel 60 precoated plates (E. Merck, Darmstadt, West Germany) in the solvent system chloroform/methanol/water with 1% $CaCl_2$ (20:35:7, v/v/v) (18).

By brief exposure to iodine vapor, individual neutral glycolipids and ceramide were identified and then quantified, after scraping the silica gel area corresponding to their position following migration. The number of sphingoid bases liberated by methanolysis was determined by fluorometry, following reaction of the free bases with fluorescamine (17). Quantification of the various gangliosides was performed using a Beckman densitometer as described by Mullin et al. (18). In the present experiments, all of the bands from each ganglioside species were analyzed. Using radiolabeled glycosphingolipids, recoveries were determined from tissue homogenates, as previously described by Suzuki et al. (14). Recoveries for G_{M3}, ceramide, glucosyl-, lactosyl-, globotriaosyl- and globotetraosylceramide were 77 ± 4, 82 ± 3, 82 ± 5, 80 ± 3, 83 ± 6 and 81 ± 5%, respectively (N = 4). The variations in recoveries of these various lipids were not found to be significantly different.

Desialylation of G_{M3}. Desialylation of purified G_{M3} was performed by acid hydrolysis using 0.1 M H_2SO_4 at 80 C for 1.5 hr, as previously described (19). On HPTLC plates, N-glycolyl and N-acetylneuraminic acids were separated, using a solvent system of n-propyl-alcohol/water/ammonium hydroxide (60:28:1.5, v/v/v) (20), and visualized with resorcinol.

Analysis of carbohydrate moieties of G_{M3} and neutral glycolipids. Carbohydrate moieties were identified by gas-liquid chromatographic analysis of their trimethylsilyl derivatives, as previously described (13,21).

Analysis of fatty acids and long-chain bases of glycosphingolipids and ceramide. Individual glycosphingolipids and ceramide were separated and identified by HPTLC and, after scraping the silica gel areas corresponding to their positions, were hydrolyzed in 1 ml of dry methanolic HCl (0.75 N) at 80 C for 16 hr. This was followed by extraction of the fatty acid methyl esters by hexane (22). The methanolic phase then was alkalinized with aqueous NaOH and the long-chain bases were extracted by diethyl ether (23).

Nonhydroxy and hydroxy fatty acids were separated by chromatography on a Florisil column, as previously described (24). In certain experiments, a known amount of C_{21} fatty acid methyl ester was added as an internal standard to quantitate the nonhydroxy and hydroxy fatty acids in the samples (25). Nonhydroxy fatty acid methyl esters were dissolved in a small volume of hexane, and hydroxy fatty acid methyl esters were silylated prior to chromatography (25). Analyses of both nonhydroxy and hydroxy fatty acids were performed on a Hewlett-Packard 5790A gas-liquid chromatograph (GLC) equipped with a flame ionization detector and interfaced with a Hewlett-Packard 3390A integrator, as previously described (25). Peak identification was based on retention times, identical to known standards run under the same conditions (25).

Long-chain bases, free from fatty acids, were dissolved in chloroform, washed with 0.1 M NaOH and then washed repeatedly with water. The chloroform phase was dried under N_2 and the residue silylated, as described by Carter and Gaver (26). The long-chain bases then were analyzed by GLC on an OV-1 column operated with temperature programming from 245 to 305 C at 3 C per min (25). Identification was based on retention times, identical to known standards run under the same conditions (25).

Statistical methods. Unless otherwise indicated, all results were expressed as mean value ± SE. Paired or unpaired t-tests were used for all statistical analysis. $P < 0.05$ was considered significant.

RESULTS

Analyses of kidney glycosphingolipids and ceramide in control and dexamethasone-treated animals. In agreement with earlier studies of control animals (1), glucosyl- and globotetraosylceramide were found to be the principal neutral glycosphingolipids, and hematoside (G_{G3}) was the major ganglioside of this organ (Tables 1 and 2,

TABLE 1

Contents and Relative Percentages of Ceramide and Neutral Glycosphingolipids in Kidneys of Dexamethasone-treated and Control Rats[a]

	Control		Dexamethasone-treated	
	Content	%	Content	%

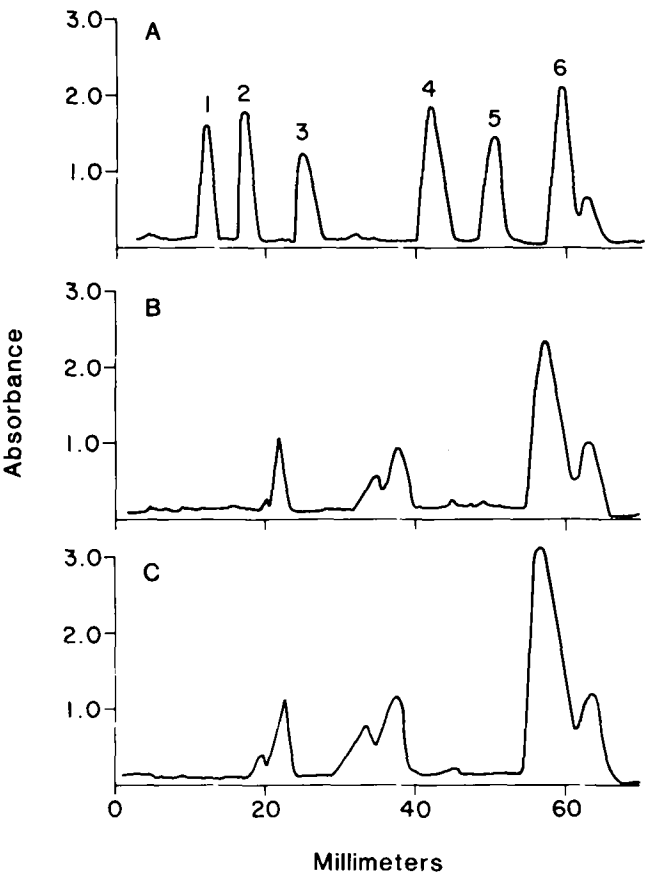

FIG. 2. Representative densitometric tracings of: A, standards; B, control; and C, dexamethasone-treated gangliosides. 1, GT_{1b}; 2, GT_{1a}; 3, GD_{1a}; 4, G_{M1}; 5, G_{M2}; and 6, G_{M3}.

Figs. 1 and 2). Smaller amounts of lactosyl- and globotriaosylceramide, as well as ceramide, a nonsugar containing compound, also were present (Table 1, Fig. 1). In dexamethasone-treated kidneys, the total content of neutral glycosphingolipids and ceramide was found to be significantly increased when compared with control kidneys (Table 1, Fig. 1). Moreover, the relative percentages of globotriaosyl- and globotetraosylceramide were increased by dexamethasone, and, after administration of this synthetic glucocorticoid for four days, the relative percentage of glucosylceramide was decreased.

As shown in Table 2, the total content of gangliosides also was increased in the kidneys of treated animals. The relative percentages of G_{M3} and the other gangliosides, however, were decreased and increased, respectively, by dexamethasone administration (Table 2, Fig. 2).

GLC analyses of the sugar moieties of control and treated tissue further established their identities and showed similar molar ratios for each of the glycosphingolipids of control and dexamethasone-treated kidneys (Table 3).

After acid hydrolysis of control and treated kidneys, the sialic acid moieties of G_{M3} were found to contain both N-acetyl- and N-glycolylneuraminic acid. Although the latter form predominated in both, the relative percentage of N-glycolylneuraminic acid was found to be significantly greater in dexamethasone-treated kidneys (Table 4).

In order to detect additional differences between the glycosphingolipids of control and treated tissue, the long-chain bases and fatty acids of the major glycosphingolipids were examined and compared. As shown in Table 5, sphingosine was the predominant long-chain base of glucosyl-, globotetraosylceramide and G_{M3} in control kidneys. Furthermore, no significant differences were noted in the relative percentages of the long-chain bases of kidneys of control and treated animals (Table 5).

In contrast to these latter findings, dexamethasone treatment appeared to modify the fatty acids of the major kidney glycosphingolipids. As shown in Table 6, the present treatment regimen with this synthetic glucocorticoid significantly altered the individual hydroxy and nonhydroxy fatty acids of glucosyl- and globotetraosylceramide, as well as G_{M3}. As can be seen, dexamethasone administration, in general, decreased the hydroxy and nonhydroxy fatty acid chain length of these major glycosphingolipids, particularly glucosylceramide and G_{M3} (Table 6).

DISCUSSION

Prior studies from a number of laboratories have demonstrated that glucocorticoid hormones, including dexamethasone, could influence the glycerolipid and phospholipid composition of various cell types (27–29). Administration of dexamethasone (2 mg/kg body wt/day)

TABLE 3

Analysis of Sugar Moieties in Neutral Glycosphingolipids and G_{M3} of Control and Dexamethasone-treated Kidneys[a]

	Control		Treated	
	Sugar	Molar ratios	Sugar	Molar ratios
Glucosylceramide	Glc	—	Glc	—
Lactosylceramide	Gal/Glc	1.0:1.0	Gal/Glc	1.1:1.0
Globotriaosylceramide	Gal/Glc	2.1:1.0	Gal/Glc	2.0:1.1
Globotetraosylceramide	Gal/Glc/$GalNA_c$	2.0:1.0:1.1	Gal/Glc/$GalNA_c$	2.1:1.1:1.0
G_{M3}	Gal/Glc/SA	1.0:1.0:1.0	Gal/Glc/SA	0.9:1.1:1.0

[a]Glycosphingolipid classes were separated by TLC, and trimethylsilyl esters prepared and analyzed by GLC, as described in Materials and Methods section.

Glc, glucose; Gal, galactose; $GalNA_c$, N-acetylglucosamine; and SA, sialic acid.

TABLE 4

Relative Percentages of N-acetyl- and N-glycolylneuraminic Acid in G_{M3} of Kidney in Control and Dexamethasone-treated Rats[a]

Form of sialic acid	Control	Dexamethasone-treated

to adult male rats for 1 wk, however, failed to alter the total phospholipid content in the kidneys of these animals (29).

Corticosteroids also have been shown to alter the acidic glycosphingolipids of rabbit thymocytes (12). More recently, our laboratory (11) has shown that subcutaneous dexamethasone administration (100 μg/100 g body wt/day) for four days induced changes in the glycosphingolipids of the rat proximal small intestinal mucosa. The present experiments demonstrated, for the first time, that this dexamethasone treatment regimen also results in significant quantitative and qualitative alterations in the neutral and acidic glycosphingolipids of the rat kidney.

Since previous studies have suggested that the glycosphingolipid composition of animals, including rats, is organ-specific (1), it was of particular interest, in the present studies, to compare the effects of dexamethasone treatment on rat kidneys with effects previously seen in the rat small intestine (11). In this regard, dexamethasone significantly increased the total content of ceramide and the neutral glycosphingolipids by ca. 50% in the rat kidney, and moreover, increased the relative percentages of globotriaosyl- and globotetraosylceramide, but reduced the relative percentage of glucosylceramide. In contrast to these current findings, previous administrations of the hormone were not found to affect these lipids in the rat small intestine (11).

In both kidney and small intestine, dexamethasone increased the total content of acidic glycosphingolipids by ca. 50%. In the kidneys, this was associated with a small decrease (10%) in the relative percentage of G_{M3}, but in the small intestine, there was an ca. 15% relative percentage increase (11). Dexamethasone, however, increased the relative percentage of N-glycolylneuraminic acid of G_{M3} in both organs. In the present studies, long-chain bases of the major kidney glycosphingolipids, including G_{M3}, were not found to be influenced by this synthetic glucocorticoid. In earlier studies (11), however, this agent produced decreases in the relative percentage of phytosphingosine in G_{M3}, as well as in glucosyl- and globotriaosylceramide, the major neutral glycolipids of the rat small intestine.

Additionally, relatively minor changes were previously seen in the hydroxy and nonhydroxy fatty acids of small intestinal G_{M3}, secondary to dexamethasone administration (11), but in the present studies, administration of this hormone produced more impressive changes in the relative percentages and chain lengths of these fatty acids in the major kidney neutral and acidic glycolipids. These results deserve further comment.

First, the present results, taken together with our earlier data (11), demonstrate clearly that dexamethasone can influence the glycosphingolipid composition of both the rat kidney and the rat small intestine. In general, however, the alterations induced by this hormone were more extensive in the rat kidney, involving both the neutral and acidic glycosphingolipids. It would appear, therefore, that dexamethasone-induced glycosphingolipid alterations, indeed, are organ-specific in the rat.

Second, treatment with dexamethasone increased the relative percentage of N-glycolylneuraminic acid in G_{M3} of both rat kidney and small intestine. This hormone, however, decreased the relative percentages of phytosphingosine in the major small intestinal glycosphingolipids (11), but in the current experiments, was not found to alter the long-chain bases of these glycolipids in the kidneys. Because the conversion of N-glycolyl- from N-acetylneuraminic acid (30,31) and phytosphingosine from sphinganine (31) involves hydroxylation reactions, it appears that this synthetic glucocorticoid has different affects on these reactions in both organs.

Similarly, intraperitoneal injection of cortisone acetate for 48 hr has been shown previously to decrease the levels of N-glycolylneuraminic acid in G_{M3} of rabbit thymocytes, to not affect its long-chain bases and to increase the chain length of the fatty acids of this ganglioside (12). As noted earlier, in the rat kidney, but not in the intestine (11), dexamethasone produced decreases in the chain length of G_{M3} and the major neutral glycosphingolipids. Taken together, these results suggest that the effects of this hormone on acidic and neutral glycosphingolipids are very complex and are not only organ-specific, but also species-specific.

Third, the mechanism(s) underlying the present quantitative and qualitative alterations in the dexamethasone-induced, rat kidney glycosphingolipids are unclear at this time. Earlier studies concerning sex-hormone effects on rat and mouse kidney glycolipids suggested that these hormones may increase the activities of certain enzymes involved in the biosynthesis of glycosphingolipids (2–5). The increased neutral and acidic glycolipid content seen in the rat kidneys, after dexamethasone administration, may be due to increased rates of lipid biosynthesis, decreased rates of degradation or a combination of both (32). Further studies, therefore, will be necessary to clarify this issue. Regardless of the mechanism(s) involved, however, the present data demonstrate that administration of this synthetic glucocorticoid leads to alterations in both the acidic and neutral glycosphingolipids in rat kidneys.

Finally, it should be noted that, while the physiological significance of these dexamethasone-induced, renal glycosphingolipid alterations remain unclear, prior studies of a number of different organs (1,6–10,33–36), including the rat kidney (1), have suggested that neutral and acidic glycosphingolipids may play a role in several important physiological and pathological processes. For example, addition of exogenous G_{M3} to various cell lines has been shown, in fact, to inhibit cell growth (37). Further studies should elucidate the mechanism(s) responsible for these dexamethasone-induced alterations in the glycolipids of the rat kidney and clarify their functional significance.

ACKNOWLEDGMENTS

Characterization of Skin-surface Lipids from the Monkey *(Macaca fascicularis)*

Tomoko Nishimaki-Mogami*, Ken-ichiro Minegishi, Atushi Takahashi, Yasushi Kawasaki, Yuji Kurokawa and **Mitsuru Uchiyama**
National Institute of Hygienic Sciences, Kamiyoga 1-18-1, Setagaya, Tokyo 158, Japan

Skin-surface lipids from the monkey *Macaca fascicularis* are composed of sterol esters (38%), cholesterol (4%) and two types of wax diesters, identified as Type II (IIa and IIb, 17% and 40%, respectively). Type IIa contained diesters of 1,2-alkanediols esterified with two molecules of long-chain (C_{14}–C_{34}) fatty acids having straight and branched chains. In the diesters IIa, fatty acids shorter than C_{19} predominated in position 1, and fatty acids longer than C_{20} predominated in position 2. Type IIb contained diesters of 1,2-alkanediols esterified with C_4 and C_5 branched-chain fatty acids (predominantly isovaleric acid) at position 1 and long-chain (C_{14}–C_{27}) acids, having straight and branched chains, at position 2. The short-chain acids were converted to 2-nitrophenylhydrazides and analyzed by high-performance liquid chromatography (HPLC). Ammonia chemical ionization (CI)–gas chromatography (GC)–mass spectrometry (MS) resolved the intact diesters IIb into 12 peaks corresponding to molecular weights ranging from 597 to 748, and showed that the molecular species, such as C_{21}-C_{16}-C_5 (diol, fatty acid in position 2, fatty acid in position 1), C_{22}-C_{16}-C_5 and C_{23}-C_{16}-C_5, were prevalent. The fatty acids from both diesters were mostly (>98%) saturated. The 1,2-alkanediols from both diesters consisted of C_{16}-C_{26} saturated straight- and branched-chain components. The acyl groups of sterol esters contained 86% C_{14}-C_{34} branched-chain acids. The unsaturated fatty acids (5.4%) belonged to a straight-chain monoenoic series having extremely long chains (C_{18}-C_{34}). The branched-chain structures in the fatty acids and diols were iso and anteiso. These results show the species-specific profile for the skin-surface lipid synthesis.
Lipids 23, 869–877 (1988).

Besides their physiological functions, skin-surface lipids are thought to play a significant role in excreting lipophilic compounds from the body. Wolff (1) analyzed halogenated hydrocarbons in human skin-surface lipids for estimation of human body burden. For assessment of human exposure to environmental pollutants, using skin lipids as a specimen, animal experiments are required.

Skin-surface lipids contain unusual lipids that are not commonly found in the internal tissues, and there is a wide variation between species, both in the classes of lipids present and in the structures of the aliphatic moieties (2–12). Human skin-surface lipids differ markedly from those of animals; they contain triacylglycerols and squalene as major constituents, whereas those of other animals consist primarily of a variety of wax mono- and diesters (9,10). It, therefore, was of interest to examine the skin-surface lipids of primates. An early investigation of primates used thin-layer chromatography (TLC) for the study of the surface lipids of the chimpanzee and baboon (2). To evaluate the use of animal models, detailed surface-lipid characterization is required to decide whether the origin and biosynthesis of the lipids is comparable with those of humans.

In the present study, the monkey *Macaca fascicularis* was chosen to determine in detail the composition and structures of its skin-surface lipids. On the basis of these results, lipogenesis in the sebaceous gland was deduced. In addition, it was shown that the derivatization to 2-nitrophenylhydrazide was useful for the analysis of short-chain fatty acids in diesters, and that ammonia chemical ionization–gas chromatography–mass spectrometry (CI-GC-MS) was suitable for the molecular species analysis of the diesters.

MATERIALS AND METHODS

Collection of the skin-surface lipids. The skin-surface lipids were collected from the backs of three male monkeys *(M. fascicularis).* After being shaven, the backs (10 × 10 cm) were wiped with gauze (10 × 10 cm) soaked in acetone/hexane (1:1, v/v), that had been exhaustively extracted with the solvent. The lipids were eluted from the gauze with acetone/hexane (1:1, v/v) on a sintered glass filter. The solvent was evaporated, yielding 6–15 mg of lipids per animal. Because preliminary analysis showed no significant difference in the composition of lipid classes and the constituent fatty acids between individual animals, the collection was repeated 3–4 times (once a day at intervals of 3–4 days); the lipid samples were combined and used for determination of chemical structures. The results were an average of three separate experiments.

Separation of lipid classes. The total-surface lipids were fractionated on a 0.25-mm-thick silica gel plate (Merck $60F_{254}$), using hexane/benzene (2:3, v/v). The lipid bands were located with iodine vapor and separately scraped from the plate, after which the lipids were eluted with diethyl ether. The sterol ester fraction was rechromatographed on magnesium hydroxide TLC with hexane/ethyl acetate (100:1, v/v) (12). This procedure separated the sterol esters from a small amount of wax monoesters, as described by Stewart and Downing (12). The bands were visualized under UV-light after spraying with 2′,7′-dichlorofluorescein in methanol (1 mg/ml).

Sterol esters. The sterol esters were saponified in 1 ml 0.5 N NaOH in 95% methanol/benzene (4:1, v/v) at 60 C for one hr. After acidification with 1 N HCl, the products were recovered in hexane, and then treated with 1 ml benzene/5% HCl in methanol (1:2, v/v) at 100 C for 30 min. After adding water, the products were extracted with diethyl ether, and then fractionated by TLC (10 × 10 cm).

Abbreviations: FAS, fatty acid synthetase; TMS, trimethylsilyl; CI, chemical ionization; CI-GC-MS, chemical ionization-gas chromatography-mass spectrometry; ECL, equivalent chain length; EI, electron impact; FCL, fractional chain length; GC-MS, gas chromatography-mass spectrometry; HPLC, high-performance liquid chromatography; TIC, total ion monitoring; TLC, thin-layer chromatography.

After successive development with hexane/benzene (2:3, v/v, to 10 cm), followed by benzene/ethyl acetate (1:1, v/v, to 4 cm), the two bands were scraped from the plate, and the fatty acid methyl esters and free sterols were eluted from the adsorbent with diethyl ether and chloroform/methanol (2:1, v/v), respectively. The free sterols separated by TLC were converted to their TMS-derivatives by treatment with N,*O*-bis(trimethylsilyl)acetamide at 60 C for one hr.

An aliquot of the fatty acid methyl esters was converted to pyrrolidides by heating with 1 ml pyrrolidine/acetic acid (10:1, v/v) at 100 C for one hr. After adding 3 N HCl (3 ml), the products were extracted with hexane. The extract was successively washed with 3 N HCl and then with water, after which it was dried over anhydrous magnesium sulfate. After removing the solvent under a stream of nitrogen, the residue was subjected to GC.

The saturated and monounsaturated fatty acid methyl esters were separated by argentation-TLC using hexane/diethyl ether (9:1). The plates were prepared by immersion of precoated silica gel plates in a solution of 4% silver nitrate in acetone/water (9:1, v/v). The methyl esters were located with 2′,7′-dichlorofluorescein and recovered in ether. The double bonds of the unsaturated fatty acids were cleaved by Lemieux-von Rudloff oxidation (13), as described in the next section. After 60 hr, the fatty acids were extracted and treated with diazomethane. Hydrogenation was carried out by bubbling hydrogen through the methanol solution (0.5 ml) of the unsaturated fraction in the presence of 5% Pd-$CaCO_3$ (1–2 mg). The structure of each fatty acid was assigned from the mass spectra of methyl ester and/or pyrrolidide according to established data (14,15).

Wax diesters. Each of the isolated wax diester fractions (IIa and IIb) was saponified and then processed in the same manner as the sterol esters.

The wax diols were converted to their isopropylidene derivatives by treatment with 1 ml acetone and 2 μl 70% perchloric acid at room temperature. After 30 min, the mixture was made alkaline with ammonium hydroxide and evaporated to dryness under a nitrogen stream. The products were extracted into hexane. Traces of polar material were removed by preparative TLC and developed in hexane/benzene (2:3, v/v).

Aliquots of the diols were oxidized by the Lemieux and von Rudloff method (13). To the solution of alkanediols in 0.5 ml tert-butanol were added 0.2 ml 0.1 N Na_2CO_3, 0.2 ml 0.5 N $NaIO_4$ and 0.1 ml 8 mM $KMnO_4$. After 24 hr, the fatty acids formed were extracted with hexane from the acidified reaction mixture. The extract was washed with water, dried with anhydrous magnesium sulfate and evaporated to dryness. The fatty acids were converted to methyl esters by treatment with diazomethane for GC analysis.

A portion of the diesters IIb was treated with 0.2 ml pyrrolidine and 20 μl acetic acid, and the component fatty acids were converted directly to pyrrolidides. After heating at 100 C for two hr, an aliquot was submitted to GC–MS analysis. Authentic samples of the short-chain fatty acid pyrrolidides were prepared from their ethyl or propyl esters. Their mass spectra were as follows: 2-methylpropanoyl pyrrolidine, m/z (rel intensity): 141 (M^+, 44), 126 (15), 112 (4), 98 (100); 2-methylbutanoyl pyrrolidine, 155 (M^+, 36), 140 (38), 127 (100), 112 (8), 98 (94); 3-methylbutanoyl pyrrolidine, 155 (M^+, 29), 140 (6), 113 (100), 98 (21). Wax diesters IIb (0.5 mg) were saponified with 0.1 ml 2.5 M KOH in 85% ethanol at 90 C for one hr. The free fatty acids were converted to the 2-nitrophenylhydrazides by treatment with 2-nitrophenylhydrazine hydrochloride (2-NPH · HCl) in the presence of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (1-EDC · HCl) as a coupling agent (16).

Lipase hydrolysis. Wax diesters IIa (6 mg/2 ml) were emulsified, and then hydrolyzed with 25 μl of lipase solution (*Rhizopus arrhizus,* 10 mg/ml, Boehringer-Mannheim, Mannheim, FRG) at 39 C, as described by Schmid and Schmid (17). After 1.5 hr, the products were extracted and analyzed by TLC using hexane/diethyl ether/acetic acid (80:20:1, v/v/v), as described (17). The fractionation was carried out by TLC using benzene/ethyl acetate (5:2, v/v). Unhydrolyzed diesters ($R_f \sim 0.98$), 2-acyl diols ($R_f \sim 0.8$), and free fatty acids ($R_f \sim 0.5$) were isolated. During this process, free diols ($R_f \sim 0.2$) were not detected. Free fatty acids or 2-acyldiols were treated with benzene/5% HCl in methanol (1:2, v/v) at 100 C for two hr. Methyl esters from 2-acyl diols were purified by TLC in hexane/benzene (4:6, v/v) before analysis by GC.

Dieters IIb (6.0 mg) also were hydrolyzed with 50 μl of lipase. After four hr, an aliquot of the reaction mixture was treated with the 2-NPH and 1-EDC solution, as described by Miwa and Yamamoto (18), and the free fatty acids were converted to 2-nitrophenylhydrazides for high-performance liquid chromatography (HPLC) analyses. The hydrolysis products were extracted from the remainder and fractionated by TLC in the same manner as previously described. No free fatty acids were detected by TLC. The 2-acyldiols or unhydrolyzed diesters were hydrolyzed with alkali, and the constituted fatty acids were converted to methyl esters or 2-nitrophenylhydrazides.

GC. GC analyses were performed with a Shimadzu GC 9A gas chromatograph equipped with a flame-ionization detector and a 30 m × 0.25 mm DB-5 column (J & W Scientific Inc., Folsom, CA). Helium at 1.3 kg/cm² pressure was used as the carrier gas. The column was programmed at 4 C/min at 200–320 C for the fatty acid methyl esters, at 250–320 C for the fatty acid pyrrolidide, at 220–300 C for the isopropylidene derivatives of alkanediols, and at 300–320 C for the TMS-derivatives of sterols. For measuring the equivalent chain lengths (ECL), appropriate isothermal conditions were used. The sample was introduced by the split technique with a 50:1 split ratio.

GC–MS and MS. EI–GC–MS analyses were performed with a JEOL DX-300 mass spectrometer interfaced to a GCG06 gas chromatograph and to a JMA–5000 mass data system. The column was a 30 m × 0.25 mm DB-5 capillary terminating inside the ion source. Operating conditions for the column were the same as mentioned above. The split ratio was 10:1. Mass spectra were obtained at a scan speed of 1 s decade^{-1}, an accelerating voltage of 70 eV and an ion source temperature of 250 C.

For analyses of the intact diesters IIb, the compounds were introduced by direct insertion probe or by GC inlet via a glass jet separator. The CBP1 column (4 m × 0.53 mm, Shimadzu Co. Ltd., Kyoto, Japan) was programmed at 270–320 C at 8 C/min. The injector and jet separator were held at 300 C. The ion source temperatures

were 200 C for the direct inlet system and 270 C for the GC inlet system. CI spectra were obtained at 250 eV.

HPLC. HPLC analyses were carried out using a Shimadzu Model LC-3A liquid chromatograph. The column was Zorbax ODS (5 μm, 4.6 mm × 25 cm, Du Pont Co., Wilmington, DE). The eluents were acetonitrile/water (40:60, v/v) for short-chain (C_2–C_6) 2-nitrophenylhydrazide derivatives and (95:5, v/v) for the long-chain (C_{14}–C_{20}) derivatives; they were adjusted to pH 4.5 with 0.1 N HCl, as described by Miwa and Yamamoto (16,18). The column effluent was monitored at 390 nm at a flow rate of 1.2 ml/min.

RESULTS

Separation of lipid classes. TLC analysis showed the presence of four major neutral lipid constituents. They were ultimately identified as sterol esters, free cholesterols and two types (IIa and IIb) of Type II wax diesters (Fig. 1). One (IIa, $R_f \sim 0.57$) migrated like a Type II diester (diacyl alkanediols) from the rat skin (4) on TLC, and the other (IIb) showed a lower mobility ($R_f \sim 0.48$). The contents, based on their weight, were 38% sterol esters, 17% IIa, 40% IIb and 4% free cholesterols.

Sterol esters. After magnesium hydroxide TLC, the sterol ester fraction showed one major spot, corresponding to the sterol esters, and one minor spot, corresponding to the wax monoester standard. However, no detailed examination of the latter component was carried out, because the content was extremely low. After saponification, followed by methylation, the purified sterol esters showed two spots on TLC due to fatty acid methyl esters and sterols. GC and GC–MS of the TMS-derivatives of the sterol fraction yielded only one peak coinciding with the cholesterol-TMS standard.

The fatty acid methyl esters were examined by argentation-TLC and by capillary-GC, before and after hydrogenation with H_2/Pd-$CaCO_3$. The saturated fatty acids were grouped into three homologous series according to their fractional chain length (FCL) (ECL − carbon number) values. The carbon skeletal types of the series having FCL values of 0.00, 0.64 and 0.74 were assigned to straight, iso and anteiso, respectively, from GC–MS analyses of the pyrrolidides (shorter chains than C_{27}) and the methyl esters. The chain lengths of the fatty acids showed a wide distribution, ranging from C_{14}–C_{34}, with a maximum around C_{20}–C_{21} (Table 1).

The content of unsaturated fatty acids was extremely low (total 5.4%). They were predominantly a monoenoic series, having C_{18}–C_{34} chains. Hydrogenation with H_2/Pd-$CaCO_3$ showed that 99% of them had straight chains. Determination of the double-bond position for each peak was not carried out, because their amounts were low and pyrrolidides longer than C_{28} were unsuitable for GC (or GC–MS) analysis. However, Lemiuex-von Rudloff oxidation of the total unsaturated fatty acids produced heptanoic and nonanoic acids, and a series of odd-chain C_{21}–C_{27} dicarboxylic acids (predominantly C_{23} and C_{25}), showing that most of these monoenoic acids belonged to the n-7 or the n-9 series.

Wax diesters IIa. After saponification and methylation, diesters IIa gave two spots on TLC, due to fatty acid methyl esters and a polar component.

The polar component was converted to the isopropylidene derivative, showing the presence of a vicinal-diol (-CH(OH)-CH(OH)-) group. Only one spot, corresponding to saturated diol isopropylidene derivatives, was detected by argentation-TLC. When the mass spectra of the free diols and the corresponding isopropylidene derivatives were compared, the characteristic ions due to cleavage of a bond between the two hydroxy groups on

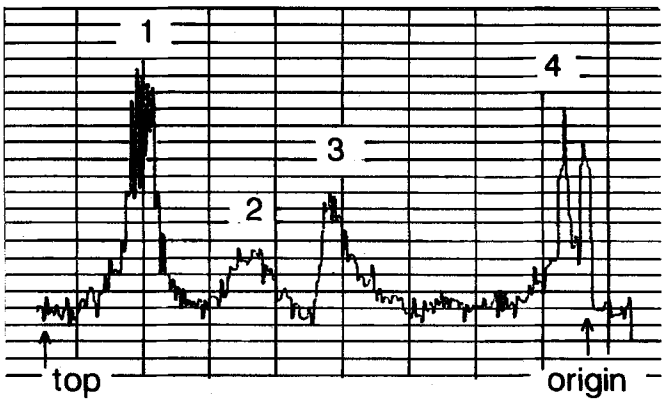

FIG. 1. Densitometer scan of a thin-layer chromatogram of monkey skin-surface lipids. The chromatogram was developed with hexane/benzene (2:3), sprayed with 50% sulfuric acid and charred at 220 C. Numbers above the chromatogram indicate: 1, sterol esters; 2, wax diesters IIa; 3, wax diesters IIb; 4, cholesterol.

[b-n]ECL of each peaks is as follows: b, 17.72; c, 17.77; d, 17.82; e, 21.78; f, 21.85; g, 23.88; h, 27.92; i, 29.86; j, 29.93; k, 31.84; l, 31.90; m, 33.79; n, 33.86.

[o]$C_{18:2}$.

the spectrum of the free diols were observed at $[M - 31]^+$, but not at $[M - 45]^+$. This result indicates that the two hydroxy groups were located at positions 1 and 2 of the alkanediols ($R-CH(OH)-CH_2(OH)$). Furthermore, the diols were chemically cleaved by Lemiuex-von Rudloff oxidation and the resulting fatty acids were esterified. GC analysis of these methyl esters showed a chain-length distribution pattern similar to that of the original diols, but with the corresponding peaks containing one less carbon atom, thus confirming the 1,2-structure in the diols. In addition, GC–MS analysis of these methyl esters indicated that the alkyl-chain structures of the original diols were straight, iso and anteiso. The diols contained 74.8% branched and 25.2% straight components, ranging from C_{16}-C_{26}, with a maximum around C_{20}-C_{22} (Table 2).

The fatty acids consisted of straight-, iso- and anteiso-chain components, ranging from C_{14}-C_{34} (Table 3). Of the straight-chain components, the largest peak was C_{16}. In contrast, branched-chain components gave a two-cluster profile, with a maxima around C_{16}-C_{17} and C_{21}-C_{22}.

The result of the lipase hydrolysis showed nonrandom distribution of the fatty acids between positions 1 and 2 of the 1,2-diols (Table 3). Although the straight-chain C_{16} species was the most abundant constituent in both positions, the shorter chain acids ($<C_{20}$) were prevalent in position 1 and the longer chain acids ($\geq C_{20}$) were prevalent in position 2. In particular, this tendency was observed in the branched-chain components.

Wax diesters IIb. Saponification, followed by methylation of diesters IIb, yielded fatty acid methyl esters and diols. The composition of the diols from this fraction was similar to that from diesters IIa. The long-chain fatty acids had the same types of carbon skeletons as those from IIa, and the straight-chain components were more abundant (69.9%) than those from diesters IIa. The carbon chain lengths (C_{14}-C_{26}) were shorter than those from diesters IIa (Table 4).

Dog diesters, which had a lower mobility than Type II diesters, contained isovaleric acid, together with long-chain fatty acids (6). The diesters IIb were examined for the presence of short-chain fatty acids by conversion to their pyrrolidides and 2-nitrophenylhydrazides. Because saponified samples can be derivatized into hydrazides without extraction (16), short-chain acids can be detected quantitatively as their hydrazides. HPLC analysis of the hydrazides from the hydrolysate showed one major peak, corresponding to isovaleric acid hydrazide, and two minor peaks, corresponding to 2-methylbutyric acid and isobutyric acid hydrazides (Fig. 2A). These short-chain acids were identified by GC–MS as their pyrrolidides (Fig. 2B), in comparison with authentic samples.

Figure 3 shows mass spectra for the intact diesters IIb, measured via direct probe under CI conditions. A cluster of ions, m/z 623–679, were observed in isobutane CI (Fig. 3A), and m/z 640–696, in ammonia CI (Fig. 3B). They correspond to $[M+H]^+$ and $[M+NH_4]^+$, respectively, if one molecule of the diesters IIb contains equimolar of short- and long-chain fatty acids and the molecular weight is calculated on the basis of the chain-length composition of the constituents.

Lipase hydrolysis of IIb yielded exclusively short-chain (C_4 and C_5) acids; upon HPLC of the hydrazides of the lipase hydrolysate, only short-chain (C_4-C_5) acids were detected (Table 4). On the contrary, the 2-acyldiol fraction contained exclusively long-chain acids with compositions consistent with those of the long-chain acids from the original IIb. Therefore, it appears that position 1 of 1,2-diols was esterified with one molecule of a short-chain (C_4-C_5) fatty acid, and that position 2 was esterified with one molecule of a long-chain (C_{14}-C_{26}) fatty acid. However, lipase hydrolysis yielded a low proportion of isovaleric acid. Since lipase hydrolysis of IIb was slow and the unhydrolyzed IIb (ca. 70% of the original IIb) contained exclusively isovaleric acids as the short-chain constituent, it is possible that the ester bond of isovaleric acid is resistant to hydrolysis by *Rhizopus arrhizus* lipase. The long-chain fatty acid composition of the unhydrolyzed IIb was identical with that of the original IIb.

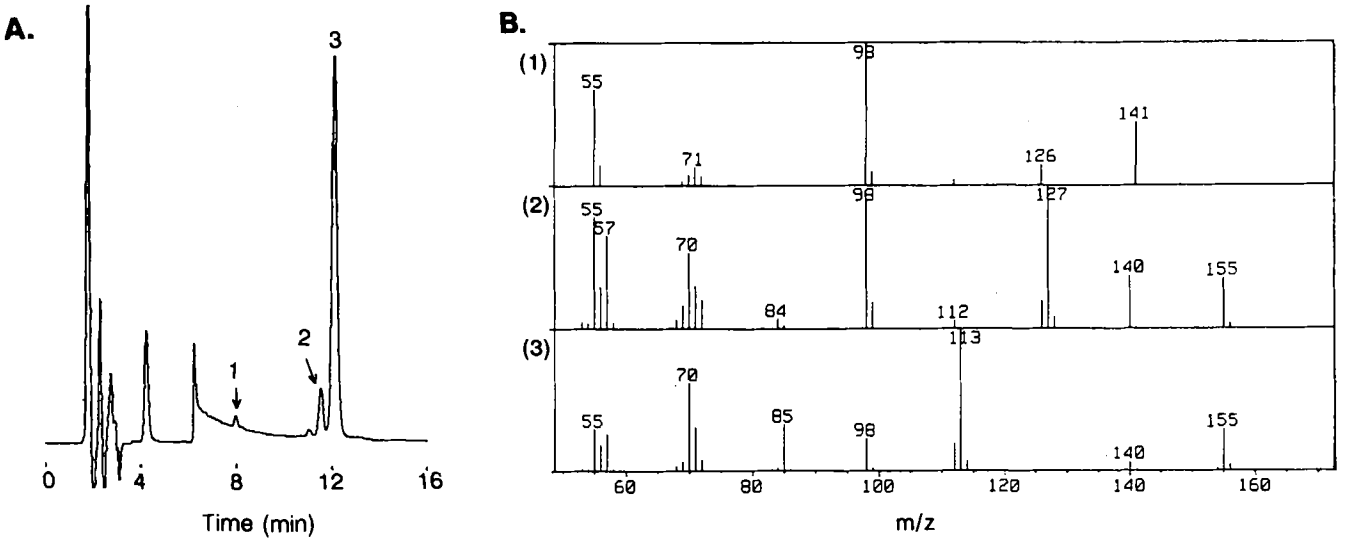

FIG. 2. Short-chain fatty acids of diester IIb. (A) High-performance liquid chromatogram of the 2-nitrophenylhydrazides of the short-chain fatty acids. The peaks 1-3 correspond to isobutyric, 2-methylbutyric and isovaleric acid pyrrolidides, respectively. The other peaks originate from the excess reagents or the reaction byproducts that were observed in a blank run. (B) Mass spectra for the short-chain fatty acid pyrrolidides. Spectra (1)-(3) represent isobutyric, 2-methylbutyric and isovaleric acid pyrrolidides. Each spectrum was identical with that of the standard.

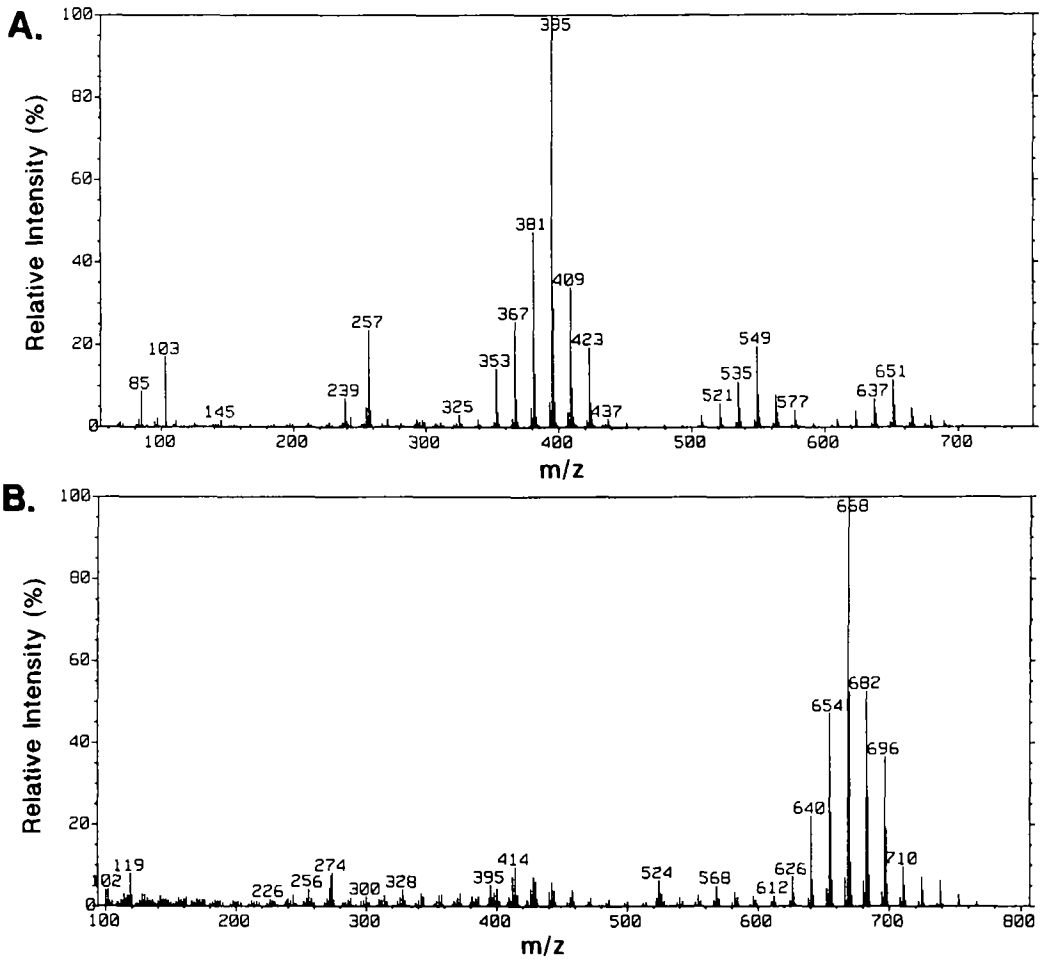

FIG. 3. Mass spectra for intact diesters IIb introduced by direct probe: (A) Isobutane chemical ionization; (B) ammonia chemical ionization.

Furthermore, ammonia CI-GC-MS provided additional evidence to confirm the proposed structure. The spectrum of the largest peak showed that the three diagnostic ions corresponded to $[M+NH_4]^+$ of M+18, $[MH-C_4H_9COOH]^+$ of M − 102, and $[MH-C_{15}H_{31}COOH]^+$ of M − 256 (Fig. 4A).

As shown in Figure 4B, the total ion monitoring (TIC) did not give a complete resolution of the peaks, probably owing to the components having odd carbon numbers and/or branched chains. However, by monitoring the $[M+18]^+$ ions, the diesters were resolved into 12 peaks, because of the carbon numbers. The composition calculated from the peak areas (Table 5) was close to the theoretical values calculated from the components. The average molecular weight based on the peak area was 665, and that on the components was 668.

Mass chromatograms monitoring the $[MH-102]^+$ ions (m/z 507-647) depicted the same pattern as those for the $[M+18]^+$ ions, showing that all peaks had C_5 acid as a major short-chain constituent. Therefore, the $[MH-RCOOH]^+$ ion, that resulted with the loss of the long-chain fatty acid and corresponds to [diol + short-chain acid − 34], can provide the information regarding the diol component. Moreover, compared with the corresponding $[M+18]^+$ ion, the long-chain fatty acid component can be deduced. Table 5 shows the major molecular

TABLE 5

Composition of Diesters IIb Ascertained by GC-MS Under Ammonia CI Condition

M+18 (m/z)	%[a]	Molecular species[b]

species deduced from the monitoring of the $[M+18]^+$ and $[MH-RCOOH]^+$ ions, shown in Figure 4B.

DISCUSSION

Wax diesters are widely distributed in the surface lipids from a variety of animals (2). They are of two types: diesters of hydroxy fatty acids with fatty acids and fatty alcohols (Type I), and diesters of alkanediols with fatty acids (Type II) (4). For primates, Type II diesters were found, by TLC, in the surface lipids of the baboon, and the surface lipids from the chimpanzee contained only sterol esters (2).

The present study showed that the major constituents of the monkey skin-surface lipids were cholesteryl esters, cholesterol and two species of Type II alkanediol diesters. Type IIa migrated like Type II diesters from the rat on TLC, and contained 1,2-alkanediols esterified with two equivalents of long-chain fatty acids; the shorter-chain ($<C_{20}$) fatty acids predominated at position 1 and the longer-chain ($\geqslant C_{20}$) fatty acids predominated at position 2. This distribution pattern for the fatty acids was similar to that for the hamster diol diesters (17), but the 1,2-alkanediols from the hamster diesters, with its major constituent being 15-methyl-1,2-hexadecanediol (17), had shorter chains than those from the monkey. On the contrary, in the mouse diol diesters, although the chain lengths of the constituent 1,2-alkanediols were close to those of the monkey, the shorter-chain acids were found exclusively at position 2 (17). Consequently, although Type II diesters have been found widely in a variety of animals, including the rat (4), mouse (2), guinea pig (5) and hamster (17), there is a pronounced difference between species with regard to the composition of the fatty acids and diols, and in the distribution pattern for the fatty acids.

The other diesters (IIb) contained 1,2-alkanediols esterified with one equivalent of the short-chain (C_4-C_5)

fatty acid at position 1 and one equivalent of the long-chain (C_{14}-C_{26}) acid at position 2. Type II diesters containing one equimolar of isovaleric acid were found in the dog surface lipids. This structure has been assumed on the basis of the quantitative GC analysis of the constituent short- and long-chain fatty acids (6). In the present study, CI-GC-MS analysis of the intact diesters IIb from the monkey surface lipids presented unambiguous evidence supporting the proposed structure. Furthermore, it was shown that CI-GC-MS was useful for the molecular species analysis of diesters IIb.

The unsaturated fatty acids in the human skin-surface lipids had a characteristic feature (10). They contained straight- and branched-chain components having n-10 double bonds, produced by Δ^6-desaturation, that normally does not occur in other animal tissues (10). In contrast, the unsaturated fatty acids from the monkey surface lipids, that were contained only in 1.5–5.4%, were exclusively straight-chain components having n-7 or n-9 double bonds and having a wide range of chain lengths (C_{18}–C_{34}). The monkey sebaceous gland probably did not have the fatty acid desaturase system. It seems probable that the unsaturated fatty acids originated exclusively from the surrounding tissues and were incorporated into the surface lipids directly or after undergoing chain elongation.

Most animals, except for a few species (2,11), have branched-chain fatty acids as a major constituent of the surface lipids, but information regarding the position of the methyl branching has not been fully provided. The present study showed that the monkey surface lipids contained the monobranched-chain fatty acids having iso and anteiso structures. In general, the iso and anteiso fatty acids of odd carbon number, and iso acids of even carbon number are synthesized by fatty acid synthetase (FAS) from the primer of isovaleryl-CoA, 2-methylbutyryl-CoA and isobutyryl-CoA, respectively (10). In contrast to the human surface lipids (19), the monkey lipids did not contain the branched-chain acids with branches located at the even numbered carbon atoms, except the terminal. These acids, having internal methyl branches, are synthesized with methylmalonyl-CoA as a C_2 unit (20). The present study indicates the diversity in the substrate specificity of the FAS in sebaceous glands among species.

The branched-chain fatty acid in both diesters IIa and IIb shows a two-cluster profile, with maxima around C_{16}-C_{17} and C_{21}-C_{22}. Unsaturated fatty acids from diesters IIa show a three-cluster profile, with maxima at C_{18}, C_{22} and C_{33}. It is probable that C_{16}-C_{17} fatty acids, synthesized by FAS, were elongated by one or two chain-elongation systems, as in the bovine meibomian gland (21).

The 1,2-alkanediols in the monkey surface lipids were saturated components having straight- and branched-chain (iso and anteiso) structures. The diversity in the 1,2-alkanediols has been observed among a variety of animals (2,4–6,8,11). Kolattukudy et al. (22) indicated that the 1,2-alkanediols in the sparrow uropygial gland were derived from 2-hydroxy fatty acids by enzymatic reduction. However, the monkey surface lipids did not contain 2-hydroxy fatty acids. Similarly, the dog and mouse surface lipids had Type II diesters, but not Type I diesters containing 2-hydroxy fatty acids, whereas the rat surface lipids had both Types I and II diesters (2). In the former group, synthesized 2-hydroxy fatty acids might be reduced rapidly to the corresponding 1,2-diols.

In addition to isovaleric acid that has been reported as a short-chain component of the dog diesters (6), the current study showed that 2-methylbutyric acid and isobutyric acid were present in the diester IIb in the monkey. This result suggests that these short-chain fatty acids, that are assumed to be abundantly present as primers of fatty acid synthesis in the sebaceous glands, can be incorporated into the diester IIb, but that the enzyme responsible for the incorporation of these short-chain fatty acids has a relatively high specificity for isovaleric acid.

The sterol fraction from the sterol esters, as well as from the free sterols, contained solely cholesterol. The intermediate of cholesterol biosynthesis, such as lathosterol, that was found in the surface lipids of the guinea pig (5) and dog (6), was not detected in the monkey surface lipids.

These results provide detailed evidence regarding the diversity in skin-surface lipids among species, and the occurrence of the constituents.

ACKNOWLEDGMENT

We thank T. Yamazaki for his valuable advice and T. Ochiai for help in collecting surface lipids.

[Received March 7, 1988; Revision accepted May 25, 1988]

Integral Lipids of Human Hair

Philip W. Wertz* and **Donald T. Downing**
The Marshall Dermatology Research Laboratories, Department of Dermatology, University of Iowa College of Medicine, Iowa City, Iowa 52242

It has long been recognized that hair is coated with nonpolar lipids originating in the sebaceous glands, and recently it has been shown that hair also contains cholesterol sulfate and small amounts of ceramides, similar to those found in the keratinized portion of the epidermis. In the present study, it is demonstrated that significant amounts of several additional lipids are tightly associated with hair in such a way as to be highly resistant to solvent extraction.

These integral hair lipids included cholesterol sulfate (3.3 mg/g of extracted hair), cholesterol (0.6 mg/g), fatty alcohols (0.2 mg/g) and free fatty acids (4.3 mg/g). The principal fatty acid, comprising 40% of the total fatty acids, was identified as 18-methyl-eicosanoic acid by cochromatography with authentic standard on gas-liquid chromatography (GLC) and by mass spectrometry (MS).

***Lipids 23,* 878–881 (1988).**

Human scalp hairs consist of a central medulla of loosely connected keratinized cells surrounded by more-tightly-packed, 80–100 μ-long cortical cells with 6 to 10 outer layers of flattened, rectangular cuticle cells (1). Late in the sequence of differentiative events leading to formation of the mature cuticle and cortex cells, a multilayered material is deposited between the bounding membranes of the individual cells to form membrane complexes (2–4). Although it is chemically undefined, the intercellular material (3,4) has been referred to as a cement substance (3). The chemical nature of the cell periphery in hair, like that of the cornified epidermal cell, also has been somewhat of a puzzle because hair does not contain the usual membrane-forming phospholipids (5).

Associated with the hair follicles are sebaceous glands that provide abundant nonpolar lipids to the skin surface and the hair (6,7). While these sebaceous lipids may serve to lubricate and waterproof, they are not membrane-forming lipids. Recently, it has been demonstrated that hair from several species of mammals contains cholesterol sulfate and several series of ceramides similar to those found in the keratinized portion of the epidermis, or stratum corneum, and it has been postulated that these lipids are of structural significance in hair (5). However, the amounts of these polar lipids were low, and it was uncertain as to whether they provided enough material to account for the observed membranes.

More recently, the occurrence of significant amounts of covalently bound lipid in the stratum corneum has been demonstrated (8). This material consists mainly of an unusual ω-hydroxyacylsphingosine ester-linked to a cross-linked protein envelope to form what appears like a plasma membrane (8,9). It is actually an integral part of the cell envelope and can be removed from the cell surface only after saponification (8,9).

The purpose of the present investigation was to determine whether human hair, a keratinized epidermal appendage, contains covalently bound lipids as found in the stratum corneum. To answer this question, one pooled sample of hair clippings from several people and samples from three individuals were obtained. After extensive extraction with chloroform/methanol mixtures to remove all of the extractable lipids, the hair samples were saponified and reextracted. Additional lipids recovered in this way included major amounts of cholesterol sulfate (3.3 mg/g extracted hair) and free fatty acids (4.3 mg/g) and small amounts of cholesterol, fatty alcohol and several unidentified components. The major fatty acid, comprising 40% of the total fatty acids, proved to be 18-methyl-eicosanoic acid.

MATERIALS AND METHODS

Preparation of delipidized hair. Samples of human hair were repeatedly rinsed with distilled water. They were then extracted, first with methanol and then with chloroform/methanol 2:1, 1:1 and 1:2, for 2 hr each, at room temperature. Each of the chloroform/methanol extractions was then repeated for 24 hr. Finally, the hair was extracted with chloroform in a Soxhlet extractor, continuously for 24 hr. The extracted hair was thoroughly dried en vacuo and weighed. One large sample (100 g) of pooled hair from several individuals and smaller (3.5–8.9 g) hair samples from three individuals were processed by this method.

Saponification and recovery of constitutive lipids. Extracted hair samples (3–5 g after extraction) were saponified by heating for 2 hr at 60 C in 200 ml 1 M NaOH in 90% methanol. The reaction was cooled to room temperature, and 88 ml of water and 360 ml of chloroform were added. The mixture was shaken and the phases were separated in a separatory funnel. The lower chloroform layer was transferred to a flask, and the upper phase and hair residue were acidified by addition of 50 ml of 6 N HCl. The acidified upper phase was extracted with an additional 360 ml of chloroform, and the combined chloroform extracts were taken to dryness with a rotary evaporator. The dried residue was dissolved in 5 ml chloroform:methanol, 2:1, and washed with 1 ml of 2 M KCl containing 0.1 M HCl. The lower chloroform phase then was filtered through a solvent-resistant, 0.5-micron millipore filter, and the filtrate was collected and taken to dryness in a tared glass tube. The wt of the dried lipid was determined, and chloroform:methanol was added to produce a solution containing 20 mg lipid per ml.

Thin-layer chromatography (TLC). Analytical TLC was done on 0.25-mm layers of Silica Gel G (E.M. Reagents, Darmstadt, West Germany) on 20 × 20 cm glass plates. Samples were applied 2 cm from the bottom

Abbreviations: ECL, equivalent chain lengths; GLC, gas-liquid chromatography; MS, mass spectrometry; TLC, thin-layer chromatography.

edge of the plate, which was developed first to 9 cm with chloroform/methanol/acetic acid/water (40:10:1:1), and then to 20 cm with hexane/ether/acetic acid (70:30:1). After drying, the plate was sprayed with 50% sulfuric acid and charred by slowly heating to 220 C. The charred chromatograms were quantitated by photodensitometry (10) with a Shimadzu model CS-930 photodensitometer. Known amounts of stearic acid, stearyl alcohol, cholesterol and cholesterol sulfate were used as standards.

Fatty acids, fatty alcohols and the sterol fraction were isolated by preparative TLC on 0.5-mm Silica Gel H (E.M. Reagents) using a mobile phase of hexane/ether/acetic acid (70:30:1). Cholesterol sulfate was isolated using chloroform/methanol/acetic acid/water (40:10:1:1) as the mobile phase.

The isolated fractions, as well as the solvolysis product derived from cholesterol sulfate, were checked for purity by TLC with solvent systems of hexane/ether/acetic acid (70:30:1), chloroform/methanol/acetic acid (190:9:1), chloroform/methanol/water (40:10:1) and chloroform/methanol/acetic acid/water (40:10:1:1). Each fraction was judged to be chromatographically pure.

Acetylated sterols, acetylated fatty alcohols and fatty acid methyl esters were purified by preparative TLC using a mobile phase of toluene.

Chemical procedures. The isolated fatty acid fraction was converted to methyl esters by treatment with 10% BCl_3 in methanol at 50 C for 1 hr. The reaction mixture was dried under nitrogen.

Cholesterol sulfate was solvolyzed overnight by treatment with 10% BCl_3 in methanol at 55 C. The sample was dried under nitrogen.

The free sterol, fatty alcohol and the sterol obtained after solvolysis of cholesterol sulfate were acetylated by treatment with acetic anhydride in pyridine at room temperature for 2 hr. Excess reagents were removed by evaporation under a gentle stream of nitrogen.

Gas-liquid chromatography (GLC). The fatty acid methyl esters were examined by GLC on a 50 m CP-SIL 88 quartz capillary column (Chrompack, Inc., Bridgewater, NJ). An initial temperature of 160 C was maintained for 5 min, after which the temperature was increased linearly at a rate of 5 C/min, until 220 C was reached. The final temperature was maintained until no further peaks eluted. The fatty acid methyl esters also were examined isothermally at 160 C and 175 C on the CP-SIL 88 column, as well as at 200 C on a nonpolar 25-m BP-1 quartz capillary column (Scientific Glass Engineering, Inc., Austin, TX).

Standard fatty acid methyl ester mixtures included 16:0, 18:0, 18:1, 18:2, 18:3, 20:0 (15A, NuChek Prep, Elysian, MN); 14:0, 16:0, 16:1, 18:0, 18:1, 18:2, 18:3 (CE1-62, NuChek Prep); 20:0, 20:1, 20:4, 22:1, 22:6 (L-209, Applied Science, State College, PA); and fatty acids isolated from wool wax (11).

GLC of fractions isolated by argentation-TLC was used to confirm the identification of saturated and monoenoic fatty acid methyl esters.

The acetylated sterols derived from both the free sterol fraction and the sterol sulfate fraction were examined by GLC with the CP-SIL 88 column at 220 C and on BP-1 at 290 C. Authentic cholesterol acetate and cholestanol acetate were used as standards.

The fatty alcohol acetates also were examined by GLC with the CP-SIL 88 column, both isothermally at 160 C and with the temperature program described above. Standard fatty alcohol acetates included C14:0, C16:0, C18:0 and C20:0.

Mass spectrometry. Fatty acid methyl esters were separated on a 25-m CP-SIL 5 quartz capillary column operated with a temperature program, starting at 150 C and increasing 5 C/min, until a final temperature of 250 C was attained. Mass spectra were recorded with a Nermag R 10-10 C mass spectrometer with an ionizing voltage of 70 eV. A range of mass/charge from 40 through 600 was examined.

RESULTS

Composition of constitutive hair lipids. A typical densitometer tracing of a thin-layer chromatogram of the lipids released by saponification of previously extracted hair is presented as Figure 1. As described below, the most prominent components were identified as free fatty acids and cholesterol sulfate, and minor components included cholesterol and fatty alcohols. Some lipid material appearing between R_f 0.2–0.4 was not identified and variable amounts of origin material not thought to be lipid were sometimes present. The quantitative results of such TLC analyses are summarized in Table 1.

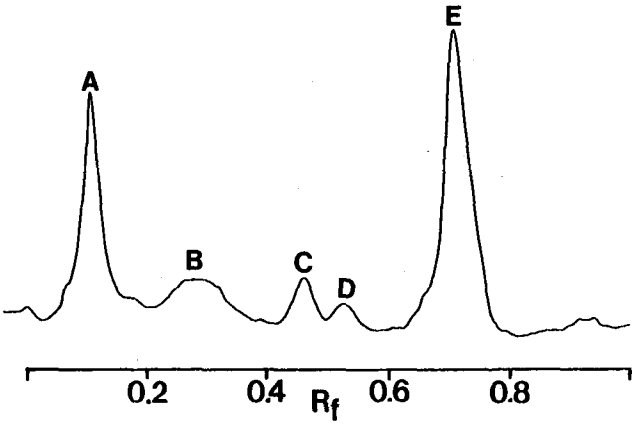

FIG. 1. Densitometer tracing of a thin-layer chromatogram of the constitutive lipids of hair. The chromatogram was developed to R_f 0.30 with chloroform/methanol/water/acetic acid (40:10:1:1) and then to the top with hexane/ether/acetic acid (70:30:1). The charred chromatogram was scanned with a Shimadzu model CS-930 photodensitometer. Peak identification: A, cholesterol sulfate; B, unidentified; C, cholesterol; D, fatty alcohols; E, fatty acids.

TABLE 1

Constitutive Lipids of Human Hair

	Mg lipid per g extracted hair			
Sample	Fatty acid	Cholesterol sulfate	Cholesterol	Fatty alcohol
A	4.7	3.8	0.7	0.1
B	4.2	3.2	0.4	0.2
C	3.2	1.8	0.5	0.1
Pool	5.2	4.2	0.6	0.3
Mean	4.3	3.3	0.6	0.2
SD	0.7	0.9	0.1	0.1

Weights of lipid were estimated by quantitative TLC.

Identification of cholesterol sulfate. The identification of cholesterol sulfate was based on its chromatographic and chemical properties. The isolated material behaved like authentic cholesterol sulfate in terms of both its mobility on TLC in several solvent systems and the pink-violet color produced on heating with sulfuric acid prior to charring. Also, the products produced by hydrolysis and hydrolysis plus acetylation of the isolated lipid behaved during TLC and charring like authentic cholesterol and cholesterol acetate respectively. Finally, the acetylated product gave rise to a single major (96.6% of the total) peak when examined by GLC with either a polar (CP-SIL 88) or nonpolar (BP-1) column. This major component comigrated with authentic cholesterol acetate. Several minor components were not identified.

Identification of free sterol. The isolated free sterol was identified as cholesterol by essentially the same criteria used to identify the sterol released by solvolysis of the sterol sulfate fraction. GLC of the sterol acetate gave one major peak (96.9%) that cochromatographed with cholesterol acetate on both the polar and the nonpolar columns.

Identification of fatty alcohols. The fatty alcohols had the same mobility as authentic fatty alcohols on TLC with mobile phases of hexane/ether/acetic acid (70:30:1) and chloroform/methanol/acetic acid (190:9:1). Like the free sterol, acetylation yielded a single less polar product that migrated on TLC like authentic fatty alcohol acetate.

Examination by GLC revealed a complex mixture. Although the major components accounting for 63.3% of the total were identified as members of the straight-chain saturated series by comparison with standards and construction of plots of carbon number vs log retention time from isothermal chromatograms, the remainder consisted of components with fractional equivalent chain lengths (ECL). The fatty alcohol acetates were identified as either saturated (86%) or unsaturated (14%) after fractionation of the acetates on silver nitrate-impregnated silicic acid. This information is summarized in Table 2.

Identification of fatty acids. The fatty acids were converted to methyl esters and examined by GLC and by GLC-mass spectrometry (MS). A representative chromatogram is shown in Figure 2, and the composition is summarized in Table 3.

The major fatty acid was identified as 18-methyl-eicosanoic acid on the basis of its GLC behavior and its mass spectrum, presented as Figure 3. ECL values of 20.74 and 20.67 were determined from isothermal chromatograms obtained with CP-SIL 88 and BP-1, respectively. A value of 20.72 would be expected for 18-methyl-eicosanoic acid (12). Furthermore, on both the polar and nonpolar columns, the fatty acid methyl ester in question cochromatographed with the C-21 anteiso methyl-branched fatty acid methyl ester derived from wool wax (11).

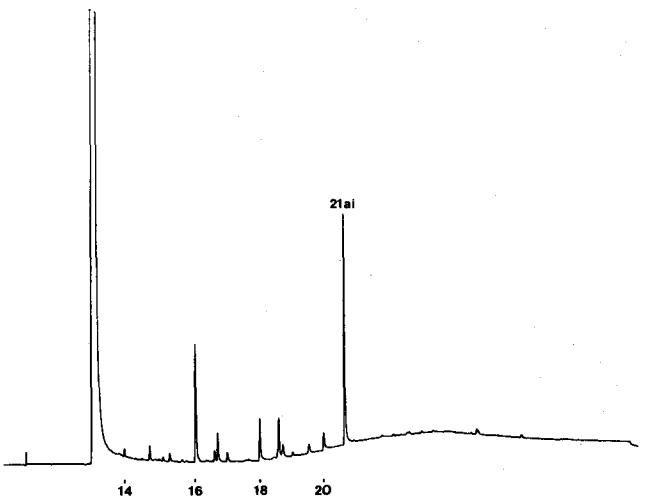

FIG. 2. Gas-liquid chromatogram of methyl esters prepared from the fatty acid fraction of hair constitutive lipids. The methyl esters were chromatographed on a CP-SIL 88 quartz capillary column with a temperature program as explained under Materials and Methods. The straight-chained saturated species and the 21-carbon anteiso-branched component are indicated.

Several saturated species indicated by br, appear to be branched.

FIG. 3. Electron impact mass spectrum of methyl-18-methyl-eicosanoate. The molecular ion (M) and other significant fragments are indicated.

The identification was confirmed by the mass spectrum (Fig. 2). The spectrum included a molecular ion at m/e 340, consistent with the formula $C_{22}H_{44}O_2$. The spectrum also included a number of features characteristic of fatty acid methyl esters. These included a base peak at m/e 74, and prominent fragments at m/e 87 and 143. Also, characteristic chain-degradation fragments (C3–C8) were present. Of particular significance are the peaks at M-29 and M-31 (13). M-31 is present in all methyl esters and is thought to represent formation of an acylium ion. The M-29 represents loss of ethyl, and is more prominent than M-31 only in cases of anteiso methyl branching. In the present spectra, M-29/M-31 = 2.2.

DISCUSSION

The present results demonstrate that human scalp hair contains constitutive lipids that are not removable by exhaustive extraction with chloroform/methanol mixtures. These lipids, that together represent 0.7–1.3% of the weight of hair, were recovered only after treatment with alkaline methanol. The major lipid class recovered in this way is fatty acid, which is present at a level of 4.3 mg per g of hair. This fatty acid is likely attached to the cell surface through ester or thioester linkages. Cholesterol sulfate is the second most abundant of the hair constitutive lipids and constitutes 3.3 mg of each g of hair. The nature of the strong interaction of this lipid with hair is uncertain; however, it may be present in the form of an insoluble salt rather than a covalent adduct. Cholesterol and fatty alcohol, both relatively minor constitutive lipids, could be esterified to acidic groups at the cell surface.

Recently, covalently bound lipids have been identified in mammalian epidermis (8,9,14). In contrast to the present findings, the major bound lipid found in the epidermis is an unusual ceramide consisting of a long-chain (30–34 carbon) ω-hydroxy acid in amide linkage with sphingosine. This is the predominant bound lipid in the stratum corneum, where it is thought to comprise a lipid envelope on the exterior of each keratinized cell. By analogy, the constitutive lipids of hair also may be bound to the cell surface to make a pliable but environmentally resistant lipid coat or envelope.

Perhaps the most striking result of the present investigation was the finding that 40% of the fatty acid bound to hair is 18-methyl-eicosanoic acid. This anteiso methyl-branched fatty acid is present in small amounts in human sebum and vernix caseosa (15) and in wool wax (11), but is not abundant in any source other than hair. Shorter 13–17 carbon anteiso fatty acids are major lipid components of some microorganisms (16–18), where it is thought that they are used, instead of unsaturated fatty acids, to make fluid membranes. It seems feasible that the 21-carbon anteiso fatty acid in hair also may serve to fluidize membranes. In this capacity, the branched-chain acid would have an advantage over unsaturated fatty acids in being resistant to oxidative damage on long exposure to the atmosphere.

Fatty Acid Metabolism in Renal Ischemia

E. Ruidera[a], C.E. Irazu[b], P.R. Rajagopalan[a], J.K. Orak[b], C.T. Fitts[a] and I. Singh[b,*]
[b]Pediatrics and [a]Surgery, Room 323, Clinical Sciences Building, Medical University of South Carolina, Charleston, SC 29425

The increase in free fatty acids in the ischemic tissue is a consistent observation and these free fatty acids are considered to play a role in the cellular toxicity. To elucidate the cause of higher levels of free fatty acids in ischemic tissue, we examined the catabolism of fatty acids. The β-oxidation of lignoceric (24:0), palmitic (16:0) and octanoic (8:0) acids and the peroxidation of fatty acids were measured at different times of renal ischemia in whole kidney homogenate. The enzymatic activities for the oxidation of fatty acids decreased with the increase in ischemia time. However, the lipid peroxide levels increased 2.5-fold of control with ischemic injury. Sixty min of ischemia reduced the rate of oxidation of octanoic, palmitic and lignoceric acids by 57, 59 and 69%, respectively. Almost similar loss of fatty acid oxidation activity was observed in the peroxisomes and mitochondria. These data suggest that loss of mitochondrial and peroxisomal fatty acid β-oxidation enzyme activities from ischemic injury may be one of the factors responsible for the higher levels of free fatty acids. *Lipids 23,* 882–884 (1988)

Renal ischemia is of clinical interest because of its role in acute renal failure (1). Following ischemia, changes that occur in the membranes and the toxic effect of metabolic products lead to the activation of calcium-dependent catabolic enzymes (2). There are numerous intracellular events taking place during the initial ischemic period, such as influx and efflux of ions, nuclear chromatin denaturation, swelling or shrinking of intracellular compartments and changes in lipid metabolism. These injurious events lead to irreversible cell injury and cell death within a relatively short period of time (3). Sixty min of ischemia in the rat kidney produces irreversible ischemic damage correlated with excessive degradation of phosphatidylcholine and an increase in free fatty acids, lysophosphatidylcholine and diacylglycerol (4). These changes in membrane lipids and/or the fatty acid toxicity may result in alterations in the membrane enzyme activities that may, in turn, lead to loss of organelle functions and cell damage. This study reports that ischemic injury leads to loss of the fatty acid β-oxidation activities of both the mitochondria and peroxisomes.

MATERIALS AND METHODS

Materials. [1-^{14}C]Palmitic acid (58.7 mCi/mmol) was purchased from New England Nuclear (Boston, MA). [1-^{14}C]Lignoceric acid (53.8 mCi/mmol) was synthesized in our laboratory (5). Malate, FAD, NAD, L-carnitine and α-cyclodextrin were purchased from Sigma Chemical Co. (St. Louis, MO). ATP and CoASH were obtained from PL Biochemicals (Milwaukee, WI). Thiobarbituric acid, sodium dodecyl sulfate and tetraethoxypropane were products of Sigma Chemical Co. (St. Louis, MO).

Operative procedure. Male Sprague-Dawley rats, weighing 250 g, were obtained from the Charles River Breeding Laboratories (Wilmington, MA). The rats were anesthetized with sodium pentobarbital (50 mg/kg/rat). Heparin (250 units) was injected into the left femoral vein to prevent coagulation. Under clean, but not sterile conditions, the abdomen was opened through a midline incision. The left kidney was carefully mobilized and the renal vessels were ligated with 40 silk suture. The abdomen was closed with running suture. At 15, 30, 60, 90, 120 and 180 min, the abdomen was reopened, both kidneys were removed and immediately placed in ice-cold 0.25 M sucrose in 10 mM MOPS (3-(N-morpholino)propane sulfonic acid) buffer, pH 7.4. The kidneys were individually homogenized in 20 ml of the same solution using a glass-teflon homogenizer. The mitochondria from control and ischemic kidney were 85–90% intact as determined by glutamate dehydrogenase assay in the presence and absence of Triton X-100 (6). Fractions of whole kidney homogenate were used for different assays. The right kidney served as the nonischemic control in all cases.

Fatty acid oxidation to acetate. Enzyme activity for the oxidation of [1-^{14}C]labeled fatty acids to acetate (water soluble products) was measured with modification of the previous procedure (7). The reaction mixture (0.5 ml) contained 12 μM [1-^{14}C]labeled fatty acid coated in Celite, 20 mM MOPS buffer (pH 7.8), 30 mM KCl, 8 mM ATP, 0.25 mM NAD, 0.17 mM FAD, 2.5 mM L-carnitine, 0.08 mM CoASH and 1 mg α-cyclodextrin. The reaction mixture was incubated in a shaking water bath at 37 C and started by addition of 100 μl of whole kidney homogenate (500–800 μg of protein). It was stopped 30 min later with 1.25 ml of 1 M potassium hydroxide. The supernatant fraction was transferred to another tube, incubated at 60 C for 1 hr and partitioned by the procedure of Folch et al. (8), after neutralization with acid. The radioactivity in the upper layer was measured and the amount of radioactivity is an index of the [1-^{14}C]labeled fatty acid oxidized to acetate. Protein was measured by the procedure of Lowry et al. (9), using bovine serum albumin as standard.

Lipid peroxidation. Lipid peroxidation was measured using a slight modification of the thiobarbituric acid (TBA) method (10). The reaction mixture contained 0.25 ml of whole kidney homogenate (1,250–2,000 μg of protein), 0.2 ml of 8.1% sodium dodecyl sulfate, 1 ml of 20% acetic acid (pH 3.5) and 1 ml of 0.8% TBA in water. The mixture was heated at 95 C in an oil bath for 60 min. After cooling in ice-cold water, 2.5 ml of the mixture of n-butanol and pyridine (15:1) were added, vortexed and centrifuged at 4,000 rpm for 10 min. The absorbance of organic layer (upper layer) was measured at 532 nm. The standard used was tetraethoxypropane, as modified by Shlafer and Shepard (11).

RESULTS AND DISCUSSION

Following ischemia, membrane changes appear to play a crucial role determining integrity of the ischemic cell. The accelerated catabolism of phospholipids by the abnormal increase in the activities of intracellular calcium-activated phospholipases in ischemia is associated with membrane dysfunction (12–13). Increase in free fatty acids and decrease in the level of ATP are consistent findings in ischemic injury. We examined the effect of ischemia on the fatty acid catabolism in the kidney.

Fatty acids can be catabolized by α-, β- or ω-oxidation, but β-oxidation is the predominant pathway. At the subcellular level, fatty acids can be β-oxidized in mitochondria and peroxisomes (14–17). Although both β-oxidation systems are functionally similar with respect to degradation of fatty acids by two carbon units per cycle, they are structurally different (16). Predominant oxidation of short-chain ($< C_{10}$) fatty acids is in mitochondria (15) and of very-long-chain fatty acids (lignoceric acid, C_{24}) is in peroxisomes (18,19), whereas long-chain (C_{12}–C_{20}) fatty acids are oxidized both in mitochondria and peroxisomes (14–15). The results shown in Figures 1–3 demonstrate that ischemia leads to a decrease in enzyme activities both in mitochondria (Figs. 1 and 2) and peroxisomes (Fig. 3). Sixty min of ischemia reduced the rate of oxidation of octanoic, palmitic and lignoceric acids by 57, 59 and 69%, respectively. Activation of fatty acids to acyl-CoA derivatives is the prerequisite for the oxidation of fatty acids and ATP is needed for this reaction (20–22). The assay system for the measurement of β-oxidation contained 8 mM of ATP for both control and ischemic tissue, thus, decreased activ-

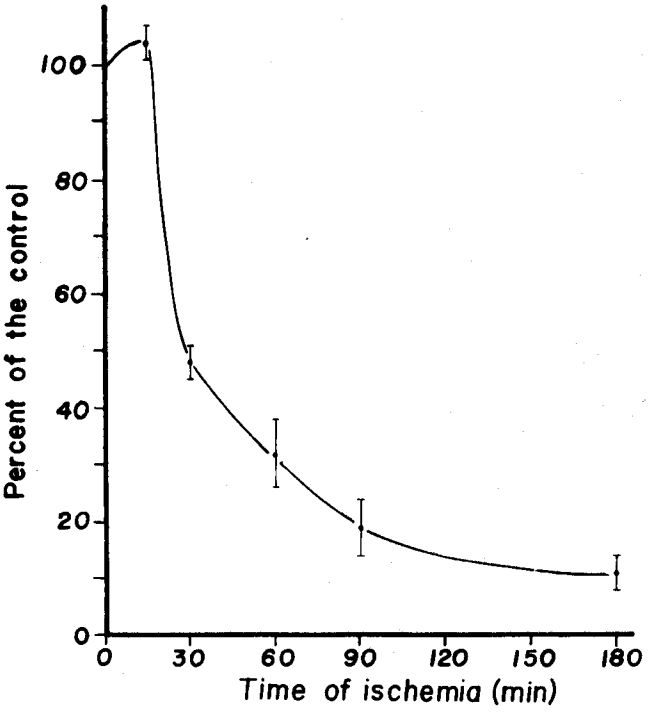

FIG. 3. The rate of β-oxidation of lignoceric acid by kidney homogenate with respect to time of ischemia. The enzyme assays were performed in duplicate as described under Methods. The results are expressed as percentage of the control kidneys ± SD (n = 5).

ity of β-oxidation is not due to the limited amount of ATP present in the ischemic tissue. Moreover, the increase in free fatty acids in ischemic tissue (4) was much smaller than exogenously added radiolabel fatty acid to account for any significant dilution of the substrate. Membrane phospholipids contain high amounts of unsaturated fatty acids, especially arachidonic acid (23,24). Degradation of phospholipids by phospholipase A_2 during ischemic injury contributes to higher levels of unsaturated fatty acids (25). The presence of higher levels of unsaturated fatty acids, when their mitochondrial-peroxisomal catabolism is inhibited (Figs. 1-3), may overwhelm the endoplasmic reticulum capacity for their metabolism and result in their auto-oxidation to lipid peroxides (26). In the ischemic kidney, the levels of lipid peroxides were 250% higher than in the control (Fig. 4). The lipid peroxidation is associated with the generation of lipid-derived intermediate products including hydroperoxides, hydroxyaldehydes and malondialdehyde. These intermediates have been suggested to play an important role in cellular damage (27,28). Normally the cell is provided by enzymes with a protective mechanism (superoxide dismutase, catalase and glutathione oxidase) that detoxifies both reactive oxygen metabolites and lipid-derived intermediates. However, in ischemia, this cellular control seems to be disturbed, because levels of lipid peroxides increases with ischemic injury (Fig. 4).

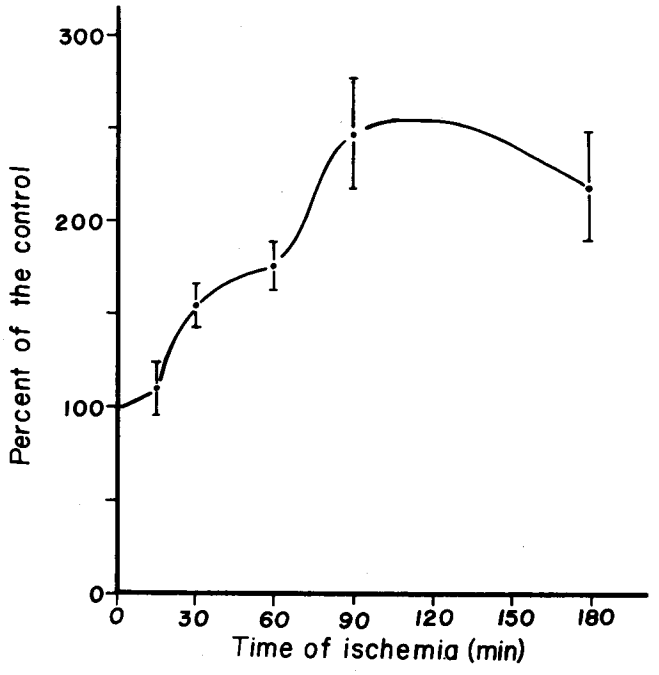

FIG. 4. The levels of lipid peroxides in kidney with respect to time of ischemia. The assays were performed in triplicate as described under Methods. The results are expressed as percentage of the control kidney ± SD, (n = 5).

In summary, the results reported here demonstrate that lipid alterations in membranes and high concentrations of toxic free-fatty acids and lipid peroxides in ischemia may impair the functional properties of subcellular organelles (e.g., mitochondria and peroxisomes).

Linoleic Acid-induced Fatty Acid Changes in Platelet and Aorta of the Rat: Effect of Age and Cholesterol

R. Takahashi* and **D.F. Horrobin**
Efamol Research Institute, P.O. Box 818, Kentville, Nova Scotia, Canada B4N 4H8

The influence of age and cholesterol on polyunsaturated fatty acids (PUFA) levels was studied in young and old male Sprague-Dawley rats. Animals were fed a fat-free diet supplemented with 10% (by wt) safflower oil with or without 1% cholesterol for 8 wk. As a result of cholesterol feeding, proportions of linoleic acid (18:2n-6) and dihomo-γ-linolenic acid (20:3n-6) were increased and and that of arachidonic acid (20:4n-6) was decreased in the liver and platelet phospholipids in 64-wk-old rats, suggesting inhibitory effects of cholesterol on 20:4n-6 synthesis from 18:2n-6. The prominent age-dependent effect on the levels of PUFA was a retention of C-22 n-3 PUFA, accompanied by decreased C-22 n-6 PUFA and increased 20:3n-6 in the liver and platelet phospholipids. Ratio of 20:3n-6/20:4n-6 increased in 64-wk-old rats regardless of dietary cholesterol, suggesting depressed Δ5-desaturase with age. In aorta phospholipids, 20:3n-6 content and 20:3n-6/20:4n-6 ratio increased with cholesterol supplementation, but not with age. These results suggest that changes of PUFA composition of platelet phospholipids with age are closely linked with changes in liver phospholipids. The 20:4n-6 content in both platelet and aorta phospholipids is kept constant, despite other n-6 and n-3 PUFA being affected by age.
Lipids 23, 885–890 (1988).

The metabolism of polyunsaturated fatty acids (PUFA) is affected by dietary and metabolic factors (1,2). It is of interest to study PUFA metabolism at different ages because hormonal and metabolic conditions change with age, and because the incidences of diabetes and hypercholesterolemia, which are known to relate to PUFA metabolism (3,4), increase with age (5,6). While an age-dependent decrease of synthesis of desaturated and elongated metabolites of linoleic acid has been shown during the maturation period in rat testicles (7,8), PUFA status in other tissues is less clear. Arachidonic acid (20:4n-6), dihomo-γ-linolenic acid (20:3n-6) and eicosapentaenoic acid (20:5n-3) are the precursors of antiaggregatory prostaglandins I_2, E_1 and I_3, and the potent aggregatory thromboxane A_2 in vascular tissue and platelets (9–13). These PUFA compete with each other for the cyclooxygenase enzyme (12,13). Furthermore, these PUFA also have a lipid-lowering effect (14,15). Therefore, an altered tissue content of these PUFA could contribute to atherogenesis and thrombotic disorders with increasing age. The purpose of the present study was to examine the n-6 and n-3 PUFA profiles in liver, platelet and aorta phospholipids and adipose tissue lipids in weanling and 56-week-old rats, in response to feeding a diet which contained only an n-6 fatty acid (linoleic acid, 18:2n-6) as a PUFA source. The effect of dietary cholesterol, which has been suggested to inhibit Δ6- and Δ5-desaturase activity on PUFA metabolism in immature rats (16), was also examined.

METHODS

Male weanling (3 wk of age) and 56 wk of age Sprague-Dawley rats were obtained from Canadian Hybrid Farms, Halls Harbour, NS. The animals and their dams, for at least several generations, had been fed a nonpurified diet (Purina Rodent Chow) until receipt in our laboratory. After arrival, the rats were randomly divided into four age-matched groups of seven rats each and were fed for eight wk with a 10% (by wt) safflower oil-supplemented fat-free diet that was ca. 16% energy (Teklad Test Diets, Madison, WI). Half of the 14 animals in each different age group also were given 1% (by wt) cholesterol in the diet. The experimental diet composition and the fatty acid composition of Purina Rodent Chow and safflower oil are shown in Tables 1 and 2.

TABLE 1

Composition of the Experimental Diet

	g/kg
Sucrose	607.0
Casein, vitamin-free	193.0
Safflower oil	100.0
Cellulose	50.0
Mineral mix, AIN-76	35.0
Vitamin mix, AIN-76A	10.0
DL-Methionine	3.0
Choline bitartrate	2.0

TABLE 2

Fatty Acid Composition of Purina Rodent Chow and Safflower Oil

Fatty acid	Purina rodent chow	Safflower oil
14:0	2.0	0.1
16:0	20.9	6.6
16:1	3.4	—
18:0	8.8	2.1
18:1	29.9	11.0
18:2n-6	28.5	80.0
18:3n-3	3.0	—
20:4n-6	0.2	—
20:5n-3	1.8	—
22:5n-3	0.4	—
22:6n-3	1.1	—

Results are shown as mg/100 mg total fatty acids present. Total fat in the rodent chow was 45 g/kg.

All animals were kept in groups of two to four in plastic cages and had free access to food and water. One rat was killed because it had been severely wounded by another rat. After the feeding period, cardiac punctures to collect blood were performed under ether anesthesia. Aorta, liver and epididymal fat were removed, trimmed, rinsed in saline, blotted and frozen at −20 C. Macroscopically, no abnormal finding was observed in any of the animals. Platelets were separated from plasma by centrifugation (12), washed by calcium-free Tyrode's buffer and frozen at −20 C. Liver, platelets and aorta lipids were extracted by the method of Bligh and Dyer (17). The phospholipid fractions were separated by thin layer chromatography (TLC), methylated and subjected to gas liquid chromatography (GLC) for determination of fatty acid composition as previously described (18). A 10% Silar 10 C on Gas Chrom Q column was used with a Hewlett-Packard 5880A machine with automated integration. Identification was based on retention time with respect to standard methyl ester mixtures (Nu-Chek Preps, Elysian, MN). As over 95% (by wt) of adipose tissue consists of triglycerides, a small amount of the epididymal fat was directly methylated without extraction.

Total phospholipid concentration in liver lipid extracts was measured by the method of Stewart (19). Liver protein was determined using Bio-Rad protein assay (Bio-Rad Laboratories, Richmond, CA). Plasma cholesterol and triglyceride concentrations were determined enzymatically using a Cobas-Bio centrifugal analyzer (Hoffman-La Roche, Nutley, NJ). Statistical analysis was performed using the Tukey-Kramer test preceded by ANOVA (20).

RESULTS

Cholesterol feeding caused a significant increase in the liver wt of both 11-week-old and 64-week-old rats, but had no effect on body wt (Table 3). Liver phospholipid concentration was significantly reduced by cholesterol feeding, but this was not significant when values were expressed as a function of protein concentrations (Table 3). There was no age-dependent difference in liver phospholipid concentration. Cholesterol and triglyceride levels in plasma were higher in the older animals (Table 3). In both young and old animals, feeding cholesterol elevated plasma cholesterol and lowered plasma triglyceride concentrations.

Fatty acid compositions of liver and platelet phospholipids, following administration of safflower oil with or without cholesterol, are shown in Tables 4 and 5. Dietary cholesterol supplementation lead to the following changes: 1) The levels of Δ9-desaturase products (palmitoleic [16:1n-7] or oleic [18:1n-9] acids) are increased; 2) the levels of precursor fatty acids for 20:4n-6 synthesis (18:2n-6, eicosadienoic [20:2n-6] or 20:3n-6 acids) are increased, and in the liver C-22 PUFA (docosatetraenoic [22:4n-6], docosapentaenoic [22:5n-6] acids or docosahexaenoic acid [22:6n-3]) are decreased; and 3) 20:4n-6 is decreased in liver and platelet phospholipids of 64-week-old rats and in platelet, but not in liver, phospholipids of 11-week-old rats.

The effects of age on the fatty acid compositions of the liver and platelet phospholipids are as follows: 1) The levels of 20:3n-6 are increased; 2) the ratios of 20:3n-6/20:4n-6 are increased; 3) the levels of C-22 n-6 PUFA (22:4n-6 or 22:5n-6) are reduced and 20:5n-3, 22:5n-3 or 22:6n-3 are retained; and 4) no apparent influence on the levels of 20:4n-6 in either liver or platelet phospholipids was observed.

The effects of dietary cholesterol on fatty acid compositions in aorta phospholipids were less marked than in liver and platelet phospholipids (Table 6). Increased 20:3n-6 and 20:3n-6/20:4n-6 ratio were the only results of administering cholesterol and were obtained both in 11-week-old and 64-week-old rats. On the other hand, decreased 22:5n-6 and increased 22:5n-3 and 22:6n-3 were observed with aging, regardless of cholesterol supplementation, with 20:3n-6/20:4n-6 ratio being unaffected and 20:4n-6 being kept invariably constant (Table 6).

In adipose tissue lipids, the effects of cholesterol

*Significantly different than the corresponding young group ($p < 0.05$).

**Significantly different than the age-matched group without cholesterol feeding ($p < 0.05$).

feeding on fatty acid compositions were only small, and were obtained only in 11-week-old rats (Table 7). 18:1n-9 and 18:3n-3 PUFA were increased and 18:2n-6 PUFA was decreased in 64-week-old rats, in comparison with 11-week-old rats. Marked elevation of the 18:1n-9/18:2n-6 ratio was shown, regardless of cholesterol supplementation.

There were no significant correlations between the plasma cholesterol level and individual fatty acid concentrations in the various tissues in any group of animals or in the whole population. However, in all the tissues in the whole population, the plasma cholesterol was correlated significantly with the 20:3n-6/20:4n-6 ratio (liver, $r = 0.58$, $p < 0.01$; platelets, $r = 0.58$, $p < 0.01$; aorta, $r = 0.43$, $p < 0.05$). Positive but nonsignificant correlations were obtained between plasma cholesterol and the 18:2n-6/20:4n-6 ratios in liver ($r = 0.36$) and platelets ($r = 0.35$).

DISCUSSION

It has been postulated that blood vessel wall/platelet interaction plays a crucial role in the development of atherosclerosis and thrombosis (21,22). Much research on PUFA metabolism in platelets and vascular cells has been performed, because these cells produce biologically active prostaglandins and thromboxanes. Changes in cellular PUFA composition may affect agonist-antagonist reactivity through modifying membrane lipid structure and eicosanoid precursor levels. The PUFA almost certainly have major roles in membranes that are independent of their conversion to eicosanoids. The present study showed that age, which is a risk factor for atherogenesis that cannot be manipulated, and dietary cholesterol, which is a well-known dietary risk factor, substantially affected PUFA compositions in the liver and platelet phospholipids. It has been reported that synthesis of 20:4n-6 from 18:2n-6 is suppressed in the growing rat liver by dietary cholesterol (16). Increased 18:2n-6 and 20:3n-6 levels and 20:3n-6/20:4n-6 ratio in liver phospholipids of 11-week-old and 64-week-old rats, as a result of cholesterol feeding, support this idea. However, in this study, 20:4n-6 was decreased significantly only in 64-week-old rats (Table 4). The positive correlations between plasma cholesterol and the 20:3n-6/20:4n-6 and 18:2n-6/20:4n-6 ratios are consistent with, but do not prove, an inhibitory effect of cholesterol on Δ5- and Δ6-desaturase (16). In platelets, the effects of age and cholesterol were consistent with the results in the liver. PUFA composition of platelets seems to be determined by megakaryocytes in bone marrow (23), and the present study suggests that this process is closely linked with similar PUFA changes in the liver. In contrast, 20:3n-6 content and 20:3n-6/20:4n-6 ratio in aorta phospholipids were unaffected by age, while clearly augmented by dietary cholesterol. Vascular endothelial cells have desaturase and elongation enzyme activities (24,25), that by their own actions might regulate the composition of their fatty acids in diverse ways in response to different modulating factors. The fatty acids in adipose tissue were less affected by cholesterol. However, increase of 18:1n-9 and decrease of 18:2n-6 and subsequent increase of 18:1n-9/18:2n-6 ratio were observed with age. This may be due to increased requirement for PUFA (18:2n-6) with age or may be a reflection of increased 18:1n-9 content as a storage fat pool with age.

TABLE 7

Fatty Acid Composition of Adipose Tissue Lipids in Rats With or Without Cholesterol (CHO) Feeding

	11 Weeks of age		64 Weeks of age	
	CHO(−)	CHO(+)	CHO(−)	CHO(+)
Number	7	7	6	7
Fatty acid				
14:0	1.2 ± 0.1	1.1 ± 0.3	1.2 ± 0.1	1.3 ± 0.2
16:0	18.8 ± 2.2	15.1 ± 2.6**	18.6 ± 2.8	18.3 ± 1.0
16:1n-7	5.2 ± 0.9	6.0 ± 2.4**	7.8 ± 1.9	7.7 ± 1.8
18:0	2.1 ± 0.3	1.6 ± 0.2	1.6 ± 0.6	1.9 ± 0.3
18:1n-9	18.6 ± 0.6	18.2 ± 1.4	32.5 ± 2.9*	30.6 ± 1.7*
18:2n-6	50.9 ± 3.7	58.7 ± 12.7	35.4 ± 1.7*	36.7 ± 3.4*
18:3n-6	—	0.2 ± 0.1	—	—
18:3n-3	—	0.0 ± 0.0	0.4 ± 0.2	0.5 ± 0.2*
20:2n-6	0.4 ± 0.4	0.4 ± 0.1	0.2 ± 0.1	0.4 ± 0.4
20:3n-6	0.4 ± 0.8	0.4 ± 0.1	0.2 ± 0.0	0.3 ± 0.1
20:4n-6	1.3 ± 0.3	1.0 ± 0.3	0.7 ± 0.2*	0.5 ± 0.1*
22:4n-6	0.3 ± 0.1	0.2 ± 0.1	0.2 ± 0.1*	—
22:5n-6	0.2 ± 0.0	0.1 ± 0.0	0.1 ± 0.0*	—
22:5n-3	—	—	0.2 ± 0.1	0.3 ± 0.1
22:6n-3	—	—	0.3 ± 0.2	0.4 ± 0.1
18:1n-9/18:2n-6	0.37 ± 0.02	0.34 ± 0.02	0.92 ± 0.05*	0.84 ± 0.05*

Values are means ± S.D.

Results are shown as mg/100 mg total fatty acids present.

*Significantly different than the corresponding young group ($p < 0.05$).

**Significantly different than the age-matched group without cholesterol feeding ($p < 0.05$).

20:4n-6 is a principal PUFA in the phospholipid fraction and is both a lipid structural component and a precursor for prostaglandin and thromboxane synthesis. Proportions of 20:4n-6 in platelet and aorta phospholipids did not change with increasing age. 20:3n-6 content and 20:3n-6/20:4n-6 ratio in liver and platelet phospholipids were increased with age, suggesting a possible decline of Δ5-desaturase activity, or alternatively, reduced conversion of 20:3n-6 to 1 series prostaglandins. If formation of 20:4n-6 was reduced by age, it must have been compensated by utilizing other 20:4n-6 supplementary pools. 22:5n-6 can be saturated to 22:4n-6 by 4-enoyl-CoA reductase (26), and 22:4n-6 can act as pools for 20:4n-6 formation (8,27), with 22:4n-6 being shortened to 20:4n-6 in the liver peroxisomes (28). An age-dependent increase of peroxisomal C-22 n-6 fatty acids retroconversion, decreased elongation enzyme activity or enhanced incorporation of 20:4n-6 into platelet membrane may be mechanisms for maintaining the 20:4n-6 level constant.

The retention of n-3 PUFA, especially the C-22 fatty acids, was found in all the tissues examined in 64-week-old rats. Whether reduction of n-3 PUFA in 11-week-old rats is a simple reflection of dietary 18:2n-6-induced dilution is uncertain, but there is evidence of an age-dependent increase of 22:6n-3 in brains and other tissues of humans, mice and rats (29–32). N-3 PUFA may turn over at a low rate, a fact which may imply physiological significance. Deficiency of n-3 PUFA has been reported to lead to different kinds of pathological conditions (33,34), including neurological deficits (35), disturbed learning capacity (36), reduced 5′-mononucleotidase in brain (37), visual loss (38) and decreased electrical responses of photoreceptors (39). These phenomena are thought to be related to the normally very high concentrations of 22:6n-3 in the cerebral cortex and in the retina (33,40).

In summary, PUFA levels in platelet phospholipids were affected with age, but 20:4n-6 content was kept constant, though coupled with an increase in 20:3n-6 and a decrease in C-22 n-6 PUFA. The aorta was invulnerable to the effect of age, but was affected by dietary cholesterol, probably due to different responses of enzyme activities for both PUFA synthesis and deacylation-reacylation. The biochemical mechanism of the retention of C-22 n-3 PUFA with age is unknown. Differential utilization of C-22 n-6 and n-3 PUFA requires further investigation in relation to their physiological roles.

[Received March 9, 1987; Revision accepted May 18, 1988]

Accumulation of (n-9)-Eicosatrienoic and Docosatrienoic Acids in Human Fibroblast Phospholipids[1]

Soverin Karmiol and **William J. Bettger***
Cellular Nutrition and Metabolism Research Unit, Dept. of Nutritional Sciences, College of Biological Science, University of Guelph, Guelph, Ontario, N1G 2W1

An essential fatty acid (EFA) deficiency-like profile of fatty acids has been observed in HF-1 human skin fibroblasts cultured at clonal densities in MCDB 110 and 0.4% fetal bovine serum (FBS). The profile was characterized by an accumulation of 16:1n-7, 18:1n-9, 20:3n-9 and 22:3n-9, a reduction of n-6 fatty acids and a reduction in total polyunsaturated fatty acids (PUFA). The fatty acid composition of sphingomyelin (SPH), phosphatidylcholine (PC), phosphatidylserine (PS), phosphatidylinositol (PI) and phosphatidylethanolamine (PE) was determined and, except for SPH, each displayed an EFA deficiency-like profile. The triene to tetraene ratio (20:3n-9/20:4n-6) ranged from 5.3 in PI to 0.9 in PE. In addition, the highest percentage of 20:3n-9 was present in the PI and the highest percentage of 22:3n-9, in PE. Other human fibroblasts (normal, transformed and at different population doubling number levels [PDL]) were grown under the same conditions and were found to display triene to tetraene ratios (20:3n-9/20:4n-6) in total cellular lipids ranging from 0.7 to 4.5. The accumulation of 20:3n-9 and 22:3n-9 is due primarily to the existence of a basal nutrient medium (MCDB 110) that allows for the rapid clonal growth of human fibroblasts at reduced serum levels (0.4%). This culture procedure can be exploited to further elucidate various aspects of lipid metabolism in human fibroblasts. ***Lipids 23,*** **891–898 (1988).**

A consistent biochemical feature of n-6 fatty acid deficiency in mammals fed a fat-free diet is the reduction of n-6 fatty acids and the accumulation of 20:3n-9 and other 18:1n-9 metabolites in the cellular lipids (1–3). Clinical assessment of essential fatty acid (EFA) status is based most frequently on the triene to tetraene ratio (20:3n-9/20:4n-6) in tissue or plasma lipid fractions (4,5). The 20:3n-9 accumulates in various lipid classes, the extent and pattern of which depend on species, age and sex of the animal, length and severity of the deficiency, and tissue and/or subcellular fraction analyzed within a tissue (6–9).

Linoleic acid or other n-6 polyunsaturated fatty acids (PUFA) have not been proven to be essential nutrients for the multiplication of mammalian cells in culture (10–13). The mass accumulation of 20:3n-9 and related fatty acids coming from de novo synthesis has been described for mammalian cells in culture under rare and/or unusual circumstances. Bailey et al. (14) describe the adaptation of monolayer cultures of MB III cells (mouse lymphoma) to the lipid free medium 7CLF. After seven wk under these culture conditions, the cell monolayer accumulated 20:3n-9 and 22:3n-9, as 29.0% and 42.6% of their total cell fatty acids, respectively. A similar phenomenon occurred with Chang liver cells (human, transformed), but not with mouse L fibroblasts (transformed). Rat embryo fibroblasts do not accumulate 20:3n-9 in cellular phospholipids when cultured in minimum essential medium (MEM) plus 10% tryptose phosphate broth and 10% fetal bovine serum (FBS); however, herpes simplex virus-transformed rat embryo fibroblasts accumulate 20:3n-9 in phospholipid under these culture conditions (15). Hyman et al. (16) have described the accumulation of 20:3n-9 in the phospholipids of mouse 3T3 fibroblasts (ATCC CCL 92 and 92.1) (heteroploid, some transformed characteristics) cultured as confluent monolayers in Dulbecco-modified Eagle medium (DME) plus 10% FBS. Although a variety of other transformed cell types produce lesser amounts of 20:3n-9, human skin fibroblasts (normal diploid) or endothelial cells (normal diploid) do not accumulate this fatty acid under these conditions (17,18). Balb c/3T3 cells and SV-40 transformed Balb c/3T3 cells also accumulate 20:3n-9 during multiplication in a modified MEM supplemented with 10% FBS. The content of 20:3n-9 increases when FBS is replaced with delipidized FBS (19). Rosenthal and Whitehurst (20) describe the accumulation of 20:3n-9 and 22:3n-9 in the total cellular lipids of GM-10 human fetal skin fibroblasts (normal diploid) from log phase cultures of cells grown in MEM plus 5% delipidized bovine serum over an eight-day period. The GM-10 fibroblasts were apparently selected for their ability to multiply rapidly under these conditions, that would normally inhibit the rate of multiplication of other human (21,22) and mouse (19,23) fibroblast cell lines. Laposta et al. (24), after adaptation in Ham's F-10 plus 4.2% delipidized horse serum, generated an EFD-1 cell line with epithelial morphology from HSDM$_1$C mouse fibroblast (transformed). The cells accumulate 20:3n-9 in total cellular lipid under high-density growth conditions in F-10 plus delipidized serum. Primary cultures of mouse brain cells cultured in medium supplemented with 10% FBS (25) and rat normal and transformed glial cells (26), cultured in DME supplemented with 10 and 5% FBS, respectively, accumulate 20:3n-9 in cellular phospholipid.

The experiments in this communication describe the production of an EFA deficient-type fatty acid profile in the phospholipids of a wide variety of human fibroblasts undergoing rapid multiplication in culture. A detailed fatty acid analysis of cellular phospholipid is undertaken to accurately define the accumulation of 20:3n-9 and 22:3n-9 in the structural lipids of the cells.

[1]Fatty acids are abbreviated as number of carbon atoms:number of double bonds, followed by an n-number to designate the position of the first double bond with respect to the methyl carbon. Thus, Mead acid is 20:3n-9 and its elongation product is 22:3n-9.

Abbreviations: ANS, 8-anilino-1-naphthalene-sulfonic acid; BHT, butylated hydroxytoluene; CS_2, carbon disulfide; EFA, essential fatty acid; FAME, fatty acid methyl ester; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; SPH, sphingomyelin; DME, Dulbecco-modified Eagle medium; FBS, fetal bovine serum; GLC, gas liquid chromatography; MECL, modified equivalent chain length; MEM, minimum essential medium; PDL, population doubling number level; TLC, thin layer chromatography.

MATERIALS AND METHODS

Cells. HF-1 and HF-2 are human fibroblasts from newborn foreskins generated in this laboratory by primary culture (27). Flow 2,000 human fibroblasts were purchased from Flow Laboratories (Mississauga, Ontario). WI-38, WI-26VA4 and WI-38VA13 human fibroblasts were purchased from the American Type Tissue Culture Collection (Bethesda, MD) and GM 6171, GM 637A from Institute for Medical Research (Camden, NJ).

Cell aging. The cells were routinely passed at a 1:5 split ratio in T-75 flasks (Falcon) in DME (Flow Laboratories) containing 10% (v/v) FBS (Flow), 100 mg/l penicillin-G (Sigma, 1670 units/mg), 100 mg/l streptomycin sulfate (Sigma) and 10 mg/l gentamycin sulfate (Sigma). The pH was controlled with 30 mM HEPES (Calbiochem) and adjusted to 7.6. Incubation occurred in a water-jacketed incubator (Forma Scientific) saturated with water vapor and adjusted to 2% CO_2. The age of the cells in culture was calculated using the evaluation of the population doubling number level (PDL) (28).

Cell storage. At the appropriate cumulative PDL, cells were stored in liquid nitrogen for later use. One day prior to storage, the cells were refed with fresh culture medium. The cells were suspended after trypsinization in DME containing 20% FBS, 10% dimethylsulfoxide (Sigma) and the antibiotics mentioned above, and aliquoted in 1.0 ml portions into sterile freezer vials (Fisher). The vials were placed at 4 C for 30 min, −70 C for 4 hr and then stored in liquid nitrogen.

Preparation for clonal growth. MCDB 110 was prepared in this laboratory from individually prepared stocks (29,30). The frozen cells were quickly thawed and their contents introduced into T-75 flasks containing freshly prepared MCDB 110, 10% FBS and the antibiotics previously mentioned for 12–24 hr. At that time, the medium was changed to one containing MCDB 110 and 2% FBS, plus antibiotics, for 48 hr. The medium was changed again to one containing 0.1% serum, without antibiotics, for 24 hr; after this point no antibiotics were introduced into the medium. On the day of the beginning of the growth period, the cells were incubated for ca. six hr in MCDB 110 with no serum supplement.

Clonal growth. The cells were trypsinized by a cold trypsinization technique (31) using 0.005% trypsin in Solution A (30 mM HEPES-NaOH [pH 7.6], 10 mM glucose, 130 mM NaCl, 1.0 mM Na_2HPO_4 and 3 mM KCl). The cells were counted by hemocytometer and inoculated into T-75 flasks at 100 cells/cm² for HF-1 PDL 15, 400 cells/cm² for HF-1 PDL 39 and at 200 cells/cm² for the other cells. The incubation period was 11 days.

Cells were grown in the presence of MCDB 110 containing either 4% serum (serum complete medium), in 8–10 T-75 flasks, or 0.4% serum (serum deficient medium), in 15–20 T-75 flasks, 20 ml final volume. For growth at 0.4% serum, the growth surface of the flasks was coated with poly-D-lysine to improve cell attachment (32).

Cell harvesting. At the end of the growth period, the flasks were removed from the incubator and placed on an ice bath for 15 min, prior to the removal of the medium. The cell layer was washed with three 10-ml portions of ice-cold Solution A and subsequently removed from the surface of the culture flask by scraping with a rubber policeman. The harvested cells were centrifuged at 500 × *g* for 5 min at 4 C and resuspended in a small volume of Solution A. Aliquots were taken for protein determination (33) and lipid analysis.

Lipid analysis. All containers were initially rinsed with chloroform/methanol (2:1, v/v). For the cells, the lipids were extracted by the method of Bligh and Dyer (34), and for the FBS, the lipids were extracted by the method of Folch et al. (35). All lipid extractions were performed in the presence of 10^{-9} M butylated hydroxytoluene (BHT) (Sigma).

Chromatography of phospholipids. An aliquot of the lipid extract was applied to a silica gel 60 thin layer chromatography (TLC) plate (Merck) previously activated at 110 C for 1 hr. The TLC plate was developed with chloroform/methanol/acetic acid/water (50:37.5:4:2, v/v/v/v) (36) containing 0.01% BHT (37). The phospholipids were visualized by a UV light source after spraying with 0.1% 8-anilino-1-naphthalene-sulfonic acid (ANS) (Sigma) (38). Phospholipid standards were purchased from Sigma.

The phospholipids were quantitated by the method described by Christie et al. (39). The mol of each identified fatty acid were determined by initially evaluating its mass by a comparison with an internal standard and then by employing the corresponding molecular weight. The unidentified fatty acids were included in the quantitation of the phospholipids. The mol of the unidentified fatty acids were determined using the weighed average molecular weight of the identified fatty acids. The numbers of mol of phosphatidylcholine (PC), phosphatidylserine (PS), phosphatidylinositol (PI) and phosphatidylethanolamine (PE) were determined by dividing the number of mol of fatty acids in each phospholipid by 2, and of sphingomyelin (SPH), the number of mol of fatty acids were divided by 1.

Transmethylation. All methylations, either total lipid or phospholipid in the presence of silica gel, were performed with 3.0 ml of 6% sulfuric acid in methanol for 14 hr at 75–80 C (40) in the presence of a known mass of 17:0 (Nu-Chek Prep., Elysian, MN). After cooling to room temperature, 2.0 ml of hexane were added and the contents vortexed for 20 sec. Then, 1.0 ml of water was added and the contents vortexed again. The upper hexane layer was removed and dried under oxygen-free nitrogen.

The methylation products from phospholipid fractions were redissolved in 20 μl of carbon disulfide (CS_2) and an aliquot applied directly to a gas liquid chromatography (GLC) column for analysis. The methylation products from a total lipid extract, either from fibroblasts or FBS, were redissolved in 20 μl hexane and applied to a TLC plate (Merck) and chromatographed in a tank containing 1,2-dichloroethane (41) for isolation of the fatty acid methyl esters (FAME). The FAME band was visualized by ANS and scraped. The FAME were released from the gel using 2 ml methanol, 2 ml hexane and 1 ml deionized water. The hexane layer was removed and processed as described for the phospholipid fractions.

GLC. The FAME were separated on a Hewlett-Packard 5890A gas chromatograph equipped with a flame ionization detector system, N_2 as make-up gas, with a 30 m DB-255 megabore column (J & W Scientific, Rancho Cordova, CA). The column temperature was maintained at 210 C and inlet and detector temperatures each at 250 C. The column gas was helium at 6.7 ml/min with a 1:3 split.

The FAME were identified by comparison of retention times with those of known standards (Nu-Chek Prep.), except for 20:3n-9 and 22:3n-9. The mass of the FAME were calculated by comparison with the area of the internal standard peak using a Spectra Physics integrator.

Identification of n-9 fatty acids. Three methods were used to identify 20:3n-9 and 22:3n-9 fatty acids in human skin fibroblast phospholipids. First, the lipid extracts of the livers of rats fed a fat-free diet were used as a biological standard. Second, argentation-TLC and GLC with appropriate standards were used to confirm that the unknown fatty acids were trienes. Third, indirect GLC-identification techniques for long-chain unsaturated fatty acids were used. Weanling, male Wistar rats were fed semipurified diets (42) that were either fat-free or supplemented with 5% corn oil. After 30 days, the rats were killed, livers removed and liver lipids extracted (35). Total phospholipids were isolated by TLC (43) and then transmethylated as above. Comparison of the phospholipid fatty acids from the rats fed the fat-free and corn oil-supplemented diets revealed two new peaks from the extracts of the rats fed a fat-free diet—one that was 12.0 ± 0.07 mol% and the other, with a longer retention time, that was 0.30 ± 0.01 mol%. Separation of the triene fatty acids by argentation-chromatography and subsequent GLC revealed that these two fatty acids belonged to the triene class of fatty acids and, thus, were identified as 20:3n-9 and 22:3n-9. These fatty acids have been reported to accumulate in liver phospholipids of EFA-deficient rats at similar concentrations (44–46). Lipid extracts from human fibroblasts cultured in 0.4% serum also contained two new peaks with retention times identical to the 20:3n-9 and 22:3n-9 fatty acids found in the phospholipids of rats fed the fat-free semipurified diet. With argentation-chromatography, these two fatty acids were found to be triene fatty acids. In an attempt to confirm that these two fatty acids belonged to the n-9 family of fatty acids, separation factors and modified equivalent chain lengths (MECL) were employed. The column from which retention times were taken was a 0.53 mm open tubular column 30 m long. The stationary phase was 1.0 μ in thickness and composed of 25% cyanopropyl, 25% phenyl and 50% methyl polysiloxane (Megabore DB-225). The MECL values were evaluated according to Jamieson (47): $MECL = 2[\log R_x - \log R_n/\log R_{n+2} - \log R_n] + n$, where R_x, R_n and R_{n+2} are the retention times of the unknown acid and of the n - 9 monoene acids of chain length n and n + 2. The result of this calculation gave observed values. The graph of log retention time vs the carbon number from 16:1n-9 to 22:1n-9 had a linear regression coefficient equal to 0.999. The MECL of 20:3n-9 and 22:3n-9 were calculated according to Jamieson and Reid (48): $MECL_x = MECL_y - \text{Type } II_{6/9}$, where, for the case of 20:3n-9, x refers to 20:3n-9 and y to 20:4n-6, and for the case of 22:3n-9, x refers to 22:3n-9 and y refers to 22:4n-6, and Type $II_{6/9}$ refers to the difference in MECL values of the pairs of esters used to calculate the Type II separation factors. The result of this calculation gave expected values. The observed and expected values for 20:3n-9 were 20.38 ± 0.01 and 20.37 ± 0.01, and for 22:3n-9, the corresponding values were 22.44 ± 0.01 and 22.42 ± 0.01.

The retention times of 20:3n-9 on our standard (210 C isothermal) GLC analysis results in a significant overlap of the 20:3n-9 and 20:2n-6 peaks. However, human fibroblasts cultured under these conditions have undetectable levels of 20:2n-6 in total phospholipid fatty acids and in each phospholipid fraction except PI (4.0% serum). This was determined by analysis of diene fatty acids after argentation-chromatography and by analysis of fatty acids at 160 C isothermal, which completely separates 20:3n-9 and 20:2n-6, with 20:3n-9 eluting first.

Argentation-chromatography. Eight g of silver nitrate were dissolved in 80 ml of water, to which 40 g of silica gel (CAMAG DS-5) were added, and the contents were poured on 20 × 20 cm glass plates (0.35-mm thick) and allowed to dry. FAME from the various lipid extracts were spiked with 18:3n-3 and chromatographed. The plate was developed in chloroform/methanol (99:1, v/v) and the triene bands scraped, the FAME eluted and analyzed by GLC, as previously described.

Statistical analysis. Data within a phospholipid were analyzed for variance (ANOVA) followed by a Tukey's studentized range test; this was done so that the residuals could be used to test whether the data came from a normal distribution using the Shapiro-Wilk statistic, W. Data were log transformed before analysis, if necessary, to achieve a normal distribution (49).

RESULTS

Human HF-1 fibroblasts cultured at a density of 8×10^3 cells/T-75 flask in MCDB 110 plus 0.4% FBS exhibited significantly less total growth over the 13-day assay period than the cells cultured in MCDB 110 plus 4.0% FBS, 0.99 ± 0.04 vs 1.65 ± 0.11 × 10^6 cells/T-75 flask ($P < 0.05$, $n = 4$), respectively. The effect of culturing HF-1 fibroblasts in MCDB 110 plus 0.4% FBS on the phospholipid profile is shown in Table 1. Compared to the profile of phospholipids found in cells cultured in MCDB 110 plus 4.0% fetal calf serum, cells cultured with 0.4%

TABLE 1

Effect of Serum Concentration on the Distribution of Phospholipids in HF-1 Human Skin Fibroblasts in a Clonal Growth Assay

	Phospholipid distribution % Fetal bovine serum[a]	
Phospholipid	4.0	0.4
	mol%[b,c]	
Sphingomyelin	9.9 ± 0.4	9.0 ± 0.5
Phosphatidylcholine	48.4 ± 1.1	46.1 ± 1.3
Phosphatidylserine	10.1 ± 0.5	9.8 ± 0.6
Phosphatidylinositol	7.9 ± 0.3	8.4 ± 0.4
Phosphatidylethanolamine	23.7 ± 0.7[d]	26.7 ± 0.8

[a]Fetal bovine serum lot #1.

[b]Values are mean ± SEM, n = 6 for 4.0%, n = 5 for 0.4% FBS. The data represent results from 4 independent experiments utilizing fresh media and new cells brought up from frozen stocks. In one experiment, 3 sets of assay flasks were processed for 4.0% serum, 2 for 0.4% serum.

[c]Percent distribution of phospholipids is based on the five phospholipid groups that were analyzed and not on the total phospholipids in the cell.

[d]Values are significantly different by the Tukey's test ($P < 0.05$).

[a]Fetal bovine serum lot #1. The fatty acid composition of this serum lot is shown in Table 3.

[b]Values are presented as mean ± SEM, n = 6 and 5 for phospholipids at 4.0 and 0.4% serum, respectively. The data represent results from 4 independent experiments utilizing fresh media and new cells brought up from frozen stocks. In one experiment, 3 sets of assay flasks were processed for 4.9% serum, 2 for 0.4% serum.

[c]Values are significantly different by Tukey's studentized range test. Only values within a particular phospholipid are statistically compared.

[d]Represents multiple positional and/or *cis/trans* isomers.

[e]Average number of double bonds per fatty acid in the sample.

[f]Double bond index/mol% of total saturated fatty acids × 100 (8).

[g]This data was log transformed to achieve a normal distribution prior to the application of analysis of variance followed by a Tukey's studentized range test.

Tr, trace (<0.5%); ND, not detectable (<0.1%).

fetal calf serum have significantly more PE. Cells cultured under both conditions have similar total phospholipid (sum of those detected), 323 ± 17 and 300 ± 18 nmol/mg protein ($P > 0.05$) for cells cultured with 0.4 and 4.0% FBS, resepectively.

The fatty acid composition of the phospholipids of HF-1 fibroblasts cultured under the experimental conditions is shown in Table 2. The fatty acid composition of the FBS used to culture these cells is shown in Table 3 (serum lot 1). In SPH, cells cultured with 0.4% FBS have significantly more 14:0 and fewer 20:0, compared with 4.0% controls. The cells also have a significantly higher number of total monounsaturated fatty acids. In PI, cells have significantly fewer 20:3n-6 and 20:4n-6, and 22:4n-6 and 22:5n-3 concentrations drop to trace (<0.5%) and not-detectable (<0.1%) levels, respectively. The cells have significantly more 16:1 and 18:1 and show an accumulation of 20:3n-9 and 22:3n-9. In this phospholipid, cells have significantly fewer total saturated fatty acids, a lower double bond index and more total monounsaturated fatty acids, when cultured with 0.4% vs 4.0% FBS. In PE, cells have significantly fewer 18:0, 20:4n-6, 22:4n-6, 22:5n-3 and 22:6n-3. The cells have significantly more 16:1, 18:1 and fewer 18:0 and show an accumulation of 20:3n-9 and 22:3n-9. The cells have significantly fewer total saturated fatty acids, total PUFA and a lower double bond index and more total monounsaturated fatty acids in PE. In PC, the cells cultured with 0.4% FBS have significantly fewer 16:0, 18:0 and 20:4n-6 and 20:3n-6 and 20:3n-6 falls to trace levels. The cells have significantly more 14:0 and 16:1 and have an accumulation of 20:3n-9 and 22:3n-9. They have fewer total saturated fatty acids, fewer total PUFA, a smaller unsaturated to saturated ratio and greater total monounsaturated fatty acids in this phospholipod. In PS, the cells have significantly fewer 18:0, 18:2 (total isomers), 20:3n-6, 20:4n-6, 22:4n-6, 22:5n-3, 22:6n-3 and 24:0 and significantly more 16:1, 18:1 and 22:0, when cultured in 0.4% FBS. The cells accumulate 20:3n-9 and 22:3n-9 in PS under these conditions. The cells have more total monounsaturated fatty acids, but fewer total saturated PUFA, a lower double bond index and lower unsaturated-to-saturated ratio in this phospholipid under these conditions.

A comparison of the accumulation of 20:3n-9 and 22:3n-9 among the phospholipid fractions of HF-1 cells cultured in MCDB 110 plus 0.4% FBS is shown in Table 4. As a mol% of total fatty acids, 20:3n-9 accumulates in phospholipids as follows: PI > PE > PC = PS; and 22:3n-9 accumulates in phospholipids: PE > PS = PI > PC. However, as a mol% of the total 20:3n-9 found in phospholipids of the cells, 20:3n-9 accumulates as follows: PI > PC = PE > PS; and 22:3n-9 as PE > PC = PS with PS = PI, but PC > PI. In terms of the ratio 20:3n-9/20:4n-6, the cells have the following distribution in phospholipids: PI > PE, but PI = PS = PC and PS = PC = PE. These values are compared by the Tukey's studentized range test and are significantly different at the $P < 0.05$ level, $n = 5$.

The effect of fibroblast cell type on the accumulation of 20:3n-9 in cells cultured in MCDB 110 plus 0.4% FBS is shown in Table 5. All fibroblasts tested showed an accumulation of 20:3n-9, regardless of whether they were of lung or skin origin, normal or transformed, low or high PDL. The mol% of 20:3n-9 in total fatty acids from these cells ranged from 0.8 to 3.7, and 20:3n-9/20:4n-6 ratios ranged from 0.6 to 4.5. None of the cells had any detectable 20:3n-9, when cultured with 4.0% FBS. The lot of FBS used appeared to have a minimal effect on the accumulation of 20:3n-9 in fibroblasts (Tables 3 and 5).

TABLE 3

Fatty Acid Composition of Fetal Bovine Serum

Fatty acid	Serum lot number[a]		
	1	2	3
		(mol%)[b,c]

[a]Mean ± SEM of analysis of serum lots; lot 1, n = 4, lots 2 and 3, n = 3.

[b]Mean values below 0.5 mol% are listed as trace (tr) levels.

[c]All serum lots have trace levels (<0.5%) of 20:3n-9 and nondetectable levels of 22:3n-9 (<0.1%).

DISCUSSION

Research in our laboratory has utilized three observations to cultivate rapidly dividing human fibroblasts that have a phospholipid fatty acid composition that closely resembles the fatty acid profile from the tissue of EFA-deficient animals (4,50) and humans (5). First, fibroblasts in culture preferentially utilize exogenously supplied lipids to meet their metabolic needs, however, they are capable of increasing their rates of fatty acid and cholesterol biosynthesis when the culture medium has a low lipid content (11). Second, in rapidly dividing fibroblasts, there is a high demand for lipid material because the cells must assemble a large quantity of membrane lipids as part of the general mitotic process, in addition to the continuous turnover of existing membrane structures (12). Third, the qualitative and quantitative optimization of the concentration of nutrients in a cell-culture medium can reduce the amount of FBS necessary for maximal rates of cell multiplication for a variety of cell types (51). The utilization of MCDB 110 as the culture medium, which has been optimized specifically for the clonal growth of human diploid fibroblasts with low levels of FBS supplementation (29,30), appears to have resulted in cells with rates of multiplication, and thus the need for membrane lipid material, that significantly exceed the rate at which they can take up and utilize lipid from

TABLE 4

Comparison of the Distribution of 20:3n-9 and 22:3n-9 Among Phospholipids in HF-1 Human Fibroblasts in a Clonal Growth Assay at 0.4% Serum

[a]N refers to normal diploid fibroblasts, T refers to SV-40 transformed fibroblasts.

[b]Population doubling number at the start of the clonal growth assay. This is an indicator of the number of previous replications in culture. The population doubling number of the transformed cells is unknown.

[c]The fatty acid composition of the different lots of sera are displayed in Table 3.

[d]Values are presented as mean ± SEM, n = 3 except HF-1, PDL 15, n = 4, WI-38 and GM 6171, n = 2. The data represent results from independent experiments utilizing fresh media and new cells brought up from frozen stocks.

ND, not detectable.

medium supplemented with 0.4% FBS. Fibroblasts cultivated under these conditions synthesize PUFA not found in FBS and insert them into phospholipid. Apparently, this response of the cells is necessary to maintain their rate of multiplication in this chemical milieu. The phenomenon occurs in all the human fibroblast cell types tested and appears highly reproducible.

As studied in HF-1 human foreskin fibroblasts, the general response for fibroblasts cultured in MCDB 110 plus 0.4% serum is to replace n-6 PUFA in phospholipids with 20:3n-9 and 22:3n-9. The HF-1 cells exhibit a distinct pattern of incorporation of n-9 PUFA into phospholipid, i.e., 20:3n-9 is incorporated mainly into PI, and 22:3n-9 mainly into PE. Other types of cells in culture exhibit selectivity for the incorporation of endogenous 20:3n-9 into particular phospholipid classes, however, the selectivity apparently depends on cell type and culture conditions (15,16,19,20,24). In HF-1 cells, the 18:2 isomers are conserved largely in each phospholipid class, presumably because of the accumulation of n-9, n-7 and other isomers (19,24,52). This general pattern of fatty acid distribution is characteristic of EFA deficiency in whole animals (2,45). The 20:3n-9/20:4n-6 ratios observed in human fibroblasts cultured under these conditions ranged from 0.6 to 4.5, and these ratios are greater than the value of 0.2 that has been proposed as the biochemical index of EFA deficiency in human tissue (53). The change in phospholipid composition seen in the HF-1 cells, namely to significantly increase PE, the phospholipid with the highest PUFA, has not been described in tissue from EFA-deficient animals and may be unique to fibroblasts under these culture conditions.

It cannot be determined from these experiments whether human fibroblasts in culture have a requirement for n-6 fatty acids for maximal rates of cell multiplication. In animals with EFA deficiency, the double bond index (degree of unsaturation) of liver fatty acids does not progressively decrease from an index of 1.2–1.3 (4) with increasing time on a fat-free diet, but levels off to approximately 0.8 and is maintained (2). Interestingly, the HF-1 fibroblasts described in these experiments have a double bond index in their total phospholipid fatty acids of 0.84 $\pm$ 0.02, compared with 1.08 $\pm$ 0.02 ($P < 0.05$) for controls. The normal human diploid fibroblasts listed in Table 5 had double bond indices ranging from 0.76 (HF-1 PDL 39) to 0.87 (GM 6171) in their total cellular fatty acids when cultured in MCDB 110 plus 0.4% FBS. The average double bond index of the normal cell types under these conditions was 0.82 $\pm$ 0.02. Of the five phospholipids analyzed, only the unsaturated/saturated ratios (8) of PC and PS were significantly greater for cells grown at 4.0% serum compared with cells grown at 0.4% serum. In terms of total phospholipid fatty acids, the cells cultured in 0.4% serum have a small but statistically significant decrease (2.9 $\pm$ 0.1 vs 3.3 $\pm$ 0.1, $P < 0.05$) in the unsaturated/saturated ratio. It appears that normal human fibroblasts in culture may accumulate n-9 and n-7 monoenes, n-9 and n-7 dienes and trienes, and alter their phospholipid composition to maintain a minimal level of the degree of unsaturation of membrane fatty acids. It is not known whether human fibroblasts can attain maximal rates of cell multiplication while maintaining a double bond index of ca. 0.8 or a slightly reduced unsaturated/saturated ratio. The reduced multiplication rate of human fibroblast cells cultured in MCDB 104 or 110 at $\leq$0.4% serum cannot be overcome by supplementation with linoleate (51,54).

Though the procedure outlined in this communication may not establish a n-6 fatty acid requirement for the proliferation of fibroblasts in culture, it allows for the elucidation of various aspects of their lipid metabolism.

Effects of Aurothioglucose on Iron-induced Rat Liver Microsomal Lipid Peroxidation

Jeffrey K. Beckman* and **Harry L. Greene**
Department of Pediatrics, Division of Gastroenterology and Nutrition, Vanderbilt University School of Medicine, Nashville, TN 37232

Aurothioglucose (ATG), an inhibitor of selenium-dependent glutathione peroxidase activity, at a concentration of 100 μM, strongly increases lipid peroxidation of rat liver microsomes exposed to either ferrous ion (10 μM) or the combination of ferric ion (10 μM) and ascorbic acid (500 μM), in the presence of reduced glutathione (GSH, 800 μM). This effect was not achieved using heat-inactivated microsomes and was dependent on the presence of GSH. ATG did not affect the lag period associated with ascorbic acid/ferric ion-induced microsomal lipid peroxidation (previously attributed to an undefined GSH-dependent microsomal agent), but did increase the rate of peroxidation subsequent to the lag period. The potent GSH-dependent inhibition of microsomal lipid peroxidation by cytosol (10% of total volume) was completely reversed by ATG (100 μM). ATG similarly reversed an inhibition of phosphatidylcholine hydroperoxide-dependent liposomal peroxidation that has been attributed to phospholipid hydroperoxide glutathione peroxidase (PHGPX), an enzyme distinct from the classical glutathione that cannot utilize intact phospholipids.

ATG inhibited, in addition to the classical selenium-dependent glutathione peroxidase, both cytosolic and microsomal (basal and N-ethyl maleimide-stimulated) glutathione S-transferase activities with greater than 80% inhibition achieved at 100 μM ATG. ATG, at concentrations up to 250 μM, did not inhibit PHGPX activity measured by the coupled-enzyme method in the presence of Triton X-100 (0.1%). These data demonstrate the potential of ATG to increase toxicity of lipid peroxidative stimuli by inhibition of microsomal and cytosolic defense mechanisms. Although ATG did not inhibit Triton-enhanced PHGPX activity, overall evidence points toward inhibition of this enzyme as the mechanism for ATG-augmented lipid peroxidation and supports the conclusion that PHGPX plays a major role in the cellular defense mechanism.
Lipids 23, 899–903 (1988).

Several reports indicated that hepatic cytosol contains an unidentified reduced glutathione (GSH)-dependent defense mechanism(s) that protects against microsomal lipid peroxidation (1–5). Because the Se-dependent GSH-peroxidase and GSH-transferase activities of the cytosol are inactive against intact phospholipids (3), their potential involvement in the cytosolic peroxidative defense has been largely discounted. On the other hand, Sevanian et al. (6) have demonstrated that oxidized phospholipids are preferred substrates for phospholipase A_2 (PLA_2) and suggested that PLA_2-mediated release of fatty acyl hydroperoxides would allow GSH-peroxidase and transferase to protect against peroxidative damage, because the enzymes can reduce fatty acyl hydroperoxides (3). In support of this suggestion, we have recently described peroxidation-induced activation of microsomal phospholipase A_1 and A_2 activities (7). In contrast, Gibson et al. (3) have demonstrated that direct addition of partially purified glutathione peroxidase or glutathione S-transferase had no protective effect against lipid peroxidation, and have alternatively described a GSH-dependent cytosolic factor distinct from glutathione peroxidase/transferase activities that prevents the initiation of peroxidation reactions (4). In addition, Ursini et al. (5) have demonstrated a GSH-dependent phospholipid hydroperoxide glutathione (PHGPX) that reduces intact phospholipid hydroperoxides to the corresponding alcohols. This enzyme, thus, potentially could protect against propagation reactions.

In addition to the cytosolic defense against microsomal peroxidation, microsomes, themselves, contain a GSH-dependent microsomal defense mechanism (8). This defense mechanism manifests itself by a lag period, the length of which correlates directly with the microsomal vitamin E content. No particular enzyme involved in this protective effect has been elucidated. One possible candidate for this enzymatic role is microsomal GSH S-transferase, although its activity is much lower than that present in cytosol (9). The ability to greatly augment the microsomal GSH S-transferase by N-ethyl maleimide (10) suggests substantial latent activity of the enzyme. This latent activity of microsomal GSH S-transferase may be responsible for peroxidative protection following the lag phase.

Aurothioglucose (ATG) is a potent inhibitor of the classical cytosolic glutathione peroxidase (11,12). We postulated that this agent could be used to explore further the roles of cytosolic glutathione peroxidase, as well as related GSH-dependent enzymes in lipid peroxidation. The purpose of this study, therefore, was to further define the effects of ATG on microsomal and cytosolic protective enzyme activities and on lipid peroxidation.

EXPERIMENTAL PROCEDURES

Isolation of microsomes and cytosol. Male Sprague-Dawley rats (200-300 g) were obtained from Harlan Sprague-Dawley, Inc. (Indianapolis, IN). Liver microsomes were obtained by differential centrifugation from a 10% homogenate in 0.15 M KCl, 10 μM Tris buffer, pH 7.4. The 100,000 × *g* pellet obtained from the 20,000 × *g* supernatant was washed by recentrifuging at 100,000 × *g*, was resuspended in homogenization buffer (5-10 mg of protein/ml) and assayed for protein content (13). The first 100,000 × *g* supernatant was dialyzed overnight against homogenization buffer and stored frozen at −40 C.

Lipid peroxidation assay. Microsomes (500 μg of protein/ml) were incubated at 37 C in 100 mM Tris buffer, pH 7.,4 (0.5 ml total volume), in the presence of the described peroxidative stimuli and the indicated levels of glutathione, ATG and/or cytosol. Following incubation, the method of Mihara et al. (14) was used to

Abbreviations: ATG, aurothioglucose; GSH, reduced glutathione; PHGPX, phospholipid hydroperoxide glutathione peroxidase; PLA_2, phospholipase A_2; TBA, 2-thiobarbituric acid.

derivatize 2-thiobarbituric acid (TBA)-reactive substances that were assayed spectrofluorometricaly by the method of Yagi (15).

Preparation of phospholipid hydroperoxides and phospholipid liposomes. Phospholipid hydroperoxides were prepared from egg phosphatidylcholine (Type III E, Sigma Chemical Co., St. Louis, MO) using soybean lipoxygenase-I (Sigma), as described by Eskola and Laakso (16). Chloroform/methanol solutions of phospholipid hydroperoxide and fresh unoxidized phosphatidylcholine were combined such that 10% of the lipid was hydroperoxide. Following evaporation of organic solvents, phospholipid liposomes were prepared by sonication in water to a concentration of 1 mM phosphatidylcholine. Control phospholipid liposomes containing only the fresh phosphatidylcholine were prepared in parallel.

Enzyme assays. Glutathione S-transferase activity was measured with 1-chloro-2,4-dinitrobenzene by the method of Habig et al. (17). Microsomal glutathione S-transferase was activated by N-ethyl maleimide pretreatment, as described by Morgenstern et al. (10). Total glutathione peroxidase activity was measured using a t-butyl hydroperoxide substrate (18). Superoxide dismutase activity was measured by inhibition of superoxide anion-mediated reduction of cytochrome c (19). PHGPX activity was measured by the glutathione peroxidase assay using as substrate phosphatidylcholine hydroperoxide-containing phosphatidylcholine liposomes (prepared as described) at a concentration of 200 μM. Triton X-100 augments PHGPX activity (20) and was required for its measurement (0.1%) final concentration. Controls included activity in the absence of phospholipid or glutathione or using fresh phosphatidylcholine liposomes.

RESULTS

As shown in Figure 1, the peroxidative response of microsomes exposed to ferrous sulfate (10 μM) in the presence of GSH (800 μM) was potentiated by ATG in a dose-dependent manner. However, it did not induce lipid peroxidation in the absence of ferrous ion. In contrast, heat inactivation of microsomes (heated at 100 C for 10 min.) resulted in no increase in lipid peroxidation by any dose (10–200 μM) of ATG. In addition, peroxidation of untreated (not heat inactivated) microsomes in the absence of GSH was not affected by ATG (data not shown). Ferrous ion-induced lipid peroxidation was increased with increased levels of GSH as follows: 100 μM GSH, 210%; 200 μM GSH, 225%; 400 μM GSH, 320%; and 800 μM GSH, 335%. In an effort to observe the effects of ATG on microsomal GSH-dependent protective activity, we subsequently used the ferric ion/ascorbic acid system as a peroxidation stimulus, which is better defined in this regard (8). The peroxidative response of ferric ion/ascorbic acid exhibited a GSH-dependent lag period as previously reported (8). ATG (100 μM) did not affect the length of the lag (obtained using 3 mM GSH), but increased the rate of peroxidation once underway (Fig. 2). Addition of cytosol (25–100 μl from a 10% homogenate/500 μl incubation) inhibited the microsomal peroxidative response to ferric ion/ascorbic acid (measured at 30 min; post lag period). ATG (100 μM) completely reversed the cytosolic inhibition, and 25–50 μM ATG exhibited partial inhibition of the cytosolic protection (Fig. 3).

In order to further explore the effects of ATG on cytosolic protective enzymes, we utilized liposomal sub-

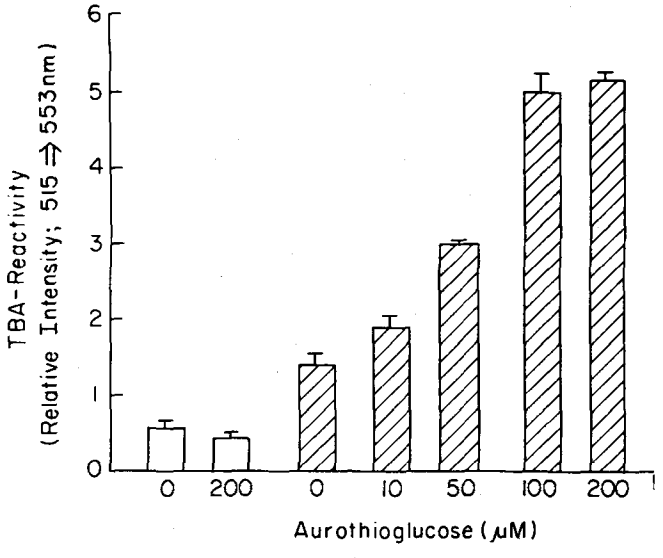

FIG. 1. Promotion of ferrous ion-induced lipid peroxidation by ATG. Rat liver microsomes were exposed to ferrous sulfate (10 μM) (cross-hatched bars) or to control 15 min incubation (open bars) in the presence of the indicated concentration of ATG. All reaction mixtures contained glutathione (800 μM). Lipid peroxidation was assessed by a spectrofluorometric assay of TBA-reactivity as described in the methods. Brackets denote the SEM of 6 observations.

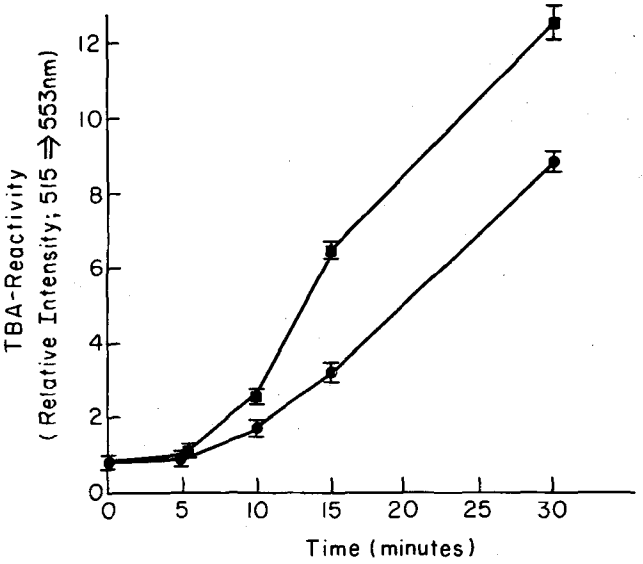

FIG. 2. Potentiation of the postlag phase ferric ion/ascorbic acid-promoted lipid peroxidation by ATG. Rat liver microsomes were exposed to ferric chloride (10 μM) and ascorbic acid (500 μM), in Tris buffer containing 3 mM GSH and no additional agents (closed circles) or ATG (100 μM) (closed squares), for the indicated duration. Lipid peroxidation was assessed as described in Figure 1 and in the methods. Brackets denote the SEM of 4 samples.

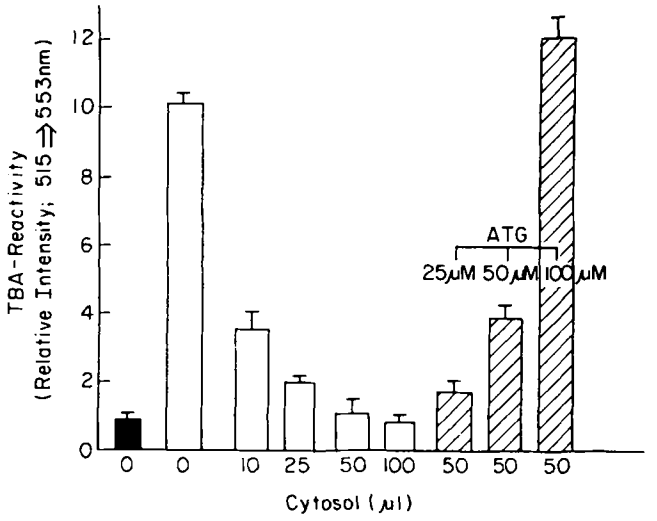

FIG. 3. Inhibition of ferric ion/ascorbic acid-induced lipid peroxidation by cytosol and reversal by ATG. Rat liver microsomes were exposed for 30 min to the peroxidation stimulus ferric chloride (10 μM/ascorbic acid (500 μM), in the presence of GSH (3 mM) and the indicated level of dialyzed cytosol and ATG (cross-hatched bars). Lipid peroxidation was assessed as described above. Brackets denote the SEM of 4 observations.

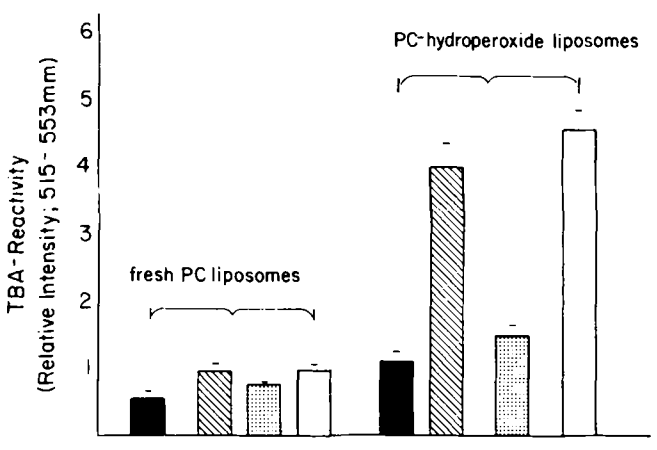

FIG. 4. Inhibition of phosphatidylcholine hydroperoxide-dependent lipid peroxidation by cytosol and reversal by ATG. Rat liver cytosol (or control incubation) was preincubated for 5 min in Tris buffer, pH 7.4, with liposomes prepared from fresh solutions of phosphatidylcholine or liposomes containing both phosphatidylcholine and phosphatidylcholine hydroperoxides (10% of phospholipid oxidized). Some preincubations also contained ATG (100 μM final concentration). Peroxidation reactions were induced by subsequent incubation for 15 min with ferrous sulfate (10 μM), except where noted, and lipid peroxidation assessed as described above. Solid bars; without iron, cross-hatched bars; iron only, dotted bars; cytosol (50 μl) and iron, open bars; cytosol (50 μl) + ATG (100 μM) + iron. Brackets denote the SEM of four observations.

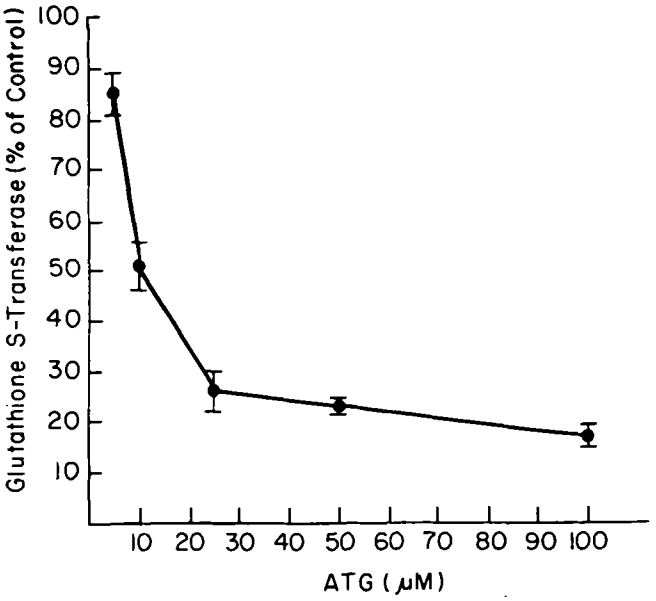

FIG. 5. Inhibition of cytosolic glutathione S-transferase by ATG. Glutathione S-transferase activity was measured as described in the methods. Brackets denote the SEM of 4 observations.

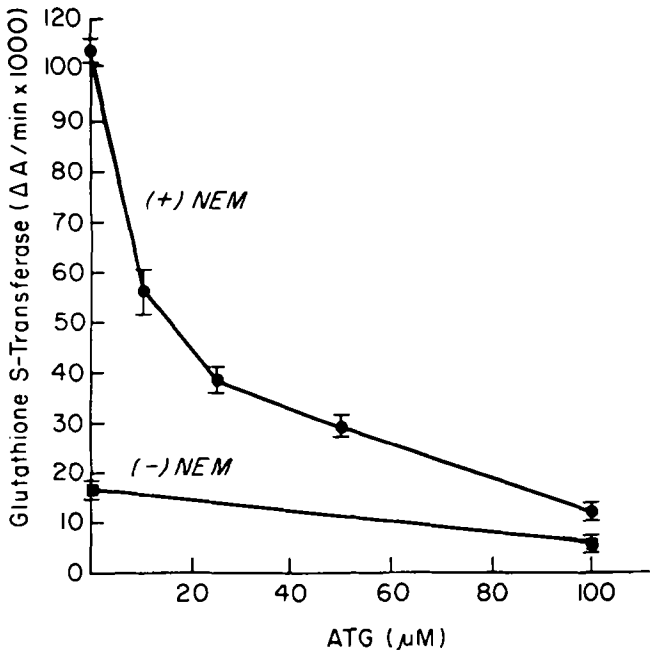

FIG. 6. Inhibition of microsomal glutathione S-transferase activity by ATG. Basal levels of microsomal glutathione S-transferase activity (closed squares) and N-ethyl maleimide augmented activity (closed circles) were measured, as described in the methods, in the presence of the indicated concentration of ATG. Brackets denote the SEM of 4 observations.

strates, consisting of sonicates of phosphatidylcholine containing phosphatidylcholine hydroperoxide (10% of total phospholipid) or of equivalent liposomes prepared from fresh phosphatidylcholine solutions only. Cytosol (with GSH, 500 μM) was preincubated with ATG (5 min), prior to the addition of phospholipid hydroperoxide liposomes and an additional 15 min preincubation. Ferrous sulfate (10 μM) then was added to promote peroxidation. Control experiments were run in the absence of ATG and/or using fresh phosphatidylcholine liposomes. ATG (100 μM final concentration) reversed the inhibition of peroxidation of phosphatidylcholine hydroperoxide liposomes afforded by cytosol (Fig. 4). Liposomes prepared from fresh phosphatidylchyoline (without added hydroperoxide) were peroxidized to a much lesser degree than the hydroperoxide-containing liposomes (Fig. 4),

indicating that most of the peroxidative response in this system resulted from iron-induced phospholipid hydroperoxide-dependent propagation reactions, rather than initiation. Thus ATG, appears to reverse an inhibition of propagation reactions afforded by cytosol.

ATG inhibited cytosolic glutathione S-transferase activity (Fig. 5) and both the basal and the N-ethyl maleimide-augmented microsomal glutathione S-transferase (Fig. 6). The dose-response curves were similar for the ATG-induced inhibition of cytosolic and augmented microsomal activities, with greater than 80% inhibition achieved at 100 μM ATG. Total glutathione peroxidase activity of cytosol, measured using t-butyl hydroperoxide substrate, was inhibited by ATG (72.5% by 100 μM, in close agreement with previous studies [13]. ATG did not affect microsomal or cytosolic superoxide dismutase activity (data not shown). ATG, at concentrations up to 250 μM, did not inhibit PHGPX activity measured in the presence of Triton X-100 (0.1%). PHGPX activity was not detectable in the absence of Triton. (Control experiments showed that Triton, itself, does not elicit apparent activity.)

DISCUSSION

These results have demonstrated that the glutathione peroxidase inhibitor, ATG is a potent enhancer of iron-induced microsomal lipid peroxidation (in the absence of cytosol) and an inhibitor of the cytosolic defense against microsomal lipid peroxidation. The former (microsomal) response to ATG was heat labile (i.e., heat inactivated microsomes were readily peroxidized, with or without ATG, to an equal extent) and was GSH-dependent, suggesting that ATG was inhibiting a GSH-dependent microsomal protein. ATG, however, did not affect the lag period for iron-induced microsomal lipid peroxidation (in the presence of GSH) that has been associated with vitamin E and a GSH-dependent microsomal protein, but instead inhibited peroxidative responses following the lag period. Thus, ATG appears to inhibit a separate GSH-dependent microsomal defense mechanism and, from that, causes the lag period. The cytosolic inhibition was GSH-dependent, as described previously (1-5), and the effect of ATG in overcoming the cytosolic defense was similarly due to inhibition of a cytosolic GSH-dependent enzyme. It is unlikely that glutathione depletion is a major mechanism for the peroxidative response to ATG, as the potentiation was higher using a 800 μM level of GSH than at 100-200 μM GSH.

ATG reversed phospholipid hydroperoxide-dependent liposomal lipid peroxidation (propagation) promoted by iron. This effect could not be due to the classical glutathione peroxidase or glutathione S-transferase, as these enzymes are inactive against intact phospholipids (3), and phospholipases are absent in this system. The activity reported by Gibson et al. (4) inhibits initiation and, thus, should not be involved in a phospholipid hydroperoxide-dependent response. The PHGPX described by Ursini (5) utilizes the phospholipid hydroperoxide substrate and likely is responsible for the cytosolic inhibition that is blocked by ATG. ATG, however, did not inhibit PHGPX using the coupled enzyme assay with NADPH-dependent glutathione reductase and Triton X-100. Measurement of PHGPX by this assay is difficult, using crude enzyme sources (5), but is facilitated by the addition of Triton X-100 (20). It is possible that ATG effects might be masked under the conditions appropriate for this assay.

The possible effect of ATG on cytosolic PHGPX does not explain why microsomal lipid peroxidation was enhanced in the absence of cytosol, and raises the possibility that the reversal of cytosolic inhibition was due to a stimulatory mechanism. The GSH-dependence and heat-labile nature of the effect of ATG on iron-induced microsomal peroxidation argue for the involvement of GSH-dependent enzymes. Although largely recovered in the soluble portion of tissues, PHGPX has been extracted from microsomes and mitochondria using high ionic strength treatment (21), and thus may be involved in the in vitro microsomal peroxidation system. ATG did not enhance liposomal lipid peroxidation in the absence of PC-hydroperoxide and cytosolic enzymes (Fig. 4), indicating that nonenzyme-related stimulatory mechanisms probably are not operative with microsomes.

ATG inhibited GSH S-transferase activity, in addition to GSH peroxidase activity. Although GSH S-transferase apparently is not involved in protection against lipid peroxidation (3), as assessed by general determinations, it is possible that the role of this enzyme is glutathione conjugation reactions may affect the overall toxicity of a peroxidative response. In this regard, the bioactive aldehydic lipid peroxidation product 4-hydroxy nonenal has recently been reported to be a substrate for glutathione S-transferase (conjugation reaction) (22). Investigations of levels of specific peroxidation products may better define the importance of this and similar reactions of glutathione S-transferase.

In conclusion, our results have demonstrated that ATG inhibits cytosolic and microsomal defense mechanisms against lipid peroxidation. In view of the multiple effects of the agent on enzyme activities, it it not possible to draw absolute conclusions about the protective enzyme associated with ATG-induced peroxidative responses. The reversal of the cytosolic inhibition of phospholipid hydroperoxide-dependent propagation reactions by ATG, however, does suggest strongly an involvement of PHGPX, despite the lack of effect of ATG on the associated enzyme assay. The implication of a prominent role for PHGPX in the peroxidation defense mechanism argues against the suggested role of phospholipases A as a protective agents (6).

[Received April 25, 1988; Revision accepted June 20, 1988]

Effects of 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) on de novo Fatty Acid and Cholesterol Synthesis in the Rat

M.R. Lakshman*, Barbara S. Campbell, Stuart J. Chirtel and Nisa Ekarohita
Lipid Research Laboratory, V.A. Medical Center, Washington, DC 20422

The effects of 1, 5, 10 and 20 μg/kg dosages of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) upon de novo fatty acid and cholesterol synthesis in liver and adipose tissue were determined in pair-fed rats. The incorporation of tritium from ^3H_2O into tissue lipids was measured. Hepatic and adipose fatty acid synthetic rates (μmoles acetyl units g^{-1} hr^{-1}) in the control groups were 19.6 ± 4 and 75.7 ± 18.5, respectively, and the liver cholesterol synthetic rate was 2.9 ± 0.5. TCDD (1 μg/kg) inhibited fatty acid synthesis in the liver and adipose tissue, by 44% and 41%, respectively, and the liver cholesterol synthesis was inhibited by 37%. The extent of these inhibitions increased with increasing dosages of TCDD. The effect of TCDD on sterol synthesis in adipose tissue could not be determined, because the tritium incorporation into the sterol fraction in this tissue was not detectable.
***Lipids 23,* 904–906 (1988).**

2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) is the most toxic contaminant of the herbicides used as defoliants. It also has been implicated in several accidental poisonings (1–3). So far, the mechanism of its toxicity (acute or chronic) has not been elucidated. Our recent studies on long-term pharmacokinetics of TCDD (4) have established that orally administered TCDD is transported in the blood compartment as chylomicrons and that the bulk of it is deposited in the liver and adipose tissues with half-lives of 5.3 and 7.6 weeks, respectively. Therefore, these two tissues seem to be the major target organs for the toxic manifestations of TCDD.

TCDD dramatically alters the lipid profiles in laboratory animals and man. Elegant studies by Albro et al. (5) and McConnell et al. (6) have shown clearly that a sublethal dose of TCDD causes a transient increase in serum triglycerides and free fatty acids and a decrease in steryl esters, while a lethal dose causes fatty liver and large increases in serum cholesteryl esters and free fatty acids without significant change in triglyceride levels. Attempts to determine the effects of TCDD on hepatic lipid synthesis have been inconclusive, because of the use of labeled acetate as the precursor for the measurement of absolute rates of lipid synthesis (7). Since the concentration of the intracellular pool of acetate can vary significantly, depending on the nutritional state of the animal, the specific activity of injected labeled acetate in vivo cannot be accurately determined. Therefore, measurements of lipid synthetic rates based on labeled acetate incorporation have been questioned (8–11). In contrast, the incorporation of tritium from tritiated water into body lipids has been demonstrated to give an accurate measure of lipid synthetic rates because the specific activity of body water can be determined precisely (8–11). Furthermore, because the lipid synthetic rates are maximal in fully fed animals, it is important to perform these studies under carefully controlled conditions, such as in a meal-fed state (12,13). As shown by Seefeld and Peterson (14) and by Gorski and Rozman (15), TCDD administration significantly affects the food consumption for at least 5 days. In order to rule out any secondary effects of TCDD on lipid synthesis due to impaired food consumption, the control and experimental animals were not only meal-fed, but also pair-fed, for seven days in the present studies so that the true effects of TCDD on hepatic and adipose tissue synthetic rates of de novo fatty acid and cholesterol could be determined. It will be demonstrated that a dosage of TCDD as low as 1 μg/kg causes a significant inhibition of both fatty acid and cholesterol synthesis in the liver and of fatty acid synthesis in the adipose tissue.

MATERIAL AND METHODS

TCDD. 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin was purchased from the IIT Research Institute Chemical Carcinogen Standard Reference Repository, Chicago, IL, and was found to be more than 98% pure, based on high-performance liquid chromatography (HPLC) (4). All other chemicals and reagents were of analytical grade.

Animals. Wistar rats (body wt 170–190 g) were procured from Charles River, Wilmington, MA, and were maintained on the normal Wayne Lablox chow (4.4% fat content) ad libitum for two weeks before experimentation. All the rats were meal-fed the same diet between 9 am and 12 noon every day for a week and divided into control and experimental groups of at least six rats each.

Effect of dosage of TCDD. Each animal in the experimental groups received an intraperitoneal injection of 1, 5, 10 or 20 μg/kg body wt of TCDD in corn oil. The animals in the corresponding control groups received an equivalent volume of corn oil vehicle only. All the animals were meal-fed for a further period of one wk. The animals in any control group were pair-fed with the animals in the corresponding experimental group.

Determination of fatty acid and cholesterol synthetic rates in liver and adipose tissues in vivo. The tritium incorporation method is based on the work of Fain and Scow (8), as well as that of Jungus (9), and has been successfully validated by Brunengraber et al. (10) and by Lakshman and Veech (11). Briefly, the rats from all the groups were injected intraperitoneally with tritiated water (1 mCi/kg body wt) at the end of the last meal-feeding period. They were killed after 60 min and the blood plasma, liver and the adipose tissue were saved, and the lipid synthetic rates were measured as described previously (10–13).

RESULTS

Effect of various dosages of TCDD on the weights of body, liver and fat pads. The effect of TCDD administration at dosages of 1, 5, 10 and 20 μg/kg body wt on the weights of body, liver and fat pads are presented in Table 1. TCDD at the dosages of 1, 5 and 20 μg/kg did not significantly affect the body weight within seven days of treatment. However, the mean body weight of the animals receiving 10 μg/kg TCDD was significantly lower than that of the animals in the corresponding control group ($P < 0.01$). Long-term treatment of rats with TCDD, especially at higher dosages, is known to reduce the body weight (14,15). In contrast, the mean liver weight increased with increasing dosage of TCDD. Thus, the liver weight expressed as percentage of the body weight was 15% higher at 1 μg/kg and 46% higher at 20 μg/kg dosage ($P < 0.01$), compared with the corresponding control groups. Significantly, TCDD failed to affect the weight of the epididymal fat pads at least at the dosages and duration of exposure in the present studies (Table 1).

Effect of varying dosages of TCDD on de novo hepatic fatty acid and cholesterol synthesis. Hepatic de novo fatty acid and cholesterol synthetic rates in TCDD-treated and pair-fed control animals are reported in Table 2. The hepatic fatty acid synthetic rate was 19.6 μmol acetyl units incorporated per gram per hour, and the cholesterol synthetic rate was 2.9 μmol acetyl units incorporated per gram per hour, in the control animals corresponding to the 1 and 5 μg/kg TCDD groups. The fatty acid synthetic rate in the adipose tissue of control animals of these groups was 75.7 μmol acetyl units incorporated per gram per hour. TCDD, at 1 and 5 μg/kg dosages, caused significant inhibitions of hepatic fatty acid and cholesterol syntheses (Table 2). These inhibitory effects increased with increasing dosage of TCDD, in spite of the fact that the synthetic rates in the control animals pair-fed with the animals in 10 and 20 μg/kg experimental groups were significantly lower than the corresponding rates observed in the control animals pair-fed with the animals from 1 and 5 μg/kg experimental groups (Table 2). The tritium incorporation into nonsaponifiable fraction also was inhibited proportionately with increasing dosage of TCDD (data not shown).

Adipose tissue also showed a marked 41% inhibition of fatty acid synthesis at a dosage of 1 μg/kg TCDD (Table 2). The extent of this inhibition increased gradually with increasing dosage of TCDD. The effect of TCDD on sterol synthesis in adipose tissue could not be determined

TABLE 1

Effect of Various Dosages of TCDD On the Weights of Body, Liver and Fat Pads

	Dosage μg/kg	# of animals	Body wt		Liver wt		Fat pad wt	
			Initial	Final	g	As % of body wt	g	As % of body wt
Control		6	195 ± 9	220 ± 3	6.5 ± 0.2	2.96	2.1 ± 0.1	0.88
Exptl	1.0	6	189 ± 9[a]	211 ± 4[a]	7.1 ± 0.2	3.39[b]	2.0 ± 0.2	0.86[a]
Control		6	195 ± 9	220 ± 6	6.5 ± 0.2	2.96	2.1 ± 0.1	0.88

TABLE 2

Effect of Various Dosages of TCDD On Lipid Synthesis

Tissue	Lipid class	Lipid synthetic rate[a] in control animals		% Inhibition at TCDD dosages of μg/kg			
		1 & 5 μg group	10 & 20 μg group	1	5	10	20
Liver	Fatty acids	19.6 ± 4.0	12.6 ± 3.0	44	48	52	62
	Cholesterol	2.96 ± 1.2	1.7 ± 0.8	37	42	52	63
Adipose	Fatty acids	75.7 ± 18.5	38.0 ± 14.4	41	44	54	56

Various groups of rats were injected with the indicated dosages of TCDD and meal-fed for 7 days. The corresponding groups of control animals received the corn oil vehicle only and were pair-fed with the respective experimental groups. Lipid synthetic rates in the liver and adipose tissues were determined as described in "Materials and Methods" section. The observed inhibitions in the experimental groups are reported as % of the rates observed in the corresponding control groups.

[a]μmoles acetyl units g^{-1} hr^{-1}; each value is the mean ± SD.

because the tritium incorporation into sterol fraction in this tissue was not detectable.

DISCUSSION

It is well known that TCDD can cause significant weight loss and depletion of body fat, depending on its dosage and the duration of exposure (5,16-20). In the present studies, TCDD was found to affect significantly the body weight of the animals only at the dosage of 10 μg/kg, seven days after exposure (Table 1). This may have been due to slightly lower initial body weight of this group compared with its corresponding control group. Furthermore, none of the dosages of TCDD used in this study affected the epididymal fat pad weight. In contrast, the liver weight increased markedly at all the dosages of TCDD tested, presumably due to hypertrophy or hyperplasia. In fact, the liver weight, as percentage of the body weight, increased by 46% ($p < 0.01$) in the 20 μg/kg experimental group compared with the corresponding control group (Table 2).

The observed rates of fatty acid and cholesterol syntheses in the control animals pair-fed with the animals in the 1 and 5 μg/kg experimental groups (Table 2) are comparable with physiological rates (12,13) found in normal meal-fed rats. The significantly lower lipid synthetic rates observed in the control group pair-fed with the 10 and 20 μg/kg experimental group likely are due to the fact that pair-feeding led to a lower amount of food consumed by the control group, corresponding to higher dosages of TCDD (8 ± 1 g/day) than those corresponding to lower dosages of TCDD (13 ± 1.2 g/day). Nonetheless, TCDD inhibited markedly the absolute rates of both fatty acid and cholesterol synthesis in the liver and fatty acid synthesis in the adipose tissue, even at a dose of 1 μg/kg body wt (Table 2). The extent of this inhibition increased with increasing dosage of TCDD. The reason the magnitude of this inhibition did not become more severe at 10 and 20 μg/kg TCDD dosages may be due to the fact that the lipid synthetic rates in these control groups themselves were lower than the rates observed in the control groups corresponding to lower dosages (Table 2).

It must be pointed out that the absolute rate of lipid synthesis calculated on the basis of tritium incorporation is dependent on the constant amount of $^3H/C$ ratio, as reported by a number of workers (8-11,21-23). However, this has been questioned by in vitro studies (24,25) in isolated hepatocytes, where this ratio was shown to vary with the time of incubation and by the addition of pyruvate and glucagon to the incubation medium. But, the pioneering work of Dietschy and his associates (21-23) indicates clearly that the $^3H/C$ ratio remains constant for each molecule of sterol, synthesized in both liver and intestine, that is independent of the metabolic state, the rate of lipid synthesis and the type and concentration of the substrate from which the acetyl CoA pool is derived. Therefore, the tritium incorporation method is the most accurate of currently available methods for measuring the absolute rate of lipid synthesis. Whether TCDD treatment affects the $^3H/C$ ratio remains to be clarified.

Based on the present data, it is reasonable to conclude that, long before its toxic manifestations on body weight and depot fat, TCDD impairs body lipid synthetic rates within a week at as low as 1 μg/kg dosage (equivalent to endogenous TCDD concentration of 1 ppb). This biochemical effect may have important clinical implications in TCDD induced weight and fat loss in human populations who might have accumulated as low as 1 ppb TCDD after exposure. Further studies on the duration and mechanism of action of TCDD on lipid synthetic rates are currently in progress.

Lipid Composition of Platelets From Patients With Atherosclerosis: Effect of Purified Eicosapentaenoic Acid Ethyl Ester Administration

Hiroshi Kamido*, Yuji Matsuzawa and **Seiichiro Tarui**
The Second Department of Internal Medicine, Osaka University Medical School, Fukushima, Fukushima-ku, Osaka 553, Japan

Although eicosapentaenoic acid (EPA) has been shown to have beneficial effects in the prevention of atherosclerosis, the mechanism by which these effects occur is not entirely clear. We investigated the lipid composition of platelets in paired subjects with and without atherosclerotic disease, either hypercholesterolemic (low density lipoprotein [LDL] cholesterol [Chol] ⩾ 170 mg/dl) or normocholesterolemic (LDL-Chol < 170 mg/dl). Platelets from patients with atherosclerotic disease had a lower phosphatidylcholine (PC)/Chol ratio, when compared with those from patients without atherosclerotic disease, irrespective of LDL-Chol levels. Eleven patients with atherosclerotic disease were treated with purified EPA ethyl ester (1.8 g/day), and changes in lipid composition of platelets were investigated. Plasma levels of total Chol and LDL-Chol decreased significantly after EPA administration. The phospholipid (PL)/Chol ratio and the PC/Chol ratio in platelets from patients with atherosclerotic disease increased significantly after 4–10 wk EPA treatment. The EPA content in platelets increased, while the arachidonic acid (AA) content decreased. EPA-induced changes in the PL/Chol and the PC/Chol ratios of platelets, as well as fatty acyl chain shifts, may be related to the beneficial effects in preventing atherosclerosis, possibly by increase in the membrane fluidity. *Lipids 23,* 917–923 (1988).

Platelet activation is thought to be important in the generation of atherosclerotic disease (1). The lipid composition of the platelet affects not only prostaglandin metabolism (2,3), but also membrane fluidity of platelets (4), and thus, might affect platelet aggregation. Determinants of membrane fluidity are the phospholipid (PL)/cholesterol (Chol) ratio and the class of PL, as well as the fatty acid composition in the membrane (5).

Considerable evidence suggests that hypercholesterolemia, particularly the increase in the low density lipoprotein (LDL) Chol fraction, is associated with increased platelet aggregation (6). Patients with atherosclerotic disease also are reported to have enhanced platelet activity (7,8). One of the aims of the present study is to analyze separately the effects of hypercholesterolemia and atherosclerotic disease on the lipid composition of platelets, and to clarify the characteristics of lipid composition including PL class composition in platelets of patients with atherosclerotic disease.

Since Dyerberg et al. (9,10) reported the relationship between the diet of Eskimos and the low incidence of myocardial infarction, which might be accounted for by a reduction in platelet aggregation, the effects of fish diet or a supplement of fish oil on platelet aggregation and prostaglandin metabolism in platelets has been extensively investigated (8,11,12). However, there have been few studies investigating the effect of eicosapentaenoic acid (EPA) administration on the composition of platelet lipids other than fatty acids (13,14). Therefore, in this study, we also investigated the effect of purified EPA ethyl ester on platelet lipid composition, including Chol content and PL class composition, as well as fatty acid composition, in patients with atherosclerotic disease.

MATERIALS AND METHODS

Subjects. Forty-four persons were enrolled in the present study, consisting of 11 subjects with normal LDL-Chol level and without atherosclerotic disease (aged 25–66 yr), 11 with normal LDL-Chol level and with atherosclerotic disease (31–70 yr), 11 with high LDL-Chol level and without atherosclerotic disease (22–68 yr) and 11 with high LDL-Chol level and with atherosclerotic disease (33–63 yr). The clinical findings of each group are shown in Table 1. Patients with atherosclerotic disease included 18 patients with ischemic heart disease, as diagnosed by exercise electrocardiography (six were angiographically confirmed), two with old cerebral infarction as diagnosed by brain computerized tomography and two with peripheral arterial disease as determined by angiography. Plasma LDL-Chol level was calculated by Friedewald's equation: LDL-Chol = total Chol − ([triglycerides/5] + HDL-Chol) (15). These subjects were arbitrarily classified into those with normal plasma LDL-Chol level (<170 mg/dl) and those with high plasma LDL-Chol level (⩾170 mg/dl). The 170 mg/dl plasma level of LDL-Chol was chosen as the "cut off" point, because the level represents the moderate-risk level even in subjects older than 50 (16).

EPA administration. Among the 22 patients with atherosclerotic disease, 11 patients (seven with normal LDL-Chol levels, four with high LDL-Chol levels) were treated with EPA ethyl ester on an outpatient basis. They were selected for their willingness to be treated with EPA ethyl ester. Their clinical characteristics are shown in Table 2. Diet and other drugs administrated concomitantly were unchanged during this study. Subjects were consuming an ordinary Japanese diet, and none were obese. Patient 10 was taking cholestyramine; patient 9, niceritrol (a derivative of nicotinic acid); and the remainder were not taking hypolipidemic medications. Each patient was treated with EPA ethyl ester 1.8 g/day (six capsules/day) in three divided doses for 4–10 wk. Seven patients were studied at four wk. One patient was studied at six wk (patient 4), two at eight wk (patients 5 and 6), and one was studied at 10 wk (patient 3). The encapsulated EPA ethyl ester was provided by Mochida Pharmaceutical Company. Each gelatin-coated soft capsule weighed 400 mg and contained ethyl esters containing 75% EPA, 1–4% C18:4, 1–4% C20:4, 1% C22:5, 4–6%

[e]IHD, ischemic heart disease; PAD, peripheral arterial disease; OCI, old cerebral infarction.

C22:6 and 0.2% α-tocopherol. Informed consent was obtained from each patient before EPA ethyl ester administration.

Preparation of platelet suspensions. Fresh venous blood was drawn from patients and anticoagulated by collecting it in a plastic tube with EDTA 3.5 mM (final concentration). Platelet-rich plasma was prepared by centrifugation of whole blood at 250 *g* for 10 min. The platelets were then sedimented at 1100 *g* for 10 min and routinely washed two times in a washing buffer (9 mM EDTA phosphate buffered saline, pH 6.2). Microscopic observation revealed that the contamination by erythrocytes was negligible.

Homogenization of the platelets. Isolated platelets were homogenized by sonication with microtip, eight times for 15 seconds at 70% intensity, with intervening cooling periods between them. Platelet protein content was measured by the method of Lowry (17).

Lipid analysis. Lipid extraction of the homogenized platelets was carried out by the method of Folch et al. (18), using a chloroform/methanol solution (2:1, v/v). Platelet Chol content was determined by the method of Rudel and Morris (19). Platelet lipid phosphorus content was estimated by a modified Chen's method (20). Total PL content was taken to equal lipid phosphorus times 25. Plasma Chol and triglyceride (TG) concentrations were

measured by the enzymatic method (21,22). High density lipoprotein (HDL)-Chol levels were evaluated by selective precipitation (heparin-calcium method) (23). Analysis of PL composition was carried out by two-dimensional thin-layer chromatography (TLC) by the method of Rouser et al. (24). Total lipids (approximately 150 μg of PL) were applied to Silica Gel 60 H impregnated with 0.01 M magnesium acetate plate and developed in the first dimension with chloroform/methanol/aq NH_3 (28%)/water, 120:80:10:5 (v/v/v/v) and in the second dimension with chloroform/acetone/methanol/acetate/water, 100:40:30:20:12 (v/v/v/v/v). After visualization of the lipids by charring at 180°C for 30 min with 20% aqueous solution of ammonium sulfate containing 4% H_2SO_4, the silica areas were scraped into tubes and lipid phosphorus was estimated by the method of Rouser et al. (24).

The fatty acids of total lipids in platelets were analyzed as their methyl esters by gas-liquid chromatography (GLC) using a Shimadzu GC-8A gas chromatograph equipped with a hydrogen flame ionization detector. A 2.6 mm i.d. × 2 m glass column packed with SILAR-10C on 100–120 mesh was used. Analyses were carried out at an injection temperature of 250°C and a column temperature of 185°C. The signals were analyzed by a Chromatopac C-R1A (Shimadzu) computer analyzer. Each peak was identified by comparing it with those of assays on standard mixtures of fatty acids supplied by Applied Science Laboratories Inc. A standard mixture including docosapentaenoic acid (DPA) (ω-3) was supplied by Mochida Pharmaceutical Company.

Statistical evaluation. The four groups were compared by a two-way analysis of variance. By using this approach, each analysis of variance yielded three p values (Table 3). The p value for the comparison labeled N/H refers to differences between the entire normocholesterolemic and the entire hypercholesterolemic group, whereas the comparison −/+ compares all nonatherosclerotic with all atherosclerotic patients. The third p value determines whether hypercholesterolemia and atherosclerosis have a significant interactive effect on each dependent variable (L/A). Two-sample comparisons between values obtained before and after EPA administration were made with a paired-sample t-test.

RESULTS

Comparison of platelet lipid composition in normal LDL-cholesterolemic and high LDL-cholesterolemic subjects. The PC/Chol ratio of platelets was significantly ($F(1,40) = 4.93$, $p < 0.05$) lower in high LDL-cholesterolemic (≥170 mg/dl) subjects than that in normal LDL-cholesterolemic subjects (Table 3). The phosphatidylinositol (PI)/Chol ratio also was significantly ($F(1,40) = 5.21$, $P < 0.05$) lower in high LDL-cholesterolemic subjects than that in normal LDL-cholesterolemic subjects. The other parameters of platelet lipid in high LDL-cholesterolemic subjects were not significantly different than those in normal LDL-cholesterolemic subjects.

Comparison of platelet lipid composition in subjects with and without atherosclerotic disease. Platelets from

[a] Values are presented as mean ± SD.

[b] N/N = significance between all normal LDL-cholesterolemic (<170 mg/dl) and high LDL-cholesterolemic (≥170 mg/dl) subjects (independent of classification according to atherosclerotic disease); −/+ = significance between all subjects without atherosclerotic disease and those with atherosclerotic disease (independent of classification according to the levels of plasma LDL-Cholesterol); L/A = interaction between the effects of plasma LDL-Cholesterol level and atherosclerotic disease; NS = not significant.

[c] Abbreviations: Chol, cholesterol; PL, phospholipid; LPC, lysophosphatidylcholine; PC, phosphatidylcholine; SM, sphingomyelin; PI, phosphatidylinositol; PS, phosphatidylserine; PE, phosphatidylethanolamine.

subjects with atherosclerotic disease had a significantly ($F(1,40) = 6.70$, $p < 0.025$) lower PC/Chol ratio than those from subjects without atherosclerotic disease. The other parameters of platelets in subjects with atherosclerotic disease were not significantly different than those in subjects without atherosclerotic disease. The PC/protein (prot) ratio ($F(1,40) = 3.29$), the PL/Chol ratio ($F(1,40) = 3.94$), the phosphatidylserine (PS)/Chol ratio ($F(1,40) = 4.06$), the phosphatidylethanolamine (PE)/Chol ratio ($F(1,40) = 3.21$), and the PC/sphingomyelin (SM) ratio ($F(1,40) = 3.28$) tended to decrease in platelets from subjects with atherosclerotic disease ($0.05 < p < 0.10$) (Table 3).

Effect of EPA administration on plasma lipids in patients with atherosclerotic disease. Changes of plasma lipids after EPA administration are shown in Figure 1. Plasma levels of total Chol and LDL-Chol decreased ($p < 0.01$ and $p < 0.05$, respectively) after EPA administration. Plasma levels of TG and HDL-Chol did not change with EPA administration.

Effect of EPA administration on platelet lipid composition in patients with atherosclerotic disease. The PC/Chol ratio of platelets increased significantly ($p < 0.02$) from 0.483 ± 0.133 to 0.608 ± 0.127 (mean $\pm$ SD) after EPA administration (Table 4, Figure 2). The PC/prot ratio and the PL/Chol ratio also increased ($p < 0.05$) with EPA ingestion. The other characteristics did not change significantly. The PL/prot ratio, the SM/Chol ratio and the PE/Chol ratio tended to increase with EPA administration ($0.05 < p < 0.10$).

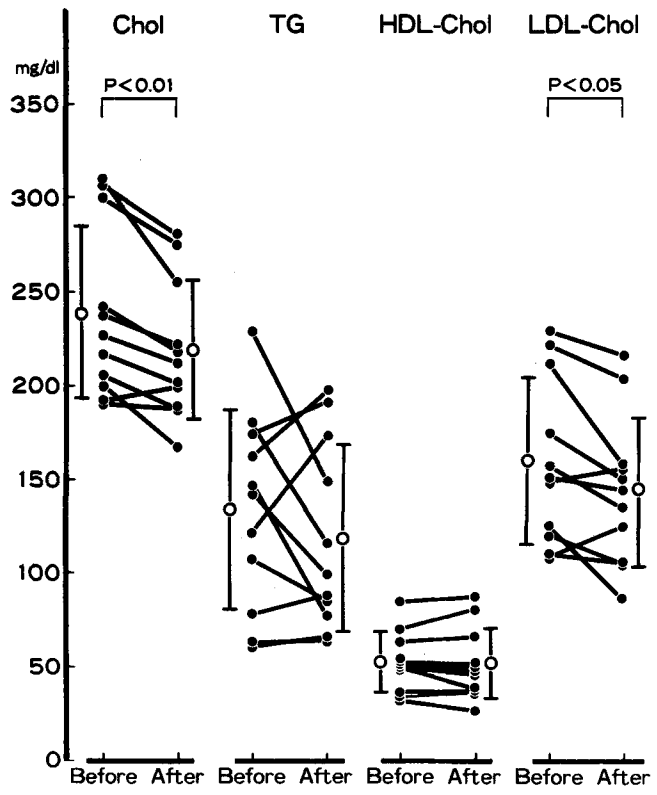

FIG. 1. Plasma lipid levels in patients with atherosclerotic disease before and after eicosapentaenoic acid ethyl ester (EPA-E) administration (Chol, cholesterol; TG, triglycerides; HDL, high density lipoprotein; LDL, low density lipoprotein).

[a] Values are presented as mean ± SD.

[b] Abbreviations: Chol, cholesterol; PL, phospholipid; LPC, lysophosphatidylcholine; PC, phosphatidylcholine; SM, sphingomyelin; PI, phosphatidylinositol; PS, phosphatidylserine; PE, phosphatidylethanolamine.

[c] Significantly different from before EPA-E administration at $p < 0.05$ (Student's t-test; paired).

[d] Significantly different from before EPA-E administration at $p < 0.02$ (Student's t-test; paired).

Effect of EPA administration on platelet fatty acid composition in patients with atherosclerotic disease. Relative content of each fatty acid is expressed as wt% of total fatty acids in total lipids (Table 5). The content of EPA (C20:5) in platelet lipid increased in all patients, and mean EPA content increased ($p < 0.001$) from $2.3 \pm 1.1\%$ (mean $\pm$SD) to $3.9 \pm 1.1\%$ with EPA administration. Arachidonic acid (AA) (C20:4) content decreased ($p < 0.01$). Consequently, the ratio of EPA to AA (20:5/20:4) in platelet lipid increased ($p < 0.001$) from 0.098 ± 0.047 to 0.185 ± 0.057 after ingestion of EPA ethyl ester. DPA (C22:5) content also increased significantly ($p < 0.01$); however, docosahexaenoic acid (DHA) (C22:6) content was not changed by EPA administration.

DISCUSSION

In this study, molar ratio of PL to Chol was not different in platelets from hypercholesterolemic and normocholesterolemic subjects, in agreement with the report by Jakubowski et al. (25). The PC/Chol ratio in platelets from hypercholesterolemic subjects was significantly decreased, compared with normocholesterolemic subjects.

Platelets from subjects with atherosclerotic disease had changes in lipid composition similar to those from hypercholesterolemic subjects. The PL/Chol ratio was not decreased in platelets from subjects with atherosclerotic disease, which is similar to the findings of Shattil et al. (26). This study extends their observations; we demonstrated a significant decrease of the PC/Chol ratio in platelets from subjects with atherosclerotic disease.

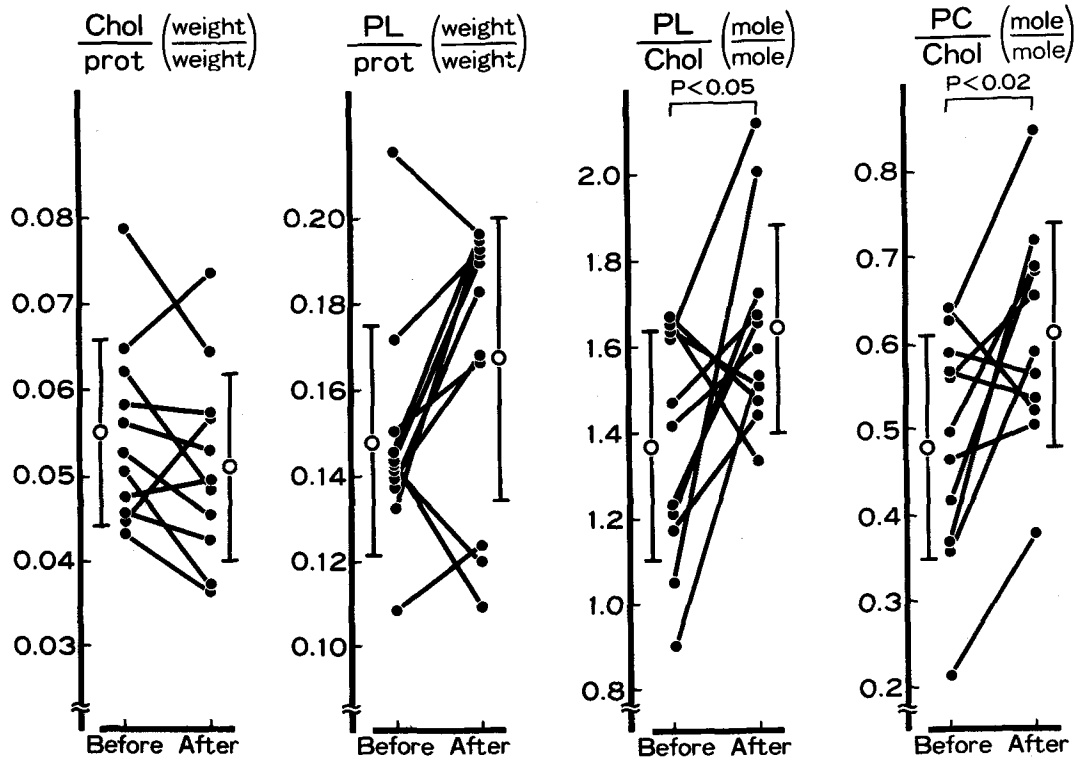

FIG. 2. Lipid composition of platelets in patients with atherosclerotic disease before and after eicosapentaenoic acid ethyl ester (EPA-E) administration (PL, phospholipids; Chol, cholesterol; prot, protein; PC, phosphatidylcholine).

TABLE 5

Fatty Acid Composition of Platelets in Patients with Atherosclerotic Disease before and after Purified Eicosapentaenoic Acid Ethyl Ester (EPA-E) Administration

Fatty acid[a]	Before	After
16:0	19.5 ± 3.1	19.4 ± 2.1
18:0	17.0 ± 1.6	17.7 ± 1.7
18:1 (ω-9)	17.3 ± 1.3	17.7 ± 0.6

20:4 (ω-6)	23.9 ± 3.5	21.1 ± 2.4[b]
20:5 (ω-3)	2.3 ± 1.1	3.9 ± 1.1[c]
22:5 (ω-3)	2.3 ± 1.2	3.1 ± 1.4[b]
22:6 (ω-3)	4.3 ± 1.3	4.3 ± 2.0
Others	6.5 ± 2.4	6.4 ± 1.9
20:5/20:4 (×100)	9.8 ± 4.7	18.5 ± 5.7[c]

[a]Fatty acids are denoted by ratio of chain length to number of double bonds. Values are expressed as percentage of total peak area and presented as mean ± SD.

[b]Significantly different from before EPA-E administration at $P < 0.01$ (Student's t-test; paired).

[c]Significantly different from before EPA-E administration at $P < 0.001$ (Student's t-test; paired).

The PC/free Chol ratio in plasma from patients with atheroselerotic disease also was found to be decreased. Kuksis et al. (27,28) proposed the ratio as an indicator for atherosclerosis. Several reports have shown similar changes in the composition of lipids from the atherosclerotic aorta. Böttcher et al. (29,30) investigated composition of lipids from aorta at different stages of atherosclerosis. Their data showed that the percentage of PL decreased, while free Chol increased, as atherosclerosis became more severe (29). In addition, they reported that the main feature of PL class composition of the atherosclerotic aorta is the increase in SM percentage in parallel with the degree of atherosclerosis, with corresponding decrease in PC content (30). These findings are in agreement with the changes in the lipid composition of platelets from patients with atherosclerotic disease, as shown in this study.

The parallel changes in the lipid composition of plasma, platelet and the arterial tissues do not necessarily establish a causal relationship, although one might assume that the changes in plasma precede those in the tissues (31). The accumulation of lipid within the vessel wall, that results in the development of the initial fatty atheromatous lesion, is usually preceded by hypercholesterolemia (32), and we observed changes in the platelet lipid composition of hypercholesterolemic patients similar to those of atherosclerotic patients.

The ratio of serum glycerophospholipids/free Chol, in particular, the PC/free Chol ratio, has been suggested as a possible indicator of asymmetric fluidity of lipoproteins in disease (33). Abnormalities of cell-membrane fluidity has been thought to be important in the pathogenesis of several diseases, because membrane fluidity affects cell behavior (5). Thus, the decreased PC/Chol ratio of platelets might be a physicochemical basis for the role of them in the pathogenesis of atherosclerosis.

The mechanism of the change of PC/Chol ratio in platelets from patients with atherosclerotic disease has

not been elucidated. This change in lipid composition of platelets might be partly secondary to the change in plasma from patients with ischemic vascular disease (27,34). Platelets cannot synthesize Chol (35), but they are capable of synthesizing and degrading PL (36,37). The change of PC/Chol ratio in platelets, therefore, might reflect the changes in PL metabolism in platelets themselves. In this study, we observed that the PL/Chol ratio and the PC content had a tendency to decrease in platelets from patients with atherosclerotic disease. The results indicate that enhanced degradation of PL, especially PC, might occur in platelets from patients with atherosclerotic disease. Indeed, Chol-rich platelets have an augmented capability of Thromboxane A_2 production (3), and phospholipase A_2 acting on PC is markedly enhanced in platelets with elevated Chol/PL ratio (38). Arachidonate also can be liberated by phospholipase C indirectly from PI via mediation of diglyceride lipase (39). In this context, it is interesting that the PI/Chol ratio decreased only in platelets from hypercholesterolemic patients.

The ratio of PC to Chol in platelet lipids from patients with atherosclerotic disease significantly increased with administration of 1.8 g/day of EPA ethylester for 4–10 wk. The duration of EPA administration (4–10 weeks) did not have a significant effect on the change in PC/Chol ratio. The mechanism of the increase in PC/Chol ratio by EPA administration has not been elucidated yet. Shepherd et al. (40) reported that the relative percentage Chol in the LDL fraction fell, while that of PL rose, during polyunsaturated fat feeding. Therefore, the increases in PL/Chol and PC/Chol ratio in platelets may be due, in part, to those in LDL. There are some reports that polyunsaturated fatty acids enhance PC synthesis (41, 42), and the PC/prot ratio increased with ingestion of EPA. Thus EPA must directly affect PL metabolism in platelets.

EPA content in platelet lipid in patients with atherosclerotic disease increased with administration of 1.8 g/day of EPA ethyl ester for 4–10 wk, while AA content decreased. These results, except for the AA decrease, are similar to the findings in healthy volunteers reported by Terano et al. (13). Goodnight et al. (43) proposed two mechanisms of reduction of AA during a fish diet. One mechanism is that the decreased dietary linoleic acid (most fish oils contain only 1% to 2% linoleic acid) may lead to reduced arachidonate levels in plasma and, hence, platelet membrane PL. The other is that AA simply may be displaced by other fatty acid. In our study, the patients did not change their dietary habits and the linoleic acid (C18:2) content in platelet lipid did not change significantly; therefore, AA was probably replaced by EPA and DPA. The DHA content of platelets in patients with atherosclerotic disease was unchanged, while the DPA content increased after EPA administration. Therefore, the ability exists for elongation of EPA into DPA, but DPA cannot be desaturated into DHA.

In conclusion, this report establishes that EPA increases the PL/Chol ratio and the PC/Chol ratio of platelets from patients with atherosclerosis. These ratio shifts, in addition to fatty acyl chain alterations, might increase the membrane fluidity of platelets from patients with atherosclerosis. This observation may demonstrate another benefit of EPA administration to patients with atherosclerotic disease.

The effect of fish diet on 43 healthy male students was studied. They ate a fish-containing meal for 15 weeks on an average of 3.7 times per week. Twenty-one of them voluntarily restricted their lipid intake while the rest ate normally. Controls continued their usual eating habits (19 students). The meals consisted of Finnish freshwater fish (87%) (vendace, pike, perch and rainbow trout) and brackish water fish (13%) (Baltic herring) that provided about 1 g of ω-3 polyunsaturated fatty acids per day (0.25 g eicosapentaenoic acid and 0.55 g docosahexaenoic acid). During the diet, ω-3 fatty acids increased in erythrocyte ghosts and platelets at the expense of ω-6 fatty acids. The concentration of serum cholesterol diminished in those fish consumers who lowered their lipid intake. Apolipoprotein A_1 and B were lowered in both fish-consuming groups. Triglyceride levels also showed a tendency to decrease. The formation of thromboxane B_2 during incubation of whole blood decreased in both fish-consuming groups. The decrease of plasma 6-keto-$PGF_{1\alpha}$ was not statistically significant, if compared with the controls. The results obtained indicate that a moderate intake of fish-containing meals has some beneficial effects on the plasma lipid and prostanoid metabolism, when coronary heart disease risk factors are considered.
Lipids 23, 924–929 (1988).

There are several reports on the consumption of fish or their oils and their positive effects on coronary disease risk factors. Eating fish lowers serum triglycerides (1) and cholesterol (2). Furthermore, the aggregation of platelets diminishes (3) and thromboxane production is inhibited (4). The bleeding time is prolonged (5). Blood viscosity is lowered (6) and the deformability of red cells is increased (7). Many of these positive effects, however, appear to require rather high intakes of fish oil. There are three epidemiological reports of positive effects, on coronary heart disease risk factors, by a modest fish-consuming diet with an affluent western type of diet (8–10). Furthermore, two reports have been published with negative results (11,12). Consumption of freshwater fish has been studied much less, and no reports of controlled studies of the effects on coronary heart disease risk factors are available. We have found that, at least in the boreal region of Europe, quite significant amounts of ω-3 fatty acids occur in freshwater fish tissues (13). This suggests that, by eating freshwater fish meals, it also might be possible to obtain positive effects against risk factors. The aim of this study was to determine if such effects could be seen in male students who were offered one fish meal during working days over a period of ca. 100 days. The meals were planned so that they could be prepared in public restaurants using readily available materials within the price range for normal operation. The results indicate that such meals can cause some positive changes in lipid metabolism in an area like Eastern Finland where high coronary morbidity and mortality are prevalent (14).

Abbreviations: EDTA, ethylenediamine tetraacetic acid; 6-keto-$PGF_{1\alpha}$, 6-ketoprostaglandin $F_{1\alpha}$.

SUBJECTS AND MEALS

Healthy male students (n = 62) voluntarily participated in the study. The study was approved by the Ethical Committee of the University of Kuopio. None of the students exhibited allergies to fish. The participants' anthropometric properties are in Table 1.

Following base-line measurements, the students were randomly divided into three groups by drawing letters generated by a random-number generator. There were 19 students in the control group; the remainder were provided with a fish meal every working day, and 21 were furthermore asked to voluntarily diminish their fat intake, especially saturated-fat dairy products. All students in the study received a meal (free of charge) once per working day for 103 days. Food consumption was recorded.

The fish were prepared by usual cooking methods used in public catering systems including frying and baking. The same recipe was used only twice during the study. The portion of fish served per meal was 180 g. The average amount of ω-3 fatty acids was estimated to be about 1.8 g per meal (range = 0.6–3.0 g). One fish meal per two weeks was served to the control group, according to the normal frequency of fish meals in the university restaurant.

TABLE 1

The Anthropometric Data and Starting Blood Pressures of Male Students Participating in the Study (means ± SD)

	Controls	Fish eaters	Fish eaters with reduced fat intake
Number of students	19	22	21
Age	23 ± 2	22 ± 3	22 ± 2
Length (cm)	181 ± 5	178 ± 5	181 ± 5
Weight (kg)	74 ± 8	71 ± 7	71 ± 6
Body mass index (kg/m^2)	22.6 ± 1.8	22.3 ± 1.9	21.6 ± 1.8
Systolic blood pressure (mm Hg)	130 ± 15	125 ± 13	126 ± 16
Diastolic blood pressure (mm Hg)	83 ± 10	78 ± 9	83 ± 12

The compliance of the students to a dietary regimen was followed. The fish-consuming groups showed somewhat higher compliance (76%) than the control group (68%). On an average, the fish-eating groups consumed 3.7 ± 0.8 fish meals per week and about 1 g of ω-3 fatty acids per day, which included 0.25 g eicosapentaenoic and 0.55 g docosahexaenoic acid. The meals were found to be palatable. The only reasons for dropping out of the study were inability to remain in the city and other similar reasons. The controls ate, on an average, 0.25 fish-containing meals per week.

The blood samples were drawn before the fish diet was started and, again, when it had been eaten for 7 and 15 weeks. These three samples were taken and analyzed satisfactorily from 13–15 subjects of each group. Furthermore, additional samples were collected in the following autumn when the students had been consuming a usual diet for about five months. These samples could not be taken earlier because of the summer holidays.

METHODS

Before the blood samples were taken, the students were advised not to consume alcohol or acetylsalicylic acid for seven days and to avoid heavy exercise for three days. During the morning before the collection of blood samples, the students did not eat breakfast. The blood samples were drawn before, during (7 and 15 wk) and after (20 wk) the study, between 7:30 and 10:30 AM, after each student had been lying on a bed, totally relaxed for 30 min. All of the blood samples were placed in vacuum tubes without a tourniquet, by the same nurse in the following order: the first two 5-ml samples for serum (apolipoprotein, cholesterol, triglyceride and selenium analyses), the next two 5-ml samples were drawn into Terumo Venoject tubes containing dipotassium-EDTA (5 mg) and acetylsalicylic acid (0.09 mg) (6-keto-$PGF_{1\alpha}$ determinations), two 5-ml samples into EDTA-tubes (preparation of platelets and erythrocyte ghosts for fatty acid analyses), one 5-ml sample into a precooled Terumo Venoject tube (thromboxane B_2 analysis) and one 5-ml sample into a EDTA-tube for the analysis of hemoglobin and blood picture (measured with the aid of a Coulter Counter). The most important purpose of this particular sampling order, and the limitations before drawing samples, was to minimize errors in the very sensitive prostanoid determinations.

The samples for thromboxane B_2 determination were transferred immediately into a water bath (37°C) for 30 min, after which the tubes were placed in ice bath and spun at 4°C for 15 min at 2,000 *g* to separate the serum. The 6-keto-$PGF_{1\alpha}$ samples were spun in the same way to get the plasma.

All the plasma and serum samples were stored at −80°C until analyzed.

The platelets and erythrocyte ghosts were separated for fatty acid analysis. Platelet-rich plasma was obtained by spinning the blood samples at low speed (120 *g* for 10 min at 4°C). The platelets were separated by centrifugation at 2,000 *g* for 15 min (4°C) and, then washed with TRIS-HCl buffer (pH 7.6, 172 mmol/l). Erythrocytes were washed with the same buffer and hemolyzed in the same diluted buffer (11 mmol/l). Ghosts were prepared by centrifugation at 20,000 *g* for 20 min at 4°C. Both platelet and erythrocyte ghost sediments were sonicated in the TRIS-HCl buffer (172 mmol/l) and stored at −80°C until analyzed.

The serum cholesterol and triglyceride concentrations were determined with a Hitachi 705 Analyzer using enzymatic methods (Boehringer Mannheim, GmbH, Mannheim, FRG). Apolipoprotein A_1 and B were measured by immunoturbidometry using antisera obtained from Orion Diagnostica (Orion Ltd, Espoo, Finland). Standardization of the apolipoprotein determination was performed as described earlier (15).

The fatty acids of the platelets and erythrocyte ghosts were transmethylated with sodium methoxide and analyzed by capillary gas-liquid chromatography (Carlo Erba Fractovap 2350, Milano, Italy) in a 15 m OV-351 fused-silica capillary column (Nordion Instruments Ltd, Helsinki, Finland) as described earlier (13). Samples taken 20 weeks after the programmed meals were pooled within the groups and no fatty acid analyses were made from the individual samples.

The 6-keto-$PGF_{1\alpha}$ and thromboxane B_2 were isolated and purified using Sep-pak C 18 cartridges (Waters Associates, USA) (16). Their concentrations were measured by radioimmunoassay kits (New England Nuclear, USA). These use iodinated analogs of these prostanoids as tracers. The corresponding metabolites (tyrosyl methyl esters) labeled with ^{125}I were added to the samples to monitor the recovery.

The rubidium efflux through the erythrocyte cell membrane was measured as described earlier (17).

The data obtained were statistically analyzed by using nonparametric methods. Wilcoxon matched-pairs, signed-ranks test was used for the comparisons inside the groups and Mann-Whitney U-test between the groups.

RESULTS

The serum triglyceride and apolipoprotein A_1 and B levels decreased, during the study, in most students on the fish diet. However, changes in the means were small, due to a couple of very exceptional values. Thus, the significance at $p < 0.1$ was used in Table 2 to indicate the tendencies. The serum cholesterol level decreased in those fish eaters who voluntarily reduced their fat intake. Those fish eaters who continued their usual eating habits, had similar cholesterol levels as the controls at the end of the fish diet. The high basal level of cholesterol in the control group is caused mostly by two subjects with exceptionally high values (>8 mmol/l), which decreased during the study. The changes in the serum cholesterol and triglyceride values during the diet correlated strongly with the changes of the apolipoprotein B. Five months after the fish-eating period, no differences were observed between the groups. The only exception was the apolipoprotein A_1, which still remained at lowered level in the fish-diet group with no limitations of fat intake.

The shifts in fatty acids in the platelets and erythrocyte ghosts, due to fish-containing meals, are summarized in Tables 3 and 4. No significant changes were observed in the controls. The content of arachidonic (20:4ω6) and docosatetranoic (22:4ω6) acids decreased with the increase of eicosapentaenoic (20:5ω3) and docosahexaenoic (22:6ω3) acid contents in both particles. Furthermore, a decrease was observed in the content of dihomogamma-

TABLE 2

Serum Triglyceride, Cholesterol and Apolipoprotein A_1 and B Levels in Male Students Consuming an Average of 3.7 Fish Meals/Week up to 15 Weeks (means ± SD, n = number of students)

	Predietary period	Dietary period	
		7 weeks	15 weeks
Controls, n = 12

Triglycerides (mmol/l)	0.86 ± 0.26	0.81 ± 0.27	0.78 ± 0.26[a,d]
Cholesterol (mmol/l)	4.49 ± 0.62	4.46 ± 0.64	4.25 ± 0.82[f]
Apolipoprotein A_1 (g/l)	1.23 ± 0.15	1.20 ± 0.16	1.15 ± 0.16[f]
Apolipoprotein B (g/l)	0.63 ± 0.10	0.62 ± 0.10	0.58 ± 0.10[f]

[a] Significant at $p < 0.1$,

[b] Significant at $p < 0.01$,

[c] Significant at $p < 0.001$, when compared with initial level (Wilcoxon matched-pairs, signed-ranks test).

[d] Significant at $p < 0.05$,

[e] Significant at $p < 0.001$, when the change in 15 weeks is compared with controls (Mann-Whitney U-test).

[f] Significant at $p < 0.05$, when compared with initial level (Wilcoxon matched-pairs, signed-ranks test).

linolenic acid (20:3ω6) and oleic acid (18:1ω9) in erythrocyte ghosts. Only minor changes were observed in the other fatty acids. The changes in the polyunsaturated fatty acids took place faster in the platelets than in the erythrocyte ghosts (Fig. 1). When the students had been on their usual diets for 5 months after the fish regimen, the proportions of the fatty acids had returned to prestudy levels.

The thromboxane B_2 production during the incubation of the blood samples decreased significantly during the 15 weeks on the fish diet (Table 5). During the first seven weeks, the decrease did not reach the level of statistical significance. The decrease was similar in lipid restricted and nonrestricted fish diet. In the control group, a slight decrease also was observed during the follow-up period, but this was not statistically significant.

During the fish diet, the plasma level of 6-keto-$PGF_{1\alpha}$ showed a decrease that was statistically significant after 15 weeks (Table 5). A slight decrease also was seen in the control group.

The flux of rubidium through the erythrocyte cell membrane was measured at the end of the fish regimen. The rate constant of rubidium efflux was slightly greater in the fish-eating group ($5.99 + 0.61 \times 10^3$ min^{-1}, n = 9) than in the controls ($5.66 + 0.84 \times 10^3$ min^{-1}, n = 8), but the difference did not reach the level of statistical significance.

No changes in the blood picture were observed.

DISCUSSION

The results of this study indicate that freshwater fish contain adequate amounts of ω-3 polyunsaturated fatty acids to permit demonstration of distinct effects in the platelet and erythrocyte ghosts, as well as in the metabolism of these acids, when consumed over a 15-week period. The freshwater fish tissues contain relatively large amounts of ω-3 polyunsaturated fatty acids (13,18), as do marine fish (19). There are several reports on the effects of the marine fish diets on the fatty acid patterns and their metabolites in human populations (20). Thus, both kinds of fish are effectively utilized in the human body.

The proportions of eicosapentaenoic and docosahexaenoic acids increased both in the erythrocyte ghosts and platelets, as was expected. Changes in the erythrocyte ghosts in 15 weeks were similar, as reported earlier by Sanders et al. (21), with essentially higher intake of ω-3 fatty acids for six weeks (20 ml cod-liver oil per day containing 1.8 g eicosapentaenoic and 2.2 g docosahexaenoic

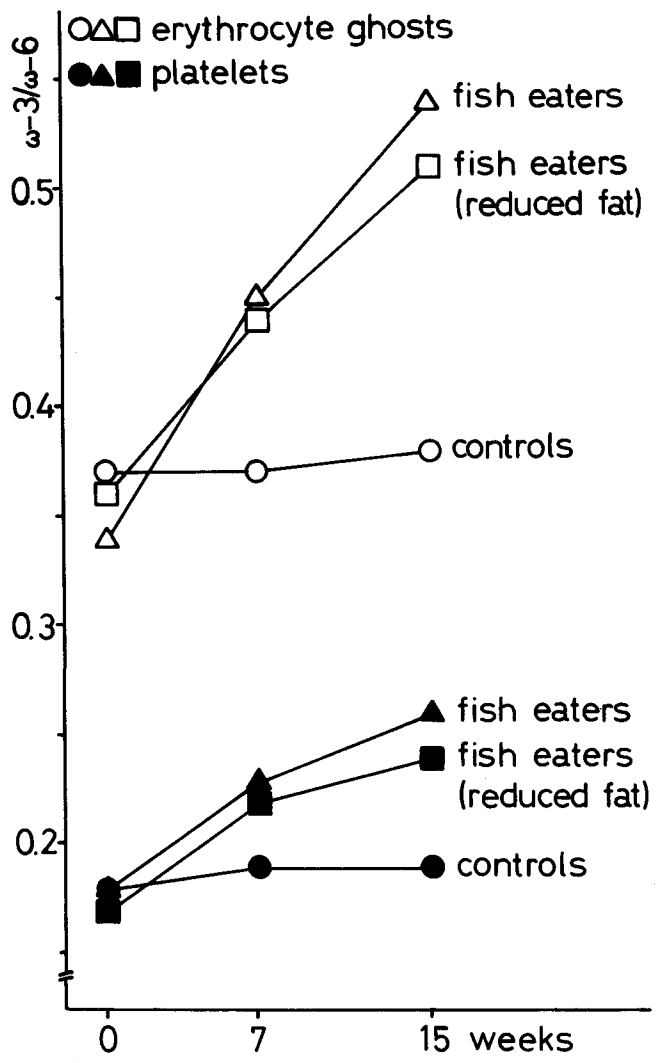

FIG. 1. The ω-3/ω-6 ratio in fatty acids of platelets and erythrocyte ghosts in male students eating an average of 3.7 weekly fish meals for 15 weeks.

acid). The changes in platelets reported by Sanders et al. (21) were somewhat greater than those in the present study. This can be explained by the shorter turnover time of platelets than of erythrocytes. Also, in the present study, the changes took place earlier in the platelets than in erythrocytes.

There are only a few controlled studies published where fish-containing meals have been added to the western diet. No similar studies have been reported with as great a number of healthy people using a normal catering system, over such a long time, as in the present study. In most of those studies, rather large amounts of marine fish have been used, and the follow-up periods have been rather short. There are, however, two previous studies in which the administration of marine fish has been comparable with our experiment. During 11 weeks (daily intake of 150–200 g fish, mainly herring, mackerel and salmon) (22) and three months (at least twice a week and at least 100 g fatty fish, i.e., 0.3–0.6 g of eicosapentaenoic acid per day) (23), a lowering of serum triglycerides was observed, although no change took place in serum cholesterol. A lowering of cholesterol has been observed when large amounts of fish have been eaten (24). In the present study, the quantity of fish corresponded to about 100 g and 1 g of ω-3 fatty acids per day. Thus, this is the smallest amount so far reported to cause a decrease in the serum triglyceride level. The dosage was, in addition, also effective in lowering apolipoprotein levels. Thorngren and coworkers (22) were unable to detect any changes in apolipoproteins in their 11-week study.

Two metabolites of arachidonic acid were measured in this study. Thromboxane B_2 is a stable hydrolyzation product of thromboxane A_2, which promotes platelet aggregation and is a vasoconstrictor. The other metabolite, 6-keto-$PGF_{1\alpha}$, is a conversion product of prostacyclin. Prostacyclin prevents aggregation and is a vasodilator.

In our study, a diminished production of thromboxane B_2 in platelets was found. Such an effect has not been previously reported with such a low intake of fish. The decrease was significant only after 15 weeks on the fish regimen. Thus, the low doses require more time to produce

significant effects. It has been reported that 1 g of eicosapentaenoic acid in capsule form, after a 10 g daily dosage, is not enough to keep the thromboxane B_2 production depressed in two patients with atherosclerosis (25). The present results indicate that already the dosage of 0.25 g per day can cause a decrease in the thromboxane B_2 formation. Although it is not possible to draw any definite conclusions, it might be more profitable to get ω-3 fatty acids in fish-containing meal than in concentrated oil form.

In the present study, a lowering of plasma 6-keto-$PGF_{1\alpha}$ was observed. It has been suggested that fish oils have little or no effect on prostacycline production in the endothelial wall (26). There is, however, one report where a lowering has been observed (24). This suggests that the fatty acid spectrum in the vascular endothelium is changing, parallel with the erythrocytes and platelets.

The students who were asked to voluntarily decrease their lipid intake showed a decrease in their serum cholesterol levels. The lowering of the lipid intake did not, however, clarify the observed differences in the fatty acid composition and prostanoid production. This suggests that the effective incorporation of ω-3 fatty acids in the membrane lipids, and subsequent changes in the prostanoid metabolism, are not necessarily dependent on the amount of other fatty acids present in the diet.

The boreal freshwater fish diet provided by public catering system, modified lipid metabolism in 15 weeks. Further deepening of the responses still could have been expected, if the diet had been continued. The results stress the importance of the diet duration when the effects of different ω-3 fatty acid doses are estimated. The results support the hypothesis of the protective effect of moderate fish consumption against coronary heart disease.

[Received January 11, 1988; Revision accepted June 8, 1988]

Induction of Long-lasting Hypercholesterolemia in the Rat Fed a Cystine-enriched Diet

C. Sérougne[a,*], **D. Mathé**[b] and **C. Lutton**[a]

[a]Laboratoire de Physiologie de la Nutrition - Bâtiment 447, CNRS UA 646, Université de Paris-Sud, 91405 ORSAY Cedex, France; and [b]Unité de Recherches sur les dyslipidémies et l'athérosclérose (U 32), Hopital Henri Mondor, 94010 CRETEIL, France

The influence of dietary excess (5%) of L-cystine on rat plasma lipoproteins was examined. After only one week of cystine feeding, an increase in the plasma cholesterol level and a decrease in triglyceride levels were observed. The increase in cholesterol level became greater when the duration of cystine-enriched diet increased until eight weeks (+131% after eight weeks), but no further increase occurred between 8 and 20 weeks. This change was essentially due to the progressive increase in cholesterol levels in high density lipoproteins (HDL) and in lipoproteins isolated between 1.040 and 1.063 g/ml, i.e., certain low density lipoproteins (LDL_2), and containing mainly apoE-rich lipoproteins (HDL_1). The decrease in plasma triglycerides resulted from that of chylomicrons and very low density lipoproteins (VLDL). The effects observed after four or eight weeks of cystine feeding were maintained for eight weeks after replacing the cystine diet by the standard diet. Ingestion of the standard diet containing either cholestyramine (2%) or probucol (0.25%) following eight weeks of cystine feeding significantly decreased plasma cholesterol levels. It is concluded that cystine-fed rats are a useful tool of investigation for understanding mechanisms leading to increased plasma cholesterol level and for hypocholesterolemic drug trials.
***Lipids 23,* 930-936 (1988).**

Hypercholesterolemic animals are useful models for studies concerning cholesterol homeostasis and for hypocholesterolemic drug trials. In the rat, hypercholesterolemia has generally been induced by feeding diets supplemented with cholesterol, antithyroid drugs and/or bile acids (1-6). The hyperlipoproteinemia observed was mainly characterized by an increase in very low density (VLDL) and VLDL-like particles enriched in esterified cholesterol, a pattern quite different from that observed in human hypercholesterolemia (7).

An attempt has been previously carried out to obtain hypercholesterolemic rats with amino acid-enriched diets (8). It was found that cystine supplementation (5%) was very effective. Hypercholesterolemia was due to enhanced cholesterol levels in low density lipoproteins (LDL) of density 1.040-1.063 g/ml and in high density lipoproteins (HDL) of density 1.063-1.210 g/ml, and cholesterol content in chylomicrons and VLDL (d < 1.006 g/ml) was decreased (9). These results were obtained after two months of ingestion of the cystine-enriched diet and only cholesterol and protein contents of lipoproteins were determined.

The present work was carried out in order to study how hypercholesterolemia appeared as a function of the duration of cystine-enriched-diet administration. It also was investigated whether the effect of the cystine-enriched diet on plasma lipoproteins remained unchanged after replacing this diet with the control diet. The efficacy of two hypocholesterolemic drugs, cholestyramine and probucol, was tested in rats fed the cystine-enriched diet. Plasma lipoproteins were isolated in a density gradient and analyzed for their cholesterol, triglyceride, phospholipid and protein contents. The apolipoprotein composition of some of these lipoproteins was also determined.

Abbreviations: CETP, cholesteryl ester transfer protein; EDTA, ethylenediamine tetraacetic acid; HDL, high density lipoprotein; LCAT, lecithin:cholesterol acyl transferase; (V)LDL, (very) low density lipoprotein; MIA, monoiodoacetamide; PTU, propylthiouracil.

METHODS

Animals and diets. Male Wistar rats (from Elevage Janvier, France) weighing about 350 g were used. The standard semipurified diet (S) contained essentially sucrose 53%, casein 23% and lard 9%; the mineral mix contained copper and the cholesterol content was 0.015% (10). Rats, randomly divided into groups of four or five, were first fed the cystine-enriched diet for one to eight weeks (C groups) and then the standard diet for eight additional weeks (CS groups). A control group (n = 5) received the standard diet for 16 weeks. Two groups of rats were fed the cystine-enriched diet for four weeks, and then, for the next four weeks, the standard diet supplemented with either cholestyramine (2%) or probucol (0.25%). Blood samples (about 1 ml) were obtained at different times from the retroorbital venous sinus with heparinized capillary pipettes under light diethylether anesthesia. Plasma was separated from cells after 2 min centrifugation in an Eppendorf-type centrifuge. At the end of the experiments, blood was collected by puncture of the abdominal aorta on 4%-ethylenediamine tetraacetic acid (EDTA-4%-monoiodoacetamie (MIA) and centrifuged at 2000 *g* for 10 min at 4°C. All blood samplings were performed between 10 a.m. and noon on animals not previously starved. Cholesterol, triglyceride and phospholipids were determined in plasma samples.

Lipoprotein isolation. A density gradient (adapted from [11] was prepared in tubes with saline solutions of densities as follows: 1.5 ml, 1.006 g/ml; 1.5 ml, 1.020 g/ml; 2 ml, 1.040 g/ml; 3 ml, 1.063 g/ml; 2 ml of plasma adjusted to 1.21 g/ml by the addition of solid KBr; and 1 ml, 1.25 g/ml. The tubes were centrifuged for 24 hr at 15°C in a SW 40.1 Ti Beckman rotor at 40,000 rpm. The first 18 fractions (0.5 ml each) were collected from the meniscus of the tubes. Each fraction of lipoprotein was assayed for cholesterol content. The chemical composition of lipoproteins was determined in pooled fractions corresponding to chylomicrons and VLDL (d < 1.006 g/ml: fractions 1 and 2), LDL_1 (LDL of density between 1.006 and 1.040 g/ml: fractions 3 to 6), LDL_2 (LDL of density between 1.040 and 1.063 g/ml: fractions 7 to 11) and HDL (HDL of density between 1.063 and 1.210 g/ml: fractions 12 to 18).

Chemical analysis. Cholesterol, phospholipids and triglyceride contents were assayed using enzymatic methods

with commercial kits (Boehringer-Mannheim, Wako, TX). Proteins were determined by the method of Lowry et al. (12) using bovine serum albumin as the standard. Samples were extracted with chloroform after color development in order to avoid turbidity due to lipids.

Apolipoprotein separation. LDL_2 and HDL samples were extensively dialyzed against 0.05% EDTA, 0.9% NaCl, 0.02% NaN_3 (pH 7.4) at 4°C. The dialyzed samples were lyophilized and dissolved in Tris 0.02 M, urea 6 M, sodium dodecyl sulfate (SDS) 0.1 M, pH 8.4. A discontinuous gradient of polyacrylamide gels (5–10%) was prepared in glass tubes with added glycerol (12%), according to Connelly and Kuksis (13), in order to use non-delipidated lipoproteins. The lipoprotein samples (about 50 µl and containing 50 µg of protein, each) were mixed with isopropanol (10 µl), SDS 20% (10 µl), dithiothreitol 400 mM (10 µl), bromophenol blue 0.02% (5 µl) and glycerol (5 µl). After boiling for 3 min, the mixture was applied to the polyacrylamide gels. Electrophoresis was carried out at 1.5 mA per gel for 15 hr in a Pharmacia electrophoresis apparatus with 0.1% SDS, 0.1 M phosphate buffer solution, pH 7.0. Gels were stained with 0.25% Coomassie Brilliant Blue k-250 (in 50% methanol) and 9.2% acetic acid, and destained with 5% methanol and 7.5% acetic acid (14). Gels were scanned with an LKB 2202 Ultrascan integrator. The apolipoprotein bands were identified on the basis of molecular weights as determined by reference to purified protein standards and by comparison with published SDS gel electrophoretograms of rat apolipoproteins (6,15). All the results were expressed as means ± standard error of the mean. Significant differences were estimated either by the Student's t test or by the paired t test.

RESULTS

Body weights and food intakes. As reported in Table 1, body weights for rats at the same age were lower for those fed the cystine diet than for those fed the standard diet. This difference, however, was only significant in the C8S8 group, in which body weights were 76% of the weights in the S16 group, during the eighth week of the experiment. Food intakes observed during all the periods of feeding the standard diet, even following administration of the cystine diet, varied between 16.4 ± 0.7 (n = 5) and 20.9 ± 1.2 g/day (n = 5), without any significant differences among the various groups. However, almost all the periods of feeding the cystine diet were characterized by a food intake significantly lower than in standard animals. The greatest differences occurred during the first three weeks of cystine feeding, with a mean value of food intake of 12.1 ± 0.4 to 14.8 ± 0.7 g/day.

Plasma lipid composition. The cholesterol, triglyceride and phospholipid contents in plasma obtained from rats fed the standard diet, or the cystine-enriched diet followed by the standard diet, are reported in Table 2. Cholesterol and phospholipid contents of plasma from rats fed the standard diet did not change significantly during the 16 weeks of experiment (S16 compared with S0). The plasma-triglyceride content decreased by 32%. In rats fed the cystine-enriched diet, some changes in lipid composition of plasma appeared after only one week (C1 group): compared with C0 group, the cholesterol content increased by 45%, whereas the triglyceride content decreased by 52%. Similar changes, compared with C0 group, occurred during the following weeks of cystine feeding with progressive increases in the cholesterol amounts: 53% (C2), 87% (C4) and 131% (C8), and decreases in the triglyceride amounts: 76% (C2), 55% (C4) and 77% (C8). Except for the C2 and the C4 groups, in which the plasma-phospholipid contents were lower and higher than in control rats (−31% and +23%, respectively), no changes in this content were observed during cystine feeding. Replacement of the cystine-enriched diet by the control diet did not significantly alter plasma-cholesterol and phospholipid levels obtained with the cystine-enriched diet. However, plasma-triglyceride content was significantly increased (+71%) in the C2S8 group compared with the C2 group.

Cholesterol distribution in the lipoproteins. The cholesterol contents in the 18 lipoprotein fractions isolated by density-gradient ultracentrifugation from the plasma of rats fed only the standard diet and rats fed the cystine-enriched diet for one to eight weeks are reported in Figure 1. In control rats, plasma cholesterol was distributed as follows: 15% in fractions 1 and 2 (chylomicrons and VLDL), 3.4% in fractions 3–6 (LDL_1), 19% in fractions 7–11 (LDL_2) and 62% in fractions 12–18 (HDL). After one week of cystine feeding (C1 group), these proportions were not modified. The 48% increase of the total plasma-

Cholesterol, Triglyceride and Phospholipid Contents (mg/ml) of Plasma[a]

Groups	Cholesterol	Triglycerides	Phospholipids
C0	0.71 ± 0.02	2.92 ± 1.16	1.91 ± 0.05
C1	1.03 ± 0.07[b]	1.39 ± 0.19[c]	2.13 ± 0.11
C1S8	0.97 ± 0.07	2.37 ± 0.40	1.79 ± 0.12
C2	1.09 ± 0.07[d]	0.70 ± 0.05[e]	1.52 ± 0.04[d]
C2S8	1.04 ± 0.07	2.45 ± 0.45[f]	2.28 ± 0.21
C4	1.33 ± 0.07[e]	1.31 ± 0.12[e]	2.35 ± 0.06[d]
C4S8	1.18 ± 0.09	1.34 ± 0.19	2.63 ± 0.15
C8	1.64 ± 0.25[c]	0.67 ± 0.13[e]	2.57 ± 0.29
C8S8	1.32 ± 0.15	1.46 ± 0.72	2.29 ± 0.19
S0	0.82 ± 0.06	3.41 ± 0.43	2.42 ± 0.16
S16	0.99 ± 0.11	2.30 ± 0.41[f]	2.01 ± 0.15

[a]From rats fed the standard diet from the start of the experiment (C0, S0) to 16 weeks later (S16), the cystine-enriched diet for 1 to 8 weeks (C1 to C8) followed by the standard diet for 8 weeks (C1S8 to C8S8). Except for C0 group (n = 25), which is constituted by the rats of all the groups at the start of the experiment, each group contains 5 rats.

[b]$P < 0.005$,

[c]$P < 0.02$,

[d]$P < 0.01$ and

[e]$P < 0.001$, are significantly different (C1, C2, C4 and C8 groups), when compared with values in C (Student's t test).

[f]$P < 0.05$, significantly different, when values of C1S8, C2S8, C4S8 and S16 are compared wth those of C1, C2, C4, C8 and S0 groups (paired t test), respectively.

Mean values ± SEM.

cholesterol content was due to a slight increase in all of the lipoprotein fractions, but mainly in fractions 11–15 (density 1.063 to 1.150 g/ml). After two weeks of cystine feeding, a decrease in plasma cholesterol carried by chylomicrons and VLDL, and an increase in that carried by LDL_2, became apparent. The two measurements represented 7% and 27%, respectively, of the total plasma-cholesterol content. These proportions were 4% and 30% after four weeks of cystine feeding, and 2% and 41% after eight weeks. At this time, the marked increase (131%) in the plasma-cholesterol level, compared with rats fed the standard diet, essentially was due to an increase in LDL_2 and HDL cholesterol. The most marked increase was observed in fraction 10 (d: 1.058 g/ml): 395%.

Figure 2 shows the distribution of cholesterol among 18 lipoprotein fractions isolated from rats fed the cystine diet for four weeks, and from rats fed the cystine diet for four weeks and then the standard diet for either four or eight weeks. In comparison with the profile obtained after four weeks of cystine feeding, no major changes occurred after replacing this diet by the standard one for four or eight weeks. A slight increase was observed in LDL_2 after four weeks, and a slight decrease occurred in HDL at four or eight weeks. Similar observations were made when rats were fed the cystine diet for eight weeks followed by the standard diet.

Lipoprotein composition. The chemical composition of lipoproteins (proteins, cholesterol, triglycerides and phospholipids expressed as percentage of the total lipoprotein weight) from rats fed the standard diet (C0 group), or the cystine-enriched diet for four weeks (C4 group) or eight weeks (C8 group), followed by the standard diet for eight weeks (C4S8 and C8S8 groups), are reported in Table 3.

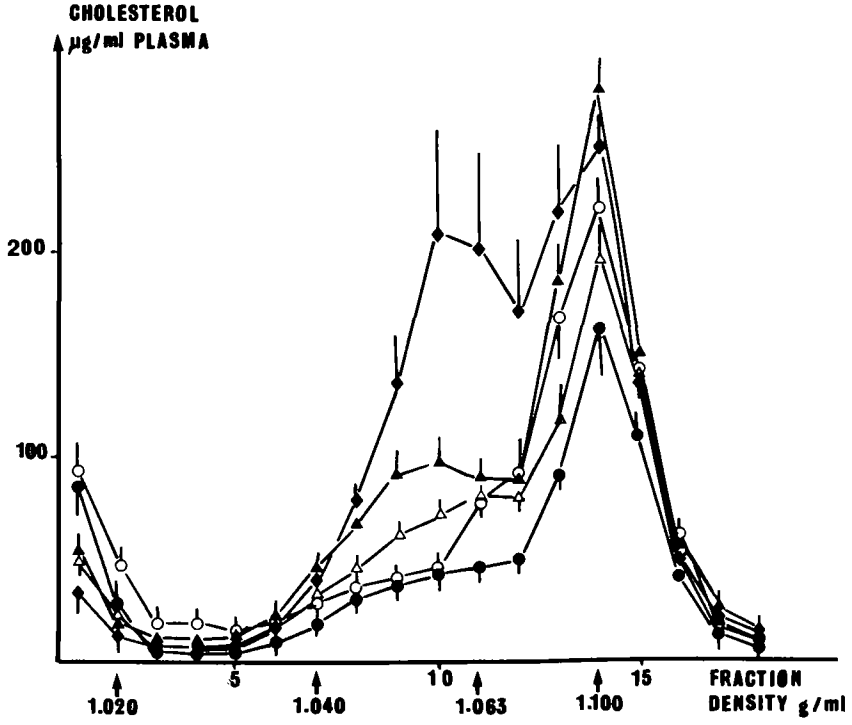

FIG. 1. Cholesterol distribution in 18 lipoprotein fractions from rats fed the standard diet (●) or the cystine-enriched diet for 1 (○), 2 (△), 4 (▲) or 8 (◆) weeks (n = 5 for each group, means ± SEM).

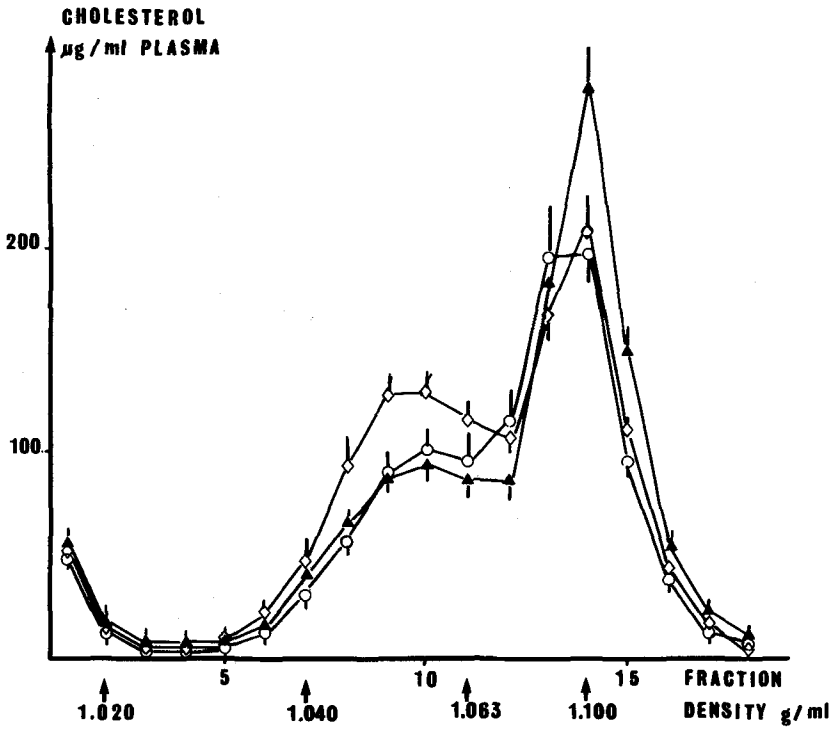

FIG. 2. Cholesterol distribution in 18 lipoprotein fractions from rats fed a cystine-enriched diet for 4 weeks (▲) or for 4 weeks followed by 4 (◊) or 8 (○) weeks of standard diet (n = 5 for each group, means ± SEM).

TABLE 3

Protein, Cholesterol, Triglyceride and Phospholipid Content (as Percentage of Total Lipoprotein) in Lipoproteins[a]

Constitutent	Groups	Chylomicrons + VLDL	LDL_1	LDL_2	HDL
Proteins	C0	7.5 ± 0.5	17.0 ± 1.2	35.4 ± 2.0	56.5 ± 0.9
	C4	9.7 ± 0.4[c]	19.6 ± 1.8	27.2 ± 0.7[d]	50.0 ± 1.1[d]
	C4S8	8.6 ± 0.8	17.9 ± 1.9	30.5 ± 0.6[b,h]	49.0 ± 0.2[d]
	C8	12.8 ± 1.9[b]	24.6 ± 1.0[d]	31.7	53.6 ± 1.4
	C8S8	12.2 ± 1.4[b]	24.0 ± 2.2	34.1 ± 0.5	53.8 ± 0.8
Cholesterol	C0	2.8 ± 0.3	7.0 ± 2.7	27.7 ± 1.6	16.5 ± 2.1
	C4	5.6 ± 0.4[d]	26.2 ± 3.9[c]	34.0 ± 0.7[d]	17.7 ± 0.3
	C4S8	4.4 ± 0.3[c]	13.5 ± 1.3[b,f]	29.2 ± 0.9[h]	16.1 ± 0.5[f]
	C8	11.1 ± 2.5[b]	24.2 ± 3.6[c]	34.2	18.9 ± 0.6
	C8S8	7.5 ± 1.4[b]	27.2 ± 4.4[c]	33.1 ± 1.1[b]	18.2 ± 0.5
Triglycerides	C0	75.0 ± 1.5	58.2 ± 6.5	12.5 ± 2.5	2.7 ± 0.7
	C4	71.3 ± 1.3	31.5 ± 6.6[b]	1.8 ± 0.3[b]	1.1 ± 0.1
	C4S8	71.2 ± 1.3	45.5 ± 2.7	1.1 ± 0.5[b]	1.4 ± 0.2
	C8	54.5 ± 5.4[c]	33.7 ± 4.0[c]	3.0	3.8 ± 0.6
	C8S8	67.1 ± 4.1	28.3 ± 8.1[b]	2.5 ± 1.0[d]	1.3 ± 0.3[g]
Phospholipids	C0	14.6 ± 1.0	17.8 ± 0.3	24.4 ± 2.0	26.7 ± 1.3
	C4	13.3 ± 0.5	22.7 ± 1.9	37.0 ± 1.1[e]	31.2 ± 1.0[b]
	C4S8	15.8 ± 0.7[f]	23.1 ± 0.8	39.1 ± 0.8[e]	33.4 ± 0.4[c]
	C8	15.9 ± 1.9	17.5 ± 1.3	31.0	23.7 ± 1.3
	C8S8	12.9 ± 1.3	20.4 ± 1.7	30.3 ± 0.7[b]	26.7 ± 0.5

[a]Isolated from rats fed the standard diet (C0), or the cystine-enriched diet for 4 (C4) or 8 weeks (C8) followed by the standard diet for 8 weeks (C4S8 and C8S8).

[b]$P < 0.05$,

[c]$P < 0.02$,

[d]$P < 0.01$ and

[e]$P < 0.001$ (Student's t test), are significantly different than those values obtained in the C0 group.

[f]$P < 0.05$ and

[g]$P < 0.01$ (paired t test), are values significantly different in the C4S8 group compared with the C4 group, or in the C8S8 group compared with the C8 group.

Means ± SEM (n = 5, for each group).

TABLE 4

Apoprotein Composition (as Percentage of Total Apoproteins) of LDL_2 and HDL[a]

	Groups	$ApoB_{100}$	$ApoB_{48}$	$ApoA_{IV}$	ApoE	$ApoA_I$	ApoC
LDL_2	S16	4 ± 2	1	—	34 ± 1	21 ± 1	40 ± 2
	C8	13 ± 4	3	1	46 ± 3[c]	20 ± 3	16 ± 2[d]
	C8S8	2 ± 1	1	1	37 ± 4	33 ± 3[c]	28 ± 4[b]
HDL	S16	—	—	12 ± 1	3 ± 1	56 ± 3	29 ± 1
	C8	—	—	11 ± 1	10 ± 2[b]	53 ± 3	26 ± 1
	C8S8	—	—	8 ± 1	1 ± 1	61 ± 4	29 ± 2

[a]From rats (3–4 per group) fed the standard diet for 16 weeks (S16), or rats fed the cystine-enriched diet for 8 weeks (C8) followed by the standard diet for 8 weeks (C8S8).

[b]$P < 0.02$,

[c]$P < 0.01$ and

[d]$P < 0.001$, are significantly different than those values obtained in the S16 group.

Means ± SEM.

The major changes occurring after feeding the cystine-enriched diet were an increase in the relative proportion of cholesterol in the lighest lipoproteins, chylomicrons and VLDL (+100% after four weeks and +296% after eight weeks) and LDL_1 (+274% after four weeks and +246% after eight weeks). A decrease in the triglyceride proportion was shown for LDL_1 and LDL_2 after four weeks of cystine feeding (−46% and −86%, respectively) and appeared in chylomicrons and VLDL after eight weeks (−27%). After replacing the cystine-enriched diet with the standard diet, the cholesterol enrichment persisted in chylomicrons plus VLDL and in LDL_1 (+57% and +93%, respectively, for the C4S8 group; and +168% and +288%, respectively, for the C8S8 group). The decrease in the triglyceride proportion of LDL_2 remained quite unchanged (−76%).

Apolipoproteins. The apolipoprotein composition (expressed as percentage of total apolipoproteins) of LDL_2 and HDL from rats fed the standard diet for 16 weeks (S16), and rats fed the cystine-enriched diet for eight weeks (C8) followed by the standard diet for eight weeks (C8S8), is reported in Table 4. An enrichment in apoE was observed in LDL_2 and HDL after eight weeks of cystine feeding (34% and 233%, respectively). In LDL_2, this enrichment was associated with a decrease in the apoC proportion (by (60%). Eight weeks after replacement of the cystine diet with the standard diet, the apoE proportion in LDL_2 and HDL returned to a value close to that of control rats (S16), whereas in LDL_2, the apoC proportion still remained slightly lower than in control rats and the $apoA_I$ proportion was slightly higher.

Drug trials. Plasma cholesterol was significantly decreased by probucol and cholestyramine (29% and 28%, respectively), in rats previously fed a cystine-enriched diet (Table 5). Cholesterol concentrations were decreased in LDL_2 and HDL and the values for HDL returned to the levels observed in control rats. However, LDL_2-cholesterol concentrations still remained higher than in control rats.

TABLE 5

Cholesterol Levels (μg/ml) in Plasma, LDL_2 and HDL of Rats[a]

Groups	Plasma	LDL_2	HDL
C0	801 ± 63	153 ± 39	501 ± 29
C4S4	1320 ± 70	532 ± 26	663 ± 49
C4Pro	940 ± 50[c]	323 ± 49[c,d]	539 ± 32
C4Cy	950 ± 50[c]	305 ± 40[c,d]	490 ± 31[b]

[a]Fed either the standard diet (C0) or the cystine-enriched diet for 4 weeks, and then either the standard diet (C4S4) alone or the standard diet supplemented with probucol (0.25%, C4Pro) or cholestyramine (2%, C4Cy) for 4 weeks.

[b]$P < 0.02$ and

[c]$P < 0.01$, are significantly different in the C Pro and C Cy groups than in the C S group.

[d]$P < 0.05$, is significantly different in the C Pro and C Cy groups than in the C group.

Means ± SEM (n = 5).

DISCUSSION

Studies carried out in man and in experimental animals have clearly shown that the plasma-cholesterol level can be influenced by the nature of dietary proteins (16,17). In the rat (18–20) and in hypercholesterolemic subjects (21–23), plasma cholesterol was lower with soy protein than with casein diet. The amino acid composition of these proteins has been implicated in that effect (17,18,24,25). It has been reported, in various species, that some individual amino acids added in excess into diets increase the plasma cholesterol levels, whereas others decrease it or have no effect. It has been observed that, among six amino acids used in excess in the diet, only cystine (5% added) increases the rat plasma cholesterol level (8). Therefore, a new model of hypercholesterolemia of endogenous origin was available. This model brought forth new information concerning the regulation of plasma cholesterol (26).

From the first week onwards, the cystine-enriched diet reduced body weight increase and food intake, as previously described (8), increased plasma-cholesterol level and decreased plasma-triglyceride levels. These above changes were amplified with the duration of cystine ingestion to reach maximal effect after eight weeks
